The N-serve literature points out that a nitrification inhibitor is helpful only when conditions favor high nitrogen loss from the soil. Such conditions are heavy rainfall or heavy irrigation, coarse-textured soil, and soil in the pH range where nitrification readily occurs. Nitrate thus formed will leach down into anaerobic soil layers.

Potassium azide (2–6% KN3) dissolved in anhydrous ammonia was effective in lowering the rate of nitrification in tests conducted by the U.S. Department of Agriculture in cooperation with agricultural experiment stations in the states of Louisiana and Washington. PPG Industries, Inc., is exploring this and other agricultural uses (e.g. as a herbicide in rice culture) for the azide.

Another nitrification inhibitor that has received much attention in Japan is 2-amino-4-chloro-6-methyl pyrimidine. It is manufactured by Mitsui Toatsu Chemicals, Inc. (formerly Toyo Koatsu Industries, Inc.) under the trade name AM. Other nitrification inhibitors that have been used in Japan in compound fertilizers are sulfathiazole, dicyandiamide, thiourea, N-2, 5-dichorphenyl succinamide, 4-amino-1, 2, 4-triazole hydrochloride, and guanylthiourea [50].

In flooded or waterlogged soils, as for example, in a continuously flooded rice paddy, anaerobic (reducing) conditions exist in the soil below the surface, and hence nitrification of ammoniacal nitrogen does not occur in this layer. Therefore, when ammonia, ammonium salts, or urea (which hydrolyzes in the soil to ammonia and carbon dioxide) is placed in the reducing zone of the soil, it remains in the ammonium form and is more or less immobilized by sorption on the clay. Some of the advantages of controlled release may be attained by placement of ammoniacal nitrogen in the reducing zone of the rice paddy soil. However, this placement is difficult since applicators quickly become clogged with mud and wet fertilizer. To facilitate subsurface placement, large granules or briquettes of urea have been produced experimentally that can be pressed into the soil by hand (or foot) (Fig. 24.24). Experiments with this placement have shown substantially increased efficiency of nitrogen utilization by rice as compared with the usual broadcast placement.

IFDC has designed a village-level briquetting machine that can produce urea briquettes ranging in weight from 1 to 2.7 g (Fig. 24.25). The capacity of these machines varies from 20 kg/h to 1 ton/h and can be operated intermittently. As of 2004 more than 1,000 of these machines are operating in Bangladesh, providing briquettes for nearly 500,000 ha of rice paddy. Using this technology the farmers are able to increase rice yields by about 20% while using 25% less urea. This technology is now being tested in Vietnam, Cambodia, and several countries in Africa. A hand-held applicator for deep placement of briquettes is also being tested in Bangladesh.

Physical Quality of Fertilizers

Physical quality is an important determinant used by a farmer-consumer in selecting a particular fertilizer. The acceptability of a fertilizer in the marketplace depends not only on its nutrient content but also on its physical quality. Although the available nutrient content and its effect on crop response is the ultimate reason for the use of fertilizers, physical quality is often the reason for selecting one fertilizer over another. It is important that fertilizers remain free-flowing (noncaking), relatively nondusty, and be able to withstand a reasonable amount of exposure to normal atmospheric humidity to withstand transportation, distribution, and application. Many production techniques, including various physical conditioning treatments, have been developed to provide favorable physical properties [54].

The quality of a fertilizer product is basically judged by two criteria: chemical properties and physical properties. The chemical properties (nutrient content, form, and availability to the crop) and their effectiveness for crop growth are the main reasons for using a fertilizer. In contrast, physical properties of a fertilizer product are important with respect to processing, handling, storage, and field application.

The consumer, through simple observation, cannot ascertain whether a fertilizer actually meets the guaranteed nutrient content; however, federal or state laws normally regulate the nutrient content thereby giving some protection to the consumer. In contrast, physical condition usually is a matter only of agreement between purchaser and supplier. Normally fertilizer regulatory laws do not regulate fertilizer physical properties. However, the consumer can certainly see whether a fertilizer is caked or free-flowing, dusty or dust-free, wet and sticky or dry. The most frequently encountered problems resulting from deficiencies in physical properties are caking (agglomeration or lump formation), dustiness, poor flowability, excessive hygroscopicity (moisture-absorptioncharacteristics), and segregation (non uniformity of composition throughout a fertilizer lot).

The physical quality of a fertilizer can be evaluated by many different methods that can vary from simple observation to sophisticated techniques. Producers have adopted and/or developed methods to evaluate their particular products. International, national, and regional organizations have adopted, developed, and/or published procedures intended for general application to a variety of fertilizer products and raw materials [3, 55, 56].

Next Generation of Fertilizers

As discussed earlier, fertilizers have an important role in production and productivity increases. Most of the fertilizers in use today were developed between the 1940s and 1980s by scientists of TVA, an agency of the U.S. Government, along with those from the fertilizer industry and state land-grant university research and extension systems. The bulk of R&D was conducted on the TVA Reservation in Muscle Shoals, Alabama, USA. Unfortunately, since the early 1990s, public funds for new fertilizer technology R&D programs have essentially disappeared. Further, fertilizer companies are currently investing almost nothing in R&D. Not surprisingly, over the past 25 years, no new, significantly more efficient fertilizer products have been developed that are cost-effective for use on food crops by farmers in less developed countries. Yet efficiency of fertilizer technology is closely linked with key factors determining the future of humankind—food security, availability of natural resources, and the environment.

The world's resources of rock phosphorus (P) and potassium (K) from which fertilizers are made are finite. Nitrogen production is extremely energy intensive: it takes the energy equivalent contained in four barrels of oil to make one ton of urea, i.e., the equivalent of 480 million barrels of oil is needed to produce today's supply of 120 million metric tons (mmt). Moreover, current fertilizer technologies result in great losses either at the production or utilization stage. Up to two-thirds of the urea applied is wasted due to crop use inefficiencies, and the current technologies used to produce phosphate concentrate from mined ore generate significant losses of phosphate.

The potential impact of improving the efficiency of fertilizer technology is vast. For example, a gradual 50% improvement in average nitrogen use efficiency in cereal crops by 2050 would:

- Reduce total accumulated nitrogen losses from 1,281 to 817 mmt.
- Save $403 billion (at $400/mt for urea).
- Reduce by the equivalent of four billion barrels of oil the amount of energy used to produce urea fertilizer.
- Reduce N losses significantly:
- Volatile N_2O-NO_X by about 974 mmt of CO_2 equivalents;
- Leaching to freshwater and marine ecosystems with the latter particularly affected by N.

Most significantly, more efficient fertilizer technologies can help better meet future food security at farm, national, and global levels. Farmers will have to apply less fertilizer to get more yield, while improving their profits. National governments will be able to reduce their importation of fertilizer and/or, in case of subsidies, the drain on their budgets, while increasing agricultural production. At the global level, food security would increase while negative impacts on environment and resource availability would decrease.

Driven by these issues, the International Fertilizer Development Center (IFDC) launched the Virtual Fertilizer Research Center (VFRC) to create the next generation of fertilizers and production technologies to help feed the world's growing population and provide sustainable food security. It is *virtual* in the sense that it is intended to be comprised of the work of multiple research institutions cooperating via communications technology to advance a unified research agenda.

Sulfur and Sulfuric Acid

25

Gerard E. d'Aquin and Robert C. Fell

Sulfur

Sulfur is one of the few elements that is found in its elemental form in nature. Typical sulfur deposits occur in sedimentary limestone/gypsum formations, in limestone/anhydrite formations associated with salt domes or in volcanic rock [1]. A yellow solid at normal temperature, sulfur becomes progressively lighter in color at lower temperatures and is almost white at the temperature of liquid air. It melts at 114–119°C (depending on crystalline form) to a yellow liquid which turns orange as the temperature is increased. The low viscosity of the liquid begins to rise sharply above 160°C, peaking at 93 Pas at 188°C, and then falling as the temperature continues to rise to its boiling point of 445°C. This and other anomalous properties of the liquid state are due to equilibria between the various molecular species of sulfur which includes small chains and rings.

Sulfur is also found as sulfide minerals in combination with iron or base metals (e.g., pyrites) and as sulfates in combination with alkali metals (copper) and alkaline earths (e.g., gypsum). Hydrogen sulfide, with its "rotten egg" odor, and carbon dioxide are the principal "sour" components of sour gas. Crude oil and coal include a variety of complex organic species containing sulfur. Such compounds are removed from the liquid fuels by treatment with hydrogen to convert the sulfur component to hydrogen sulfide which is removed from the fuel stream. Removal of sulfur from fuels for technical and environmental reasons represents the largest current source of elemental sulfur.

World elemental sulfur production in 2009 was almost 48 million metric tons, up 3 million tons since 2003. Other sources (pyrites roasting in China and cleaning smelter gas-effluent globally) have added 25 million tons to the sulfur balance (Table 25.1).

Currently, almost all sulfur is derived from hydrocarbon processing. Minor quantities are still mined. Poland has a capacity of 700,000 t with a long history in Frasch mining. Mexico restarted one of its idled mines in 2010 (Jaltipan) with an output of about 100–200 t per day. Iraq's Mishraq mine is said to be trying to restart. Most sulfur mines are associated with oil deposits found in conjunction with geologic formations known as salt domes. In situ cross contamination with hydrocarbons (as at the Jaltipan and Mishraq mines) leads to the production of "dark" sulfur with technically and commercially unacceptable levels of carbon contamination. Volcanic sulfur deposits yield bright sulfur, but it is often contaminated with toxic metal oxides. Small quantities of several specialty sulfurs are produced for a variety of other applications, including fungicides, bleaching, fumigation, pharmaceuticals, rubber manufacture, and cutting oils. Applications of elemental sulfur as a fertilizer are growing globally. The Sulphur Institute (www.sulphurinstitute.org) recently launched a program entitled: *Sulfur—An Advantaged Element*. Additionally, an excellent publication by the USGS entitled "Materials Flow of Sulfur" is available at http://minerals.USGS.gov/minerals/pubs/commodity/sulfur/index.html.

Transportation and Storage

Although all sulfur is produced and most is consumed in a molten state, the preponderance of international commerce outside of North America and Europe uses solid sulfur. Vancouver was once the world's leading sulfur exporting port. Volumes peaked at 6.3 million tons in 2004, declining to 3.6 million tons in 2010 [2]. Qatar should surpass Vancouver no later than 2013 given expansion plans and continued decline in Canada's "commercially available" sulfur output.

Prior to bulk transport, solid sulfur is normally "formed" into a variety of shapes associated with individual solidification processes. These will be discussed in the following section. "Formed" solid sulfur is easily transported by truck, railcar, barge, or ocean vessel. It is classified as a nonhazardous material "granular formed sulfur". Caution must be exercised in order to avoid fugitive dust and spillage. Sulfur dust is highly visible, will become corrosive, and under certain circumstances, explosive.

In the case of marine transport, which may last several weeks, the risk of corrosion during transit must be addressed.

Vessel holds must be coated prior to loading, to prevent direct sulfur-steel contact. A new coat of paint covering all steel is good. However, nicks and scratches quickly expose steel. Various products and means of coating holds are employed by knowledgeable companies prior to loading. This preparation avoids a range of potentially severe consequences and cannot be bypassed without significant risk to cargo and vessel. Spraying water with surfactants, or aqueous foam, on sulfur as it is being loaded or unloaded is another key safety measure which mitigates dust dispersion. Water used in dust suppression as sulfur is loaded will move to the bottom of holds during transit. Daily pumping of this residue to sea is necessary to avoid the accumulation of up to several feet of standing water in the bottom of the hold. Prior to loading and following discharge, formed sulfur is often stored in the open air.

In contrast, domestically produced sulfur destined for internal use in the USA, Canada, and Europe is almost exclusively transported in liquid form. This has led to the establishment of an extensive sulfur infrastructure consisting of molten sulfur terminals, tanker ships and barges, rail tank-cars, and tank-trucks. In the cases of marine transport, vessels range from 23,000 to 9,500 t and barges from 1,000 to 2,500 t. Overseas, molten shipments can be received in Morocco, Tunisia and one port in India. Japan prohibits solid sulfur, even in the case of export activities. This has led to a fleet of coastal vessels, some as small as 1,000 t, for exporting Japanese molten sulfur to users in China, Taiwan, and formerly, Korea.

Molten sulfur in ships is maintained in a liquid state using heating coils. When transported by rail tank-car, at least a portion of the sulfur cools and solidifies during transit. It is re-liquefied prior to discharge. The re-melting process can take up to 3 days (i.e., in the United States with sulfur coming from Canada during winter). Re-melt is accomplished by passing low pressure steam through coils located between the car's inner tank and outer skin. Care must be taken to use a low heating temperature to avoid turning sulfur into a viscous material. Trucks normally operate within distances which preclude cooling and solidification. Nevertheless, limited coiling allows for emergency steaming. In Tampa, FL, many sulfur truck trailers are designed for round trip carriage. An inner tank carries sulfur from the port and, depending on the design, phosphoric acid, solid fertilizers, or phosphate rock in an outer container on the return.

Certain countries have regulations that require molten sulfur be treated (de-gassed) at the production point to reduce the hydrogen sulfide level below 10 ppm weight. The City of Vancouver requires formed sulfur transshipped at the port to test below 30 ppm weight. Neither US nor Canadian governments have a national maximum hydrogen sulfide content standard for sulfur.

Storage of molten sulfur requires insulated tanks equipped with heating coils through which steam or glycol is constantly circulated. The tank's internal surfaces, particularly the roof, must be protected against corrosion and carefully monitored. Corrosion occurs most often when moisture enters through tank vents while it empties, condenses on the wall, and mixes with vapors of sulfur and its compounds. In recent years, CSI Controls has developed an enhanced system to heat sulfur tanks externally to prevent sulfur from freezing on the walls. It also evaporates all moisture from the walls and roof. Tanks, pumps, and lines must also be properly insulated and heated. A means of injecting steam into the tank void must be provided for fire control. Finally, depending on environmental regulations, tank vents may require scrubbing systems. In the case of marine terminals, these must be sized to accommodate large volumes of air as vessels discharge. "Formed" solid sulfur, on the other hand, can be stored in a pile exposed to the open air. Runoff water containment and neutralization is required around such sites. Some localities may have maximum H_2S content standards, protective walls, enclosed storage, windbreakers, and sprinkling systems to prevent blowing dust. Another means of storage, employed to minimize cost and maximize volume in any given area, is to "vat" or "block" the sulfur. In this case, a properly constructed impermeable "base pad" surface is prepared. This is then enclosed (surrounded by) with aluminum plates (forms) which are 50–75 cm high. A thin layer of molten sulfur is poured onto the pad and allowed to solidify. The process is repeated until the level of sulfur reaches the top of the aluminum forms wall. Another set of forms is then attached to the top edge of the solidified sulfur and the process is repeated. In this manner, sulfur "blocks" over 10 m high and several hundred meters long are created. Sulfur from blocks is reclaimed on-site, by melting, or by mechanical means followed by melting or shipment as the "crushed bulk" material. Despite its apparent simplicity, innumerable technical issues affect every aspect of the block construction, pouring, maintenance, and reclamation. Among these are insuring no liquid, dust, or gas effluent escapes from the site; as well as corrosion; overcoming the effects of sun, rain, and freezing; insuring proper solidification of the sulfur being poured; wall degradation; etc. Companies experienced in creating sulfur blocks and providing equipment are Devco USA (http://www.devcousa.com/), Enersul Inc. (http://www.enersul.com), and Hazco Environmental Services (http://www.hazco.com). Considerable information on these matters can be obtained from *Sulfur*, a BC Insight.com publication.

A key final consideration when storing solid sulfur is the inevitable presence of sulfuric acid. Sulfur can become naturally contaminated with sulfuric acid through the action of thiobacilli thiooxidans [3] or continuous exposure to direct sunlight [4] and the presence of moisture. Recent research has demonstrated the short-term effectiveness of certain bactericides in delaying bacterial colonization. Nevertheless, discrete pockets of weak (highly corrosive) sulfuric acid should always be presumed to exist within a sulfur storage pile. Hydrochloric acid, may also be present when solid sulfur has been transported by ocean vessel [5]. Ocean deliveries of solid sulfur should be neutralized to avoid potentially disastrous corrosion of downstream equipment.

Solidification and Melting

For many years, the standard industry practice was to ship solid sulfur as a "crushed bulk". The words adequately describe its appearance and dustiness. *Crushed bulk* is the least acceptable type of solid sulfur. It is created when using earthmoving equipment to recover sulfur which has been allowed to solidify in blocks, sheets, or vats. Obviously, the product is extremely dusty. Very few producers (Russia, Kazakhstan, and Iran) still ship crushed bulk. Most consumers refuse to accept shiploads even at significant price discounts due to dustiness, related contamination, and product loss. "Lump and Crushed" sulfur is classified as a hazardous material by the International Maritime Organization (IMO).

Slate, another type of formed sulfur, was the sulfur industry's first attempt at developing a type of solid sulfur which was less dusty than "crushed bulk". Slate is produced by pouring a thin (usually up to 3 cm) layer of molten sulfur onto a moving belt while simultaneously cooling the belt's underside. Solidified sulfur breaks off into irregular shapes when falling off the end of the belt, leading it to resemble pieces of "peanut brittle." Owing to its greater dustiness, slate sulfur is a less desirable form of formed sulfur and faces commercial resistance. Slate is classified as nonhazardous by the IMO.

Best Available Current Technologies (BACT) for solidifying sulfur creates a pelletized, prilled, or granular product. These types of "formed" sulfur were developed in the late 1970s through today. They minimize breakage and sharp edges which create dust during handling. As the product names imply: *pelletized* sulfur is a pellet generated when a discrete amount of sulfur is deposited and cooled on a conveyor belt. It has the shape of an egg yolk on a plate. The most common processes are offered by "Sandvik" [6] and "Berndorf" [7] but other licensors exist. *Prilled* sulfur is created when sulfur droplets are cooled by a surrounding fluid, which may be air or water. *Air-prills* are created by spraying sulfur from the top of a tower into a strong updraft of cool air. It is an extremely smooth product which resembles prilled urea or ammonium nitrate. No air-prilling facilities have been built in almost three decades due the process' inevitable emission of sulfur dust to the environment. High volume air scrubbing systems to eliminate dust pollution have not been successful. In addition, the last two installations at Jubail, Saudi Arabia, were destroyed by a fire believed to have been ignited by static electricity. *Wet-prills* are created when sulfur droplets enter a cool water bath. They have a slightly irregular texture caused by water's more rapid cooling action. Devco [8] USA, Martin Sulphur [9] and Enersul [10] have fairly similar technologies and products. Current processes create a homogeneous product which resembles small nuggets. At this writing, all sulfur-forming operations in the United States produce wet-prill. *Granular* sulfur, as the name implies, is created through the gradual buildup of successive layers of sulfur around a central core. As a result, the ultimate product size can be controlled. Enersul [10] possesses the most widespread granulation system, with installations in Canada, the Former Soviet Union, Europe, and the Middle East. Kaltenbach-Thuring [11] provides another type of granulation technology. Most recently (4/11), Martin Sulphur [9] has announced a proprietary (patent pending) granulation process.

Despite developments in forming technology and dust suppressants, moisture remains the primary tool for dust mitigation. To that end, a mixture of water and surfactant should be applied during all bulk transfer operations. A US Patent was recently issued to Con-Sul, Inc.'s Gerard d'Aquin for a revolutionary solid sulfur ship unloading system which

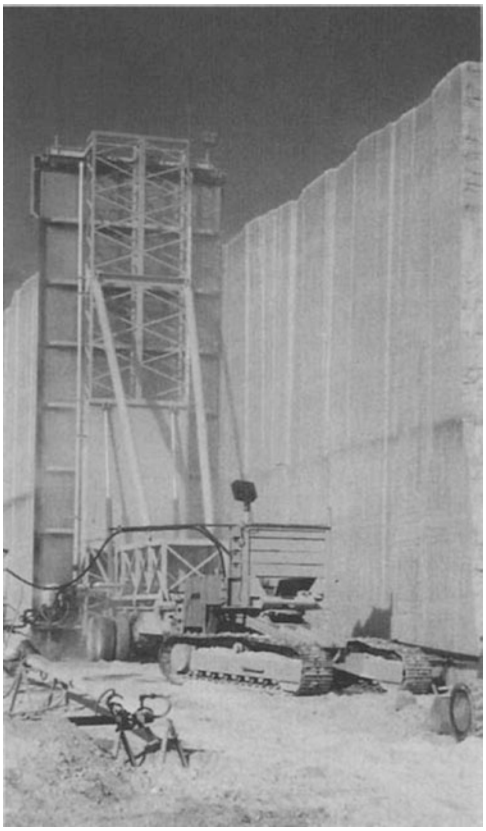

Fig. 25.1 An ellethorpe melter. (*Courtesy* Con-Sul, Inc.)

eliminates dust, controls acidity, and de-waters most types of formed sulfur [12].

Melting block inventory is most often accomplished using a track-mounted Ellethorpe melter (Fig. 25.1). This resembles a rectangular ironing-board mounted on tracks. The "hot" portion is placed vertically against the blocks side. Sulfur melted by the rectangular surface is collected at the base and piped to filtration (if appropriate) and storage. Mechanical reclamation, normally from inside the block to minimize dust emissions, crushes sulfur and transfers the lumps to a static pit or above ground tank melter.

Problems can surface. Melting or re-melting solid sulfur that has been transported by vessel requires proper knowledge and equipment. Contaminants, including sand, dirt, rocks, and rusted metal, which can mix with solid sulfur during transit and storage must be removed. Sulfuric acid is another issue: weak acid is almost always present in solid sulfur that has been stored for some time, let alone stored, transported by vessel, and then stored again. While customers can require a specification "below 100 ppm free acid" at load-port, they may receive several times that level when measured at the destination melter. The currently accepted practice is to mix lime or a liquid oxidizer with the material being melted to neutralize all acids. Liming, in turn, requires a filtration stage—large installations use steam jacketed pressure leaf filters, containing a diatomaceous earth medium over a stainless steel mesh, to remove the lime/ash residue. An alternative is to allow ash to settle prior to transfer from an intermediate pit.

Carbon compound molecules contained within sulfur will be converted to an extremely hard (Car-Sul) material when solid sulfur is re-liquefied. Car-Sul, which can be filtered, abrades sulfur burner spray nozzles [13]. Users of sulfur in the sulfuric acid industry therefore prefer receiving sulfur which has never been solidified rather than incurring the foregoing operating costs and losses of sulfur in filtrate residue. Owing to the volume of production, legislation, and a developed liquid infrastructure, most sulfur consumed in North America, Europe, Japan, and Korea is never solidified.

Development of the Sulfur Industry

Early mankind doubtless found elemental sulfur in volcanic craters, encrusting the edges of hot sulfur springs, and embedded in limestone formations. They discovered that it would burn and used it for medicinal purposes, as a bleach, fumigant, colorant, and incense. These uses are mentioned in ancient writings. The Romans produced incendiary weapons from sulfur. In the thirteenth century, the Chinese invented gunpowder using sulfur, nitrate, and charcoal.

The earliest commercial sulfur came from limestone deposits. Those in Sicily and the Italian mainland developed world markets in the eighteenth and nineteenth centuries. Traditional mining methods were used to produce sulfur ore, which was burned slowly in a pile (Calcarone) to yield crude sulfur [14]. Steam smelting in autoclaves came into use about 1859. In 1890, Robert Gill built a multi-chamber furnace to improve the process's production rate and efficiency. Italian monopoly of the sulfur markets continued until the early 1900s when the Frasch process brought previously unrecoverable sulfur deposits on the North American Gulf Coast into production. Oil exploration efforts in Texas and Louisiana in the late 1800s uncovered sulfur deposits in limestone at depths of 200–300 m, but mining was complicated by the intervening layers of quicksand and the presence of hydrogen sulfide gas. Numerous conventional mining attempts at Sulphur, LA, failed.

Finally, in December 1894, Hermann Frasch demonstrated the hot water process for mining underground sulfur deposits. With its favorable economics, the Frasch process completely displaced the Italian sulfur industry. The ready availability of low-cost sulfur opened the way for commercial sulfuric acid production by burning sulfur. This eventually supplanted the long-standing iron pyrite combustion process for sulfuric acid production by eliminating its extensive gas-cleaning operations.

In 1883, the Claus process for producing sulfur from hydrogen sulfide through partial combustion over an iron oxide catalyst was patented. It had limited success over the following 50 years as a method for producing sulfur and its primary use was to remove the sour component in gas processing.

The number of Claus installations grew during the second half of the twentieth century. An increase in sour gas and liquid petroleum feedstocks, processing and, more recently, environmental regulations led to greater quantities of sulfur being removed from hydrocarbon fuels. Sulfur extracted from oil and gas has increased dramatically since the 1970s when environmental legislation took hold. In 1985, Frasch and recovered sulfur in the United States each accounted for about five million tons of production. By 1995, US Frasch output had declined to 3.1 million tons and recovered represented 7.3 million tons. In 2001, faced with oil companies disposal of recovered sulfur at low prices and rising natural gas costs to heat mine-water, US Frasch mining ceased [15]. Frasch sulfur technology, with its colorful and inventive history, lasted just over 100 years in the United States. For the world, removing sulfur from hydrocarbons provided virtually all of the 48 million tons of elemental sulfur generated during 2010 [16].

The cessation of US Frasch output at the end of the 1990s brought the demise of associated infrastructure and dissipated the industries commercial focus. Since 2001, sulfur producers have been unable to effectively match supply with consumer demand through inventory management.

The consequence has been a series of value fluctuations (most notably declines in 2001, 2004, and 2008–2009) due to declines in phosphate fertilizer output which led to a collapse of sulfur prices [17] (see Fig. 25.2).

Contrary to normal economic reasoning, fluctuations in price are not due to large imbalances between demand and commercially available supply. Rather, they are due to small imbalances, compared to the 48 million tons of annual output. Even small fluctuations cannot be accommodated in the industry's limited commercial storage facilities. Refineries and sour-gas processing plants must dispose of their sulfur output. Volumes in excess of the limited storage capacity available normally forces refineries to cease operations due to environmental regulations. Therefore, any reduction in demand and a smooth outflow to consumers, will lead to aggressive price discounting.

While Frasch sulfur companies maintained a working storage capacity of approximately seven million tons of solid sulfur at several locations in the early 1980s, total US solid block storage is currently below 600,000 t. Such storage also helped reduce upward movements in price when weather or accidents restricted deliveries. As sulfur went through periods of low value, producers in more distant locations (Canada, Russia, Saudi Arabia, Kazakhstan) have resorted to blocking the material (see section "Solidification and Melting"). This occurred during the late 1960s along the Alberta Foothills area (East of the Rocky Mountains from the US border to well North of Edmonton, Canada).

In the late 1970s the area contained upward of 22 million tons of elemental sulfur. With US stockpiles, it served as the world's reserve. Over the past three decades Alberta's stockpiles have been as low as 4 million tons and as high as 16 million tons. Today, the figure stands at about 12

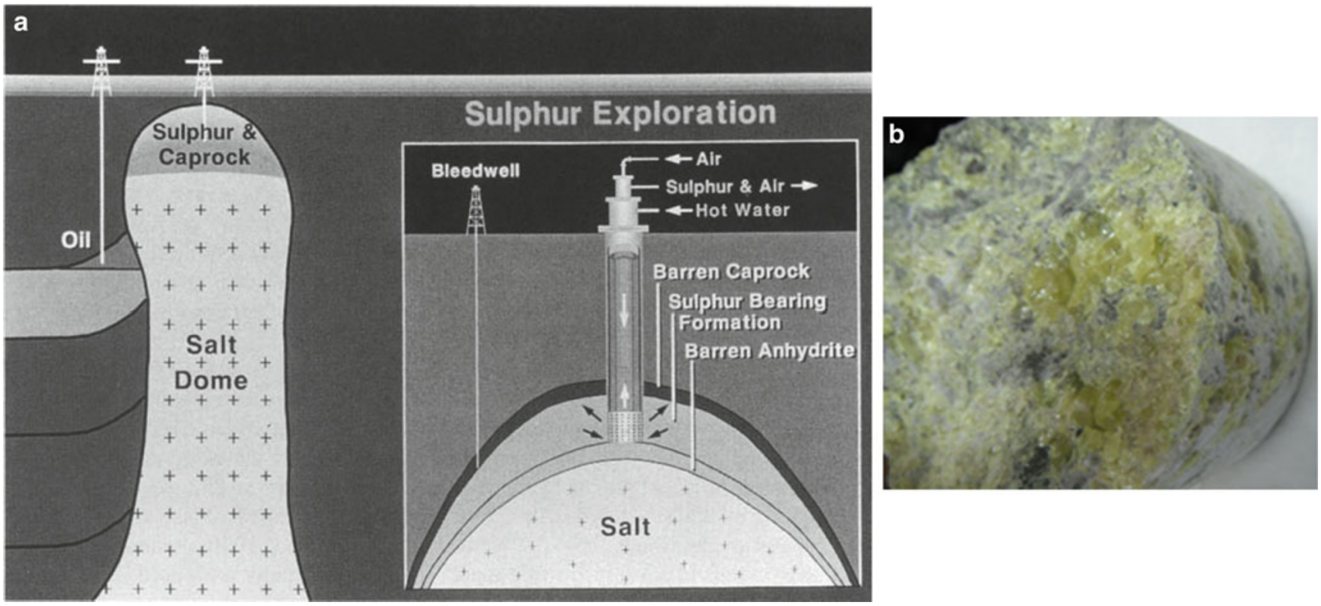

Fig. 25.3 (**a**) Frasch process for mining sulfur from salt-dome formations. (*Courtesy* Freeport Sulphur Co.). (**b**) Sulfur-bearing limestone

million tons; 3 million in the Foothills and 9+ million in the Oil Sands producing area. Sulfur produced and stored in the Oil Sands, as differentiated with the limited production and storage in the Foothills, has only a limited "commercial availability" due to constraints in transportation infrastructure and costs. Changing these conditions requires capital investment and governmental approval. Neither one is likely given the volatile nature of sulfur demand and prices. Therefore, Syncrude's nine million ton block of sulfur and parts of the 900,000 t produced per year are commercially unavailable. In stark contrast, had production and inventory been located in the Foothills, and had reclamation and transportation existed, it would have been shipped to markets in 2009, 2010, and 2011.

Other areas where a significant volume of sulfur inventory accumulation has taken place when prices do not justify the cost of commercial disposal are Saudi Arabia (1970s to early 1980s and 2000–2009), Russia (depleted in 2011) and Kazakhstan (still with 6 million tons of inventory).

Sulfur industry practice when calculating an outlook of annual supply/demand balances uses total production less demand with no differentiation for "commercially available" or "commercially unavailable" supply sulfur. Similarly, no distinction is made for "commercially available sulfur" inventory at Alberta Foothills locations and non-commercially available at Syncrude's Oil Sands location.

One means of disposing of unwanted sulfur streams is re-injection of H_2S and CO_2. The process has long been used in Canada and the USA on a small scale. The largest project is currently at ExxonMobil's La Barge, Wyoming gas plant where up to 400,000 t per year of elemental sulfur has been removed from the market since 2005. Huge projects to re-inject sulfur at the Kashagan field in Kazakhstan and at various Arab Gulf locations are underway or contemplated.

Sulfur is also produced from sulfide ores (pyrites) by thermal decomposition in the absence of air, by roasting/smelting under reducing conditions, or by reaction of the ore with SO_2. Hydrometallurgical processes have produced sulfur from metal pyrites as a by-product.

Except for China, pyrites roasting no longer accounts for significant quantities of sulfur values. And even China has embarked on a rapid conversion to using elemental sulfur in former pyrites roasters in order to lower production costs and pollution. Canadian sulfur exporters, who initiated this trend with the development and introduction of innovative technology, have gained the most. The Canadian exports of sulfur to China rose from 31,000 t in 1995 to a peak of 3.9 million tons in 2005 [18]. Since then the volume declined to 1.5 million tons in 2010.

Sulfur Production Processes

Despite the economically driven closure of the Main Pass 299 sulfur mine in 2000 (just 8 years after initial output), the Frasch process remains the most effective method for extracting sulfur from native deposits. Certain constraints on the geological formations required by the Frasch process limit its use to deposits along the Gulf of Mexico, Poland, the Former Soviet Union, Mexico, and Iraq. Other sulfur deposits may yield to the Frasch process. Figure 25.3 shows the structure needed for Frasch mining from salt domes.

The sulfur-bearing limestone must have sufficient porosity to allow sulfur to migrate upon melting. Both the caprock and the underlying anhydrite formation should be impervious to prevent the loss of the hot water pumped into the mine. These salt-dome deposits are typically lens shaped and are 175 m thick with diameters of a few hundred meters up to several kilometers. Some horizontal deposits exist and have been exploited.

A sulfur well consists of a casing and three concentric pipes reaching into the sulfur-bearing strata. The outer 8–10 in. pipe carries 165°C water pumped into the formation to melt the sulfur. An inner cement-lined 3–6 in. pipe is used to transport the melted sulfur to the surface. Compressed air is passed through the l inch tube in the center to air lift the sulfur. Without the air lift, the molten sulfur would rise only part way in the middle pipe. The compressed air produces a low-density sulfur froth that rises to the surface. The superheated water melts the sulfur in the vicinity of the well, forming a molten sulfur pool at the bottom of the well. As production continues, the formation fills with water. To continue production, bleed wells are drilled at the periphery of the formation to allow for discharge of the cooled mine water. In some mine fields, sufficient mine water is lost to the geological formation to provide for continued production. To limit mine water loss and reduce water heating costs, mud, or synthetic foam is sometimes pumped into the formation to seal major crevices.

Although most US Frasch mines were located inland, Freeport Sulfur Company pioneered offshore sulfur mining in the 1960s [19].· The company utilized offshore oil drilling techniques to access several shallow water deposits. Developing a means to utilize saltwater to provide heated mine water presented the company with unique challenges in corrosion and scaling control. The now defunct Main Pass 299 facility located in 200 ft of water 10 miles from the Mississippi Delta, commenced production in 1992 and closed in 2000.

Sulfur produced from salt-dome structures can be quite pure, but it often contains up to 1% of bituminous residues, which render it dark and can make it unacceptable for sulfuric acid production. Some purification is obtained by filtering the dark sulfur through diatomaceous earth. Nevertheless, the most effective means of meeting maximum commercial specifications for carbon is through blending dark sulfur with bright recovered sulfur devoid of carbon. That practice was widely used by Louisiana Frasch producers. To improve filtration, carbonaceous material is converted into larger, filterable, particles (Car-Sul) by treating the sulfur with heat or sulfuric acid. Freeport's submerged combustion distillation process was used from 1966 until 1979 to purify Frasch sulfur with up to 2% carbonaceous material. It was also going to be used to purify sulfur extracted at Mishraq, Iraq in 1990.

Recovered Sulfur

Hydrogen sulfide is recovered from natural gas or refinery gases by absorption in a solvent or by regenerative chemical absorption [20].· In either case a concentrated hydrogen sulfide stream is produced that is treated further by the Claus process. A typical Claus plant has a feed stream of at least 45% H_2S, but with modifications can handle streams containing as little as 5% H_2S. For gas streams with low concentrations of hydrogen sulfide, direct conversion of the hydrogen sulfide to sulfur is accomplished in a solvent system, as in the Stretford or CrystaSulf processes.

The Claus process is based on the reaction of H_2S with sulfur dioxide according to the highly exothermic reaction:

$$2H_2S + SO_2 \rightarrow 3S + 2H_2O$$

In practice, sulfur dioxide is produced in situ by partial oxidation of the hydrogen sulfide with air or oxygen in a furnace. In the split-flow arrangement, one-third of the H_2S stream is burned and then recombined with the remaining two-thirds before entering the Claus reactor. In the straight-through version, the entire H_2S stream is sent through the burner and the extent of H_2S combustion is controlled by the air feed rate.

A flow diagram for a typical Claus process is shown in Fig. 25.4. The hydrogen sulfide is burned in a fuel-fired furnace (950–1,250°C) with air to produce sulfur and a gas stream containing H_2S and SO_2. Process controls maintain the H_2S:SO_2 ratio near 2, in accordance with the stoichiometry. Heat is removed from the gas stream in a waste heat boiler to control the process gas temperature. The process gas is passed through one or more catalyst beds to convert the H_2S and SO_2 to sulfur, which is then removed in condensers between each bed. A high temperature shifts the equilibria toward the reactants, whereas a low temperature causes sulfur condensation on the catalyst bed, leading to decreased catalyst activity, requiring bed switching/regeneration to achieve modem recovery standards. In practice the temperature is closely controlled for each Claus reactor, with higher temperatures at the first reactor where compounds such as COS and CS_2 are converted to S. Much research and development into H_2S conversation has occurred in the past decades. Three-state Claus units are now capable of achieving recoveries of 98+ percent, a significant improvement over the 85–90% range of the late 1980s [21].·

Figure 25.4 shows a typical sulfur recovery plant based on the Claus process, and Fig. 25.5 provides a photographic overview of an installation. The tail gas from the Claus reactors may be further processed to remove any remaining sulfur compounds. Combined H_2S removal efficiencies of 99.5–99.99% are achievable [20]. This may be done by low-temperature Claus-type solid-bed processes (e.g., the Sulfreen process), wet-Claus absorption/oxidation processes

(e.g., the Clauspol 1500 process), or hydrogenation of the off-gas to form H_2S for recycle (e.g., the SCOT process). Residual sulfur compounds in the tail gas are then incinerated to SO_2. The residual SO_2 in the oxidized tail gas may be scrubbed by any of several processes (e.g., the Wellman-Lord process) before being vented to the environment. It is feasible to bring the H_2S content of the treated tail gas to as little as 150–10 ppm weight, depending on the solvent used [22].

Production and Consumption of Sulfur

World production of sulfur in all forms reached 68 million tons in 2009 [23]—up from 57.1 million tons in 1999 [24]. The lower growth rate than anticipated at the end of the 1990s and early 2000s arose principally from delays in implementing Caspian and Arabian Gulf sour oil and gas projects. Schedules slipped due to technical difficulties (Caspian—Kashagan field, Government issues at Tenghiz) and cost escalation/over-ambition and economic setbacks (Arab Gulf). Non-elemental sulfur output has seen a significant change in composition. Volumes arising from environmentally mandated stack-gas effluent recovery have increased. Within the mix, pyrites-derived production continues to decline, though only slightly now that China is the lone remaining producer of substance.

Table 25.1 summarizes the dramatic shifts in the sources of sulfur during this period. It shows the demise of Frasch and native sources of supply and a 9 million ton increase in recovered volume in 10 years. Added sulfuric acid and SO_2 recoveries from effluent gas added four million tons.

US output from 2000 to 2010, see Table 25.2, changed dramatically. Elemental sulfur production declined 1.3 million tonnes. Graph 25.1 provides a historical perspective of changes from 1980 to 2000.

Canada’s sulfur production is concentrated in Alberta. Table 25.3 provides output data for the three western most provinces. Over the past decade, sulfur generated in the region collapsed from 8.5 million tons in 1999 to 5.8 million tons in 2010—a drop (2.7) million, or (31%). The primary causes were:

Exhaustion of sour gas deposits, some under exploitation for more than 30 years.

Failure of new sour gas deposits to yield the needed replacement output—the Caroline gas plant area being just one.

Appreciation of the Canadian dollar having the impact of lowering Canadian Gas producers’ revenues on gas sent to the United States.

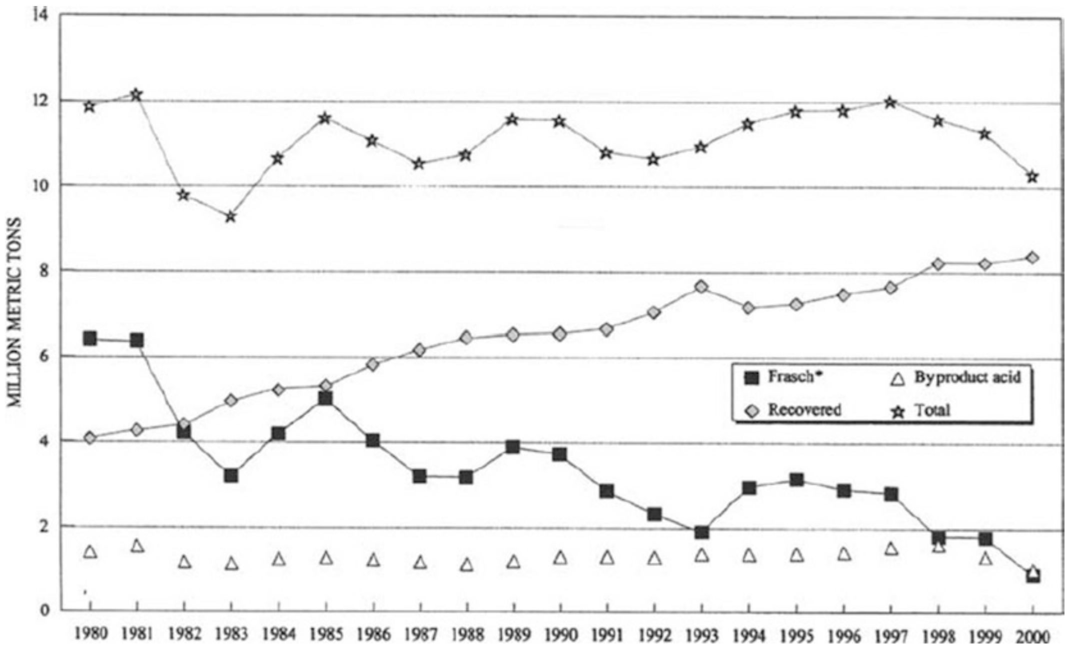
A climate of falling US gas price leading to sour gas exploration and exploitation ceasing.

Delays in the development of oil sands upgrading facilities which were expected to provide replacement volumes of sulfur. Wild cost inflation in the mid-2000s, inadequate physical, human, and regulatory resources, the financial bubble of 2007 and its subsequent collapse, all contributed.

From 1999 to 2003, and in 2009, production exceeded export shipments to the USA and Overseas. As a result, inventories in the oil sands region of Alberta grew significantly. From 2004 forward production was below export demand, leading to withdrawal of sulfur from inventory located in Alberta’s foothills.

Regional shipments and local use fell during the time frame from 7.3 million tons to 6.1 million tons—a 1.2 million tons annual decline.

Canadian exports by rail, in liquid form, to the United States and overseas, as a solidified material, through the port of Vancouver also declined.



Graph 25.1 Trends in the production of all forms of sulfur in the United States (Adapted from *Ober J,* Op Cit.)

[a] *Note*: Alberta, British Columbia, and Saskatchewan

Loss of the US Frasch companies' commercial structure affected North American markets dramatically. Recovered producers, devoid of storage capabilities and marketing experience, and needing to dispose of sulfur to avoid affecting refinery operating rates just pushed it out the door. Sulfur prices embarked on a decline which culminated with spot sulfur prices falling to the $10s per ton in Tampa, FL, and Vancouver, Canada, by mid-2001. In contrast, prices during 1990 were $140/t and $108/, respectively. A second collapse occurred in 2008–2009, leading to a Tampa price of zero during the first quarter of 2009 (see Fig. 25.2).

The United States remains the largest producer and consumer of sulfur in all forms. US production and consumption data are provided in Table 25.2. Fertilizers and agrochemicals represent the largest use for sulfur, 69%. Phosphatic fertilizers consume 7.1 million metric tons, 57%, in the form of sulfuric acid. Agro-chemicals account for 1.3 million metric tons, 10%, all in the form of elemental sulfur. Sulfur, surprisingly, represents the largest fungicide and pesticide product applied in the United States. Refining use, for alkylation, is the second largest segment of consumption. It is also one of the most difficult segments to track accurately. This arises from refineries not reporting a portion of their production and using that material directly for internal use. Accordingly, a portion of actual sulfur output does not get reported within the scope of "production of sulfur," causing total uses to exceed production by 1.1 million metric tons.

US production of elemental sulfur has fluctuated dramatically in recent years due to the cessation of Frasch mining operations. Output was 9.5 million tons in 2000, 8.7 million tons in 2005, only 8 million tons in 2008 and is estimated to have rebounded to 8.2 million tons in 2010.

Sulfuric Acid

Sulfuric acid is the largest-volume chemical manufactured in the world and its consumption is often cited as an indicator of the general state of the nation's economy [25]. According to the US Geological Survey's Mineral Industry Survey, about 27 million tons of sulfuric acid were produced in the United States in 2008, of which approximately 74% was used in fertilizer production. Its use extends to nearly every major chemical sector. This versatile acid is truly the "workhorse" of the chemical industry (Table 25.5).

Pure sulfuric acid is an oily, water-white, slightly viscous liquid with a melting point of 104°C and a boiling point of 279°C. It is infinitely miscible with water, forming sulfuric acid solutions characterized by their weight percent H_2SO_4. Oleum may be formed by dissolving SO_3 in sulfuric acid to attain fuming sulfuric acid, with concentrations nominally greater than 100% H_2SO_4. Historically, sulfuric acid concentrations were determined by measuring the solution density using hydrometers calibrated in degrees Baume (Be). This practice is waning, although some specifications and tables of properties still include this measurement (Table 25.4).

Uses of Sulfuric Acid

The primary industrial uses of sulfuric acid are in phosphate fertilizer manufacture, petroleum refining, copper ore leaching, synthetic rubber and plastics, and pulp and paper mills [26]. It is used as a solvent, a dehydrating agent, a reagent in chemical reactions or processes, an acid, a catalyst, and an absorbent, and in many other applications. In spite of its wide usage, sulfuric acid rarely is contained in the final product. Sulfuric acid ends up as gypsum in phosphate fertilizer manufacture, for example. In many other processes the sulfuric acid is converted to a waste product that requires disposal or reuse. Because disposal of waste sulfuric acid and of sulfur compound air emissions are becoming increasingly unacceptable environmentally, the recycle and capture of sulfur values from waste sulfuric acid has become widespread.

Table 25.4 Estimated annual export summary—total Canadian exports (million metric tons)

	‘11	‘10	‘09	‘08	‘07	‘06	‘05	‘04	‘03	‘02	‘01	‘00
Vancouver	3.4	3.6	4.1	4.7	5.2	5.8	6.1	6.3	5.3	5.1	5.2	5.3
US	2.6	2.3	1.5	2.2	2.1	2.0	2.0	2.0	2.0	1.9	1.1	1.5
Total	6.0	5.9	5.6	6.9	7.3	7.8	8.1	8.3	7.3	7.0	6.3	6.8

Nearly all sulfuric acid is manufactured by the contact process in which sulfur trioxide is absorbed into 93–98% H_2SO_4. The acid may be sold at various strengths, usually depending on the requirements of the consumer. It is generally marketed on a 100% basis, but normally is shipped as 93% H_2SO_4 (66°Be), as 98% acid, or as 20–22% fuming oleum. Table 25.6 shows common acid strengths and end uses. Concentrated acid may be stored in mild steel tanks, but dilute acid must be contained in lead-lined or plastic tanks. Bulk shipments of concentrated acid are made in steel tanks on ships, tank barges, or railcars. Reagent grade acid is commonly sold in 5-L glass bottles.

Development of the Sulfuric Acid Industry

Sulfuric acid is formed in nature by the oxidation and chemical decomposition of naturally occurring sulfur and sulfur-containing compounds. It is made by the action of bacteria (*Thiobacillus ferrooxidans* and *thiooxidans*) on coal wastes or iron disulfide discarded on refuse dumps at coal and copper mines; it is produced in the atmosphere by the oxidation of sulfur dioxide emitted from the combustion of coal, oil, and other substances; and it also is formed by chemical decomposition resulting from geological changes.

Although there were vague references to “spirits” expelled from alum by Arabian alchemists in the tenth century and by Roman alchemists in the thirteenth century, the first distinct mention of sulfuric acid has been credited to Basil Valentine in late 1400 [27]. He burned sulfur with

saltpeter in glass retorts or bell jars with a little water, and he also calcined copper as (ferrous sulfate heptahydrate) with silica, with both processes yielding sulfuric acid, although he took them to be different substances. These processes for making sulfuric acid continued until 1746 when Dr Roebuck constructed a lead chamber in England for sulfuric acid manufacture. This marked the beginning of the "chamber process" for sulfuric acid, which was to continue in use for the next two centuries [28].

The first lead chamber was 1.8 m^2, and 8:1 mixtures of sulfur and saltpeter in iron carts were rolled into it and burned with intermittent admission of air [29]. As in glass retorts, the sulfur trioxide that was formed combined with water to produce sulfuric acid, which condensed on the walls and collected in pans. Steam was introduced into the chambers in 1774, and continuous addition of air was begun in 1793. It then was recognized that the sulfurous acid from the burning of sulfur was oxidized by air and needed saltpeter only as a catalyst. In 1827, Gay-Lussac invented a tower for recovering the nitrogen oxides escaping from the chamber. The nitrogen oxides were condensed in sulfuric acid but could not be economically recovered from the acid until the invention of the Glover de-nitrating tower in 1859. The introduction of these two towers completed the chamber process except for various refinements to reduce costs. The process could produce acid with up to 77% H_2SO_4 but generally yielded strengths in a 65–68% range. Higher-strength acid was produced by boiling chamber acid to remove water. A platinum still for producing concentrated sulfuric acid from chamber acid was first built for the Harrison Works in Philadelphia in 1814.

The developing markets for sulfuric acid in the late eighteenth century increased the demand for Sicilian sulfur. By 1832, sulfur prices had risen to $80/t, and stocks rose; then in 1833 the market broke, with the price at $15/t. Sicilian government attempts to stabilize sulfur at $70/t failed, in part because of an 1833 discovery by a French chemist that sulfur dioxide could be obtained by roasting pyrites in a furnace. Process improvements in pyrite roasting by 1870 made pyrites competitive with sulfur as a raw material. By 1880, with the single exception of the United States, the sulfuric acid industries had gone to a pyrites basis. By 1909, virtually all US sulfuric acid came from pyrites and as by-product acid from zinc and copper smelters. In the late 1890s, development of the Frasch process for sulfur mining lowered the price of sulfur. This change, coupled with new developments in sulfur burners, led sulfuric acid manufacturers back to sulfur as a raw material source. During World War I gypsum was burned with coal to produce SO_2 for sulfuric acid production. This process continued in Europe until the 1950s, with the last plant (in Great Britain) shut down in 1975. Today sulfuric acid production from pyrite roasting remains important in Spain, the Former Soviet Union, China, Japan, South Africa, Turkey, and some eastern European nations [30]. The Bosveld No. 2 plant in South Africa operated on gypsum until the early 1980s when it was shut down.

The contact process for sulfuric acid dates from 1831, when a Briton patented a method for converting sulfur dioxide to sulfur trioxide by passing the gas through a heated tube filled with finely divided platinum. The sulfur trioxide was adsorbed in chamber acid to produce concentrated and fuming sulfuric acids. Commercialization of the new process was delayed by lack of markets for the concentrated acid and poor understanding of the process parameters. About 1870, demand for fuming sulfuric acid spurred German development of the contact process. In 1901, BASF reported that the governing principles for the successful manufacture of contact acid were well understood. These included cleaning of the sulfur dioxide gas stream, use of excess oxygen, and temperature control of the catalyst bed. However, the reliance of the contact process on feed acid produced by the chamber process limited its development until about 1930. It became known that the acid in the final SO_3 absorption tower had to be kept in the range 98.5–99.0% H_2SO_4 to be effective. Accurate dilution techniques to allow recycle of the absorber acid were developed in the late 1920s. The contact process then could continuously produce diluted acid, and no longer required chamber acid. The development of poison-resistant vanadium catalysts for SO_2 conversion allowed the use of smelter gases in the contact process. With its lower capital and operating costs, the contact process then supplanted the chamber process for sulfuric acid production. By 1940, the United States had equal numbers of chamber and contact processes. Today no commercial chamber plants are operating in the United States.

Since the 1940s most developments in the contact process have focused on energy recovery and pollution abatement. The production of SO_2, its conversion to SO_3, and the dilution of H_2SO_4 are exothermic processes that are exploited to reduce energy costs at sulfuric acid plants. Sulfur emissions have been sharply reduced by using two SO_3 absorbers, although one absorber is the economic choice. Tail gas scrubbing processes have been developed to further reduce sulfur emissions from sulfuric acid plants. No single absorber plants have been built in the United States since the 1970s, although there were still some in operation as recently as 2000. As of the early 1970s, US EPA regulations limited new sulfur-burning sulfuric acid plant emissions to 2 kg SO_2 and 0.075 kg acid mist per metric ton of H_2SO_4 produced, and metallurgical plants to 650 ppm volume SO_2. During the 1990s some local requirements exceeded the EPA regulations and several plants were constructed with SO_2 limited to 100 ppm SO_2 (about 0.5 kg SO_2 per metric ton H_2SO_4 produced). One double absorption plant followed by an ammonia based DynaWave scrubber, built under Monsanto Enviro-Chem license in Ulsan, Korea, started operation in 1999 with SO_2 at 30 ppm.

Manufacture of Sulfuric Acid by the Contact Process

The basic steps in the contact process are: (1) production of sulfur dioxide; (2) cooling and, for smelters, cleaning of the process gas; (3) conversion of the sulfur dioxide to sulfur trioxide; (4) cooling of the sulfur trioxide gas; and (5) absorption of the sulfur trioxide in sulfuric acid [31]. Figure 25.6a is a photograph of a contact process plant. A simplified diagram of a double absorption contact sulfuric acid process is shown in Fig. 25.6b. Because sulfur dioxide is produced by several processes, it is convenient to separate the discussion of sulfur dioxide production from its conversion to sulfuric acid.

Sulfur Dioxide Production

Sulfur is converted to sulfur dioxide by burning molten sulfur with dried air in a sulfur burner to yield a 1,000–1,200°C gas stream containing 10–12% SO_2. The burner is mounted at one end of a sulfur furnace, and the gas passed through a waste heat boiler at the other end. The gas temperature is reduced to 420–440°C on residual oxygen level limits the formation of nitrogen oxides, which otherwise would be very high at the combustion temperature of 1,750°C. The combustion gas then is cooled to 620–650°C, and additional dried air is injected to burn the residual sulfur in an afterburner. A second waste heat boiler cools the process gas to 420–440°C before sending it to the converter.

Pyrites and other iron sulfides are roasted to produce an iron oxide cinder and an off-gas containing 7–14% SO_2 which is contaminated with varying amounts of arsenic, lead, zinc, and other metal oxides. The off-gas must be cleaned before it is sent to the converter. Various types of pyrite roasting equipment have been used in the past, including shaft furnaces, multiple hearth roasters, rotary kilns, and dust roasters. Fluid-bed roasters now are widely used for their superior process technology, throughput rates, and economics. The roasting process must be controlled between 850 and 940°C. At lower temperatures the reaction is incomplete, whereas at higher temperatures the iron oxides and sulfides form a eutectic melt that inhibits the reaction rate. Fluid-bed roasters surpass other types in temperature control and temperature uniformity throughout the bed. Fluid-bed technology for SO_2 production was introduced in the early 1950s by Dorr Oliver in the United States and by BASF in the Federal Republic of Germany.

Copper, lead, zinc, and other sulfide ores may be processed by roasting or smelting. Roasting or sintering of sulfide ore is essentially identical with pyrite roasting. Sulfur melting generally occurs at higher temperatures. Older reverberatory furnace smelters produce off-gas with only 1–2% SO_2 too low for its economical recovery as acid. By using an oxygen-enriched air feed, the off-gas can be raised to 6–8% SO_2 Bath smelters (Mitsubishi, Noranda), where the ore concentrates are heated and reacted in the slag/matte melt, produce an off-gas with 10–20% SO_2 [32]. Flash smelters (lnco, Outokumpu), which involve suspension and reaction of the concentrates in an oxidizing gas stream, operate at 1,200–1,300°C and produce a waste gas with 10–15% SO_2 Oxygen enrichment of the feed air can raise the SO_2 level in the off-gas to 30–80%. The Kivcet process smelts with pure oxygen and produces off-gas with 80–85% SO_2 [33]. Normally strong gases are diluted with air to 14% SO_2 in order to limit outlet temperatures in the converter first pass to less than 640°C and to provide sufficient oxygen to convert the SO_2 to $SO_{3.}$ In 1996 the original Olympic Dam sulfuric acid plant in South Australia was modified to

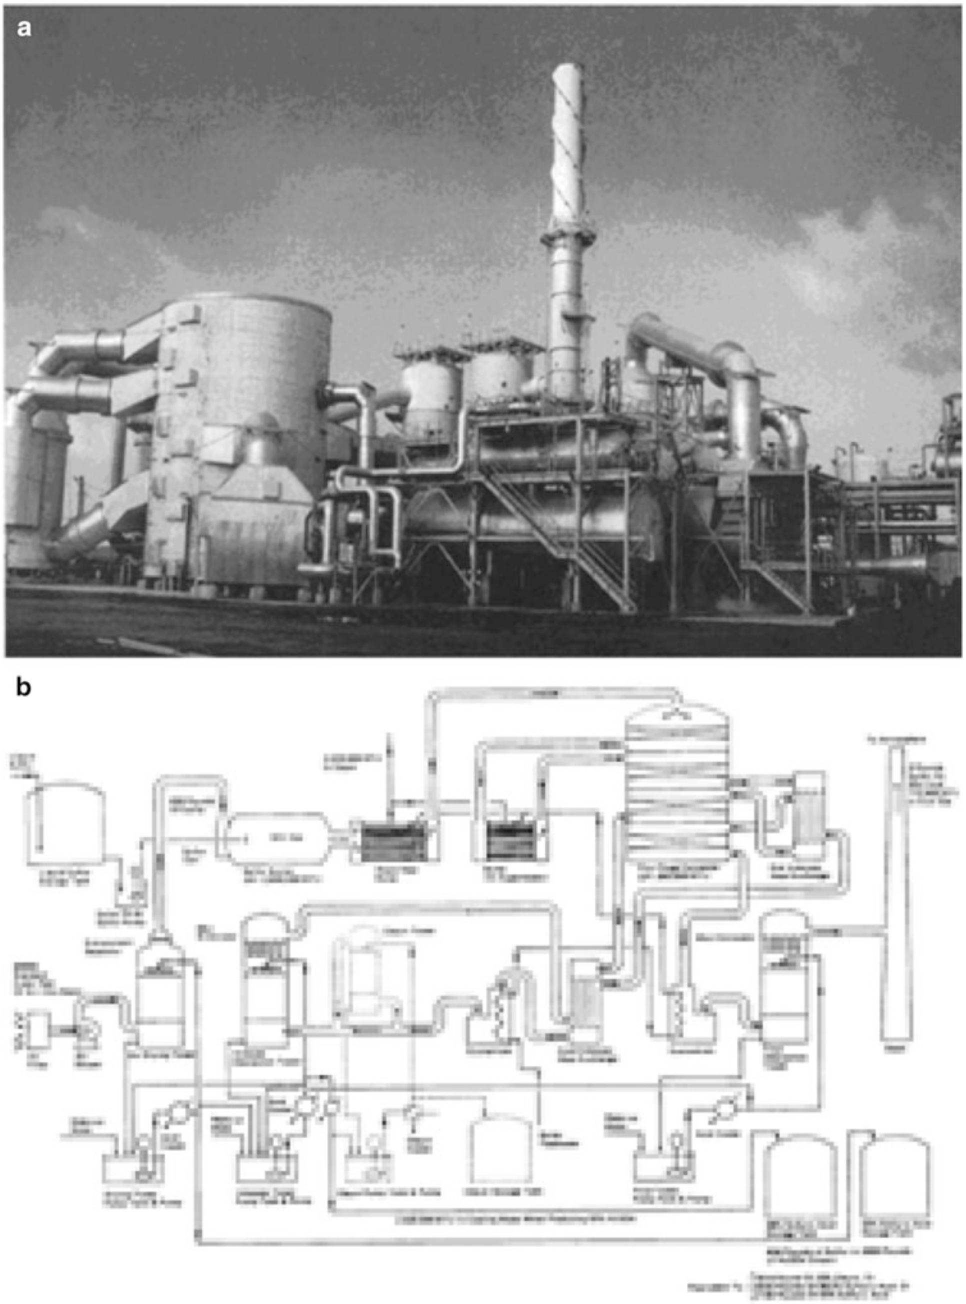

Fig. 25.6 (**a**) Modern double absorption sulfuric acid plant with view of sulfur furnace in foreground. (*Courtesy* Monsanto Enviro-Chem.). (**b**) Schematic flow diagram of a double absorption contact process for sulfuric acid manufacture

operate with 18% equivalent SO_2 gas strength. This plant used a Monsanto pre-converter and a cesium promoted catalyst [34]. Figure 25.7 is a photo of a metallurgical gas sulfuric acid plant.

Off-gas from roasting and smelting operations may contain dust, SO_3, halogens, NO_x, arsenic and other toxic metal fumes, and mercury [35, 36]. These components must be removed from the gas stream before it is sent to the converter. Although SO_3 is produced in the converter, its presence in the cooled gases upstream of the converter will cause excessive corrosion by forming sulfuric acid mists. The cleaning plant steps are: (1) hot-gas dedusting; (2) wet scrubbing; (3) gas cooling; (4) mist removal; and, if necessary, (5) mercury removal. The hot gases generally are passed first through a waste heat boiler to reduce the temperature to 250–400°C. Cyclones followed by hot-gas electrostatic precipitators (50–90 kV) remove nearly all (99+%) of the dust. The gas then is contacted with weak (5–30%) H_2SO_4 in an open spray tower which removes metal vapors and additional solids, cools the gas to 50–80°C, and converts SO_3 to acid mist for later removal. If higher levels of particulate removal are required, a venturi, Swemco, or DynaWave scrubbers may be used. The saturated gas is next cooled in a packed tower or shell and

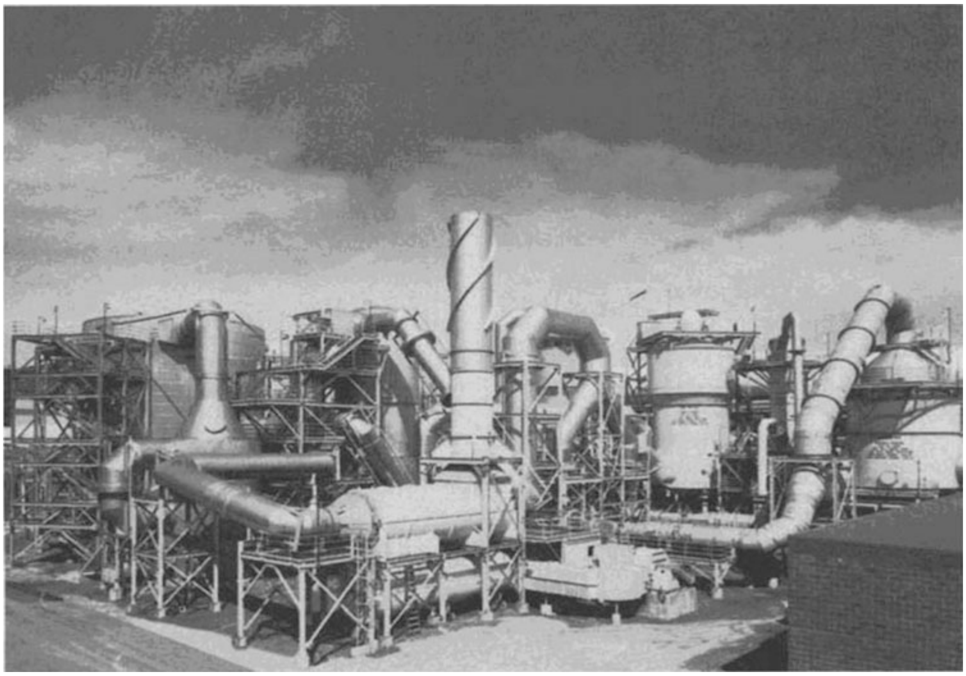

Fig. 25.7 Modern metallurgical sulfuric acid plant with view of preheating furnace in foreground. (*Courtesy* Kennecott, Monsanto Envior-Chem, and Manly Prim Photography)

tube heat exchanger to condense excess water. Shell and tube heat exchangers of graphite or alloy construction are generally used only in smaller size sulfuric plants or where the gas temperature has a tight approach to available cooling water. Silica packing is used in the towers, or sodium silicate is added to the weak acid circuits to remove fluorides as flourosilicic acid.

In cases where the fluoride levels are very high, additional liquid–gas contacting stages are provided to reduce the gas phase concentration of fluorides. Acid mist is removed in wet electrostatic precipitators fitted with lead tubes and star wires or, more recently, with FRP or PVC tubes specially treated to maintain a conductive liquid film surface (Lurgi) [37] and composite wires fabricated with barbs to promote corona discharge [38]. If present, mercury is removed in an additional tower by scrubbing with mercury chloride solution (Boliden) [39], hydrochloric acid solution, or 70–85% sulfuric acid.

Waste sulfuric acid sludges from petroleum refineries are disposed of by conversion to SO_2 for production of fresh sulfuric acid. The heavy organic components of the sludges can be decomposed thermally at 800–1,300°C (Lurgi, Monsanto Enviro-Chem) or reductivity at 200–600°C with coal in a rotary kiln (Chemico). Thermal decomposition is accomplished in a fuel-fired vertical or horizontal furnace. The acid sludge also can be injected into fluid-bed pyrite roasters as a means of disposing of the acid and reducing fossil fuel consumption. Dilute acid sludges must be concentrated to 60–75% H_2SO_4 for economical conversion. This is generally done by using waste heat from the decomposition process. The sulfur dioxide gas stream from these processes requires cleaning, as described above for roasting the smelting plants.

Calcium sulfate may be decomposed to cement clinker and sulfur dioxide gas in a coke-fired rotary kiln at 900–1,400°C (Miiller-Kiihne) [40]. However, the unfavorable economics of this process relegate it to countries that do not have other sources of sulfur. Phosphogypsum (gypsum produced by the acidulation of phosphate rock) may be decomposed in this way as a means of recycling the sulfur values in the large waste phosphogypsum piles at fertilizer plants (OWS-Krupp and FIPR/Davy McKee).

This process is hampered by the more extensive gas cleaning requirements for decomposing phosphogypsum as compared with natural gypsum. During the early 1980s there was some interest in recycling phosphogypsum. By 2000, because of the high cost of these processes, there was little commercial interest. Environmental forces also are behind the recycling of ferrous sulfate from metals industry pickling liquors. This “green salt” is decomposed to sulfur dioxide and iron dioxide in pyrite roasters. Elemental sulfur, coal, or fuel oil may be used as supplementary fuels.

Refinery waste gases may be burned to eliminate hydrogen sulfide and other sulfur containing contaminants. Streams containing small amounts of H_2S or constituents unsuitable for Claus plants may require combustion to SO_2 as the means of disposing of the toxic gas. The resulting effluent gas usually is low in SO_2 and contains water vapor and carbon dioxide. Flue gases from fossil fuel power plants also fall into this category. Recovery of the sulfur values from these dilute gases usually is driven by environmental considerations rather than economics. In the United States, power plant flue gas often is scrubbed with lime to convert the SO_2 to gypsum sludge for landfill disposal. Alternatively, the BergbauForschung process recovers sulfur dioxide by dry adsorption on activated coke at 130°C. The SO_2 is released by heating the coke to 600–650°C. Sulfur dioxide can be absorbed in a sodium sulfite solution (Wellman-Lord) to produce sodium bisulfite. Pure moist sulfur dioxide can be recovered by heating the sodium bisulfite.

Single Versus Double Contact Process

The single absorption contact process for sulfuric acid is characterized by four main process steps: gas drying, catalytic conversion of SO_2 to SO_3, absorption of SO_3, and acid cooling. The maximum SO_2 conversion for a single absorption plant is about 97.5–98%. By adding a second SO_3 absorber with one or two catalyst beds between absorbers, the SO_2 conversion can be increased to 99.5–99.8% or even as high as 99.9% with a cesium promoted catalyst, resulting in lower SO_2 emissions. The so-called double absorption process is now the industry standard.

If water vapor is present in the gas stream or the gas temperature or metal surface temperatures drop below the dew point, liquid acid is formed by condensation of H_2SO_4 vapor rather than by absorption of SO_3. Therefore, the SO_2 laden process gas sent to the converter must be dry to protect the downstream process equipment against corrosion. The drying generally is done in a packed tower with recirculating concentrated (93–98%) sulfuric acid kept at 50–60°C by indirect cooling. The tower acid stream is heated by condensation of the water and by dilution of the acid. The tower temperature is used to control the moisture level of the gas sent to the converter. Acid from the drying tower is cross flowed to the absorber or is sent to storage tanks for shipment. When sulfur is burned, the combustion air to the sulfur burner is dried because the combustion of sulfur does not produce water. Off-gases from pyrite roasters and metallurgical smelters are dried as part of the gas cleaning process. For roaster gases with low SO_2 concentrations, a predryer may be added upstream of the main dryer.

Oxidation of SO_2

Oxidation of SO_2 to SO_3 is accomplished in multi-stage, fixed-bed catalytic converters equipped with interstage boilers or heat exchangers to remove the heat of reaction. Typically, four stages are compartmented within a single vertical converter, which may be brick-lined, steel, or cast iron. Newer converters are stainless steel, and some have five stages for higher conversion. Isothermal tubular converters are no longer suited to modem high-capacity plants. The extruded cylindrical catalyst pellets are usually 4–9% V_2O_5 with alkali metal sulfate promoters on a silica carrier (diatomaceous earth, silica gel, or zeolites). The reaction temperature for vanadium catalyst is generally 410–440°C. In the late 1980s a cesium promoted catalyst became commercially available from Topsoe and Monsanto. These low-strike catalysts operate at 360–400°C. Higher temperatures (~600°C) reduce the SO_2 conversion and lead to structural damage of the catalyst. High-pressure drops across catalyst beds from catalyst dust formed during processing require periodic catalyst removal and screening to remove dust. Ring-shaped catalysts developed by Topsoe and others have lower dust pressure drops and are now in wide use. Other catalyst shapes used are ribbed rings and cylinders. The usual catalyst loading per 1 t/day sulfuric acid capacity is 150–200 L in a double absorption plant and 200–260 L in a single absorption plant. Bayer developed and operates fluid-bed converters that utilize special 0.3–1 mm abrasion-resistant catalysts.

Absorption of SO_3

Sulfur trioxide from the converter is absorbed in 98% H_2SO_4 recirculated counter currently through a packed tower maintained at 60–80°C by indirect cooling. The optimum concentration of the absorber acid is near the H_2O–H_2SO_4 azeotrope, 98.3% H_2SO_4, where the SO_3, H_2SO_4, and H_2O vapor pressures are at their lowest values. Absorption efficiencies in excess of 99.9% generally are obtained. On leaving the converter, the process gas is cooled first with feed gas in a gas-gas heat exchanger and then with boiler water in an economizer to 180–220°C before it enters the absorber. An impingement separator, or Teflon or glass fiber mist eliminator, is placed in the top of the absorber to remove acid mists. If oleum is produced at the plant, it is made in a separate oleum tower upstream of the absorber. A portion of the SO_3 stream to the absorber is diverted to the oleum tower where it is absorbed in a recirculating stream of oleum.

In double absorption plants an intermediate absorber is placed between the second and third (or between the third and fourth) converter beds. By removing SO_3 from the gas stream at this intermediate point, higher SO_2 conversions are attained in the downstream converter beds, and the overall SO_2 conversion is increased. The cooled gas from the intermediate absorber is reheated by hot converter gas in gas–gas heat exchangers before returning to the converter. An oleum tower may be placed before the intermediate absorber.

Acid Cooling

Absorption of SO_3 in concentrated sulfuric acid and the formation of H_2SO_4 from SO_3 and H_2O produce heat in the absorber, as does acid dilution from the addition of makeup

water. Process control requires that the acid be cooled before it is recirculated to the dryer or absorber towers or sent to storage. Earlier acid coolers of parallel banks of stacked, irrigated, cast iron sections have been largely replaced by stainless steel shell and tube or plate exchangers, with or without anodic protection. Hastelloy, Sandvik SX, ZeCor, and Saramet alloys and Teflon linings are also used in acid piping and coolers [41–44].

Tail gas emissions are controlled by improving the SO_2 conversion efficiency and by scrubbing the tail gas. In a double absorption process plant, a five-bed converter has 0.3% unconverted SO_2, as compared with 0.5% for a four-bed converter. A Lurgi Peracidox scrubber may be used to remove up to 90% of the residual SO_2 in the tail gas from a double absorption plant. Hydrogen peroxide or electrolytically produced peroxymonosulfuric acid is used to convert the SO_2 to H_2SO_4 in the Lurgi scrubber.

Other Modifications to the Sulfuric Process [45]

Tail gas from single absorption plants may be absorbed on activated carbon (Sulfacid) or scrubbed with ammonia (Monsanto AMMSOX) or sodium sulfite (Wellman Lord). Metallurgical acid plants differ from sulfur-burning plants in that the cleaned SO_2 process gas must be heated before it is sent to the converter. Many of these plants have weak SO_2 streams that require large gas–gas heat exchangers for temperature control. Four plants in the Former Soviet Union processing 2–4% SO_2 use an unsteady-state oxidation process in which the cold (40–70°C) SO_2 gas is reacted on hot catalyst beds without intervening heat exchangers [46, 47]. As the temperature front moves through the bed to the exit side, the flow is reversed. Cycle times are 30–120 min, and single-bed conversions of 80–90% are reported as compared with 55–60% for conventional processes at higher exit temperatures.

The thermal capacity of a 1,000 t/day sulfuric acid plant is about 63 MW This heat liberation must be controlled in a manner that maintains optimum gas temperatures in the converter system and optimum acid temperatures in the dryer and absorber circuits. Tail gas emissions also are affected by the energy balance. Figure 25.8 shows an energy flow diagram for a contemporary sulfur-burning sulfuric acid plant. About 97% of the total energy input derives from burning sulfur, and 3% comes from the electricity consumed to drive the gases through the plant. Most plants can recover 55–60% of the energy as high-pressure steam (40–60 bar, 400–480°C), but about 40% is lost as waste heat dissipated to the environment in the form of hot water from acid coolers.

During the late 1970s acid plants were optimized to generate more steam. Steam can be produced at pressures up to 80 bar from high-temperature sulfur burners such as the Lurgi two-stage combustion system. The high-pressure steam is let down to low pressure steam through a turbogenerator that co-generates electricity. In double absorption plants, economizers were installed upstream or downstream of the heat exchanger servicing the intermediate absorber. Boiler feed water is preheated to 90–95°C in this economizer to increase steam production. The energy production from acid plants was increased to 70% by installing low-gas-temperature economizers, low pressure-drop catalysts, and suction drying towers, by increasing the SO_2 feed gas concentration, and by preheating the boiler feed water with hot acid. Further energy recovery requires higher operating temperatures for the absorbers and acid coolers. Venturi concurrent absorbers operating at acid temperatures of 130–140°C are installed in several plants. To recover acid

heat directly as steam, it was necessary to increase the acid temperatures from 110 to 120°C to about 200°C.

As of 2005 Monsanto Enviro-Chem had built 21 Heat Recovery System (HRS) units since demonstrating the first HRS at Namhae Chemical in South Korea in 1987 [48, 49]. The process is based on 310 stainless steel, which resists corrosion in 98.5% H_2SO_4 at temperatures up to 220°C. The intermediate absorber at Namhae takes 194°C gas from the converter third stage economizer and absorbs the SO_3 in 199°C, 99% acid. Recirculated acid from the absorber is cooled from 220°C in a 10-bar HRS boiler. The added energy recovery for this process is reported to increase the total recovery to 90%. Monsanto's proposed Monarch process combines HRS technology with the wet catalytic converter process (Lurgi) to increase heat recovery and shift it to high-pressure steam production for electric power generation [50].

Other Sources of Sulfuric Acid

Spent sulfuric acid usually is diluted in the process in which it is used: titanium dioxide pigment processing, plastics manufacture, and so on. The dilute acid may be used in processes requiring dilute acid or may be concentrated for reuse by a number of vacuum evaporation processes (Simonson-Mantius, Chemetics) [51] or by thin-film evaporation (DuPont, Bofors). In the submerged combustion distillation process, water is evaporated from the dilute acid by forcing hot flue gases from a fuel-fired burner below the acid surface (Chemico). The concentration of 75% acid to 95–98% H_2SO_4 by the Pauling-Plinke process is done by feeding the 75% acid to a stripping column fitted with a stirred cast iron pot mounted in a furnace. The acid concentration in the pot must be kept above 80% to minimize corrosion.

Chemetics has developed a process for treating spent alkylation sulfuric acid with nitric acid to produce a sulfuric acid that can be used to acidulate phosphate rock, the major use for sulfuric acid. The organic contaminants are converted to carbon particles that are removed with the gypsum on filtration of the phosphoric acid. Special alloys are used in the fabrication of the acid reactor. Topsoe developed and, by the year 2005 had built, more than 45 wet sulfuric acid (WSA) process units. This process is especially suited for low-strength, less than 4%, SO_2 gas streams which would not be auto thermal or meet water balance conditions in the conventional dry sulfuric acid contact process. In the WSA process wet SO_2 gases pass through converter beds where the SO_2 is oxidized to SO_3. The SO_3 reacts with water vapor to form H_2SO_4 in the gas phase. The acid is condensed in proprietary WSA condensers. Sulfuric acid is produced at concentrations around 98% [52, 53].

Production and Consumption of Sulfuric Acid

The world production of sulfuric acid (2008 and 1999) is given in Table 25.7. Production increased 32 million tons. Output from elemental sulfur feedstock rose about 10% while that from "other" sources increased by 40%. Increased recovery from smelters were a major contributor in the latter's increase. While China reduced output from pyrites slightly, environmental recovery projects at smelters added a considerable volume.

China represents the most dramatic change: 21.6 million tons of output in 1999 versus 53.8 million tons in 2008. Of that, only 4 million tons were produced using elemental sulfur in 1999 vs. 21 million tons in 2008. The increase from effluent recovery was also impressive—from 5 million to 14 million tons in 2008 as China recognized its global environmental responsibilities and the positive economics of such investments.

Table 25.9 lists the sulfuric-acid-consuming industries in the United States and shows the trends in their acid consumption rates from the 1980s to date (Table 25.8).

Nearly all the sulfuric acid consumed in agriculture was reacted with phosphate rock (principally $Ca_9(PO_4)_6CaF_2$) to produce phosphoric acid. Granular phosphate fertilizers are produced by ammoniating phosphoric acid to yield mono- and di-ammonium phosphates; ammonium phosphate is also produced as a fertilizer. Petroleum refining is the largest non-fertilizer use for US sulfuric acid. The acid competes with hydrogen fluoride as a catalyst in petroleum alkylation reactions for gasoline production. Sulfuric acid acts as a catalyst in synthetic rubber and plastics manufacture. Copper ore leaching is carried out by distributing the acid over leach piles of the ore and collecting the copper-rich leachate for processing. Sulfuric acid from nearby smelters is normally used in copper ore leaching.

Thomas F. O'Brien

Sodium Chloride

There are very many inorganic salts, but only one of them, sodium chloride, is commonly referred to by the simple name "salt." Sodium chloride is ubiquitous, and more than 14,000 uses have been tabulated [1]. It is a raw material in the production of many chemicals, including chlorine, caustic soda (sodium hydroxide), synthetic soda ash (sodium carbonate), sodium chlorate, sodium sulfate, and metallic sodium. Indirectly, it is also used to produce many other sodium salts and the very useful hydrochloric acid.

Pure sodium chloride crystals (halite) are colorless to white and contain 39.34% Na and 60.66% Cl. NaCl is rather soluble in water, and temperature has little effect on its solubility. A saturated solution holds 26.3% (w/w) NaCl at 0°C and 28.1% at 100°C.

Salt is a nutrient essential to both humans and animals. It has been a vital commodity throughout human history. Wars have been fought over its supply, words derived from "salt" appear in all languages and a vast number of place names, and the very spread of civilization depended on its availability.

Besides serving as a chemical feedstock, sodium chloride is used in food processing to add flavor and palatability and as a texturizing agent in bread and other baked goods. Salt also is used as a fermentation controller in dairy products, a bactericide in preserved foods, and a color developer in processed meats. A few of its other applications are hide-processing, leather tanning, fabric dyeing, and water softening. China and the United States are the leading producers of salt (Table 26.1). Between them, they account for more than 40% of the world's supply. Germany, India, Canada, and Australia form the next tier, producing more that 20% of the total. One of the largest uses in the United States is as a highway de-icing and anti-icing chemical [2]. Table 26.2 summarizes US consumption of salt by its principal uses. Annual consumption can fluctuate widely, as shown by the first column of Table 26.3. This is almost entirely due to variations in highway salt usage (column 2).

There are underground deposits of salt ("rock salt") throughout the world. NaCl also makes up about 3% of seawater [3]. The latter is an inexhaustible supply, used in many parts of the world to produce solid salt ("solar salt") by evaporation. In the United States, rock salt predominates. There are mines in Kansas, Louisiana, Michigan, New Mexico, New York, North Dakota, Ohio, Oklahoma, and Texas. Some Canadian provinces also mine salt deposits.

There are two distinct types of rock salt deposit, stratified beds and domes. In the first of these, the salt is in relatively shallow layers that often cover great areas. They may be roughly horizontal or disturbed by tectonic movements. Depths below the surface may range from 100 m to more than a kilometer. Shafts from the surface to the deposit typically are 6 m in diameter. Usually, the salt is in a number of strata, interspersed for the most part with shale or anhydrite. Total thickness of the deposit may be several hundred meters. Each stratum may be mined separately by drilling and blasting or by using a continuous machine. Mining is by the room-and-pillar method, with frequent crosscuts between rooms. A typical room may be 15 m wide and 8 m high.

The configuration of salt domes is very different. A dome forms when deep-lying salt is forced into plastic flow through faults in its overburden. The dimensions of a dome may be measured in kilometers, and it may contain many billions of tons of salt. In the United States, domes are found on or near the Gulf Coast. Mining is similar in principle to that practiced in bedded deposits, but individual blasts may be on a much larger scale.

Salt can also be extracted from underground deposits by solution mining. In this process, a small-bored shaft is drilled into the cavity or deposit. It is then fitted with concentric pipes, one to pump water into the deposit and the other to

bring saturated brine back to the surface. The purity of the brine is enhanced because insoluble and very slowly soluble impurities, notably anhydrite (calcium sulfate), remain in the cavity as settled residue. The geometry of a bedded salt deposit (large area, small thickness) does not favor injection and withdrawal at essentially the same point. Instead, it is normal practice to operate galleries that contain numbers of pipes placed at horizontal intervals along the deposit. The dissolving fluid goes down one pipe, and the saturated brine rises through another some distance away. The cavity naturally formed as salt dissolves then takes the shape of the deposit much more efficiently.

Many processors mine their own deposits this way and feed the salt solution (brine) directly into their processes. Other companies specialize in large-scale solution mining and serve the processing industry as brine merchants. When it is not necessary to evaporate the brine down to solid salt, this is normally the cheapest form of supply.

The saturated raw brine can be handled in several ways. Evaporation in vacuum pans without chemical treatment produces evaporated granular salt, which usually assays more than 99% NaCl. The evaporation always is in multiple-effect systems, in which the vapor produced in one effect becomes the heating medium in another, or in vapor-recompression systems. The steam economy achieved in either case can be quite high. Evaporator condensate can be used as process water or as a source of steam.

Chemical treatment of raw brine before evaporation enhances the purity of the final product salt. For the most part, this involves the precipitation of calcium and magnesium by adding, respectively, soda ash and caustic soda:

$$\mathrm{Ca^{2+} + Na_2CO_3 \rightarrow 2Na^+ + CaCO_3}$$

$$\mathrm{Mg^{2+} + 2NaOH \rightarrow 2Na^+ + Mg(OH)_2}$$

After clarification of the brine to remove the precipitated mud, evaporation produces a salt that is more than 99.95% NaCl, often 99.99%. The higher purity is advantageous in all processes and allows the use of salt in new applications. Examples are food (human and animal), raw material for certain chemical reactions, and polishing pharmaceutical tablets. Purified salt can also be used in the pharmaceutical industry to make hemodialysis and intravenous fluids [4].

Sea salt, or solar salt, is harvested in many countries. Flat coastlines, warm breezes, plentiful sunlight, and little rainfall are all desirable, and operation may be seasonal. Solar salt works naturally are most common in low-latitude countries. Production also is favored in inland locations where brines more concentrated than seawater are available. The process is passive; salt water from lake or ocean is trapped into shallow ponds and allowed to concentrate under the influence of solar energy. In the case of seawater, about 90% of the volume must evaporate before salt begins to precipitate.

The salinity of seawater varies with its location, but a global average is about 3.5 wt.% total dissolved solids. Reported compositions frequently are normalized to this basis. The composition of seawater is complex, and total evaporation would produce solids that are only about 78% NaCl (anhydrous basis). Production of salt therefore involves a series of fractional crystallizations, and a solar salt plant will include a large number of separate ponds with different functions. These include (a) concentrating ponds, which allow suspended solids to settle and bring the brine close to saturation, (b) lime ponds, which allow species less soluble than NaCl (principally calcium compounds) to

precipitate, (c) crystallizers, which produce salt crystals, and (d) bitterns ponds, which hold concentrated solutions rich in magnesium salts. Proper management of the process requires transfer of brine from pond to pond at the proper time, and it is not uncommon for seawater to require 2 years or more in process. Division of the stages of precipitation is not clear cut; thus, magnesium precipitation begins before sodium precipitation is complete. The cutoff point is a compromise between yield and quality. Typically, NaCl is collected until the liquor reaches a certain specific gravity, at which point the brine is transferred to the bitterns ponds. Recovery of the NaCl originally present in seawater generally is 70–80%.

The quality of solar salt is determined primarily by the care taken in separating the various products of crystallization and in harvesting salt from the bottom of the crystallizing ponds. Attempts to increase the size of the NaCl cut necessarily increase the level of contamination. Washing of the recovered salt in any case can improve its quality [5]. Magnesium deposited on the crystals and held in occluded bitterns is most easily removed. More vigorous processing can also remove inclusions of calcium, and as a result washed salts may contain more 99% NaCl. Table 26.4 compares this to typical rock and purified vacuum salts. Table 26.5 then breaks down US consumption by type of salt. It reflects the widespread use of on- or near-site solution mining by the chemical industry, followed by direct use of brine.

Particularly when salt is recovered from inland brines, the bitterns may contain valuable minerals and justify further processing. To take a single example, Dead Sea water is rich in bromine and is one of the world's major sources of the element (*infra*).

Sodium chloride is the ultimate source of many industrial chemicals, and this chapter treats a number of them. Sodium phosphates and phosphoric acid are important examples. They do not appear here but rather are covered in Chap. 23.

It is also worth noting that potassium chemicals have similar chemistry and that many of them are produced simply by replacing Na in the raw material with the scarcer and more expensive K.

Sodium Carbonate (Soda Ash)

Soda ash, or sodium carbonate, is derived commercially from three sources: trona/nahcolite ores, naturally occurring alkaline brines, and synthetic processes. Most common in the last category is the Solvay ammonia-soda process. Variations of this process operate in many parts of the world. The United States has 95% of all known deposits of trona. Since natural production has significant cost advantages, the United States no longer produces synthetic soda ash. Because natural reserves are limited elsewhere, synthetic processes still provide about three-quarters of the world's supply of Na_2CO_3. China is the leading producer, with about 40% of the total. The United States produces about 22% of all soda ash. Data on natural soda ash production and reserves are in Table 26.6. Market distribution in the United States is shown in Table 26.7.

The area near Green River, Wyoming, is the primary source of natural ash. The deposit contains over 10^{11} metric tons of trona, enough to satisfy global demand for over 2,000 years [6]. Significant amounts are also recovered from the alkaline brines of Searles Lake in California.

"Trona" is the dihydrate of sodium sesquicarbonate, $Na_2CO_3{\cdot}NaHCO_3{\cdot}2H_2O$. Processing is required to purify it and to calcine the bicarbonate portion. There are two approaches to this task. Purification may either precede or follow calcination. The older (sesquicarbonate) process first hot-leaches the crushed ore to extract the mineral. Purification involves clarification, filtration, and crystallization by cooling. The refined trona then is calcined to form soda ash. The newer (monohydrate) process first calcines the crushed ore to form a crude carbonate. This is dissolved and the solution evaporated to crystallize the monohydrate, $Na_2CO_3{\cdot}H_2O$. Mild calcination then yields the anhydrous soda ash. The monohydrate process is normally more energy efficient. Because trona has low solubility, the dissolving and separation steps in the sesquicarbonate process are at high temperature. The higher temperature and CO_2 concentration make the process fluids more corrosive. The disadvantage of the monohydrate process is contamination of the carbonate solution with organics and minerals. A purge of the crystallizer mother liquor is necessary, its size dependent on the extent of contamination.

Table 26.6 World production and reserves of natural soda ash in 2010[a]

Mechanical mining of trona resembles that of coal or salt. The ore is disposed in nearly horizontal beds 2.5–5 m thick and found at depths of 250 to more than 1,000 m [7]. Solution mining is an alternative. The solubility of the bicarbonate can be enhanced by using a dilute solution of NaOH. This converts the bicarbonate portion of trona into the more soluble carbonate. Production of a 30% solution of Na_2CO_3 theoretically requires about a 6% solution of NaOH [9].

Figure 26.1 is a block flow sheet of the ammonia-soda process. The description that follows is keyed to the numbered blocks. NaCl enters the process as a solution, or brine. It must first have been purified to remove calcium and magnesium ions, so that they will not precipitate within the process, contaminating the product and fouling the equipment. Solutions of soda ash and caustic soda are added to the brine, precipitating $CaCO_3$ and $Mg(OH)_2$ according to the equations noted in the preceding section. The solids are flocculated, removed in a clarifier, and discarded. The purified brine goes to the ammonia absorber (1) in the main process.

The other major raw material is limestone. Normally, the best available limestone is calcined in vertical-shaft kilns (2) at high temperature to produce lime and carbon dioxide. Kilns typically are fired with foundry coke. Their design is highly efficient and produces a gas containing very little oxygen and more than 40% CO_2. Lime from the kiln is cooled by the entering combustion air, which is thereby preheated. Similarly, gas leaving the kiln preheats incoming limestone and fuel, again promoting energy economy. Economizing steps such as these are frequent in the Solvay process because of its normally large scale and high utility demands. The dry lime is slaked (3) before use in the process.

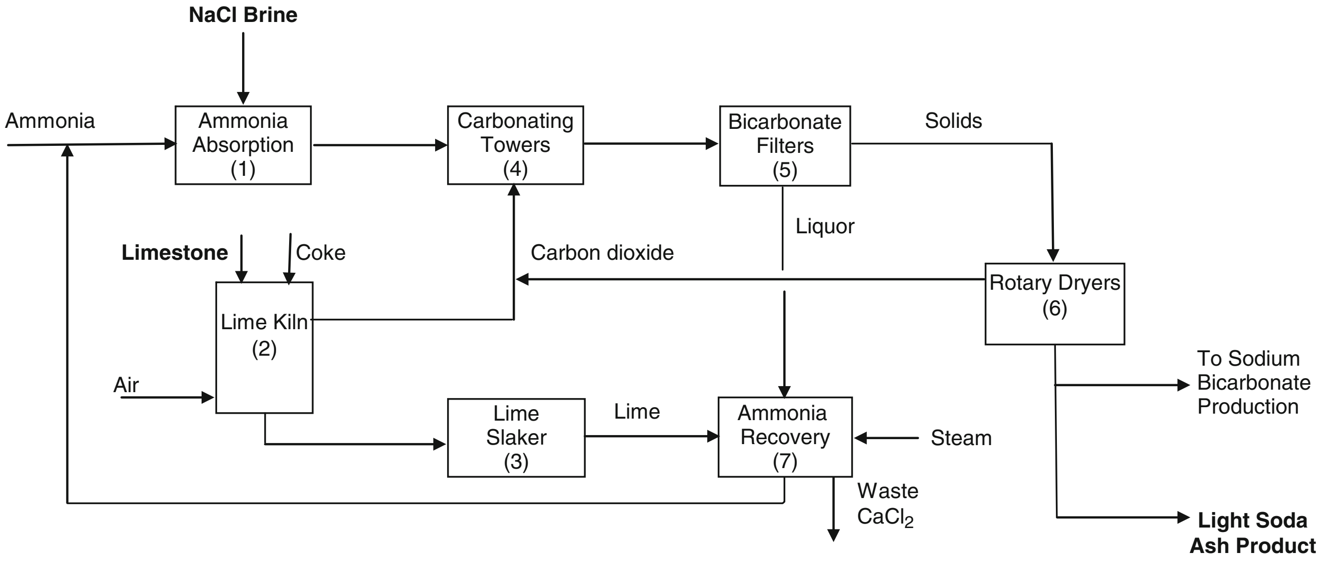

Fig. 26.1 Block flow sheet for Solvay ammonia-soda process for production of soda ash

The overall stoichiometry of the Solvay process is quite simple and involves only salt and limestone:

$$2NaCl + CaCO_3 \rightarrow Na_2CO_3 + CaCl_2$$

However, direct carbonation of NaCl solution is not feasible because of the acidity due to the implied formation of HCl from NaCl and carbonic acid. The ammoniation of the brine in step (1) creates an alkaline solution of NH_4Cl and allows the carbonation to proceed. Ammoniated brine then enters near the top of a carbonating tower (4) and cascades down over a set of disc-and-donut baffles. Carbon dioxide enters both at the bottom of the column and approximately at the midpoint. Off-gases vent from the top, and bicarbonate slurry leaves the bottom.

The carbonation area includes groups of identical towers. The alternating discs and rings promote mixing of the falling liquor with the rising gas stream and resist plugging by the crystallizing solid phase. The lower parts of the towers also include series of heat-exchange bundles. Still, several days' operation as a crystallizing unit tends to plug the internals with sodium bicarbonate. Then, ammoniated brine is passed downward through the column while gas from the kilns provides agitation and heat to dissolve the scale and bring the liquor close to saturation. After adjustment to the desired temperature, this liquor passes to the tops of the other towers in the equipment group.

Mixing 40% CO_2 gas from the kilns with 90% gas from the calcination of bicarbonate gives 60–75% CO_2 as feed to the crystallizing units. The heat evolved from absorption and neutralization of carbonic acid gas and the crystallization of bicarbonate tend to raise the temperature of the liquid in the column by about 25°C. In normal operation, the temperature of the discharged slurry is held at about 27°C by flow of water through cooling tubes. The heat removed from the carbonator is about 75,000 kcal/net metric ton of ash produced, whereas that removed from the crystallizing units is 350,000 kcal/t (all "tons" in this chapter are metric).

Washed bicarbonate is recovered from reactor slurry on rotary vacuum filters (5). The filtrate and wash liquor flow to the distillation unit for recovery of ammonia. The crude solid contains 3–4% NH_4HCO_3 (dry basis) and so is not an item of commerce. It will assay about 80% $NaHCO_3$ and have a water content of 12–15% $NaHCO_3$. Its calcination produces the carbonate while releasing half of the CO_2 content:

$$2NaHCO_3 \rightarrow Na_2CO_3 + H_2O + CO_2$$

This is achieved in rotary dryers (6) with rotating seals and gas-tight feed and discharge mechanisms. The design excludes air and keeps the concentration of CO_2 in the gas as high as 90%. The product of the reaction is about 99.7% Na_2CO_3, containing 0.1–0.15% each of NaCl and water, along with small concentrations of metallic impurities. The heat consumed in the process is about 560,000 kcal/t of soda ash produced.

The second major product of the carbonation of ammoniated brine is ammonium chloride, NH_4Cl. It collects in the liquor from the bicarbonate filters. Ammonia is regenerated (7) by reacting filtrate with milk of lime. The reaction is

$$Ca(OH)_2 + 2NH_4Cl \rightarrow 2NH_3 + CaCl_2 + 2H_2O$$

The resulting solution goes to the top of a distillation column, with steam injected at the bottom. The stripped ammonia is ready for recycle to the process, and the residual calcium chloride liquor normally contains less than 10 ppm NH_3.

The amount of ammonia in circulation is large, and there are a number of gas streams that contain NH_3. Several of these are scrubbed to prevent losses. Thus, the incoming purified brine first washes the ammonia-bearing air pulled through the bicarbonate cake on the vacuum filters. This is accomplished in a packed absorber. The brine then passes through a second packed section, where it absorbs the NH_3 in the gases from the carbonating towers, and finally flows to the main NH_3 absorber. A small amount of makeup ammonia enters the process here, and the absorber also picks up CO_2 and traces of H_2S from the carbonators. Heat released in the absorption process is about 345,000 kcal/t of soda ash produced. It is removed by circulating brine through water-cooled heat exchangers. The ammoniated brine typically is at a temperature of 38°C and contains 260 g/L NaCl, 90 g/L NH_3, 40 g/L CO_2, and 0.1 g/L H_2S.

It is worthy of note that sulfide will maintain a protective film of iron sulfide on the cast iron equipment and minimize contamination of the crystals by iron corrosion products. A solution containing sulfide ion therefore is usually added to the liquor before the ammonia distillation pre-heater. After preheating, the process stream enters a stripper where excess CO_2 is removed.

Byproduct $CaCl_2$ may be recovered from process waste liquor by evaporation. Most often, the solution is clarified and pumped into watercourses whose natural flow is sufficient to provide the dilution needed for disposal.

The normal product is "light" soda ash. This can be reprocessed to give higher bulk density, less tendency to dust, and better flow properties. The latter product is preferred in some applications (e.g., glassmaking). Some soda ash also is used to produce sodium bicarbonate (*infra*) and, by causticization with lime, caustic soda without chlorine as a co-product.

The natural alkaline brines referred to at the beginning of this section are a relatively small source of Na_2CO_3. It is recovered by a process of fractional crystallization that also produces other sodium and potassium salts. Formation of Na_2CO_3 may be promoted by carbonation of the brine.

Sodium Bicarbonate

Further carbonation of a saturated solution of sodium carbonate produces the bicarbonate:

$$Na_2CO_3 + CO_2 + H_2O \rightarrow 2NaHCO_3$$

The Na_2CO_3 may be produced synthetically or mined as a natural ore (*supra*). The relatively insoluble bicarbonate crystals precipitate from solution and are centrifuged and then dried. Drying temperatures below 50°C prevent reversion to carbonate.

Sodium bicarbonate also can be obtained by solution mining of the mineral nahcolite. Wells are drilled in groups or in pairs. Steam or hot water (175–215°C) is pumped down one well to dissolve the ore, and the resulting solution is pumped up from another. The solid product may be obtained by crystallization. In some circumstances, such as those in which the mined solution must be transferred a long distance for processing, direct recovery may not be feasible. The positive temperature coefficient of solubility of $NaHCO_3$ would allow plugging of piping or equipment. In such cases, the bicarbonate first is converted to carbonate, which is reprocessed at the destination.

Nahcolite is often associated with oil shale or with deposits of salt or trona [9]. Reserves in the Piceance Creek basin in northwestern Colorado alone amount to nearly 30 billion tons [10]. This amount would supply the world for about 20,000 years. Total US capacity for $NaHCO_3$ is about 780,000 t/year, two-thirds of it in Wyoming and Colorado. Current production is about 600,000 t/year, with a long-term growth rate of 2–3%/year [11].

As the common name "baking soda" implies, most applications of $NaHCO_3$ (~60%) are in the food industry. The product must be purified as necessary and handled in accordance with all food-grade rules. Refined product accordingly has some use in pharmaceuticals. Sodium bicarbonate's use as a rising agent in baked goods derives from its alkalinity and the fact that CO_2 evolves at the convenient temperature of 70°C. It is also used as a buffer, an antacid, and a cattle feed supplement/rumen pH regulator. A very successful application in the household market is as a deodorizer and air freshener. It has also established a market as a paint remover, replacing the environmentally unacceptable methylene chloride. Some traditional applications now are shared with the sesquicarbonate, and this change should perhaps not be viewed as a true loss of market.

Sodium Sulfate

Sodium sulfate classically was a co-product (with HCl) of the reaction of salt with sulfuric acid (Mannheim process) or SO_2 and air (Hargreaves process). While these processes may survive elsewhere, they are no longer in use in the United States. Instead, all production is by recovery from natural sources or as a byproduct of other operations. US production is approximately evenly split between these two categories [12]. Estimates of worldwide production in 2010 are six million tons from natural sources and 1.5–2 million tons as byproduct. Known reserves, shown in Table 26.8, are widespread and would last hundreds of years at the present rate of consumption. Reserves in China are extensive. Production is concentrated in Jiangsu Province, where annual production of 4.8 million tons is anticipated by 2013 [12].

There are two producers of natural sodium sulfate in the United States, one in Texas and one in California. The former location has the advantage that the brine is located near salt domes and natural gas wells. Byproduct Na_2SO_4 is recovered in 11 plants in 9 states. Sources include battery reclamation and the production of ascorbic acid, cellulose, chromium chemicals, rayon, resorcinol, and silica pigments. Approximate consumption by end use is summarized in Table 26.9.

A frequent advantage of natural products over synthetic and byproduct materials is their higher purity. In one process, natural brine containing about 10% Na_2SO_4 is saturated with NaCl by pumping it through a salt deposit. Cooling the concentrated brine to about −10°C produces quite pure crystals of Glauber's salt ($Na_2SO_4 \cdot 10H_2O$). This is then melted and the water of hydration removed by evaporation driven by a submerged burner. The wet Na_2SO_4 is dried in a rotary kiln until anhydrous. More than 10 t of natural brine and 450,000 kcal are required per ton of product. In a similar process, a different brine is first carbonated and chilled to remove sodium carbonate and borax. Further chilling crystallizes Glauber's salt and some residual borax. After recovery by hydraulic classification, the sulfate fraction is handled as described above to recover the anhydrous salt.

An alternative process when carbonate is also present in a brine (e.g., Searles Lake) is evaporation to produce NaCl and a double salt of Na_2CO_3 and Na_2SO_4. The two solids are separated in a hydraulic classifier, and the sulfate fraction is re-dissolved and re-crystallized as Glauber's salt. Anhydrous Na_2SO_4 can be recovered without the need for thermal decomposition by adding the Glauber's salt to concentrated NaCl brine. The altered solubility characteristic forces the unhydrated sulfate to precipitate. In the first process mentioned above, it was Glauber's salt that precipitated from solution; in the final step here, it is anhydrous Na_2SO_4. The difference is explained by different positions on the graph of mutual solubilities of NaCl and Na_2SO_4. The first process takes place in the low-chloride region, and the process follows a Glauber's salt isotherm. Addition of small amounts of water or salt may be necessary to the material balance in a continuous crystallization process.

Sodium sulfate often is a byproduct of the reaction of sulfuric acid with a sodium salt or of the neutralization of caustic soda. An example is the viscose rayon process, in which cellulose xanthate reacts with H_2SO_4, which also neutralizes free NaOH in the fiber spinning bath. Evaporation of spin-bath liquor produces crystals of Glauber's salt, which are centrifuged off, melted and evaporated to produce anhydrous Na_2SO_4. The sulfate produced actually outweighs the rayon product by 10%.

Changes in markets or regulation can affect the available supply of byproduct Na_2SO_4. Thus, for example, increased on-site generation of chlorine dioxide for bleaching itself produces more Na_2SO_4 byproduct. Opposing this change, the production of sodium dichromate and its byproduct sulfate has declined with mandated recycling of electroplating wastes. Other changes affect demand. The kraft pulping process formerly consumed huge quantities of Na_2SO_4. Changes in the process and tightening of the sulfur balance have caused a major reduction in its use. Next, the use of Na_2SO_4 as an inert filler in detergent formulations has decreased as liquid detergents have become more common and dry products have become more concentrated. Finally, sulfate also is gradually disappearing from glass manufacture, where it has been used as a fluxing and fining agent. The consumption of Na_2SO_4 in the United States therefore is much lower than it was in previous decades. As Table 26.10 shows, it has been dropping irregularly in recent years. Variations have been much smaller in production than in consumption, the difference being picked up by a shifting trade balance. Worldwide production of sodium sulfate continued to increase into the 1990s before similar trends prevailed and total consumption became stagnant [13].

Sodium Sulfides

Sodium sulfide, Na_2S, and sodium hydrosulfide or sulfhydrate, NaHS (often written as NaSH), both are derived from caustic soda and H_2S. Controlled caustic scrubbing of H_2S forms a solution of the half-neutralized NaHS:

$$NaOH + H_2S \rightarrow NaHS + H_2O$$

The NaHS solution is filtered to remove heavy metal sulfides. The clear filtrate may be sold as a 44–46% solution or evaporated in stainless steel equipment to produce a flaked product containing 70–72% NaHS. There is ample capacity for generation of NaHS from waste gases. Approximate capacity in the United States in 2006 was 240,000 t/year, but production was only about 77,000 t [14].

Treating NaHS solution of the proper concentration with solid caustic soda yields a hydrated product of 60–62% Na_2S:

$$NaHS + NaOH \rightarrow Na_2S + H_2O$$

This is sold as flakes or cast solid in drums. High-quality raw materials produce Na_2S suitable for use in dyes, photography, rayon, and leather manufacture. Lower-quality sulfides are obtained by using H_2S byproduct from the manufacture of CS_2 from methane (or other low molecular weight hydrocarbons) and sulfur:

$$CH_4 + 4S \rightarrow CS_2 + 2H_2S$$

The gas from this catalytic reaction is cooled and then scrubbed with caustic soda. The sulfide produced contains small amounts of mercaptans (e.g., CH_3SH), and thus has a very objectionable odor.

The manufacture of $BaCO_3$ from barite ore also yields a sodium sulfide byproduct. The process involves roasting with coal, leaching with water, and treatment with soda ash:

$$BaSO_4 + 4C \rightarrow BaS + 4CO$$

$$BaS + Na_2CO_3 \rightarrow Na_2S + BaCO_3$$

The principal use for sodium sulfide in the United States is de-hairing leather before tanning. In Western Europe it is further used in tanning and in Japan more extensively in synthetic chemistry. Most NaHS in the United States is used in the pulp and paper industry (42%). The market has grown at the expense of the more expensive sodium sulfate [14]. Other uses are in metals and minerals, most especially as a copper mineral flotation agent (30%), and in chemicals and dyes (13%). Leather processing (10%) is a declining market. Again in Japan, NaHS historically has found more downstream uses in chemicals, dyes, wastewater treatment, and leather tanning [15].

A solution of sodium sulfide can dissolve elemental sulfur, which then forms covalently linked chains of sulfur atoms and polysulfide ions S_n^{2-}. Chain lengths vary from three to more than ten [16]. One of the uses of sodium polysulfide is the production of polymers that are insoluble in water, oils, and most organic solvents. The polymers are used widely as sealants. They form by condensation with bifunctional derivatives of hydrocarbons. Ethylene dichloride (EDC) is an example:

$$Na_2S_n + ClCH_2CH_2Cl \rightarrow (CH_2CH_2S_n) + 2NaCl$$

Sodium Thiosulfate

Most sodium thiosulfate, $Na_2S_2O_3$, is obtained as a byproduct in the manufacture of sulfur dyes and Na_2S. In the case of sulfur dyes, byproduct leach liquor contains thiosulfate, which can be recovered by evaporation and crystallization in stainless steel equipment. Much of this is sold as the pentahydrate. Of less importance today is the older soda ash-sulfur process. A liquor containing $NaHSO_3$ (made by absorbing SO_2 into soda ash solution) is heated with powdered sulfur in an agitated stainless steel digestion tank. Evaporative crystallization again yields the pentahydrate. After centrifuging, washing, and drying, this material is packaged in airtight containers, in order to prevent efflorescence.

$Na_2S_2O_3{\cdot}5H_2O$ is the photographer's "hypo." While many photographic markets are declining or growing only slowly because of the advance of digital technology, this remains the principal use of the product. Its value lies in its ability to dissolve water-insoluble silver salts. Other uses include leather processing, water treatment, and oil recovery. It is also used as an active chlorine scavenger, particularly in Western Europe. It has the advantage of an average sulfur valence state of only +2, giving it twice the reducing power of other sulfur-based agents. However, other reactions can occur at low pH [17], and $Na_2S_2O_3$ is fully effective only at pH 11 and higher [18].

Sodium Sulfite

Sodium sulfite (Na_2SO_3) is produced by reacting sulfur dioxide with an alkaline solution, either sodium carbonate or sodium hydroxide. It is also recovered as a byproduct of various processes. Its principal use historically has been in the pulp and paper industry. While improvements in mill efficiency and substantial reductions in sulfur discharges have tended to reduce its use there, the spread of chemithermomechanical processing from Europe has helped to keep this market strong. The pulp industry accounts for about 55% of the market in the United States [19]. Other large uses are in water treatment (20%), the photographic industry (10%), and oil recovery (5%).

Sodium sulfite is a white crystalline or powdered compound. It is readily soluble in water and decomposes on heating. It is a strong reducing agent and so is subject to oxidation; the solid compound is more stable than solutions in this regard. Na_2SO_3 is used in water treatment as an oxygen and free chlorine scavenger and in the photographic industry to protect developer solutions from oxidation. Miscellaneous applications are in the textile industry as a bleaching, desulfurizing, and dechlorinating agent; in the leather trade in the sulfitization of tanning extracts; and in the organic chemical industry as a sulfonation and sulfomethylation agent. It forms adducts with aldehydes and ketones and so plays a role in purifying and isolating those compounds. Other applications include ore flotation, oil recovery, food preservation, dye making, detergent production, and the production of sodium thiosulfate (*supra*).

Yearly production in the United States is about 90,000 t, with an installed capacity of about 245,000 t/year. These figures are inexact largely because they exclude the substantial and variable captive production and use [19].

Sodium Bisulfite

Sodium bisulfite may be supplied as a solution or as a solid. The solution normally contains 23–27 wt.% SO_2 equivalent. The solid product actually is in the form of sodium metabisulfite, which is the anhydride $Na_2S_2O_5$. Commercial metabisulfite is about 98% pure, typically containing 1.5% Na_2SO_3 and 0.5% Na_2SO_4.

Methods of production are all variations on the same theme:

$$Na_2CO_3 + 2SO_2 \rightarrow Na_2S_2O_5 + CO_2$$

In one version, SO_2 is sparged into a stainless steel absorber through which a solution of Na_2CO_3 flows. The product crystallizes when the saturated solution is cooled. Recovery is by centrifugation, and then the crystals are dried. The last step must be rapid, as in a flash dryer, in order to avoid air oxidation to sulfate.

Markets for sodium bisulfite are diverse [20]. They include chemical intermediates, pharmaceuticals, food preservation, water treatment, and dye fixing. Additionally, sodium bisulfite is used in photography, in the manufacture of sodium hydrosulfite (*infra*), and as an active chlorine scavenger in pulp bleaching and chlor-alkali brine dechlorination.

Sodium sulfite and bisulfite are interchangeable in many applications, and some producing plants can switch between the two forms. Their reducing power (and that of SO_2) in all cases depends on the oxidation of S^{+4} to S^{+6}. Proton shifts between HSO_3^- and SO_3^{2-} are rapid [21], and so the form of the anion actually present in solution is determined by the pH.

Sodium Hydrosulfite (Sodium Hyposulfite)

$Na_2S_2O_4$ is variously referred to as sodium hydrosulfite, sodium hyposulfite, and dithionite. It is a powerful reducing agent used principally for the reduction of vat dyes and the brightening of mechanical wood pulps and clays. There are several methods for its production, all of which involve reduction of SO_2 or $NaHSO_3$. Reducing agents include sodium amalgam, sodium formate, and sodium borohydride. Previous editions of this handbook also described two methods for reduction by zinc powder. These are obsolescent because of the environmental problems associated with the release of zinc.

The amalgam process [22] uses the dilute (<0.5%) sodium amalgam from a chlorine cell (*infra*). Reaction of the amalgam with bisulfite solution at pH 5–7 produces the hydrosulfite along with a sodium sulfite co-product:

$$4NaHSO_3 + 2Na(Hg) \rightarrow Na_2S_2O_4 + 2Na_2SO_3 + 2H_2O + (Hg)$$

The parentheses indicate that mercury is not involved in stoichiometric quantities. The mercury returns to the electrolytic cell to form more amalgam. The sulfite is reacted with SO_2 in aqueous solution to regenerate bisulfite for recycle:

$$Na_2SO_3 + SO_2 + H_2O \rightarrow 2NaHSO_3$$

SO_2 normally supplies the sulfur value in the formate process:

$$HCOONa + NaOH + 2SO_2 \rightarrow Na_2S_2O_4 + H_2O + CO_2$$

This reaction requires the use of acidified methanol. The anhydrous sodium hydrosulfite precipitates and is recovered by filtration.

In pulp and paper mills, the hydrosulfite often is produced in situ at low concentrations (5–7%). Here, SO_2 reacts with alkaline sodium borohydride:

$$\begin{aligned} &(NaBH_4 \cdot 3.4NaOH) + 5.6NaOH + 9SO_2 \rightarrow \\ &\qquad \text{(borol solution)} \\ &\qquad 4Na_2S_2O_4 + NaBO_2 + NaHSO_3 + 6H_2O \end{aligned}$$

Finally, hydrosulfite can be produced by the direct electrolysis of a bisulfite solution [23]. The cathode reaction is:

$$2HSO_3^- + 2H^+ + 2e \rightarrow S_2O_4^{2-} + 2H_2O$$

Such a process might be useful for on-site production.

Sodium Silicates

In the sodium silicate family, a series of derivatives is produced by reacting Na_2CO_3 with varying amounts of silica. The products normally are referred to by their ratios of SiO_2 to Na_2O. The custom in the United States, followed here, is to express these in terms of weight. In some other parts of the world, molar ratios are used. Since the formula weights of the two species are nearly equal (60 and 62), the numerical differences are not large but still may confuse the unwary. The normal product is called *water glass* because while solid it actually is a glass, but, unlike lime-soda glass, it is soluble in water.

In the standard process, high-purity sand and soda ash are fused in a large tank furnace similar to the type used for flat glass. The raw materials, often premixed, are introduced at one end of the furnace and the product

Table 26.11 Properties of typical commercial sodium silicate solutions

Ratio, SiO_2/ Na_2O	Wt. % SiO_2	Wt. % Na_2O	Density, g/ mL	Viscosity, cp	pH

drawn off at the other. The product ratio is set by the raw material mixture:

$$Na_2CO_3 + nSiO_2 \rightarrow Na_2O(SiO_2)_n + CO_2$$

The reaction temperature is about 1,300°C. Large furnaces are regenerative or recuperative, in order to reduce heat loss by way of combustion offgas. Particularly on smaller scale, electrically heated melters may replace the fuel-fired version. Another variation has been the use of a rotary kiln in place of a stationary furnace. As the melt leaves the furnace, a stream of cold water shatters it into fragments, or it is collected and cooled in molds that form a moving chain. The solid material can be dissolved in hot water/superheated steam in tall steel cylinders. Sodium silicates normally are sold in solutions of varying density and viscosity. Compositions and physical properties of typical commercial grades are shown in Table 26.11. Dry solids also are marketed, usually with ratios between 2.0 and 3.25 [24]. Since some solid silicates are hygroscopic, they may be blended with Na_2SO_4 to prevent caking.

Caustic soda is a possible replacement for soda ash in the silicate process:

$$2NaOH + nSiO_2 \rightarrow Na_2O(SiO_2)_n + H_2O$$

Those who can use either NaOH or Na_2CO_3 as a source of alkalinity must continually be aware of the comparative economics of the two, and it is useful to have the option to switch materials when desired. Unfortunately, the use of caustic soda, solid or liquid, is not practicable in the glass furnace. Instead, standard practice is to use an autoclave to dissolve sand in NaOH solution. Results are limited by the solubility of crystalline silica to ratios less than about 2.4.

The buffering capacity of silicate solutions is important to the many applications that depend on their alkalinity (e.g., detergents, oxide bleaching of wood pulp, de-inking of waste paper). Figure 26.2 shows that silicate solutions are superior in this respect to the other salts shown. The increased use of peroxide bleaching of wood pulp and the growing importance of waste paper de-inking have increased sodium silicate demand in the pulp and paper industry. Silicates sequester iron and other metal ions that reduce the efficiency of the peroxide. They also buffer the pH in the alkaline range required for bleaching. In the de-inking process, in addition to its buffering and sequestering action, silicate provides detergency and helps to prevent redeposition.

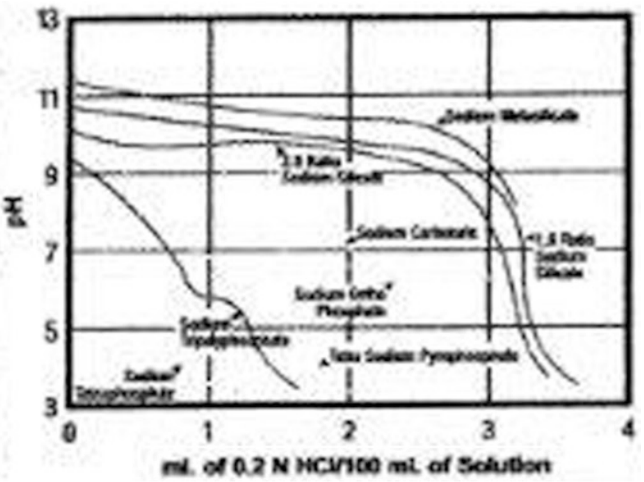

Fig. 26.2 Alkaline buffering capacities of several compounds (Courtesy of PQ Corporation)

While the uses of dissolved silicates are extraordinarily diverse, the most rapid growth in the sodium silicate market is in custom derivatives such as precipitated silicas and zeolite catalysts. Processing of silicate solutions with mineral acids yields hydrated silica, which forms silica gel when dried. Silica gel finds wide application as an adsorbent and is used in the manufacture of catalysts (petroleum cracking and hydrocracking, hydrocarbon isomerization, etc.). Modified processing can yield silica sols, which are useful in water treatment. Zeolites primarily are aluminosilicates, made in many different grades. Properties depend on SiO_2/Al_2O_3 ratio, particle size, and cell structure. Varying the positive counterion and incorporating different metals into the structure give a wide variety of catalytic functions.

Other specialized products are those of higher alkalinity, such as the metasilicate, Na_2SiO_3 (molar ratio 1.0), and the orthosilicate, Na_4SiO_4 (molar ratio 0.5). Such high alkalinity would be corrosive to normal furnace refractories, and so these products are made in special apparatus by adding caustic soda to sil4icates of higher ratio [25]. The metasilicate is supplied in the anhydrous form and as the pentahydrate. Solid products with the SiO_2/Na_2O ratio of orthosilicate may be supplied as the compound or as a mixture of solid metasilicate and anhydrous NaOH beads.

Chlor-Alkali (Chlorine and Caustic Soda)

The most important use of salt in the chemical industry is the production of chlorine and caustic soda (sodium hydroxide, NaOH). Each is among the world's ten largest volume commodity chemicals. In 2009, combined production in the United States was 21.5 million metric tons [26]. This may have been a recessional anomaly, as in each of the preceding 5 years the total was between 22.8 and 24.7 million tons. Global production of chlorine alone in 2008 was about 42 million metric tons, distributed by region as shown in Table 26.12 [27].

Historically, electrolysis of NaCl brine accounts for about 96% of all chlorine production. It consumes about 2% of the electrical power generated in much of the industrial world. One of the difficulties faced by chlorine/caustic soda merchants is the fixed ratio of the amounts of the two products that are generated. Theoretically, nearly 1.13 kg of NaOH accompany each kilogram of chlorine. In the United States, the ratio in the electrolytic industry has hovered around 1.05–1.06. The same ratio applies to the data in Table 26.12. This reflects the fact that some plants produce chlorine without NaOH. Co-products may be Na, Mg, or KOH. There is also some production of chlorine by electrolysis of HCl. At the same time, there is some production of caustic soda without chlorine by reaction of sodium carbonate with lime. These alternative processes are described in standard texts [28, 29].

The chlor-alkali industry in the United States has been consolidating. Some merchants who supplied the pulp and paper industry, for instance, have left the business. Growth has been in the form of large plants integrated forward to produce EDC. The number of producers has been declining. Table 26.13 shows that four of them accounted for more than 80% of the capacity in 2010. Applications of caustic soda are quite diverse. Table 26.14, in which 30% is assigned to the very broad category of "organics," confirms this. The uses of chlorine historically were just as diverse, but social and environmental pressures have removed certain market segments (e.g., pulp bleaching, some chlorinated solvents). As a result, the chlorine market depends more heavily on vinyl chloride monomer (VCM) and its polymers. Table 26.15 shows 43% of the American market in this single use [27].

The heart of the chlor-alkali process is an electrolytic cell in which a nearly saturated solution of purified NaCl is decomposed. The three types of cell now in use are shown schematically in Fig. 26.3. The anode reaction is the same in every case:

$$2\mathrm{Cl}^- \rightarrow \mathrm{Cl}_2 + 2e$$

Simple discharge of the sodium ion cannot occur in an aqueous medium; the favored reaction instead would be

$$2\mathrm{H}_2\mathrm{O} + 2e \rightarrow \mathrm{H}_2 + 2\mathrm{OH}^-$$

Chlorine and hydroxide ion would react immediately to form chloride and hypochlorite if the anolyte and catholyte were

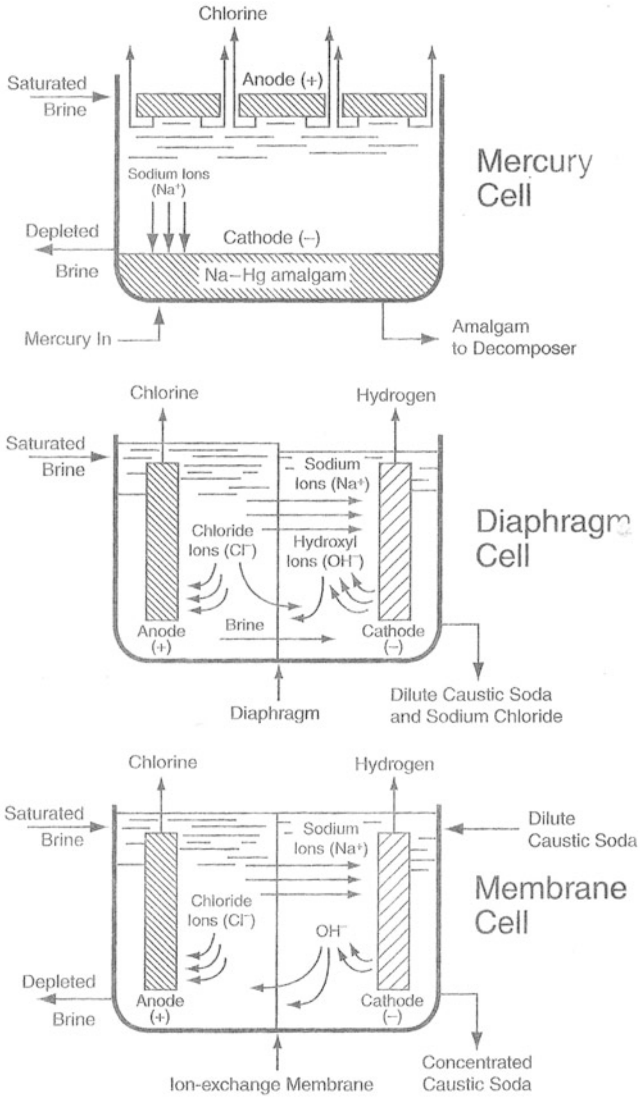

Fig. 26.3 Schematics of mercury, diaphragm, and membrane chlor-alkali cells (Reproduced from Handbook of Chlor-Alkali Technology, vol. I, p. 38. Copyright 2005 Springer Science + Media and reproduced with permission.)

allowed to mix. Chlor-alkali cells must be designed to prevent this mixing. Diaphragm and membrane cells physically separate anolyte and catholyte. Mercury cells rely on a different chemistry. The cathode there is a dilute sodium amalgam flowing over a sloped floor of carbon steel. The sodium ion discharges to Na^0, amalgamated with the mercury. The amalgam that leaves the main part of the cell then flows through a decomposer, or denuder, forming caustic soda by its reaction with purified water:

$$2Na(Hg) + 2H_2O \rightarrow 2NaOH + H_2 + (Hg)$$

The parentheses indicate that mercury is not involved in stoichiometric quantities; the amalgam is in fact quite dilute ($<0.5\%$) in sodium. The flow rate of water, when correctly proportioned to the rate of production, controls the strength of the NaOH solution. The denuded amalgam is recycled to the cell.

In the diaphragm cell, a fibrous mat separates anolyte and catholyte. The feed brine enters the anode side of the cells, and the anolyte flows through the diaphragm into the cathode side. The chlorine formed at the anode passes off as a gas. Not all the chloride ion is oxidized; practical considerations limit its conversion to about 50%. The unreacted chloride ion goes into the catholyte. Hydrogen gas and caustic soda form at the cathode. Figure 26.4 shows the components of a modern diaphragm cell.

Diaphragm-cell liquor contains roughly equal amounts of chloride and hydroxide (molar basis). This is the fundamental disadvantage of the diaphragm cell because extensive processing is required to produce a high-quality NaOH product and recover the unconverted salt for recycle. Another disadvantage, which also goes to explain the continuing gradual replacement of diaphragm cells, is that the fiber used to form the diaphragms classically has been asbestos. Modern cells use a modified form into which a fused fluoropolymer is incorporated. All such formulations are gradually disappearing, largely because of the toxicity of asbestos and increasing restrictions on its use. Synthetic diaphragms free of asbestos are available and are gradually replacing the older types [30].

The technical advantage of membrane cells over diaphragm cells lies in the selectivity of the interelectrode barrier, shown as an ion-exchange membrane in the bottom part of Fig. 26.3. Membranes are sheets of perfluorinated polymer that are designed to permit the flow of water and alkali metal ions from anolyte to catholyte and to block the flow of anions in either direction. This means that chloride ions do not pass into the catholyte to any great extent, and so their concentration in the final product caustic usually is measured in tens of parts per million. To a lesser extent, the passage of hydroxide from catholyte to anolyte also is restricted. The hydroxide flow is a few percent of the total ionic flux through a properly performing membrane. The efficiency of its rejection is determined by the nature of the polymer facing the catholyte. For best efficiency, the ion-exchange group in the polymer will be based on a carboxylic acid. Carboxylate polymers have the disadvantage of low electrical conductivity. Perfluorosulfonate polymers are more conductive but operate at lower current efficiency. The typical membrane therefore has composite construction. It may also include PTFE fibers for physical reinforcement and a surface coating that promotes the release of gas bubbles when the gaps between cell components are small. Figure 26.5 shows how these features are combined in a commercial membrane.

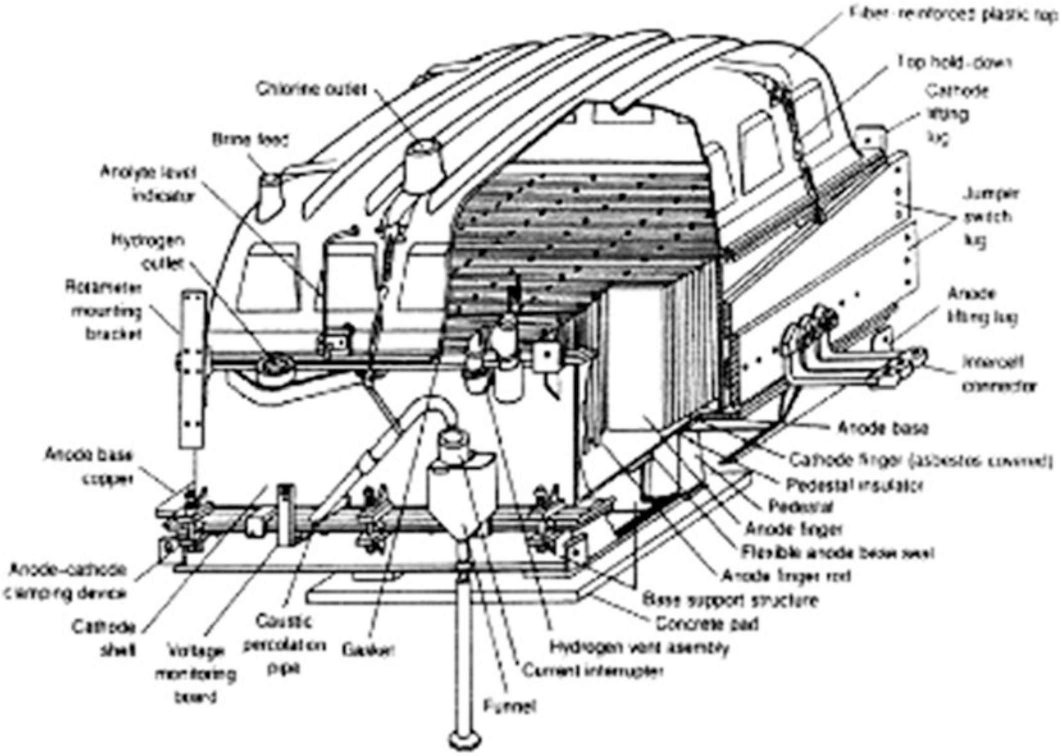

Fig. 26.4 Cut view of ELTECH diaphragm cell (Courtesy of ELTECH Systems Corporation)

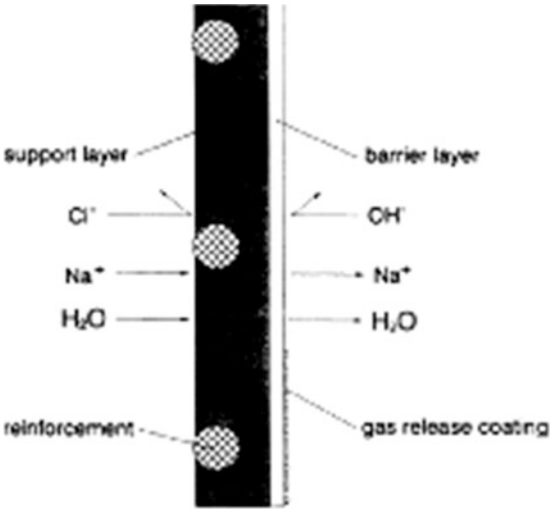

Fig. 26.5 Chlor-alkali membrane cross-section

Before the commercial advent of the membrane cell, diaphragm and mercury technologies competed primarily on the bases of energy consumption and product quality. Mercury cells consume more electrical energy, and this is their chief economic drawback. On the other hand, they operate at much higher current densities and produce caustic soda at commercial strength without extensive processing. The liquor produced in a diaphragm cell is much weaker and has a high concentration of dissolved salt. Expensive multi-effect crystallizing evaporators are required, with large steam consumption and the need to recover and recycle salt. Removal of the dissolved salt is not perfect, and 50% diaphragm-cell caustic soda typically contains 1% residual NaCl. Mercury-cell caustic, often referred to as "rayon-grade," therefore was preferred for some applications and often could be sold at a premium price. The cells are sensitive to a different set of brine impurities, i.e., those that can interfere with amalgam chemistry. Their defining disadvantage, however, is simply the presence and inevitable release of small amounts of the highly toxic mercury. Societal and regulatory pressures against the use of mercury continue to increase. The use of mercury cells has been in steady decline, and their days are numbered.

Membrane cells generally consume less electrical energy than do diaphragm cells. Evaporators are required, but they are simpler in construction and consume much less steam than their diaphragm-cell counterparts. The caustic product is somewhat less pure than mercury-cell caustic, and the stringent brine purity requirements add to the cost and complexity of the process. The advantages outweigh the disadvantages, and the membrane cell is now the technology of choice. It is the universal choice for new installations and frequently is used in conversion of plants from the older technologies. A typical installation of new bipolar membrane cells is shown in Fig. 26.6. Figure 26.7 shows the

assembly of a typical state-of-the-art electrolyzer. Cells such as these can operate at 3 V or less at membrane current densities of 6 kA/m^2 (Table 26.16).

The United States has resisted the change to membrane-cell technology longer than most countries. Most US capacity (>70%) is on the Gulf Coast, where several factors continue to favor diaphragm cells. There are extensive salt deposits, and solution-mined brine is readily available. Diaphragm cells can operate without penalty when salt is supplied as concentrated brine, which Table 26.5 shows to be the cheapest form. Fuel is plentiful and relatively cheap, so the large evaporative demand of the diaphragm cell is less of a liability. Also, the balance between electrical and thermal demand of a diaphragm plant is better suited to the operation of a cogeneration system. Finally, continued improvement in cell components has reduced energy consumption and increased on-line time between maintenance shutdowns [31]. In 2008, 67% of US chlorine capacity was in diaphragm cells. Membrane cells provided 26% and mercury cells, expected to phase out within the current decade, 4%. The situation in Europe was different. Mercury cells had been favored, but there, too, they are being phased out. Membrane-cell capacity became more than 50% of Europe's total in 2011 [32].

Table 26.16 Components of membrane electrolyzer voltage (Courtesy of Chlorine Engineers Corporation, Ltd)

Component	Voltage	% of total
Decomposition voltage	2.26	76.3
Anodic overpotential	0.06	2.0
Cathodic overpotential	0.07	2.4
IR losses[a]	0.57	19.3
Total	2.96[b]	100.0

[a] Include gas effects and IR drops through solution, membrane, and structure

[b] 32% NaOH, 90 °C, 6 kA/m^2

Membrane cells provide more compact installations, and conversion from one of the older technologies frequently has allowed an increase in capacity within an existing footprint. Evolution of the technology has continually increased the maximum practicable current density. Any new project requires an economic balance between the lower capital cost associated with increasing current density and the resulting higher operating voltage that increases energy cost. The recent trend in the industry is to higher current densities and little improvement in energy consumption. It is interesting to note that this parallels the history of development of the mercury cell many years ago [33].

Figure 26.8 shows the elements of the electrolyte processing required with each type of cell. In every case, NaCl brine is the major feed material. The first step in its treatment is the removal of hardness elements and heavy metals by chemical precipitation. The solids that form are removed by settling and one or two stages of filtration. The resulting brine, with a few ppm of hardness remaining, is suitable for use in diaphragm or mercury cells. Membrane

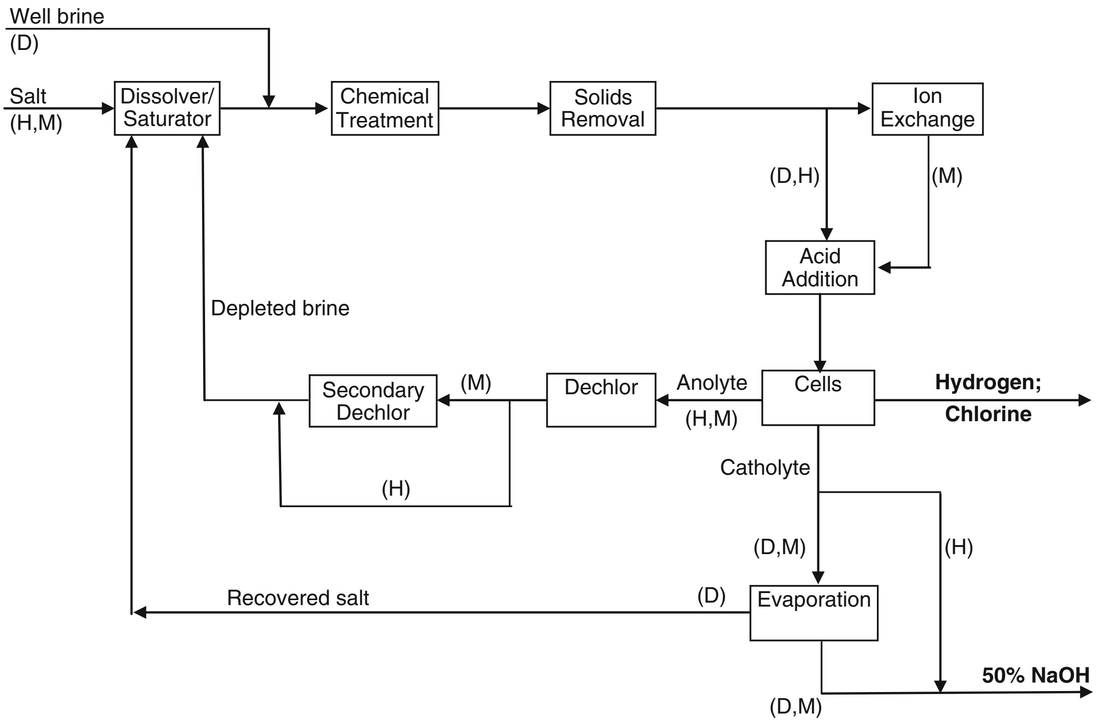

Fig. 26.8 Chlor-alkali electrolyte processing key: D, diaphragm cells; H, mercury cells; M, membrane cells

cells require additional treatment with a chelating ion-exchange resin to reduce hardness to a low ppb level. The treated brine will be alkaline and will contain dissolved CO_2. The addition of acid has several advantages including the removal of the CO_2, improving the quality of the cell gas, and scavenging of some of the OH^- that leaks back from the catholyte in some cells.

The cells produce hydrogen and chlorine gases at their electrodes. The quality of the gases does not depend greatly on the type of cell. The hydrogen is quite pure, and extensive processing is required only for special applications. At the anode, several reactions compete with chlorine formation. Impurity concentrations in the chlorine gas will amount to several percent.

The processing of hydrogen depends on its end use. It is frequently used for its fuel value. All that is required then is to deliver it at a useful pressure and with an acceptable water content. Membrane cells can operate under modest positive pressure. This at least relieves the problem of ingress of air and may also eliminate the need for compression. Other cells may require a blower. The cooling duty depends strongly on the type of cell. Latent heat being a large fraction of the total, process duty correlates with the amount of water accompanying the hydrogen. With mercury cells, the duty is quite small. Membrane cells are the intermediate case. The hydrogen is saturated with water over 30–35% NaOH. In diaphragm cells, the catholyte is more dilute in NaOH, and so the water content of the hydrogen is higher. To choose single values for comparison, with unity assigned to membrane-cell hydrogen, one might say that the cooling duty with mercury-cell hydrogen is about 0.1 and with diaphragm-cell hydrogen about 3 or 4 [34].

Chlorine may be used on site, transferred by pipeline, or liquefied for export. Broadly, about half the chlorine produced is consumed as the liquid. The full process then includes cooling, drying, compression, and liquefaction. Modern practice is to cool the gas, incidentally removing most of its water, in vertical shell-and-tube exchangers with titanium on the process side. Drying is by countercurrent contact with concentrated sulfuric acid [35]. As more water is removed during the cooling process, the cost of supply and disposal of sulfuric acid goes down. Design, however, does not involve simply an economic balance; there are technical limits on the amount of water that can safely be removed. Below 10°C, a solid hydrate of chlorine forms (approximate composition $Cl_2{\cdot}7.2H_2O$). This can deposit in equipment and cut off flow. Upon shutdown, it will melt, causing very rapid corrosion. Next, the titanium used in the coolers is suitable for service in wet chlorine because a resistant oxide film forms by hydrolysis of the metal. The film must be continuously renewed to prevent contact and rapid reaction of the metal with Cl_2. Cooling must not deplete the water content of the gas to a level where it cannot maintain the TiO_2 film.

Dry gas can be handled in ferrous-metal equipment. Centrifugal compressors are standard in large plants; liquefaction is by indirect contact with boiling refrigerant [36]. Centrifugal compressors in chlorine service are restricted in compression ratio, because temperature must be limited in order to prevent combustive reaction between the gas and the metal of the compressor. Compression then becomes a multistage process, with gas coolers operating between stages. In older and smaller plants, liquid-ring compressors are a frequent choice. The sealing liquid is concentrated sulfuric acid. These compressors have much lower energy efficiency, but the circulating acid removes much of the heat of compression, and so the compression ratio can be higher without producing excessive temperature.

The final pressure on the chlorine normally is 2–10 atm. It is determined by downstream needs if the chlorine is to be processed immediately or by a balance between refrigeration and chlorine compression costs when the gas is to be liquefied.

The impurities present in chlorine are mostly permanent gases that do not condense in the liquefaction system. They leave as a vent stream, carrying chlorine at a partial pressure equal to its vapor pressure at liquefaction temperature. The extent of liquefaction therefore increases at higher pressure and lower temperature. It, too, may be a multistage operation. Since deeper liquefaction requires higher severity, energy can be saved by liquefying most of the chlorine under relatively mild conditions and then increasing the severity to reach the desired recovery.

The presence of chlorine in the uncondensed tail gas is a problem that must be dealt with. It can be destroyed by conversion to an innocuous waste, converted to another useful product, or recovered as the element. There are many processes for treating tail gas. The paper by Silver [37] remains a good summary. Destruction most often is by scrubbing with an alkaline liquor. This absorbs the chlorine from the gas and first converts it to hypochlorite, as in the equation above. Some of this will react to form chlorate (*infra*), and the rest can be chemically or catalytically reduced to chloride.

Controlled absorption with precautions not to decompose the hypochlorite is one example of conversion to a useful product. Production of hypochlorite bleach in this way is discussed below. Another option is the production of hydrochloric acid (*infra*). This can be an especially attractive operation as it upgrades some of the hydrogen from the cells and provides a material for internal consumption in brine treatment and dechlorination. Still another option is production of ferrous and ferric chlorides from the metal.

For recovery as the element, absorption/desorption processes suggest themselves. Chlorine would be absorbed from the tail gas at high pressure and low temperature and then released under opposite conditions as a nearly pure vapor.

The ideal characteristics of a solvent have been enumerated [38]. Several plants have operated with carbon tetrachloride as solvent. Environmental restrictions on CCl_4 have put a stop to this practice, and some recovery units have been scrapped. The usual choice for their replacement has been enhanced liquefaction. This might take the form of a tertiary stage where the gas after further compression is exposed again to the lowest temperature in the liquefaction process.

Anolyte, which is a separate stream only with mercury and membrane cells, will contain dissolved chlorine. Most of this can be removed by adding acid to reverse its hydrolysis and reducing the operating pressure. It can join the chlorine from the cells for processing. A small amount of chlorine will remain in the brine. With mercury cells, this is tolerable and may even be beneficial by keeping mercury in solution and preventing deposits of the metal in the brine system. In the membrane-cell process, the residual Cl_2 is not tolerable. A second stage of dechlorination then is necessary. Here, Cl_2 and OCl^- are chemically or catalytically reduced to Cl^-. The depleted and dechlorinated brine then returns to the brine feed process.

Differences in caustic soda processing are profound, reflecting the differences among the various cell products:

1. Mercury cells: NaOH at sales or use concentration, low levels of impurities
2. Membrane cells: 30–35% NaOH, some anionic impurities (Cl^-, ClO_3^-, SO_4^{2-})
3. Diaphragm cells: 10–12% NaOH, ~15% NaCl, other anionic impurities

Mercury-cell caustic requires very little processing. The evaporation of membrane-cell caustic is a straightforward process in which the amount of water to be removed is roughly equal to the amount of contained NaOH. A typical evaporation system will have two or three effects. The nature of diaphragm-cell caustic complicates the evaporation process. The combined presence of NaCl and NaOH will exceed the limits of solubility well before reaching the desired concentration of 48–50% NaOH. NaCl then begins to drop out of solution. Evaporation of about 85% of the water releases about 95% of the salt as crystals that form a concentrated slurry in NaOH solution. The salt, recovered on centrifuges, returns to the brine system for another pass through the cells. The solution is then cooled, releasing more dissolved salt, and is at its final concentration. The newly crystallized salt is removed from the solution by another set of centrifuges. Filtration of the product NaOH solution, which in the 50% grade still contains about 1% dissolved NaCl, normally is necessary to remove the last traces of solid salt.

Most diaphragm-cell caustic is sold with its residual dissolved NaCl. This has been a marked disadvantage in some applications. The less attractive composition of the product, the complexity and cost of an evaporation plant, and the increased energy requirement all favor the replacement of diaphragm with membrane cells. The evaporative load is about five times as great as that in a membrane-cell evaporator. As a result, diaphragm-cell evaporators generally have three or four effects.

A small fraction of the diaphragm-cell caustic output is purified to remove anionic impurities, principally Cl^-. This involves extraction by anhydrous ammonia in a column at high pressure. Extensive processing removes traces of ammonia from the purified caustic and reconstitutes the ammonia for recycle. The byproduct of this process is a stream of caustic soda with an elevated concentration of impurities. It may become a waste or may be used as a source of alkalinity.

In some applications, the water accompanying the caustic is undesirable or unacceptable in further processing. The cost of shipping it along with the caustic is always undesirable. Approximately 5% of the NaOH produced therefore is concentrated beyond 50%. Simple concentrating evaporators can produce 70–73% NaOH in one stage. More complex processing gives products that are 98–99.5% solids. Typically, this involves evaporation in vertical units heated by a molten salt followed by vacuum flashing to remove further traces of water. The molten product may be merely cast in drums. More elaborate processes include the formation of flakes on a cooled roll equipped with doctor knife and the formation of nearly spherical particles by atomization into a stream of dry, relatively cool air.

All the products of a chlor-alkali plant are hazardous, and the hazards are diverse. It would be unwise to provide an inadequate summary here. The interested reader may consult the voluminous safety literature, the guides and publications of industry associations [39, 40], and the standard references already cited here [41, 42].

Hydrochloric Acid

More than 93% of the hydrogen chloride used in the United States is obtained as a byproduct. The chief source is the chlorination of hydrocarbons. Other important sources are isocyanate and fluorocarbon production and the thermal oxidation of chlorinated organic wastes. In substitution chlorination of paraffinic hydrocarbons, HCl is generated in the chlorination reaction. Chlorine never enters the organic molecule during the preparation of isocyanates. Its function is that of a carbonyl carrier, being used first to produce phosgene. Phosgenation of an amino compound then produces two molecules of byproduct HCl.

After addition chlorination of olefins, HCl may be generated by a pyrolysis that leaves a monochlorinated olefin product. In the classical process, this is so in the case of

VCM, the principal derivative of chlorine (*supra*). Addition of Cl_2 to ethylene produces ethylene dichloride. VCM results when a molecule of HCl is split off. If all VCM were produced this way, there would be a serious glut of HCl. This fact provided much of the incentive for development of the oxychlorination process in which HCl is oxidized as it forms to regenerate chlorine:

$$4HCl + O_2 \rightarrow 2Cl_2 + 2H_2O$$

Ideally, all of the chlorine value goes into the product, with no net formation of HCl.

Most synthetic HCl is the product of combustion of chlorine with hydrogen. This is a convenient way to upgrade the tail gas from chlorine liquefaction (*supra*). HCl is recovered as the acid, and much of it is recycled for internal use. Accurate data on hydrogen chloride production and consumption are difficult to obtain because of the large numbers of producers and consumers, the variety of grades, and the confidentiality of information relating to captive use of HCl.

Hydrogen chloride is marketed both as anhydrous HCl and as hydrochloric acid, typically a 32% solution. HCl normally is absorbed in a falling film column followed by a packed tails tower that vents inerts into the atmosphere. The weak acid from the tails tower flows to the primary absorber. The heat of absorption of HCl is about 400 kcal/kg and requires that the primary absorber be water-cooled. With the addition of a ceramic burner to produce HCl from H_2 and Cl_2, similar apparatus becomes an HCl synthesis unit.

Acid made by burning hydrogen in chlorine tail gas is quite pure and requires no further treatment except, in some cases, for the removal of traces of dissolved chlorine. Byproduct acid requires purification in packed scrubbers in which the parent hydrocarbon is circulated in the scrubbing tower before flowing to the chlorinator. Frequently, the absorption efficiency is improved by cooling the scrubbing liquor with a refrigerant.

Bromine and Sodium Bromide

Bromine has long been produced by the displacement of bromides from seawater. While this is an inexhaustible source (10^{14} metric tons Br), operation is expensive because of the low concentration of bromide (about 65 ppm [43]), and the process no longer operates in the United States. Rather, underground brines found in Arkansas at depths of about 2,400 m and containing up to 0.6% Br are the favored source. There are two US producers with combined capacity of 278,000 t/year [44].

The United States is the world's largest producer of bromine (about one-third of the total), but China and the Dead Sea countries account for a large and growing share.

Table 26.17 US production and consumption of bromine

	2007	2008	2009	2010
Production	243	w[a]	w[a]	w[a]
Exports	8.6	9.6	8.1	8.0
Imports	32.2	41.2	34.2	45.0

Others	3	(from bitterns)
Total non-US	450	Large

Sources: US Geological Survey: Mineral Commodity Summary, *Bromine*, 2011; advanced release of 2010 Minerals Yearbook

All quantities in thousands of metric tons bromine equivalent

[a] China has a total of 3.5 million metric tons of base reserves of uncertain quality and value (reported elsewhere)

Table 26.17 shows that production and consumption rates in the United States are hard to obtain because data are not reported when there are fewer than three active producers. Table 26.18 shows worldwide production and reserves. Non-US production in 2010 was about 10% higher than the average of the previous 4 years. Bitterns of potash production from Dead Sea brines, used in Israel and Jordan, are very rich in bromide, containing 1.0–1.2% Br (w/v). The total amount of bromine available there is about 10^9 metric tons. Some countries produce relatively small amounts of bromine by recovering it from solar salt or potash bitterns.

There are four major steps in the recovery of bromine from brine: (1) oxidation of Br^- by injection of chlorine, (2) stripping of elemental bromine from solution, (3) recovery of bromine from vapor, and (4) purification. The first step depends on the equilibrium between chlorine and bromine:

$$Cl_2 + 2Br^- \leftrightarrow 2Cl^- + Br_2$$

In the second step, elemental bromine is released by contact of the solution with air or steam. There is an economic balance here between the cost of steam and the difficulty of recovering bromine from air in the third step.

Generally, steam is favored when processing brines and air when processing the much more dilute seawater. The use of air requires the bromine to be trapped in an alkaline or reducing solution to concentrate it.

Operating a steam-based process under vacuum allows bromine to be stripped at lower temperature. Claimed benefits are increases in steam economy and plant capacity and reductions in chlorine loss, spent brine treating requirements, maintenance costs, and atmospheric emissions [45, 46].

Primary uses of bromine and bromine chemicals are in flame retardants, drilling fluids, water treatment, and pesticides. The once-prominent market in petroleum additives has declined with the phase-out of lead-based antiknocks, which consumed ethylene bromide. Similarly, certain brominated flame retardants are being withdrawn from the market [44]. A growing application is the use of bromine to bond with mercury in flue gases. In some cases, it replaces chlorine as a scavenger. The mercuric bromide that forms is relatively easy to remove in flue-gas scrubbers. One process uses fine powdered carbon impregnated with about 10% bromine [47].

Sodium bromide sometimes is recovered as a byproduct of other operations, and it can be prepared by adding excess bromine to a solution of NaOH. After evaporation to dryness, treatment with a reducing agent converts sodium bromate to NaBr. It is used as an intermediate in production of other chemicals, often by double decomposition with organic chlorides. Bromides are the proverbial sedatives, and other uses are as algaecides and photographic chemicals. Their major use has been in drilling fluids, where the high density of concentrated aqueous solutions (up to 1.55 g/cm^3) is useful in well completions. NaBr is the form of supply when using bromine as a biocide. The active form is released by activators such as hypochlorites and chlorinated isocyanurates.

Recovery of bromine from byproduct solutions and HBr emitted in organic brominations is the source of roughly one-third of total production. Incineration of plastics that contain brominated flame retardants also provides bromine for recovery [48].

Bleaches and Disinfectants

The oxidative and biocidal properties of chlorine have been widely exploited from the beginnings of the chemical industry. Textile manufacturers and the paper industry have long recognized the value of bleach in their operations. The extensive use of chlorine and its derivatives to bleach wood pulp is described in Chap. 28.

Active chlorine compounds also find wide use as disinfectants and in laundry bleaching. The spread of the great killer diseases cholera and typhoid was checked by the addition of small amounts of chlorine bleach to wastewater and drinking water. Today, potable water disinfection accounts for only a few percent of the world's chlorine consumption (see Table 26.15) but remains perhaps its most important and most beneficial use. The use of chlorination is widespread only in the developed world, and an estimated one-third of deaths and 80% of all diseases in developing countries are due to consumption of contaminated water [49].

When chlorine is added to water, it hydrolyzes to form hydrochloric and hypochlorous acids:

$$Cl_2 + H_2O \rightarrow H^+ + Cl^- + HOCl$$

HOCl is a strong disinfectant that is not ionized at low pH. Rather than transport and handle liquid chlorine, both hazardous undertakings, treatment plant operators may use solutions of sodium hypochlorite. This is produced, along with an equal amount of salt, by absorption of chlorine into a solution of caustic soda:

$$Cl_2 + 2NaOH \rightarrow NaCl + NaOCl + H_2O$$

The strength of the solution may vary to suit the application. The use of 20% NaOH gives a 16% solution of NaOCl, which is regarded as commercial strength. At high pH, hypochlorite is completely ionized. It is less effective in this form, and, at lower pH at the point of application, it may convert to the more active HOCl.

Before the commercialization of chlorine liquefaction, bleaching compounds were the only transportable form of chlorine. The earliest practice was to absorb chlorine in hydrated lime, $Ca(OH)_2$. This forms chloride of lime, $CaOCl_2$, which is easily transported as a solid. Dissolved in water, it forms equal moles of $CaCl_2$ and $Ca(OCl)_2$:

$$2CaOCl_2(\text{dissolved}) \rightarrow CaCl_2 + Ca(OCl)_2$$

Chlorination of milk of lime or of a slurry of lime produces the same mixture, in which calcium hypochlorite is the active ingredient [50]. If sodium hypochlorite is separately produced or if a mixture of lime and caustic soda is used, the lower solubility of $Ca(OCl)_2$ allows double decomposition of NaOCl and $CaCl_2$, and all the calcium value can be converted to bleach. The overall reaction becomes, ideally:

$$2Cl_2 + Ca(OH)_2 + 2NaOH \rightarrow 2NaCl + 2H_2O + Ca(OCl)_2 \downarrow$$

$Ca(OCl)_2$ has characteristics similar to those of NaOCl, but it is approximately neutral and in its granular form has a high available chlorine content. The chloride of lime as produced in the past contained only about 35% available chlorine.

The term "available chlorine" describes the bleaching capacity of a substance or solution referred to an equal weight of elemental chlorine. The chloride ion that results from hydrolysis of Cl_2 is not a bleaching agent, but the hypochlorite ion can abstract two electrons (the chlorine atom is in the +1 oxidation state, and $Cl^{1+}O^{2-}$ is a more informative notation). The net result of hydrolysis and bleaching is as if each chlorine atom picked up one electron in oxidation of the material being treated. A hypochlorite group, it will be seen, then has all the bleaching capacity of a molecule of chlorine. Pure calcium hypochlorite, noted above, therefore contains $2 \times 100 \times 71/143 = 99.3\%$ available chlorine. The commercial product actually is the dihydrate $Ca(OCl)_2{\cdot}2H_2O$. Its strength varies with the purity of the lime used in its preparation, the purity of the mixed crystals formed in precipitation, the degree of contamination by unreacted lime, and the final processing conditions. Centrifugation, granulation, and air drying normally yield a product with 65–70% available chlorine. This is the form packaged for sale.

Chlorine/hypochlorite has largely been displaced from wood pulp bleaching in the move to elemental chlorine-free (ECF) bleaching. It still is widely used in household bleaches because of its ease of manufacture and handling, as well as its low cost. Many plants are dedicated to the production of bleach and operate on purchased chlorine and caustic soda. Others are attached to chlor-alkali plants (*supra*) and frequently operate on liquefaction plant tail gas. Commercial soda bleaches vary in their NaOCl content up to 15–16%, the higher NaOCl contents requiring higher excess concentrations of caustic to maintain stability. Household bleach is relatively dilute and normally contains 5–6% available Cl_2. Lacking the additives found in many consumer products, bleach has few residual effects, and the Centers for Disease Control and Prevention recommend its use for all sanitizing purposes [51].

The conventional expression "trade %" is simply the available chlorine content in weight/vol.%. Thus,

$$(\text{trade \% available } Cl_2) = (\text{weight \% available } Cl_2) \times (\text{specific gravity})$$

Since pure sodium hypochlorite has 95.3% available chlorine, one also can write

$$(\text{trade \% available } Cl_2) = (\text{gpl NaOCl}) \times 0.0953$$

Bleach also can be produced by the absorption of chlorine from liquefaction tail gas. Even the liquor from an emergency vent scrubber may be a useful bleach. Maintaining the quality of the bleach often is at cross purposes with the function of an emergency scrubber. Design and operating technique can overcome some of the difficulties. Some key points as well as the problems of decomposition of hypochlorite and the use of filtration and proper materials of construction to improve product stability are discussed elsewhere [52].

A much weaker bleach results from electrolysis of seawater in undivided cells. The electrode products, NaOH and Cl_2, react as noted above to produce hypochlorite. As a low-level bleach and disinfectant, it can serve as a utility-type water and sewage treating agent. It is a natural choice for marine sanitation and as an algaecide in seawater evaporation plants.

Dilute sodium hypochlorite is approved for sanitization of food processing equipment. A concentration of 200 ppm available chlorine is acceptable without washing if equipment is adequately drained [53]. More concentrated solutions may be used along with proper rinsing protocols.

The insoluble components in lime-based products are especially objectionable in laundry and dishwashing uses. Sodium compounds are preferred, and sometimes in spite of their greater cost, lithium compounds. LiOCl can be prepared by absorbing chlorine in LiOH or by adding LiCl to soda bleach. In the latter case, it is the insolubility of NaCl in concentrated solution that drives the double decomposition:

$$NaOCl + LiCl \rightarrow LiOCl + NaCl \downarrow$$

The demand for chlorine dioxide was an early beneficiary of the move away from chlorine bleaching of wood pulp. For many years, ClO_2 had been used late in many pulp-bleaching sequences. It is a strong bleaching agent that can remove certain compounds that resist bleaching by chlorine. Its use thus increases the brightness of the final product. It also produces fewer waste products that require disposal [54] and in particular produces much less adsorbable organic halide and no dioxin [55]. The use of more ClO_2 in earlier stages permitted the reduction or elimination of chlorine bleaching.

The shift to ClO_2 increased the market for sodium chlorate. Chlorine dioxide is very unstable and cannot be safely and economically transported. Instead, it is produced at the point of use by treating a solution of $NaClO_3$ and NaCl with acid and a reducing agent. There are several different types of commercial chlorine dioxide generator in operation, classified by acid medium (sulfuric, hydrochloric) and reducing agent (sulfur dioxide, methanol, sodium chloride, hydrochloric acid). Most processes generate some elemental chlorine as a byproduct. The use of sulfuric acid or SO_2 also produces sodium sulfate or waste acid for disposal. As an example of the chemistry, consider HCl, which serves both as acid and as reducing agent:

$$NaClO_3 + 2HCl \rightarrow ClO_2 + {}^1\!/_2 Cl_2 + NaCl + H_2O$$

Generators must be operated with care to avoid ClO_2 concentrations above 10%, which can lead to explosive decomposition. The reactor offgas therefore is diluted with air, and the ClO_2 is immediately absorbed in water. The molar ratio of ClO_2 to Cl_2 formed is typically 2:1. If this level of Cl_2 is objectionable, the gas is passed through a tower in contact with circulating chilled water. This dissolves all the ClO_2 but only about 25% of the Cl_2, raising the molar ratio to $8ClO_2{:}1Cl_2$. The remaining Cl_2 can be removed by scrubbing with alkali.

Since the oxidation state of chlorine in ClO_2 is +4, it abstracts five electrons as it is reduced to chloride. A chlorine molecule, as we have seen, transfers only two. The available chlorine content of ClO_2 therefore is $5/2 \times 100 \times 71/67.5 = 263\%$.

Sodium Chlorate

Sodium chlorate is produced by the electrolysis of NaCl brine in a cell similar to a chlor-alkali cell but lacking means to separate the products of the two electrodes. The chlorine and caustic soda produced in the cell therefore react immediately, producing sodium hypochlorite:

$$Cl_2 + 2NaOH \rightarrow NaOCl + NaCl + H_2O$$

The cell liquor is kept hot (80–95°C) in a vessel that provides enough residence time for the hypochlorite to disproportionate into chlorate and chloride:

$$3NaOCl \rightarrow NaClO_3 + 2NaCl$$

The overall reaction, requiring 6 F/mole, becomes

$$NaCl + 3H_2O \rightarrow NaClO_3 + 3H_2$$

Optimum cell conditions are 80–90°C and pH 6–6.5. The liquor contains 550–750 gpl $NaClO_3$ and 100–120 gpl NaCl [56]. Coated titanium anodes and steel cathodes are used, and small amounts of dichromate are added to the cell liquor to prevent the cathodic reduction of chlorate or hypochlorite. Resulting current efficiencies are above 90%, and energy consumption is in the vicinity of 4,500 kWh/metric ton.

The adoption of permanent metal anodes permitted an increase in sodium chlorate and a reduction in salt concentrations in the liquor without loss of current efficiency. This in turn allowed direct recovery of sodium chlorate by evaporative crystallization [57]. This was an advance on the process described in previous editions of this handbook. The earlier process yielded solid salt when the liquor was evaporated. After removal of the salt, cooling of the liquor produced $NaClO_3$ crystals.

Nearly all the sodium chlorate made in North America is used in the on-site manufacture of chlorine dioxide for pulp bleaching. The surge in demand due to the industry's adoption of ECF bleaching has run its course. The rest is used to produce other chlorates, perchlorates, and chlorites; in water treatment; and in the hydrometallurgical recovery of uranium. Sodium chlorate also is a nonselective herbicide. While this market might tend to increase along with GDP, there is also pressure to convert to total chlorine-free (TCF) bleaching. The market for $NaClO_3$ has been growing faster where conditions are more favorable. In Asia and South America, the abundance of faster-growing pulps presents more opportunity. Russia, with 22% of the world's forest and relatively cheap electricity, also has seen some growth. Where electricity is more expensive, the higher cost of $NaClO_3$ has allowed H_2O_2 to penetrate the bleaching-chemical market. In Europe and Japan, where ClO_2 accounts for only 90 and 84% of consumption, respectively, the use of sodium chlorate as a herbicide is more common. However, this market is threatened by a European Union directive to withdraw sodium chlorate products from the market [58].

Potassium chlorate can in some circumstances be produced electrolytically from KCl. It is more common to produce it from $NaClO_3$ by double decomposition:

$$KCl + NaClO_3 \rightarrow KClO_3 + NaCl$$

After the reaction is carried out in solution, crystallization yields solid $KClO_3$. $KClO_3$ is used in matches, pyrotechnic products, explosives, cosmetics, and pharmaceuticals [59].

Bromates are produced electrolytically, like chlorate, or by bromination of the respective carbonates. Bromates are used in small quantities, but they are important in the bread-making industry for maturing flour and conditioning dough. They also are used in permanent-wave lotions and in the manufacture of dyes.

Both chlorates and bromates have substantial oxidizing power, and care must be taken in their storage and handling. Contact with reducing agents or combustibles can be disastrous.

Industrial Gases

27

Steven J. Cooke

Overview

Industrial gases may actually be used as gases, liquids, or cryogenic liquids. Industrial users generally accept them as those gases used primarily in their pure form in large quantities. Most of the gases we consider to be industrial gases have been in use for many years. Processes for the cryogenic separation of the air gases were developed as early as 1895, with commercial production of oxygen beginning in 1902. Nitrous oxide was used as an anesthetic as early as 1799. Carbon dioxide had been identified as a specific substance by 1608. Methane has been used as an energy source since the 1700s. Other gaseous compounds commonly used today for specific manufacturing processes (e.g., electronics/semiconductors, plastics) are discussed in other chapters of this Handbook related to those processes.

The reactivity of gases can be summarized into three classes: oxidizers, inert gases, and flammable gases. The gases that fall into the category of inert are nitrogen, argon, helium, and carbon dioxide. The oxidizers are oxygen, chlorine, and nitrous oxide. Acetylene, liquefied natural gas (LNG), and hydrogen are the flammable gases. These elements and compounds by no means encompass all gases considered to be industrial gases, but they represent the major gases used and produced in industry (see Table 27.1) [1].

The cryogenic air separation process, in which air is liquefied and separated into its major constituents (oxygen, nitrogen, argon) by the use of cryogenic technology, is the major source of nitrogen, oxygen, and argon produced for industry, as well as the noble gases krypton, neon, and xenon. Table 27.2 gives the cryogenic boiling point temperatures and concentrations for some of the gases present in the atmosphere.

The cryogenic air separation process starts with air entering the plant through air filters, where it is compressed and cooled. The air is passed through heat exchangers for further cooling and for removal of water vapor and carbon dioxide by liquid condensation. Solid adsorbents, such as molecular sieves, silicas, and aluminas, can also be used to remove the water and carbon dioxide by adsorption before separation of the air. When the air reaches a temperature of −338°F, it is sufficiently free of water and carbon dioxide and ready to be passed into the distillation column [6].

Separation occurs by distillation, which is the physical partition of compounds by the differences in their boiling points (see Fig. 27.5 below in the section "Argon"). The distillation method used is referred to as "double column," as it contains two separate distillation columns operated at two different pressures. The cooled air is fed to the bottom of the high-pressure column. Air is distilled in this column where the higher boiling temperature fluid oxygen stays at the bottom and the lower boiling temperature nitrogen boils to the top as a distillate product. The crude liquid oxygen from the high-pressure column is flashed into the low-pressure column as the two columns are thermally linked by a common reboiler/condenser.

Vapor is withdrawn from the middle of the low-pressure column and is passed as feed to the crude argon column. The vapor in that column is condensed and taken off as liquid crude argon. Pure nitrogen vapor is extracted from the top of the low-pressure distillation column, and liquid oxygen is taken from the bottom of this column. Figure 27.1 shows an air separation plant with a molecular sieve front-end cleanup and liquid storage tanks.

Alternatives to the cryogenic separation process include the membrane separation process and adsorption processes. The adsorption processes include pressure swing adsorption (PSA) [15] and vacuum swing adsorption (VSA). These methods are non-cryogenic and produce a vapor product only. This reduces the cost of production considerably when the local use of gas-phase product is the primary objective.

The membrane separation process is used to produce a number of gases for industrial use. Many membrane technologies have been developed over the last 10 years, including various polymer and pure carbon membranes [13, 17]. A common polymer membrane may consist of a microporous substructure of cellulose acetate and a thin layer of dense cellulose acetate (active layer) on the upper surface, resembling a sponge covered by a plastic film. The membrane is cast into a supporting cloth for added mechanical strength. The active layer serves as the separating barrier

Fig. 27.1 Air separation plant with a front-end cleanup, cold box tower and liquid storage tanks. (Courtesy Air Liquide.)

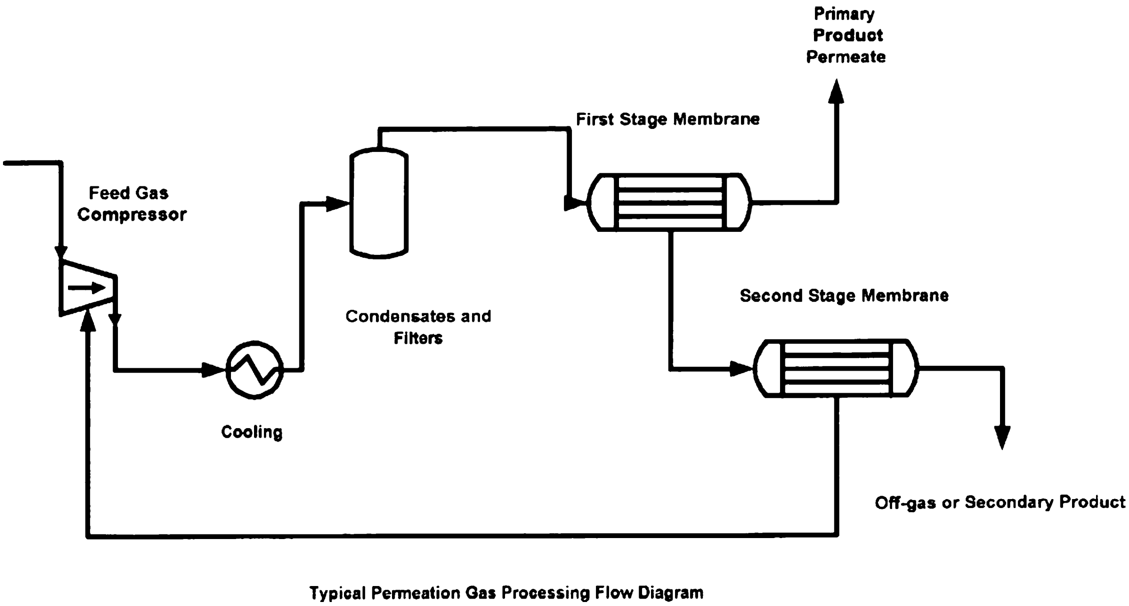

Fig. 27.2 Typical permeation gas processing flow diagram

and, because of its thinness, provides very high transport rates. The membrane selectively allows the smaller molecular-sized components to pass through the membrane substructure, thereby accomplishing the separation process. Carbon and zeolite-based membranes depend on the relative molecular size of the gases to effect the separation of the gases. A typical membrane separation flow system is shown in Fig. 27.2.

The VSA system is a non-cryogenic process that makes use of pressure that is less than atmospheric (vacuum) and adsorbents to separate nitrogen, and carbon dioxide from air. The PSA system is a similar process for producing a particular gas by passing a pressurized gas stream through a set of adsorbent beds. The impurities are selectively adsorbed using a molecular sieve or other selective adsorbents to trap the undesired components. In the production of oxygen using the VSA process, the VSA system separates air at ambient temperature by passing it through a column of adsorbent. The adsorbent, which is an inorganic crystal material, selectively adsorbs nitrogen molecules on its

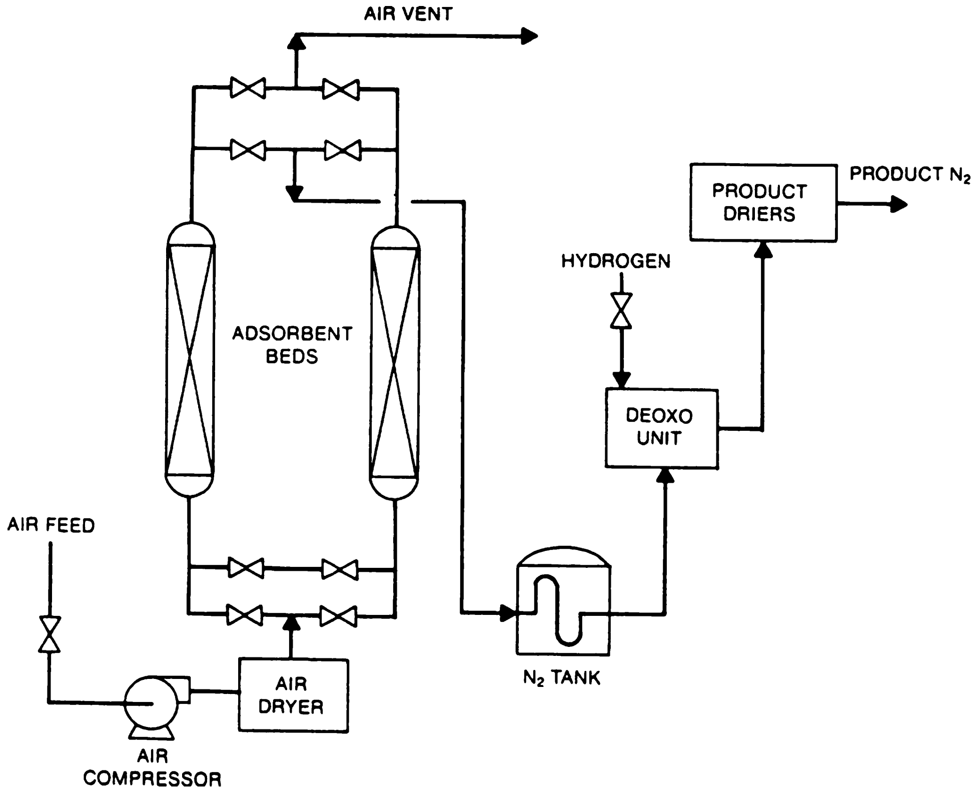

Fig. 27.3 Process diagram for nitrogen PSA system. (Courtesy Air Products and Chemicals, Inc.)

surface, while the oxygen molecules pass on through the adsorbent column.

The final oxygen product exits the adsorber column. The nitrogen adsorbed is released when the adsorber column is reactivated by use of differential pressure from a vacuum. Once the adsorber column is reactivated, the cycle is ready to be repeated. In the PSA system, compressed air is passed through a column of chemical adsorbent, which is a carbon-based material that essentially traps the oxygen molecules and allows the nitrogen molecule to pass through to the use point. Figure 27.3 shows the process flow of a PSA system, which can produce 98–99.5% pure nitrogen without the need for downstream purification. These adsorption systems usually are located at customer sites. See Fig. 27.4 for an example of an on-site PSA.

Small-volume users of the industrial gases are supplied by high-pressure gas cylinders filled with the desired product. These cylinders then are loaded onto flatbed trucks for delivery. For larger-volume gas transportation, long-length gas cylinders are permanently mounted on trailer frames. These high-pressure-cylinder vehicles commonly are referred to as tube trailers. The cylinders are constructed of alloy steels, and are designed, built, tested, and maintained in accordance with US Department of Transportation (DOT) regulations in the United States. Similar regulatory agencies in other countries define the requirements for safe transport and storage of compressed gases (e.g., Transport Canada, Ministère des Transports (France), Department for Transport (UK), and other national regulators). The typical small-volume cylinders are constructed to a DOT 3A or 3AA specification, and typically have rated service pressures from 2,015 to 2,640 psig and water volumes from 0.39 to 1.75 ft^3. The larger cylinders often have similar pressure ratings but water volumes of approximately 75 ft^3.

The containers used for transporting and storing the majority of cryogenic liquids are insulated cryogenic tankers, liquid cylinders (sometimes referred to as Dewars), and stationary storage tanks. These containers are similar in design to a Thermos® bottle. There is an inner vessel, which contains the cryogenic product, and an outer vessel. The space between the two vessels is under a vacuum and usually contains a wrapped insulation material such as aluminized Mylar, or it may contain a powdered insulation such as expanded perlite. The liquid cylinders, usually 160–250 L in capacity, are constructed to a DOT 4 L specification and operate with pressure up to 235 psig.

The cryogenic tank trucks may be constructed to a DOT MC-338 specification, and range in capacity from 3,000 to 14,000 gal, usually depending on the product. The operating pressures may range from 25 to 150 psig, and the vehicles often are equipped with cryogenic pumps used to deliver the

Fig. 27.4 An on-site nitrogen PSA supply system. The large vessels are absorbers and the smaller ones are dryers. (Courtesy Cirmac International, BY, Netherlands.)

product to higher-pressure storage tanks. The stationary storage tanks are designed and built to ASME standards, typically are constructed for pressures of 250 psig or less, and may range in capacity from 500 to 70,000 gal [3].

Nitrogen

Nitrogen makes up 78% of the earth's atmosphere. It is a colorless, tasteless, nontoxic, and relatively inert gas. Nitrogen does not support combustion nor does it support respiration; but it reacts with the more active metals such as lithium and magnesium to form nitrides, and at high temperatures it will combine with hydrogen, oxygen, and other elements. As a cryogenic liquid, nitrogen is nonmagnetic, stable against mechanical shock, and free from toxic or irritant vapor.

Nitrogen usually is produced by cryogenic air separation, liquefaction of atmospheric air, and removal of the nitrogen by distillation, as described earlier. Non-cryogenic adsorption technology, including PSA and VSA systems, economically provides nitrogen for requirements between 4,000 and 30,000 standard cubic feet per hour (SCFH) [13]. The development of more efficient membrane separation systems has happened in the last 10 years. The production of gaseous nitrogen for refinery instrumentation and vessel purging needs has shifted more to the use of membrane systems on site rather than cryogenic liquid in bulk storage due to significant cost savings.

Nitrogen has many applications, both as a gas and as a liquid. Gaseous nitrogen is widely used for inerting and pressurizing systems. Applications include the agitation of color film solutions in photographic processing; blanketing and deaeration of oxygen-sensitive liquids, volatile liquid chemicals, and nonferrous metals; and in the production of semiconductor electronic components, primary metals heat treating, and brazing of copper tubing. It is used to pressurize aircraft tires and emergency gas bottles to operate landing gear; and often to purge and pressurize pipelines, reactor vessels, or storage tanks throughout the petrochemical industry [1].

Gaseous and liquid nitrogen have applications in the foods industry in the areas of food processing and packaging. Liquid nitrogen is used for rapid freezing of expensive or highly perishable foods, such as shrimp and other meat products, as well as to refrigerate foods in long-distance hauling. A gaseous nitrogen atmosphere can help to retard the spoilage of some food products.

Liquid nitrogen is used in the cold-trapping of materials such as carbon dioxide and volatile organic carbons (VOCs) from gas streams, as a coolant for electronic equipment, for pulverizing plastics or rubber material, for deflashing of rubber tires, and for simulating the conditions of outer space. It is used to freeze liquids in pipelines during repairs to the pipeline. It can be used to generate very high-pressure gaseous nitrogen (15,000 psig) by liquid pumping. Liquid nitrogen is frequently used in medicine to remove skin blemishes in dermatology, and to preserve whole blood, livestock sperm, and other biological specimens.

Liquid nitrogen gas is transported in liquid cylinders, nonpressurized Dewars, cryogenic tankers, and trailers. Gaseous nitrogen is also transported in high-pressure gas cylinders and tube trailers. Both forms of nitrogen also are transported via pipelines when the sources are at economical locations and distances from the applications.

Oxygen

This gas, which occupies approximately 21% of the earth's atmosphere at sea level, has a number of very important uses. Oxygen is a colorless, odorless, and tasteless gas that is essential to the support of life. All elements except the inert gases combine directly with oxygen to form oxides. Oxygen is nonflammable, but is an oxidizer that readily supports combustion.

A large percentage of the oxygen produced commercially is made by cryogenic air separation. It may also be produced by PSA and membrane systems, as described in the production of nitrogen. Oxygen also may be made by the most common decomposition reaction, electrolysis of water.

Small quantities of pure oxygen may also be made by other chemical reactions. These reactions produce not only oxygen but by-products as well, and they are not usually as economical an alternative when compared with the other technologies.

Applications in enhanced combustion and life-support systems provide the majority of the demand for oxygen. It is used extensively in medical applications for therapeutic purposes, for resuscitation in asphyxia, and with other gases in anesthesia. Also it is used in high-altitude flying and deep-sea diving, and it is used for life-support and as a fuel oxidizer in the US space program [1].

For industrial applications, oxygen is in large demand for use with acetylene, hydrogen, and other fuel gases for purposes such as metal cutting, welding, hardening, and dehydrating. Oxygen enhances the capability of steel and iron furnaces. Oxygen is used in the production of synthesis gas–hydrogen–carbon monoxide mixtures from coal, natural gas, or liquid fuels; the synthesis gases are used to make gasoline, methanol, and ammonia. Oxygen may be used for the cracking of methane or natural gas by partial oxidation to produce acetylene, and in the production of nitric acid, ethylene, and other basic chemical feedstocks.

One of the largest commercial applications for oxygen is the Basic Oxygen Furnace (BOF) for refining iron and making steel. Another common application is its use in oxyfuel burners in the steel industry. It is used in electric arc furnaces, which melt scrap metals by passing an electric current through large graphite electrodes.

Oxygen enrichment is a process whereby oxygen is added to an air stream to improve a plant's efficiency. Combustion results in the generation of heat and gaseous by-products, usually carbon monoxide, carbon dioxide, and water vapor. Oxygen enrichment decreases the amount of nitrogen in the air stream, improving the combustion reactions while reducing the formation of undesired by-product gases. Oxygen enrichment is used in pulp mills to increase lime production from existing equipment and eliminate the need to purchase lime from other industries. It is also used in pulp mills to reduce airborne sulfur emissions to comply with federal environment regulations.

Gaseous oxygen is transported in high-pressure gas cylinders, tube trailers, and portable cylinder modules. Liquid oxygen is transported as a cryogenic fluid in liquid cylinders and insulated cryogenic tankers. Customer on-site storage is usually accomplished in large insulated cryogenic tanks.

Argon

Argon, a relatively scarce gas, is colorless, odorless, tasteless, and nontoxic. It forms no known chemical compound; thus it is extremely inert. Representing only 0.93% of the earth's atmosphere, it is the most valuable of the commodity air gases. Argon is utilized in a variety of applications. In the manufacture of lighting devices, it is used to fill lamp bulbs and to produce colors in display tubes for lighted signs.

Argon provides an inert atmosphere for the production of semiconductors and specialty metals, such as titanium and zirconium. It is often used to provide a protective shield for the growing of silicon and germanium crystals. Some metal welding and cutting applications require an inert gas shield, and argon gas often is used to fill this requirement [1].

Argon is manufactured in oxygen–nitrogen plants by means of fractional distillation after the liquefaction of air as described previously, in the cryogenic air separation process. In the distillation process where air is separated into oxygen and nitrogen, a stream of gas is withdrawn from the low-pressure column to enter the crude argon column. The argon content of the gas, initially 10%, is increased to 95% by subjecting the gas to several stages of distillation. This "crude" argon is further purified to yield the final pure argon product. Figure 27.5 shows a typical air separation process flow diagram. Argon is most economically shipped as a liquid. Liquid argon commonly is transported in liquid cylinders, cryogenic trailers, and portable tanks. Argon can be shipped in high-pressure gas cylinders and high-pressure cylinder trailers.

Hydrogen

Hydrogen, the lightest element known, is extremely flammable and is found in 0.00005% concentration in the air (0.5 parts-per-million). It has received notoriety in the late 1990s into the twenty-first century as a potential replacement for hydrocarbon fuels. This is because the actual combustion of hydrogen results only in the emission of water and the generation of heat which can be used in any of the existing forms of energy generation. However, as the subsequent discussion of hydrogen generation illustrates, there is much more to the carbon cycle of hydrogen use than the final combustion step [2].

The hydrogen molecule exists in two distinct forms: ortho and para, named according to their types of nuclear spins. *Ortho*-hydrogen molecules have a parallel spin, and *para*-hydrogen molecules have an anti-parallel spin. There is no difference in the chemical or transport properties of these forms, but there is a difference in the thermodynamic properties. *Para*-hydrogen is the form preferred for rocket fuels. Hydrogen consists of about three parts ortho and one part para as a gas at room temperature, which is referred to as normal or equilibrium hydrogen. The concentration of the para form increases with decreasing temperature until, for the liquid, the para concentration is nearly 100%. If hydrogen should

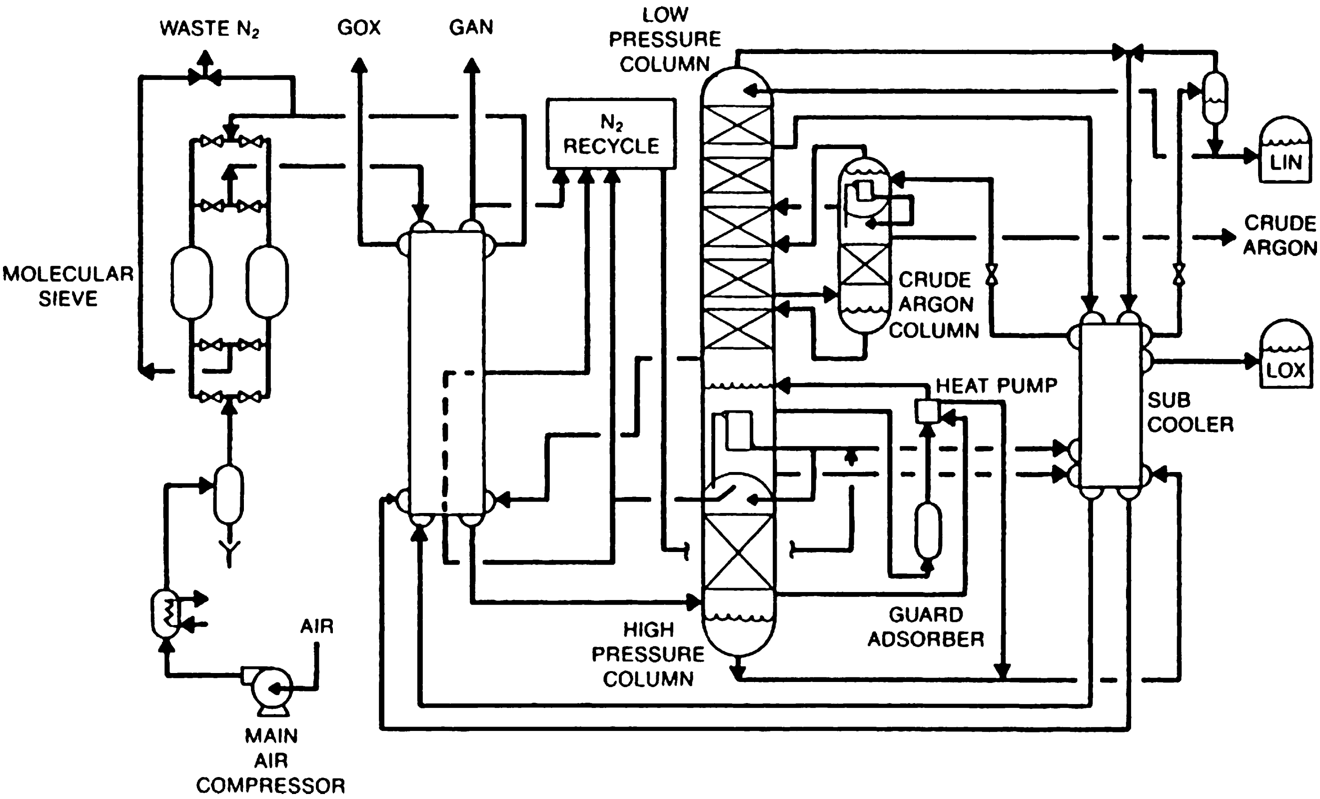

Fig. 27.5 Flow diagram for an air separation plant. (Courtesy Air Products and Chemicals, Inc.)

be cooled and liquefied rapidly, the relative three-to-one concentration of ortho to para would not immediately change [3].

Conversion to the para form takes place at a relatively slow rate and is accompanied by the release of heat. For each pound of rapidly cooled hydrogen that changes to the para form, enough heat is liberated to vaporize approximately 1.5 lb (0.68 kg) of liquid hydrogen. However, if a catalyst is used in the liquefaction cycle, para-hydrogen can be produced directly without loss from self-generated heat.

Hydrogen can be produced by steam methane reformation (the most widely used process) or by off-gas purification. Hydrogen can be produced at normal purity (95–98%) or at ultra-high purity (99.99%). The first step to obtain pure hydrogen in the steam reformer process when using a natural gas feedstock is to perform a pretreatment. There are small amounts of sulfur in natural gas that must be removed. Sulfur removal is done by preheating the natural gas to 700°F, and then sending it through a catalytic reactor. The catalyst inside the reactor adsorbs the sulfur. The second step is steam methane reforming. In this procedure, natural gas and steam are sent through a set of reformer tubes that are packed with a reforming catalyst. A furnace inside the reformer heats the reaction. The methane and steam react, and the results are 45% hydrogen, 40% steam, 8% carbon monoxide, and 7% carbon dioxide. The third step to obtain normal purity hydrogen is gas shifting.

Carbon monoxide, hydrogen, and steam are sent through a shift converter where the gas is heated between 400 and 700°F. The carbon monoxide and steam react to yield hydrogen and carbon dioxide. To produce pure hydrogen, the carbon dioxide must be removed. The gas passes through a carbon dioxide removal system, which contains a chemical solvent that selectively absorbs the carbon dioxide as the gas passes through the solvent [18]. Heat then is added to the solvent to discharge the carbon dioxide. The regenerated solvent is returned to the system to continue the removal of carbon dioxide (see also Chap. 22 for a detailed description of the water shift process).

To obtain ultra-pure hydrogen, a PSA [15] system may be used. In this process, the hydrogen, steam, and carbon dioxide are introduced to the system. At high pressure, the gas is passed through an adsorbent bed, and the adsorbent picks up the impurities and allows hydrogen to pass through the bed. In the regeneration process, the pressure is lowered to purge out the impurities. Then the hydrogen is used to rinse the adsorbent and repressurize the vessel. The efficiency of the hydrogen purification system is optimized at an operating pressure that allows use of a catalyst tube in the reformer. There are four other distinct processes by which hydrogen may be produced under the off-gas purification method: PSA, membrane separation, catalytic purification, and cryogenic separation. The cryogenic separation process uses

Fig. 27.6 A typical facility where liquid hydrogen is produced and stored. (Courtesy Air Liquide Canada.)

cryogenic principles to condense and separate the impurities from hydrogen. Impure hydrogen is introduced to the cryogenic system or "cold box." The impurities are condensed out, and pure hydrogen is obtained. Figure 27.6 shows a typical facility where liquid hydrogen is stored and produced. Membrane separation makes use of two layers of membrane material; the first layer is nonporous, and the second layer is porous [17, 19, 20]. A gas mixture under increased pressure is subjected to the surface, which allows a smaller molecule such as hydrogen to permeate faster than a larger molecule such as carbon dioxide.

The catalytic purification process requires the use of many catalysts to convert impurities into removable compounds. Hydrogen, chlorides, oxygen, and carbon oxides are passed through several catalytic reactors. In the first reactor, the chlorides are absorbed. In the second reactor, oxygen and hydrogen react to obtain water/steam, which is easily removed. In the third reactor, the carbon oxides react with hydrogen to yield methane, which would be considered an acceptable impurity in this particular hydrogen product stream. Some other sources of hydrogen are the dissociation of ammonia, steam reforming of light hydrocarbons, and by-product streams of chemical and petroleum processing. The "steam–iron" process is another method used to make hydrogen. Passing steam over heated, spongy iron reduces the steam to hydrogen with additional formation of iron oxide. There are several varieties of this process. The water–gas reaction is a reaction of steam with incandescent coke or coal; it is a source of hydrogen with carbon monoxide as an additional product. In the catalytic version of this reaction, excess steam breaks down to form more hydrogen while oxidizing the carbon monoxide to form carbon dioxide. Hydrogen frequently is obtained as a by-product of cracking operations using petroleum liquids or vapors as feedstock. Also hydrogen may be produced through the electrolysis of water.

Nearly all hydrogen production in the United States today is by steam reformation of natural gas. This, however, releases fossil carbon dioxide in the process and trades one relatively clean fuel for another, with associated energy loss, so does little to meet national energy needs. For high purity needs, a small amount of hydrogen is produced by electrolysis, but this again is only as good as the energy source used to produce the electricity used. Electrolysis can electrochemically split water into hydrogen and oxygen in essentially the reverse of the reaction in a fuel cell. To make sense for large-scale use, this process must use an inexpensive source of electricity. Because wind energy is currently the lowest cost renewable energy, it is the leading candidate. It is also a variable source that would benefit from being able to produce hydrogen when its electricity is not needed and to add fuel-cell generation when electricity demand exceeds what the wind turbines can provide. The combination also benefits because electrolyzers require direct current and wind turbine power is produced as direct current before conversion back to alternating current suitable for the electric grid [4].

In recent years, considerable research and interest has been given to the potential use of hydrogen as a nonpolluting energy source, in particular, the use of hydrogen in chemical fuel cells, in which the gas reacts with the oxygen from ambient air to directly produce an electric current. Although this has an immediate appeal for environmentalists, it remains to be seen whether the total production and use cycle can really achieve a lower environmental impact than the existing energy production methods.

Based on current production methods, which involve steam reforming of natural gas, hydrogen cuts carbon dioxide emissions for each kilometer driven by up to 30% compared with conventional petrol and diesel cars. A study sponsored by a European Union Commission and completed in 2010 shows that the 95% reduction target can be achieved by 2050 with the help of various hydrogen production methods, with an increasing share of renewable sources in the mix.

In its “balanced” scenario, the study assumes that fuel-cell vehicles will account for 25% of all cars on the road by 2050. This requires an investment of around three billion euros in a Europe-wide hydrogen refueling infrastructure by 2020. Expressed as a percentage of the total cost of ownership, this corresponds to a mere 5% [5].

Although the actual use of hydrogen in a fuel cell produces only energy and water as a by-product, it is in the actual production of hydrogen as previously discussed that the environmental effects of carbon dioxide and carbon monoxide releases are realized. With the current ability to use fuel cells with existing fuel sources such as methane and methanol, the pursuit of a purely hydrogen fuel cell may not be the environmental solution that is often implied by its proponents. However, the increased efficiency and use of renewable resources (including solar) to generate hydrogen may overcome this barrier.

It is estimated that the global hydrogen production capacity required to replace the entire current fossil fuel-based energy system would need to be of the order of about 2,500 Tg H_2 yr^{-1} [7]. The United States used about 177 billion gallons of gasoline for transportation in 2009 [8].Using one type of commercial electrolyzer, one can make 0.38 kg of gaseous hydrogen per gallon of water. Conversion of the current US light-duty fleet (some 230 million vehicles) to fuel-cell vehicles would require about 110 billion gallons of water/year to supply the needed hydrogen. For comparison, the United States uses about 300 billion gallons of water/year for the production of gasoline [9], about three times the amount needed for hydrogen. However, that amount is used and recycled, not consumed as it is in the hydrogen production process. Domestic personal water use in the United States is about 4,800 billion gallons/year.

For an estimate of the amount of water needed for hydrogen-powered fuel-cell vehicles, assume a vehicle fuel economy of 60 miles per kg of H_2 (the Honda FCX Clarity gets 72), that vehicle miles traveled $= 2.6 \times 10^{12}$ miles/year, and that you can make 0.38 kg of H_2 from 1 gal of water using Proton Energy System’s H6m Electrolyzer. Total water required for the US fleet = (2.6×10^{12} miles/year)(1 kg of H_2/60 miles)(1 gal H_2O/0.38 kg of H2) $= 1.1 \times 10^{11}$ gal of H_2O/year. This represents the water used directly for fuel. If one considers all water uses along the chain; for example, from construction of wind farms to the electrolysis systems (life cycle assessment), then the total water use would be in the range of 3.3×10^{11} gal H_2O/year.

For a detailed description of the electrolytic process of hydrogen generation, also see Chap. 22. The energy required to produce hydrogen at atmospheric pressure via electrolysis (assuming 1.23 V) is about 32.9 kWh/kg. A kilogram is about 2.2 lb. For 1 mole (2 g) of hydrogen the energy is about 0.066 kWh/mole. Compressing or liquefying the hydrogen would take additional energy. One company produces hydrogen through electrolysis at about 7,000 psi at an energy usage of about 60 kWh/kg Hydrogen.

Because a Watt is Voltage × Current, this is equivalent to Power × Rate × Time. The power in this case is the voltage required to split water into hydrogen and oxygen (1.23 V at 25°C). The rate is the current flow and relates directly to how fast hydrogen is produced. Time, of course, is how long the reaction runs. It turns out that voltage and current flow are interrelated. To run the water splitting reaction at a higher rate (generating more hydrogen in a given time), more voltage must be applied (similar to pushing down on the accelerator of a car; more gas is used to make the car go faster.) For commercial electrolysis systems that operate at about 1 A/cm^2, a voltage of 1.75 is required. This translates into about 46.8 kW-hr/kg, which corresponds to an energy efficiency of 70%.

Lowering the voltage for electrolysis, which will increase the energy efficiency of the process, is an important area for research [11].

The one possible solution to effective renewable energy from water may be in the current research centered around catalytic thermal decomposition of water using solar energy. In this process, first developed by the Solar Hydrogen Energy

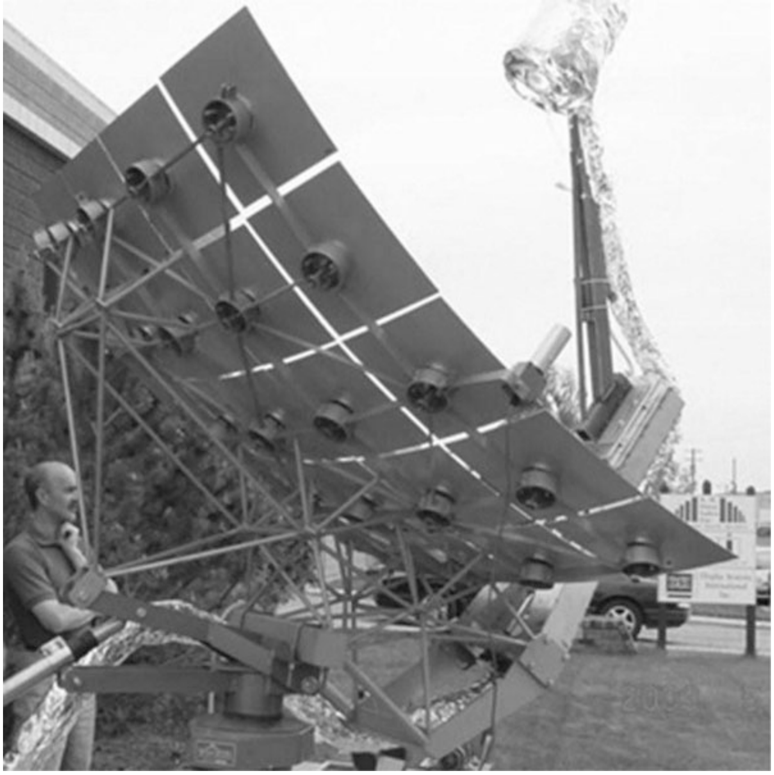

Fig. 27.7 Solar Hydrogen Catalytic Generator—small-scale prototype. (Courtesy of SHEC LABS.)

Corporation (SHEC) in Canada and now pursued in multiple laboratories, including the Global Photonic Energy Corporation in the United States, water is catalytically broken down into hydrogen and oxygen. The unique application of solar energy as the driving force, enhanced by the catalytic system, bypasses the usual thermodynamic barrier of standard electrolysis, which requires more energy (from a fossil fuel source) to generate the hydrogen than the energy that can be obtained from the hydrogen in a fuel cell (Fig. 27.7).

Other options proposed, such as the use of ammonia as a fuel, are still based on the production of hydrogen as the primary feedstock for the alternative fuels [12].

There are many applications for hydrogen. It is used to make fertilizers, as the active ingredient in detergents, and in the manufacture of polyurethanes. It finds application in the production of semiconductor devices, in the process of refining crude oil, in food processing for edible oils and shortening, and as fuel for the space shuttle. The hydrogenation of edible oils in soybeans, fish, cottonseed, and corn produces solids used in shortening and other foods. Many alcohols also are produced by the hydrogenation of the corresponding acids and aldehydes. It is possible to use hydrogen in low concentrations as a physiologically inert gas for a breathing atmosphere where multiple gases are involved. Hydrogen is an important gas in several semiconductor-manufacturing stages. It is used as a protective atmosphere in silicon crystal growth, as a reactant and carrier gas during semiconductor chip manufacturing, and as a reducing atmosphere for sintering and the bonding of leads to the finished chip [1].

The world economy currently consumes about 42 million tons of hydrogen per year. About 60% of this becomes feedstock for ammonia production and subsequent use in fertilizer (ORNL, 2003). Petroleum refining consumes another 23%, chiefly to remove sulfur and to upgrade the heavier fractions into more valuable products. Another 9% is used to manufacture methanol (ORNL, 2003), and the remainder goes for chemical, metallurgical, and space purposes (Holt 2003) [14].

Some recent worldwide hydrogen production totals are shown below [14]:

Origin	Amount in billions (Nm_3/year)	Percent
Natural gas	240	48
Oil	150	30
Coal	90	18
Electrolysis	20	4
Total	500	100

Each year, the United States uses more than nine million tons (about 90 billion normal cubic meters, 3.2 trillion standard cubic feet) of hydrogen, 7.5 million tons of which are consumed at the place of manufacture. The remaining 1.5 million tons are considered to be “merchant” hydrogen, or hydrogen that is sold. Today, most of this hydrogen is used as a chemical, rather than a fuel, in a variety of commercial applications [14]:

- Commercial fixation of nitrogen from the air to produce ammonia for fertilizer (about two-thirds of commercial hydrogen is used for this)
- Hydrogenation of fats and oils, in which vegetable oils are changed from liquids to solids; shortening is an example of a hydrogenated oil
- Methanol production, in hydrodealkylation, hydrocracking, and hydrodesulphurization
- Welding
- Hydrochloric acid production
- Metallic ore reduction
- Cryogenics and the study of superconductivity (liquid hydrogen)
- Preventing oxidation in the manufacturing of semiconductors
- Cooling turbines (hydrogen transfers heat very well)
- Hydrogen's main use as a fuel is in the space program. Today hydrogen fuels both the main engine of the Space Shuttle and the onboard fuel cells that provide the Shuttle's electric power.

Merchant hydrogen will remain the largest and fastest growing product in the US refinery chemical market. Advances will be driven by tightening sulfur standards for diesel fuels. Such environmental regulations promote the use of hydrotreating as a means of removing sulfur and other contaminants. As of 2010, diesel fuel must meet a 15 part-per-million (ppm) sulfur limit, and going forward, significant sulfur reductions are also expected for heating oil. Hydrocracking represents another growth application for merchant hydrogen, as US refineries continue to expand their hydrocracking capacity in efforts to boost gasoline and diesel fuel yields [16].

In the metals industry, hydrogen is used for applications such as annealing metals. It is also used as a fuel in underwater oxy-hydrogen torches and with oxy-hydrogen welding and cutting systems. Hydrogen serves as a nonoxidizing shield alone or with other gases in furnace brazing and in welding aluminum, magnesium, and lead. The temperature in the oxy-hydrogen flames is about 4,000°F, which is suitable for low-temperature welding and brazing. Oxy-hydrogen flames are used in the fabrication of quartz and glass, and hydrogen is used as a protective atmosphere in the float glass process whereby molten glass is floated on a pool of liquid tin. Atomic hydrogen welding is suitable for very thin stock and can be used with virtually all nonferrous alloys. In the process, an arc with a temperature of about 11,000°F is maintained between two nonconsumable metal electrodes. Molecular hydrogen fed into the arc is transformed into atomic hydrogen, which sends heat from the arc to the weld zone. At the surface of the welding area the atomic hydrogen recombines with molecular hydrogen, with the release of heat.

Liquid hydrogen is very important as a fuel for powering missiles and rockets. It is used in laboratory research on the properties of some materials at cryogenic temperatures, work often associated with studies of superconductivity. Liquid hydrogen can be used as a fuel, for either propulsion or heating.

Hydrogen gas is shipped in high-pressure gas cylinders and high-pressure cylinder trailers. Liquid hydrogen is shipped in insulated portable containers and in cryogenic tankers. The normal liquid hydrogen supply system utilizes a cryogenic stationary storage tank rated at 150 psig, just below the critical pressure of hydrogen. A cryogenic pumping station, which has a liquid hydrogen storage tank, a high-pressure cryogenic pump capable of supplying liquid hydrogen at 3,000 psig, and high-pressure gas storage tubes, often is used to supply large quantities at pressure above 150 psig.

Helium

Helium was discovered during a solar eclipse as an orange line in the spectrum of the sun's atmosphere. Physically, helium is colorless, odorless, and tasteless; and it is the second lightest element, second only to hydrogen. Helium is chemically inert and has only a 5 ppm concentration in the atmosphere (0.0005%).

Small amounts of helium are extracted from the atmosphere by fractionation methods, but not commercially because of the small amount of helium in the atmosphere. A number of natural gas wells contain helium, which can be recovered by a liquefaction and stripping process. Natural gas containing at least 0.2% helium has been found in the American Southwest, where the natural gas fields are the major US source of helium. Those helium-rich fields are within 250 miles of Amarillo, Texas; other helium-bearing fields have been found in Saskatchewan, Canada, and in areas near the Black Sea.

Helium cannot be synthesized; so conservation and cleanup recycle systems for "spent" gas are important means of preserving the earth's helium resources. One of helium's first uses was as a nonflammable replacement for hydrogen for inflation of lighter-than-air aircraft. Today liquid helium is vitally important in cryogenic research, as it is the only known substance to remain fluid at temperatures near absolute zero. It has a unique use as a refrigerant in cryogenics and is the only nuclear reactor coolant that does not become radioactive. Liquid helium is used extensively with superconducting magnets; in the medical field, it is used to cool the superconducting magnets for magnetic resonance imaging (MRI). It is used to purge and pressurize NASA vehicle liquid hydrogen tanks because it is the only gas that remains a vapor at liquid hydrogen temperatures.

Helium has a variety of other uses in welding and lighting. It is used as an inert gas shield in arc welding, for filling cold weather fluorescent lamps, and to trace leaks in refrigeration and other closed systems. Also helium is used for specialized purging and pressurizing applications. Helium can be used in place of or together with nitrogen as the inert portion of the atmosphere in sealed environments such as space vehicles, deep-sea submergence vehicles, and diving suits. The use of helium shield gas in a plasma arc furnace is a popular method for melting precious metal ores and scrap. Helium is very important for use in lasers and fiber-optic production, as well as in the production of germanium and silicon crystals for semiconductors.

Gaseous helium is stored and transported in high-pressure gas cylinders, high-pressure gas trailers, and portable cylinder modules. Liquid helium is transported in liquid cylinders, portable tanks, and cryogenic tankers. Because of the extremely low temperature of liquid helium and the cost of producing it, special design considerations must be given to storage containers in order to maintain the helium in the liquid phase. Some containers are designed to include a sacrificial liquid nitrogen shield that intercepts heat before it is transferred into the liquid helium.

Carbon Dioxide

The carbon dioxide market in the United States is served by gaseous, liquid, and solid carbon dioxide. The consumption of carbon dioxide gas is approximately 25 million tons per year with the enhanced oil recovery and urea production markets being the primary consumers. Liquid and solid consumption is about 7.5 million tons per year, serving primarily the food and beverage processing industries [21]. Carbon dioxide is used extensively in a variety of areas. It is used for pressurizing, and as a source of the bubbles and the acidic taste in soft drinks. Carbon dioxide is used to fill a type of fire extinguisher that literally depends on the inertness of the compound. Carbon dioxide is also used in freezing specialty and quality foods. Supercritical carbon dioxide (a dense, high pressure, single-phase form) is finding many new applications in pharmaceutical processing, plastics recycling, dry cleaning, flavor and fragrance extractions, and other solvent-based processes [1].

More specifically, each physical phase of carbon dioxide has uses in many areas. Gaseous carbon dioxide is used for pH control in water treatment and as a growth stimulant for plant life. It has been used successfully as a grain storage fumigant against pests and as a wide area mosquito lure to enhance chemical spraying effectiveness. Alone and in combination with other gases, carbon dioxide in food packaging extends the freshness and shelf-life of many products. It is second only to argon as a welding shield gas, and is used for flammable tank purging and inert blanketing of reactive liquids. Liquid carbon dioxide has multiple applications as a rapid, controllable refrigerant. It is used in one case as an expendable refrigerant for low-temperature testing of aviation, missiles, and electronic components. Carbon dioxide is also used in controlling chemical reactions and for stimulation of oil and gas wells. It is used extensively in food chilling and freezing applications, both in processing and in transportation.

Solid carbon dioxide, commonly called “dry ice,” is used extensively as a refrigerant for dairy products, meat products, and other frozen foods while in transit. It is also used as a cooling agent in many industrial processes such as grinding heat-sensitive materials, cold-treating metals, shrink-fitting machinery parts, in vacuum cold traps, in cryo-surgery, and specimen preservation and storage. It is used as a residue-free abrasive cleaner for many industrial equipment cleaning applications through the use of special air-driven particle blasting machines.

Carbon dioxide is usually nonreactive and nontoxic. At normal atmospheric pressure and temperature, it is colorless and odorless. Carbon dioxide will not burn, nor will it support combustion. Unrefined carbon dioxide gas is typically obtained from the combustion reaction of coal, coke, natural gas, and other carboniferous fuels. Other major sources are ethanol fermentation plants and the development of landfill gases as renewable sources.

The gas obtained is liquefied and purified by several different processes to a purity of about 99.99%. The major source of carbon dioxide is as a by-product of steam–methane reforming. The resulting reformer syngas may utilize one of the following three processes in the production of carbon dioxide. Recovery of pure carbon dioxide from reformer syngas has most often been accomplished through absorption by liquid solvents. The solvents used are monoethanolamine (MEA), diethanolamine (DEA), and methyl diethanolamine (MDEA).

A hot potassium carbonate solution may also be used in some applications (see Fig. 27.8 for the process flow diagram). In this process, the syngas stream from the reformer is sent to the stripper column where the carbon dioxide is absorbed by the solvent. The residual gas stream components are discharged from the stripper column. The carbon dioxide in solvent is sent to the regeneration column where the carbon dioxide is regenerated and discharged for further purification by compression dehydration and

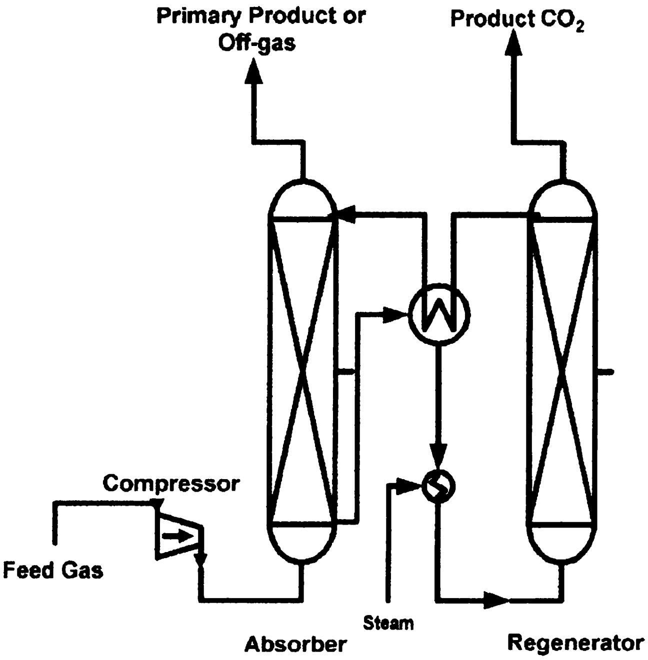

Fig. 27.8 CO_2 recovery by solvent adsorption process. (Courtesy Process Systems Consulting, Inc.)

refrigeration steps. The solvent is returned to the stripper column. The final product is essentially 99.99% pure.

Carbon dioxide may be manufactured at 95% purity by the membrane separation process from a similar gas or from natural gas [18, 19, 22]. In the recovery of high-purity carbon dioxide from the syngas or natural gas, and before any separations can occur, a pretreatment step removes any contaminants and any condensate liquids that may be present. The feed gas then enters the membrane system at 300–1,000 psig. The permeate gas is delivered at pressures between 50 and 150 psig and at a carbon dioxide purity of about 95%. The high-pressure residual gas containing 10–30% carbon dioxide enters a conventional treatment process such as MEA or DEA for a final cleanup. The carbon dioxide off-gas from the conventional treatment process is then elevated to the same pressure as that of the permeate gas from the membrane systems.

The combined streams may be further compressed to higher pressures, such as 2,000 psig for applications in carbon dioxide flooding in enhanced oil recovery. The third process used in the production of carbon dioxide is PSA. The feed gas usually contains approximately 20% carbon dioxide, 70% hydrogen, and the remainder methane, carbon monoxide, nitrogen, and water. The feed gas is typically under a pressure of 125–400 psig at temperatures of 80–120°F. The carbon dioxide and water are strongly adsorbed in the adsorb beds and the residual gas stream is depressurized for further recovery. The adsorber vessel is then evacuated through vacuum blowers where the carbon dioxide, which has been adsorbed by the bed, is released at purities of essentially 99%.

Carbon dioxide produced from ethanol fermentation plants or landfill gas may be recovered with similar processes. Unique to the fermentation plant is the ability to recover the carbon dioxide directly from the ethanol distillation tower, followed by a secondary water wash. Final purification and liquefaction stages then follow the normal process flow. Landfill gas recovery is unique in requiring essentially the removal of the methane and trace impurities [10, 23]. Several processes exist to provide two gas products (via membrane separation), a liquid methane and gaseous carbon dioxide stream (via the CryoFuel® system), or a gaseous methane and liquid carbon dioxide stream (via the Acrion® process). The Acrion® system is unique in that it uses the carbon dioxide as part of the purification process instead of relying on additional chemical treatments. Figure 27.9 shows the process flow diagram for the Acrion® system. Liquid carbon dioxide is normally stored in a foam-insulated tank that has a refrigeration unit to maintain the tank temperature and pressure.

Liquefied Natural Gas

(For Methane, or Compressed Natural Gas, See Chap. 20, Methane)

The primary advantage of LNG over gaseous natural gas is the cost and space savings due to the tremendous change in the product volume. Over 600 standard cubic feet of natural gas occupy only 1 ft^3 of space in its liquid form at −260°F and atmospheric pressure. This significant volume reduction reduces the storage and transport volume, and allows shipment of natural gas in areas where pipelines were never feasible.

The primary vehicle for transporting LNG is the cryogenic tanker. It also is transported in specially designed ships. LNG comes primarily from natural underground reservoirs. Significant quantities are now being recovered from both landfill sources and bioreactor sources around the world. LNG is composed predominantly of methane, which may contain minor quantities of ethane, propane, nitrogen, helium, and other components normally found in natural gas.

In the past the liquefaction of natural gas used a classic cascade cycle. The process required 120,000 hp for liquefaction of over 150 million standard cubic feet (mmscf) per day. Provisions are made for some of these cycles to use seawater for cooling. Later, baseload LNG plants utilized mixed refrigerant cycles, such as Air Products and Chemicals, Inc.'s propane precooled mixed refrigerant system. Baseload plant capacities range from about 70 mmscf/day to about 350 mmscf/day of LNG. Baseload plants move LNG from remote sites by ship to populated

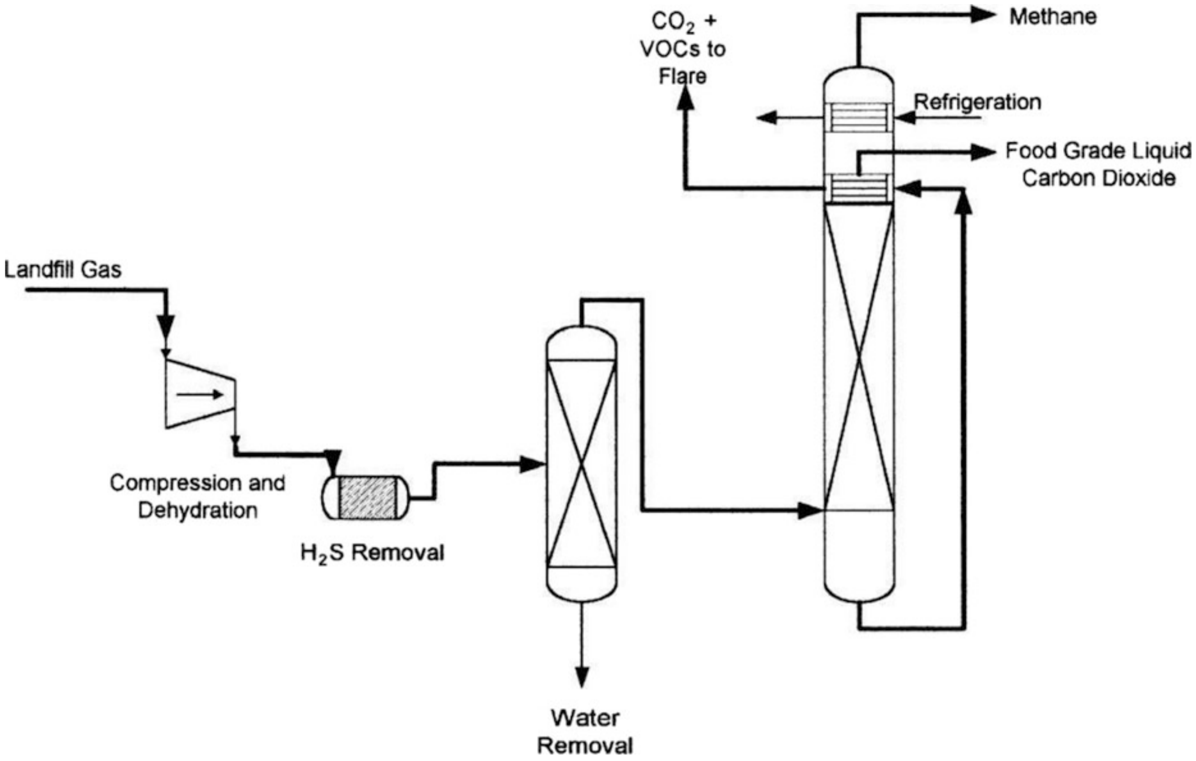

Fig. 27.9 Acrion CO_2 wash process flow diagram. (Courtesy Acrion Technologies, Inc.)

areas. For example, Indonesia and the United Arab Emirates supply LNG to Japan for electric power generation [10].

At baseload LNG production plants, natural gas enters the plant at near 85°F and 600 psig. The gas is treated to remove carbon dioxide and any sulfur compounds, and it is cooled with high-level propane refrigerant to remove as much water as possible. Dehydration to a dew point of about −100°F is done by carrying out regeneration with dried outlet gas by way of a high-pressure steam heater and a regeneration gas compressor. The dry, treated gas is passed through a stationary bed of activated carbon for removal of mercury, and is cooled with two successively lower levels of propane refrigeration. A scrub column flows to a fractionation train, which consists of a deethanizer, a depropanizer, and a debutanizer where relatively pure ethane and propane are produced. Excess ethane, propane, and butane from the fractionation process are reinjected into the main gas stream just prior to liquefaction. The overhead from the scrub column flows to the main heat exchanger for liquefaction to LNG. Figure 27.10 shows the process flow for an LNG plant [24]. For years LNG has been used for peakshaving purposes, which is the storage of excess capacity of LNG to be revaporized for the coldest days of the year [25]. In recent years LNG has been used in heating and vehicle propulsion. Also LNG is used to produce carbon black, which has applications in the manufacture of rubber products and printing ink. The burning of high-purity LNG (methane) is done to make carbon black for particular use in electronic devices.

Acetylene

Acetylene (C_2H_2) is a colorless and flammable gas. At 100% purity, acetylene is odorless, but at commercial purity it has a garlic-like odor. Acetylene can be liquefied and solidified with ease, although in both cases it explodes with extreme violence when ignited. Acetylene can be inhaled in rather high concentrations without chronic, harmful effects. In fact, it has been used as an anesthetic. However, it is a simple asphyxiant if present in concentrations high enough to deprive the lungs of oxygen and produce suffocation [1].

A primary method for the manufacture of acetylene is to react calcium carbide, the principal raw material, with water to produce acetylene with calcium hydroxide as a by-product:

$$CaC_2 + 2H_2O \rightarrow C_2H_2 + Ca(OH)_2$$

Acetylene also is manufactured by thermal or arc cracking of hydrocarbons and by a process utilizing the partial

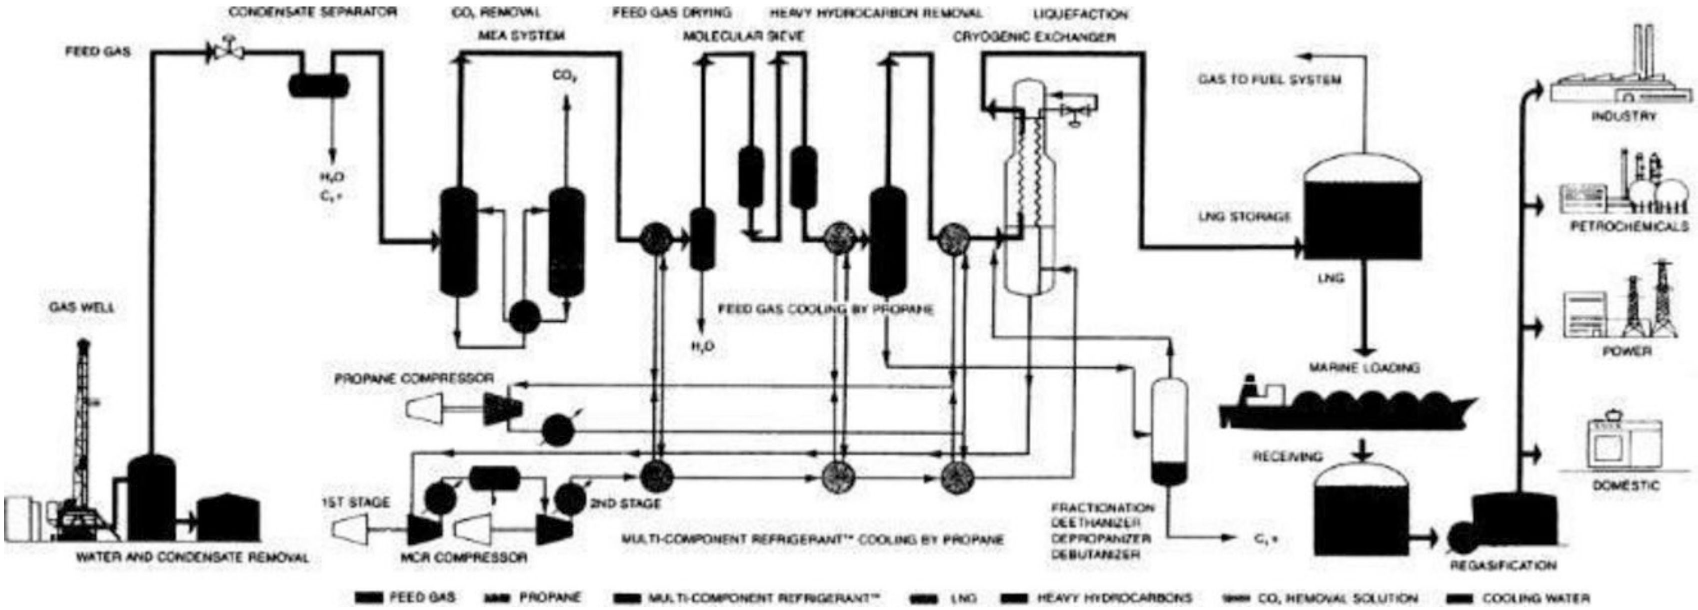

Fig. 27.10 Schematic of process flow for a baseload LNG plant. (Courtesy Air Products and Chemicals, Inc.)

combustion of methane with oxygen. The acetylene produced from calcium carbide is basically pure, with only water and air as impurities. Eighty percent of the acetylene produced is used for chemical synthesis.

Acetylene is an important raw material for a series of organic compounds such as acetaldehyde, acetic acid, acetic anhydride, acetone, and vinyl chloride. Those compounds are used to manufacture a large group of products, including plastics, synthetic rubber, dyestuffs, solvents, and pharmaceuticals, and in the manufacture of carbon black. The other 20% is used for oxy-acetylene welding, cutting, heat treating, lighting purposes, buoys, and beacons [1].

In the primary method for producing acetylene, calcium carbide is fed into a generator containing water. The resulting wet acetylene gas at 120–140°F is piped to a cooler condenser where it is cooled to 80–90°F and the water vapor is condensed. This is the first step in the drying process. The gas then goes to a low-pressure dryer filled with calcium chloride. The calcium chloride absorbs the moisture from the acetylene gas, which then enters a compressor, where the pressure is increased to 200–375 psig. An oil separator filters out excess impurities and oil. The gas next goes to a high-pressure dryer, where all remaining water is removed. The gas is then pumped into cylinders for shipment. The by-product, calcium hydroxide, is sent to a storage tank, where water is decanted off the top, and is recovered.

The only method of distributing acetylene, other than pipeline, is by means of portable steel tanks containing a porous solid filler saturated with acetone or other suitable solvent, in which the acetylene is dissolved under pressure. Acetylene alone is not handled at pressures higher than 30 psig because of its tendency to decompose explosively. Dissolved in acetone it may be stored at pressures of 150–250 psig.

Nitrous Oxide

Nitrous oxide (N_2O), commonly known as laughing gas, is a colorless and virtually odorless, tasteless, nontoxic gas. Nitrous oxide is an oxidizer that will support combustion, but it is a nonflammable gas. It is water-soluble; but when it is dissolved, its acidity does not change. The primary commercial method for producing nitrous oxide is by thermal decomposition of ammonium nitrate, with nitrous oxide and water in the primary reaction:

$$NH_4NO_3 \rightarrow N_2O + 2H_2O$$

The impurities formed are mostly high oxides of nitrogen and are highly toxic. After the water is removed in a condenser, the gas is washed in a solution of potassium dichromate to remove nitric oxide, in caustic to remove nitric acid, and finally in water. Nitrous oxide is an inhalant type of anesthetic or analgesic gas. It serves as a propellant for various aerosol products, particularly with foods such as whipped cream; and it is used as an oxidizing agent in blow-torches, atomic spectroscopy instruments, and in the manufacture of various compounds, both organic and inorganic. It also serves as fuel oxidant in rocket fuel and high-performance vehicles, and it is used as part of the working fluid in hypersonic wind tunnels that have been investigated recently. It has applications in cryosurgery similar to nitrogen [1].

Nitrous oxide is contained and transported in its liquid phase in high-pressure gas cylinders or in liquid cylinders. It is transported as a liquefied compressed gas under high pressure in cylinders and at lower pressures and reduced temperatures in refrigerated cargo tanks and insulated portable tanks. Nitrous oxide is stored in a foam-insulated tank accompanied by a refrigeration unit, which is similar to the tank used for carbon dioxide.

Wood and Wood Products

Yuan-Zong Lai

Introduction

Wood along with the outer portion of tree trunk (bark) [1] (Fig. 28.1) represents the bulk of forest biomass materials and has been utilized by humans since antiquity. Trees provided a source of many products required by early humans such as food, medicine, fuel, and tools. For example, the bark of the willow tree, when chewed, was used as a painkiller in early Greece and was the precursor of the present-day aspirin. The leaf extracts and nuts from Gingo trees have been used in traditional Chinese medicines for thousands of years. Wood served as the primary fuel in the United States until about the turn of the nineteenth century, and even today over one-half of the wood now harvested in the world is used for heating fuel.

Throughout history different types of wood have served many purposes. The tough, strong, and durable white oak, for example, was a well-proven raw material for ships, bridges, cooperage, barn timbers, farm implements, railroad ties, fence posts, flooring, paneling, and other products. In contrast, woods such as black walnut and cherry became primarily cabinet woods. Hickory was manufactured into tough, hard, resilient tool handles. Black locust was used for barn timbers and treenails. What the early artisan learned by trial and error became the basis for intelligent decisions concerning which species was best suited to a given purpose, as well as what characteristics should be looked for in selecting trees for different applications. It was known that wood from trees grown in certain locations was stronger, more durable, and more easily worked with tools than wood from the same species grown in other locations. Modern wood quality research has substantiated that location and growth conditions significantly affect wood properties [2, 3].

In the United States more than 100 kinds of wood [1, 3] are available to the prospective user, but it is very unlikely that all are available in any one locality. About 60 native woods are of major commercial importance. Another 30 wood types are commonly imported in the form of logs, cants, lumber, and veneer for industrial uses, the building trades, and crafts.

The wood from many different species of trees is generally divided into two major categories according to the botanical classification of seed plants. The softwoods are derived from the gymnosperms (naked seeds), generally characterized as cone-bearing trees with persistent needle-like foliage; the hardwoods are from the angiosperms (encased seeds), which are generally the deciduous broad-leaved trees. The majority of the trees in the former classification fall into the division Coniferophyta and thus are often referred to as conifers. However, woods are often designated based on their physical appearance or wood structure (Table 28.1). Thus, softwoods are also called conifers, evergreen, or nonporous wood while hardwood are called broadleaves, deciduous or porous wood.

It is important to note that the terms "hardwood" and "softwood" have no direct relation to the hardness or softness of the wood. In fact, hardwood trees such as cottonwood, aspen, and balsa have softer wood than the western white pines and true firs; and certain softwoods, such as longleaf pine and Douglas fir, produce wood that is much harder than that of basswood or yellow poplar. Although typical softwood has needlelike foliage, there are exceptions. For example, Gingo tree is softwood in wood structure and has the appearance just like a typical deciduous hardwood.

The importance of wood as a raw material supplying fiber, energy, and chemicals is similar in magnitude to its use as a solid material. Lumber, plywood, and reconstituted boards consume about one-half of the timber harvest; usage for fiber, chemicals, and fuels accounts for the remaining half. Fiber production consumes about 25% of the total timber use. Although the relative value of wood as a source

of energy and chemicals has varied considerably through the decades, it has become a major emphasis in recent years to cope with the increasing global demand of energy and the soaring price of fossil fuels. These have stimulated a great deal of interest and developments in the production of biofuels and bioproducts under the umbrella of biorefinery [4, 5]. The many uses for wood are summarized in Fig. 28.2. This chapter discusses the chemical and physical nature of wood, the technology for conversion of wood to pulp fibers for making paper and related products, to wood-based composites, to fuels for energy, and to chemicals for industry and consumers.

Chemical Composition of Wood

Wood is composed of mainly three major polymers (cellulose, hemicelluloses, and lignin) and some extraneous substances called extractives. Table 28.2 lists the variation of these components in softwood and hardwood for five wood species each [6]. The combined polysaccharide components (cellulose plus hemicelluloses) often termed as holocellulose account for about 75% of the wood materials. Major uses of these polysaccharide components have been in the form of fibers for making paper, paperboard, and other fiber products by the paper industry. Recently, the potential utilization of woody polysaccharides as feedstock for conversion to biofuels and chemicals has been examined quite extensively [4, 5].

Higher plants commonly are referred to as lignocellulosic materials because of the typical joint occurrence in them of lignin and cellulose. Lignin being a phenolic polymer is often considered as the gluing or encrusting substance of wood cells and adds mechanical strength or stiffness to the tree and wood. Lignin usually plays a negative role in the chemical utilization of woody materials and must be modified, partially degraded, or completely removed depending on the end uses of the final products. These lignin modification or delignification reactions constitute the commercial pulping and bleaching operations in producing papermaking fibers.

Cellulose

Cellulose is the key component occurring in the cell wall. It is a linear polymer of β (1→ 4)-D-glucan (Fig. 28.3) with a degree of polymerization (DP) of approximately 10,000. Cellulose molecules, because of their unique structure, have a strong tendency to form extensive hydrogen bondings. The molecules could align together in a highly ordered fashion to form a crystalline region, whereas the less ordered molecules being noncrystalline are usually termed amorphous materials.

The cellulose molecules in nature are organized into *elementary fibrils*. Each one has an average width of 3.5 nm and contains about 36 parallel cellulose molecules held together by hydrogen bonding. They are then aggregated into strands called *microfibrils*, which are 5–30 nm in width and contain both the crystalline and amorphous regions. *Microfibrils* are further organized into fibrils and then fibers.

The proportion of the ordered and disordered regions of cellulose (crystallinity) varies considerably with its origin. The crystallinity for wood pulps is about 60% and higher for cotton cellulose (73%). Although the crystalline cellulose contributes to the strength of cellulose polymer, it is a key factor causing the recalcitrance of woody biomass to saccharification for the biofuel production.

Hemicelluloses

Closely associated with cellulose in the wood structure and paper products are the other polysaccharides called hemicelluloses, which consist of both glucose and nonglucose units. They are amorphous and slightly branched polymers.

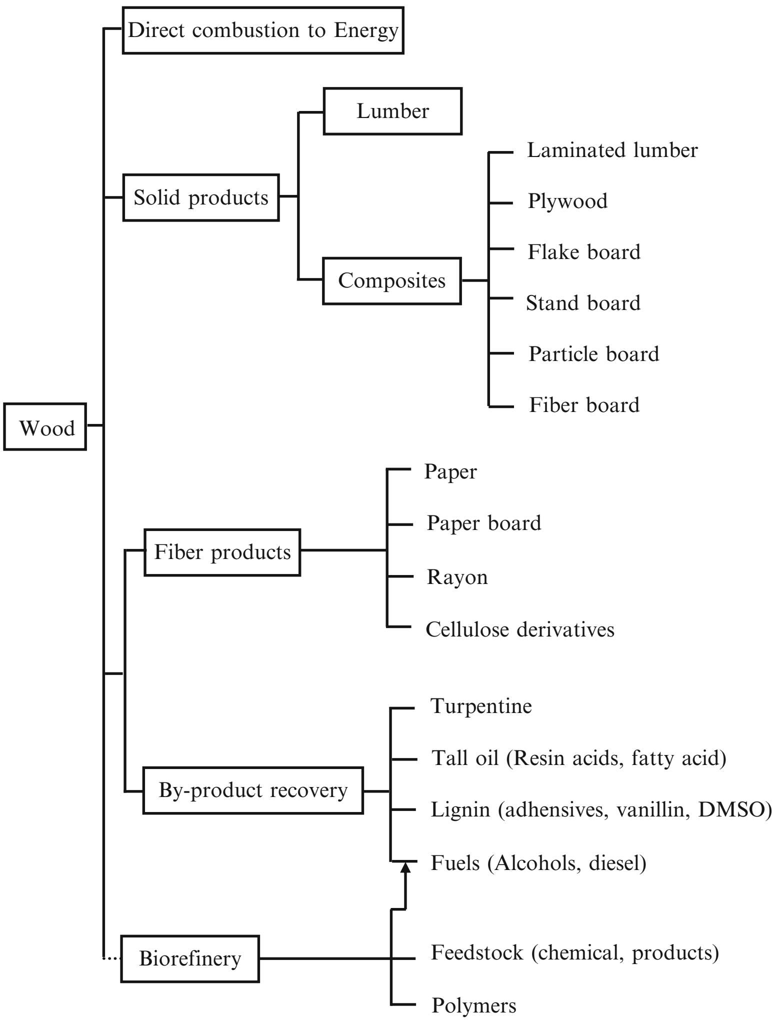

Fig. 28.2 Major uses of wood (DMSO stands for dimethyl sulfoxide)

Table 28.2 Chemical composition of wood [6]

Component	Softwood (%)	Hardwood (%)
Cellulose	42	42
Hemicelluloses		
Xylan	10	20–35
Glucomannan	20	3–4
Lignin	25–35	18–25
Extractives	2–5	2–4

They are often labeled as the matrix material of wood. Of the hemicelluloses, the xylan (polymer of xylose) is dominant in hardwoods, whereas glucomannan is the major type occurring in softwoods (Table 28.2). The DP of hemicelluloses being in the range of 100–200 is much less than that of cellulose.

Xylan. The content of xylan in hardwood (19–35%) is much higher than that of softwood (10–14%). Basically, xylan is a linear polymer of β (1→ 4)-D-xylose containing some 4-O-methyl α-D-glucuronic acid attached to the C_3-position of xylose unit. In hardwood, some of the C_2- or C_3-position of xylose also contains acetyl groups (Fig. 28.4). In case of softwood, the xylan does not contain any acetyl group and instead, some of the C_2-position of xylose units are linked to an α-L-arabinofuranose unit. The presence of these branched units does have an impact in the pulping and bleaching operations.

Glucomannan. Softwood has a significantly higher content of glucomannan (12–18%) than hardwood (3–4%). The structure of glucomannan in hardwood is quite simple being a linear molecule of β (1→ 4)-D-glucose and mannose in a molar ratio of 1:1.5 (Fig. 28.5). In case of softwood, the glucomannan contains some α-D-galactose units linked to the C_2-position of the glucose or mannose unit. Also, some of the glucose or mannose units contain an acetyl group.

Lignin

Lignin is a three-dimensional polymer derived from the enzyme-initiated dehydrogenative polymerization of three

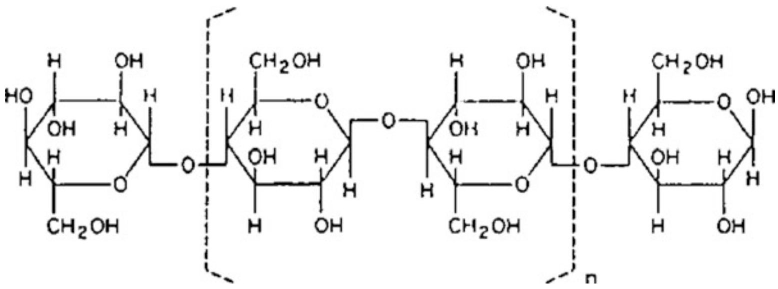

Fig. 28.3 Structure of cellulose

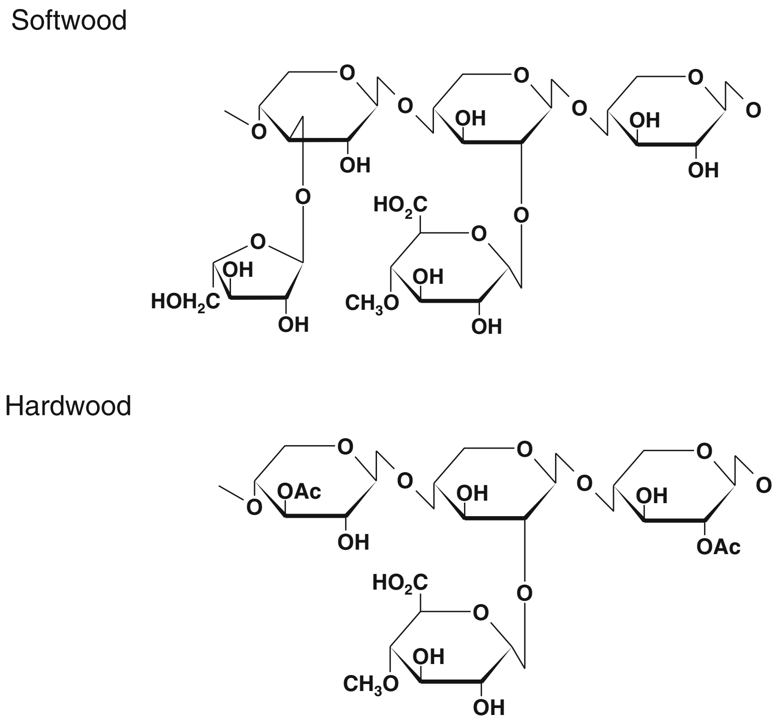

Fig. 28.4 Structure of xylan in wood

major precursors: coniferyl (H), sinapyl (S), and *p*-coumaryl (H) alcohol (Fig. 28.6). Softwood lignin is derived mainly from the G-type precursor (95%) with some H unit (5%) and is generally referred as a guaiacyl (G) type lignin. Whereas hardwood lignin is derived from a mixture of G and S units and its ratio differs considerably among different wood species. The presence of the S-type unit makes the lignin more reactive and renders the hardwood being easier to pulp or degrade. Thus, extensive efforts are continued to breed trees having a high content of the S-type lignin.

Although the approximate contents of major lignin linkages are reasonably well understood now, the chemical structure of lignin, unlike cellulose or hemicelluloses, still cannot be precisely defined. Figure 28.7 illustrates a segment of lignin structure to include all major types of linkages established for softwood. As indicated, lignin contains mainly the linkages of ether and carbon–carbon types. Since carbon–carbon linkages are very resistant to chemical attack, the degradation or fragmentation of lignin is largely limited to the cleavages of ether units at the α- and β-positions. This is the reason that the commercial pulping process generally requires drastic conditions for the lignin removal (delignification reaction) being practiced in the paper industry.

Extractives

Wood contains a variety of minor components that can be extracted by neutral solvents like organic solvents or water. Those soluble in organic solvents are generally classified into wood resins (terpenes, resin acids), fats, unsaponifiable (steroids), and phenolic components (lignan, stilbenes, and tropolones). Those water-soluble extractives include pectin, starch, and polyphenols such as tannins. A specific example for most of these extractives is shown in Fig. 28.8. Although extractives are present in small quantity, they play a significant role in determining the utilization for a number of wood species.

Wood Structure

The tree trunk is consisted of mainly wood (xylem) with bark (phloem) around (Fig. 28.1). Cambium, an active tissue lies between the xylem and phloem, is responsible for tree growth by adding new tissues inward (sapwood) and outward (inner bark). Unlike the sapwood that is continued to accumulate annual growth, the outer bark would often rupture and be placed by the inner bark as the trunk gets bigger.

The physical nature of new tissues generated depends on the growing conditions like seasonal weather. The alternate dark and light bands showing on the cross-section of a softwood tree (Fig. 28.1) reflect the variation of seasonal growth. This pattern constitutes the so-called annual ring. The lighter band corresponds to the growth from the early growing season (springwood or early wood). The darker band termed summerwood or latewood is derived from the later season.

Wood Cells

Wood is the aggregate of countless elongated cells [1]. The bulk of vascular tissues in softwood (90–95%) are in the form of fiber tracheids (Fig. 28.9e). These fibers provide the function of liquid conduction and physical strength for the tree. The remaining wood tissue (5–10%) is consisted of *parenchyma* cells.

One of the functions for parenchyma cells is to convert sugars into storage starch to serve as food reserves for the

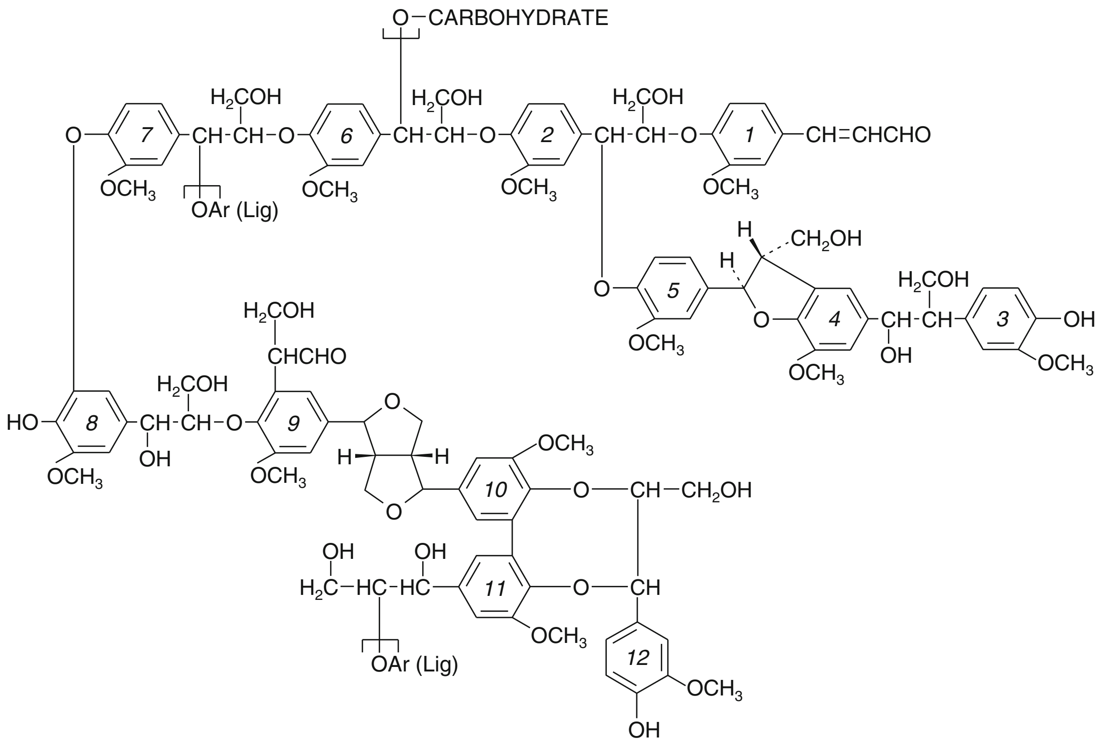

Fig. 28.7 Major types of linkages occurred in softwood lignin

tree and to reconvert starch to sugars when they are needed for growth. The starch and sugar content of sapwood is one reason why most wood-damaging organisms prefer dead sapwood over heartwood, and why sapwood is never quite as durable as heartwood, except in living trees whose sapwood cells fight for the attacking organisms.

Hardwood trees evolved after the softwood and have specialized water conduction cells called vessels (Fig. 28.9a–c). Each vessel consists of numerous drum shaped vessel members with open ends, stacked one above the other to form a continuous vessel pipeline from root tips to the leaves. The physical support for hardwood trees is provided by the libriform fiber, which along with the vessel element is much shorter than the fiber tracheids present in softwood wood (Table 28.3 and Fig. 28.9). The vessels in oaks and some other broad-leaved trees are large enough to be seen with the unaided eye.

Distinct differences between the earlywood (springwood) and latewood (summerwood) are further reflected from the scanning electron micrographs. For red pine (Fig. 28.10a) and white pine (Fig. 28.10b), the wood cell of earlywood is significantly larger in size with a thinner wall as compared to that of latewood. The transition was quite abrupt in case of red pine (Fig. 28.10a) while a gradual change was found in white pine (Fig. 28.10b).

Figure 28.11 is the photomicrography of hardwood cross-sections showing the distinct feature of vessels. For black ash as in oak, the vessels in the earlywood are much wider than those in latewood (Fig. 28.11a). These trees form the distinct growth rings and are generally referred as the ring-porous woods. In case of yellow birch, the vessels are essentially the same size throughout the growth ring (Fig. 28.11c) and these are called the diffuse-porous wood. Also, between these two extremes, a semi-ring-porous pattern was observed for wood like persimmon (Fig. 28.11b). Since coniferous woods lack vessels, they often are referred as the nonporous wood.

The proportion of different wood cells [7] varies considerably among hardwood species (Table 28.3). For example, the proportion of vessel could range from 12% for black ash to 55% for sweetgum. Whereas, the percent fiber content by volume could range from 30% in sweetgum to 70% in black ash wood. Thus, the quality and utilization of hardwood vary considerably with wood species.

Virtually all cavities of wood cells are interconnected, as mentioned earlier for the vessel members of hardwoods. Tiny openings in the cell walls of overlapping ends of tracheids provide vertical passageways for water rising from cell to cell in conifers. Thin walls of ray cells are perforated for the radial transport of sugars, and tangential connections provide for growing cells. Hence, wood is permeable in all three of its cardinal directions. The longitudinal orientation of most cells, however, causes liquids and gases to flow and diffuse many times faster in the longitudinal or fiber direction than in the two transverse directions.

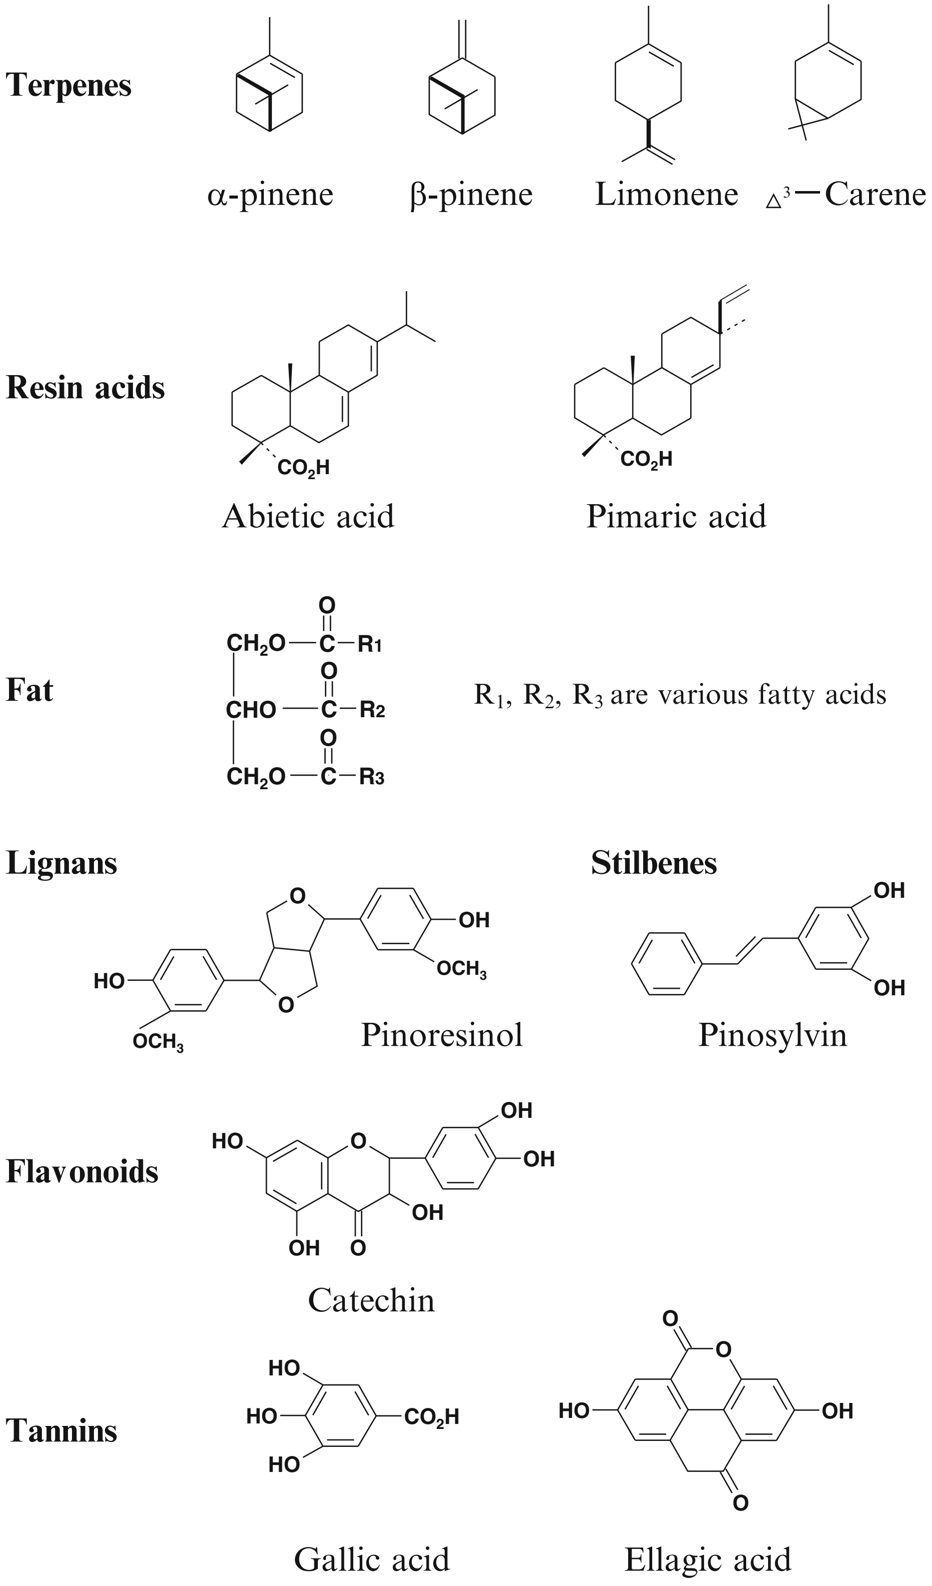

Fig. 28.8 Examples of some wood extractives

This explains why stacked firewood dries predominantly at the exposed ends. The radial orientation of rays allows liquids and gases to move radially up to twice as rapidly as tangentially [8].

As a porous material, wood contains air-filled or water-filled cell cavities surrounded by cell walls. The cell wall substance is remarkably uniform; it differs very little even between conifers and broad-leaves trees and has a constant

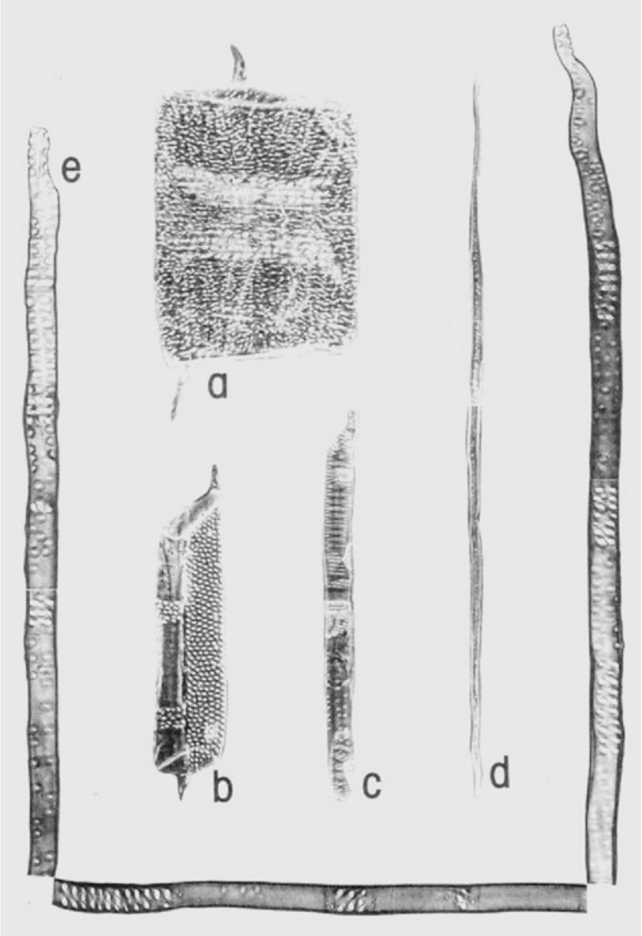

Fig. 28.9 Photomicrographs of major hardwood and softwood cell types illustrating the comparative size and shape of various elements [1]. Note especially how much longer the softwood tracheid (**e**) is than the vessel segments (**a**–**c**). Also shown is the libriform fiber (**d**) from hardwood. To give an indication of scale, the softwood tracheid is approximately 3.5 mm in length (from Core et al. [1], Copyright © 1976, with permission of the copyright owner)

Table 28.3 Proportion and length of wood cells[a]

Length (mm)	–	0.2–1.1
Rays		
Proportion (%)	5–10	6–20

[a] Taken from the range for 12 softwood and 13 hardwood species [7]

density of around 1.5 g/cm^3. The density of wood thus depends on the proportion of the cell wall volume to the volume of the bulk wood.

Wood density is *the* indicator of nearly all wood properties and of wood quality. Relatively dense species are strong, as one might expect from their large cell wall mass. Wood species also vary in features not related to density, such as color, percentage and arrangement of cell types, and minor chemical constituents. Therefore, even woods of the same density are likely to differ, with the properties varying more than the densities.

The widespread use of wood is due to its many advantages, including its very high strength-to-mass ratio, good toughness, low cost and availability, workability, attractive appearance, and good thermal and electrical insulating properties. However, there also are a number of disadvantages of wood, which have limited its usage for many applications; these include its lack of plasticity and fusibility, shrinkage and swelling properties, deterioration due to fungi and insects, and variability. Fortunately, most of its negative properties can be corrected by proper treatment and modification, as described later in this chapter.

Cell Wall Composite

Wood cells or fibers are joined together by an intercellular layer or so-called middle lamella (ML) being very rich in lignin content (Fig. 28.12). This is the general contention that lignin functions as a natural adhesive to glue the cells (fibers) together. Each cell wall consists of an outer primary wall (P) and a secondary wall (S). The S wall is comprised of three sublayers: outer (S1), middle (S2), and inner (S3) layers. Inside the S3 layer, there is a rough or warty surface, generally termed as warty (W) layer.

One of the interesting features in this cell wall structure is the orientation of microfibrils (aggregates of cellulose molecules), which vary among different layers. As indicated, the microfibril orientation is random in the P wall, almost perpendicular to the long axis of the cell in both S1 and S3 layer, and approximately parallel to the cell axis in the S2 layer. Thus, each cell structure may be considered as a mini cellulose-reinforced composite with the hemicelluloses and lignin being functioned as fillers.

The cellulose polymers in nature, as mentioned earlier, are laid down uniformly with chains paralleling each other. The long-chain molecules associated strongly through extensive hydrogen bondings to form so-called microfibrils. The microfibrils contain regions with perfect cellulose chain alignments known as micelles or microcrystallites (Fig. 28.13).

However, the structure of the microfibrils is not completely uniform in terms of the alignment of the cellulose macromolecules. The regions of nonuniformity between the micelles in the microfibrils are called amorphous regions.

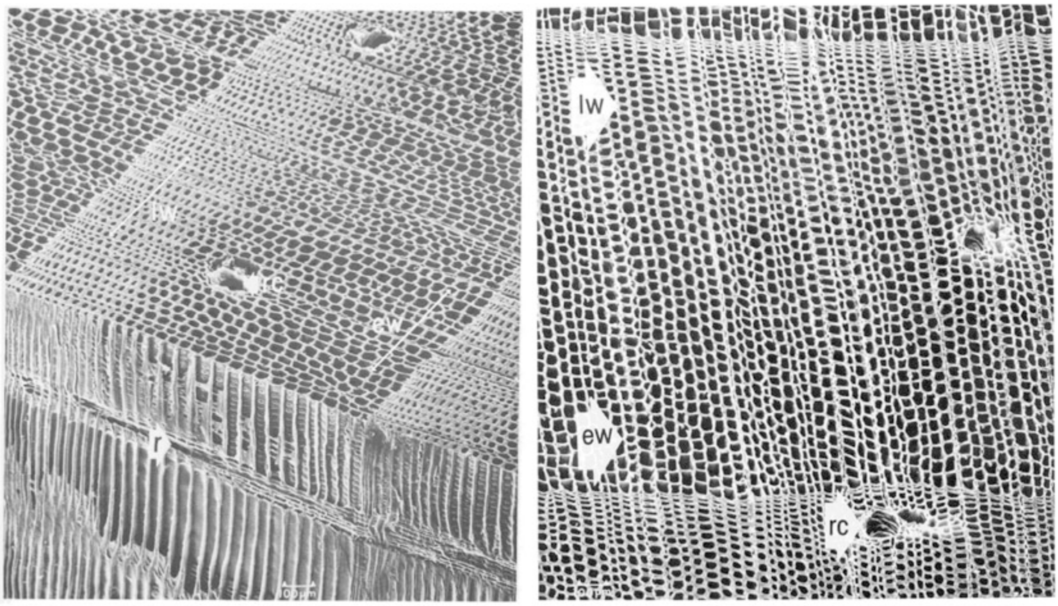

Fig. 28.10 (**a**) The scanning electron micrograph of red pine showing abrupt change in tracheid size from earlywood (ew) to latewood (lw) (from Core et al. [1], Copyright © 1976, with permission of the copyright owner). (**b**) The scanning electron micrograph of eastern white pine showing a gradual change in tracheid size from earlywood (ew) to latewood (lw) (from Core et al. [1], Copyright © 1976, with permission of the copyright owner)

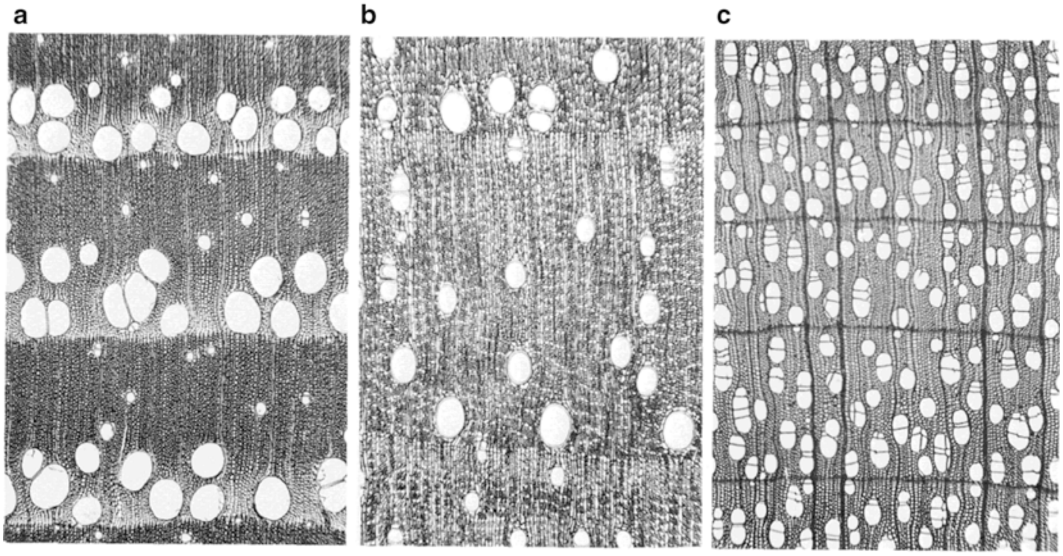

Fig. 28.11 Examples of hardwood groupings based on the pore size changes across the growth increment: (**a**) ring-porous (black ash); (**b**) semi-ring-porous (persimmon); (**c**) diffuse-porous (yellow birch) (from Core et al. [1], Copyright © 1976, with permission of the copyright owner)

Thus, the cellulose microfibril has a crystalline–amorphous character. Water molecules enter the amorphous regions and swell the microfibrils; ultimately this is the mechanism by which fibers and wood swell in moist or wet environments.

The final fiber cell wall structure is essentially layers of the microfibrils or macrofibrils aligned in several different directions, as shown in Fig. 28.12. The microfibrils that make up the wood fiber are visible under the scanning electron microscope, which has a greater magnification than the light microscope.

The entity holding the fibers together, the middle lamella, is almost entirely lignin (90%), as mentioned earlier. For the

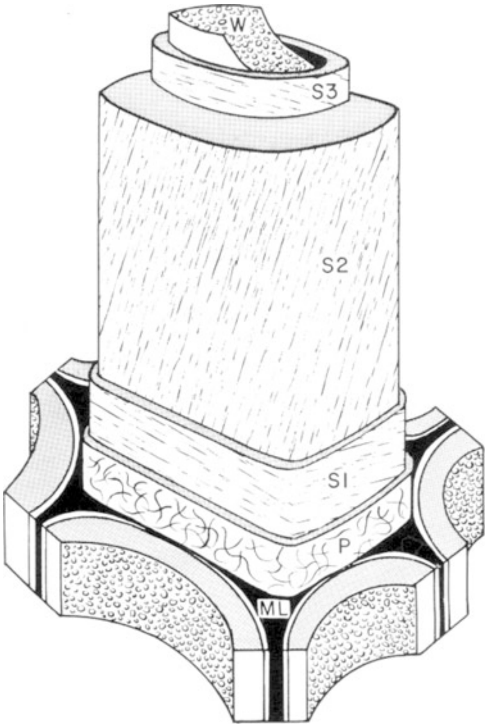

Fig. 28.12 A simplified cell wall structure showing the middle lamella (P), the primary wall (P); the outer (S1), middle (S2), and inner (S1) layers of the secondary wall; and the warty (W) layer (from Core et al. [1], Copyright © 1976, with permission of the copyright owner)

cellulose fibers to be separated, the middle lamella lignin must be chemically removed, a process that also removes most of the hemicelluloses, or must be mechanically degraded to free the fibers for papermaking. A paper sheet then can be formed from the separated cellulose fibers by depositing them from a water slurry onto a wire screen. The water drains away and the fibers collapse, leaving a fiber mat that derives its main strength from reassociation of the fibers through many hydrogen bondings—the same type of bondings that gives mechanical integrity to the fibers [9].

The long fibers from softwoods (Table 28.3) usually are preferred in papermaking for products that must resist tearing, such as grocery bags, whereas the shorter hardwood fibers give improved opacity, or covering power, and printability to the final paper sheet. The type of pulping process also affects the pulp properties, as described in a later section.

Pulp and Paper

The concept of making paper from the fibers derived from lignocellulosic materials—an integrated system of fiber separation (pulping) and re-forming of the fibers into a mat (papermaking)—is attributed to T'sai Lun, a court official in southeast China in AD 105. The first fibers were obtained from old hemp rags and ramie fishnets, but shortly thereafter, the inner bark fibers from paper mulberry trees also were utilized for papermaking. Bamboo was used as a source of fiber several centuries later. The rags were macerated into a pulp in water with a mortar and pestle; then, after dilution in a vat, the pulp was formed into a wet mat on a bamboo frame equipped with a cloth screen to drain the free water. The mat was dried in the sun. The invention was based on the need for a writing material to replace the expensive silk and inconvenient bamboo strips. The invention was a closely guarded secret for many centuries but eventually filtered west, reaching Europe in 1151 and the United States (Pennsylvania) in 1690 [9].

The importance of the pulp and paper industry to the American economy is exemplified by the growth rate in the use of paper and paper products. New uses continually are being found for paper, and these developments together with a rising standard of living have resulted in a constant increase in the per capita consumption of paper. The industry has shown constant growth since about the middle of the nineteenth century, when processes were invented for the production of fiber from wood, replacing reliance on cotton rags as a source of fiber (Fig. 28.14). The relative paper consumption by grade is shown in Fig. 28.15, and differences in the economies of developed and less developed countries are demonstrated in Fig. 28.16 by the wide disparity in per capita consumption of paper and paperboard.

In 2003, a total of 328 million metric tons of paper and paperboard was produced in hundreds of separate mills. This paper and board was made from 170 million metric tons of pulp, produced primarily from wood in over 200 pulp mills, supplemented by recycled paper [10].

The five leading states for the fine paper production are Wisconsin, Maine, Washington, Alabama, and Louisiana. Only a small amount of paper is made from rags or other fiber sources (agricultural residues); so most wood pulp is produced from those areas of the country that are heavily forested. With the exception of Maine and Wisconsin, pulp production is concentrated in the southern and northwestern sections of the United States. Georgia and Washington are the top pulp-producing states. Although a high percentage of pulp is converted into paper or board at the same plant site, a significant portion (classified as "market pulp") is sold in bales to mills in other sections of the country for subsequent manufacture into paper. Thus, New York and Michigan are relatively important in papermaking, but they rank quite low as pulp producers. However, both New York and Michigan are large users of waste paper that is reprocessed into usable fiber.

Raw materials for the pulp and paper industry can be classified as fibrous and nonfibrous. Wood accounts for over 95% of the fibrous raw material (other than waste paper) in the United States. Cotton and linen rags, cotton

linters, cereal straws, esparto, hemp, jute, flax, bagasse, and bamboo also are used and in some countries are the major source of papermaking fibers.

Wood is converted into pulp by mechanical, chemical, or semichemical processes. Sulfite and kraft (sulfate) are the common chemical processes, and neutral sulfite is the principal semichemical process (neutral sulfite semichemical [NSSC]). Coniferous wood species (softwoods) are the most desirable, but the deciduous, broad-leaved species (hardwoods) have gained rapidly in their usage and constitute about 25% of pulpwood.

Table 28.4 summarizes the conditions utilized with the various pulping processes, and Fig. 28.17 shows the relative production of pulp by the major processes [9].

These various mechanical and chemical pulps vary considerably in the papermaking property and have different applications. In terms of the tensile-tear property [11] (Fig. 28.18), the SBK (semibleached kraft) is the strongest follower by UBS (unbleached sulfite), chemithermomechanical pulp (CTMP), thermomechanical pulp (TMP), refiner mechanical pulping (RMP), and GWD mechanical pulps. In contrast, the trend is reversed with respect to the tensile and light-scattering coefficient [11] (Fig. 28.19). Thus, kraft pulp makes a stronger paper while the GWD is very suitable for newsprint application.

Nonfibrous raw materials include the chemicals used for the preparation of pulping liquors and bleaching solutions and the various additions to the fiber during the papermaking process. For pulping and bleaching, these raw materials include sulfur, lime, limestone, caustic soda, salt cake, soda ash, hydrogen peroxide, chlorine, sodium chlorate, and magnesium hydroxide. For papermaking, they include

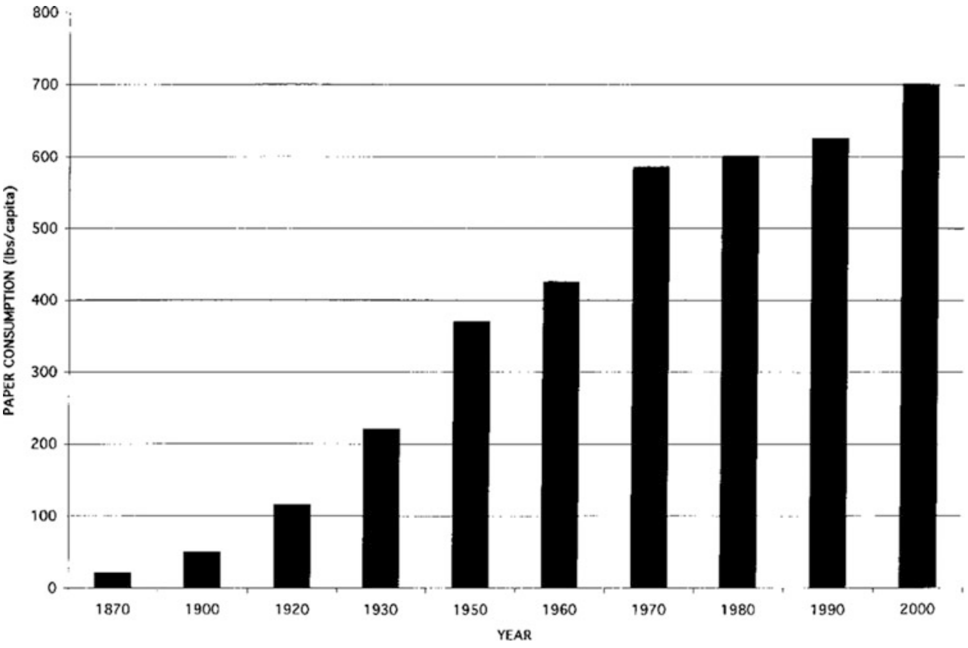

Fig. 28.14 Consumption of paper in the United States since 1860

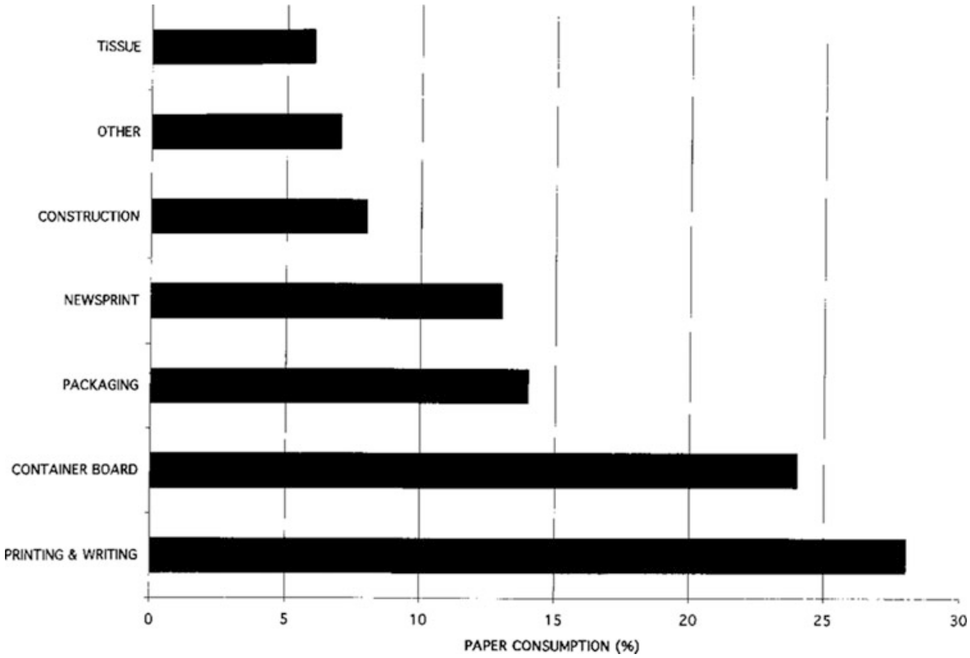

Fig. 28.15 Relative consumption of paper by grade

rosin, starch, alum, kaolin clay, titanium dioxide, dyestuffs, and numerous other specialty chemicals.

Wood Preparation

The bark of trees contains relatively little fiber and much strongly colored nonfibrous material; what fiber there is, is of poor quality. The nonfibrous material usually will appear as dark-colored dirt specks in the finished paper. Therefore, for all but low-grade pulps, bark should be removed as thoroughly as possible, and this removal must be very thorough in the case of groundwood and sulfite pulps if the finished paper is to appear clean.

Debarking usually is done in a drum barker, where the bark is removed by the rubbing action of logs against each other in a large rotating drum. Hydraulic barkers using high-pressure water jets are excellent for large logs and are common on the West Coast. Mechanical knife barkers are becoming more common and are used extensively in smaller

operations because of their relatively low capital cost. Also they have found widespread use in sawmills to debark logs prior to sawing so that the wood wastes can be used to produce pulp.

Wood cut in the spring of the year during the active growing season is very easy to peel. Much of the spruce and fir cut in the North is still hand-peeled during this season and usually represents the optimum in bark removal.

The standard log length used in the Northeast is 48 in., whereas 63 in. is common in the South. Wood generally is measured by log volume, a standard cord being considered to contain 128 ft^3. Large timber on the West Coast generally is measured in board feet of solid volume. Measurement and purchase of wood on a weight basis are practiced, and are desirable because weight is directly related to fiber content [2].

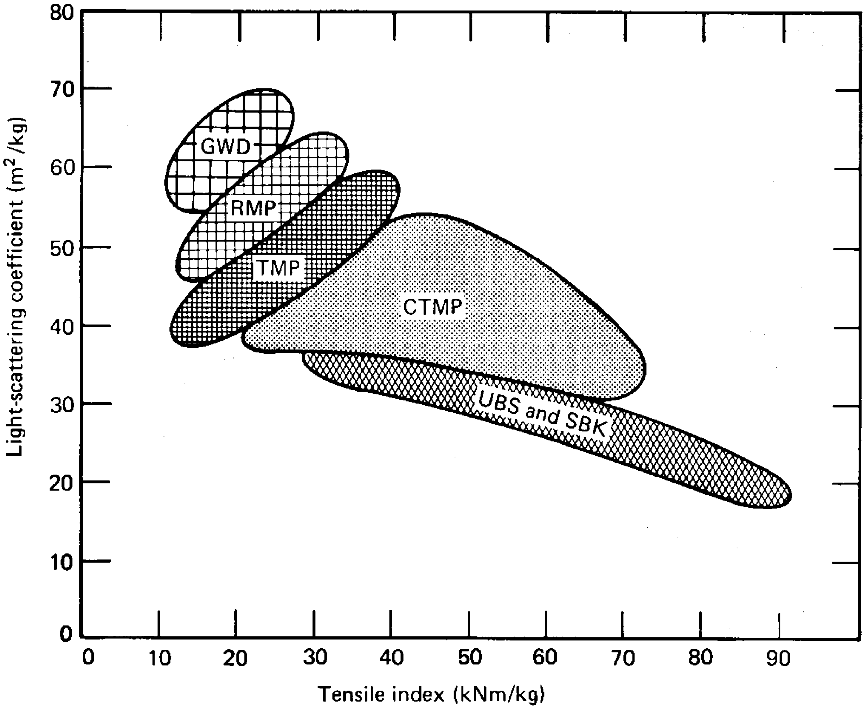

Fig. 28.19 Comparison of the tensile and light-scattering coefficient for stone groundwood (GWD), refiner mechanical pulp (RMP), TMP, CTMP, unbleached sulfite pulp (UBS), and semibleached pulp (SBK) (from McGovern [11], with permission of the copyright owner)

The growth in the use of wood residues has been substantial. By barking the sawlogs, the slabs, edgings, and other trimmings that formerly were burned now can be used to make pulp. Almost 28% of the wood used by the pulp industry is classified as waste wood. Several mills have been built that use no logs whatsoever but depend on residuals from satellite sawmill operations. Special sawmilling equipment has been developed to produce sawdust of a proper size so that it too can be used.

Wood used in producing groundwood pulp requires no further preparation after debarking, but that used in the other refiner mechanical or chemical processes must first be chipped into small pieces averaging 0.5–1 in. in length and about 1/8–1/4 in. in thickness.

Chipping is accomplished with a machine consisting of a rotating disc with knives mounted radially in slots in the face of the disc. Modern chippers have up to 12 knives; the ends of the logs are fed against the disc at about a 45 angle.

Mechanical Pulping

Mechanical pulping, as the name implies, involves mainly a grinding or abrading action to produce wood fibers. The stone groundwood process (SGW) is the conventional mechanical pulping, in which the log bolts are pressed against an abrasive grindstone. Developments in stone grinding include application of pressure to the grinder (PGW) and control of temperature. At one time, natural sandstone was used for the grindstone, but modern stones are either silicon carbide or aluminum oxide grits in a vitrified clay binder. Groundwood pulp is the primary component of newsprint. The characteristics of the stone can be varied to produce pulps "tailor-made" to fit their desired end use. For roofing or flooring felts, fibers must be extremely coarse and free-draining, so they require a stone with large grits, whereas newsprint pulps are very fine and require the use of small grits.

Pulp characteristics also can be varied by changing the stone surface pattern, the stone speed, the pressure of the logs against the stone, and the temperature of the groundpulp slurry. Generally a coarser and more freely draining pulp is obtained with a coarse surface pattern and high speed, pressure, and temperature. The type and the condition of the wood also are factors, but groundwood pulps usually are made from the coniferous or long fibered species because the deciduous or short-fibered species give very weak pulps.

Since 1975, SGW process has been gradually replaced by the RMP of chips. Basically, chips are pressed through the single- or double-rotating plates of a vertical-disc attrition mill. This RMP process has several advantages. In contrast to the SGW being limited to the use of log bolts, RMP fibers can be produced from chips or sawdust with improved strength properties (Fig. 28.18).

Groundwood or RMP pulp is low in strength compared with the chemical pulps. It is composed of a mixture of individual fibers, broken fibers, fines, and bundles of fibers. Papers made from these pulps also lose strength and turn yellow with time. Thus, these pulps are used only in relatively impermanent papers such as for newsprint, catalogs, magazines, and paperboard. Groundwood papers have excellent printing qualities because of high bulk, smoothness, resiliency, and good ink absorption. Newsprint contains about 80% groundwood, and the other publication paper grades contain about 30–70%, with the remainder a chemical pulp to provide greater strength. Groundwood is the cheapest pulp made and also utilizes the entire wood, giving close to a 100% yield. Now, the RMP is dominated in the production of mechanical pulps and their fiber characteristics can also be readily improved by modification of refining conditions leading to the development of many new products.

Major improvements in mechanical pulping technology include the pretreating chips with chemicals, steam, or both. When chips are steamed at about 130°C and 40 psi for 2–4 min followed by pressure refining, it produces a TMP, which has a significantly higher strength than the RMP or SGW fibers (Fig. 28.18). Similarly, chips can be pretreated with chemicals followed by disc refining. Various combinations of chemical and mechanical treatments have been used to produce pulps with specific properties. The chemimechanical pulping (CMP) refers to a mild chemical treatment while the semichemical pulping includes a mild cooking stage for a partial removal of the lignin.

Chemimechanic pulping (*CMP*). CMP pulps usually are produced by mild treatment of chips with caustic soda, sulfite, or peroxide followed by refining under atmospheric pressure. Chemical consumption is very low, and yields are usually 85–95%. When chemical pretreatment and pressure steaming are combined, it is called CTMP. The main purpose of chemical treatments is not to remove but to modify the lignin component. On this aspect, a pretreatment with sulfite is much more effective than alkalis, as it introduces the sulfonate group into the lignin (sulfonation) and softens the cell wall matrix. Thus, the sulfite treatment facilitates the mechanical fiber separation and thus improves the sheet strength property. The strength of CTMP is very comparable to that of the conventional acid-sulfite chemical pulps (Fig. 28.18). In fact, newsprint is produced commercially from the TMP or CTMP fibers alone without the use of any chemical pulps.

Semichemical Pulping

This is a two-stage process involving a mild cooking of chips for a partial removal of the lignin components followed by refining to separate the fibers. This semichemical process differs from the CMP in having a moderate degradation of the lignin component. The chemical stage can apply any of the chemical pulping process with reduced chemical charge, temperature, or cooking time. For hardwood, it is quite common to use a neutral sulfite liquor (Na_2SO_3 + Na_2CO_3) or green liquor (Na_2CO_3 + Na_2SH). The major uses of semichemical pulps are in making corrugating medium and linerboard.

The NSSC is one in which wood chips, usually from hardwoods, are cooked with Na_2SO_3 liquor buffered with either $NaHCO_3$, Na_2CO_3, or NaOH to maintain a slightly alkaline pH during the cook. Unbleached pulp from hardwoods cooked to a yield of about 75% is widely used for the corrugating medium. Although bleachable pulps can be produced by this process, they require large quantities of bleaching chemicals, and the waste liquors are difficult to recover. Currently many NSSC mills are located adjacent to kraft mills, and the liquors can be treated in the same furnace. Thus, the waste liquor from the NSSC mill becomes the makeup chemical for the kraft mill, solving the waste problem. NSSC hardwood pulp is the premier pulp for the corrugating medium and cannot be matched by any other process.

Chemical Pulping

The main purpose of chemical pulping is to remove the lignin portion of wood so that wood fibers can be liberated freely with very little mechanical treatment. The degree of lignin removal (or delignification) depends on the end uses of the final products. For making shopping bags, it is not necessary to remove all the lignin. However, a complete delignification, essential for making a permanent white paper, has to be achieved by separate bleaching operations.

Many variations are used throughout the world; the simplest classification of pulping methods depends on whether they are acidic or alkaline. Each has its own specific advantages and disadvantages, but the kraft (alkaline) process accounts for over 90% of all chemical pulp produced in the United States. The important acidic process is the sulfite, which however can be applied to the whole pH range now. All present commercial processes use aqueous systems under pressure at elevated temperatures, although several organosolv systems have reached the demonstration-plant stage.

Kraft Process

The kraft (sulfate) process uses a mixture of sodium hydroxide (NaOH) and sodium sulfide (Na_2S) as the active chemical. Although the designation of sulfate process could be misleading, it sometimes is used because sodium sulfate is the makeup chemical in the process. The word “kraft” now is mainly used to describe this process, derived from the Swedish or German word for strength, as this process produces the

Table 28.5 Typical kraft pulping conditions

Alkali charge[a]	15–20%
Temperature	170–175°C
Pressure	100–110 psig
Duration	2–3 h
Liquor to wood ratio	4:1 by weight

[a] Based on wood and calculated as Na_2O; consisting of approximately $5NaOH + 2Na_2S$

strongest pulp. Historically, sodium hydroxide alone (soda process) first was used as the alkaline pulping agent, but all these mills have converted to the kraft process because the soda pulp is weak and inferior to kraft pulp. The addition of Na_2S greatly enhances the lignin degradation and removal, which is the key mechanism in alkaline pulping.

The pulping (cooking) process traditionally was performed on a batch basis in a large pressure vessel called a digester. Conditions vary depending upon the type of wood being pulped and the quality of end product desired. Typical conditions for kraft cooking are listed in Table 28.5.

Digesters are cylindrical in shape with a dome at the top and a cone at the bottom. Ranging in size up to 40 ft high and 20 ft in diameter; the largest will hold about 7,000 ft^3 of wood chips (about 35 t) for each charge. The chips are admitted through a large valve at the top, and at the end of the cook they are blown from the bottom through a valve to a large blow tank. During the cook, the liquor is heated by circulation through a steam heat exchanger, which also avoids the dilution of the cooling liquor that would occur from heating by direct injection of steam.

The development of continuous digester significantly facilitated the production of kraft pulps. Figures 28.20 and 28.21 illustrate a two vessel vapor/liquor phase digester system [12] for a modified kraft cooking to achieve a maximum removal of the lignin while maintaining the pulp quality. Key features include the impregnation of wood chips with white liquor, injection of white liquor at three locations to maintain the alkali concentration nearly uniform throughout the cook, and a countercurrent mode to facilitate the lignin dissolution.

Kraft delignification. A key delignification reaction in kraft pulping is attributed to the cleavages of major lignin units (β-aryl ether) and to generate the phenolic hydroxyl group (PhOH). This fragmentation process requires a combination of both sodium hydroxide and sodium sulfide at elevated temperatures (170°C). Once the lignin fragments contain enough of these hydrophilic PhOH groups, they become soluble in alkalis. Figure 28.22 illustrates the overall process of lignin removal in a kraft process [13]. The extent of cooking is expressed as H-factor, which represents a combination of the cooking duration and temperatures.

The lignin-removal process is consisted of three distinct phases. The initial phase occurring during the heating period (up to 170°C) readily removes about 20% of wood lignin. Although the lignin dissolved was often referred to as "extracted lignin," it does involve the degradation of more reactive lignin structure. The bulk phase removes additional 70% of lignin, whereas the remaining residual lignin (5–10%) was very resistant to degradation. In commercial operation, the cooking has to be terminated at the inter-phase of the bulk and residual delignification. The residual lignin of kraft pulps has to be removed by the subsequent bleaching process.

Although kraft process is effective in the sense that it can pulp virtually any kind of wood, it is not very efficient, as about one third of the polysaccharides mainly hemicelluloses are degraded and removed during the process. As illustrated in Fig. 28.23, the delignification selectivity (a ratio of lignin removal to carbohydrate degradation), also displays three distinct stages [14, 15]. Both the initial and residual phases are very nonselective. Again, the curve suggests that the kraft pulping has to be terminated at the end of the bulk phase to avoid an excessive degradation of the polysaccharides to preserve the fiber quality.

The brown stock after cooking is washed in a countercurrent rotary vacuum washer system using three or four stages to remove the residual chemicals. The resulting pulp is ready for bleaching or for making papers such as grocery bags where the brown color is not objectionable. The separated liquor being very dark in color is known as "black liquor." The black liquor generally has a solid content of 15–20% containing mainly the dissolved lignin and hydroxyl acids from carbohydrate degradation with some extractives. After partial evaporation, the "tall oil" skimming containing mainly the wood resins is recovered as by-products (see section on "Chemicals from Wood Extractives").

Chemical recovery. The black liquor is concentrated further by multiple-effect evaporators to 60–65% solids. At this concentration, the quantity of dissolved organic components from the wood (lignin and carbohydrate degradation products) is sufficient to allow the liquor to be burned in the recovery furnace (Fig. 28.24).

By controlling the amount of excess air admitted to the furnace and the temperatures, the organics in the liquor can be burned. The chemical reactions occurring in the furnace consist of three different zones (drying, oxidizing, and reduction). The sodium carbonate and sodium sulfate formed on the top oxidizing zone will be dropped to the bottom of furnace. At the bottom reducing zone, the sodium sulfate formed or added to the liquor as make up will be reduced by carbon to sodium sulfide. After dissolving the molten smelt of Na_2CO_3 and Na_2S in water, the mixture (called "green liquor") is reacted further with slaked lime:

$$Na_2OH + Ca(OH)_2 \rightarrow 2NaOH + CaCO_3$$

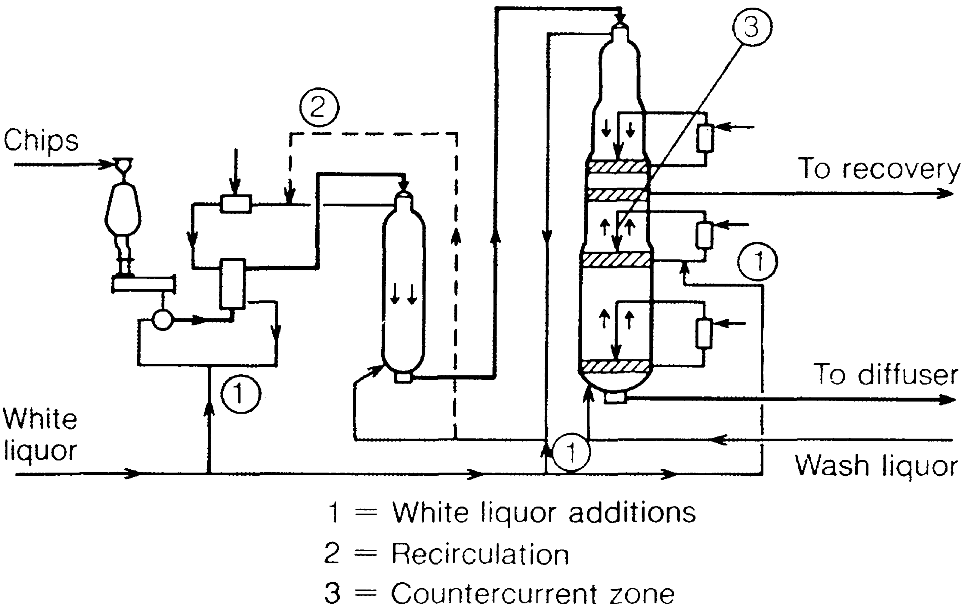

Fig. 28.20 Two-vessel vapor-liquid phase digester adapted for extended delignification (from Johansson et al. [12]; Smook GA (1992) Handbook for pulp and paper technologies, 2nd edn. Angus Wilde Publications, with permission)

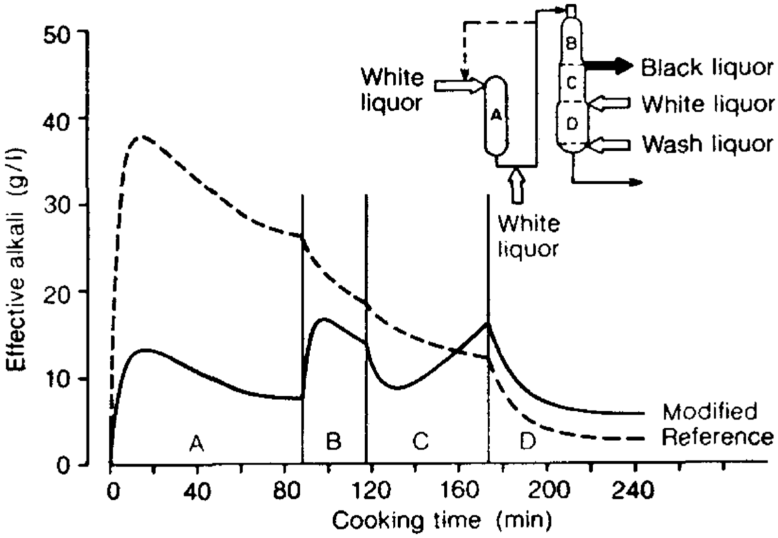

Fig. 28.21 Concentration profile of effective alkali inside chips in a two-vessel vapor/liquid phase digester system—conventional system compared with modified system as calculated by the mathematic model (from Johansson et al. [12]; Smook GA (1992) Handbook for pulp and paper technologies, 2nd edn. Angus Wilde Publications, with permission)

The Na_2S does not react with the lime, so the resultant mixture of NaOH and Na_2S (called "white liquor") can be reused to pulp more wood. The $CaCO_3$ sludge is filtered off, burned in a lime kiln, and reused. Thus, the chemical system is a closed one, as shown in Fig. 28.25, and this minimizes costs and pollution.

Kraft mill odor. A major drawback in kraft pulping is the odor produced associated with the sodium sulfide (Na_2S) used. This compound promotes the lignin degradation and dissolution and induces the formation of hydrogen sulfide (H_2S), methyl mercaptan (CH_3SH), dimethyl sulfide ($CH_3S–CH_3$), dimethyl disulfide ($CH_3S–SCH_3$). These four compounds constitute the so-called kraft mill odor. However, the paper company has done a great job in controlling the emission of these compounds through a combination of various techniques including a black liquor oxidation, improved evaporators and furnaces. Now, one can hardly recognize the existence of a kraft mill just based on the odor alone.

Future prospects. Virtually any kind of wood can be pulped by the kraft process; because it produces the strongest pulps with good economies, it has grown to be the dominant process in the world. Although the odor problem is a major concern, it does not appear that this process will be supplanted in the near future; instead, it will be improved and modified further.

When pulping resin-rich woods such as southern pine, the kraft process yields turpentine and tall oil as valuable by-products. The steam generated in the recovery furnace

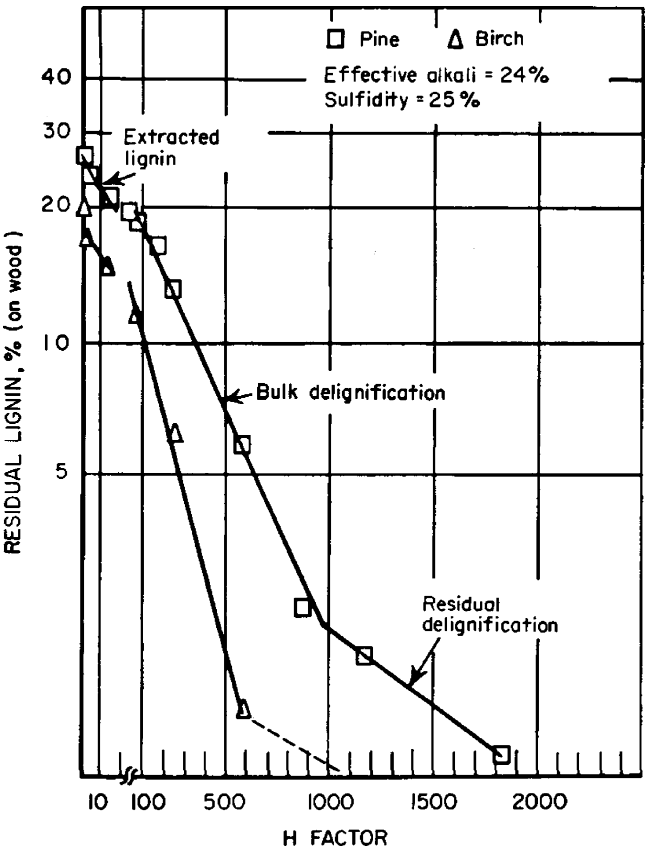

Fig. 28.22 Kraft delignification process as a function of H-factors (from Kleppe and Tappi [13]; Smook GA (1992) Handbook for pulp and paper technologies, 2nd edn. Angus Wilde Publications, with permission)

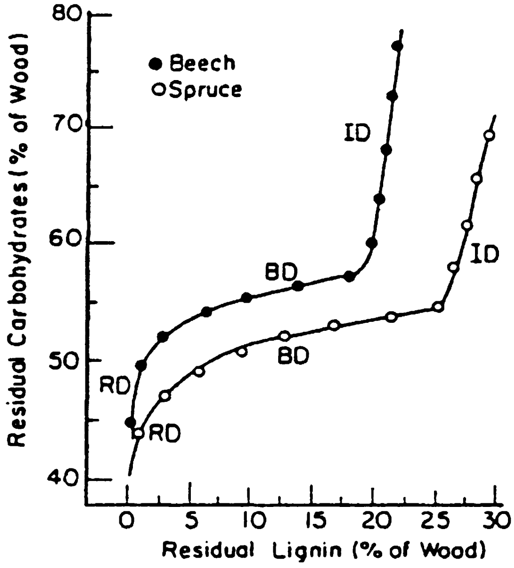

Fig. 28.23 A typical delignification selectivity in kraft pulping of softwood and hardwood [14, 15]

is almost enough to make the pulp mill energy self-sufficient. The discovery that small amounts of anthraquinone (0.05–0.25% on wood) added to alkali liquors can enhance delignification and produce the kraft quality pulp has been of great interest. Although the price of anthraquinone (AQ) is high and the chemical is not recovered, only small quantities are required, and the benefits outweigh the costs sufficiently that a number of mills around the world now routinely add AQ to the kraft pulpwood digester.

Sulfite Process

The conventional acid sulfite pulping is often called sulfite process and uses a cooking liquor of sulfurous acid (H_2SO_3) and calcium salt of the acid at pH around 1.5. This is the only acid process used in commercial pulping operation. For many years, this was the preferred process because it produced pulps of light color that could easily be bleached, it used cheap chemicals in fairly limited amounts so that no recovery was necessary, and it was a relatively simple process to operate.

Although the production of sulfite pulp has remained relatively constant for the last 30 years, the rapid growth of kraft pulping has reduced sulfite's share to less than 10% of the chemical pulp produced. There are several reasons for this, but the primary ones are the inability to cook resinous woods such as pine, problems in producing strong pulps from hardwoods, and of the greatest importance, the lack of a cheap and simple recovery system to reduce water pollution problems. However, this process produces dissolving pulps (pure cellulose) with special qualities such as high alpha-cellulose grades for rayon, so it will continue to be used.

Acidic delignification. The mechanism of sulfite delignification is distinctly different from the kraft pulping. The key reaction in acid sulfite cooking is the sulfonation (Fig. 28.26) and the lignosulfonates are soluble in water. In contrast, kraft delignification relies on an extensive degradation of lignin unit to lower molecular weight fragments. Although these lignin fragments are soluble in alkalis, they are not soluble in an acidic medium. Therefore, the lignosulfonate and kraft lignin have different molecular property and applications as a polymer.

Use of soluble bases. Initially, calcium was the preferred base because it was cheap and convenient to use. However, no recovery system is available for this base, so most calcium-base mills either have ceased operation or have converted to the more soluble bases. With magnesium, the cooking pH can be extended to the bisulfite range while the whole range of pH is applicable by using sodium or ammonium as summarized in Fig. 28.27. As the pH

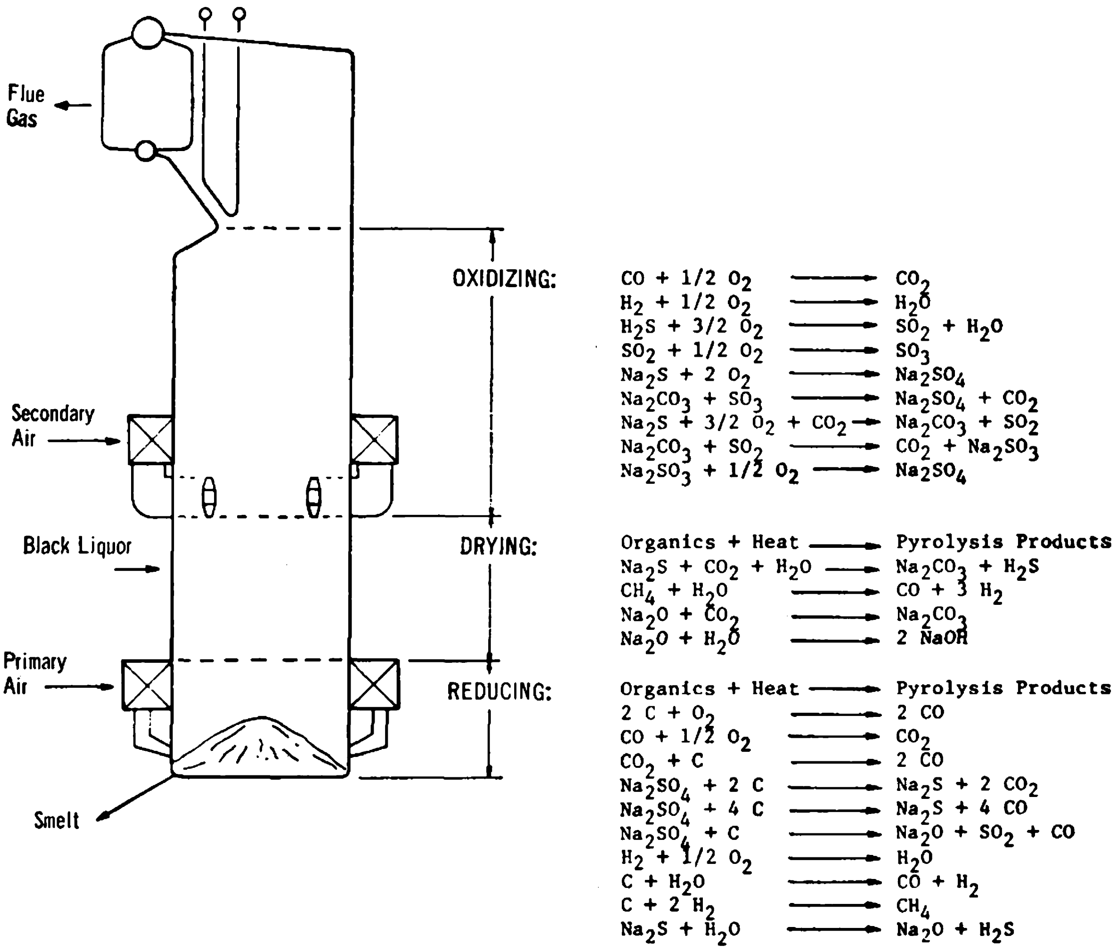

Fig. 28.24 Chemical recovery furnace (from Smook GA (1992) Handbook for pulp and paper technologies, 2nd edn. Angus Wilde Publications, with permission)

increases, the cooking can be conducted at higher temperatures and shorter.

In sulfite process, it is essential to have a well impregnation of chips prior reaching the maximum temperature. Thus, an extremely long cooking duration (7–10 h) is necessary with acid sulfite, whereas 4–5 h is sufficient with bisulfite at a higher temperature. Also, the higher pH cooking produces stronger pulps.

Different bases used were shown having noticeable effects on the pulping operations. Under identical cooking conditions (temperature, pH, and sulfur dioxide concentration), the ammonium base has the highest cooking rate and followed by magnesium and sodium. However, the ammonium bisulfite pulp has a lower brightness and is more difficult to bleach.

Chemical recovery. Sodium base is the easiest one to prepare (Na_2CO_3 or NaOH usually is used as the makeup chemical) and gives the highest quality pulp. However, the recovery processes, though available, is complicated and expensive. The magnesium-based bisulfite (Magnefite) process has been used in several mills and has a cutting edge in the chemical recovery. After cooking, the magnesium sulfite spent liquor (Mg-SSL) is processed and burned just like the kraft black liquor in a recovery furnace with the exception of no melts formation. All the inorganic components would be converted into SO_2 and MgO and they are be recovered by adsorption with scrubbers and by dust collectors, respectively.

In ammonium-based (from NH_4OH) process, the ammonia cannot be recovered, but the liquor can be evaporated and burned without leaving any solid residue, thus reducing water pollution. As long as aqueous ammonia remains low in price, this process will be attractive because the SO_2 can be recovered from the waste gases by passing them through a wet scrubber flooded with fresh ammonium hydroxide.

Modified sulfite process. Although the conventional acid sulfite has limited uses in the production of chemical pulps, the sulfite treatments, which can be conducted in the whole range of pH, has been extensively used especially in

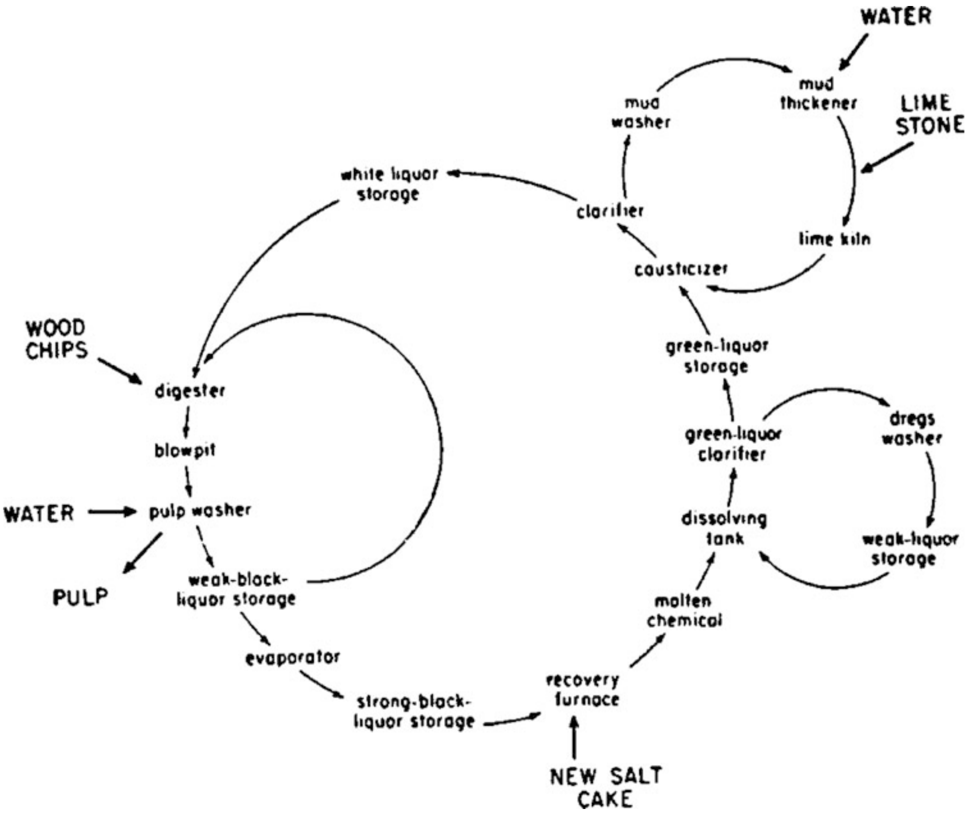

Fig. 28.25 Diagram showing cyclic nature of kraft recovery process (from Casey JP (ed) Pulp and paper, 3rd edn. Wiley-Interscience, New York. Copyright © 1980 John Wiley & Sons, New York; with permission of Copyright owner)

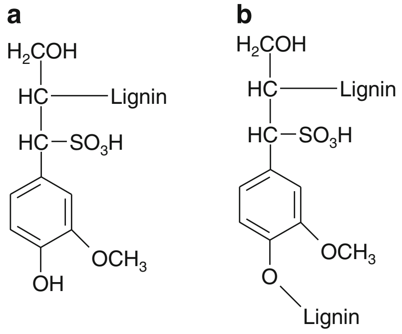

Fig. 28.26 Lignin sulfonation

conjunction with the production of chemimechanical or semichemical pulps. Interestingly, the NS (neutral sulfite)-AQ process can be used to produce chemical pulps from pine and birch wood with yields significantly higher than that from birch wood [16]. However, the NS-AQ delignification is a very slow process and produces a weaker pulp than kraft. More research is needed to improve the NS-AQ process.

Organosolv Pulping

The concept of using solvents to dissolve lignin is not new. In the 1930s, Kleinert and Tayenthal already developed and patented the first solvent (organosolv) pulping process based on aqueous ethanol (25–80% alcohol) [17]. Until recently there was little incentive to pursue alternatives to the kraft process because energy and chemicals were reasonably cheap, there were few environmental regulations, and there was little interest in by-products. However, new, strict environmental regulations, rising energy and chemical costs, and the very large capital investments needed to construct new kraft mills have stimulated research and investment in alternate solvent pulping processes [18–20].

The organosolv pulping includes the use of alcohols (methanol or ethanol), organic acids (acetic acid or formic acid), and others. In general, wood chips are contacted with an aqueous solvent mixture and cooked (digested) for a period of time at elevated temperatures. Digestion pressures range from atmospheric to 500 psig. Cooking initially releases acetic and formic acids from ester functionalities in the wood, and these acids further promote hydrolysis of lignin and hemicelluloses to low molecular weight species. Catalysts such as mineral acids (HCl), organic acids (acetic, formic), sulfonic acids, and Lewis acids and bases ($AlCl_3$, $Fe_2(SiO_4)_3$, $Mg(SO_4)$, $CaCl_2$) can be employed to promote delignification. Cellulose pulp is filtered from the liquor, and the solvent is recovered, usually by distillation. Lignin becomes insoluble at this point and precipitates from the liquor, leaving an aqueous solution of primarily hemicellulosic sugars.

Several processes have reached the demonstration-plant scale and none are currently used in commercial production.

Fig. 28.27 Summary of sulfite pulping processes

	Acid Sulphite	Bisulfite	Neutral Sulfite Semichemical
pH	1.5	4 - 5	8 - 9
Chemicals	H_2SO_3, $NaHSO_3$	$NaHSO_3$	Na_2SO_3, Na_2CO_3
Base	Ca, Na, Mg, NH_4	Na, Mg, NH_4	Na, NH_4
Rate of Cooking (Given temp.)	——— Decreasing ———→		
Temperature	140°C	170°C	170 - 180°C
Brightness	— Slight increase →		— Decrease →
Strength Characteristics (Given yield)	——— Increasing ———→		
Species	Nonresinous	Hardwood & Softwood	Hardwood
Equipment Corrosion	——— Decreasing ———→		

Processes [18–20] that had received much attention are briefly outlined in the following.

ALCELL process. This process based on the original concept patented by Kleinert and Tayenthal [17] is the simplest organosolv pulping system for hardwood using aqueous ethanol. It is an auto-catalyzed process (conducted at 190–200°C for 1–2 h), as the acetic acid generated from the acetyl group of hemicelluloses served as catalyst. A demonstration plant, producing 15 metric tons of organosolv pulp a day, was constructed in New Brunswick, Ontario. The flow sheet for the Alcell pulping process and by-product recovery is illustrated in Fig. 28.28 [20].

Both the Alcell and kraft processes were reported being quite comparable in pulping hardwood in terms of pulp properties (strength and bleachability) [20]. The Alcell process may have an advantage of being a more environmentally friendly process, if all the ethanol used could be quantitatively recovered. Also, the dissolved carbohydrate and lignin can be readily recovered for conversion to biofuel and bioproducts. The Alcell lignin being the only sulfur-free lignin product available in the market would be very attractive for industrial applications. However, the Alcell process being largely confined to pulp hardwood and nonwood species is not applicable for softwood.

Organocell process. This process [18, 20], developed in Germany, was a methanol-based solvent pulping intended for softwood. Wood chips were first impregnated with 50% aqueous methanol. In the original concept, the impregnated chips were subjected to the first cooking stage (operated under 40-bar pressure at 195°C) to remove approximately 20% of the lignin and a major part of the hemicelluloses. The partially cooked chips are then subjected to a second-stage cooking with an alkali charge of 15–20% based on wood in 30% aqueous methanol at 170°C. The combined residence time in both reactors is only 45 min. This two-stage concept was later modified to a totally alkaline process by cooking with a mixture of methanol, alkalis, and AQ (anthraquinone). The strength properties of the pulps produced were only slightly lower than those of corresponding kraft pulps.

ASAM process. This process stands for the Alkaline Sulfite Anthraquinone Methanol process and was derived essentially from the addition of methanol and AQ to an alkaline sulfite liquor [21]. The ASAM process was substantially more effective than the NS-AQ process [16] in delignification. It can be applied to both hardwood and softwood and produce pulps with strength properties being slightly lower than the kraft pulp.

Milox process. This is a three-stage process based on the use of formic acid to achieve both the pulping and bleaching operations [22]. Both the first and third stages use a mixture of formic acid and hydrogen peroxide conducted at 80°C, so peroxyformic acid is a major reactive species. Whereas

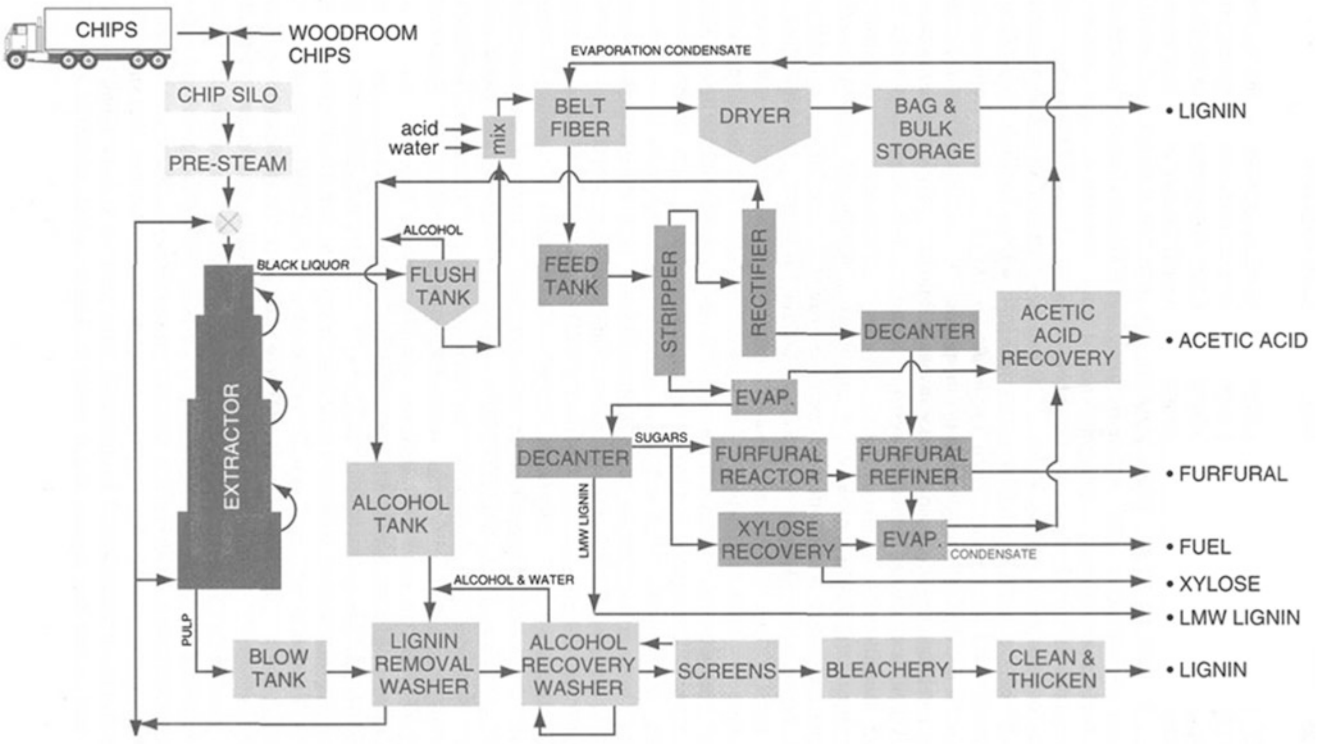

Fig. 28.28 Flow sheet for the ALCELL pulping and by-product recovery (from Hergert [20], with permission)

formic acid is employed in the second stage conducted in 100–140°C range. The Milox process has been successfully applied to all the woody substrates including hardwood, softwood, and nonwood species.

Acetic acid-based systems. A variety of organosolv processes were developed based on the use of acetic acid [20]. For example, the Acetosolv process was conducted in a 95% acetic acid solution containing about 0.15% HCl at 110°C for 2–5 h. This process because of the corrosion problem was modified to an Acetocell process by using a lower concentration of acetic acid (80–90%) conducted at higher temperatures (170–190°C).

For the Formacell process, it utilized a mixture of acetic acid, formic acid, and water in various proportions and was conducted in a series of extractors in the 130–160°C range. Although the organic acid-based systems can be operated at much lower temperatures, they may be labile to equipment corrosion and more difficult in the chemical recovery process.

Screening and Cleaning of Wood Pulp

The desired pulp fibers for papermaking applications are usually between 1 and 3 mm in length with a diameter about one-hundredth as large. Any bundles of fibers or other impurities would show up as defects in the finished paper and must be screened out. Wood knots usually are difficult to pulp and must be removed.

Screening is usually a two-stage process with the coarse material being removed by screens with relatively large perforations $\left(\frac{1}{4}\text{–}\frac{3}{8}\text{ in.}\right)$. Additional fine screening is done with screens using very small (0.008–0.014 in.) slots to ensure the removal of oversized impurities. Screen size openings will depend on the species of wood being processed and the desired quality of the end product. Because of the tendency of the fibers to agglomerate when suspended in water, it is customary to screen at very low solid contents (consistencies) of about 0.5% fiber and 99.5% water.

To meet the ever-increasing demands for cleaner pulps, centrifugal cyclone cleaners have come into almost universal use. The screened pulp is pumped through these units at low consistencies and high velocities. The fiber slurry enters the cone tangentially at the top, and a free vortex is formed with the velocity of the flow greatly increased as the diameter of the conical section is reduced. Heavier particles of sand, scale, or other dirt are forced to the outside of the cleaner and are discharged from the bottom tip through a small orifice. Because of the velocity gradients existing in the cone, the longer fibers (75–95%) are carried into the ascending center column and are discharged through the larger accept nozzle at the top. In a properly designed and operated unit, a shape separation also is made so that round particles, even though of the same specific gravity as the good fibers, will be discharged as rejects through the bottom orifice. In this way, small pieces of bark also are removed. To reduce the quantity of rejects to an acceptable level, they in turn are processed through a second, a third, or even a fourth stage of cleaners, thus holding the final loss of pulp to about 0.25–1% of the feed, depending upon quality demands and the dirt level of the incoming pulp.

Bleaching of Wood Pulp

The color of unbleached pulp varies considerably with the pulping process. It ranges from cream or tan (50–65% brightness) for the acid sulfite and groundwood pulps to dark brown (15–30% brightness) for kraft pulps. These pulps in general are too dark in color for many paper-grade products, although they could be used in the packaging grade or newsprint. The light-absorbing groups (or called chromophores) in unbleached pulps are associated mainly with the lignin component. Thus, a total removal of the residual lignin in unbleached pulps is essential to achieve a high and stable brightness (>90%). This is the purpose in bleaching of chemical pulps.

In case of the high-yield groundwood or chemimechanical pulps, they still contain practically all the wood lignin. The bleaching of these pulps is not by removal of the lignin to retain the advantage of high yield and is achieved by a modification or removal of the chromophores groups. Thus, the bleaching of high yield pulps is generally referred to a brightening process and differs distinctly from the bleaching of chemical pulps.

Bleaching chemicals. Table 28.6 lists the chemicals that have been used in the bleaching or brightening of wood pulps. The commercial bleaching of chemical pulps has gone significant developments in recent years. Among these, the chlorination (C) and hypochlorite (H) are not longer used in pulp bleaching due to the environmental concern. Current bleaching of chemical pulps relies heavily on the oxygen delignification (O), chlorine dioxide (D), and alkali extraction (E).

Although it is possible to improve the brightness (whiteness) of pulps in one stage, the economic achievement of high brightness requires the use of several stages. A bleaching sequence without the use of a chlorination (C) stage is termed as elemental chlorine free (ECF) bleaching in a sequence like ODEDE. Regulatory agencies in Europe, and particularly in Scandinavia, has imposed even greater restriction on emissions from pulp mill bleach plants and another new approach has been developed, namely totally chlorine free (TCF) bleaching of pulps. For TCF, more radical changes are necessary with the substitution of both C and D stages with oxygen (O), ozone (Z), peroxide (P), and enzyme (X) stages in a sequence such as OXZP [19].

Table 28.6 Chemicals used in pulp bleaching

Bleaching stage	Chemical	Symbol
O_2 bleaching	$NaOH + O_2$	O
Alkali extraction	NaOH	E
Alkali extraction reinforced with O_2	$NaOH + O_2$	E_o
Alkali extraction reinforced with H_2O_2	$NaOH + H_2O_2$	E_p
Chlorine dioxide	ClO_2	D
Hypochlorite	NaOCl	H
Hydrogen peroxide	H_2O_2	P
Chelating agent treatment	EDTA or DTPA	Q
Enzyme treatment	Xylanases	X
Ozone	O_3	Z
Dithionite	$Na_2S_2O_4$	Y

Bleaching of chemical pulps. After the kraft or other chemical pulping, the unbleached pulp is then subjected to an O_2 bleaching for further delignification. This oxygen stage is almost a standard practice in the industry now and is commonly referred as a prebleaching stage. A typical O_2-delignification removes about 50% of the residual lignin in kraft pulps in order to avoid an excessive degradation of the cellulose component.

For a typical ECF bleaching, a common bleaching sequence to follow is D_1ED_2 with typical conditions listed in Table 28.7. The amounts of chlorine dioxide charged depended on the content of residual lignin in the pulp and distributed properly between the D_1 and D_2 stages. For some mills, the O_2-delignification was also conducted in two separate stages aimed at further reducing the residual lignin content of pulp prior to entering the D stage.

In addition, the alkali extraction stage (E) commonly used to remove the degraded lignin can be enhanced by the addition of O_2 (Eo), peroxide (Ep), or both (Eop). For a TCF bleaching, the O_2-delignification is generally followed by an ozone (Z) and a peroxide (P) stage in a sequence such as OXZP [19].

Bleaching (brightening) of mechanical pulps. The brightening of high yield pulps is commonly achieved by treatments with a reducing agent, sodium hydrosulfite ($Na_2S_2O_4$) or with an oxidizing agent (peroxide, H_2O_2). Unlike the bleaching of chemical pulps, the brightness from a single treatment of mechanical pulps (Table 28.8) is generally sufficient for making the newsprint-grade papers. Also, a high brightness of pulps (over 80) can be achieved by a two-stage peroxide process. However, the brightness of these pulps is not stable on exposure to light and air. This yellowing problem limits many applications for the high-yield pulps.

Table 28.7 Typical conditions for bleaching chemical pulps

Stage	% Chemical on pulp	Temperature (°C)	Time (min)
O_2 Bleaching (O)	1.5–3.5 (NaOH) O_2 pressure (100 psig)	100	60
Chlorine dioxide (D)	1–2	70	180
Alkali extraction (E)	2–3 (NaOH)	70	60

Table 28.8 Typical conditions for brightening of high-yield pulps

Conditions	Sodium hydrosulfite	Hydrogen peroxide
Chemical charge, % of pulps	1	1–2
Temperature (°C)	40–100	35–60
Retention time (min)	30–60	1–3
pH	4.5–6.5	10.5–11.2
Consistency (%)	3–30	
Silicate (%)	–	5
$MgSO_4$	–	0.05

Recycling

Worldwide, approximately 38% of wastepaper is recycled; however, the rate of recycling varies between countries with the United States at a 45% recycle rate. The United States is a major exporter of waste paper, with the majority going to "fiber-poor" countries such as Korea and China that have much less virgin fibers.

A variety of problems are associated with paper recycling, such as collection, distribution, and wild cyclic swings in the market. However, with landfill sites at a premium and paper representing 30–40% of the municipal solid waste, it makes good sense in the long run to promote paper recycling, which reduces landfill needs and the consumption of virgin timber. The paper industry in the United States has now set a goal of 50% paper recycling rate.

There are a wide range of different grades of wastepaper available, depending on the source and the extent of separation. As the name implies, wastepaper designated as "direct pulp substitutes" is utilized with little treatment before reslushing in a hydrapulper. The direct pulp substitutes are the highest grade of wastepaper.

The majority of recycled paper (about 75%) is used with no attempt to remove inks, dyes, or pigments from the paper. The resultant pulp is of rather poor color and quality, and is used primarily as filler stock in paperboard. The bulk grades are the largest-volume wastepaper source.

Deinked grades of wastepaper require special techniques and equipment to remove inks, coatings, adhesives, and so on. The deinking process is complicated and time-consuming; depending on the quality of deinked pulp required, the process may involve a number of combinations of washing, flotation, dispersion, screening, and the use of cyclone cleaners. The newer noncontact inks present special removal problems, as do wet-strength agents, adhesives, and the so-called stickies.

Stickies are derived from hot-melt adhesives (vinyl acetate polymers and copolymers), pressure-sensitive adhesives (styrene-butadiene), and lattices (natural and synthetic rubber). Tackifiers and waxes also are usually included in these adhesive formulations. A variety of additives are used to help remove stickies and other contaminants from wastepaper, including solvents, nonionic and cationic surfactants, zirconium compounds (to reduce tackiness), and talc. Of course, all of the additional steps and additives add to the expense of recycling. There is also the problem of waste disposal from the deinking process, which must be properly handled.

Stock Preparation

Stock preparation in a paper mill includes all intermediate operations between preparation of the pulp and the final papermaking process [23]. It can be subdivided into (1) preparation of the "furnish" and (2) "beating" or "refining." Furnish is the name for the water slurry of fibers and other chemicals that goes to the paper machine. Beating or refining refers to the mechanical treatment given to the furnish to develop the strength properties of the pulp and impart the proper characteristics to the finished paper.

Cellulosic fibers are unique in that, when suspended in water, they will bond to each other very strongly as the water is removed by filtration and drying, with no need for an additional adhesive. This is so because of the large number of hydrogen bondings that form between the surfaces of fibers that are in close contact as the water is removed. This bonding is reversible and accounts for the well-known fact that paper loses most of its strength when wet. If paper is suspended in water and agitated, it will separate into the individual fibers, a behavior that allows the easy reuse of wastepaper or the processing waste from the paper mill.

Refining. In order to enhance the bonding capability of the fibers, it is necessary to mechanically beat or refine them in equipment such as beaters, jordans, or disc refiners. This treatment of the pulp slurry at about 3–6% consistency is done by passing the pulp between the two rotating surfaces of the refiner. These surfaces contain metal bars and operate at very close clearances. As the fibers pass between the bars, they are made more flexible, and a larger surface for bonding is developed by the mechanical action.

This refining brings about fundamental changes in the pulp fibers and increases the degree of interfiber bonding in the final sheet of paper. Thus, the final properties of the paper can be significantly changed by varying the degree and type of refining. As additional refining is performed, properties such as tensile strength, fold, and density are increased while tear resistance, opacity, thickness, and dimensional stability are decreased. Thus, the proper refining conditions must be selected to bring out the desired properties without detracting too much from other properties.

Furnish. The furnish for a paper machine varies widely, depending on the grade of paper being made. Newsprint usually consists of about 80% groundwood and 20% chemical fiber (sulfite or semibleached kraft). Bag papers and linerboard are usually 100% unbleached softwood kraft. Printing papers are made from bleached pulps and contain both hardwoods and softwoods. By selecting the proper pulps and refining conditions, a wide variety of paper qualities can be achieved.

Additives. The paper industry is a large user of chemicals because relatively small quantities of additives can materially change the properties of paper. The use of 1–2% rosin size and 2–3% alum [$Al_2(SO_4)_3$] will greatly increase the resistance of paper to penetration by water or ink. Pigments such as kaolin clay, calcium carbonate, and titanium dioxide are added in amounts up to 15% to increase opacity and give a better printing surface. Organic dyes and colored pigments are added to produce the highly colored papers used for business and printing papers.

Other additives such as wet-strength resins, retention aids, and starch can be used to give particular properties that are needed. Thus, in order to produce the wide variety of grades of paper now available, the papermaker selects the proper pulps, refining conditions, and additives, and then combines the pulp and additives before sending them on to the paper machine for the final step in the process.

Papermaking Process

Some paper mills are not integrated with pulp mills, and it is necessary for these mills to use dried, baled pulp manufactured at a separate location. Many mills making limited quantities of highly specialized papers fall into this category, as it allows maximum flexibility in selecting the optimum pulps for a particular paper grade. However, the papermaking process is the same regardless of the source of pulp.

After the furnish has been prepared with the proper refining treatment and additives, it is stored in the machine chest and then fed continuously into the paper machine system. A refiner or jordan is placed in this line to give the paper machine operators the opportunity to make small adjustments in the quality of the furnish as needed to give the desired paper properties. Screens and centrifugal cleaners also are included to ensure a high-quality paper.

The papermaking process is essentially a system whereby the pulp is diluted to a very low consistency (about 0.5%) and continuously formed into a sheet of paper at high speeds, and then the water is removed by filtration, pressing, and drying. The basic units of the fourdrinier paper machine are diagrammed in Fig. 28.29 and a picture is shown in Fig. 28.30.

Wet end. The section of the paper machine, where the sheet is formed, is referred to as the “wet end.” The fourdrinier machine is characterized by a headbox that allows the diluted stock to flow through an orifice (slice) onto the flat moving wire. This is actually an endless wire belt that returns on the underside of the machine, thus allowing the process to proceed continuously. Because a low headbox consistency (about 0.5%) is necessary for good formation, the volumes of water handled are very large (about 10,000 gal/min for a machine producing 300 t/day). Much of the water is removed through the wire by the action of the table rolls and foils that support the wires in the forming area immediately following the headbox. At this point the stock consistency has been raised to about 2%, and the stock no longer drains freely. By passing it over suction boxes operating at fairly high vacuum (6–8 in. Hg), the consistency is raised to about 15–20%.

A dandy roll (covered with woven wire) rotating on top of the wet paper is used to improve the formation and can impact a watermark if it contains the proper pattern. The suction roll after the suction boxes has several functions: it removes additional water; it serves as the driving roll for the wire; and it serves as the point at which the paper separates from the wire and passes into the press section while the wire returns to pick up additional pulp at the headbox.

Modern fourdrinier machines are available up to a width of 360 in. and can operate at speeds up to 3,000 ft/min. Newsprint machines are usually the widest and fastest, whereas hose making heavier grades such as linerboard run somewhat more slowly. In the United States, there are several machines capable of producing over 1,000 t/day of linerboard. More specialized grades such as bond and printing papers are usually produced at a lower speed on narrower machines, and 150–250 t/day would be considered a high output.

Many specialized grades such as filter paper and tracing paper are produced on very small, slow machines producing

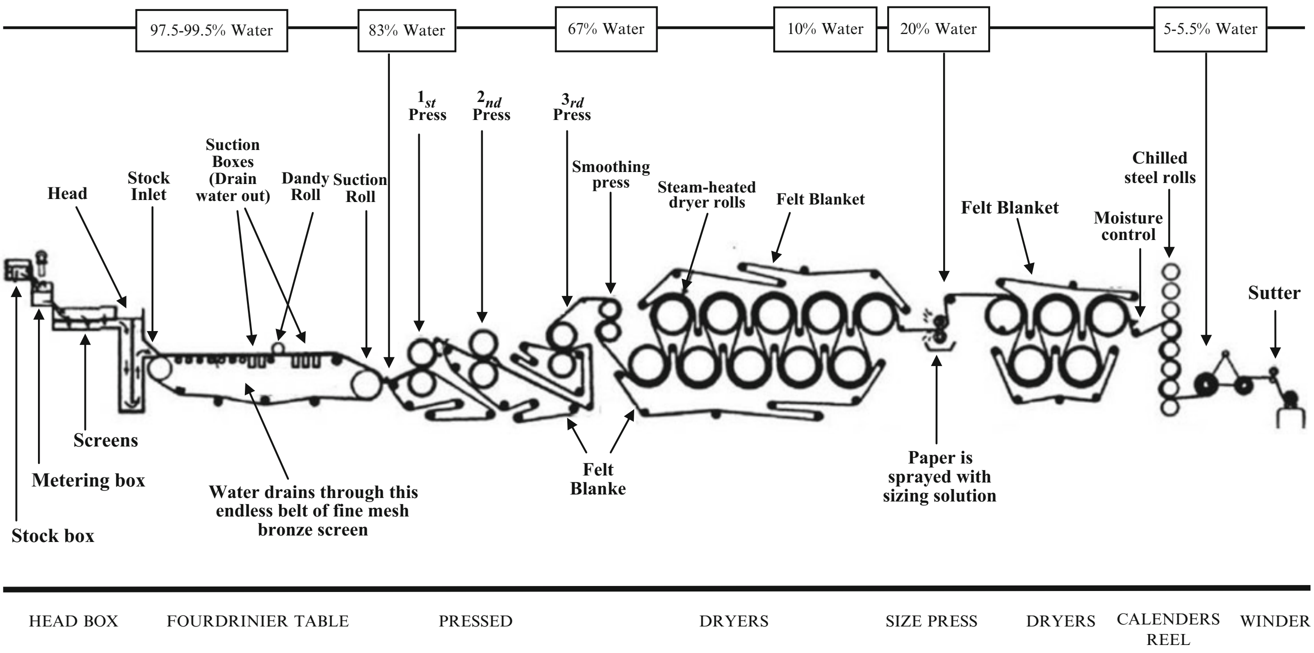

Fig. 28.29 Schematic of a fourdrinier paper machine

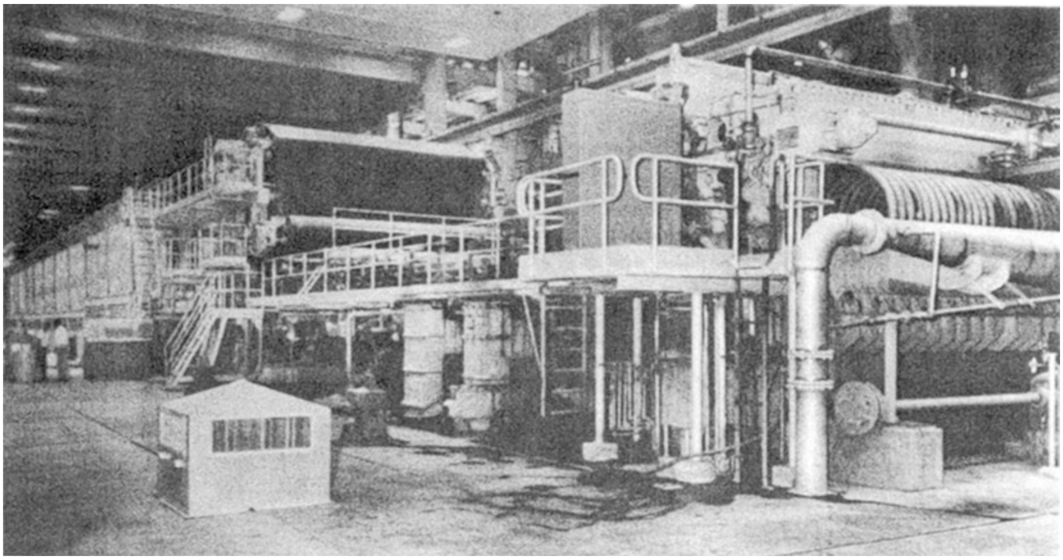

Fig. 28.30 Modern high-speed paper machine (Courtesy Beloit Corp.)

only a few tons per day. Machines making tissue paper for sanitary purposes use modifications of the standard fourdrinier to produce tissue at speeds of up to 5,000 ft/min. Because of the light weight of this paper, it is necessary to make many modifications in the equipment shown in Fig. 28.29.

Other sheet forming methods. Many new methods of forming a sheet of paper are being developed. The most common concept is to introduce the pulp slurry between two converging wires and remove the water from both sides. This is termed “twin-wire” forming, and many variations are now in operation. This technique has many advantages and may eventually replace the fourdrinier.

A second method of forming paper uses the cylinder machine. Actually these machines are used primarily to form the multiply board used in packaging such as cereal boxes. The cylinder wet end consists of one or more (up to eight) cylinder vats, each of which forms a separate wet web of fibers. Each vat contains a woven wire-covered cylinder

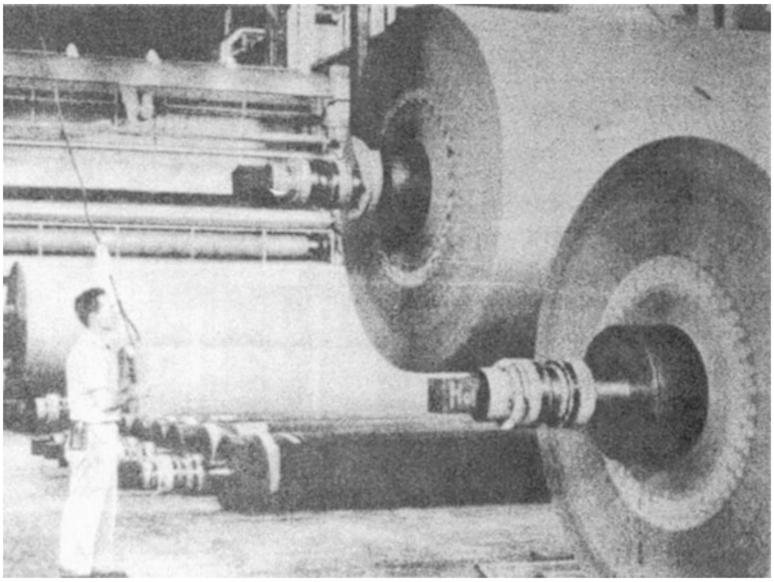

Fig. 28.31 Dry end of a large Fourdriner paper machine (Courtesy of Regis Paper Co.)

rotating in the diluted pulp slurry. The liquid head on the outside of the cylinder is greater than that on the inside, resulting in a flow of water through the wire and out of the vat. The pulp mat that is formed on the face of the cylinder is removed by an endless woolen felt that moves in contact with the cylinder by means of a rubber roll riding on top of the felt.

With machines having more than one cylinder, the same felt moves from one cylinder to the next, and the wet sheets from each cylinder are laminated to each other on the bottom side of the felt. Thus, very heavy papers or boards can be fabricated by multivat machines. Because each vat can be supplied with a different type of pulp, it is possible to make boards with a white surface of high-quality pulp and a center of low-cost pulp from waste newspaper or other cheap grades. Because of hydrodynamic problems, cylinder-machine speeds are limited to about 250 ft/min and widths of about 150 in. However, because of the heavyweight board produced and the widespread use of cheap waste paper for most of the furnish, the cylinder machine is widely used. New forming units looking like miniature fourdrinier units (Ultraformer, Inverformer) have been developed and are rapidly replacing the old-fashioned cylinder vat because their speed is not so limited.

Press section. From the wet end of the machine, the wet sheet is conveyed by woolen felts through a series of roll-type presses for further water removal, increasing the consistency to about 35%. The sheet then is threaded through the dryer section, consisting of a long series of steam-heated cast iron cylinders that reduce the moisture content to approximately 5%, which is about the equilibrium moisture content for cellulosic fibers at 40–50% relative humidity. Tissue machines use one large dryer (called a Yankee dryer), ranging from 8 to 18 ft in diameter. Because of the light weight of the tissue paper, it can be dried at high speeds on a single dryer.

After drying, the paper is compacted and smoothed by passing through a calender stack consisting of a vertical row of highly polished cast iron rolls. Then the paper is wound into rolls on the reel, as shown in Fig. 28.31.

Furnishing and Converting

The objectives in the final stage of the total papermaking system are to improve the paper surface, to reduce rolls and sheets in size, to modify paper for special properties, such as coat or emboss, to convert to finished products, such as bags and corrugated boxes, and to package for shipping. Corrugated boxboard is made by gluing sheets of linerboard to each side of a fluted sheet of the corrugating medium. Papers for packing may be laminated to polyethylene film or aluminum foil, or coated with waxes and hot-melt resins. The printing and bag- and box-making industries depend on the production of many mills that produce the several hundred grades of paper used in the United States, and each user may require special paper characteristics to match its process.

Surface treatments. The quality of many papers is improved by a surface treatment. A size press about two-thirds of the way along the dryer section can apply a solution of starch to improve surface bonding. Also, paper generally is coated to improve printing properties. A surface coating of a pigment (usually kaolin or china clay, calcium carbonate, or titanium dioxide) and an adhesive (such as starch, casein, and others) is applied to the partially dried web by brush, blade, spray, or

Table 28.9 Summary of pollution abatements in pulp and paper mill operations

Type of pollutant	Mill operation	Treatment
Effluents		
Suspended solids (SS): fiber fragments, inerts, clay	Papermaking	Primary—clarification
Pulping residuals	Pulping	Secondary—biological treatment and clarification
Air emissions		
Total reduced sulfur (TRS)	Kraft liquor recovery	Oxidation, precipitation, scrubbing, incineration
Sulfur dioxide	Sulfite pulping	
Particulates	Steam generation	Precipitation, scrubbing
Solid wastes	Effluent treatment	Landfill, utilization, incineration
Toxic wastes: chlorinated compounds	Bleaching	Lime pretreatment, oxidation, biological

other method, and dried during the papermaking (on-machine) operation or in a separate operation. The paper surface is brought to a high finish by passage through the calenders referred to above or through supercalenders. Supercalenders are stacks of alternate steel and densified fiber rolls that create a rubbing action on the sheet, imparting an extra-high gloss to the sheet surface.

Environmental Protection

The manufacture of pulp and paper is a chemical process industry and produces air emissions, effluents, and solid and toxic wastes that are potential hazards. The paper industry uses large volumes of water as a fiber carrier and as a dispersing medium. An increasing volume of water is being recycled, but makeup water still is required to cover losses. A bleached-pulp and paper mill may use 100 m^3 (26,400 gal) of fresh water per metric ton of product and 50,000 m^3 (13.2 million gal) daily for a plant producing 500 metric tons of products.

In addition to the aqueous effluent that the mill must clean up, it must contend with polluted air and solid and toxic wastes. The nature of these emanations, their sources, and their treatments are summarized in Table 28.9. In this connection the paper industry generally has been in good compliance with government environmental regulations although at considerable nonreimbursed capital expense, which amounts to about 10% of the cost of the mill.

Using a revolving cylinder or other equipment (save-alls) in the 1930s, mills recovered for reuse fibers and clay from the paper water (white water) system. In the 1970s, procedures for removal of the fibers and clay from the paper mill effluent were incorporated through settling or clarification or primary effluent treatment. About the same time, secondary effluent treatment (biochemical treatment) of the pulp mill effluent was necessary to remove pulping residuals. The purpose of this treatment is to reduce the biological oxygen demand (BOD) of the effluent, which, if untreated, reduces the oxygen content of the stream to a level incapable of supporting aquatic life. The most common method uses microorganisms that react with the wood sugars and other oxygen-consuming compounds in the spent liquors; this is called the activated-sludge method. The products of primary and secondary treatments are sludges, the handling of which is discussed later under solid wastes.

Two objectionable air emissions have characterized pulp mills for years: the sulfur dioxide of the sulfite pulping mill and the malodorous reduced sulfur compounds (TRS) (mercaptans and hydrogen sulfide) of the kraft mill. Still another less noxious air emission is the particulate matter from steam boilers. Coal-burning boilers also emit sulfur dioxide, as is well known. The treatments for the particulate emissions are given in Table 28.9.

Solid wastes represent the ultimate in mill residues and include the accumulated refuse of the mill and the sludges from primary and secondary effluent treatment. There is difficulty in removing water from the secondary sludge; the primary and secondary sludges often are mixed to aid in water removal, which is important if the sludge is to be incinerated for disposal. The sludges from pulp and paper mills are handled mostly as landfill, and sometimes, if not toxic, they are spread for agricultural purposes.

Since chlorine is no longer used in pulp bleaching, the toxicity of most mill solids is greatly reduced. This toxicity can be further reduced with lime pretreatment and biological treatment. It was a main concern of governmental regulating bodies in the past.

Chemical Commodities Associated with Paper Industry

Although paper is the dominant use of pulp fibers, a variety of commodities are produced from the pulping operations. Besides papermaking fibers, the paper industry produces a specialty pulp called dissolving pulps (pure cellulose) for making a variety of cellulose products. To prepare this cellulose pulp, a prehydrolysis stage to remove the hemicellulose components is needed prior to the kraft delignification [23].

Also after pulping, the black liquor contains, in addition to residual chemicals, significant amounts of dissolved wood components that are useful for many applications. The chemical nature of these organic materials differs considerably between the acid sulfite and kraft process and the wood species.

Cellulose Products

Major uses of dissolving pulps are in the making of the so-called regenerated cellulose and cellulose derivatives [24]. Traditionally, the regenerated cellulose is prepared from cellulose by a series of mercerization (treating with high concentration of alkali), dissolution (by reacting with carbon disulfide in alkalis), and precipitation in acid bath in the form of film (cellophane) or fiber (rayon).

Recently, a new alternative to prepare the regenerated cellulose is by a direct dissolution of cellulose in N-methyl-morpholine-*N*-Oxide (NMMO) followed by a subsequent precipitation of the cellulose filaments in a NMMO–water mixture [24]. These regenerated fibers are called Lyocell fibers, which like rayon fibers are used mainly in the textiles applications.

A variety of cellulose derivatives has been produced including cellulose acetates (for film), cellulose nitrate (explosives), and carboxymethylcellulose (CMC). The latter CMC being a water-soluble polymer is widely used as dispersing or thickening agent in the food, pharmaceutical, and cosmetic industry.

Products from Sulfite Pulping Liquor

Lignosulfonate. The current world-wise production of linosulfonate is about 1,000,000 t/year and the Borregaard Lignotech is the major producer with facilities in six different countries [24]. Lignosulfonates are used mainly in areas of industrial binders and dispersing agents. Also, lignosulfonates have been used to produce vanillin by alkali treatment at elevated temperatures under oxidative conditions. The production of vanillin is around 3,500 t/year [24]. It is used as flavoring agent for food and beverages. Also, vanillin can be obtained from natural sources such as vanilla beans.

Dissolved carbohydrates. In acid sulfite pulping, a portion of wood polysaccharides was hydrolyzed to hexoses and pentoses. These sugars have been used to produce ethanol. The Domsjö mill in Sweden produces the ethanol about 10,000 t/year [24].

Products from Kraft Pulping Liquor

Many useful products can be derived from the kraft pulping liquor of softwood. These include turpentine and tall oil from the wood extractives as well as dimethyl sulfoxide (DMSO) from the kraft lignin. The production of kraft turpentine and tall oil will be discussed in more detail in a later section on "Naval Stores."

Kraft turpentine. It contains mainly the volatile monoterpenes and was isolated in a yield of approximately 10 kg/t of pulp. The major uses of turpentine are in the area of resins, fragrances, and flavors especially for the pine oil production.

Tall oil. It is derived from the nonvolatile extractives, mainly soaps of resin acids and fatty acids. They are separated from the black liquor by acidification. The yield of tall oil might reach ~50 kg/t of pulp. Main components of tall oil are rosin and fatty acids, whereas the remainder forms tall oil pitch. Much of the rosin products are used in the sizing of paper as adhesives and in printing inks whereas a major use of the fatty acids is in alkyd resins.

Kraft lignin. It can be isolated from the black liquor by precipitation with flue gas or acid. Only a few mills produce the kraft lignin due to its limited applications. At present [24], the total production is in the order of 100,000 t/year from Westvaco (USA) and Lignotech (Norway). The major use of kraft lignins is as a dispersant in aqueous solution. Quite often, kraft lignin is further modified by sulfonation to yield products similar to the lignosulfonate derived from the acid sulfite process.

Dimethyl sulfoxide. Dimethyl sulfoxide (DMSO) is an important solvent for many applications including a medicinal of interest in the treatment of arthritis. It is produced from the oxidation of dimethyl sulfide (DMS). DMS is an odorant for natural gas and a solvent recovered from the black liquor. The content of DMS in the black liquor can be increased by reaction with elemental sulfur.

Board and Structural Materials

Lumber, boards, sheets, panels, and other structural materials are manufactured from solid wood and wood veneers, fibers, and particles. Traditional industries producing these products are not generally classified as chemical industries. Recent trends have been on the development of using wood as an engineering material. Among many wood-based composites, the production of wood–polymer composites is one of fast growing segments of the forest

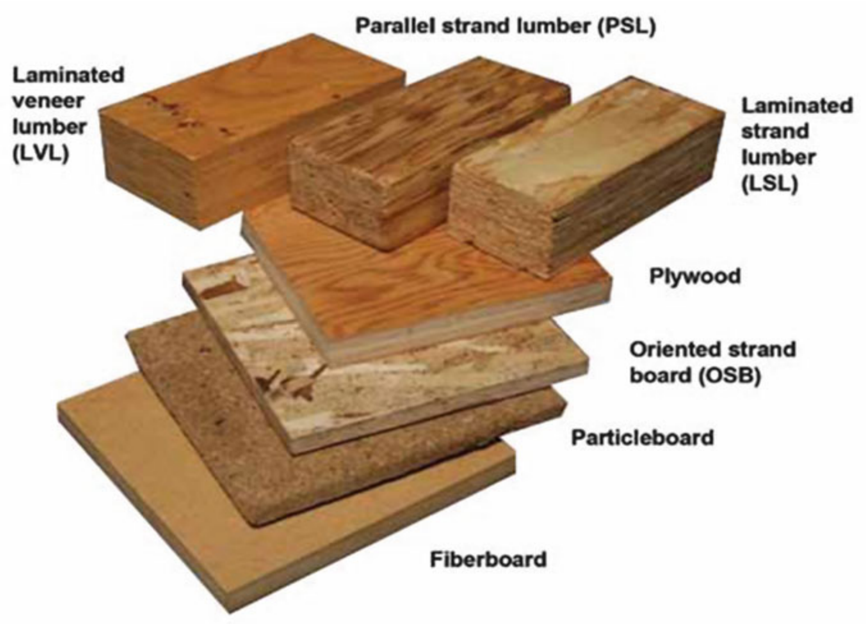

Fig. 28.32 Examples of various composite products. From *top left*, clockwise: LVL, PSL, LSL, plywood, OSB, particleboard, and fiberboard (from Stark et al. [25])

product industry and is a close association between the wood and chemical industry. The composite products represent a more efficient utilization of renewable resources, as all types of wood materials can be applied. Thus, wood adhesives play an increasing role in the forest products industry. Figure 28.32 illustrates the examples of some wood-based composites [25].

Lumber

A log, when sawn, yields round timber, ties, or lumber of varying quality. There are two different types of mills (hardwood and softwood) for manufacturing lumber. Hardwood lumbers are used commonly for flooring, paneling, or manufacture into furniture, cabinetwork, or pallets, whereas softwood lumbers are suitable for both construction and manufacture applications.

A hardwood sawmill typically produces 1–15 million board feet annually. Most of the lumber produced is 4/4 thick (4/4, pronounced “four quarter,” is the number of quarter inches of thickness; 8/4 would be 2 in. thick). Lengths run from 4 to 16 ft; width is random. The primary quality factor is the amount of large clear areas. The lumber is dried and then sawn into smaller pieces for furniture, millwork, and cabinets.

A softwood sawmill typically produces in excess of 200 million board feet annually. Most of the lumber is 8/4 nominal thickness (would be sold as 2 in. by a specified width), although the actual thickness is 1.5 in. Lengths are usually 8–20 ft; widths would typically be 4, 6, 8, or 10 in. nominal size or 3–1/2, 5–1/2, 7–1/2, and 9–1/4 in. actual size. Most softwood lumber will be dried, planed, and graded, and then used “as is” without additional manufacturing, except cutting to length at times.

A modern softwood sawmill producing lumber for construction is highly automated, with high manufacturing efficiency and high production, thereby assuring good profitability and good stewardship of the natural resource. In a typical mill, logs are debarked, scanned for metal, scanned for size to determine the best sawing pattern, and sawn into lumber and cants at the headrig. Then cants are resawn into lumber. Any pieces with wane (wane is the absence of wood) are edged. Lumber is then trimmed and sorted by size. Most of these processing procedures are computer controlled with manual override possible. Volume conversion efficiencies can exceed 65%; the 35% of the log not converted into lumber is used for pulp and for fuel. After the green lumber is produced, the lumber is kiln dried, planed, and graded according to the rules of the American Lumber Standard.

Wood Adhesives

Adhesives play a decisive role in making composite materials and their performance. Thermosetting (heat-curing) resins are commonly used as adhesives in the manufacture of wood-based composites [25]. These include the phenol-formaldehyde, urea-formaldehyde, melamine-formaldehyde, and isocyanate resins.

Phenol-formaldehyde (PF) resin. The PF resin is typically used in the manufacture of construction plywood and oriented strandboard (OSB). The slow-curing process of this phenolic resin generally requires a higher temperature and longer press time than other resins. Cured phenolic resins remain chemically stable at elevated temperatures. The darker color of phenoic resin as compared with other resins may be less attractive for product applications such as interior paneling and furniture.

Urea-formaldehyde (UF) resin. The UF resin is commonly used in the manufacture of products for interior applications. It is lighter in color and easier to cure but more sensitive to moisture and heat [25]. Excessive heat exposure could breakdown the resin and release the formaldehyde, which is a growing health concern.

Melamine-formaldehyde (MF) resin. This resin is more expensive than the PF resin and is used primarily for decorative laminates and paper coating. Also, it is often used as an ingredient to improve the performance of UF resin.

Isocyanate-based resin. This isocyanate adhesive is a polymeric methylene diisocyanate (pMDI). It is more costly than the PF resins but has an advantage of being easier to cure. Although the cured pMDI resin poses no recognized health concerns, special precautionary protective measures are needed for the facility handling the pMDI, as the uncured resin can result in chemical sensitization for persons exposed to it [25].

Future perspectives. Current emphases on using renewable (green) products have stimulated a renewed interest in using bio-based adhesives [25]. The protein-based glues were widely used in the construction plywood prior to the early 1970s. They were replaced in mid-1970s by the PF resin being a better bonding resin. However, the performance of soy protein-based resin systems has been improved considerably in recent years and could be quite comparable to phenolic resin in performance now.

Also, useful adhesives have been prepared from the phenolic lignin (a major wood component) or tannin (being rich in wood bark). Extensive efforts are continued to improve the performance of these natural adhesives. The development of lignin-based adhesives is of special significance, as plenty of technical lignin is readily available as by-products from the pulping operations.

Laminated Timber (Glulam)

Glulam is one of the oldest glued engineered wood products [25]. It consists of two or more layers of lumber that are glued together with the grain of all layers parallel to the length. The maximum lamination thickness is about 2 in. A major advantage of this process is that the larger size of timber can be produced from small-diameter trees. By combining the lumber in glulam, the production of large structural elements like 100 ft is very common. This represents an improved utilization of forest resources.

Structural Composite Lumber

The structural composite lumbers [25] are produced from gluing smaller pieces of wood together into sizes common for the solid-sawn lumber. This process like Glulam greatly enhances the utilization of small trees. Different composite lumbers have been produced based on the nature of wood elements used.

Laminated veneer lumber (*LVL*). This LVL lumber is produced by laminating veneer with all plies parallel to the length. Specially graded veneer are selected for the product to achieve the desired engineering properties.

Parallel strand lumber (*PSL*). PSL is a composite of wood strand elements with fibers oriented primarily along the length. The least dimension of the strands must not exceed 0.25 in. The product is often used for large beams and columns, typically as a replacement of solid-sawn lumber or glulam.

Laminated strand lumber (*LSL*) *and oriented strand lumber* (*OSL*). Both LSL and OSL represent an extension of the technology used to produce OSB. The main difference is that the aspect ratio of strands used in LSL is higher than for OSL. For example, one type of LSL uses strands about 12 in. in length, which is somewhat longer than that commonly used for OSB. The LSL and OSL products are used for band joists in floor construction and as substitutes for studs and rafters in wall and roof construction.

Conventionally Wood-Based Composite Panels

Wood-based composites panels contain several products that differ primarily on the size of wood elements used. These variations lead to the production of plywood, oriented strand board, particle board, and hardboard (Fig. 28.33) [25].

Plywood. Plywood panels consist of several large thin wood veneer-type layers joined with adhesive. Some or all of the layers are sheets of veneer. Other layers, particularly in the core, may be particleboard, hardboard, lumber strips, or special materials. The fiber direction of each layer is at right angles to that of the adjoining layer. This cross-banding makes plywood more uniform and less anisotropic than

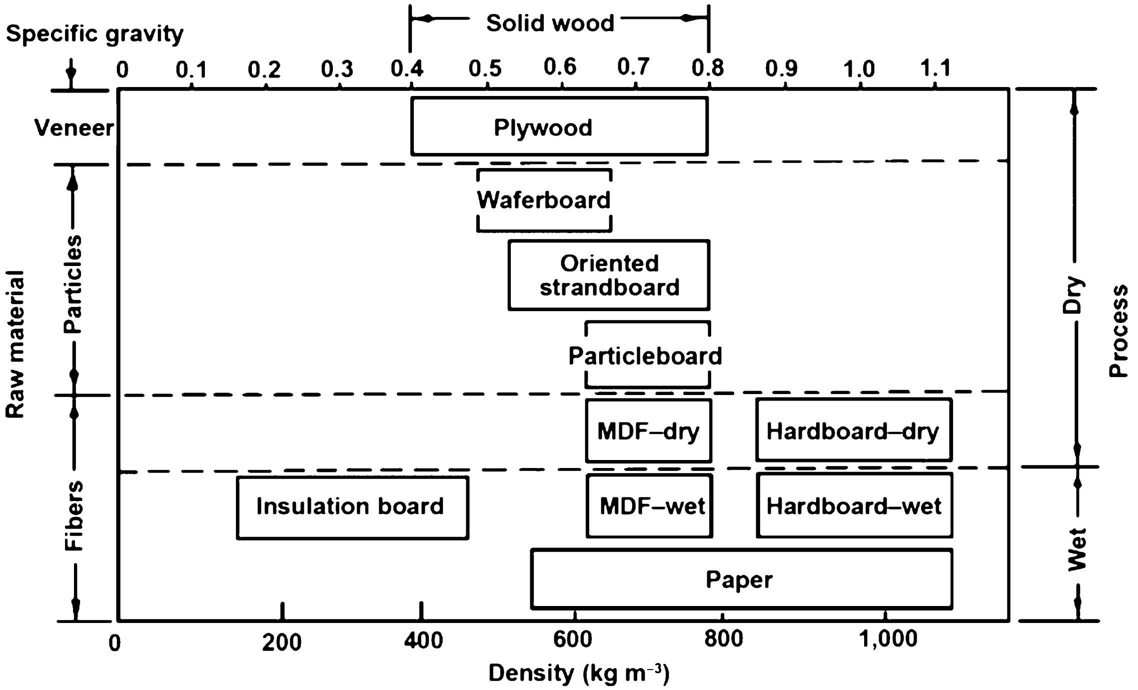

Fig. 28.33 Classification of wood composite panels by particle size, density, and process [76]. Note that insulation board is now known as cellulosic fiberboard (from Stark et al. [25])

lumber; its properties in the direction of panel length resemble those in the direction of panel width. Cross-banding affects strength in a logical way in both directions of the plane.

The panel is as strong as the combined layers. Because in any one of the two directions transverse layers contribute practically no strength, plywood is roughly one-half as strong as lumber is lengthwise. But by the same principle plywood is stronger than lumber in the direction of width and can therefore be thinner. Moreover, it does not split like solid-wood products. Plywood and lumber properties naturally are the same in the thickness direction, provided that the layers are adequately bonded together. Cross-banding also imparts dimensional stability to the plywood.

Many plywood panels are 6 mm (1/4 in.) thick; the thinnest measure about 1 mm, and the thickest several centimeters. In addition to house sheathing and siding, much plywood is used in cabinets, billboards, furniture, bookshelves, concrete forms, skins of flush doors, paneling, boxes, in mobile homes and for trailers. Plywood is also used as a component in other engineered wood products like the LVL mentioned earlier.

Oriented strandboard (*OSB*). OSB is an engineered product from thin wood strands bonded together with a water-resistant resin. The wood strands typically have an aspect ratio (strand length divided by width) of at least 3. Since small trees and crooked stems can be effectively utilized, the raw material cost, compared to product cost, is about 38%. Plywood requires more than double the raw material cost. Lumber requires even more. As a result, OSB has rapidly gained acceptance in the construction market. OSB plant capacities exceed 20 million cubic meters annually; more new plants are being constructed each year.

The typical material flow in an OSB plant provides very high conversion efficiencies. Any “waste” is used for fuel for the manufacturing process. Logs are debarked, heated in hot water, cut into short lengths, flaked into wafers or strands using knives. The strands are dried in large drum driers, coated with adhesive, and assembled into a thick mat. The strands in the mat are oriented to provide parallel strands in the various layers in the mat. The mat is compressed and heated, and cut to size. By controlling the panel density, the amount of adhesive, and the strand orientation, a panel can be designed and produced with properties that meet the engineering needs of the building designer and engineer [2].

If lumber were used to do to the same job as OSB, an excess of eight billion more board feet of lumber would be needed annually, and this lumber would have to come from larger, higher quality, more expensive trees. It is easy to understand why OSB is considered as the wood product of future in the construction business.

Similarly, the LVL, PSL, and LSL, and OSL are also rapidly moving into the market as engineered wood products [26, 27].

Particleboard. Particleboards are composed of discrete particles of wood bonded together by a synthetic resin adhesive, most commonly urea-formaldehyde or phenol-formaldehyde. The material is consolidated and the resin cured under heat and pressure. The strength of the product depends mainly upon the adhesive, although the size and shape of the particles influence strength properties. They may be fine slivers, coarse slivers, planar shavings, shreds, or flakes, and they are divided into two main groups: (1) hammer-mill-produced particles (slivers and splinters from solid wood residues, feather-like wisps to block-shaped pieces from planar shavings) and (2) cutter-type particles, sometimes termed "engineered" particles (flakes and shreds).

Hammer-milled particles usually vary appreciably in size. Dry raw material produces greater amounts of fines than green wood. Cutting machines (either cylinder-type or rotating-disc-type) give more uniform particles, with the length dimension in the direction of the grain of the wood. The thickness, size, and shape of particles influence the strength of the board. Boards made from sawdust have the lowest strength properties, hammer-milled particles give boards of intermediate strength, and solid wood, cut to flakes, gives boards of highest strength. The latter often are referred to as wafer boards.

Particleboards may be made in a wide range of densities. Low-density or insulating types are a comparatively recent development in Central Europe, whereas the high-density-hardboard types are a U.S. development. Most particleboard production is in the middle-density range.

Particleboards most commonly are used as core stock for veneer in furniture and in doors, as interior panels for walls and ceilings, as subflooring, as sheathing and siding, and as components in interior millwork. The dense types are used in the same way as fiberboard hardboard, described earlier. Both dense particleboards and hardboards, after receiving a surface coating, may be printed with decorative designs.

Particleboard production has increased rapidly, both in the United States and worldwide. Until recently the most significant limitation on the market for particleboard was the availability of inexpensive plywood. Now plywood is no longer inexpensive relative to particleboard, and the cost factor would seem to favor continued growth of the particleboard industry.

Fiberboard. Fiberboard is the name for rigid or semirigid sheet materials of widely varying densities and thicknesses manufactured from wood or other vegetable fibers. The board is formed by the felting of the fibers from a water slurry or an air suspension to produce a mat. Bonding agents may be incorporated to increase the strength, and other materials may be added to give special properties, such as resistance to moisture, fire, or decay.

Fiberboards are manufactured primarily for panels, insulation, and cover materials in buildings and other structures where flat sheets of moderate strength and/or insulating capacity are required. They also are used as components in doors, cupboards, cabinets, furniture, and mill work. Fiberboard is normally classified by density and can be made by either dry or wet processes.

Dry processes are applicable to boards with high density (hardboard) and medium density (MDF). Wet processes are applicable to both high-density hardboard and low-density cellulosic fiberboard. These products are manufactured for many specific uses, and they vary accordingly.

The dry-process fiberboard is made in a similar fashion to the formation of particleboard. In general, the resin and other additives are applied to the fibers by spraying in a blender or refiner. The adhesive-coated fibers are then air-laid into a mat followed by pressing.

The wet-process hardboard differs from the dry-process fiberboard in several ways. First, water is used as the fiber distribution medium for the mat formation. The technology is really an extension of papermaking process. Second, some wet-process boards are made without additional binders, as the hemicelluloses and lignin present may serve as the binder. Also, under heat and pressure, the lignin will further serve as a thermosetting adhesive. Thus, refining plays a significant role in developing the strength of the wet-process hardboards.

For making the cellulosic fiberboard, the process is similar to the papermaking technology. It does not require a binder as in the wet-process hard board. After drying, the board may be treated for specific applications. Cellulosic fiberboard products include sound-deadening board, insulation boards, structural and nonstructural sheathings, backer board, and roof decking in various thicknesses.

Wood-Polymer Composites

The wood-polymer composites (WPC) represent a class of composites containing a wood and a polymer component [25, 28, 29]. The wood element is usually a flour or fiber. Among others, the plastic polymers are of special significance and consist of two major types (thermoset and thermoplastic). The thermoset polymers are the plastics and once cured cannot be remelted by heating. These include the phenolic resin used as adhesive in making the wood-based composites discussed earlier. In contrast, the thermoplastics can be melted repeatedly and are used in making many diverse commercial products ranging from milk jugs, grocery bags to the siding for homes. The production of these wood thermoplastic composites is one of the fast growing segments of the wood industry.

Wood elements. Wood flour is the most commonly used in the WPC application and contains mainly very short fiber bundles. It can be produced from any woody materials including scrap wood from various processing plants (planer shavings, chips, and sawdust). In case of using wood fibers, they can be produced by a variety of pulping methods (Table 28.4) depending on the desired quality of the WPC. Fibers can be used instead of flour and serve as reinforcement of the matrix. They enhance the mechanical property but fibers are more difficult to handle due to the low bulk density. More intensive mixing and the use of special feeding equipment may be necessary to handle longer fibers.

Thermoplastic polymers. Due to the low thermal stability of wood flour, the plastics that can be processed at temperatures below 200°C are commonly used in the WPC. These polymers include the polyethylene (PE), polypropylene (PP), polystyrene (PS), and polyvinyl chloride (PVC) and the PE is wildly used in North America.

Wood-thermoplastic composites (*WTC*). WTC has two types based on the relative proportion of wood elements and polymers [25]. The first type has a high thermoplastic content (>60%) and the wood element serves as reinforcement of the plastic matrix or filler. In another type, the thermoplastic serves as a binder for the wood elements much like the conventional wood-based composites.

The bulk of commercial WTC products have a high thermoplastic content. A variety of WTC products are manufactured by varying the forming processes. The most common types of product-forming involve forcing molten material through a die (sheet or profile extrusion) or into a cold mold (injection molding); or pressing in calendars (calendering) or between mold halves (thermoforming and compression molding). A profile extrusion yields products such as decking, siding, railings, and window profiles. An injection-molded process produces the consumer household goods and furniture parts, which are gaining acceptance.

Also, a major application of the molded products would be for interior uses in automobiles, such as head liners, door panels, and dashboards. Although this is a low-cost and low-performance application, it represents a very large-volume market. Indeed, wood is already utilized in applications of this type, but as a finely ground flour that serves as filler (up to 40%) in extrusion-molded polyolefin products. The use of recycled fiber offers the potential of even greater cost reductions and could also alleviate the solid waste disposable problems.

Modified Wood

Wood has a number of disadvantageous properties, as described earlier in this chapter. It is biodegradable, flammable, dimensionally unstable to water, and degradable by ultraviolet light, acids, and bases. There has been a considerable amount of research expended over the years to correct these defective properties for both solid wood and reconstituted wood products.

Heat treatments. A wood product of improved dimensional stability can be produced by heat treatment of wood at temperatures varying from 150 to 320°C [30]. For good temperature control and avoiding the strength loss, a heat treatment is performed under the surface of molten metal or a fused salt for exclusion of oxygen. The modified wood product is referred as Staybwood in United States or Thermonwood in Finland. The heat treatment causes the loss of water followed by modification and degradation of the wood components, especially the hemicelluloses. The wood could become brittle from an extensive heat treatment.

Polyethylene glycol treatment (*PEG*). Treatment of wood with polyethylene glycol (PEG) is the most commonly used method to impart dimensional stability to wood. PEG in a water solution can be used to permeate the lumens and penetrate the cell wall. A 30–50% solution of PEG in water generally is used on green wood; no pressure is required. Treatment times are adjusted so that a uniform uptake of 25–30% of PEG is achieved, based on the dry weight of the wood; temperatures range from 21 to 60°C. The wood may require weeks of soaking, depending on species, density, and thickness. After treatment, the wood is dried in a well-ventilated space, preferably heated.

The PEG is not "fixed" or cured in the wood, and it leaches out if the wood contacts water. For this reason, PEG-treated wood usually is finished with a penetrating oil or polyurethane varnish. PEG is used primarily to treat cross-sections of trees for plaques, clock faces, and tabletops. It also is used to stabilize bowls and other turnings, carvings, and rifle stocks, and to treat archaeological water-logged wood.

Resin impregnation. Resin impregnation can be used to add bulking agents to the wood cell wall. These resins have a low degree of polymerization, or the monomers are polymerized after impregnation. The best fiber-penetrating thermosetting resins are the highly water-soluble, phenol formaldehyde resin-forming systems with low initial molecular weights. Green or dry veneers usually are treated by soaking or pressure treatment with a water-soluble resin in a 30% aqueous solution. Following impregnation, the wood is dried slowly and then heated at about 150°C for 20 min to set the resin.

Similarly, laminates of treated wood are constructed by gluing the individual sheets together. This product, called Impreg, contains 25–35% resin and has a density about 20% higher than the original wood and an antishrink efficiency

(ASE) of about 65%. As with PEG, the water-soluble resin penetrates the cell wall and keeps the wood in a swollen state. Unlike PEG, the phenol formaldehyde resin is cured by heating to form a high-molecular-weight, water-insoluble resin in the cell wall. Thus, Impreg can be used in contact with water. Its compressive strength is higher than that of untreated wood, but it has much less toughness. It shows considerable resistance to decay and termite and marine-borer attack.

Treating of wood with phenolic resins imparts high acid resistance, greatly increases the temperature to which wood can be heated without appreciable change in properties, and increases electrical resistance. The largest industrial application of Impreg is in die molds for automobile body parts and other uses. Despite its high cost, the dimensional stability and plasticity of Impreg make it commercially viable.

Compreg. Compreg is a highly dense product obtained by applying pressure to dry, resin-treated veneers during heat cure. It offers most of the advantages of Impreg. Its mechanical properties are appreciably better than those of the original uncompressed wood because of a 2–3-fold increase in density (1,350 kg/m^3). The strength properties of Compreg are increased in proportion to the degree of compression. Only its toughness is lower than that of untreated wood, although greater than that of Impreg. Because of the plasticizing action of the resin-forming materials, treated wood can be compressed under considerably lower pressures than dry, untreated wood. For example, when subjected to a pressure of only 1.7 MPa (244 psi) at 149°C, treated spruce, cottonwood, and aspen wood, dried to a moisture content of about 6% but not cured, are compressed to about half the original thickness and a specific gravity of about 1.0.

In a 24-h water-soaking test, Compreg has an ASE value of 95%. The rate of water pickup is so slow that complete swelling equilibrium of a 13-mm specimen is not reached after 1 year at room temperature. The product is brown and can be buffed to a high polish. Compreg is produced commercially in small quantities and is used for knife handles, gears, certain musical instruments, and decorative articles.

Vinyl polymer composites. Composites of wood with vinyl polymers have been developed. Because the vinyl polymers are clear, colorless, thermoplastic materials, they do not significantly discolor the wood; thus its natural beauty is retained, whereas the phenolic resins darken the wood. However, the hygroscopic characteristics of the wood substance are unaffected because little, if any, resin penetrates the cell walls; the ASE is only about 10–15%. The high resin content (70–100%) greatly reduces the normally high void volume of wood, however. Thus, the elimination of this important pathway for vapor diffusion slows down the response of the wood substance to changes in relative humidity, and its moisture resistance is greatly improved compared with the original wood. The hardness of the wood–plastic composite also is greatly improved.

A variety of vinyl monomers, such as methyl methacrylate and styrene, may be used. Complete filling of the cell lumens and other voids (in the "full-cell process") is easily accomplished by first subjecting the wood to a partial vacuum (about 0.3 in. of Hg) and then covering it with the monomer and soaking it for 2–6 h, depending upon the species of wood and its dimensions. Some penetration of the monomer into the cell walls also may be obtained by using a diffusion process, such as a solvent-exchange method.

Polymerization of the vinyl monomer in the wood may be done with either radiation or free radical catalysts. The polymerization of the vinyl monomers in both processes depends upon the same mechanism, that is, initiation by free radicals. In the radiation process, the gamma rays passing through the monomer and the woody tissue create a large number of excited and ionized molecules, many of which break into fragments, namely organic free radicals (R^-). These act as the initiator for the polymerization of an unsaturated monomer. Alternatively, the free radicals may be formed by thermal decomposition of compounds involving a weak bond. Commercially, the catalyst 2,2′-azobisisobutyronitrile now is most widely used, as it forms free radicals at a lower temperature than benzoyl peroxide [31].

If the end use of the wood–polymer composite requires an abrasive (sanding) or cutting process that brings about high temperatures, the thermoplastic polymer will melt, causing machining difficulties. To prevent such melting, a cross-linking substance such as diethylene glycol dimethacrylate is added to the monomer before impregnation into the wood (about 5% of the volume of the monomer). Wood–plastic materials are used in parquet flooring, certain sporting equipment, musical instruments, and decorative articles.

Chemical modifications. Wood also can be modified by chemical reactions directly with the hydroxyl groups present in wood polymer. This treatment confers bulk to the cell wall with the help of a permanently bonded chemical. Many reactive chemicals have been used to modify wood. For best results, the chemicals should be capable of reacting with the wood hydroxyl groups under neutral or mildly alkaline conditions at temperatures below 120°C. The chemical system should be simple and must be capable of swelling the wood structure to facilitate penetration. The complete molecule must react quickly with wood components, yielding stable chemical bonds; the treated wood still must possess the desirable properties of untreated wood.

The treatments of wood [32] with anhydrides, epoxides, and isocyanates appear to be most attractive conferring ASE

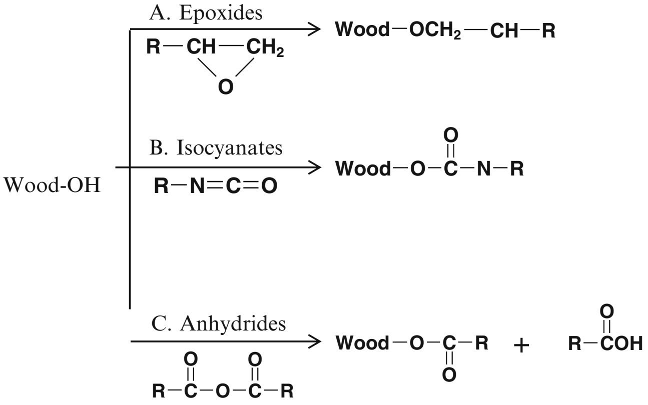

Fig. 28.34 Chemical modification of wood based on the reactions of hydroxyl groups

values of 60–75% at chemical weight gains of 20–30%. These chemical reactions as illustrated in Fig. 28.34 induced the formation of stable chemical linkages with the hydroxyl groups of wood polymers.

Of several anhydrides studied, acetic anhydride reacted the most readily. Reactions were carried out by refluxing the wood in a xylene/acetic anhydride solution or with acetic anhydride vapors alone at 120°C. With this system, for each mole of acetate bonded onto the wood a mole of acetic acid is generated as a by-product. Although this by-product generation is a disadvantage of the process, the chemical system does penetrate and react quickly with wood, without a catalyst. It is not so sensitive to moisture as are the epoxide and isocyanate systems.

A very facile dip acetylation procedure was developed for wood chips and fibers. The wood is dried at 105°C and then dipped in acetic anhydride for 1 min and drained. Then the sample is placed in a preheated (120°C) reactor for different lengths of time, depending on the degree of substitution of acetyl groups desired in the sample [33]. The swelling of aspen flakeboard made from such chemically modified flakes is dramatically reduced. For example, while unmodified flake board swelled by over 60% after immersion in water for 5 days, the modified material swelled by only about 8–22%, depending on the extent of chemical modification.

Acetylated wood [30] is now a commercial product being sold by Titanwood in Amhem, The Netherlands. It is under the name of Accoya and available in several species of wood in Europe, North America, and Asia.

Preservative Treatment of Wood

Wood, as a natural plant tissue, is subject to attack by fungi, insects, and marine borers. Some species of wood are more resistant to decay than others (e.g., the heartwood of cedars, cypress, and redwood) because of the presence of natural toxic substances among the extractable components. Most woods, however, are rapidly attacked when used in contact with soil or water, or when exposed to high relative humidities without adequate air circulation. Wood for such service conditions requires chemical treatment with toxic chemicals, collectively termed wood preservatives. The service life of wood may be increased 5–15-fold, depending upon the conditions of preservative treatment and the nature of the service.

The preservative treatment of wood is the second largest chemical wood-processing industry; pulp and paper manufacture is the most important. The more important types of wood products treated are shown in Fig. 28.35.

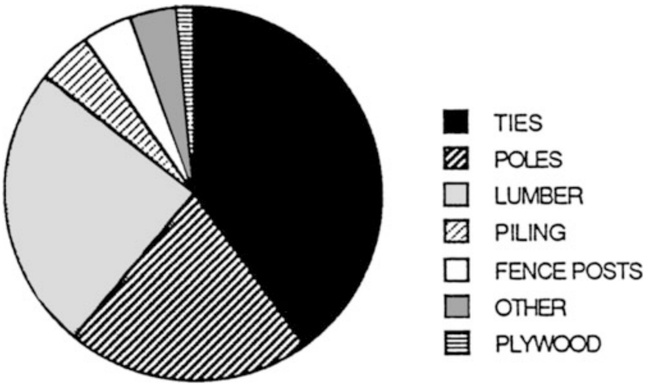

Fig. 28.35 Relative distribution of products treated with preservative

Preservative Chemicals

Owing to their toxic nature, all the commercial wood preservatives presently used in the United States are effective in preventing attack by microorganisms. However, because of concern that these chemicals will have a deleterious effect on the environment, alternative methods based on nontoxic procedures also are being investigated. These nonconventional approaches are based on chemical modification, and are described briefly at the end of this section. Wood preservatives are often classified as the oil-borne and water-borne preservatives [34].

Oil-borne type. Major preservatives of this type are creosote and pentachlorophenol. Creosote from coal tar is the most widely used wood preservative for several reasons: (1) it is highly toxic to wood-destroying organisms; (2) it has a high degree of permanence due to its relative insolubility in water and its low volatility; (3) it is easily applied, with deep penetration easily obtained; and (4) it is relatively cheap and widely available. For general outdoor service in structural timbers, poles, posts, piling, and mine props, and for marine uses, coal-tar creosote is the best and most important preservative. Because of its odor, dark color, and the fact that creosote-treated wood usually cannot be painted, creosote is unsuitable for finished lumber and for interior use.

Coal-tar creosote is a mixture of aromatic hydrocarbons containing appreciable amounts of tar acids and bases (up to about 5% of each), and has a boiling range between 200 and 355°C. The important hydrocarbons present include fluorene, anthracene, phenanthrene, and some naphthalene. The tar acids are mainly phenols, creosols, xylenols, and naphthols; the tar bases consist of pyridines, quinolines, and acridines.

Often coal tar or petroleum oil is mixed with the coal-tar creosote, in amounts up to 50%, as a means of lowering preservative costs. Because coal tar and petroleum have a low toxicity, their mixtures with creosote are less toxic than is creosote alone.

A number of phenols, especially chlorinated phenols and certain metal–organic compounds, such as copper naphthenate and phenylmercury oleate, are effective preservatives. Pentachlorophenol and copper naphthenate are most commonly used, and are carried into the wood in 1–5% solutions in petroleum oil. Pentachlorophenol is colorless, and can be applied in clear volatile mineral oils to mill-work and window sash requiring a clean, nonswelling, and paintable treatment.

Water-borne type. Copper is the primary biocide used in many wood preservative formulations. Chromated copper arsenate (CCA) and ammoniacal copper zinc arsenate (ACZA) had been the two major waterborne preservatives used in the United States, especially when cleanliness and paintability of the treated wood are required. Wood treated with CCA (commonly called green treated) dominated the treated-wood market from the late 1970s until 2004. Due to concerns over the exposure and disposal issues of CCA, now, CCA-treated products are generally not available at retail lumber yards. It can no longer be used for treatment of lumber to be used in residential decks or playground equipment. Substitutes for CCA include a copper boronazole compound and ammoniacal copper quat (ACQ). Those preservatives contain amine- or ammonia-complexed alkaline copper (II) and an organic co-biocide to control copper-tolerant fungi.

Preservation Process

Two methods are generally used for applying preservatives to wood: nonpressure and pressure processes. A variety of nonpressure processes have been used ranging from brushing, soaking to a thermal or vacuum process. The pressure process being more effective is commonly used in industrial applications. It consists of a full-cell process (Bethell) and an empty-cell process (Rueping and Lowry). They give deeper penetrations and more positive results than any of the nonpressure methods. The wood, on steel cars, is run into a long horizontal cylinder, which is closed and filled with preservative. Pressure is applied, forcing the preservative into the wood.

Nonpressure process. Brush and spray treatments usually give only limited protection because the penetration or depth of capillary absorption is slight. Dip treatments give slightly better protection. Organic chemicals dissolved in clear petroleum solvents often are applied to window sash and similar products by a dip treatment of 1–3 min.

The cold soaking of seasoned wood in low-viscosity preservative oil for several hours or days and the steeping of green or seasoned wood in waterborne preservatives for several days are methods sometimes employed for posts, lumber, and timbers on a limited basis. The diffusion process employs the water-borne preservatives that will diffuse out of the treating solution into the water in green or wet wood.

The most effective of the nonpressure processes is the thermal method of applying coal-tar creosote or other oil-soluble preservatives, such as pentachlorophenol solution. The wood is heated in the preservative liquid in an open tank for several hours, after which it is quickly submerged in cold preservative in which it is allowed to remain for several hours. This is accomplished either by transferring the wood at the proper time from the hot tank to the cold tank or by draining the hot preservative and quickly refilling the tank with cooler preservative. During the hot treatment, the air in the wood expands, and some is expelled. Heating also lowers the viscosity of the preservative so that there is better penetration. When the cooling takes place, the remaining air in the wood contracts, creating a partial vacuum that draws the preservative into the wood. For coal-tar creosote, the hot bath is at 210–235°F, and the cold bath at about 100°F. This temperature is required to keep the preservative fluid.

The hot- and cold-bath process is widely used for treating poles and, to a lesser extent, for fence posts, lumber, and timbers. This process gives the most effective results of the common nonpressure processes, which most nearly approach those obtained by the pressure processes.

The vacuum processes involve putting the wood under a vacuum to draw out part of the air. The wood may be subjected to a vacuum alone or to steaming and a vacuum before being submerged in a cold preservative. These methods are used to a limited extent in the treatment of lumber, timber, and millwork.

Pressure process. In commercial practice, wood is most often treated by immersing it in a preservative in a high-pressure apparatus and applying pressure to drive the preservative into the wood. Pressure processes differ in details, but the general principle is the same.

The empty-cell process seeks deep penetration with a relatively low net retention of preservative by forcing out the bulk liquid in the wood cells, leaving the internal capillary structure coated with preservative. The preservative liquid is forced under pressure into the wood, containing either its normal air content (Lowry process) or an excess of air, by first subjecting the wood to air pressure before applying the preservative under pressure (Rueping process). In the former case, the preservative is put in the cylinder containing the wood at atmospheric pressure, and, in the latter case, under air pressure of 25–100 psi. After the wood has been subjected to the hot preservative (about 190–200°F) under pressure (100–200 psi in the Lowry process and 150–200 psi in the Rueping process) and the pressure has been released, the back pressure of the compressed air in the wood forces out the free liquid from the wood. As much as 20–60% of the injected preservative may be recovered, yet good depth of penetration of the preservative is achieved.

The full-cell process seeks to fill the cell lumens of the wood with the preservative liquid, giving retention of a maximum quantity of preservative. The wood in the cylinder first is subjected to a vacuum of not less than 22 in. Hg for 15–60 min, to remove as much air as possible from the wood. The cylinder then is filled with hot treating liquid without admitting air. The maximum temperature for creosote and its solutions is 210°F, and for water-borne preservatives it is 120–150°F, depending upon the preservative. Then, the liquid is placed under a pressure of 125–200 psi, and the temperature and pressure are maintained for the desired length of time, usually several hours. After the liquid is drawn from the cylinder, a short vacuum is applied to free the charge of surface-dripping preservative.

Preservative Retention

Retention of preservative is generally specified in terms of the weight of preservative per cubic foot of wood, based on the total weight of preservative retained and the total volume of wood treated in a charge. Penetration and retention vary widely between different species of wood, as well as with woods of the same species grown in different areas. In most species, heartwood is much more difficult to penetrate than sapwood. Also, within each annual growth ring there is variability in penetration, the earlywood generally being more easily treated than the latewood.

The American Wood-Preservers' Association Standards specify methods of analysis to determine penetration and retention. They also specify minimum retention amounts for different preservatives according to the commodity, the species, the pretreatment of the wood, such as kiln drying, and the end use of the commodity. Heavier retention is required for products in contact with the ground (poles, timbers, etc.) or with marine waters (piles, timbers, etc.). Unprotected wood in contact with the ground is subject to severe attack by fungi and insects, and, in contact with seawater, it is quickly destroyed by marine borers. For wood products to be used in contact with the ground or marine waters, creosote is the major preservative employed because it can be readily impregnated to give high retention and good protection, and it is not leached out by water.

Increasing environmental regulations are causing greater restrictions on the use of traditional wood preservatives and alternate, nonpolluting methods are urgently needed. The use of CCA to treat wood for residential structures was phased out at the end of 2003. Arsenic, a carcinogen, imparts resistance to rot and termite damage, but there are concerns that it leaches from wood and exposes children. This forces the industry to develop more environmentally friendly preservatives [35].

Nonconventional Wood Preservation

The chemical modification of wood as a possible preservative treatment for wood is based on the theory that enzymes (like cellulases) must contact directly with the substrate (cellulose), and this substrate must have a specific configuration. If the chemical nature of cellulosic substrate is changed, this highly selective enzymatic reaction cannot take place. A major modification process is to change the hydrophilic nature of wood, which can be achieved by a thermal or chemical process as indicated earlier. In most cases, water a necessity for decay organisms is excluded from biological sites.

The chemicals used for modification need not be toxic to the organism because their action renders the substrate unrecognizable as a food source to support microbial growth. For wood preservation, this means that it is possible to treat wood in such a manner that attack by wood-destroying fungi will be prevented, and the material will be safe for humans to handle. For applications of wood in which human contact is essential and nontoxic preservatives may well be specified or required in the future. An added benefit to most of the chemically modified woods is that the resulting bulking action gives the treated wood very good dimensional stability.

A key chemical modification of wood involves the reaction of their hydroxyl groups with chemical reagents to form a covalent bond between the two (Fig. 28.34) as discussed earlier related to the dimensional stability treatments. A review on this subject shows that treatments with acetic anhydride, dimethyl sulfate, acrylonitrile, butylene oxide, phenyl isocyanate, and propiolactone all give good rot resistance at a 17–25 weight percent gain (WPG) [36]. The decay resistance of acetylated wood is proportional to the WPG, and the degree of dimensional stability also is proportional to the WPG; so the exclusion of cell wall or biological water may be a very important factor in the decay resistance mechanism [37].

In preliminary tests, alkylene oxide-treated southern pine was found to be resistant to termite attack and attack from the marine borers *Teredo* (shipworm) and *Limnoria*.

In conclusion, the modification of wood by heat treatments or by chemical reactions using acetic anhydride results in treated wood that is dimensionally stable and resistant to attack by fungi without the use of toxic chemicals [30]. The high chemical treatment level required for effectiveness may result in a rather expensive treatment. However, for those products where both the Rot resistance and dimensional stability are important, the present state of the technology is close to a viable industrial process as reflected in the commercial production of acetylated wood [30].

Fire-Retardant Treatment of Wood

The Romans first treated wood for fire retardancy in the first century AD. They used solutions of alum and vinegar to protect their boats against fire. In 1820, Gay-Lussac advocated the use of ammonium phosphates and borax for treating cellulosic material. Many of the promising inorganic chemicals used to day were identified between 1800 and 1870. Since then, the development of fire retardants for wood has accelerated. Commercially treated wood became available after the U.S. Navy (1895) specified its use in ship construction, and New York City (1899) required its use in buildings over 12 stories tall. Production reached over 65 million board feet in 1943, but by 1964 only 32 million board feet was treated annually [38].

However, starting in 1979 changes were made in some building codes that allowed structural changes if fire-retardant (FR) treated wood was used in place of untreated plywood for roof sheathing. The structural changes resulted in sufficient savings such that FR-treated wood was utilized more extensively. Also the use of FR-treated plywood was mandated at other specific sites such as prisons.

Fire-retardant treatments for wood can be grouped into two general classes: (1) those impregnated into the wood or incorporated into wood composite products and (2) those applied as paint or surface coatings [39]. Chemical impregnation has the greater use, primarily for new materials, whereas coatings have been limited primarily to materials in existing constructions. There are advantages and disadvantages to each class. Coatings are applied easily, and they are economical. Chemical impregnation usually involves full-cell pressure treatment and can be costly.

A coating is subject to abrasion or wear that can destroy the effectiveness of the fire retardant. Chemical impregnations deposit the fire retardant within the wood, so that if the surface is abraded, chemicals are still present. On-site application of surface coatings requires strict control of the amount applied to ensure correct loading levels for a particular flame spread rating.

Both coating and impregnation systems are based on the same chemical compounds although the formulations for each vary. Among the most commonly used chemicals for impregnation treatments are diammonium phosphate, ammonium sulfate, borax, boric acid, zinc chloride, and most recently the leach-resistant amino-resin systems.

The fire-retardant chemicals have different characteristics with respect to fire resistance. Ammonium phosphate, for example, is effective in checking both flaming and glowing; borax is good in checking flaming but is not a satisfactory glow retardant. Boric acid is excellent in stopping glow but not so effective in retarding flaming. Because of these different characteristics, mixtures of chemicals usually are employed in treating formulations.

Fire-Retardant Formulations

Many chemicals have been evaluated for their effectiveness as FRs. Today most FRs for wood are based on phosphorus, nitrogen, boron, aluminum trihydrate, and a few other compounds. Phosphorus and nitrogen frequently are used together because they behave synergistically; amino-resins are an example of such a combination.

Most FR formulations are not resistant to leaching by water. Therefore, there have been increased efforts to develop leach-resistant chemicals that can be impregnated into wood products for use in exterior or high-humidity applications. Some of the proposed leach-resistant systems include chemical combinations that form insoluble complexes, amino-resin systems, and monomers that polymerize in the wood. A common amino-resin system for exterior use is dicyandiamidephosphoric acid formaldehyde. Guanylurea phosphate-boric acid also is a commonly used organic phosphate salt for modern commercial FR wood.

The American Wood-Preservers' Association Standards specified the four types of FR formulations given in Table 28.10. Many newer formulations have been developed by commercial enterprises and are proprietary.

The impregnation methods are similar to those employed for the preservative treatment of wood by water-borne salts using pressure processes. The maximum temperature of the solution must not exceed 140°F for formulation Types A, B, and D, and must not be above 160°F for Type C. After

Table 28.10 Formulations of fire retardants

	Type			
Chemicals (%)	*A*	*B*	*C*	*D*
Ammonium phosphate	–	–	10	–
Ammonium sulfate	–	10	60	35
Boric acid	–	10	–	25
Sodium dichromate	20	40	–	5
Sodium tetraborate	–	–	10	
Zinc chloride	80	40	–	35

treatment, the wood must be dried to a moisture content of 19% or less. For most uses, the wood is kiln-dried to a moisture content of below 10%.

For effective fire protection larger amounts of chemicals must be deposited in the wood than the amounts necessary when water-borne chemicals are used for decay prevention. Whereas for the water-soluble toxic salts retentions from 0.22 to 1.00 lb/ft^3 of wood are specified according to commodity standards in order to give good protection against decay and insects, as much as 5–6 lb of some fire retardants may be required for a high degree of effectiveness against fire. Usually, however smaller amounts will give a good degree of protection. For example, formulation Type B when impregnated in amounts of 1.5–3 lb/ft^3 of wood provides a combined protection against fire, decay, and insects. Because the amino-resin systems are leach-resistant, high application levels are not necessary in practice.

Fire retardancy of wood involves a complex series of simultaneous chemical reactions, the products of which take part in subsequent reactions. Most FRs used for wood increase the dehydration reactions that occur during thermal degradation so that more char and fewer combustible volatiles are produced. The mechanism by which this happens depends on the particular FR and the thermal–physical environment. The effectiveness of a FR treatment depends upon the performance rating of the treated material when tested in accordance with ASTM E84 (no greater flame spread than 25).

Conversion of Wood to Energy, Fuels, and Chemicals

Wood has been a source of energy and chemicals for hundreds of years and continues to be an important raw material for specific chemicals. The use of wood as a primary source of industrial chemicals decreased dramatically in the 1940s when oil became the preferred raw material. Current interest in wood-derived fuels and chemicals has been rekindled by an increasing demand of energy and the soaring prices of petroleum products. This current biorefinery development is sustainable and also would help to reduce our dependence on fossil fuels and the greenhouse gas emission to the environment. The term “silvi-chemicals” sometimes is used to refer to wood-derived chemicals analogous to petrochemicals.

One of the recent developments in wood-based biorefinery is on the preextraction of hemicelluloses from wood as this would greatly enhance the overall utilization of wood [4]. The conversion of wood to energy or chemicals in general involves a chemical, biological, thermal, or a combined process. The specific process used varies with the nature of intended product. In this section, the improved wood utilization by preextraction of hemicelluloses, direct combustion, saccharification, fermentation, and a variety of thermal decomposition process (carbonization, pyrolysis, gasification, and liquefaction) is discussed to reflect their recent developments [40, 41].

Improved Wood Utilization by Pre-extraction of Hemicelluloses

The paper industry as noted earlier represents the largest scale in the isolation of wood polysaccharides as papermaking fibers. In the production of pulp fibers for making stable white papers, the lignin component has to be totally removed by a series of pulping and bleaching operations. Although the dominant kraft pulping is an effective process in the sense of being able to pulp all kind of plant materials, it is not an efficient operation, as approximately one third of the polysaccharides are degraded and lost resulting from the alkaline degradation reactions (Fig. 28.23).

Naturally, many wood-based biorefinery projects have emphasized on the extraction and isolation of those hemicelluloses [4, 42–45], which otherwise would be degraded in a typical kraft cooking process. The extraction methods examined ranged from a hot-water (autohydrolysis) extraction to a mild alkali treatment. The extent of the hemicellulose extraction would vary with the intent to utilize those extracted chips for the production of papermaking fibers or solid wood products like wood pellets.

A technology based on the hot-water extraction of sugar maple in the 160–170°C range has been extensively studied with respect to the characteristics and potential application of the water extracts and the extracted chips [4, 42, 45]. For example, the sugar components of water extracts after hydrolysis were shown being very responsive to fermentation for the production of biofuels (ethanol and butanol) or biopolymers like polyhydroxy-alkanoates (PHA). The extracted chips can be used for the production of papermaking fibers or reconstituted wood products with improved properties. Interestingly, the water extraction step significantly enhanced the subsequent alkaline (Kraft) delignification reaction [45].

Direct Combustion

The concept of using wood as a source of energy through direct combustion dates back to the very beginning of human existence. As soon as early people learned to use fire, wood became the major source of energy. It is important to note that fuel is still the major use of wood on a worldwide basis, amounting to an estimated 1.2×10^9 m^3/year compared with 0.8×10^9 m^3/year for lumber and other solid wood products, 0.34×10^9 m^3/year for pulp, and 0.2×10^9 m^3/year for other uses. Thus, on a global basis, nearly 50% of the wood harvest is used directly for fuel. In many nonindustrialized countries, fuel amounts to 80–90% of total wood consumption, compared with an average of 7% for industrialized regions.

The average stored energy content of wood is 8,600 BTU/lb. Variations in heat values for wood as a function of species occur within a relatively narrow range of 8,000–10,000 BTU/lb. Bark values are slightly higher than wood values, about 10,000 BTU/lb.

The greater the oxygen content of a carbon compound or carbonaceous substance, the lower the heat of combustion. Lignin, with an elemental analysis of $C_{10}H_{11}O_2$ compared with $C_6H_{10}O_5$ for cellulose, has a lower degree of oxidation and a higher heat of combustion than cellulose. The fossil fuels that have very low or no oxygen content have much higher energy contents, for example 12,000–13,500 BTU/lb for coal, 18,000–19,900 BTU/lb for oil, and 18,550 BTU/lb for natural gas.

Wood and other biomass materials are hygroscopic and retain substantial amounts of moisture (15–60%). Hence, some of the thermal energy of the wood is lost in vaporizing this water to steam during combustion. In addition, wood has a lower density than coal, so that a greater volume of material must be gathered and transported to provide the same heating value as that of coal. Wood has a negligible sulfur content, less than 0.1% compared with much larger amounts in coal (avg. 2%) and petroleum. Sulfur from coal and petroleum creates serious environmental problems by causing acid rain. Also, ash from coal presents a disposal problem and creates unhealthy fly ash, whereas the ash content of wood is less than 0.5%. The only environmental hazard produced from burning wood as a fuel is the production of particulates.

Most wood and wood-derived materials (spent pulping liquors) that are used for energy are consumed by the forest products industry itself. The source of this fuel is almost entirely in the wood-processing and manufacturing operations, termed “manufacturing residuals” or “mill residues.” Forest residues from logging operations and the noncommercial trees in the forest also are utilized for fuels.

Wood wastes supply the forest products industry with roughly 40–50% of the energy requirements in the form of spent liquors and wood and bark residues. The spent pulping liquor contains 40–50% of the wood as dissolved lignin and a large variety of other organic compounds. The spent liquor is used almost totally, after evaporation to about 65% solids, to produce steam and to recover the inorganic chemicals used in the pulping operation. The Tomlinson furnace is used almost universally and is the most efficient system for combined energy and chemical recovery yet devised.

The mixed wood and bark residues burned directly are collectively termed “hog fuel.” Over the past decade, there has been a trend to channel more and more of the cleaner, drier, and larger-sized mill residues into raw materials for products. The coarse wood residues (slabs, trim, edgings, etc.) are chipped and sent to pulp mills. Also, considerable sawdust now is being pulped instead of being burned for fuel. Some of the residues, including shavings, also are used for particleboard. This means that hog fuel contains the less desirable, dirtier, and wetter forms of waste.

Combustion technology. The hog fuel boiler represents the conventional technology of using wood for energy to produce process steam. Modern wood-fuel boilers have traveling grates and use mechanical draft fans. Many are of gigantic size, handling as much as 500,000 lb of wood per hour. Spreader stokes distribute the fuel evenly over the large grate areas to ensure efficient combustion. The ash can be removed continuously with traveling grates. Modern instrumentation meters air flow, controls fuel-to-air ratios, and meters combustion efficiency and stack emissions. With these developments, the energy recovery and environmental acceptability of wood-burning systems have been improved in the forest products industry.

The deterioration of hog fuel quality referred to above makes it more difficult to obtain efficient combustion, high reliability, and low stack emissions simultaneously. To overcome this difficulty, the fuel can be processed before combustion to remove dirt and moisture and produce clean-burning, efficient fuel. This can be done by drying, screening, grinding, washing, and pelletizing or densification of the hog fuel in order to remove noncombustible dirt and moisture, reduce the size of large and slow-burning material, and agglomerate small and fine material.

Size uniformity is important for ease in transportation, storage, and fuel feeding. Dirt and moisture reduction reduces transportation costs, promotes efficient combustion, and minimizes air emissions. Another approach for using low-quality hog fuel is the development of improved combustors. Examples are: (1) the fluidized-bed combustors, which obtain excellent wood combustion at relatively high efficiencies with low-quality, nonuniform fuels; and (2) the pyrolytic burner, which has very low stack emissions with relatively high thermal efficiencies and wood combustion rates.

Present-day wood-fired boiler systems are complicated and cost considerably more than a comparable petroleum-fired installation. As much as 25% of the capital cost is in the fuel-handling equipment, and another 20% is in the air pollution control system. Because of the high capital costs and the lower thermal efficiencies of burning wood compared with oil (68% vs. 82%), the success of the wood-fired systems depends on the low cost of the wood fuel supplies.

The North American forest products industry has been successful in developing useful technologies for the production of energy from wood residues as process heat or steam, which are cost-effective. New technologies promise even greater economic benefits.

Upgrading of solid fuels. To overcome the drawbacks of using the hog fuels as noted earlier, the recent production of densified wood fuels like pellet has been increased quite substantially. The raw materials include shavings and sawdust from sawmills as well as tree branches or low-quality wood. These solid fuel products are uniform in size and quality, and also easy to handle and transport. Wood pellets have a cylindrical form being 6–8 mm in diameter with varying length and are increasingly used in residential heating and industrial operations for generating heat and power. The energy value for 1 t of softwood pellets was estimated to be about 5 MWh, which is equal to 0.5 m^3 of oil [40]. Thus, wood pellets appear to be attractive as a good substitute for fossil fuels in many applications.

Cogeneration technology. Cogeneration is the concurrent generation of electricity and the use of exhaust heat, usually in the form of process steam, for manufacturing operations. This is done by burning fuel (in this case, wood) to make high-pressure steam, 600–1,200 lb/in.^{2}, passing this steam through a back-pressure or extraction turbine to drive a generator, and then using the steam exhausted from the turbine at lower pressures, 50–300 lb/in.^{2}, for process heat. This technology gets full use of the energy contained in the fuel. Wood at 55% moisture will generate power at about 60% efficiency.

The forest products industry is a major user of cogeneration technology, as it requires large quantities of process steam as well as electricity. It produces about 50% of its electricity needs in this way. The pulp and paper industry alone is the largest producer of energy by cogeneration of any U.S. industry. Electricity self-sufficiency is likely to increase to 80–90% for forest industries in the future through cogeneration. However, there is a minimum plant size for economical power generation. Steam usage should be more than 70,000–120,000 lb/h, equivalent to 3–5 MW of back pressure, for a plant economically to employ cogeneration systems.

Saccharification

Saccharification represents a key step to convert wood polysaccharides to liquid fuels and other chemicals. It involves the hydrolysis of cellulose and hemicelluloses to a mixture of hexoses (glucose, galactose, and mannose) and pentoses (xylose and arabinose). These monomeric sugars can then be fermented to yield ethyl alcohol (ethanol or grain alcohol, C_2H_5OH) by proper microorganism in the same way that ethanol is produced from grains or fruits. Obviously the concept of ethanol production from wood is not a new one and the polysaccharide character of wood has been known for over 100 years. A major challenge on the use of wood for the ethanol production as compared to other substrates like sugarcane or corn has been on the difficulties in separating and hydrolyzing the crystalline cellulose component in wood.

The ethanol production from the nonwoody materials is rather straightforward. To cope with the high oil prices, Brazil took the dramatic step of shifting to a much greater use of fuel alcohol produced from the sugars in sugarcane. One wood hydrolysis plant was constructed, but it was uneconomical to operate and was shut down. Since 2002, they have used the gasoline–bioethanol blend (gasohol) for motor fuels. Brazil is now second to the U.S. in the production of bioethanol.

In the United States, the interest in producing alcohols from renewable resources was revitalized by the dramatic increase in the price of petroleum in the 1970s and the push to decrease oil imports by substituting gasohol. Now, all the gasoline at gas pumps contains bioethanol (10%), which is produced largely from corn and the commercial production of cellulosic ethanol may be expected to begin in few years. Bioethanols produced from starchy substrates or sugars in food crops are generally referred as the first generation or noncellulosic ethanol, whereas the second generation ethanol refers to the cellulosic ethanol being derived from the inedible lignocellulosic materials like wood or switch grass.

Both acids and enzymes can be used to hydrolyze the cellulose to glucose, but so far only acids have been utilized commercially for wood hydrolysis to sugars notably in Russia. They continued the expansion of wood hydrolysis facilities, and about 40 such plants are presently in operation. All the Russian plants are based on dilute sulfuric acid in percolation towers. Cellulose being a partially crystalline material is closely associated with other cell wall components (hemicelluloses and lignin) in woody materials and relatively inaccessible to the chemical or enzymatic actions. A key technical challenge is in developing an economically viable saccharification process for cellulose. The characteristics of the acid and the enzymatic hydrolysis process are discussed below.

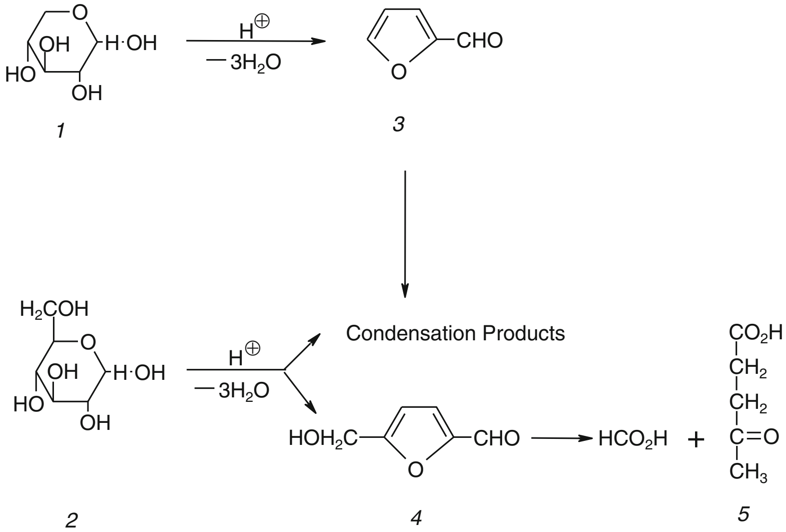

Fig. 28.36 Acid-catalyzed degradation of sugars: *1* (xylose), *2* (glucose), *3* (2-furaldehyde), *4* (5-hydroxymethyl-2-furaldehyde), and *5* (levulinic acid)

Acid hydrolysis. The acid hydrolysis of wood polysaccharides is a classic reaction and has been extensively studied related to the sugar formation [46]. Cellulose, the major component of wood, gives over 90% yield of pure glucose under laboratory hydrolysis conditions. Hemicelluloses hydrolyze much more easily and rapidly than the cellulose and give a mixture of sugars (xylose, arabinose, mannose, galactose, and glucose). Temperatures and acid concentrations that hydrolyze the cellulose to glucose in a matter of a few hours readily convert much of the hemicelluloses into simple sugars in minutes. Under industrial conditions of hydrolysis, the sugars formed undergo decomposition, with the pentoses decomposing more rapidly than the hexoses (Fig. 28.36). Thus, the conditions of hydrolysis cause variations in the ratio and yields of the various sugars due to (1) their different rates of formation by hydrolysis and (2) their different rates of decomposition. The sugar degradation products especially the furan-types compounds are the major inhibitors for the subsequent fermentation process.

The polysaccharide components of wood (holocellulose) may be hydrolyzed by two general methods: by strong acids, such as 70–72% sulfuric acid or 40–45% hydrochloric acid; or by dilute acids, such as 0.5–2.0% sulfuric acid. The hydrolysis by strong acids proceeds somewhat like a homogeneous system following a first-order reaction, as the cellulose component swells quickly and become soluble as illustrated in Reaction Scheme A (Fig. 28.37).

In dilute-acid hydrolysis, the reactions are heterogeneous and more complex, because no swelling and solubilizing of the cellulose occurs. Cleavage of the insoluble cellulose (B_3) gives the low-molecular-weight oligosaccharides (intermediate products), which are then rapidly hydrolyzed to simple sugars as indicated in Scheme B. The Reaction B_3 proceeds slowly and is the limiting factor for the whole process.

A variety of industrial processes on the hydrolysis of lignocellulosic materials for the ethanol production have been developed and evaluated over the years. They can be grouped into the concentrated acid and the dilute acid process as briefly discussed in the following.

The concentrated acid process. This process type is based on the concept that concentrated acid is capable to decrystallize the cellulose molecule and this facilitates the subsequent dilute acid hydrolysis. The yield of sugars is quite high being over 90%. Around the World War II period, the Bergius–Rheinau process was developed in Germany and was based on concentrated cold hydrochloric acids conducted at low temperatures. On the other hand, a concentrated sulfuric acid process was further developed by the U.S. Department of Agriculture (USDA) at the Northern Regional Research Laboratory in Peoria and the process is often termed the “Peoria Process.” A similar process was developed in Japan and they commercialized a concentrated sulfuric acid process in 1948.

For the concentrated acid process, the high yield of sugars is offset by higher capital costs for corrosion-resistant equipment and higher operating costs for acid recovery plus acid losses. In the 1980s, considerable efforts to improve the Peoria Process were conducted in U.S. especially at Tennessee Valley Authority (TVA) and at Purdue University. Among others, how to minimize the use of sulfuric acid and the development of a cost-effective recycling of the acid are key factors affecting the economic feasibility of the process.

Also, there is a continued interest in the concentrated hydrochloric process. In 2004, a pilot plant unit was installed in Domsjö, Sweden to evaluate the relative merit of a concentrated hydrochloric acid process (CHAP) [24, 40]. Interestingly, a recent patent indicates that the HCl can be

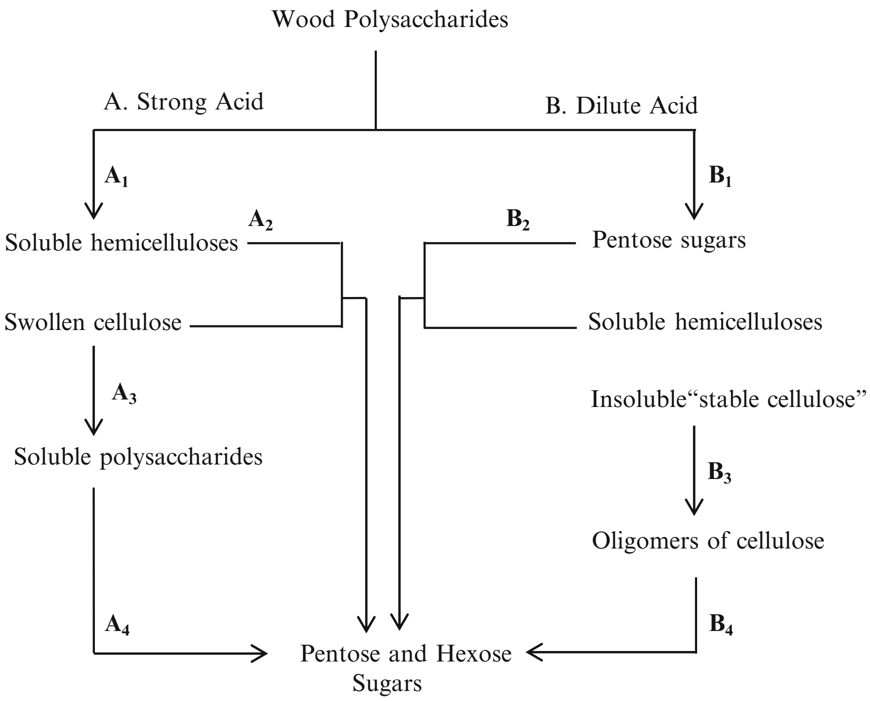

Fig. 28.37 Reaction schemes for the acid hydrolysis of wood polysaccharides

reconverted directly from an aqueous solution by using an immiscible extractant in a hydrocarbon diluent having a boiling above 210°C [47]. This improved process if confirmed would make the Bergius–Rheinau or CHAP process more attractive economically.

The dilute acid process. The Scholler–Tornesch process is a classic example for wood hydrolysis with dilute sulfuric acid conducted in the 170–180°C (338–356°F) range. It was developed originally in Germany and later modified by the research conducted at the U.S. Forest Products Laboratory (FPL) in Madison, Wisconsin. This improved process is also known as the Madison process.

In the Madison process, dilute sulfuric acid with an average concentration of 0.5% is pressed through wood in the form of sawdust and shavings. Regular flow of the acid and of the resulting sugar solution is one of the two principal requirements; the other is a lignin residue that can be discharged from the pressure vessels without manual labor. Both depend upon careful charging of the wood, which should not contain too many very fine particles, and upon maintaining a pressure differential of not more than 5–6 lb/in.^{2} between the top and the bottom of the digester.

The digesters or percolators are pressure hydrolyzing vessels, commonly employing a pressure of 150 lb/in.^{2}, and having a capacity of 2,000 ft^3 each. In the original Scholler plants in Germany, the digesters were lined with lead and acid-proof brick; in the Madison process a lining of "Everdur" metal was found to give sufficient protection.

The wood, about 15 t, is pressed down with steam and then is heated by direct steam, after which the acid is introduced. The practice in Germany was to bring the dilute acid into the digester in several batches, with rest periods of about 30 min, heating the wood to temperatures of 130°C (266°F) at first, then to 180°C (356°F), while keeping the temperature of the entering acid 10–20°C lower. A total of about 14 h was required to exhaust the wood, yielding about 50 lb of carbohydrates for 100 lb of dry wood substance. In the Madison process, continuous flow of the acid, and, correspondingly, of the sugar solution, is provided— in other words, continuous percolation. The cycle is thereby reduced to 6 h, and the yields are increased somewhat. The lignin is blown out of the digester by opening the specially constructed bottom valves while the vessel is still under pressure.

The sugar solutions usually contain about 5% sulfuric acid. The solutions, still under pressure (150 lb/in.^{2}), are flash-evaporated to 35 lb/in.^{2}, neutralized with lime at that pressure, and filtered. Calcium sulfate is much less soluble at the elevated temperature corresponding to the pressure than it is at 100°C. This is a fortunate circumstance, for it must be removed to an extent sufficient to avoid difficulties caused by the formation of incrustations in the subsequent alcohol distillation. The filtered solution is cooled by further flash evaporation and heat exchanged with water to the fermentation temperature. Sugar yields from coniferous woods (softwoods) are about 50% at an average concentration of 5%. When fermented, the average ethyl alcohol yield per ton of drywoods is 50–60 gal and sometimes higher.

The U.S. FPL in cooperation with the TVA had studied a two-stage dilute acid hydrolysis process based in part on studies of Cederquist in Sweden during the 1950s. The first stage (prehydrolysis) selectively removes the hemicellulosic sugars with dilute sulfuric acid at about 170°C prior to hydrolysis of the lignocellulosic residue to glucose in the higher temperature (230°C) second stage. The two-stage dilute acid process has a number of important advantages: (1) the carbohydrates are fractionated into hemicellulosic sugars and glucose, so that the separate utilization of each fraction is facilitated; (2) glucose is isolated in moderately good yield (~50%); (3) the glucose solution from the second stage is moderately concentrated (~10–12%); and (4) the consumption of acid and steam is relatively low.

A detailed model for the dilute acid hydrolysis of cellulose was developed at FPL in connection with studies of the two-stage dilute sulfuric acid hydrolysis process [48]. The model incorporates the effect of the neutralizing capacity of the substrate, the presence of readily hydrolyzable cellulose, and the reversion reactions of glucose in acid solution. Although general in nature, the model was developed specifically for application to the dilute, sulfuric acid hydrolysis of prehydrolyzed wood. A computer program simulating the new model can be used to predict yields of free glucose, reducing sugars, reversion material, remaining cellulose, and glucose loss due to dehydration as a function of acid concentration, temperature, and reaction time.

Also, Sweden has actively engaged in an international development project on the ethanol production from lignocellulosic feedstock [24, 40]. In 2004, a pilot plant was installed in Domsjö to evaluate the relative merits for three different saccharification processes. These include a concentrated hydrochloride acid process (CHAP) conducted at 20–40°C, a dilute acid process termed CASH (Canada-America-Sweden-Hydrolysis), and an enzymatic hydrolysis process. The CASH process includes the use of SO_2 and dilute sulfuric acid in two separate stages and appears to be the most promising among the three processes [24]. The pilot plant has the capacity to process 2 t of woody biomass per day to produce about 400 L of ethanol. Interestingly, both the CASH and the FBL-TVA systems share the same process features, as the sugars derived from the easily hydrolyzed hemicelluloses were removed prior to the subsequent hydrolysis of the cellulose component. This two-stage process naturally would minimize the further degradation of the pentoses derived from the hemicelluloses. The overall benefits of these two-stage processes as noted earlier would increase the total sugar production, reduce the formation of inhibitors like furfural (Fig. 28.36), and thus improve the overall fermentation process.

Major concerns of the acid-catalyzed saccharification as noted earlier are the equipment corrosion and the recovery of the acid used. In case of the dilute acid process, the generation of furfural and 5-hydroxyfurfural (Fig. 28.36) is also a major concern, as they are inhibitory to the subsequent fermentation process. Thus, a detoxification step is needed prior to the fermentation process.

Enzymatic hydrolysis. Saccharification of wood polysaccharides to sugars can also be accomplished by enzymatic techniques. In general, a mixture of cellulases containing endoglucanases, exoglucanases, and β-glucosidases was used to hydrolyze the cellulose [49, 50], whereas hemicellulases are used for the hemicellulose hydrolysis [51]. Important cellulolytic enzymes are produced from the fungus *Trichoderma reesi*. Enzymatic hydrolysis can be conducted as such or combined together with fermentation as a single process. The latter simultaneous saccharification and fermentation (SSF) process would greatly facilitate the ethanol production process [51, 52]. However, the most common microorganism used for the fermentation of hydrolyzates from the lignocellulosic substrates is *Saccharomyces cerevisiae*, which ferments the hexoses but not the pentoses.

The enzymatic hydrolysis as compared to acid hydrolysis has the advantages of being conducted under milder conditions with temperatures up to 60°C in the pH range of 2.5–5.5. It also produces less undesirable products like furfural which inhibits the fermentation reaction. However, the requirements of extensive pretreatment of wood substrates [52–54] and the high cost of enzymes [55] are the major concerns for its industrial applications [56].

Enzymatic methods show the biggest promise for conversion of waste paper from municipal waste into glucose for ethanol production. Because paper is composed primarily of wood cellulose fibers, the enzyme inhibition due to lack of accessibility with whole wood is partially alleviated. As mentioned previously, waste paper can represent up to 50% of typical municipal waste. Currently the separated paper from the waste is just burned for its fuel value.

Pretreatments. The current emphasis in the United States has been on the enzymatic hydrolysis process and how this hydrolysis process could be facilitated by a thermal or chemical pretreatment [52–54]. The main purpose of pretreatments is to enhance the accessibility of cellulose, which can be achieved by a controlled removal of the hemicelluloses or lignin components. Treatments with chemicals include dilute acid, alkali, ozone, organosolv, sulfite (SPORL), or green liquor systems. Thermal treatments include the steam explosion, ammonia fiber explosion, and carbon dioxide explosion process. The specific application of these methods seems to vary with nature of substrates and potential applications of the treated materials. For example, the softwood after a bisulfite-based SPORL treatment was very responsive to enzymatic hydrolysis and the subsequent fermentation process. An ethanol

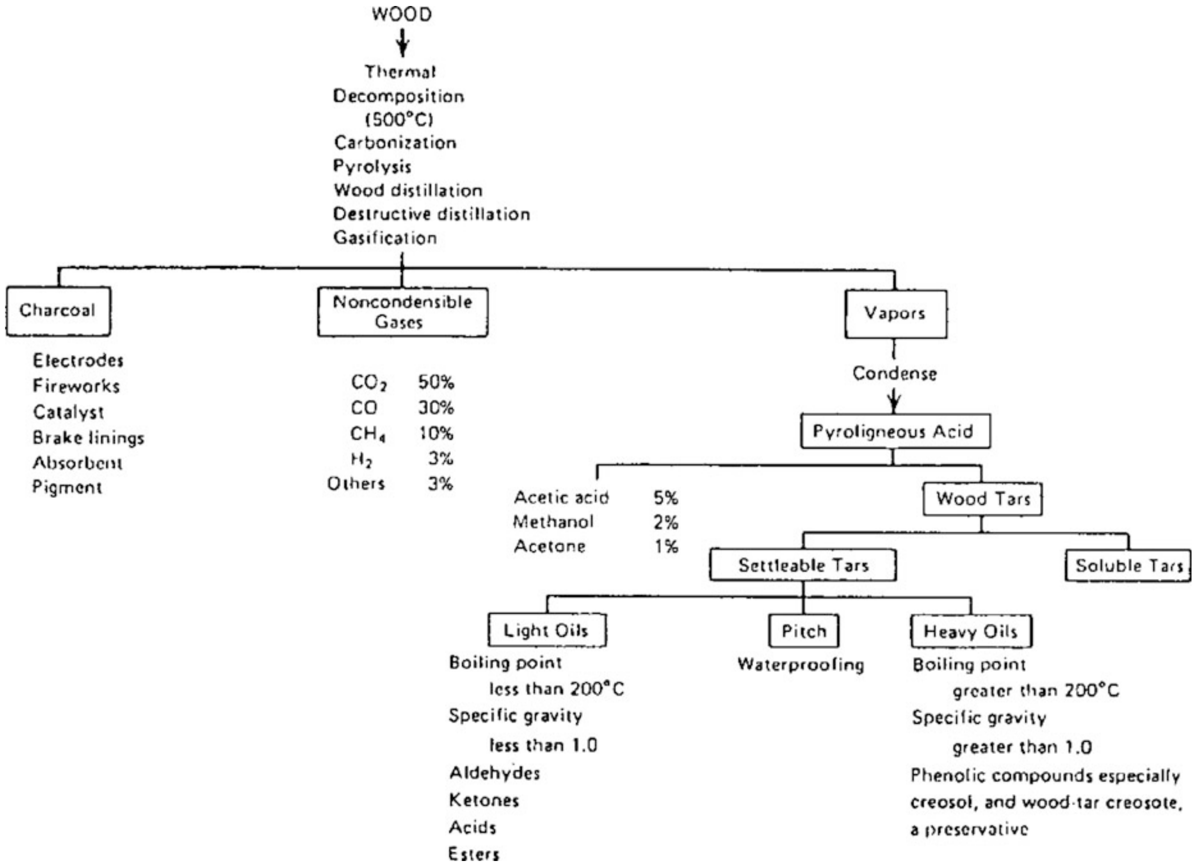

Fig. 28.38 Product obtained from thermal decomposition of wood (from Young and Giese [2], Copyright © 2004, with permission of John Wiley & Sons Publisher)

yield of 276 L/t of wood was reported for softwood and this corresponds to a 72% theoretical yield [53].

Fermentation

All the sugars derived from the hydrolysis of wood polysaccharides can now be fermented to yield ethanol and a variety of other products by a proper selection of the microorganisms.

Alcohols. As noted earlier, the yeast fermentation of hexoses with *S. cerevisiae* is essentially the same way that ethanol is produced from grains or fruits. Whereas the fermentation of five carbon sugars (xylose and arabinose) to ethanol can be achieved by many native and engineered microorganisms including *Escherichia coli* and *S. cerevisiae* [52, 53]. In addition, strains, which are able to ferment both the five- and six-carbons sugars, have been developed. This would greatly facilitate the production of ethanol from a sugar stream derived from the woody biomass [57].

Other products. In addition to ethyl alcohol, the fermentation process can yield many other useful products ranging from simple compounds like xylitol and sorbitol to biodegradable polymers like polyhydoxyalkanoate (PHA) and polylactic acid [58].

Thermal Decomposition

When wood is heated in the absence of air or with only limited amounts of air, thermal degradation takes place. This begins at about 100°C and increases with rising temperature. At about 270°C exothermic reactions set in, causing a rise in temperature (usually held at 400–500°C) bringing about complete carbonization. The resulting products are charcoal, tars (condensable liquids), and noncondensable gases. All these fractions may be used as fuels or chemicals as illustrated in Fig. 28.38.

For example, the wood gas has a fuel value of 300 BTU/ft^3. Methanol obtained from the destructive distillation of wood represented the only commercial source until the 1920s. The yield of methanol from wood by this method is low, only about 1–2% or 20 L/metric ton (6 gal/t) for hardwoods and about one-half that for softwoods. With the introduction of natural gas technology, the industry gradually switched to a synthetic methanol formed from a synthesis gas (syngas) produced from reformed natural gas.

During World War II in Germany, automobiles were fueled by the gases produced from thermal decomposition of wood; and research is ongoing today on the more efficient gasification of wood. Destructive distillation has been used throughout most recorded history to obtain turpentine from pinewood as discussed later in the chapter.

The range of materials or chemicals derivable from the thermal decomposition of wood (Fig. 28.38) varies with the species of woods used, the type of equipment and system (pyrolysis or gasification) employed, and the process variables (temperature, heating rate, and gas residence time). For example, the oil and tar yields can be varied between 1 and 40% and the char between 40 and 10% or less. Low temperatures favor liquids and char, low heating rates favor gas and char, and short gas residence favors liquids. Conversely, high temperatures favor gas, high heating rates favor liquids, and long gas residence times favor gas. Thus, the various product fractions can be preferentially manipulated by proper combinations of these variables. The thermal conversions of wood by the pyrolysis, gasification, and liquefaction processes are discussed further in the following.

Carbonization

The production of charcoal and tars by destructive distillation is the oldest of all chemical wood-processing methods. Charcoal probably was first discovered when the black material left over from a previous fire burned with intense heat and little smoke and flame. For centuries, charcoal has been used in braziers for heating purposes. Destructive distillation of hardwoods has been carried out with charcoal the product sought and volatiles as by-products; with softwoods (pines), volatiles were the principal products (naval stores), with charcoal considered a by-product.

In the United States, charcoal production began in early colonial days. During this period, principal uses of charcoal were as a fuel in blast furnaces for the production of pig iron and as an ingredient of gunpowder. Charcoal needed by the iron industry had to have a high crushing strength, and thus was from dense hardwoods such as maple, birch, oak, and hickory. A softer charcoal was preferred for making gunpowder and was produced from willow and basswood. The first successful blast furnace was built in Saugus, Massachusetts, in 1645. Other furnaces were started in close proximity to iron ore deposits. These early furnaces were small, usually producing only 1–3 metric tons of pig iron per day. In the late 1880s, wood charcoal lost its metallurgical market to coke, which was better suited to demands of larger.

Basic techniques for producing charcoal have not changed over the years although the equipment has. Charcoal is produced when wood is burned under conditions in which the supply of oxygen is severely limited. "Carbonization" is a term that aptly describes the thermal decomposition of wood for this application. Decomposition of carbon compounds takes place as the temperature rises, leading to a solid residue that is richer in carbon than the original material. Wood has a carbon content of about 50%, whereas charcoal of a quality suitable for general market acceptance will be analyzed as follows: fixed carbon 74–81%, volatiles 18–23%, moisture 2–4%, and ash 1–4%. Charcoal with a volatile content over 24% will cause smoking and is undesirable for recreational uses.

Earthen "pit kilns" originally were used to produce charcoal. A circular mound-shaped pile of wood (15–45 cords) was built up with an open core 30–60 cm (1–2 ft) in diameter to serve as a flue. The entire surface of the pile, except for the top flue opening and several small openings around the bottom periphery, then was covered with dirt or sod sufficiently thick to exclude air. The mound was allowed to "coal" for 20–30 days to give the final product.

In the second half of the nineteenth century, brick or masonry "beehive" kilns came into widespread use. The capacity of many of these kilns was from 50 to 90 cords, and operation was essentially the same as for the pit kilns. Many other types of kilns have been used from time to time. Small portable sheet-metal kilns of 1–2 cords have been widely used, and have rectangular masonry block kilns of various designs. These were predominantly used by farmers and small woodlot owners.

Large-scale production of charcoal was done by distilling the wood in steel buggies in long horizontal ovens. The buggies rode in steel rails that carried the cars in line from predryers to the ovens and then to coolers. Charcoal was produced by this method in a matter of 24 h. The latest types of charcoal-producing equipment are designed for continuous operation and make use of residues instead of roundwood. An example is the Herreshoff multiple hearth furnace, in which several hearths or burning chambers are stacked on top of one another, the number depending on capacity. Production in this type of furnace is from 1 to 2.5 metric tons of charcoal per hour.

Pyrolysis

On the pyrolysis of wood in the absence of oxygen, the temperature and heating rate plays a key role in affecting the formation and nature of the products. Conventional pyrolysis is often termed as slow pyrolysis and has been used traditionally for the production of charcoal as described earlier. This essentially is a carbonization process and includes the destructive distillation of wood to produce the charcoal and tars.

A fast pyrolysis [40, 59] refers to a high temperature process (500–700°C) with a high heating rate (300°C/min) for a short time. The major product is the bio-oil. Interestingly, the pyrolysis of pine wood samples releases significant amounts of the wood extractives (turpentine and tall oil). These products constitute the so-called naval stores chemicals and are discussed in the later wood extractives section.

Also, the pyrolysis may be conducted with a very high heating rate and a short reaction time (only a few seconds). This intensive process is often termed as flash pyrolysis and requires very small size of particles (105–250 µm).

Bio-oils. The organic liquid fraction from the wood pyrolysis is often termed as bio-oil. It is a complex mixture of alcohols, aldehyde, ketones, ester, and phenolic compounds from the fragmentation of cellulose, hemicelluloses, lignin, and extractives. The fast pyrolysis is generally employed for bio-oil production. The yields of bio-oil from wood are in the range of 70–80%. Biomass containing a higher content of lignin tends to give a lower bio-oil yield but with a higher energy density. The heating value of bio-oils is about 40–45% of that for hydrocarbon oils.

Bio-oils like the petroleum-based products can be stored, pumped, and transported. They can also be burned in boilers, gas turbines, and slow and medium-speed diesel engines for the heat and power generations.

An increasing interest in the bio-oils applications is to use as substrates like coal for conversion to syngas, as precursors for fuels and chemicals. This biorefinery of bio-oils would be parallel to the conventional oil refining.

Gasification

Gasification [60, 61] is the thermal degradation of wood or other carbonaceous material in the presence of controlled amounts of oxidizing agents, such as air or pure oxygen. It is carried out at higher temperatures than those used in the pyrolysis process, up to around 1,000°C. Hence, the reaction rates are very fast, making equipment design critical. The thermal efficiency for conversion of wood to gases is 60–80%, which compares favorably with that of coal. Wood gasification offers several advantages over coal: (1) much lower oxygen requirements, (2) virtually no steam requirements, (3) lower costs for changing H_2/CO ratios, which are already higher in wood gas, and (4) no or very little desulfurization costs. Coal has an advantage in that larger plants can be built for coal gasification than is normally the case for wood, because of its procurement advantage.

Several gasifiers have been designed to handle municipal refuse, wood wastes, and other biomass materials. Basically, gasifiers fall into two types: (1) those that use air and (2) those using oxygen. An example of the air system is the Moore–Canada gasifier. The wood residues are carried on a moving bed through stages of drying, reduction, and char oxidation, and the ash is discharged in granular form. The maximum temperature in the reaction zone is about 1,222°C. The hydrogen content of the crude gas is increased from 8–10% up to 18–22% by adding steam to the air intake.

The Union Carbide Company Purox gasifier is an example of the oxygen system. This unit also uses a moving-bed reactor. Pure oxygen is the oxidizing agent used to convert the char into CO and CO_2. Molten ash leaves the bottom at about 1,670°C. If air is used, the crude gases contain about 46% nitrogen, which must be removed by cryogenic means; but if oxygen is used, it first must be separated from air, with oxygen and nitrogen separated by a cryogenic system (see Chap. 27). The crude gases also contain an oil and tar fraction, about 2% of the wood (dry basis). Gasifiers designed for wood operate at atmospheric pressure, in contrast to coal gasifiers that operate at pressures up to 400 psi.

Wood gasification products. The composition of the wood gas varies according to the technology used. If the limited oxygen required is supplied by air, a typical gas might contain H_2 (10–18%), CO (22–23%), CO_2 (6–9%), N_2 (45–50%), and hydrocarbons (3–5%), and have a heating value of about 1,700 kcal/m^3 (180 BTU/ft^3). If pure oxygen is supplied to the process, the gas might contain H_2 (24–26%), CO (40%), hydrocarbons (10%), and CO_2 (23–25%), and have a heating value of 2,900 kcal/m^3 (350 BTU/ft^3). The gas may be used directly as a fuel in a variety of ways; for example, supplying boiler energy in an industrial plant at the rate of 2.5×10^8 kcal/h from about 136 kg/day of dry wood.

Figure 28.39 illustrates some examples of products derived from the wood gasification and from the Fischer–Tropsch synthesis of the syngas. Under gasification conditions, the carbon from woody biomass is converted to gas (CO and CO_2). With a combined reactions with oxygen and steam, a mixture of CO and H_2 is formed by a well-known Lurgi process (Eq. 1). The gas mixture is called biosyngas to differentiate it from the syngas derived from coal. A variety of products can be derived from the reforming of syngas by the so-called Fischer–Tropsch (FT) process. The products range from alkane (Eq. 2), methane (Eq. 3), to methanol (Eq. 4), and dimethyl ether (DME) (Eq. 5). The latter DME derived from the dehydration of methanol can be used as fuel in diesel engine.

The technology of gasification [60, 61] is under active development in both equipment and process design to reduce capital costs, and in the chemistry of the process to improve

Fig. 28.39 Examples of products from wood gasification and the Fischer–Tropsch synthesis of syngas [40]

Lurgi process

$$C + H_2O\ (\text{Steam}) \xrightarrow{\text{Heat}} CO + H_2 \tag{1}$$

Fischer-Tropsch synthesis

$$CO + H_2 \xrightarrow[\text{Heat, pressure}]{\text{Catalyst}} \text{Alkane} + H_2O \tag{2}$$

$$CO + 3H_2 \xrightarrow[\text{Heat, pressure}]{\text{Ni}} CH_4 + H_2O \tag{3}$$

$$CO + 2H_2 \xrightarrow{\text{Catalyst}} CH_3OH \tag{4}$$

$$2CH_3OH \xrightarrow[\text{Heat, pressure}]{\text{Catalyst}} CH_3OCH_3 \tag{5}$$

yields and obtain more favorable gas ratios. The latter includes the use of catalysts to enhance the process and to promote the formation of specific products, such as methane or ethylene or increased thermal efficiency or for feed-stocks for chemical synthesis.

Among the various chemicals or products that could be derived the wood gasification, the potential production of methanol and FT diesel has attracted much attention notably related to the paper industry. The gasification of the black cooking liquors after the kraft pulping may provide a means to recover the cooking chemicals (see the Kraft pulping section) and the production of useful chemicals. Recently, the ThermoChem Recovery International, Inc. assisted by the US Department of Energy has installed a pilot plant operation in Durham, North Carolina to produce diesel fuels and chemicals from gasification of woody biomass. This technology should be applicable to the kraft pulping liquor solids as well.

Methanol production. With the introduction of natural gas technology, the industry gradually switched to a synthetic methanol formed from a synthesis gas (syngas) produced from reformed natural gas. Two volumes of H_2 and one volume of CO are reacted in a catalytic converter at pressures of 1,500–4,000 psi to produce methanol. Presently, 99% of the methanol produced in the United States is derived from natural gas or petroleum.

The yield of methanol with present technology is about 390 L/t of oven dry wood. Conversion of wood to methanol is less efficient than producing methanol from natural gas or coal—about 38% compared with about 60%, based on the heat value of methanol as a percent of the total energy input into the plant. The raw materials cost is the most significant operating cost. The production cost for methanol from wood is estimated to be almost twice that produced from natural gas. Improving the efficiency of the gasifier reactor to increase the quantities of CO and H_2 produced from wood would enhance the process.

Recently in Austria [62], a model study was conducted to examine the optimal location of wood gasification for the methanol production with heat. The model covers the competition in all levels of a biofuel production chain like the supply of biomass, biofuel, and heat as well as the demand for bio- and fossil fuels. The results indicated that Austria could be self-sufficient in the production of methanol for blending with gasoline up to M20 (containing 20% methanol). The methanol production for the M5, M10, and M20 blends would require about 2, 4, and 8% of the arable lands, respectively. Austria had approximately 1.4 million ha of arable lands in 2005.

Liquefaction

The thermochemical liquefaction of wood, based on the nature of the product may be discussed in two major types. One is emphasized on the production of liquid fuel (bio-oil) [40, 63]. The other is on the preparation of liquefied wood as chemical feedstock for making adhesive [64] or other modified liquefied wood products [65].

Bio-oil production. The thermochemical liquefaction for the biofuel production generally requires a high-pressure and high-temperature treatment of wood chips in the presence of hydrogen gas or syngas. For example, an oil of a heating value of about 35,200 BTU/kg can be obtained by reaction of wood waste at 750°F under a pressure of 5,000 psi in the presence of syngas and a catalyst for 1 h. The feasibility of the process has been tested in a pilot plant in Albany, Oregon, based on laboratory work conducted at the U.S. Bureau of Mines. So far, it has been determined that a barrel of oil equivalent to No. 6 bunker fuel can be produced from about 405 kg of wood chips [63].

Alkali salts like sodium carbonate can be used as catalyst for the liquefaction process. Since the heavy oil obtained is a viscous tarry lump, some organic solvents (like propanol or butanol) are often added to the reaction system for easy handling. The yield of bio-oil is about 30% for the noncatalytic liquefaction and higher (60%) for the catalytic process [66]. Since the liquefaction process requires a need for more expensive reactors and fuel-feeding system, it is less attractive than the pyrolytic process for the bio-oil production [40].

Liquefied wood. The wood liquefaction can be conducted in a reagent–solvent system and an acid catalyst at temperatures below 180°C, which is significantly lower than that required for the bio-oil production (300–350°C). Phenol is a commonly used reagent solvent while sulfuric acid or oxalic acid can act as catalyst. The resulting liquefied wood can be used for the preparation of phenolic resin by reacting with formaldehyde.

Also, if the ethylene glycol and glycerol are used as a reagent–solvent system, the resulting liquefied wood contains a large number of hydroxyl groups, which can serve as reactive sites for chemical modifications. A variety of liquefied wood polymers have been synthesized including the polyester, polyurethane, and epox resin. These products were reported to be more biodegradable than those derived from the petrochemicals. Since liquefied wood represents a concept for total utilization of the woody biomass, it is an area of continued interest with many potential applications.

Chemical Conversion

Chemical reactions provide a fundamental basis for many of the wood conversion processes especially those related to the pulping and bleaching operations as discussed earlier. In the following, the chemical conversion of wood polymers to chemicals and fuels is further illustrated by the potential production of furan-type products from wood polysaccharides and lignophenols from wood lignin.

Furan-type products. The acid-catalyzed hydrolysis of wood polysaccharides is known to produce the furfural *3* and 5-hydroxymethyl furfural (HMF) *4* (Fig. 28.36). These two compounds are known to be inhibitors to the fermentation process. The furfural *3* is derived from the acidic degradation of hemicelluloses (mainly xylan) while the HMF *4* is from the degradation of hexoses (mainly from cellulose).

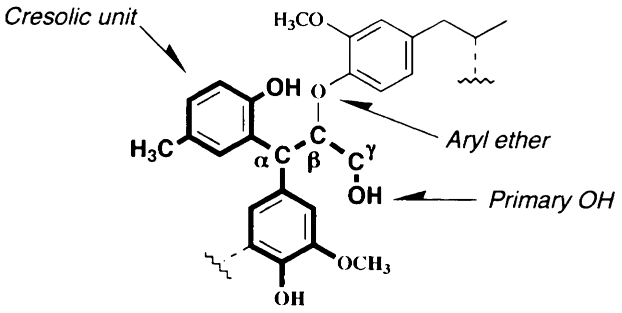

Fig. 28.40 The key structural feature of lignocresol [70]

Improved methods for the isolation of these two furan compounds have been developed by modifying the acidic treatment conditions [67].

Furfural *3* is a well-known industrial chemical and can be reduced to furfuryl alcohol (FA) and methyl furan (MF). FA has been used for polymer applications [68], while MF can be used as fuel additive. Similarly, HMF *4* can be converted to different types of useful acids, alcohols, or 2,5-dimethyl furan (DMF). The latter DMF, like MF, can be used as a fuel and its energy content is similar to that of gasoline.

Levulinic acid. This acid *5* (Fig. 28.36) is derived from the acid degradation of HMF and is a cellulose-derived product. It can be produced from a variety of woody biomass (wood wastes, agricultural residues, or municipal solid waste). Levulinic acid can be converted to a variety of industrial chemicals including tetrahydrofuran, 1,4 butanediol, diphenolic acid, and succinic acid [69].

Lignophenol. Lignophenols [70] represent a unique class of modified lignin polymers derived from lignocellulosic substrates by a phase-separation process. It is prepared by first mixing woodmeal samples with *p*-cresol in a small beaker and stirred for 10 min. After the addition of sulfuric acid (72%), the mixture was stirred vigorously at ambient temperatures for 1 h. The mixture is then separated into a cresol layer containing mainly the wood lignin and an aqueous layer of the carbohydrates.

The separated cresol layer was dropped into diethyl ether with vigorous stirring. The crude lignocresols precipitates were further purified by dissolving in acetone. The acetone-soluble material was then precipitated into the ether to give the purified lignocresols.

The key structure of lignophenol is in the formation of α-condensed 1,1-diarylpropane units (Fig. 28.40). The lignocresol is a highly phenolic polymer resulting from the grafted cresolic units and the cleavages of acid-labile aryl ether units. The total PhOH content of lignocresol per C_9 unit was about 1.3 for softwood and higher from hardwood (1.5) as compared to a value of 0.3 for typical milled wood lignin (MWL) samples.

Lignophenols have been demonstrated being quite reactive and suitable for many industrial applications including the areas of adhesives, cellulose composites, carbon molecular sieving membranes, and adsorbents for protein. Also, the dissolved carbohydrate components can be recovered for conversion to fuels or chemicals.

Thus, the phase-separation process would represent an important new approach to achieve an effective utilization of all the major biomass polymers including both the lignin and polysaccharide components. Several pilot-scale plants have been installed in Japan for further process evaluation.

Chemicals from Extractives

The most common chemicals derived wood extractives [71] are the turpentine and tall oil. They can be recovered by several processes including from the kraft pulping operation, by extraction of wood with suitable solvents, or from the exudates (oleoresin or gum) of living pine trees. The nature of these chemicals along with the tannin and other medicinal is outlined in the following.

Naval Stores

The U.S. naval stores industry began in the very early colonial days, when wooden vessels used tar and pitch from the crude gum or oleoresin collected from the wounds of living pine trees. The demand for tar and pitch from crude gum is now of minor importance. The industry is centered in the southeastern United States and is confined to the longleaf and slash pine areas. There was also a small, but locally important, naval-stores-producing area in the Landes region of southwestern France, based on the maritime pine.

There are three routes by which naval stores are produced. The oldest method is the tapping of living trees to cause a flow of oleoresin. The second method is the removal of naval stores by solvent extraction of wood. The latter extraction process now has replaced steam distillation as a means of recovering turpentine. The third route is from kraft (sulphate) pulping of pine, during which turpentine and tall oil are recovered as by-products of kraft pulp manufacture. This subject was briefly mentioned earlier in the pulping section. A fourth process, no longer used in the United States, is recovery of turpentine and pine oils by the destructive distillation of pine wood [72].

Worldwide, about 60% of naval stores are produced by tapping living trees. In the United States, the most important route is from the kraft pulping operation, whereas gum naval stores account for only 4% of the U.S. production.

Naval stores comprise two major types of products (turpentines and tall oil). Turpentines are a mixture of volatile terpenes while tall oil is consisted of three major types of components (resin acids, fatty acids, and unsaponifiables). Thus, naval stores also include important fatty acids, as well as steroids and other products. These naval stores products have a wide range of uses from ordinary household commodities to complex industrial applications [73].

Gum naval stores. The crude gum or oleoresin is obtained from healthy trees by exposing the sapwood. The lower part of the tree is faced; that is, a section of bark is removed, giving a flat wood surface for the gutters, which are inserted into a slanting cut made by a special ax. The gutters conduct the gum to a container that can hold 1–2 quarts of gum. At the top of the exposed face, a new V-shaped strip of bark is removed about every 2 weeks. The operations of inserting gutters, hanging cups, and cutting the first bark preferably are done in December or January, as early facing stimulates early season gum flow. The gum continues to flow until November, with the height of the season being from March to September.

The collected gum is distilled from a copper still; turpentine and water pass over, and the rosin is left in the still. The remaining molten rosin, plus impurities, is passed through a series of strainers and cotton batting to remove dirt particles. Then the liquid rosin is run into tank cars, drums, or multiwall paper bags for shipment.

Increases in yield of naval stores are brought about by chemical treatment of the exposed wood, especially with paraquat herbicides (dipyridyl compounds). This treatment stimulates extensive oleoresin formation and diffusion into the wood, extending to the pith of the tree and several feet above the treatment level. As much as 40% oleoresin content in the wood has been produced. Such treatment could double naval stores production, for both gum and sulfate processes. It also has the potential of providing a new type of wood naval stores by solvent extraction prior to kraft pulping or a combination of both methods.

Wood naval stores. “Wood” naval stores are produced by solvent extraction of resin-rich wood from old southern pine stumps and roots. The depletion of these stumps from the large trees of virgin forests, combined with high labor costs, has brought about a major decline in the production of wood naval stores by this process. In modern practice, all the resin products are removed from the shredded wood by solvent extraction; the solvent retained by the extracted wood chips is recovered by steaming. Extraction is carried out with naphtha (b.p. 90–115°C fraction). Multiple extractions are carried out in a series of vertical extractors in a countercurrent manner, whereby fresh solvent is used for the final extraction of a charge. The solution from the extractors is vacuum-distilled and the solvent recovered. The remaining

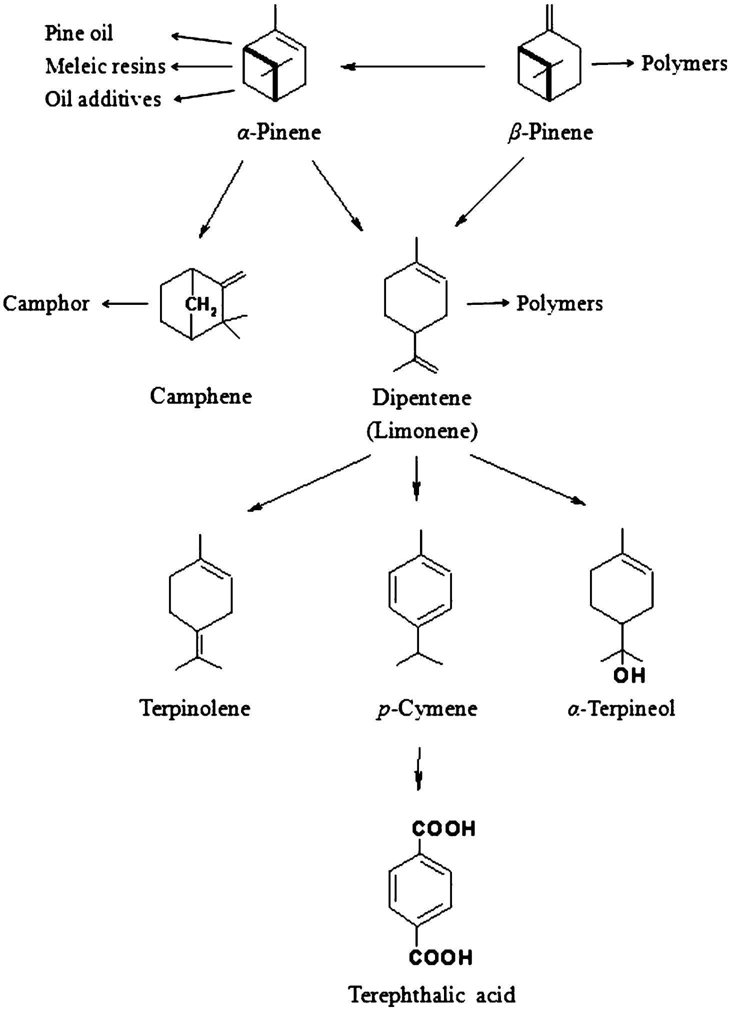

Fig. 28.41 Some reactions of α-pinene and β-pinene (adapted from Goldblatt LA. Yearbook of Agriculture, USDA, 1950–1951)

terpene oils are fractionally redistilled under vacuum and recovered as turpentine, dipentene, and pine oil. The non-volatile rosin is of dark color and is upgraded by clarification methods, such as selective absorption of its solution (bed-filtering).

Sulfate naval stores. Sulfate turpentine is obtained as a by-product during the kraft pulping of pine woods. Vapors periodically released from the top of the digesters are condensed, and the oily turpentine layer is separated and purified by fractional distillation and treatment with chemicals to remove traces of sulfur compounds. The spent black liquor from the kraft pulping of pines contains the less volatile product of the wood resin in the form of sodium salts or soaps. The liquor first is concentrated in multiple-effect evaporators, and then the concentrate is sent to settling tanks. The soaps rise to the surface, are skimmed off, and then are acidified with sulfurous or sulfuric acid. The crude tall oil rises to the top and is mechanically separated.

Turpentines. In the United States, about 80% of the annual production of turpentine is from the kraft pulping of southern pines (approximately 125 million liters). Turpentine is a volatile oil consisting primarily of terpene hydrocarbons, having two basic isoprene units (2-methylbutadiene, C_5H_8). These monoterpenes can have many different arrangements as illustrated in Fig. 28.41. Only six monoterpenes are present in appreciable amounts in commercial turpentines and their boiling points are in the 150–170°C range. These include α-pinene (156°C), β-pinene (164°C), camphene (159°C), Δ^3-carene (170°C), dipentene (limonene) (176°C), and terpinolene (188°C).

The composition of sulfate turpentine is very similar to that of gum turpentine obtained from the oleoresin of the tree (Table 28.11). The major components are α-pinene (60–70%) and β-pinene (25–35%). Sulfate turpentine from western North America woods contains appreciable amounts of Δ^3-carene which is used as a solvent. In contrast, wood turpentines contain some camphene (4–8%) with little of β-pinene.

Table 28.11 Composition of turpentines from different sources

	Types of turpentine		
Component%	Gum	Sulfate	Wood
α-Pinene	60–65	60–70	75–80
β-Pinene	25–35	20–25	0–2
Camphene	–	–	4–8
Other terpenes	5–8	6–12	15–20

Turpentine is used directly as a solvent, thinner, or additive for paints, varnishes, enamels, waxes, polishes, disinfectants, soaps, pharmaceuticals, wood stains, sealing wax, inks, and crayons, and as a general solvent. The chemistry of its monoterpenes offers many possibilities for conversion to other substances, as illustrated in Fig. 28.41. There is increasing use of turpentine to produce fine chemicals for flavors and fragrances. An important use of turpentine is in conversion by mineral acids to synthetic pine oil. It also is a raw material for making terpin hydrate, resins, camphene, insecticides, and other useful commodities. These uses are included in the following summary of its applications.

- Solvents for paints, etc. (11%)
- Synthetic pine oil (48%), used for mineral flotation, textile processing, solvents, odorants, bactericides, and conversion to their chemicals such as terpin hydrate, etc.
- Polyterpene resins (600–1,500 mol. wt.) (16%), used for adhesives, pressure-sensitive sizes (dry cleaning, paper, chewing gum)
- Camphene → toxophene insecticides
- Flavor and fragrance essential oils (9%)

Dipentene. This compound is also known as limonene derived from the higher boiling fractions of wood turpentine. Dipentene is used in paints, varnishes, and as a penetrating and softening agent in rubber reclamation.

Pine oil. Pine oil obtained from wood naval stores has similar uses to those of the synthetic pine oil made from turpentine, given earlier.

Tall oil. In the United States, tall oil like turpentines is largely derived from the kraft pulping operation. For each metric ton of pulp produced, northern pines yield about 50 kg of tall oil and higher (125 kg) from southern pines. The U.S. capacity for fractional distillation of tall oil is nearly one million metric tons per year.

Crude tall oil from southern pines contains resin acids (40–60%) and fatty acids (40–55%), and unsaponifiables or neutral substances (5–10%). These individual components are obtained by fractional distillation under vacuum. One metric ton of crude tall oil yields rosin (350 kg), fatty acids (300 kg), and the head and pitch fractions (300 kg).

Rosin. Rosin is a brittle solid that softens at 80°C. Chemically it is composed of about 90% resin acids and 10% of neutral matter. Rosin is graded and sold on the basis of color, the color grades ranging from pale yellow to dark red (almost black). The color is due almost entirely to iron contamination and oxidation products. Fresh oleoresin, as it exudes from the tree, will yield a rosin that is nearly colorless. Color bodies are removed by selective solvents and selective absorption from a 10 to 15% gasoline solution passed through beds of diatomaceous earth. About 70% of the world's rosin is produced in the United States.

Resin acids are tricyclic mono-carboxylic acids. These diterpene derivatives are often discussed in two groups (abietic or pimaric type) with the abietic type being dominant in nature (Fig. 28.8). A typical range of composition for rosin is indicated below:

1. Abietic type
    - Abietic (42–43%),
    - Neoabietic (4–5%),
    - Palustric (10–12%)
    - Lepopimaric (<0.5%)
    - Dehydroabietic (30%)
    - Other resin acids (8–12)
2. Pimaric type
    - Pimaric (4–5%),
    - Isopimaric (3–5%)
    - Sandaracopimaric acids (1–2%)

Rosin is used mainly in some modified forms. Because all the resin acids contain a carboxyl group and double bonds, they are reactive and can be used to produce salts, soaps, esters, amines, amides, nitriles, and Diels–Alder adducts. Also, they can be isomerized, disproportionated, hydrogenated, dimerized, and polymerized to provide a variety of useful products. When destructively distilled, rosin produces a viscous liquid, termed rosin oil, used in lubricating greases.

The paper industry uses large amounts of the sodium salt of rosin as paper size, which accounts for the greatest single use of rosin. The synthetic rubber industry is the second most important user of rosin. In making styrene-butadiene rubber, disproportionated rosin soaps are used alone or in combination with fatty acid soaps as emulsifiers in the polymerization process. Disproportionation decreases the number of double bonds in the abietic type of rosin, making a more stable material.

The adhesives industry is the third most important market for rosin. Rosin, modified rosins, and rosin derivatives are used in several types of adhesives, including the pressure-sensitive, hot-melt, and elastomer-based latices, and solvent rubber cements. Protective coatings are the fourth major or derivative form. Varnishes and alkyds are the most common types of protective coatings using rosin. Rosin is combined

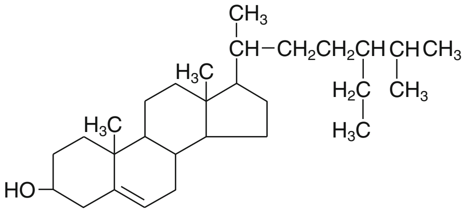

Fig. 28.42 β-Sitosterol

with a heat reactive phenol-formaldehyde resin to produce a widely used varnish. Printing inks also use substantial amounts of rosin. The above rosin uses are summarized as follows.

- Paper size (33%)
- Chemical intermediates and rubber (42%)
- Resins and ester gums (18%)
- Coatings (3.9%)
- Other uses (3.1%)

Fatty acids. The total fatty acids produced annually in the United States, amounting to more than 450,000 t and 35% of these come from tall oil. The solvent extraction of pine wood yields only 1% fatty acids and their esters. The yield is not increased, however, by paraquat (dipyridyl herbicides) treatment. Hence, the kraft-pulping industry will continue to be the major source of fatty acids from wood.

The fatty acids from tall oil have the following components: oleic (50%), linoleic (35%), conjugated oleic (8%), stearic (2%), palmitic (1%), and others (4%). From tall oil heads, a fraction is produced that is composed predominantly of saturated acids, containing 55% of palmitic acid. Oleic acid is distilled in grades that are 99.5% pure.

The approximate uses of fatty acids in various areas are:

- Intermediate chemicals (43%)
- Protective coatings (28%)
- Soaps and detergents (11%)
- Flotation (3%)
- Other uses (15%)

Additionally, the fatty acids of tall oil can be converted to bio-diesels by simple esterification reactions.

Unsaponifiables. The neutral or "unsaponifiable" materials present in tall oil contain mainly phytosterols (25–35%), higher alcohols (5–10%), hydrocarbons (33–60%), and many other minor components. For example, in the neutral fraction of southern pine tall oil soap, 80 compounds have been identified and the main component is sistosterol (25%), which accounts for 2–3% of the crude tall oil. Sistosterol is an alcohol (Fig. 28.42) and has potential applications. For example, this chemical has potential use in the synthesis of cortisones and other steroids and hormones by fermentation processes. Also, food products containing plant sterols are known to reduce the cholesterol levels.

Medicinals

The bark of the cascara tree of the northwestern region of the United States yields cascara, a laxative used in medicine. Several hundred tons of bark are harvested annually.

One of the most promising anticarcinogenic compounds discovered in the last 25 years was founding the bark and wood of the Pacific Yew tree from the Pacific Northwest of the United States. This compound, taxol, was found to be quite effective by the National Cancer Institute for the treatment of breast and ovarian cancers. The compound is now produced by partial synthetic routes and is available commercially under the generic name, paclitaxel.

Also, Gingo extracts or nuts have been used medicinally for thousands of years in China. The red gum tree of the southern United States exudes a yellowish balsamic liquid or gum from wounds, which is known as stora. It is produced by removing a section of bark and incising the wood in much the same manner as that used for the production of naval stores gum described earlier. Storax is used in medicinal and pharmaceutical preparations, such as adhesives and salves, and as an incense, in perfuming powders and soaps, and for flavoring tobacco.

Tannins

The tissues of wood, bark, and the leaves of trees contain a great variety of chemical substances of considerable scientific interest and some of practical value. Turpentine, pine oil, and rosin from the resins of pines are the most important commercial extractives from American woods. Tannin is a commercially important substance that can be extracted from the wood, bark, or leaves of certain trees and other plants. Tannins are complex dark-colored polyhydroxy phenolic compounds, related to gallic or ellagic acids (Fig. 28.8), and vary in composition from species to species. They have the important property of combining with the proteins of animal skins to produce leather. Recent interest in tannins has been on their pharmacological properties for potential applications as antiviral and antitumor agents.

For many years, most of the leather in the United States was tanned with domestic tannins from hemlock and oak bark and from chestnut wood. Today only a small amount of tannin comes from these and other domestic sources. The most important source of vegetable tannin today is the wood of the quebracho tree, which grows mainly in Paraguay and Argentina. The tannin content of this tree and a few other sources of vegetable tannin are given in Table 28.12.

For the tannin production, the wood or bark is reduced to chips and shreds by passing the material through hoggers or hammer mills. Then it is extracted with warm water in diffusion batteries. The dilute solutions are evaporated to

Table 28.12 Tannin content of some plant material

Plant material	Percent tannin
Domestic sources	
Eastern hemlock bark	9–13
Western hemlock bark	10–20
Tanbark oak	15–16
Chestnut oak	10–14
Black oak	8–12
Chestnut wood	4–15
Sumac leaves	25–32
Foreign sources	
Quebracho heartwood	20–30
Mangrove bark	15–42
Wattle (*acacia* bark)	15–50
Myrobalan nuts	30–40
Sicilian suma leaves	25–30

the desired concentration. Loss of solubility of the tannin can be counteracted by treatment of the concentrate with sodium sulfite.

Biotechnology

Biotechnology plays an important role in many aspects of the forest product industry as summarized by Henriksson and Teer [74]. These developments range from the breeding of genetically modified trees for improved wood quality and processing ability to the discovery of new enzyme systems for improved hydrolysis of wood polysaccharides, the fermentation technology, and the pulping and papermaking operations.

Genetic Modification of Trees

Advances in plant biotechnology have demonstrated that genetic engineering can improve the wood growth and quality of hardwood like poplar trees. For example, the growth of transgenic poplar as compared to the controlled tree showed an increased in height by 41% and in stem diameter by 36%. This improved wood yield represents an important trait of forest trees. Also, the lignin content of transgenic poplar was significantly reduced and the lignin was shown to have a higher proportion of the syringyl unit (S) and a lower guaiacyl (G) units. Wood lignin has a higher S/G ratio is generally more reactive and easier to delignify during the pulping operations.

As discussed earlier, softwood lignin unlike hardwood lignin does not contain the S units and is more difficult to degrade. Thus, intensive research has been conducted aiming to incorporate the S unit into the softwood trees. Initial results were quite promising. The positive outcome would facilitate the pulping and bleaching operations and preserve the fiber quality for improved products.

Enzymatic Deinking

Deinking is an essential process to reuse the recycled fibers for making white papers. The deinking process is generally based on detergents and separation of ink particles by floating. It can be substantially improved by the addition of various enzymes to the detergent mixture. Common enzymes used are fungal amylases (starch degrading enzymes), cellulases, and to some extent, lipases and hemicellulases. The enzymatic deinking is one of the most common enzymatic techniques used in the pulp and paper industry.

Biomechanical Pulping

The pulping of wood is at present based on either mechanical or chemical methods or combinations thereof, as previously described in this chapter. The interfiber lignin bond is broken down by the mechanical and chemical treatments to free the cellulose fibers for papermaking. A biomechanical pulping method that has reached the pilot plant stage and will probably be commercialized in the near future. This approach involves the use of white rot fungi to first breakdown the wood structure, and apparently modify the lignin with the result that the wood chips can then be mechanically disintegrated with much less energy input. After screening of hundreds of different species of white rot fungi at the U.S. FPL, it was found that *Ceriporiopsis subvermispora* produced the greatest reduction in energy consumption and also substantially improved the strength properties of the pulp in comparison with conventional refiner mechanical pulp. The approach is also suitable for the production of pulp from agro-based materials as well [19, 75].

Biobleaching

It is well known that the xylanase pretreatment of kraft pulps enhances the subsequent bleaching with gaseous chemicals such as chlorine dioxide or ozone. This is a well-established technology and it can reduce the chemical consumption by 10–20% while improving the pulp quality. In addition to xylanases, other hemicellulases, such as mannanases also have a similar effect.

Among the ligninases, the laccase-mediator-system (LMS) has received the most attention in delignification of pulps. This system requires the use of a mediator such as

1-hydroxybenzotriazole (HBT) or 2,2′-azino-bis-(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS) and is conducted under mild ambient conditions. The extent of LMS delignification of kraft pulps is very comparable to that of the O_2 bleaching. However, the cost of enzymes and mediator has prevented its commercial applications.

Biofuels and Bioproducts Conversion

As discussed earlier, the conversion of biomass materials can be achieved by enzymatic saccharification followed by fermentation to yield fuels (like bioethanol and butanol), chemicals (lactic acid and xylitol), biodegradable polymers (PHA), and many others [5, 58, 73]. Significant progress has been made in identifying the cellulase enzyme complex for hydrolyzing cellulose to glucose. The enzyme complex apparently contains both the decrystallizing and the hydrolysis enzymes that work together to convert cellulose to glucose. Isolation of the specific enzymes and genetic engineering could provide a more efficient complex available in the future.

Dean C. Webster and Rose A. Ryntz

Introduction

Change is constant in the coatings market. As mergers, acquisitions, and partnerships take shape, consolidation and globalization remain prominent. The 80/20 rule (20% of the firms accounting for 80% of business) takes effect as the need for regulatory and environmental compliance continues to plague the market. In 1975, the United States alone supported about 2,000 coatings companies. Today, there are less than half that many.

The global paint and coatings market garnered approximately $90 billion in sales in 2009. The major participants included: Akzo Nobel Coatings BV (Sassenheim, The Netherlands); PPG Industries, Inc. (Pittsburgh, PA); The Sherwin Williams Co. (Cleveland, OH); DuPont Performance Coatings (Wilmington, DE); BASF Coatings AG (Ludwigshafen, Germany); RPM International Inc (Medina, OH); The Valspar Corporation (Minneapolis, MN); Kansai Paint Co., Ltd. (Osaka, Japan), Nippon Paint Co., Ltd. (Kita-Ku, Osaka, Japan). Smaller companies, being forced out of the market because they lack the capital required to meet compliance issues, are forced into consolidations. Major acquisitions also highlighted the paint and coatings industry and its suppliers. These included Akzo-Nobel's acquisition of ICI Paints, PPG's acquisitions of Ameron and Sigma Kalon, Perstorp's acquisition of Rhodia, BASF's acquisitions of Ciba and Cognis, Sherwin-Williams' acquisition of Becker Acroma, the merger of Hexion and Momentive, and Dow Chemical's acquisition of Rohm and Haas. The economic downturn in 2008–2009 and sluggish recovery has affected the coatings market significantly. Although forecast growth rates of the coatings markets in the developed world is slow, about 4% annually in North America and similarly in Europe, Asian coatings growth is estimated to be about 8% annually [1]. Thus, all of the major paint and coatings manufacturers and suppliers to the industry have developed a presence in Asia, with a particular focus on China.

The auto industry is also providing coatings companies with opportunities to form increasingly important relationships. PPG was awarded an exclusive coatings contract at the Nissan plant which opened in Canton, Mississippi in 2003, providing everything from pretreatment to clearcoat. In addition, PPG formed a joint venture with a local minority-owned business, Systems Consultants Associates (Jackson, Mississippi) to coat chassis frames and other underbody components, as well as the Nissan replacement parts. The joint venture, Systems Electro Coating, is minority-owned and operated at a facility adjacent to the Nissan plant. A Toyota plant in France, which opened in 2001, procures all of its coatings materials from DuPont Herberts Automotive Systems.

Over the past decade, automotive supplier parks have proliferated in South America and Europe as automakers pursue a manufacturing value chain that is as lean and efficient as possible. That trend has recently also gained popularity in North America. Ford Motor Company launched its first North American supplier park in Chicago in 2004, where painted exterior and interior components will be produced. Chrysler is planning a supplier co-location project at the Jeep Toledo North Assembly plant, where painted vehicle body and the chassis module will be sent on conveyer lines directly into the Chrysler Group's final assembly building.

The major coatings markets in the United States consist of architectural coatings (consumer and decorative), product finishes (maintenance/protective coatings for bridges, industrial machinery, etc.), and special-purpose coatings, such as automotive finishes ((OEM) and refinish) (Table. 29.1) [2]. The volume of coatings delivered declined in 2008 and 2009 and began to show signs of recovery in 2010.

Despite years of environmental pressure to reduce the volatile organic compound (VOC) component in paints, solvent systems are still king, compromising 47% of the U. S. paint market [3]. Government pressure to reduce the contributions these systems can make to ground-level ozone formation (smog) has reached its limit. Most formulators have either substituted acceptable solvents or reduced solvent content to produce acceptable high-solids paint systems.

Not all government authorities believe that VOC reduction limits have been reached. California's South Coast Air Quality Management District (SCAQMD), which includes counties in the Los Angeles Basin, keeps squeezing paint makers for further reductions. The agency has now succeeded in regulating that liquid coatings such as wood stains, sealers, and roof coatings, contribute VOCs of only 50 g/L (approximately 0.4 lbs/gal), down by 50% from previous regulations and is proposing that additional products have reduced VOC limits in the coming years.

The coatings market is constantly being sought out by local, state, and federal governments to reduce environmental emissions even more. The key concerns of government regulators and consumers include: treating the earth as one biosphere, having an infinite capacity for cleaning itself of toxins; cleaning air from pollutants that are killing lakes and causing a dramatic increase in respiratory illnesses; ensuring that smog-enshrouded cities do not become industrial nightmares; and making the agricultural and livestock products that people eat safe for consumption over the long term.

These concerns have led to legislation over the last several years that cause manufacturers to place a greater emphasis on research that enables them to meet or exceed government and consumer demands for clean air.

VOC Regulations

The environmental demands have lead to a nationwide program to limit VOCs. The VOCs of paint are calculated as pounds of solvents per gallon of paint. Prior to 1970, the VOC content of most paints was well above 5 lb/gal. Current major industrial paints now are limited to approximately 3.5 lb/gal of VOC because of imposed environmental pressures. Stricter legislation in the future, however, will place requirements of less than 3.0 lb/gal of VOC on most markets. The issue of air quality compliance is complicated by different regulations in various states and regional areas. Although the federal government (through the U.S. EPA) has set minimum national standards, states and designated regional areas can adopt their own compliance rules.

All states and regions tend to restrict the solvent content in coatings. The following summaries indicate the wide variation in compliance requirements throughout the country.

West

California. This is where the regulations began. The regulatory activities of the SCAQMD have set a pattern that many other regulatory boards have chosen to follow. The district restricts application equipment and VOC content. The VOC requirements are continuously changing; so no attempt was made to list them here.

The SCAQMD in Southern California has mapped out a three-tier plan to bring the district into clean-air compliance. The plan will be revised periodically based on reports from over 40 monitoring stations throughout 13,350 square miles including Los Angeles, Orange, and Riverside counties and the urban portion of San Bernardino County. VOCs will not be monitored directly. Rather, ozone, which is formed when hydrocarbons (VOCs) react with nitrogen oxides in sunlight, will be measured for the presence of VOCs. The federal clean-air standard for ozone requires that ozone concentrations do not exceed 0.12 ppm more than 1 day a year.

Tier I of the three-tier plan involves 22 rules, which were adopted in 1993, to restrict the emission of VOCs from coatings. Control methods include the application of low-solvent coatings, use of high transfer efficiency (TE) techniques to apply coatings, and "to a certain extent" the use of add-on control devices (see Table. 29.2).

Tier II (adopted in 2000) reduced the VOC emissions by 50%. Reductions were achieved by further tightening the VOC content of coatings (at times to levels lower than those stated in the Federal Control Technique Guidelines (CTG)) and increasing application transfer efficiency requirements (at times to levels more stringent than those stated in the EPA "Blue Book").

Tier III (initially to be implemented by December 31, 2007) calls for applying new technology to improve waterborne, UV-cure, and two-component coatings, and prohibiting "certain high-emitting uncontrollable coating processes."

Washington. No rule prohibits any method of spray finishing. VOC guidelines are determined by subtracting

the amount of solids from the gross weight of the material used and determining whether the amount of solvent used exceeds the acceptable limits.

The maximum VOC limits (lb/gal) are: clear-coat, 4.3; color, 3.5; performance coatings, 3.5; all other coatings, 3.0. Metric limits (g/L) are defined for aerospace: primers, 650; topcoats, 600 (equivalent to 5.4 and 5.0 lb/gal, respectively).

Southwest

Texas. In Texas, regulators restrict emissions rather than equipment. Emissions are limited across the board for certain industries. Limits (lb/gal) are specified for particular coatings in other industries. For example: large appliances, 2.8; furniture, 3.0; coil coatings, 2.6; automotive OEM—primers, 1.2 if submersed and 2.8 if sprayed, topcoats, 2.8, and repair, 4.8; miscellaneous metal—color, 2.5, top clear-coat, 4.3, and all others, 3.0.

South Carolina. VOC limits (lb/gal) include: metal furniture, 3.0; appliances, 2.8; miscellaneous metal—color, 3.5, clear-coat, 4.3, and all others, 3.0; coil coating, 2.6.

North Carolina. The rules are applicable only in areas designated as nonattainment zones. If air pollution control equipment is not used, emission standards are based on the weight of solids used. High-solids coatings are automatically compliant regardless of spray equipment used. The limits (lb/gal) for automotive shops with air pollution control equipment include: primers, 1.4 if high solids, 1.2 if low solids; topcoats, 4.5 if high solids, 2.8 if low solids; repair, 13.8 if high solids, 4.8 if low solids. For automotive shops without air pollution control equipment, limits are: primers, 1.2; topcoats, 2.8; repair, 4.8. Air pollution control equipment is not precisely defined. Other limits include: metal furniture, 5.1; appliances, 2.8.

Georgia. VOC emissions are limited (lb/gal) by industry and coatings used: automotive—primers, 1.2 if dipped and 2.8 if sprayed, topcoat, 2.8, and repair, 4.8; metal furniture, 3.0; appliance, 2.8; and miscellaneous metal-performance coatings, 3.5, high-performance coatings, 6.2, clear-coat, 4.3, and all others, 3.0; coil coating, 2.6.

Midwest

Indiana. Rules in Indiana are among the most complex in the nation. They require a baseline TE, specify coatings formulations, and limit VOC emissions (lb/gal) for automotive, metal furniture, and large appliances but then only specify acceptable equipment choices for wood. Limits are: automotive—30% TE at 62% solids; metal furniture—60% TE at 59.2% solids; large appliances—60% TE at 62% solids. No TE test procedure is defined for the following VOC limits: automotive—primer, 1.9, topcoat, 2.8, and repair, 4.8; metal furniture, 3.0; large appliances, 2.8; miscellaneous metal—color, 3.5, specialty coats, 3.5, clear-coats, 4.3, coil coatings, 2.6, and all others, 3.0. In the wood industry, the state departs from these guidelines and identifies acceptable equipment choices: airless, heated airless, and air-assisted airless spray; manual and automatic electrostatic spray; and rollers brushes, or wipes. Significantly, no conventional air spray method, including HVLP, is recognized as compliant.

Illinois. A 30% minimum TE is required for automotive. Automotive VOC limits (lb/gal) are: primer/surface, 2.8; topcoat, 2.8; repair, 4.8. The rules allow higher VOC limits for automotive topcoats if the finishing method can be demonstrated to achieve a TE of over 65%. In such cases, topcoats may be used with a VOC of up to 3.6. For the wood industry, a minimum TE of 65% is required with the following VOC limits: washes, 6.5; stains, 4.7; top-stains, 6.6; sealers, 5.6; clear-coats, 5.6. No test procedure for TE has been defined.

Michigan. Although VOC guidelines are suggested, they are not stated clearly. In general, the finisher is expected to achieve minimal VOC levels when using metallic topcoats of waterborne coatings and performing touchup or repair work. Although conventional air spray is generally acceptable, some areas of Michigan require electrostatic systems with a TE of at least 40% and define VOC limitations.

East

New Jersey. A minimum of 65% TE is required for all industries except wood. Shops using waterborne coatings are automatically compliant regardless of TE. VOC limits (lb/gal) for all others are: automotive—primers, 2.8, topcoats, 2.8, specialty coats, 5.0, and repair, 4.8; automotive refinishing—basecoats, 6.0, clear-coats, 4.4, and all others, 5.0; coil coating, 2.6; miscellaneous metals—color, 4.3, performance coatings, 3.5, and all others, 3.0; leather, 5.8; urethane users, 3.8. Wood industry rules specify equipment by the shop size. Wood shops using less than 50 tons of coatings a year must achieve a minimum TE of 40%. Approved spray-finishing methods include airless, heated airless, and air-assisted airless. Wood shops that use 50 or more tons of coatings a year are required to achieve a TE of 65% or higher. Approved spray-finishing methods for these shops include airless, heated airless, air-assisted airless, electrostatic spray, or flat line finishing. VOC limits (lb/gal) are: wash-coat, 6.1; stain, 4.7; pigment, 5.0; sealer, 5.6; clear-coat, 5.6.

Pennsylvania. The rules specify only that wood cabinet and furniture finishers must use air-assisted airless or electrostatic spray.

New York. New York follows the same rules as Pennsylvania.

Ohio. Ohio has adopted VOC limitations and will require a TE of at least 30%.

Hazardous Waste Regulations

Included in regulatory compliance is the issue of hazardous wastes. On March 29, 1990, the U.S. EPA promulgated a final rule revising the procedure used to determine whether wastes are hazardous because of their potential to leach significant concentrations of toxic constituents to landfills. The extraction procedure (EP) toxicity characteristic procedure was replaced with the toxicity characteristic (TC), utilizing the toxicity characteristic leaching procedure (TCLP). The U.S. EPA also added to the list 25 organic chemicals commonly used in surface-finishing operations (i.e., methyl ethyl ketone, tetrachloroethylene, etc.).

Table 29.3 Maximum concentration of contaminants allowable from TCLP[a][5]

EPA Hazardous waste no.	Contaminant	Regulatory level (mg/L)
D004	Arsenic	5.0
D005	Barium	100.0
D018	Benzene	0.5
D006	Cadmium	1.0
D019	Carbon tetrachloride	0.5
D021	Chlorobenzene	100.0
D022	Chloroform	6.0
D007	Chromium	5.0
D023	*o*-cresol	200.0
D024	*m*-cresol	200.0
D025	*p*-cresol	200.0
D026	Cresol	200.0
D027	1,4-dichlorobenzene	7.5
D028	1,2-dichloroethane	0.5
D029	1,1-dichloroethylene	0.7
D030	2,4-dinitrotoluene	0.13
D032	Hexachlorobenzene	0.13
D033	Hexachlorobutadiene	0.5
D034	Hexachloroethane	3.0
D008	Lead	5.0
D009	Mercury	0.2
D014	Methoxychlor	10.0
D035	Methyl ethyl ketone	200.0
D036	Nitrobenzene	2.0
D037	Pentachlorophenol	100.0
D010	Selenium	1.0
D011	Silver	5.0
D039	Tetrachloroethylene	0.7
D040	Trichloroethylene	0.5
D041	2,4,5-trichlorophenol	400.0
D042	2,4,6-trichlorophenol	2.0
D043	Vinyl chloride	0.2

[a] Excluding D012–D017 and certain pesticides

Although the maximum allowable concentrations of the regulated eight metals (and pesticides, herbicides, and insecticides) do not change from those listed under the EP toxicity, the new TCLP analytical procedure may make it more difficult for listed wastes to stay under the allowable concentrations (Table. 29.3).

Technical Trends in Coatings

Through the years, improved paints have been developed because of competition from environmental and consumer activists. The objective of improving overall quality and reducing emissions of VOCs has led to a wider selection of

Table 29.4 Coatings markets served by leading paint and powder coating producers[6]

Market segment	Average percent of total coatings output
General industrial	34.4
Automotive	18.0
Metal furniture/business equipment	8.6

paint types. The user, therefore, must select a coating type that meets the cost of required application, equipment, energy costs for using, pollution and waste collection expenses, and application and cured performance requirements of the coating.

Table 29.4 lists types of coatings markets served by leading paint and powder coating producers. By far, the leading type of coating manufactured for the OEM market produced by the suppliers surveyed is waterborne (87.4%), followed by low-solids solvent-borne (78.7%), high-solids solvent-borne (74.0%), and two-component coatings (69.3%). The percentage of powder coatings produced by the surveyed producers accounted for only 26.0%, while ultrahigh solids and UV/EB coatings added an additional 22.0 and 22.8%, respectively. The majority of those producers surveyed suggested that most of their R&D spending would be on waterborne coatings. While powder coating research continues to grow, E-coat and radiation cure research continues through suppliers in niche markets. Lower co-solvent, lower cost, and shortened cure times continue to be the hottest areas of research.

A solvent-borne coating generally consists of seven major constituents:

- Resin (binder).
- Cross-linker.
- Rheology control agent.
- Catalyst.
- Pigment.
- Flow additive.
- Solvent(s).
- Weathering stabilizers (if required).

The resin (often referred to as binder) is responsible for the main attributes of the coating when cured with the cross-linker (or cross-linking agent).

The curing, or network formation, often is accelerated through the use of a catalyst. Rheology control agents, often referred to as sag control agents, are added to impart shear-thinning behavior when under high shear (i.e., spray application) and rheology or anti-sagging behavior when under low shear (applied on substrate). Pigments, discussed later in this chapter, are introduced to impart color.

The amount of pigment utilized depends on the color and the hiding power required of the coating. The flow additive often is introduced to relieve surface tension variations between the coating and substrate, to eliminate pinholes or crater formation. Solvents are added as necessary to achieve flow under application conditions.

In order to achieve a VOC-compliant coating, one must consider the molecular weight of the main binder utilized in the coating formation, as well as the effect of additives on the final viscosity. After all, application viscosity, which in turn is affected by the rheology of the coating constituents, is most often controlled by freely adding additional solvent to achieve necessary flow and leveling upon application. This in turn affects the VOC emission of the coating.

If one considers the molecular weight dependency of resins utilized in the various coating types, it is readily evident why VOC compliance is more easily achieved in radiation-curable and powder coatings. The molecular weight of nonaqueous dispersion resins, for example, exceeding 10^5 g/mol, results in very viscous materials, whereas the typical molecular weight of a radiation cure oligomer ranges from 10^2 to 10^3 g/mol, for a very low viscosity material, which requires little if any additional solvent to attain application specifications.

If we consider the evolution of coating technology over the last 70 years (see Table. 29.5) we can see that by the mid-1950s, waterborne and higher solids coatings already were under development. Powder coatings, 100% reactive liquid coatings (electron/beam and UV-cure), electro-coatings, aqueous or waterborne (water-base) coatings, and high solids coatings can all be considered as novel "non-polluting" VOC-compliant coating systems.

Powder Coatings

Today, powder coatings are one of the fastest growing finishing technologies in North America, with a growth rate (in pounds sold) of 7–9% per year over the next 5 years. The major impetus for growth can be attributed to the virtual "pollution-free" finishing system as well as the dramatic leap forward in materials and equipment technology.

Powder coating resin systems have been developed to meet specific needs of the metal finishing operations. Epoxies were utilized almost exclusively during the early years of thermosetting powder coatings and continue to be utilized in a range of applications. However, because of the poor outdoor durability of epoxy resins, acrylics, and polyester-urethane hybrids are finding increasing use.

Powder coating manufacturers continue to work on perfecting flow and leveling of the coatings, which often are prone to "orange peel." The other major disadvantage of thermosetting powder coatings is the high temperature (300–350°F) required to cure these systems. Research seeks to lower the temperature of cure.

Electron Beam and Ultraviolet Curable Coatings

Radiation-curable coatings were developed by W. J. Burlant (of the Ford Motor Company) in 1962. Acceptance of finishes designed for radiation curing (high-solids materials formulated to be cured by UV and EB systems) is growing at roughly 8% per year with a market size of approximately 85 million lb.

The major advantages of radiation-curable coatings are speed of cure, reduced emissions, 100% solids systems, and elimination of ovens, or other sources of thermal energy. The most rapidly growing areas in UV are UV-curable powder coatings and new applications for UV-curable coatings for automotive parts. The UV coating usually is comprised of unsaturated monomers that polymerize with UV light (in the presence of a photo-initiator, which absorbs radiation and initiates polymerization). Unsaturated polyesters copolymerized with vinyl monomers or multifunctional acrylates often are utilized. Most recently, however, vinyl ether monomers for cationic curing with epoxies have shown promise due to reduced shrinkage of cured films and improved adhesion to substrates. Waterborne UV-curable coatings have also recently been introduced.

Major uses for UV curing (room temperature) include use of flat stock-fillers in particle boards and hardwood flooring, and for high-gloss (no-wax) protective coatings for floor tiles, wood finishes, and other specialty uses.

Current Automotive Coating Trends

Until 1965 automotive topcoats consisted of nothing more than acrylic lacquer technology. As technology improved to include solvent-borne nonaqueous dispersions in the mid-1960s and medium solids thermoset coatings in the 1970s, two competing factors were becoming more important: control of emissions (VOC) and the quality of the appearance of the topcoat. Today, the quality of the topcoat includes chip resistance, environmental etch resistance, and metallic glamor; so virtually all automotive procedures (except in truck plants) now utilize basecoat/clear-coat technology. The basecoat is the pigmented film that is responsible for providing color. It is covered, in a wet-on-wet spray process, with a clear-coat that provides chemical resistance, UV resistance, chip resistance, and distinctness of image (DOI) (often referred to as the "wet look").

The total automotive coating composite, however, consists of more than just the basecoat/clear-coat. The metal sheet stock that is formed into the automotive car body is treated with a corrosion-resistant primer applied by cathodic electrophoresis. This coating, often referred to as "ECOAT" or "uni-prime" is a hydroxy functional epoxy/blocked isocyanate dispersion that deposits onto the cathode of an electrolytic cell at a voltage of between 250 and 425 V. Film thickness, which is dependent upon the residence time, temperature, and coating voltage of the electro-coat bath (electrolytic cell), varies between 0.8 and 1.2 mils (1 mil = 25 μm). The curing temperature required to deblock the isocyanate and yield a cross-linked network varies from 275 to 375°F for 20 min. The function of this coating is to provide a corrosion-resistant film to the metal sheet stock.

A primer surfacer, composed most often of a polyester to be cross-linked with a blocked isocyanate or melamine cross-linker, is applied next at a dry film thickness of approximately 1.0 mil by conventional spray application. The function of this coating is to provide filling and leveling properties as well as some stone-chip resistance. Cure conditions range from 250 to 325°F for 20 min.

The solvent-borne basecoat, consisting of polyester or acrylic binder to be cross-lined with melamine or isocyanate, is applied at a dry film thickness of between 0.6 and 1.5 mils, depending upon the color. Poorer-hiding colors, such as red and white straight shades, require the higher film builds, whereas metallics and darker colors are applied at the lower film builds. The solvent-borne basecoat is allowed to flash-off solvent for approximately 3–5 min at ambient conditions prior to application or the solvent-borne clear-coat. This process is referred to as a weton-wet application because the basecoat is not in its cured or cross-linked state.

Optionally, a waterborne basecoat can be utilized to achieve better aluminum orientation in metallic films. Several papers [8, 9] have described metallic orientation and the advantages of waterborne basecoats, so this concept will not be thoroughly discussed here.

The waterborne basecoat consists of a urethane or an acrylic dispersion with passivated aluminum for metallic glamor. The aluminum must be passivated to prevent reaction with water and the evolution of hydrogen gas. Passivating agents can include polymers, hexavalent chromium (now mandated for removal), or phosphate esters. The basecoat is pre-baked (with infrared or thermal ovens) to release the majority of the water prior to clear-coat application.

The solvent-borne clear-coat is spray-applied over the basecoat at a dry film thickness of 1.8–2.0 mils. The clear-coat, responsible for UV protection, chemical resistance, chip resistance, and so on, is most often composed of a hydroxy functional acrylic binder together with a melamine or an isocyanate cross-linker. UV light absorbers and hindered amine light stabilizers also are added to achieve better free-radical oxidative degradation resistance when the coating is exposed to sunlight.

The clear-coat is referred to as a two-component (2K) clear-coat when isocyanate is used as the cross-linker. The isocyanate must be added to the hydroxy functional acrylic just prior to spray application to prevent premature cross-linking (or gelation). For this reason, the two-part mixing is referred to as 2K. Cure conditions for isocyanate-cured clear-coat range from room temperature (car refinish) to 250°F for 30 min.

One component, or 1K clear-coats are equivalent to 2K clear-coats with the exception that they are cross-linked with melamines. Cure conditions for 1K clear-coats are 250°F for 30 min. Blocked isocyanate versions of 1K clear-coats also are available, but cure requirements necessitate 275°F or higher.

Significant research is being conducted on waterborne clear-coats in attempts to achieve better VOC emission levels. Waterborne clear-coat research is limited to water-dispersible acrylics because high gloss and good weatherability can be attained. Removal of water from the film, however, is a problem, as coalescence often begins prior to through-cure, often resulting in “solvent-popping.” Much work remains to be performed on optical formulation parameters (i.e., solvent blend, anticratering surfactants, rheology control, etc.) in order to attain defect-free coatings.

Coatings for Plastics

The use of plastics in automotive applications has expanded considerably over the past 20 years. In 2001, approximately 250 lb of plastics were used per automobile compared to less than 100 lb five years earlier. With the increased use of plastics, coating research has concentrated on the painting of these often difficult substrates. Among the numerous prerequisites for coatings on plastic are: wetting of the substrate; uniform film development; a cure response below the heat distortion temperature of the plastic; adhesion to the substrate; inhibition of substrate imperfections; and often a conductive nature to increase the TE of subsequent topcoat application.

Plastic types are variable, ranging from flexible to rigid and from thermoplastic to thermoset. Because of these variations, the type of coating applied to them also varies, depending on cure response, solvent sensitivity, and modulus. The type of coating also depends upon the end use of the coated plastic. For example, topcoats can be applied directly to the plastic without the use of a conductive primer if two-toning or blackout areas are not part of the styling latitude. Adhesion promoters also are often utilized if a particularly difficultto-adhere-to plastic is encountered (i.e., polypropylenes or thermoplastic polyolefins (TPOs), a blend of elastomer and olefin).

Conductivity in plastic coatings is achieved through the use of a conductive pigment, most often conductive carbon black. Conductivities of the order of 1 MΩ/cm^2 are required for effective transfer efficiencies of subsequent topcoat applications. Without the use of a conductive primer, plastics in themselves would not be conductive, and hence would be very unreceptive to topcoat transfer efficiencies of greater than 20%.

The adhesion of a coating to plastic is related to the substrate wettability and also to physical–chemical forces. Both covalent (bond formation) and dispersive (London or van der Waals) forces are responsible for the adhesion of the coating due to physical–chemical forces.

Substrate wetting often is measured by contact angle measurements: the smaller the contact angle, the better the wetting of a coating to the plastic. The wettability of a coating on a plastic substrate is related to the surface tension of the substrate: the lower the surface tension of the plastic, the more difficult it is to wet.

Polypropylene, in particular, has a very low surface tension (less than 32 dynes/cm^2). Because of the low surface tension, it is very difficult to wet out; and because of the apolar nature of the polypropylene backbone, it is a very difficult material to adhere to. Therefore, copolymers of ethylene propylene diene monomers (EPDM) with polypropylene have been developed. The higher the level of the EPDM in these TPOs, the more paintable is the substrate.

Conventional coating approaches to TPO, which rely on the use of substrate pretreatments such as flaming, corona discharge, plasma or chemical pretreatment, have led to a substantial oxidation of the surface, which enhances adhesion. These pretreatments, however, have a limited service life before the surface reverts to its unoxidized, apolar condition.

Chlorinated polyolefins (CPOs) also are a mainstay of adhesion promotion to TPO. The CPO generally is applied as a dilute solution (5–35 wt. %) in aromatic solvents to the TPO to act as a "tie-coat," to which the topcoat is applied. These materials are often humidity sensitive and only adhere to TPOs with EPDM levels of greater than 5%.

New Cross-Linking Technologies

The traditional cross-linking technologies utilized in the coatings market range from hydroxyl functional binders (acrylics or polyesters) cross-linked with melamines (1K) or isocyanates (2K) to drying oils that cure through oxidation of unsaturation in the backbone, to epoxy resins cross-linked with amino resins (amido amines, amines, etc.).

New resin and cross-linking technologies, however, have been introduced with hopes of achieving more environmentally acceptable coatings. However, most of these have not achieved widespread success with the possible exception of areas such as automotive coatings where they can provide properties such as chip resistance and resistance to "acid rain."

Bio-Based Resins

As companies begin to focus on issues such as sustainability, and "green" chemistry, interest in the use of bio-based resins in coatings has been rapidly increasing. Procter & Gamble Chemicals introduced a line of sucrose ester resins of vegetable oils for industrial applications under the brand name SEFOSE. In collaboration with Cook Composites and Polymers (CCP), they demonstrated that SEFOSE resins could be used as a reactive diluent in alkyd paints to reduce the VOC from 440 g/L to 250 g/L and won the 2009 Presidential Green Chemistry Challenge Award [10]. Other companies have also introduced new bio-based products, including the Solus line of cellulose ester resins by Eastman, Albecor-Bio, a bio-based polyester for powder coatings by Hexion, and Dow Chemical introduced the Renuva line of bio-based polyols. Sherwin-Williams received the 2011 Presidential Green Chemistry Challenge Award for their new paint technology based on soybean oil and recycled PET.

Printing Inks

Printing inks, utilized in printing and packaging applications, are colored, liquid materials consisting of essentially two components: the colorant, an insoluble solid or a dye, and the vehicle, a liquid in which the colorant is suspended or dissolved. Recent years have seen significant progress in water-based inks, but compared with the phenomenal growth in water-based paints, the advances in water-based inks have had a much smaller impact on the industry. The upsurge of interest in water-based inks, which began in the mid-1970s, was stimulated by the need to conserve expensive petrochemical-derived organic solvents, attention to environmental pollution problems, and increasing pressures from health and safety legislation.

Inks can be applied to a wide variety of substrates, including plastics, paper, textiles, metals, and glass. In contrast to paint films, inks are applied very thin, varying from 2 to 30 μm depending on the print process. The print process consists of application of the ink to the substrate by a printing press of varying design. As such, inks are classified by the type of process through which they are applied. There are five classifications: flexo-graphic, gravure, offset lithographic, letterpress, and screen.

The mechanisms of letterpress, offset lithographic/flexographic, and gravure printing processes are outlined in Fig. 29.1 [11]. In letterpress and offset lithographic processes, a thin film of ink is carried to the printing plate by means of a train of rotating rubber rollers. Both of these processes preclude the use of volatile organic solvents in the inks because of the swelling effect or attack on the rubber rollers and blankets and because of their high evaporation rates, which could lead to premature drying or tack development of the inks on rollers, blanket cylinders, and printing plates. Water, too, evaporates more rapidly than the high-boiling aliphatic-type solvents normally used in letterpress and offset lithography, and the evaporation is accelerated by the heat that can be developed (temperatures of 30 °C or more) in the rollers after a period of running.

Several different types of drying mechanisms may be operative in printing of letterpress and offset lithographic inks (see Table. 29.6) [12]. As shown in Table. 29.6, the ink distribution systems of flexo-graphic and gravure presses are quite different from those of letterpress or offset lithography. There are no long roller trains, and because the drying mechanisms depend mainly upon evaporation of volatile solvent components, it is not surprising that most of the development work has been on inks for these processes.

Inks that are printed by the flexo-graphic and gravure printing processes are characterized by their extremely fluid nature, and are generally termed "liquid inks." When

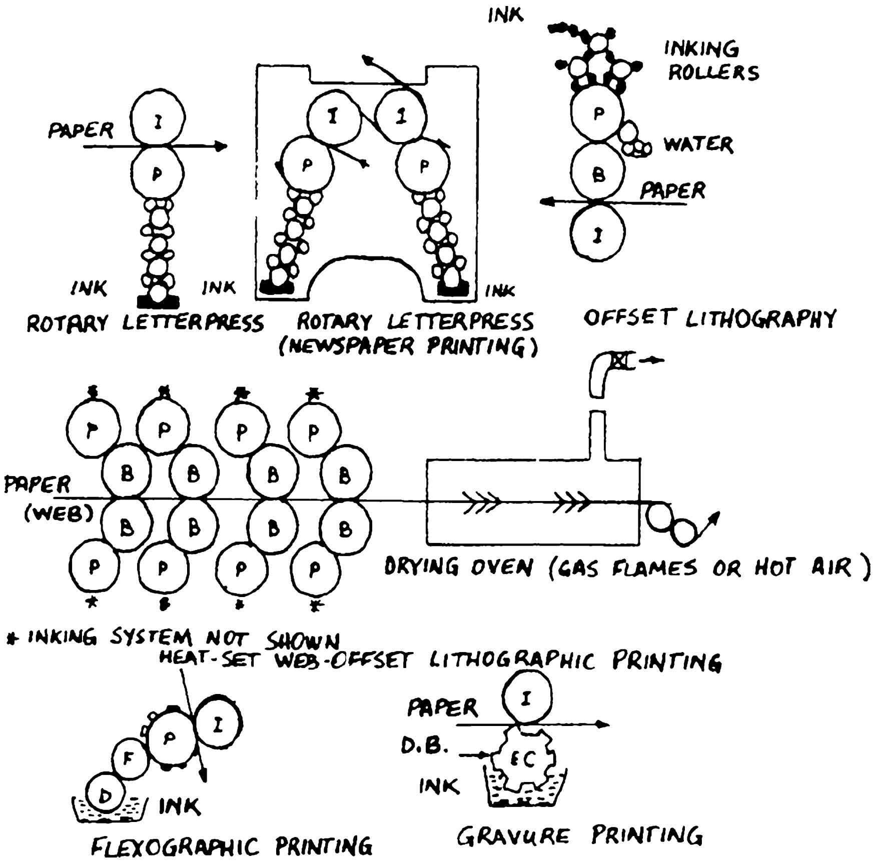

Fig. 29.1 Mechanisms of letterpress, offset lithographic/flexo-graphic, and gravure printing processes[12]

Table 29.6 Letterpress and lithographic inks—dry mechanisms[12]

Type ink or process remarks	Principal ink Vehicle	Typical substrates	Drying mechanism
Letterpress W	Mineral oil	Newsprint A	Non-volatile mineral oil
Letterpress S	Oleoresinous and solvent	Papers, boards A, O	High-boiling range solvent
Letterpress S	Resin and glycol	Papers, boards P	High-boiling glycol
Letterpress S	Polyfunctional (acrylated) compounds	Papers, boards, R foils	No solvent ultraviolet curing
Offset litho W	Mineral oil and resin and solvent	Newsprint A	High-boiling solvent
Offset litho S	Oleoresinous and solvent	Papers, boards A, O	High-boiling solvent
Offset litho S	Oleoresinous and solvent	Tinplate O, E (stoving)	High-boiling solvent
Offset litho S	Polyfunctional (acrylated) compounds	Papers, boards, R foils, tinplate	No solvent ultraviolet curing
Offset litho W	Resin/solvent	Papers A, E (heat-set)	Gas flame hot air, high-boiling solvent

compared to the fluid nature of flexo-graphic and gravure inks, lithographic and letterpress inks are much more viscous and paste-like.

In screen printing, the ink is forced through the open areas of a stencil supported on a mesh of synthetic fabric, stretched across a frame. The ink is forced through the mesh onto the substrate underneath by drawing a squeegee across the stencil. The inks have to remain fluid and coherent on the mesh before printing, transfer through the mesh without its sticking to the substrate, flow to make the ink film continuous and so avoid the pattern of the mesh but maintain the image, and then dry rapidly once applied to the substrate. Inks that are able to print by this method are of household paint consistency; they are intermediate in viscosity between the fluid flexo-graphic and gravure inks and the paste-like lithographic inks.

An ink must be transformed to a solid from its liquid supply form once on the substrate. This change of state is referred to as an ink drying, and can be physical (absorption or evaporation) or chemical (oxidative or photochemical radiation induced). There are several forms of radiation used to dry ink, including UV, infrared, EB, microwave, and radio frequency.

Pigments

Pigments are generally incorporated into paints to affect properties associated with appearance such as color, opacity, gloss, metallic look, and depth. In addition, pigments commonly are used to protect the substrate against corrosion, attack by microbes or barnacles, and to retard flammability. Other desirable properties can be obtained by the addition of pigments. For example, pigments can be used in paints to control flow and leveling as well as either spray viscosity or brush-ability, depending upon the type of system. In addition, pigments are added to paint to control the cost of raw materials.

One of the most important properties of pigments, however, is the ability to cover or "hide" the surface being painted. This property is commonly referred to as "hiding power" or opacity. The fewer coats required to hide the surface, the higher the hiding power or the pigment's opacity. Pigments of different colors have different degrees of opacity. In general, darker colors have a higher hiding power than lighter colors, in part because of their relative opacities. In practice, this trend is also dependent upon the refractive index of both the pigment and the binder; that is, the difference in refractive index between the pigment and the binder determines the hiding power of the paint. Hence, the larger the refractive index difference, the higher the hiding power. In addition, the particle size of the pigment critically affects the hiding power of the pigment. There is an optimum particle size range, 0.2–0.4 μm (which is approximately one half the wavelength of light in air), which affords maximum light scattering and hiding.

Pigments ideally should be non-soluble solids with low oil absorption to facilitate dispersion and allow maximum pigment loading, which would also reduce the VOC content of the paint. In addition, pigments should be chemically inert, thermally stable, pure in their composition, and nontoxic.

Pigments can be classified into two main categories: inorganic pigments and organic pigments. Among the more common inorganic pigments are white hiding pigments, extender pigments or fillers, blacks, colors, and metallic pigments. Organic pigments consist of colors and the carbon blacks.

Inorganic Pigments

Inorganic pigments generally hide better than organic pigments when dispersed in paint. Inorganic pigments impart flowability to paint because they do not tend to swell in the presence of common paint solvents. In addition, inorganic pigments do not bleed inorganic solvents, and they afford excellent color permanence, especially in exterior paints. Inorganic pigments are thermally stable and generally impart heat resistance to the coating.

White pigments are important not only as the principal pigment in white paint but also as hiding pigments in many shades and the tinting colors. The most commonly used of the white pigments are the nonreactive titanium dioxides and the reactive zinc oxide. These pigments are designed reactive or nonreactive, depending on whether they interact chemically with the binder or vehicle portion of the paint.

Titanium dioxide is available in two crystalline forms—anatase and rutile. The anatase form has about 75% of the hiding power of the rutile form and is less resistant to chalking than the rutile form. Because of its high refractive index (2.76), titanium dioxide imparts excellent opacity to the paint. Because the hiding power of the titanium dioxide is so high, good opacity can be achieved by the addition of small amounts of the pigment to the paint, thus not adding significantly to the cost of the paint. The rutile form is available in grades designed specifically for enamels, flats, and solvent-based and water-based coatings [13].

Although zinc oxide has about 15% of the hiding power of titanium dioxide and has a fairly high cost, it contributes a number of important properties to paint. Zinc oxide can form zinc soaps in some formulations, which can aid in pigment wetting and grinding. It also can be utilized to improve film hardness and color retention of the film on aging. The most common use of zinc oxide is in exterior finishes to reduce chalking and the growth of mildew in house paints [14].

Extender pigments, because of their relatively low refractive index, exhibit poor hiding power and must be used in conjunction with pigments of high hiding power. The principal function of extender pigments in paint is to reduce the raw material cost. They also function to reduce gloss, as well as to control texture and viscosity. Calcium carbonate, more commonly known as whiting pigment, is available in a variety of particle sizes and surface treatments and is used to control sheen, degree of flow, degree of flatting, and tint retention. Magnesium silicate or talc generally is used because of its low cost and excellent durability. Talc imparts good antisettling properties and low sheen. Aluminum silicate (China clay) is used mainly in water-based systems. China clay is easily dispersed with a high-speed dispenser and may even add to the hiding power of water-reducible paints. Other extenders such as diatomaceous silica, regular silica, barites, and mica also are frequently used to impart specific properties to coatings, which are determined mainly by the particle size and shape of the pigment.

Most of the black pigment used in coatings is organic carbon black. There are, however, a few inorganic black pigments such as black iron oxide, which is used as a tinting black having brownish tones and also is used in primers. In addition, some inorganic black pigments such as mineral or thermal blacks are used as low-cost black extender pigments.

Iron oxide pigments are low-cost, highopacity pigments that impart excellent properties to coatings. These pigments are easy to disperse in both water and oil, are alkali- and chemical-resistant, and hence can be utilized in both water-based and solvent-based systems. Although both the red and yellow iron oxides afford rather dull colors, they possess high tinting strength and are popular shading colors. In addition, iron oxide pigments are extremely durable, color-fast, and non-bleeding.

Lead chromate pigments are mainly used as corrosion inhibitive pigments. These pigments are of low opacity and can be combined with higher opacity pigments for use in primers. Zinc chromate, also an anti-corrosion pigment, is used in metal pretreatments such as "wash primer," which also promotes adhesion to aluminum and steel.

Iron blue, one of the most widely used pigments, combines low cost, good hiding power, and high tinting strength. This blue pigment exhibits good exterior durability and good heat resistance. Iron blue should not be used in water-based paints because it has very poor alkali resistance.

Ultramarine blue has poor opacity but high tinting strength, high heat resistance, and good alkali resistance. It is primarily used as a tinting color, and when added to whites makes them look whiter by giving them a bluish cast.

Chrome greens range in color from light yellow greens to dark blue greens. They are bright, durable, economical, and have high hiding power. They are used less frequently of late because of their lead content. Chrome greens are not suggested for use in aqueous systems because of their poor alkali resistance.

Chrome oxide green is a dull pigment having excellent exterior durability and very good chemical as well as alkali resistance. Thus, this pigment is suitable for use in either water-based or solvent-based systems. Chrome oxide green has moderate hiding power and is easy to emulsify, and its infrared reflectance properties make it valuable for use in camouflage paints.

Organic Pigments

Organic pigments are insoluble solids, and thus are differentiated from dyes, which are colored organic compounds that are soluble in the media in which they are used. Pigments require a binder in order to be used as colorants. Organic pigments that are insoluble in their pure form are referred to as "toners." Organic pigments that require precipitation by an inorganic base such as a metal to be insoluble are referred to as "lakes."

Organic pigments have greater decorative value than inorganic pigments; that is, organic pigments have a greater esthetic appeal due to higher chroma. The higher tinting strength of organic pigments partially offsets their higher cost. Organic pigments have a smaller particle size than inorganic pigments and a higher oil absorption. In addition, organic pigments are generally less toxic than inorganic pigments.

Hansa yellows are insoluble azo pigments having a wide range of shades. They are generally excellent in masstone lightfastness although not good enough in tint lightfastness to warrant outdoor use. Compared with the chrome yellows, they have less hiding power and greater tint strength. The Hansa yellows are most commonly used in water-based coatings and air-dried coatings. Benzidine yellows are no longer used because they have been shown to be carcinogenic. Nickel azo yellows are transparent pigments used in greenish yellow enamels and tinting enamels. These pigments have better permanency than the benzidine yellows although they tend toward darker transparent masstones. Nickel azo yellows impart excellent alkali resistance and fairly good bleed resistance. The tinting strength of these pigments increases upon aging in the formulation. Vat yellows are comprised of flavanthrones and anthrapyrimidines. Of these, the flavanthrones are the more red in hue. The vat yellows have very good lightfastness in weak tints, and they impart very good heat resistance and bleed resistance to the coatings. Tetrachloroiso-indolinone-based pigments, although relatively expensive, are of very high quality, imparting good lightfastness to the coatings.

Benzidine orange pigments are bright, strong pigments that exhibit good alkali, heat, and bleed resistance. There are both opaque and transparent versions of these pigments, and they are fairly lightfast although they are not recommended for exterior use. Benzidine orange is no longer used because of its potential carcinogenic nature. Dianisidine orange pigments are more bleedresistant than the benzidine oranges but less colorfast. Dinitroaniline orange pigments have better permanency than the two orange pigments described above. Although the dinitroaniline orange pigments bleed in most solvents, they are very stable in aqueous systems and exhibit superior lightfastness. Tetrachloroiso-indolinone, brominated anthanthrone, and perinone oranges are expensive, but very high-quality orange pigments, characterized by their excellent masstone and exterior lightfastness.

Copper phthalocyanine greens afford very clean, semi-transparent masstone, non-bleeding tints ranging from bluish green to yellowish green. These pigments have excellent heat and chemical resistance, are very lightfast in both masstone and tint, and have high tint strength. Pigment green B is an iron salt of nitro-sobetanaphthol that affords a semitransparent masstone having a dull yellowish tint. Although this material is not lightfast enough for exterior applications, it does have excellent alkali resistance and is suitable for use in aqueous pigment dispersions.

Phthalocyanine blues are very clean, semitransparent, non-bleeding pigments yielding high tint strength. As with the phthalocyanine greens, the blues have excellent heat and chemical resistance and are very lightfast in both masstone and tint. Also as with the greens, these blue pigments at high concentrations may bronze upon exterior exposure although this property is vehicle dependent. These characteristics apply to the crystallization and flocculation grades. These pigments are highly recommended for use in water-based systems. Indanthrone blues are expensive vat-type, non-bleeding, semitransparent masstone pigments having excellent masstone and tint lightfastness. Although they exhibit very good heat and chemical resistance, these pigments find limited use in coatings.

Carbazole dioxazine violets are semitransparent masstone pigments having high tint strength, excellent heat and bleed resistance, and good lightfastness. Isoviolanthrone violets afford clean tints exhibiting excellent chemical resistance and very good lightfastness, but they bleed badly in paint solvents.

Toluidine reds are insoluble azo pigments ranging from light to deep reds having excellent chroma and masstone lightfastness. Although these pigments hide very well and exhibit very good alkali resistance, they are not suitable for exterior use and bleed in paint solvents. Toluidine reds have been replaced to a large extent by a combination of molybdate orange and quinacridone or rubine toners. This combination affords better gloss and gloss retention, better bleed resistance, and less haze. Compared with the toluidine reds, this combination does sacrifice some cleanliness and brilliance of tint as well as some masstone lightfastness. Para reds are insoluble azo pigments that are deeper, less bright, and not as masstone-lightfast as the toluidine reds. They have good opacity and good alkali resistance, but they bleed very badly in paint solvents. These pigments can be utilized in inexpensive air-dried water-based systems. Quinacridones possess hues from gold to deep maroons and violets. These reds afford excellent bleed, heat, and alkali resistance, as well as very good tint and masstone lightfastness.

Carbon black is probably the most widely used pigment in the coatings industry. It is popular both as a straight shade and as a tinting color. It comes in a wide variety of particle sizes and surface treatments, the choice depending upon required jetness, tone, ease of dispersion, and of course, cost. Carbon black is characterized by excellent hiding power of high opacity, high tint strength, excellent durability, and very good lightfastness. Large-particle-size carbon blacks are chosen for their ease of dispersion and low resin demand, as well as for being less susceptible to floating and flooding than the finer particle sizes. They should, however, be used in applications that do not demand high levels of jetness. The finer particle sizes, higher surface area carbon blacks afford extremely jet, very durable, high-gloss coatings. These carbon blacks would be very suitable in automotive topcoat applications. The fine-particle-size carbon blacks also are used frequently in conductive coatings. Although all carbon blacks are good conductors, differences exist based on surface area, structure, and volatile content. In general, however, conductivity of the carbon black increases as the surface area and structure increase and as the volatile content of the carbon black decreases. The structure of the carbon black is defined as the agglomeration of the fine particle into treelike or “dendritic” shapes.

Pearlescent Pigments

Pearlescent pigments are comprised mainly of mica platelets coated with a thin layer of titanium dioxide. Co-precipitating titanium dioxide and other metal oxides onto the mica results in pigments exhibiting a colored luster effect. These pigments have a very high refractive index, indicating high hiding power or high opacity. In addition, because of their light-reflective properties, they impart some exterior durability to the coatings; and because of their small, thin, flat structure and high refractive index, they give the coated object a three-dimensional effect, that is, the appearance of depth. This is quite different from the apparent surface gloss due to the use of metallic pigments. Pearlescent pigments are available in a range of particle sizes and characteristics, and provide a variety of effects. These include a stain-luster appearance resulting from fine-particle-size pigments. These pigments are alkali- and acid-resistant and extremely durable when coated with rutile titanium dioxide. Pearlescent pigments are readily dispersible in water and afford stable metal-like water-based coatings.

Aluminum Pigments

Aluminum pigments generally are provided in paste form to eliminate the hazards of dust explosion or ignition during handling and storage, as occurs with the aluminum powders. In addition, an aluminum paste is very economical because of its high hiding power, excellent durability, and low specific density. Aluminum paint films provide excellent protection of substrates because the aluminum flakes align in many parallel layers. The layers of aluminum flake are staggered, thus yielding a tortuous path for the transmission of gases, chemicals, light, and moisture. Therefore, it takes longer for these materials to penetrate the film to get to the substrate. Aluminum paints made up of the leafing-type of aluminum paste reflect 75–80% of light and radiant heat, and are commonly used as exterior maintenance-type coatings or decorative coatings. In fact, the minute flakes in aluminum paste impart a smooth, brilliant appearance to the film. The nonleafing type of aluminum flake can be tinted with other various colored pigments to effect brilliant finishes such as those used in automotive metallic topcoats.

Lacquers

Some time before 200 BC., the Chinese used an exudate from the conifer *Rhus verniciflua* (later known as the varnish tree) as a coating. The process was further developed in Japan, where by AD. 400, the product was known as Japanese lacquer. These lacquers are a type of oleoresin that dry by oxidation in a damp atmosphere [14].

Lacquers are defined as non-convertible coatings; that is, lacquer film formation does not depend upon any chemical reaction. Film formation is dependent only upon the evaporation of solvents, and the formed film remains soluble in the parent solvent blend. Lacquers generally are spray-applied, taking advantage of the solvent's ability to dissolve the previously applied coat. Chlorinated rubbers and nitrocellulose esters are typical examples of lacquers. Nitrocellulose lacquers can form glossy coatings having excellent adhesion when other suitable resins are added that are compatible in all proportions. Two types of cellulose nitrates are available, a low-viscosity type that affords high solids, high-film-build coatings and a high-viscosity, low-solids type. The primary use of pigmented nitrocellulose lacquers has been in the car refinish and the wooden domestic furniture markets. The chlorinated rubber lacquers are used principally as protective coatings for steel and other vulnerable materials in particularly harsh environments.

Vinyl lacquers are used mainly where a high degree of chemical resistance is required; these lacquers are based on vinyl chlorides and vinyl acetates. Acrylic lacquers are based on methyl methacrylate and methyl acrylate polymers and copolymers. Other esters of acrylic and methacrylic acid also may be used to make non-convertible film formers. Judicious selection of these acrylic acid or methacrylic acid esters allows one to produce film formers with specifically designed properties such as hardness, flexibility, gloss, durability, heat, and chemical resistance. Acrylic lacquers, however, are not noted for their water resistance. The principal uses of acrylic-type lacquers are fluorescent and metallic paints, car refinish applications, clear lacquers and sealers for metals, and protective coatings for aircraft components and for vacuum-deposited metals, as well as uses in pigmented coatings for cabinets and appliances.

Vinyl emulsion paints that contain a non-convertible resin dispersed in water along with pigment can be considered as waterborne lacquers if film formation results from evaporation of the water followed by coalescence of the binder in which the pigment is dispersed. As environmental regulations become more strict, the role of traditional lacquers will essentially go the way of the dinosaur. The only allowable lacquers or non-convertible coatings eventually will be the water-based type. Indeed, as environmental regulations become more restrictive, the challenges facing the coatings chemist and the formulator become ever more demanding.

Introduction

Fermentation products have penetrated almost every sector of our daily lives. They are used in ethical and generic drugs, clinical and home diagnostics, defense products, nutritional supplements, personal care products, food and animal feed ingredients, cleaning and textile processing, and in industrial applications such as fuel ethanol production. Even before knowing about the existence of microorganisms, for thousands of years ancient people routinely used them for making cheese, soy sauces, yogurt, and bread. Although humans have used fermentation as the method of choice for manufacturing for a long time, it is only now being recognized for its potential towards sustainable industrial development.

Since the discovery of fermentative activity of microorganisms in the eighteenth century and its proof by the French scientist Louis Pasteur, fermentative production of alcohols, amino acids, enzymes (biocatalysts), organic acids, vitamins, and natural polymers for food, feed, and other industrial applications has become well established. Subsequently, microbes have been used as production workers in industry. The production of bakers' yeast in deep aerated tanks was developed towards the end of the nineteenth century. The German scientist Buchner discovered that active proteins, called enzymes, are responsible for ethanol fermentation by yeast. During World War I, Chaim Weizmann used a microbe to convert maize mash into acetone, which was essential in the manufacture of the explosive cordite. In 1923, Pfizer opened the world's first successful plant for citric acid fermentation. The process involved fermentation utilizing the mold *Aspergillus niger* whereby sugar was transformed into citric acid. Other industrial chemicals produced by fermentation were found subsequently, and the processes were reduced to commercial practice. These processes included production of butanol, acetic acid, oxalic acid, gluconic acid, fumaric acid, and many more.

The serendipitous discovery of penicillin in 1928 by Alexander Fleming, while researching agents that could be used to combat bacterial infections, opened the whole new world of antibiotics. American pharmaceutical companies such as Merck, Pfizer, and Squibb were the first in mass-producing penicillin in the early 1940s. Initially, *Penicillium notatum* was surface cultured in flasks. Later, a new strain, *Penicillium chrysogenum*, was cultured in deep aerated tanks in the presence of corn steep liquor medium, and gave 200 times more penicillin than did Fleming's mold. Streptomycin was next, an antibiotic that was particularly effective against the causative organism of tuberculosis. Today, the list of these antibiotics is long and includes among many others, such important antibiotics as chloramphenicol, the tetracyclines, bacitracin, erythromycin, novobiocin, nystatin, and kanamycin.

Besides the booming antibiotics industry, fermentative syntheses of amino acids such as L-lysine and L-glutamic acid became billion dollar businesses. Despite the long history of microbial fermentation processes, understanding of the molecular basis of biological systems has developed starting from the discovery of the double helix DNA only decades ago. The practice of modern biotechnology started when Boyer and Cohen recombined DNA, and Boyer and Swanson founded Genentech, the first biotechnology company. Soon, it became clear that novel biotechnological manipulations could create new cell systems capable of producing new molecules and modifying existing products and processes. By the 1980s, a number of new biotechnology companies such as Amgen, Biogen, Cetus, Genencor, and others started to develop products for healthcare, agricultural, and industrial applications. The promise of biotechnology has been high in terms of delivering new products through partnerships with established pharmaceutical, agricultural, and chemical companies such as Eli Lilly, Roche, Johnson & Johnson, Monsanto, Shell, and others.

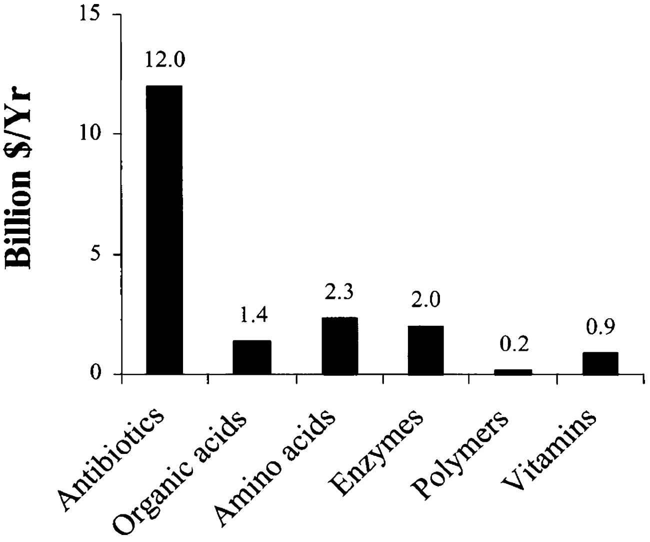

Fig. 30.1 Worldwide industrial biotechnology products market (except ethanol)

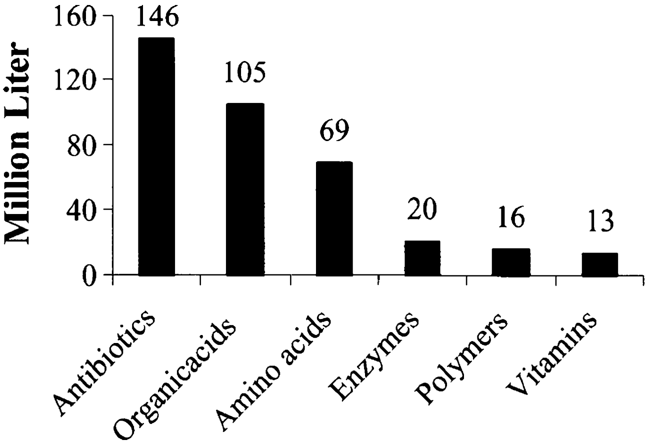

Fig. 30.2 Worldwide industrial biotechnology fermentation capacity distribution

By the end of the twentieth century, industrial applications of biotechnology started gaining momentum and proven laboratory techniques started to move into potentially huge markets. The field of industrial biotechnology (called "White Biotechnology" in Europe) was deemed the third wave of biotechnology. By definition, it is the application of scientific and engineering principles to the processing of materials by biological agents to provide goods and services. Industrial biotechnology continues to supply not only unique products, but is also considered synonymous with sustainable manufacturing processes. Some distinct advantages of industrial biotechnology include the use of renewable feedstocks (agricultural crop materials), generation of less industrial waste, lower cost for cleanup and disposal, and less pollution. The global market and fermentation capacity distribution (Figs. 30.1 and 30.2) for industrial biotechnology products, excluding ethanol, was estimated in 2002 at $17 billion. McKinsey & Company estimates that in the first decade of this century, biotechnology will affect up to 20% of the worldwide chemical market [1]. The major volumes of industrial biotechnology goods, such as alcohols, organic acids, amino acids, biopolymers, enzymes, antibiotics, vitamins, colorants, biopesticides, alkaloids, surfactants, and steroids, are expected to increase driven by innovative products, lower costs, renewable resources, and pollution reduction.

Discovery of Organisms and Molecules

Microbial Diversity

Microorganisms are chemically similar to higher plant and animal cells; they perform many of the same biochemical reactions. Generally, microorganisms exist as single cells, and they have much simpler nutrient requirements than higher life forms. Their requirements for growth usually are limited to air, a carbon source, generally in the form of sugars, a nitrogen source, and inorganic salts. Fermentation originally meant cellular activity/process without oxygen, but industrial biotechnology includes both aerobic and anaerobic fermentation processes. The nutrient source, complex (microbial, plant, or animal derived) or defined, not only provides carbon, nitrogen, and other elements (P, S, K, Mg, Ca, etc.) but also provides reducing and oxidizing agents [2]. Of course, in most of the cellular pathways, O_2 from air provides oxidation, releasing abundant metabolic energy from redox reactions. Depending on the physiological state of the cell, part of the metabolic energy escapes as heat that must be removed by the fermentor design. Sucrose, derived from sugarcane/beet and glucose derived from starch are often used as the carbon as well as energy sources for fermentation. Use of other carbon sources such as cellulose, hemicellulose, fats, etc. might increase in the near future. Proteins and fats are more reduced than saccharides and affect metabolism in terms of oxidation–reduction fluxes. The fluxes also depend on the endproduct(s) being more oxidized or reduced than the starting substrate(s).

Microbes occur in four main groups [3]:

- Bacteria and actinomycetales
- Viruses
- Fungi, including yeast
- Protozoa and algae

The chemical composition of microorganisms can be quite varied depending upon such factors as the composition of the growth medium, the age of the culture, and the cell growth rate. Table 30.1 lists the composition of a typical microbial cell [4]. All organisms contain the genetic information to produce a wide variety of enzymes and hence produce a great number of chemicals. Individual genes for

Table 30.1 Typical composition of microbial cell (about 70 % water)

Metal ions	1

specific enzymes can be organized into metabolic pathways that will define the biochemical metabolites that can be produced by the organism, which usually depends upon the environment in which the microorganism is growing. Inherent regulatory control processes allow cells to regulate their enzyme content in direct response to the environment. They prevent the formation of excess endproduct and superfluous enzymes. In this postgenomic era, the sequencing of a genome can be used for metabolic reconstruction of the microbial strain. Individual genes can be identified through homology to previously sequenced genes. Transcriptional analysis is another recent tool that allows the simultaneous measurement of all actively transcribed genes in a given organism at any given time. When combined with genomic information, attempts can be made to predict phenotypes or identify the organism.

For industrial processes, microbial strains with faulty regulation, altered permeability, enhanced enzymatic activities, or metabolic deficiencies are used to accumulate products. Such mutants have been changed so that their genetic mechanism is no longer sensitive to a particular controlling metabolite. Modern genetic engineering tools typically focus on creating such strains by making directed changes to the DNA of the organism.

Screening and Selection

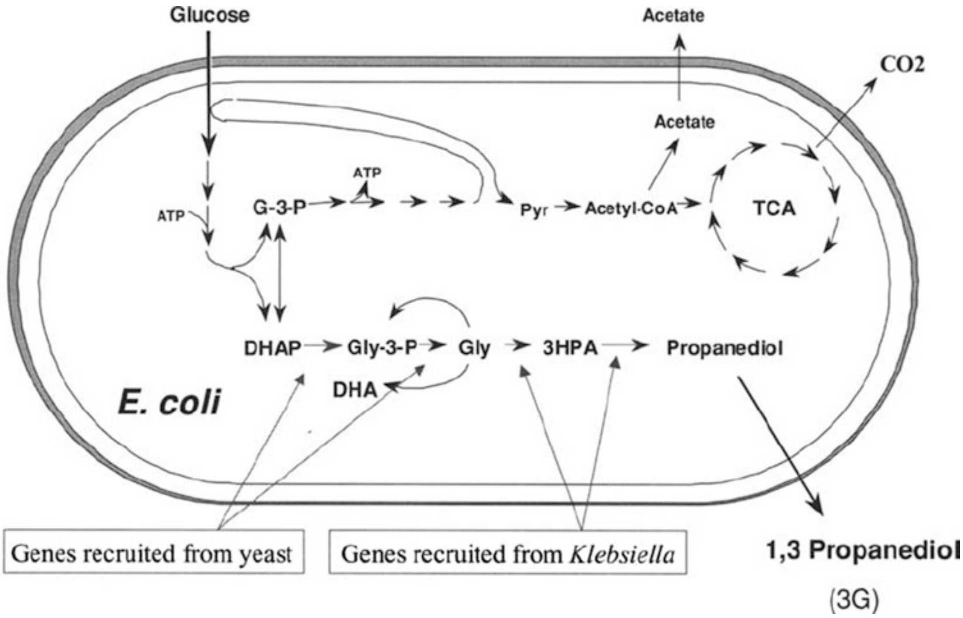
Product discovery means identifying the molecular target (enzyme, pathway, metabolite) of the intended application. A very early phase in the discovery of a microbial product involves searching for microorganism(s) that synthesize the product of interest [5, 6]. In the past this meant screening for living microorganisms. However, by applying molecular biology tools [7], today it is possible to screen for the gene (s) of interest without culturing the organisms. Of course, the rich diversity of microorganisms in nature is often the starting point for the screening/selection process. This process requires a well-designed growth medium, catalyst function, and assay. For example, a novel enzyme screening and selection strategy is based on an understanding of the real-world conditions under which the enzyme must function. Many enzymes are used in applications, for example, laundry, cooking, and solvent, that are far removed from the natural physiological conditions. Such applications expose enzymes to pH, temperature, and/or chemicals that might inactivate or inhibit them.

The classical screening method has its roots in antibiotic discovery. It involves collection of a variety of samples of soils and organic matter, and isolation of their microbial population. Being laborious at times (i.e., finding a needle in a haystack), random screening methods have been replaced in some cases by more efficient selection techniques. These techniques subject a microbial source sample to a selection pressure (i.e., pulling a needle from a haystack selectively with a magnet). For example, the growth conditions are selected such that only microorganisms expressing the desired enzyme/pathway/metabolite are able to survive. Therefore, selecting an environment (pH, T, growth nutrient) that is optimal for the growth of the desired microorganism increases the success of such a discovery. Very often, for the source of enzymes, industrial biotechnology companies look for microbes called extremophiles that live in extreme conditions, because they generally contain enzymes that perform optimally under extreme conditions.

In the last decade, tremendous progress has been made in sequencing DNA from various organisms. It is possible to extract DNA directly from the microbial community present in a sample taken from the environment. As a result, thousands of gene sequences have been deposited in public databases. This information can be used to screen for proteins/enzymes by searching for similarity at the gene level. Once a homologous gene is identified, it can be transferred to a laboratory host organism such as *Escherichia coli* or *Bacillus subtilis*. This allows for the expression of the identified gene product without making the source organism overproduce the molecule of interest. However, application of this technique is limited to microorganisms that have been isolated, characterized, and deposited in culture collections. Ironically, a very small number of microorganisms that exist in nature have been isolated and those characterized are even fewer. There may be many useful reactions in organisms yet to be discovered. Faster sequencing methods have started to exponentially expand the genomic database. Several hundred genomes are in the database and the tools of bioinformatics are vastly improving for the discovery of genes of interest.

According to J. Craig Venter Institute (http://www.venterinstitute.org), it should be possible to reduce the cost of sequencing a human individual DNA to less than $1,000. At this low cost and high speed of sequencing, we expect to learn more about human genes by comparing the human

Fig. 30.3 Rational biocatalyst design strategy for 1,3-propanediol



genome sequence to genome sequences of other species that have been thoroughly studied. Such diverse information has the potential to aid in the development of new products, processes, and applications in medicine, agriculture, energy, and the environment.

Cell Engineering

Classical strain development was traditionally dependent on the evolutionary process of random mutation. In a normal bacterial population, one mutant arises in about 10^6 cells. This low rate of spontaneous mutation is unsatisfactory for strain improvement. However, mutagens, such as *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (NTG) and Ethyl Methane Sulfonate (EMS), are available that markedly increase the rate of mutation. Although it is relatively easy to produce mutants, strain improvement requires painstaking effort and ingenuity in devising screening tests. Knowledge of microbial physiology is essential in the development of many of these screens. Screening for resistance to metabolic analogues is probably the most important screening tool for devising means around normal metabolic control mechanisms. Although truly exemplary production organisms for important medical and industrial products were created using this process, the timeframe for many of these developments can be measured in decades.

In this era of genetic and metabolic engineering, the timeframe for strain development has been reduced, although it still is a major effort requiring substantial investment. As in classical strain development, knowledge of microbial physiology remains essential to the practice of metabolic engineering. Understanding the regulation of genes, in particular the interaction of promoters and regulatory proteins, is also essential. The five key strategies for metabolic engineering can be summarized as follows [8, 9].

1. Enhance committed step from central metabolism or branch point.
2. Eliminate transcriptional and allosteric regulation.
3. Identify and relieve rate-limiting step(s).
4. Prevent carbon and energy loss to competing pathways.
5. Production of foreign enzymes or metabolites.

Sophisticated metabolic models teamed with experimental data are finding widespread use in identifying strategic sites for metabolic engineering. For example, DesignPath® [10] is an approach based on the use of mathematical models and specifically generated algorithms that can be used to predict the right combination of genes that would enable a cell to overproduce a desired biomolecule, for example, 1,3-propanediol [11], and minimize the synthesis of undesired by-products, for example, acetic acid. Using such models, scientists have been able to combine in a single host (*E. coli*), a natural biological pathway present in yeast for the production of glycerol from dihydroxyacetone phosphate, and a pathway present in the bacterium *Klebsiella pneumoniae* to convert glycerol into 1,3-propanediol, to create a novel and unique process (for details see the section, “Delivery of Products”; Fig. 30.3).

Production strains, established through classical mutagenesis and screening to produce metabolites at a commercial level, were often started from strains known to overproduce at least some amount of the desired product. These strains had already overcome some of the natural regulation to keep from overproducing metabolites. However, this often led to strains that could overproduce more than one endproduct. To maximize production of the desired endproduct alone, strains were selected that could not overproduce a sideproduct. This resulted in the development of an auxotrophic strain, which required the particular sideproduct in order to grow. The need for specialized growth media often resulted in added expense and downstream difficulties as the required component(s) were added as complex mixtures from animal or plant extracts. By using enzymes from different organisms, it is now possible to change gene regulation, prevent carbon loss to competing pathways, and eliminate auxotrophies.

The ability to use heterologous enzymes in a production host is one of the hallmarks of modern metabolic engineering. This can be accomplished by specific directed changes to the genome or by generating a high level of diversity. The goal of the effort is to improve a specific phenotype of the strain. This could be to produce a new metabolite not found in the original host or change the energy balance in the host or some other critical attribute. In any case, deep knowledge of the physiology of the organism is used to develop the appropriate screen to find the desired phenotype.

Molecular Engineering

Despite the diversity of enzymes in nature, it is rare that a screened or selected protein/enzyme might have all of the desired characteristics for a targeted application. Therefore, it may be necessary to engineer the starting protein by modifying its structure through mutation (deletion, insertion, or substitution) of one or more amino acids. Protein engineering can be carried out by genetic modification or by chemical means (acetylation, amidation, oxidation, covalent attachment of ligands). Compared to the chemical approach, site-directed genetic manipulation is more predictable. The specific changes in the gene sequence are made through the use of recombinant DNA technology. Because the structure of a protein determines its function, rational protein engineering starts with studying the three-dimensional structure of the protein either by X-ray diffraction, NMR, or molecular modeling. Often such studies take time and require access to special expertise; therefore, alternative approaches such as random mutagenesis and directed evolution have emerged.

Random mutagenesis has been used extensively as a tool for increasing the genetic variability and improving microbial strains as described earlier. However, random mutagenesis also means less control over the number and types of mutations made. A large number of clones (called a library) are first generated and then screened or selected for the targeted properties. Therefore, random mutagenesis methods tend to use high throughput or rapid and efficient screening techniques.

Directed evolution, a term that covers a wide range of techniques designed to quickly improve strain performance, uses repetitive rounds of mutagenesis along with screening/selection, until a series of mutations accumulate to give an enhanced phenotype. Once again, the key factors for success are understanding of the target gene, the method for generating variability, selection, and screening of the host. The technique makes use of the fact that enzymes retain their relevant tertiary structures and thereby function. The evolution through a range of acceptable molecular structure variations leads to better enzymes with which the organism can tolerate specific environmental stress.

Several in vivo as well as in vitro methods of molecular evolution have been developed based on the recent advances in high-throughput screening, functional genomics, proteomics, and bioinformatics. Molecular evolution technologies provide efficient tools for creating DNA libraries (random, directed, recombinational) and processes of selection for a desired function or characteristic of a target molecule. For example, “DNA shuffling” is a variation of the molecular evolution approach and involves recombination of closely related DNA sequences, for example, random fragmentation and reassembly of the fragments into genes. The method is useful to combine two or more properties, which have evolved separately, into the target molecule. Molecular engineering, optimization, evolution, and other tools enable the design of completely novel biomolecules and proteins for applications in agriculture, medicine, and industry.

Development of a Production Process

Strain

Strain development begins with identification or isolation of an organism capable of producing the molecule of interest. Invariably, the initial strain is improved by mutagenesis, screening, selection, and genetic engineering to meet the production process and economic requirements. The process requirements include handling of the strain, fermentation conditions, product recovery, formulation, and application. Not surprisingly, strain and process development take place in an integrated manner. For example, processes that are sensitive to the cost of fermentation raw materials look for carbon-efficient strains. Likewise, processes that aim to achieve high purity in product need to have fermentations that require the use of minimal medium and strains that produce minimal sideproducts. New genetic techniques allow the rational engineering of a production strain. A rational approach means that the genes defining the production of a particular metabolite are specifically engineered through mutagenesis, deletion, or over-expression. Controlling expression of such genes determines the rate (productivity), yield (carbon conversion efficiency), and titer (concentration) of the product. The result is a production organism that is optimally tailored for the process and the product.

Some bacterial and fungal strains are capable of differentiation (sporulation, filamentation). This property can affect product formation and the physical properties of the fermentation broth. Some enzymes are synthesized as secondary products and their production does not appear to be growth associated. Production strains are distinguished on the basis of their fermentation behavior such as viscosity or recoverability. They can also be distinguished by patent or proprietary status. The complexity of product synthesis ranges from a relatively simple and well-understood induction and repression to very complex regulation mechanisms. Process development must thus deal with such complexity either by changing the genetic make-up or by optimizing process conditions.

Because classical approaches to strain development are labor intensive and offer limited knowledge, new strain development methods now start with a production host that is capable of rapid genetic manipulation and efficient product synthesis. Generic hosts and techniques allow for the construction of multiple strains for multiple products utilizing a baseline fermentation and recovery process. The so-called toolbox strategy of building strains applies to production of enzymes/proteins as well as biochemicals. Generic host-based strains (denoted GRAS, Generally Recognized As Safe) have been proven for safe use in industrial processes and have been approved by regulatory agencies such as the FDA, EPA, and USDA.

Once a desired production strain is developed, it can be maintained as a stock culture. In maintaining stock cultures, genetic changes must be minimized. This is best achieved by preventing nuclear divisions as most mutations occur as errors during DNA replication. The method of choice is to store cells or spores (if these are produced) in sealed ampoules at very low temperatures (≤130°C) in liquid nitrogen. This method offers the great advantage that the culture can be stored almost indefinitely, thawed, and used immediately as an inoculum without loss of viability or diminution in metabolic rate. Cultures kept at −20 to −60°C are satisfactory but less active than those kept in liquid nitrogen. Although storage at 0–4°C allows some growth, this is better than storage at room temperature. Lyophilization (freeze-drying) is widely used and is very convenient because freeze-dried cultures retain viability without any genetic changes for years when stored at room temperature. It may be noted that all of these methods are, in effect, techniques to immobilize intracellular water and yet retain viability.

Fermentation Process

Analysis of many industrial fermentation processes shows that they are common reactions from a chemical, as well as a physical, viewpoint. Fermentation processes can be classified by the reaction mechanisms involved in converting the raw materials into products. These include reductions, simple and complex oxidations, substrate conversions, transformations, polymerizations, hydrolyses, complex biosyntheses, and the formation of cells.

Fermentation processes, except for sterilization, have in common many of the familiar chemical engineering unit operations. For example, aerobic fermentations involve the “mixing” of three heterogeneous phases: microorganisms, medium, and air. Other unit operations include “mass transfer” of oxygen from the air to the organisms and “heat transfer” from the fermentation medium.

Analysis of fermentations by the unit operation technique has added greatly to the understanding of their behavior. Of the operations auxiliary to those in the fermentor, engineers have made a major contribution towards the design of equipment to provide large volumes of sterile medium and air. Close cooperation between biologists and engineers has resulted in devising logical methods for screening large numbers of strains and translating the results of shake-flask and pilot-plant experiments to production vessels. The scale-up of fermentations, in some instances, is still empirical although sensitive oxygen probes and gas analysis techniques now available have enabled a rational approach to scaling-up aerated, Newtonian as well as non-Newtonian, fermentation processes.

Sterilization

In all fermentation processes, it is necessary to have contamination-free fermentation media and seed cultures. Liquid sterilization of the fermentation medium is conducted by two means, physical removal or inactivation by heat [12, 13]. Contaminating microorganisms can be removed from fluids by filtration. With improvements in membrane technology, sterile filtration is finding wider use, but can only be used with completely soluble media. The contaminants can also be destroyed by heat. Heat sterilization of media is the most common method used for sterilization of liquid media. This can be accomplished in either a batch or a continuous fashion.

Interest in continuous methods for sterilizing media is increasing, but for the successful operation of a continuous sterilizer, foaming of the media must be carefully controlled and the viscosity of the media must be relatively low. The advantages of continuous sterilization of media are as follows.

1. Increase in productivity because the short period of exposure to heat minimizes damage to media constituents.

2. Better control of quality.
3. Leveling of the demand for process steam.
4. Suitability for automatic control.

Design and operation of equipment for heat sterilization of media are based on the concept of thermal death of microorganisms. Consequently, an understanding of the kinetics of the death of microorganisms is important to the rational design of sterilizers.

The destruction of microorganisms by heat implies loss of viability, not necessarily destruction in the physical sense. The destruction of organisms by heat at a specific temperature follows a first order rate of reaction [14, 15]:

$$\frac{dN}{dt} = -KN = -(Ae^{-E/RT})N, \tag{30.1}$$

where K is the reaction rate constant with units of time^{-1}, N is the number of viable organisms/unit volume, t is the time, T is the absolute temperature, E is the energy of activation for death, R is the gas law constant, and A is the Arrhenius constant.

This equation can be integrated to give the design equation:

$$\ln\frac{N_0}{N_f} = A\int_0^{t_s} e^{-E/RT}\,dt, \tag{30.2}$$

where N_o is the number of contaminating organisms in the total fermentation medium to be sterilized, N_f is the level of contamination that must be achieved to produce the desired degree of apparent sterility, and t_s is the sterilization time.

In estimating the sterilization time for the medium, one must define the contamination, the desired degree of apparent sterility, and the time–temperature profile of the medium; that is, $T = f(t)$. For typical bacterial spore contaminants, the constants used in most designs have the following values.

$E = 68{,}700$ cal/g mol
$R = 1.987$ cal/g mol, K
$A = 4e^{+87.82}$, min^{-1}

Aerobic fermentation processes also require a continuous supply of large quantities of air, typically on the order of one volume of air per volume of liquid per minute, VVM. Sterilization of this air is mandatory in almost all fermentations. Absolute filter cartridges of polymeric membranes are now used almost exclusively in the fermentation industry. Relatively small units have replaced the large depth filters used in the past. Still, water and particulates pose a major problem for filters thus requiring the use of prefilters and traps to remove these contaminants before they reach the absolute filter. Parallel installation of the filters prevents a total shutdown of the fermentation process in the event of filter clogging.

Microbial Kinetics

Microbial kinetics [16, 17] can be separated in four distinct levels: at the molecular or enzyme, the macromolecular or cell component, cellular, and population level. Because each level has its own unique characteristics, different kinetic treatments are needed. Moreover, the environment in which these reactions take place also affects the kinetics. For example, reactions at the molecular/enzyme level involve enzyme-catalyzed reactions. When these reactions occur in solution, their kinetic behavior is similar to that of homogeneous catalyzed chemical reactions as described in Chap. 31. However, when enzymes are attached to inert solid supports or contained within a solid cell structure, their kinetics is similar to that of heterogeneous catalyzed chemical reactions.

As discussed in regard to microbial diversity, all microorganisms have basic requirements, those being water, a source of energy, carbon, nitrogen, salts, and trace metals, and possibly growth factors. However, the media used to isolate and screen production hosts are not necessarily those used in production fermentors. Statistical methods (Plackett–Burman, Box–Benkhen) are used for media screening and optimization. The media and conditions used may change from shake flask through the fermentor stages. The objective in developing a production medium is to maximize productivity and product quality, minimize sideproducts, and meet economics. Generally, large-scale fermentation media are made up of complex natural materials, supplemented with inorganic/organic salts [18, 19]. Development of a production medium combines understanding the physiology of growth and product formation developed through plate, shake flask, and fermentor studies.

For example, for deciding on the type of carbon source, the phenomenon of catabolite repression must be considered. Similarly, regulation of nitrogen and sometimes phosphorus metabolism are important factors to consider. Sometimes high concentrations of salts and free amino acids necessary for high cell density are inhibitory to product formation. One area often overlooked is the elimination of unwanted impurities, derived either from the raw material or produced via metabolism. These impurities represent not only a waste of the carbon source, but their accumulation at high levels may lead to inhibition of growth or even cell death.

At a population level, a material balance on cells growing by binary fission can be described by:

$$\frac{dX}{dt} = \mu \cdot X, \tag{30.3}$$

where X is the cell concentration and μ is the specific growth rate of the microbial culture.

Monod [20] suggested that cells growing on a limiting substrate were controlled by a limiting enzymatic reaction. Enzymatic reactions had been modeled using Michaelis–Menten kinetics and Monod applied the same methodology to microbial growth. He described the specific growth rate by:

$$\mu = \mu_{\max} \cdot \frac{S}{K_s + S}, \tag{30.4}$$

where $\mu_{\max}$ is the maximum growth rate of the particular strain being studied, s is the concentration of the limiting substrate, and K_s is the so-called affinity constant for the limiting substrate and is equal to the concentration of the substrate resulting in one-half the maximum growth rate. Combining the above equations results in the cell balance equation:

$$\frac{dX}{dt} = \mu_{\max} \cdot \frac{S \cdot X}{K_s + S}. \tag{30.5}$$

A similar material balance on the limiting substrate requires knowledge of the relationship between cell growth and substrate utilization. The simplest relationship would assume that a fixed amount of cells could be produced from a given amount of substrate, or the yield of biomass on substrate:

$$Y = \frac{dX/dt}{-(dS/dt)} = -\frac{dX}{dS}. \tag{30.6}$$

The linearity between cell growth and substrate consumption does not always hold true, especially at low specific growth rate. Pirt [3] first suggested the concept of maintenance. He described maintenance as the substrate required to generate energy for cell functions independent of growth rate. Examples of cell functions include maintenance of ion gradients and the turnover of macromolecules. The resulting material balance on the limiting substrate is:

$$\frac{dS}{dt} = -\left(\frac{\mu}{Y^{\max}} + m\right)X, \tag{30.7}$$

where $Y^{\max}$ is the maximum growth yield and m is the maintenance coefficient. The term in parentheses is often called the specific substrate consumption rate, q_s.

Because substrate can also be consumed to make a microbial product, the concept of specific rate can also be used for product formation,

$$\frac{dS}{dt} = -(q_s + q_p)X, \tag{30.8}$$

where q_p is the specific product formation rate. The simplest expressions relate product formation to either cell growth or substrate consumption:

$$q_p = Y_{p/s} \cdot q_s \tag{30.9a}$$

$$q_p = Y_{p/x} \cdot \mu \tag{30.9b}$$

The last equation is an example of growth-associated product formation, often observed for primary metabolites. However, for many secondary metabolites, much of the product formation takes place when growth rate slows. This is described as nongrowth-rate associated kinetics. Leudeking and Piret [21] first described a mixture of the two by the following equation, which takes into account both growth-rate associated and nongrowth-rate associated forms of production,

$$q_p = \alpha \cdot \mu + \beta. \tag{30.10}$$

Ideal Types of Fermentors

There are a large number of different types of fermentation processes that are used commercially, which are selected based on several different factors [22–24]. Depending on the strain to be used, the fermentation could be aerobic or anaerobic, and the desired product could be either the biomass itself or a metabolite or polymer produced by the biomass. The kinetics of product formation, whether growth associated or nongrowth associated, also influences the process. Often procedures downstream of the fermentation unit operation have a major control of the overall process and determine how the fermentation is conducted.

Although there are a multitude of possible different fermentation process designs, most of them can be lumped under the following four [23], shown in Fig. 30.4a–d,

- Batch
- Fed-batch
- Continuous
- Continuous with recycle

The batch process is the simplest fermentation to perform. It is a closed system with constant volume. The only addition after the start of the fermentation is air, if it is needed, resulting in a constant volume. All components are in a constant state of change as the substrate is consumed and biomass and products are produced. Figure 30.4a shows the typical batch fermentor characteristic: nutrient is present from the start of the process; nothing is fed and no steady state can be reached. In other words, characteristic volume of culture (V) is constant, denoted by $V = c$. But specific growth rate (μ) and cell mass (X) are not constant. Batch

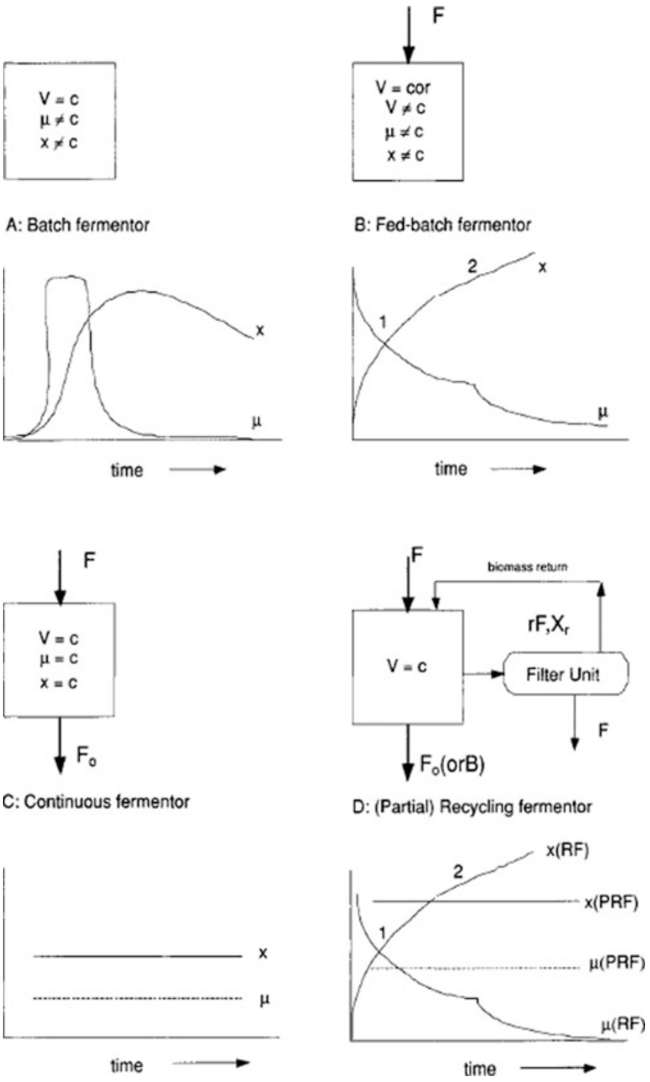


Fig. 30.4 Characteristics of major fermentor types

fermentations are often used for highly mutated strains that are developed by classical mutagenesis and selection. Such strains are easily taken over by faster-growing, less-productive strains in prolonged cultures. Batch processes are still quite common in the antibiotic, organic acid, and ethanol production industries.

In the fed-batch fermentation, nutrients can be added making it an open system for substrates, but still a closed system for biomass and biomass-derived products. As shown in Fig. 30.4b, in this type of process, the volume is not constant. The flow rate of nutrients can vary during the course of the fermentation. Fed-batch operation is very commonly used in industrial processes for the production of baker's yeast, enzymes, amino acids, and many other metabolites.

In the continuous system, as shown in Fig. 30.4c, by constantly removing contents from the fermentor, the process is now open with respect to all components. Typically, the addition of feed and the removal of broth are equal, resulting in a constant volume. Under these conditions, a steady state is achieved wherein all parameters become constant. Such a system is widely used for physiological studies. However, industrial uses are typically limited to the production of biomass (single cell protein) for food or feed, and waste treatment plants.

The final system, shown in Fig. 30.4d, is the continuous system with a partial (PRF) or complete (RF) cell recycle. It is similar to the continuous system, but cells are returned to the fermentor by means of a biomass separation device. Tangential flow-filtration units, centrifuges, and settling tanks have all been used for biomass separation [25]. In the partial cell recycle fermentor, a steady state is achieved as in the continuous system. This process is typically used to increase the productivity of the system and is used commonly in wastewater treatment and ethanol production type applications.

The differential equations shown in the Microbial Kinetics section are used to describe the batch fermentation mode. These can be solved to describe the increase in biomass and product concentrations and the decrease in substrate concentration. The fed-batch system takes into account the addition of substrate during the fermentation. The mass balance on substrate is described by

$$\frac{\mathrm{d}}{\mathrm{d}t}(V \cdot S) = F(t) \cdot S_{\mathrm{f}} - V(q_{\mathrm{s}} + q_{\mathrm{p}})X. \qquad (30.11)$$

A total mass balance on the reactor is:

$$\frac{\mathrm{d}}{\mathrm{d}t}(\rho \cdot V) = \rho_{\mathrm{F}} \cdot F(t), \qquad (30.12)$$

where ρ is the density of the fermentation broth, ρ_{F} is the density of the feed solution with S_{f} as the substrate concentration, and $F(t)$ describes the rate of addition of feed as a function of fermentation time. As in the batch fermentation, these equations can be solved to show the concentration–time profiles of substrate, biomass, and product. The last equation assumes a negligible change in the reactor mass due to air addition (humidity, oxygen) and gas removal (carbon dioxide, water). Such assumptions, in practice, must be checked.

For a typical single-stage continuous fermentor at steady state, a biomass material balance around the reactor yields the following relationship,

$$\frac{\mathrm{d}X}{\mathrm{d}t} = 0 = -\frac{F}{V}X + \mu X, \qquad (30.13)$$

from which:

$$\mu = \frac{F}{V} = D. \qquad (30.14)$$

This means that the dilution rate in the fermentor sets the growth rate of the biomass, and a change in the dilution rate will cause a change in the growth rate.

Because most single-stage continuous fermentors are used to produce biomass, they are usually operated to optimize biomass productivity. The unit volume biomass productivity of such a reactor is defined as DX. This unit volume productivity can be expressed as

$$DX = DY\left(S_0 - \frac{K_s D}{\mu_{\max} - D}\right). \qquad (30.15)$$

By taking the first derivative of the productivity expression with respect to the dilution rate and setting it equal to zero, the dilution rate of maximum productivity, D_m, can be found as

$$D_m = \mu_{\max}\left(1 - \sqrt{\frac{K_s}{K_s + S_0}}\right) \qquad (30.16)$$

and the maximum productivity, $D_m X$, as

$$D_m X = \mu_{\max}\left(1 - \sqrt{\frac{K_s}{K_s + S_0}}\right) \cdot Y \cdot \left(S_0 - \frac{K_s D_m}{\mu_{\max} - D_m}\right). \qquad (30.17)$$

Biomass recycle as sketched in Fig. 30.4d is frequently used in fermentors as a way of increasing the biomass productivity. The increased biomass productivity obtained with a recycle fermentor is a function of the recycle ratio, r, and the cell concentration factor, $C = X_r/X$, achieved in the concentrator. Equations expressing the recycle system behavior are derived from material balances around the reactor. For the cell biomass balance at steady state:

$$\frac{dX}{dt} = 0 = \frac{F}{V}(0) + \frac{rF}{V}X_r - \frac{F}{V}(1 + r)X + \mu X, \qquad (30.18)$$

from which:

$$\mu = D\left(1 + r - r\frac{X_r}{X}\right) = D(1 + r - rC) \qquad (30.19)$$

Because $(1 + r - rC) < 1$, it is possible to operate the system at dilution rates greater than the maximum growth rate. It is this stability imparted by the cell recycle fermentor system that makes it useful, especially in waste treatment applications.

Oxygen Transfer Considerations

In aerobic fermentations, oxygen is a basic substrate that must be supplied for growth. As described earlier for other substrates, the relationship between oxygen concentration and growth is of a Michaelis–Menton type and can be described by a specific rate relationship (see (30.5)). The K-value for oxygen typically ranges from 0.5 to 2.0 ppm for well-dispersed bacteria, yeast, and fungi growing at 20–30°C. For growth at temperatures greater than 30°C; the specific oxygen uptake increases only slightly with increasing oxygen concentration [14].

Under steady-state conditions, the oxygen transfer rate must be equal to the oxygen uptake rate:

$$Q_{O_2}X = k_L a(C^* - C)_{\text{mean}}, \qquad (30.20)$$

where C^* is the concentration of oxygen in the liquid that would be in equilibrium with the gas-bubble concentration. k_L is the oxygen mass transfer coefficient and a is the bubble interfacial area. In small, well-mixed systems, the gas-bubble concentration can be assumed to be equal to that in the gas escaping from the fermentor. However, in large reactors, the log-mean average between the inlet and outlet air concentrations is more appropriate. The oxygen mass transfer coefficient and interfacial area are typically lumped together as $k_L a$. It is not practical to try to separate these two terms.

Utilizing this relationship, the lumped oxygen mass transfer coefficient can be estimated as

$$k_L a = \frac{Q_{O_2}X}{(C^* - C)_{\text{mean}}}. \qquad (30.21)$$

Scale-Up/Down and Control

There are usually problems scaling up new fermentations as well as with translation of process-improvement data for well-established fermentations from laboratory operations to existing plant equipment [26]. In general, fermentations are scaled up on the basis of achieving similar oxygen transfer capabilities in the plant equipment that proved to be optimal at the bench scale.

The oxygen transfer capability required for processes can vary greatly. Organisms with a low specific growth rate may require as little as 25 mmol/L/h whereas high specific growth rate cultures could require ten times that amount. The range of airflow required can vary from as little as 0.1 VVM to >1 VVM. Likewise, mechanical power requirements can vary from less than 0.5 kW/m^3 to >5 kW/m^3.

There are various correlations between $k_L a$ and power inputs. Some design engineers prefer to scale-up/down on the following basis,

$$k_L a = k\left(\frac{P_m}{V}\right)^{\alpha}(v_s)^{\beta}, \qquad (30.22)$$

where P_m is the motor power and v_s is the superficial gas velocity. The coefficients α and β are typically in the range of 0.5 for large-scale plant equipment. Mixing is one of the most critical factors of large-scale fermentors and among agitator designs, Rushton turbine type impeller has most often been used and studied [27].

Unaerated mechanical power input can be estimated from:

$$P_u \propto \rho N^3 D^5, \tag{30.23}$$

where N is the rotation speed of the impeller shaft (rpm) and D is the diameter of the impeller.

For scale-up, however, it is usually the removal of heat that causes design problems. With the previously mentioned mechanical agitation power inputs, up to 5 kW/m^3 of energy are needed to remove mechanical heat. The peak metabolic heat load for aerobic fermentation of glucose at ~250 mmol O_2/L h uptake rate is generally greater than 35 kW/m^3. Even with a fermentation temperature as high as 37°C and cooling water temperature as low as 18°C, it is difficult to remove the heat in large fermentors without external heat exchange or extensive cooling coils in the fermentor. Internal spiral cooling coils can be undesirable because they could interfere with the mixing patterns. Thus, vertical coils that also act as mixing baffles are finding more widespread use. Chilling of the cooling water can also be used to increase heat removal.

Once a plant is built, the conditions of agitation, aeration, mass (oxygen) transfer, and heat transfer become set. Therefore, those environmental conditions achievable in plant scale equipment should be scaled down to the pilot plant and laboratory-type equipment (shake flask, micro-reactor) to ensure that the earlier studies are carried out under conditions that can be duplicated.

With the rise of the genomic and postgenomic era, high-throughput gene sequencing, proteomics, metabolomics, and systems biology have created a wealth of biological data. This has given rise to the need for higher throughput fermentation technology to screen libraries of natural and in vitro generated compounds. Initially, screens of new organisms and metabolic pathways were performed in shake flasks and throughout the last decade increasingly in microtiter plates. Although these methods are straightforward and well proven, they are laborious and do not allow complex manipulation of growth conditions. Furthermore, they do not provide a full complement of data for the knowledge-based selections of organisms or desired physiological properties.

Within the past 5 years, novel technologies have been developed that allow more directed and controlled experiments to screen organisms, fermentation, and media conditions at small scales. A number of academic and private institutions are developing machines that are capable of growing cells at the microliter and sometimes nanoliter scale. They are able to supply aeration, oxygen transfer, pH control, and online data output similar to a pilot-scale fermentor. These devices require minute amounts of cells and media and thus offer time, cost, and environmental advantage and ultimately enhance productivity. Very small scales have been described for cell growth and cell-based assays in microfluidic devices, such as the compact disk (CD) format technology by Gyros Microlabs (http://www.gyrosmicro.com). Intermediate scale microfabricated devices include the bioprocessors platform (PCT WO 2002/083852), the Micro Reactor device (http://www.gener8.com), and a number of devices by academic laboratories, most prominently, from the University of Maryland at Baltimore (http://www.umbc.edu/cbe/rao.html). For instance, the Micro Reactor device is based on a 24-well plate format with several milliliters fermentation capacity in each well. Airflow, pH, temperature, and agitation can be controlled electronically. The machine provides online readouts for pH, dissolved oxygen, and other parameters. Another larger intermediate scale machine offered by DASGIP AG, Fedbatch-Pro®, is a modular system that delivers a high degree of flexibility to perform a number of microbiological applications (http://www.dasgip.com). It remains to be seen if these machines will eventually be capable of replacing the classical scale-up versions of stainless steel fermentors.

Instrumentation and Control

In successfully scaling up/down any fermentation, knowledge of the regulatory mechanisms of metabolic pathways that synthesize the desired product and the instrumentation to detect the regulatory metabolites is necessary. To optimally run a fermentation process, it is essential to perform the initial fermentation research on fully monitored environmental systems, then correlate the environmental observations with existing knowledge of cellular control mechanisms, and finally reproduce the desired environmental control conditions through continuous computer monitoring, analysis, and feedback control of the fermentation environment.

As a result of advances made in sensor development, today more so than in the past, it is possible to rely on environmental control in order to gain economical fermentation results. Until recently fermentation control was limited to that of temperature, pH, and aeration. With the development of numerous sensors and inexpensive computing systems, the engineer can think in terms of sophisticated control systems for fermentation processes. Figure 30.5 shows how a highly instrumented fermentor is designed to secure basic information on almost all the parameters of the fermentation process. For advanced information, both

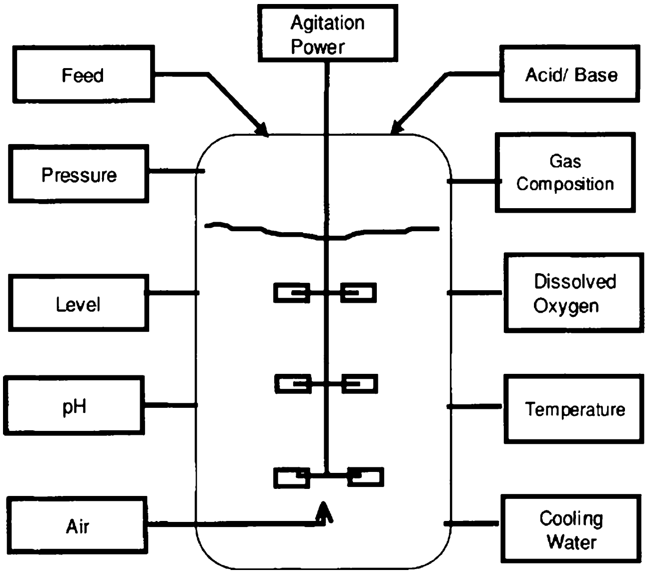

Fig. 30.5 Highly instrumented industrial fermentor

offline intracellular (e.g., messenger RNA and protein arrays, metabolites) and extracellular (e.g., metabolites, proteins/peptides by LC/GC) analyses methods are readily available.

One of the most important sensors needed is one that reliably monitors cell density. An IR fiber-optic cell density probe has been used for this because it can directly monitor cell growth (without dilution) in high-cell-density bacterial fermentations. The ability to do an online sample filtration through the use of hollow fibers or rotating filters has made possible continuous, online measurement of glucose, lactate, and other metabolites. However, glucose, nitrogen substrate, and phosphate sensors that can withstand repeated system sterilization are still needed.

Repeated sampling for measurement during a fermentation process can be tedious and thus indirect measurement via computers appears to be a viable alternative. Combined with other information obtained from sensors, these measurements make possible the calculation of several fermentation parameters, as given in Table 30.2. Computer simulation can also be used to indirectly measure a given component based on a mass balance equation of that component for the fermentation process. Besides these uses, the computer has applications in fermentation processes for continuous automated monitoring and feedback control and dynamic optimization of the process [16, 28].

Recovery of Fermentation Products

The isolation and purification of fermentation products is often collectively referred to as downstream processing. The early part of the separation of a bioproduct is the primary recovery process, whereas the elements further downstream may include purification, concentration, and formulation. The overall goal of downstream processing and formulation is to recover the product of interest cost effectively at high yield, purity, and concentration, and in a form that is stable, safe, and easy to use in a target application.

Table 30.2 Gateway measurements for fermentor monitoring and control

Parameter	Calculation
pH	Acid/base uptake or formation
Air flow rate, in and out O_2 concentration	O_2 uptake rate
Air flow rate, in and out CO_2 concentration	CO_2 production rate
O_2 uptake rate, CO_2 production rate	Respiratory quotient, specific metabolic rate
Power input, air velocity	O_2 transfer rate
Integrated CO_2 produced	Cumulative metabolic activity

Fermentation products include the cells themselves, solvents and chemicals, organic and amino acids, antibiotics, polysaccharides, lipids, RNA and DNA, vaccines, bulk and fine diagnostic and therapeutic proteins, food and feed ingredients, and enzymes. These biomolecules can differ substantially in nature and require a large variety of methods to separate and purify them. They are often produced in low concentrations in complex media together with many other components.

In the development of manufacturing processes for the production of biological molecules, much emphasis is placed on fermentor design and scale-up, thus one might assume that the recovery processes of fermentation products are rather straightforward and relatively simple. Nothing could be further from the truth. A point in case is an example of an antibiotic production plant. The investment for the recovery facilities is claimed to be about four times greater than that for the fermentor vessels and their auxiliary equipment. In organic and amino acid fermentations, as much as 60% of the fixed costs of fermentation plants is attributable to the recovery unit operations.

Figure 30.6 shows a typical recovery process for antibiotics, and a schematic overview of a typical downstream process in an enzyme plant is given in Fig. 30.7. From these diagrams it is apparent that most recovery processes involve combinations of the following procedures.

- Fermentor harvest
- Mechanical separations of cells from fermentation broth (clarification)
- Optional disruption of cells
- Extraction of the compound of interest
- Preliminary fractionation procedures
- High-resolution separation steps
- Concentration
- Formulation
- Optional drying

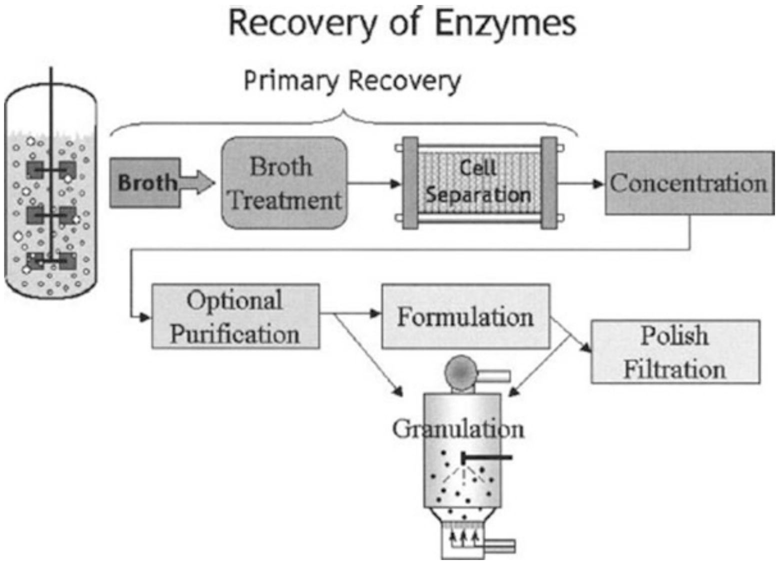

Fig. 30.7 Typical recovery process for industrial enzymes

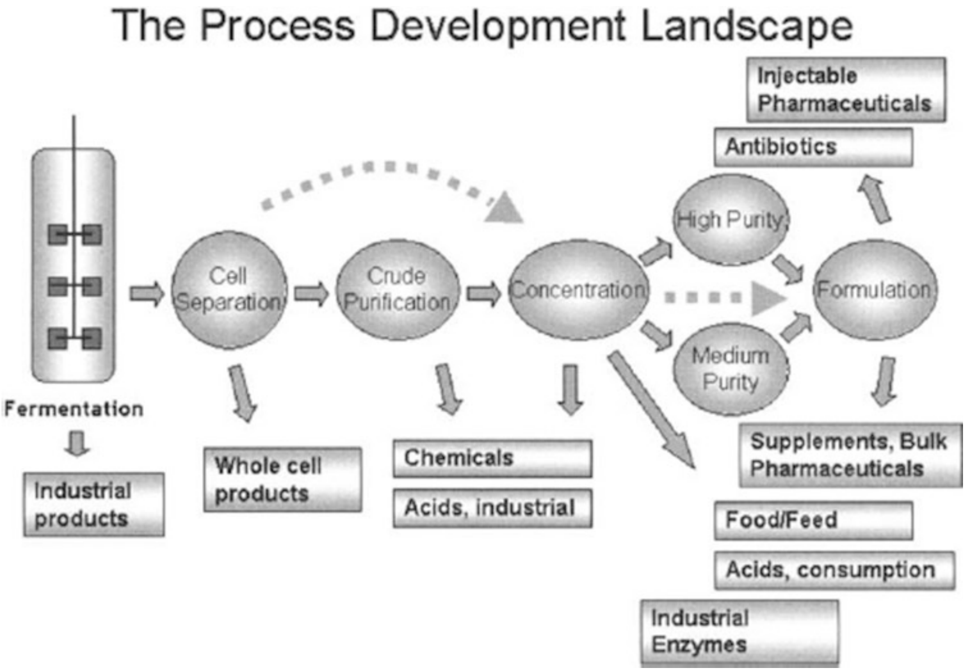

Fig. 30.8 The downstream processing cascade arranged by final product requirement

In contrast to fermentation processes, where typically one format (i.e., a fermentor vessel) is used, a number of widely differing techniques are necessary to accomplish purification and formulation of biological products. The variety of available separation technologies is large and the order and permutations of sequential processing steps are countless. Although this may hamper standardization of downstream processes, it also provides the benefit of flexibility because different unit operations can be tailored to the greatest efficiency in a cost-effective manner. Possibly a better way to illustrate a downstream process design is shown in Fig. 30.8. Here it is shown that recovery is not a linear sequential process but rather the downstream process development follows a palette of options that can be applied depending on the required specifications of the endproduct and as such, it is a modular approach.

Several general considerations limit the range of practical choices for a process design. The type of production organism (bacteria vs. fungi or mammalian cells) has an impact on the downstream process design. The fermentation media for these organisms can differ substantially and the media themselves can play an important role for the recovery strategy. Defined media often deliver a purer product but lower concentrations, whereas complex media contain more impurities but also generates more product. The physical, chemical, and biochemical properties of the desired product have an impact on the recovery strategy, as do the microbial cell's physiological states and properties. Proteins and enzymes require more "gentle" conditions to avoid unfolding or chemical denaturation than those required for small molecules. General parameters to observe are large swings in or extreme changes in pH and temperatures. Both proteins and small molecules can have hydrophobic, hydrophilic, or limited solubility properties that need to be considered when devising a recovery and purification strategy.

The principles and equipment discussed below are mostly focused on proteins and enzymes. Several other products, such as small molecules, metabolites, vitamins, and acids can require more specialized methods. However, many of the unit operations described here are also used in the recovery of these latter compounds.

Separation of Proteins and Peptides

Biological products can be inside the cells (intracellular), loosely associated with the cells, or secreted (extracellular). Each of these products requires a different approach towards the purification strategy. Intracellular and membrane-bound proteins and enzymes are more difficult to recover than the secreted ones, requiring physical or chemical disruption of cells and the challenge of separating the desired compound from viscous or entraining substances such as nucleic acids and cell wall debris. Fermentations are typically not harvested until the cell mass and the product are concentrated, often requiring some postharvest dilution to avoid entrainment losses and low equipment throughput. Continuous fermentations, on the other hand, generate a more dilute stream with a hydraulic load that can add significantly to the cost of subsequent concentration.

The simplest downstream processes include direct use of the entire fermentation broth, cells and all. This is suitable for low-cost industrial products. Another cost-effective method is the lysis of cells in the crude broth and direct use of the lysate. Yet another method that avoids lengthy purification steps is in situ extractive fermentation, whereby a product is directly extracted from the broth by use of solvents. However, many industries require more sophisticated purification methods due to safety and environmental considerations. For instance, it is imperative that live genetically modified organisms (GMO) and their DNA are not present in a released product.

As can be seen from Fig. 30.8, the nature of its final application will dictate how pure the product needs to be and which raw materials may be used in its manufacture. Typically, high purity is not required of industrial enzymes. In contrast, therapeutic proteins and small drug molecules require the highest level of purification. The purity range for food and feed compounds is somewhere in the middle. Raw materials must meet regulatory requirements for the application and must often be tested for their toxicological properties. Finally, economic considerations constrain both the range of raw materials and separations processes that can be used. Although multiple chromatographic steps are routinely included in the downstream processing of human therapeutic proteins, few industrial proteins include even a single chromatographic step [29]. Purification, if any, of industrial products is accomplished by less expensive techniques such as extraction or crystallization.

Fermentor Harvest and Primary Recovery

Extracellular products. In order to prevent cell lysis, removal of cells from a fermentation broth is usually started within hours after harvest. After cell separation, the clarified fermentation broth is more stable and can be stored refrigerated for days. Upon harvest, most primary recovery steps involve some pretreatment of the fermentation broth, which can range from simple cooling and dilution for fungal broths to pH adjustments, addition of salts, stabilizers, or flocculation agents in order to minimize degradation of the desired product and facilitate further processing. For labile compounds, such as protease enzymes, control of temperature, pH, oxidants, inhibitors, and activators is essential at harvest and throughout the recovery process. For example, it is important to maintain a molar excess of calcium ion to ensure the thermal stability of certain *Bacillus* proteases and amylases that contain calcium-binding sites.

Industrial products are mostly of the extracellular variety. They can be recovered directly from the fermentation broth. The primary recovery involves removing the cells from the broth, aptly called cell separation. Three different techniques are commonly used to achieve this goal: filtration, microfiltration, and centrifugation.

Filtration. Filtration can include filter presses, rotary drum vacuum filters (RDVFs), belt filters, and variations on synthetic membrane filtration equipment, such as filter cartridges, pancake filters, or plate and frame filter presses. These processes typically operate in a batch mode: when the filter chamber is filled up or the vacuum drum cake is exhausted, a new batch must be started. This type of filtration is also called dead-end filtration because the only fluid flow is through the membrane itself. Due to the small size of cells and their compressible nature, typical cell cakes have low permeability and filter aids, such as diatomaceous earths, perlite, or other mined materials are added to overcome this limitation. Moreover, the presence of high solids and viscous polymeric fermentation by-products can limit filtration fluxes without the use of filter aids.

In dead-end filtration, a cake forms on the surface of the pad as the filtration proceeds. The cake permeability is the most important physical property of a porous medium and the hydraulic properties of the flow and the specific cake resistance are described by Darcy's Law:

$$J = \frac{\mathrm{d}V}{A\ \mathrm{d}t} = \frac{\Delta p}{v_0 (R_\mathrm{m} + R_\mathrm{c})}, \tag{30.24}$$

where R_m is the resistance of the membrane, R_c is the resistance of the filter cake, Δp is the transmembrane pressure, A is the area available for filtration, and v_0 is the permeate viscosity. Cake resistance can be expressed in terms of the specific cake resistance:

$$R_\mathrm{c} = \alpha \rho_\mathrm{c} \frac{V}{A}, \tag{30.25}$$

where α is the specific cake resistance and ρ_c is the mass of dry filter cake per unit volume of permeate. The combination of equations (30.24) and (30.25) and integration gives:

$$\frac{tA}{V} = \frac{\rho_\mathrm{c} \alpha v_\mathrm{o}}{2\Delta_\mathrm{p}} \left(\frac{V}{A} \right) + \frac{v_\mathrm{o} R_\mathrm{m}}{\Delta p}, \tag{30.26}$$

where specific cake resistance can be obtained from the slope of a plot of tA/V vs. V/A.

Fungal fermentations, such as those of *Trichoderma* or *Aspergillus* sp., lend themselves particularly well to cell separation by filtration through a RDVF because of the ease with which the fungal mat can be shaved off by the drum's knife, renewing the filter cake surface to maintain high filtration flux.

Bacterial fermentation broths can be processed either by filtration or centrifugation, but the much smaller size of bacteria generally requires the addition of a polymeric flocculant. Most flocculants are cationic and function by bridging the negative surface charges on neighboring cells to increase the particle size and facilitate either sedimentation rate or filtration flux and clarity. The choice of flocculant and optimization of dosage is a delicate balance among obtaining good separation quality, yield, cost, and minimization of residual excess polymer in the product.

Microfiltration. Microfiltration, the use of tangential flow anisotropic membranes to permeate the product of choice while retaining solids, can be an attractive cell separation technique because it does not require the use of flocculants or filter aids. It is, in principle, a more technically sophisticated version of classic dead-end filtration processes. Microfiltration yields can be low due to progressive fouling of membranes. Advanced engineering has overcome many of the early problems and microfiltration is now used widely in the recovery of therapeutic proteins and in the food, beverage, dairy, and water treatment industries.

Microfiltration units can be configured as plate and frame flat sheet equipment, hollow fiber bundles, or spiral wound modules. The membranes are typically made of synthetic polymers such as polyethersulfone (PES), polyamide, polypropylene, or cellulosic mats. Alternate materials include ceramics, stainless steel, and carbon. Each of these comes with its own set of advantages and disadvantages. For instance, ceramic membranes are often recommended for the filtration of larger particles such as cells because of the wider lumen of the channels. However, it has been shown that spiral wound units can also be used for this purpose, provided appropriate spacers are used.

Together with related technologies such as ultrafiltration, nanofiltration, and reverse osmosis, microfiltration relies on membranes with a defined pore size. The operation mode is as "cross flow" or "tangential flow" in which filtrate is pumped parallel to the membrane surface. Cells or cell debris and large molecules are retained on one side of the membrane and the biological product solution passes through the membrane. The primary advantage of tangential flow vs. dead-end is that membrane fouling only affects the membrane pores themselves, whereas particulate matter on top of the membrane is continuously swept away. In that manner, no filter cake is created. Microfiltration is complex and much research has been done to describe the theoretical underpinnings of the process. Equipment and membrane replacement costs are high. Capital and operating costs of filters and centrifuges of equal production capacity can be more advantageous. Nevertheless, microfiltration equipment, when designed and operated properly, has the potential to deliver high throughputs due to its continuous operation, reduction of process steps, and reduction of the waste generated. It also enables the use of recycle streams to increase product yields and decrease the cost of raw materials.

Centrifugation. Centrifugation is another viable method for removing microbes from fermentation broth. Three types of centrifuges are commonly used: (a) disk-stack centrifuges (clarifiers), (b) tubular and basket centrifuges, and (c) decanter centrifuges that contain solid removing scrolls. All three can be operated in a continuous mode for higher throughput. Less common are tubular centrifuges, which generate the highest centrifugal forces but have limited throughput. The main challenge in centrifugation is to identify a suitable flocculant or process conditions whereby the cell mass is easily conveyed or discharged from the centrifuge bowl without breakup or carryover into the centrate. Although centrifugation can handle a high concentration of cell solids, filtration can provide more complete removal of trace solids that can interfere with downstream concentration or purification steps. The presence of flocculants and filter aids in cell wastes can cause added disposal costs. Often, the centrate cannot be completely clarified, thus requiring combinations of a final filtration step and centrifugation to achieve a nonturbid product.

Intracellular products. Intracellular production of bioproducts is less preferable but sometimes the only way to produce certain compounds in appreciable amounts. In this case, cell disruption is required for recovery. High-pressure homogenization, bead mills, and chemical or enzymatic disruption of the cell wall with lysozyme or similar enzymes can be used to achieve cell breakage. In the case of small molecules, organic solvent extraction has also been described. If cell debris remains in the centrate, it must be removed by methods described earlier, thus adding extra steps to the process.

Purification. Purification of the product can follow or precede the step of product concentration. Biological product purification is often and quite mistakenly equated with column chromatography. Undoubtedly, this technology is widely applied and has advanced rapidly in recent decades. Chromatography is a separation technique that includes various separation principles, such as gel filtration, size exclusion, ion exchange, hydrophobic interaction, and affinity binding/elution. A major advance has been the development of cross-linked pressure-sustaining support matrices for high volume applications. Continuous moving bed technologies, expanded bed methods, and displacement chromatography have all contributed to greater versatility and cost effectiveness of the technique and have greatly expanded the tools available for high-resolution separation. More recently, high-pressure liquid chromatography (HPLC), originally an analytical tool, has been refined for preparative separations.

Although chromatography offers the greatest potential and diversity of mechanisms for separation and purification, with some notable exceptions, it is not cost effective in the manufacture of industrial commodities due to the expense, low throughput, and low binding capacity of chromatography resins. Furthermore, the complexity and control required for reproducible operation can be cost prohibitive for very large-scale production systems. It is also uneconomical for concentration of the product. A large body of literature exists for the chromatography of biological molecules bolstered by its extensive use in the biopharmaceutical industry.

Purification can also be achieved in other ways, through precipitation with salts, crystallization, and through aqueous two-phase extraction. Some of these methods are associated with substantial capital cost, low throughput, low yields, or waste issues. Fractional precipitation, one of the oldest protein separation technologies, can be surprisingly effective to separate a compound of interest from a complex broth. For instance, the process of fractional solvent precipitation of blood plasma components has been used since World War II.

It is sometimes necessary to remove an undesirable side activity from proteins and enzymes, particularly when it is not feasible to delete the side activity genetically. A case in point is the presence of co-secreted proteases. Even if minor protease contamination from the host organism does not cause significant degradation of the product during processing, it is likely to damage the product in the final formulation over several months of storage. In other cases, side activities must be removed because they interfere in the final application. Incremental additions of chaotropic salts, such as ammonium sulfate, water-binding polymers, such as polyethylene glycol, or organic solvents are added to a solution containing the enzyme, and the relative amount of each enzyme vs. other protein impurities in each fraction is monitored. Similar to the pooling of chromatographic elution fractions, the fractional "cuts," which have the most favorable balance of net enzyme purity and recovered yield, are combined.

Crystallization is related to precipitation in that it is governed by a compound's physicochemical properties. For example, the second virial coefficient, B_{22}, which characterizes the two-body interactions between protein molecules in dilute solutions:

$$B_{22} = \frac{2\pi}{M^2} \int_0^\infty r^2 \left(1 - \mathrm{e}^{-u(r)/kT}\right) \mathrm{d}r \tag{30.27}$$

where M is the protein molecular weight, r is the intermolecular separation distance, $u(r)$ is the interaction potential, k is the Boltzmann constant, and T is the absolute temperature. The interaction potential $u(r)$ describes the interaction forces between the two protein molecules.

Proteins have long been crystallized for commercial production. This process is highly scalable, reproducible, and can be cost effective. As is the case with precipitates, crystals can be recovered via centrifugation or filtration processes. The purity achieved can be quite high, even though it is often not comparable to multiple chromatographic steps due to crystalline entrapment of impurities. Overall, it often meets the requirements for a number of industrial and food applications. A major challenge can be the time-consuming screening of appropriate precipitants, pH conditions, and temperatures and the mapping of the solubility phase diagrams. Recently developed high-throughput techniques for screening crystallization parameters have lessened the laborious nature of identifying appropriate conditions. Both precipitation and crystallization are excellent methods to concentrate the molecule of choice. A further advantage is that proteins in crystalline or precipitated form display good storage stability. Industrial biotechnology companies, such as former Genencor International, have developed large-scale crystallization methods for enzymes [30].

In the last one to two decades, aqueous two-phase extraction has become an attractive purification and concentration technique. It provides the selectivity of classical solvent extraction without its denaturing potential. Utilizing incompatible two-polymer and polymer–salt combinations and adjustments in pH and ionic strength, this technique separates proteins based on differences in hydrophobicity, surface charge, and molecular weight. Segregation of the separated molecule is governed by the partitioning coefficient (α):

$$\alpha = \frac{C_\mathrm{s}}{C_\mathrm{w}}, \tag{30.28}$$

where C_s is the concentration in the solvent phase and C_w is the concentration in the water phase. One application of the technique has been purification of genetically engineered chymosin from multiple side activities produced by the fungal host background.

An important step in the manufacture of biopharmaceutical injectables is the removal of endotoxin and viral contamination. Numerous methods have been described and include chromatographic steps and the use of filter cartridges [31].

Purification of bioproducts from fermentation, although necessary, comes with a major drawback. Biological compounds evolved in an environment of complex components are adapted to be most stable in these conditions. Highly pure forms of bioproducts have a tendency towards lower chemical and physical stability. For instance, proteases are prone to autolysis in the absence of impurities that inhibit degradation. This is one of the major challenges faced by the formulator of biological products (see section "Formulation").

Concentration. Clarified filtrates, centrates, or column eluates are usually too dilute for use in their specific applications, thus, substantial amounts of water must be removed. This can be achieved by evaporation or by ultrafiltration. Concentration methods used in industrial settings, such as evaporation, which is done under vacuum, and solvent extraction, may or may not be suitable for dewatering proteins because of their potential for thermal or chemical denaturation, and due to high energy costs associated with evaporation. The benefit of evaporation is that nonvolatile compounds that may stabilize the proteins are retained.

Ultrafiltration (UF), which can be a viable alternative, has membrane pore sizes that are much smaller than those in microfiltration, allowing only water and small molecules to travel through the membrane. Thus, proteins, peptides, and other large molecules can be retained as water is forced through the membrane. Typical molecular weight cut-off sizes for UF membranes are 5–100 kDa. This technology has emerged to become one of the most common methods for concentration of large biomolecules. UF is an attractive method because of its low energy consumption. It can be combined with diafiltration whereby repeated additions and removal of water lead to a cleaner product. UF fluxes and yields are often significantly enhanced by upstream removal or omission of potential membrane foulants, such as polysaccharides or antifoams. In the case of smaller molecules, nanofiltration can be used.

Nanofiltration membranes have a molecular weight cut-off ranging from 100 to 1,000 Da and with such small pore sizes are able to retain molecules such as humic acids and certain salts. This allows for production of parasite- and solids-free water without the need of chemicals.

Precipitation, crystallization, and extraction can also be used for concentration, but are more typically utilized as purification techniques. The latter methods also may cause problems with their environmental impact in as much as they require substantial additions of chemicals.

Decolorization and finishing. Decolorization is sometimes required for certain applications, mostly as an aesthetic preference. It is always desirable to solve these issues upstream. For example, color can be minimized by choice of fermentation medium components and control of the sterilization cycle so as to lessen the Maillard reactions between nitrogen and sugars. Color can also be reduced by treatment with activated carbon, use of antioxidants, and by diafiltration with membranes. Carbon-impregnated filter pads can be used to combine polish filtration with a decolorization step.

"Finishing," sometimes also called "polishing" refers to one or more filtration steps at the end of the downstream process that have the goal of clarifying and reducing the microbial load of the product. Solids are most conveniently removed using a filter press loaded with cellulosic, synthetic polymer pads, or disposable submicron gauge filter cartridges. Precoating pads with filter aids prevent premature fouling. All these methods can be used to remove microbes to the point of sterility if required. Often, formulation ingredients are added to the product concentrates before the final decolorization and finishing steps are performed.

Formulation

Formulation of a product depends on how the endproduct will be used and the ability to satisfy safety requirements. Many bioproducts are supplied in liquid form, as it is convenient to meter and use. If the compound is slated for dry products, the concentrate can either be stored for later use or applied directly for granulation. In many industries, proteins, peptides, and other bioproducts are supplied as encapsulates or granules in order to meet safety standards.

As with fermentation and downstream processing, precise formulation recipes are often kept as closely guarded trade secrets. Comparatively few publications on new approaches or new technologies are available in the literature [32]. However, the intellectual property landscape is filled with composition of matter patents.

Proteins are large molecules comprised of tens to hundreds of amino acid subunits. Their unique properties are associated with specific conformations of the amino acid chain. The active conformations are thermodynamically quite fragile, typically only a 5–15 kcal/mol difference in free energy between the stable and the unfolded conformations. Additionally, the amino acid subunits that define the protein contain a variety of reactive groups that are subject to chemical degradation pathways resulting in the loss of structure and/or activity. Thus, ensuring the physical and chemical integrity of a protein's native structure is a primary concern when using proteins or enzymes in applications where its structure is important. Many proteins are only soluble up to 20–30% (w/w) and therefore considerations for keeping the compounds well solubilized are of importance.

Dry formulations. Because of the long-term instability of proteins in aqueous solution, enzyme producers and formulators have attempted to produce stable solid formulations since enzymes were first used. Proteases tend to degrade via autolysis and can be incompatible with surfactants. These problems are easily overcome by storing the enzyme in the solid state. Initially, commercially produced enzymes for laundry detergents were spray-dried or sprayed onto salt cores without coating. Spray-drying provides a fast and cost-effective way of compartmentalizing

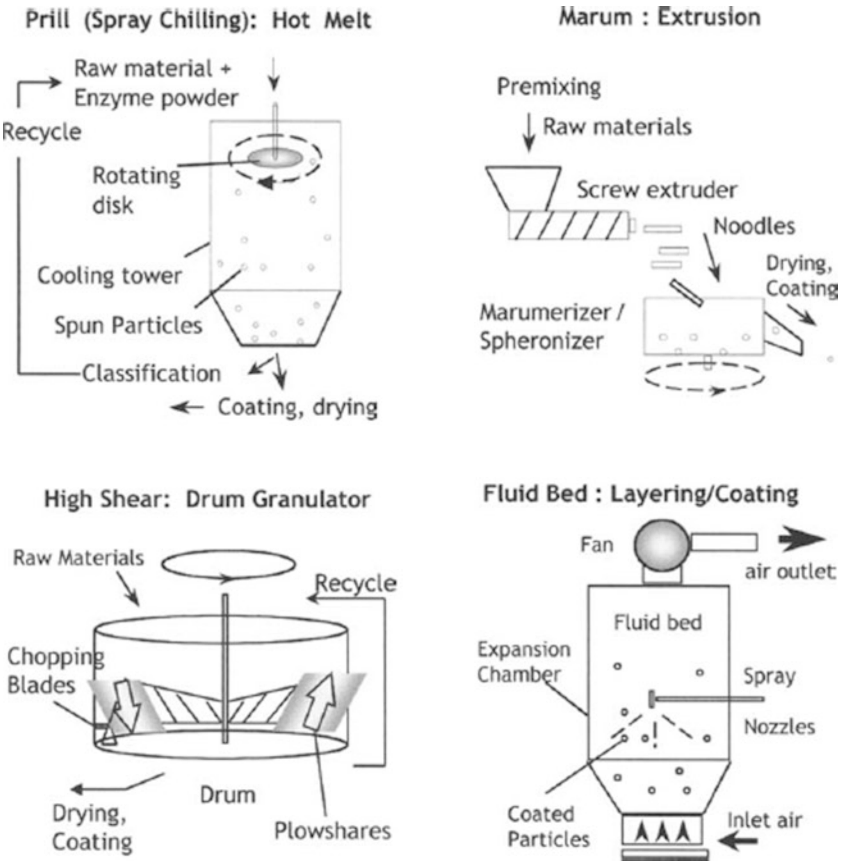

Fig. 30.9 Common granulation method in enzyme manufacturing

two incompatible ingredients and maintaining enzyme activity over a product's typical shelf life. However, noncoated granules have led to cases of allergic reactions in formulating plant personnel and resulted in a setback for the enzyme industry in 1970s. Thus, the technologies used to produce modern dry products have evolved far beyond simple spray-drying.

Product safety is an important consideration as many bioproducts can cause adverse responses in humans and many therapeutic fermentation products are very potent bioactive molecules. Negative effects can include irritation and allergic reactions, which are due to the possible immunogenic nature of many biological compounds. Lyophilization, or freeze-drying, which is used in therapeutic applications results in a powdered product that is contained in vials as an additional safety measure to prevent direct exposure. It offers a gentle way of protecting a compound's fragile nature because the drying temperature is kept below freezing. However, these technologies are expensive.

Many of today's bioproducts are supplied in a granular form. Granulation is a generic term for particle size enlargement. Granules in consumer products need to provide a tough barrier to prevent release of the bioactive molecules in airborne dust, while providing quick release once used in the final application. Enzyme granules contain coatings that are designed to withstand the physical impact and shear forces typically encountered during powder processing, maintaining excellent flowability throughout the process.

Many ways of producing enzyme granules have evolved, with just a handful of methods being currently in common use. These include prilling (spray-chilling), marumerization/spheronization, drum and high shear granulation, and fluid-bed coating (Fig. 30.9). The latter two techniques are superior in producing low dust granules. An overview of the different technologies is provided in Table 30.3. In general, fluid-bed technology (Fig. 30.10) is the most flexible approach, giving granules with the most uniform appearance and smooth coatings (Fig. 30.11). Other technologies may have an edge in either cost or throughput, as they are more amenable to continuous operation. The advantage of the fluidized-bed method is that the entire granulation process can be carried out within a single, contained piece of equipment. The spray-coating process allows the sequential application of layers of different thicknesses and compositions with almost infinite flexibility. In addition, spray coating allows one-step application of controlled release coatings.

A less commonly used method is spray-chilling, whereby the product is incorporated into meltable cores. This method is straightforward and inexpensive but has the drawback of being limited by the meltability of its ingredients. Moderate

Table 30.3 Comparison of powdered enzyme production methods

Technology	Equipment	Advantages	Disadvantages
Prilling (hot melt)	Prilling tower	Continuous process	High product dust
		High capacity	Low melting point
		Easy rework	Requires predried enzyme
Extrusion/spheronization (marum)	Screw extruder, Marumerizer, fluid bed coater	Inexpensive raw materials	Complex multistep process
		Continuous process	High dust during process and in product
			Requires highly concentrated enzyme
Drum granulation (high shear)	Lödige mixer	High capacity	Dusty, multistep process
	Littleford mixer	Continuous process	Requires highly concentrated enzyme
	Fluid bed or drum coater	Tough granules	Wide particle size distribution
Fluid bed (layering/coating)	Fluid bed coater	Single, contained reactor	Batch process
		Flexible formulation	Difficult rework
		Tough uniform granules	

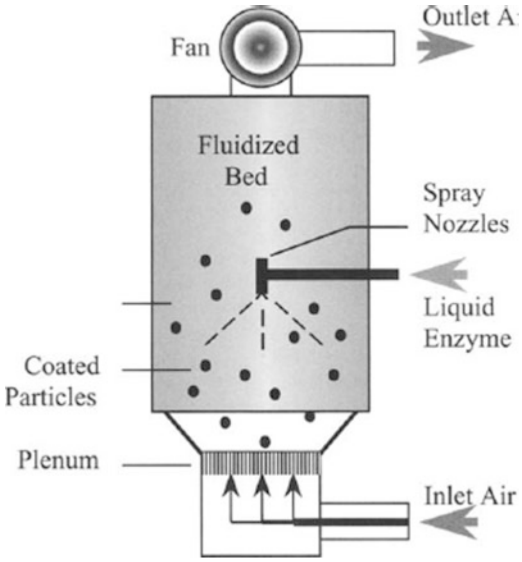

Fig. 30.10 Schematic of a fluidized-bed coater

to high temperatures during the shipping or during use of the product can lead to agglomeration of the capsules.

Solid formulations can provide some significant advantages, such as enhanced stability, delayed or controlled release, and protection against deactivation during harsh applications. One example of the latter is the use of granules to encapsulate cellulase enzymes against deactivation in the steam-pelleting process that is used in producing animal feed pellets. The use of effective stabilizers and coatings can prevent or retard exposure to moisture under high heat, yet allow release of the enzyme in the subsequent feed application.

Many therapeutic molecules can be encapsulated using other techniques, such as coacervation, micro- or nanospheres, microcapsules, or liposomes. Coacervation, often used for flavor encapsulation, can be a simple aqueous phase separation of immiscible droplets, or in the case of complex coacervation, the use of opposite electrostatic charges. It is one of the basic processes of capsule wall formation. Other biochemicals, such as flavors, vitamins, or citric acid are sold directly in the crystallized forms and can be incorporated directly into the final product, such as tablets, capsules, granules, and so on.

Liquid formulations. The successful application of enzymes in liquid formulations presents several technical obstacles that are not encountered in powders and granules. These problems stem from the fact that liquid products are complex aqueous solutions, and physical separation of enzymes from other potentially inactivating ingredients is impractical. Necessary ingredients for a viable endproduct can affect the physical and chemical stability of enzymes. In addition, as other types of enzymes are added to formulations that already contain proteases, proteolytic degradation of enzymes is a concern.

Liquid formulations can be used as pastes or slurries, dispersions or emulsions (in aqueous or other solvents) to physically separate the compound to be protected. Dispersions, pastes, or slurries are not commonly used but are a feasible approach when highly concentrated products are needed. For instance, many early analytical enzymes were sold as crystal slurries to preserve stability. Dispersions can be prepared from dry materials. Most of the dispersions are visually cloudy in appearance due to the particle size of the dispersed compounds and are thus undesirable in most endproducts.

Many catalytically active proteins are hydrolases and are subject to three principal means of deactivation: denaturing or unfolding, catalytic site inactivation, and proteolysis. Denaturation is best minimized by controlling temperature and pH and by avoiding the presence of chemical denaturants. Catalytic site inactivation is prevented by supplying sufficient levels of cofactor, typically a metal cation, and preventing oxidation of the active site, for example, by formulating with antioxidants. Alternatively, oxidative

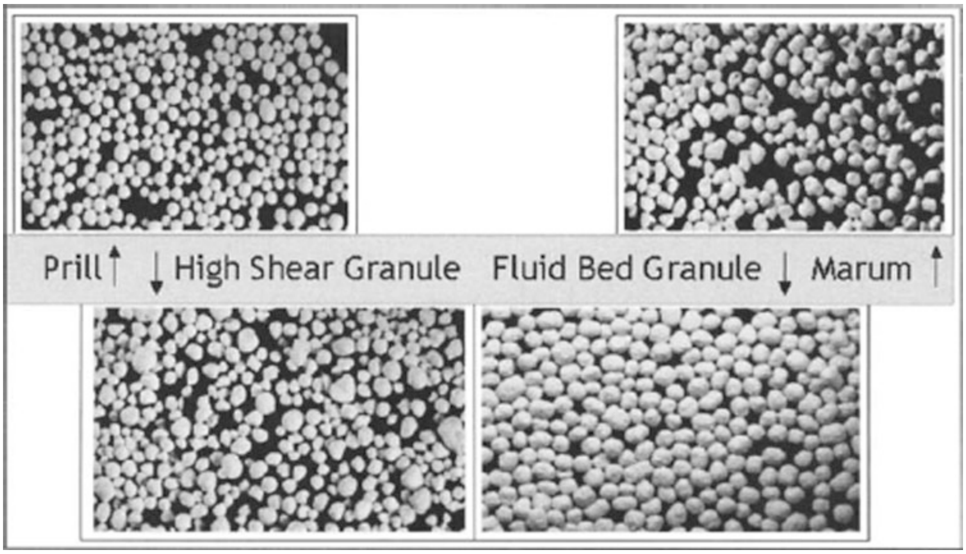

Fig. 30.11 Commercially available enzyme granules (Courtesy Genencor International)

resistance can be engineered into the protein structure. Finally, in the case of proteases, proteolysis or autodigestion can be minimized by reducing water activity or by addition of inhibitors. Thus, the final liquid formulation includes stabilizers, antimicrobial substances, and osmolytes to reduce the water activity and increase thermodynamic stability. Useful water-sequestering compounds include sugars and other polyols, such as glycerol, sorbitol, and propylene glycol. Useful inhibitors include substrate analogues such as peptides and acid salts. Once the formulation excipients are added, the last step includes a final polish filtration to provide a clear liquid.

Different industries pose different challenges to the protein formulator. Many feed enzymes are sold as formulated liquid concentrates. In this case, the major requirements for a liquid formulation are enzymatic stability and preservation against microbial growth. It is sometimes not appreciated that the dominant factor affecting enzyme stability is the intrinsic stability of the enzyme itself; formulation can do very little to correct for a structurally labile protein. Therefore, it is advisable to make stability an important criterion of the initial enzyme screening process.

An important case is the application of enzymes in laundry detergents. Market trends in the United States show that consumers prefer liquids to powder detergents by a ratio of 2 to 1. These products are stored with no temperature control on shelves in the presence of harsh surfactants, such as linear alkylbenzyl sulfonate (LAS) and require extraordinary measures for stabilization. LAS, by its nature as an effective cleaning agent, causes surfactant-induced unfolding in proteins. There are countless examples of the development of stabilization systems in the intellectual property space. A common theme is to reduce the water activity and to use borate/glycol stabilizers that bind to the active site of proteases.

Microbial growth is fairly easy to control by the addition of food grade antimicrobials such as sodium benzoate, methylparaben, and various other commercial preparations. In addition, reduction of the water activity through use of sequestering agents aids in controlling microbial growth. The prevention of precipitation and hazes is often a highly empirical challenge and one that is very specific to the enzyme and the specific raw materials used in the process. It is best to use ingredients with high solubility and to screen potential formulations by extended storage at high and low temperatures. In the case of proteins, an additional objective is to keep the pH value as far away as possible from the isoelectric point of the protein, at which the protein is least soluble.

Emulsions are the most commonly used type of formulation in the food, paint, and personal care industries. The typical emulsions are “oil in water” or “water in oil” preparations. Proteins, peptides, metabolites, and other fermentation products can be incorporated into emulsions. Covalent attachment of hydrophobic compounds, such as fatty acids or polyethylene glycols, to proteins or peptides lends these hydrophilic molecules to reside in the lipid phase.

Whole Cell Recovery

The recovery of whole cells is best explained by the manufacturing procedure for baker’s yeast. This process is almost identical to the early stage of protein recovery, except that the final product is the cell instead of the filtrate. After fermentation, the cells are spun out with a centrifuge, washed with water, and recentrifuged to yield a yeast cream with a solids concentration of approximately 18%. Cream yeast can be loaded directly into tanker trucks and delivered to customers equipped with an appropriate cream yeast handling system. Alternatively, the yeast cream can be pumped to a plate and frame filter press or an RDVF and dewatered to a cake-like consistency with 30–32% yeast solids content. The press cake yeast is crumbled into pieces and packed or spray-dried for dry products. After packaging, the yeast is ready for shipping to retail.

Separation of Small Molecules and Metabolites

Metabolites, vitamins, organic and amino acids, and specialty chemicals are commonly referred to as small molecules, particularly in the therapeutic world to differentiate these compounds from proteins or peptides, commonly named biopharmaceuticals or biologicals. Many of the same unit operations are applied for the recovery and purification of small molecules as described earlier. Purification of bulk products has cost constraints, whereas pharmaceuticals are subject to strict purity requirements.

Possibly the largest class of molecules produced in microorganisms are acids. This group includes acetic acid, citric acid, gluconic acid, lactic acid, and, of course, the amino acids. Citric acid is recovered (Fig. 30.14) after the cells have been removed by RDVF. It is then solvent extracted or precipitated as a calcium salt by adding hydrated lime [$Ca(OH)_2$]. The precipitate is recovered by a second RDVF and then acidified with sulfuric acid where it forms citric acid and calcium sulfate (gypsum). A third RDVF removes the gypsum. Lactic acid is usually produced as an alkali or earth alkali salt.

Another excellent example is given by penicillin recovery, a weak acid. Penicillin can be recovered by solvent extraction and its partitioning coefficient into solvent can be steered by the pH value. In the dissociated form it is more hydrophilic, whereas in the protonated form it is more hydrophobic. Thus, at low pH, penicillin partitions into the solvent phase.

A number of relatively new methods are being investigated to improve the recovery of small molecules. These methods include electrokinetic separators with bipolar membranes, simulated moving-bed chromatography, and supercritical fluid extraction. The latter is practiced for food components. It has also been described for proteins but has not yet found wide acceptance in this field. A fast-growing field is the production of bioethanol via fermentation processes either from milled corn or from recycled biomass. The fermentation and saccharification processes can occur simultaneously in the fermenting tank by means of saccharification enzymes (amylases, cellulases).

Once the mash is fermented, it is transferred to a distilling unit. The distilling system is designed to produce greater than 90% combustible bioethanol from fermented grain mash. The system can be arranged in an array of columns: mash columns, aldehyde-extraction columns, and rectifying columns. The remaining alcohol-free liquid is drawn off from the bottom of the rectifying column. This liquid can be blended with the watery meal from the mixing tank before cooking.

For the dehydration step, molecular sieves made of zeolite can be used. The alcohol is extracted from the molecular sieve at 99.75%, dehydrated as vapor and captured in condensers. New research focuses on alternate aspects of this separation process to improve efficiency such as developing membranes for ethanol recovery. Low-cost pervaporation, an energy efficient combination of membrane permeation and evaporation, for ethanol extraction and bioethanol production holds much promise.

The liquid left after distillation is subjected to centrifugation, where most of the suspended solids are separated. The clear liquid can be recycled by adding it back to the starch conversion stage. The moist cake released by the centrifuges is mixed with the syrup produced by the evaporator to form a homogenous mixture and is dewatered in dryers. The dryers produce a Distillers Dried Grains with Solubles (DDGS) meal, which can be formed into pellets. These are used in many applications, most prominently in animal feed.

It is evident from the discussion earlier that downstream processing and formulation depend heavily on the industry and the product. There are countless possibilities on how a molecule can be recovered, purified, and formulated. More importantly, the fermentation, recovery, and formulation processes are intimately intertwined. Depending on the type of production organism and fermentation process used, the downstream processing has to adjust accordingly. It is thus imperative that process development is highly integrated. In the modern fermentation industry, this is usually achieved with process development and formulation departments working closely to deliver the best product at a competitive cost. Moreover, optimal integration of these departments with the strain development teams is also seen. Current industry trends also include reduction in the number of process steps because each step results in a yield loss. Sustainable technologies such as reuse of water, ingredients, and minimal by-product generation are also being adopted. Ultimately, all these efforts are beneficial for improving the production economics.

Regulatory Considerations

Bioproducts are regulated according to their application, for example, whether enzymes are used in food, feed, detergents, textile processing, and so on. Regulations also differ country by country. Irrespective of legislation, it is prudent for the product manufacturer to ensure that the production process, the potential product, and its intended use are safe prior to introduction.

Along with transfer of the strain, fermentation, recovery, and formulation process to the manufacturing plant, validated quality control assays, which are suitable for ensuring product quality, must also be provided. The EPA, FDA, and other agencies throughout the world are all involved in regulation of products derived from naturally occurring organisms and GMO. Essentially the regulations require: (1) the use of nonpathogenic organisms, (2) the absence of endotoxin or other toxins, (3) a well-documented and reproducible fermentation and downstream process, and (4) use of safe and well-characterized organisms and processes. In response to the latter, not only are the GMO well characterized, they are designed to barely survive in the general environment. Because recombinant organisms can be grown under contained good large-scale industry practices, safety issues relating to environmental release are minimized.

For control and containment of waste, regulatory requirements dictate appropriate containment that is related to the risk presented by the organism. Most of the processes are contained and hence subject to guidelines for industrial applications of recombinant DNA. Containment may be achieved biologically on the basis of inherent properties of the organisms, for example, their survival in the general environment is limited. Also, operation and design of the manufacturing facility minimizes potential releases of the recombinant organism to the environment. The degree of physical containment is matched to the risk presented by the organism. The same considerations apply to products made by recombinant organisms. Air monitoring is performed in production environments to evaluate levels of protein. This is important for assessing the efficiency of containment, respiratory protection requirement, and ensuring that environment levels meet occupational exposure limits.

Delivery of Products

Figure 30.12 represents a cell factory model to produce several categories of products via fermentation and biocatalysis processes. Carbon conversion in a cell factory into product(s) is essential to maintain the necessary energy (ATP, NAD(P)H, FADH) flow for the cell to replicate and maintain itself. The production of biochemicals is strictly linked to cell functions like cell synthesis (reduction–oxidation balance, cofactor regeneration, charge neutralization), and substrate turnover. Maximization of conversion yield, therefore, requires minimization of wasteful functions. Likewise, maximization of conversion rate requires maintenance of maximum driving force, e.g., ATP per conversion, key intracellular metabolite concentration, biomass per ATP, sufficient enzymatic activities, etc. Such principles continue to evolve in developing synthetic biology based processes, but it is too early to call them "laws of biotechnology." Synthetic cell engineering continues to significantly improve beyond what nature has already made possible, reaching 85–95% of what's theoretically possible. Accordingly, most favorable hosts, enzymes, raw materials, and process steps should be optimally integrated to achieve the best product economics and production efficacies.

Synthetic cell engineering is primarily the integration of four components: mining of genetic diversity and sequencing, cell physiology analysis and system modeling, synthetic pathway design and optimizing construction, integrated process design and engineering (see Fig. 30.13). Such integration requires several upfront tools outlined below:

1. Expression vectors to clone genes and adjust their copy numbers, and multiple markers to clone multiple genes
2. Transformation methods for above, gene deletion and integration systems

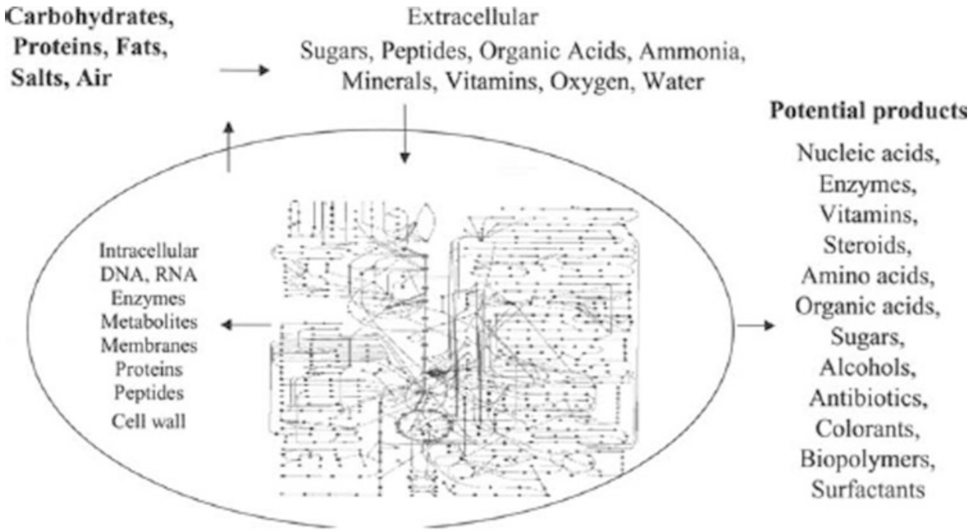

Fig. 30.12 A cell factory model

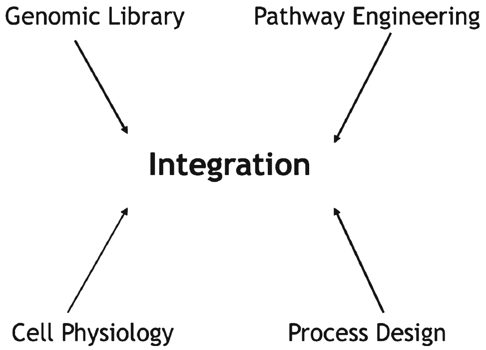

Fig. 30.13 A cell factory model depicting the four components that need to be integrated to produce several categories of products via fermentation and biocatalysis processes

3. Codon optimization of heterologous genes for higher expression
4. Mutagenesis of genes for in vivo regulation of enzymes
5. Transcriptional control, i.e., change promoter sequences to achieve different mRNA levels
6. Engineering of ribosomal sequences for translation modulation
7. Mutagenesis of pathway genes to change enzyme activity, specificity of substrate, product or inhibitor

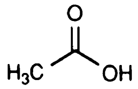
To develop cost-effective products for the biobased industry, the field of synthetic biology is continually developing a holistic understanding of microbial metabolism, and the effect of end-product on cell growth and maintenance. For example, functional genomic techniques now can monitor cell-wide transcription, translation, levels of metabolites and their interactions. By integrating the cell system-wide data and models, cell metabolism can be analyzed. The system knowledge can then be used to design/assemble cell components for specific functions and eventually build a cell factory platform.

Also, the size of the worldwide industrial chemicals business is ever increasing from $1 to $2 trillion, and global companies like DuPont, Genencor, Goodyear, BASF, DSM, Monsanto, Dow, Cargill, ADM, Tate & Lyle, Roquette, Mitsubishi, Braskem, Rohm & Haas and even new companies like Gevo, Amyris, Genomatica, Verdezyne, Ceres, and more continue to invest in industrial biotechnology to create high-value biochemicals, biomaterials, and biofuels. These companies are all interested in commercializing the biomaterial building blocks like propane diol, isoprene, succinic acid, acrylic acid, levulinic acid, isosorbide, butane diol, butylenes, ethylene glycol, ethylene, lysine, caprolactem, terephthalic acid, adipic acid, furan dicarboxylic acid, and of course natural sugar polymers like starch, cellulose, and xylose and their derivatives (see Fig. 30.14). But sustained growth, improved economics, and renewable resources will have to go hand in hand to enable replacement of petroleum derived chemicals and processes. Industrial-scale manufacturing aspects such as uses, synthesis methods, and costs of some of these bioproducts are reviewed below as well as in Chap. 31.

Organic Acids and Polymers

There are many organic acids that can be produced by microbial or biochemical means. However, at present, only acetic acid (as vinegar), citric acid, itaconic acid, gluconic acid, 2-keto-gulonic acid, and lactic acid are produced industrially by fermentation. Other organic acids, such as fumaric, gallic, malic, and tartaric acids, once produced by fermentation or enzyme processes, are now produced commercially, predominantly by the more economic means of chemical synthesis.

Acetic acid. Acetic acid as a chemical feedstock is manufactured by chemical synthesis. Acetic acid in the form of vinegar (at least 4% acetic acid by law) is produced largely via the oxidation of ethanol by bacteria of the *Acetobacter* genus [33].



Vinegar is one of the oldest known fermentation products, predated only by wine and possibly by certain foods from milk. First derived from the spoilage of wine, vinegar has been used as a condiment, food preservative, medicinal agent, primitive antibiotic, and even today as a household cleansing agent. Today, vinegar is produced almost entirely for use in foods. Vinegar may be defined as the product of a double fermentation: an alcoholic fermentation of a sugar source (fruits and their juices, cereals, syrups) usually by a selected strain of the yeast *Saccharomyces cerevisiae* or *ellipsoidens* and a second fermentation to oxidize the alcohol (including synthetic) to acetic acid by a suitable culture of *Acetobacter* organisms. The theoretical maximum yield of acetic acid on glucose by this route is 67% (two moles of acetic acid produced from every mole of glucose consumed). A homofermentative culture, *Clostridium thermoaceticum*, is known to be capable of fixing CO_2 and yielding three moles of acetic acid from one mole of glucose under anaerobic conditions. However, the technology for this process has not been commercialized.

Several vinegar-manufacturing processes are commercially used, including the following:

1. Trickling-bed reactor
2. Submerged cell reactor
3. Tower reactor

The circulating, trickling generator, which is still widely used, is a large tank generally of wood, such as redwood or

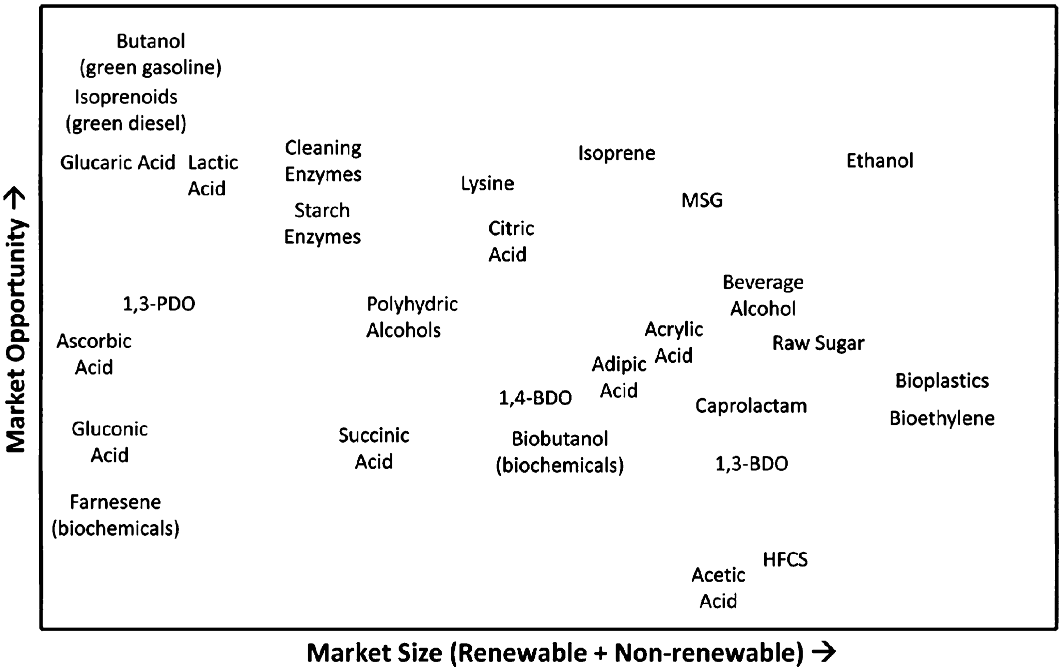


Fig. 30.14 Market opportunity (growth potential) vs. current market size of biochemicals and petrochemicals

fir but preferably cypress. Air is circulated in the generator by a number of equally spaced inlets. A pump circulates the ethanol–water–acetic acid mixture from the collection reservoir up through a cooler to the top of the tank. The liquid trickles down through the packing and returns to the bottom reservoir. The temperature of the generator is about 29°C at the top and 35°C at the bottom. A portion of the finished vinegar is periodically withdrawn from the reservoir and replaced with the ethanol-containing charge to maintain ethanol concentration in 0.2–5% range. If ethanol is depleted in the generator, the *Acetobacter* die, and the generator becomes inactive.

The Frings Acetator (produced by the Heinrich Frings Company of Bonn, Germany) is a submerged batch fermentor. It consists of a stainless steel tank with internal cooling coils, a high-speed, bottom-entering agitator, and a centrifugal foam breaker. The unique feature of this Acetator is its highly efficient method of supplying air, accomplished by high-velocity self-aspirating rotor that pulls air in from the room to the bottom of the tank. When the ethanol content falls to 0.2% by volume about 35–40% of the finished product is removed. Fresh feed is pumped in to restore the original level, and the cycle starts again. Cycle time for 12% vinegar is about 35 h, and the rate of production can be 10× that of the trickling generator. The yield of acetic acid on ethanol is higher as well, for example, 94 for the Acetator compared to 85% for the trickling generator. However, much more extensive refining equipment is necessary for filtering vinegar produced by the submerged process because the mash contains both the vinegar and the bacteria that produced it.

The tower fermentor is a relatively new aeration system applied to vinegar production. The fermentor is constructed of polypropylene reinforced with fiberglass. Aeration is accomplished through a plastic perforated plate covering the cross-section of the tower and holding up the liquid. The cost of the tower fermentor is said to be approximately half that of a Frings Acetator of equivalent productive capacity. It has been reported that the tower fermentor is satisfactory for producing all types of vinegar.

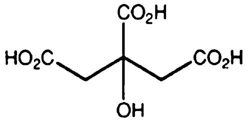
Since 1993, a two-stage submerged fermentation has been used to produce vinegar of more than 20% acetic acid. In the first fermentor, alcohol is added slowly to a total concentration of about 18.5%. After the acetic acid concentration has reached 15%, about 30% of the liquid from the first fermentor is transferred to a second fermentor. In the second fermentor, the fermentation is carried out at a reduced temperature of 18–24°C and continues until the alcohol is almost depleted.

Recombinant strains of *Acetobacter aceti*, cloned with either alcohol dehydrogenase or aldehyde dehydrogenase, have been tested for vinegar production. The bacteria with the aldehyde dehydrogenase gene produced acetic acid more rapidly than those with the alcohol dehydrogenase and were more resistant to high concentrations of acetic acid.

Vinegar clarification is accomplished by filtration, usually with the use of filter aids such as diatomaceous earth or bentonite. After clarification, vinegar is bottled, sealed tightly, pasteurized at 60–65°C for 30 min, and then cooled to 22°C. Vinegar can be concentrated by freezing or by a reverse osmosis membrane process.

The world production (excluding China and Russia) of 10% vinegar is estimated to be about two billion liters a year or about 200,000 metric tons of acetic acid. Price depends on the source (fruit, malt, grain, etc.).

Citric acid. Citric acid, whose structure is shown below, is the most important organic acid produced by means of fermentation.



Citric acid is used in soft drinks, candies, wines, desserts, jellies, jams, as an antioxidant in frozen fruits and vegetables, and as an emulsifier in cheese. As the most versatile food acidulant, citric acid accounts for about 70% of the total food acidulant market. It provides effervescence by combining the citric acid with a biocarbonate/carbonate source to form carbon dioxide. Citric acid and its salts are also used in blood anticoagulants to chelate calcium, block blood clotting, and buffer the blood. Citric acid is contained in various cosmetic products such as hair shampoos, rinses, lotions, creams, and toothpastes. More recently, citric acid has been used for metal cleaning, substituted for phosphate in detergents, for secondary oil recovery, and as a buffer/absorber in stack gas desulfurization. The use of sodium citrate in heavy-duty liquid laundry detergent formulations has resulted in a rapid increase in the use of citric acid.

Wehmet first described citric acid as a product of mold fermentation in 1893. However, it was only in 1919 that commercial fermentation processes based on sucrose were developed [34]. Although many organisms have been shown to produce citric acid from carbohydrates, *A. niger* has been the best organism for industrial production. Figure 30.15 summarizes the reactions leading to citric acid from glucose. It is worthwhile to note that one mole of glucose yields one mole of citric acid with no consumption of oxygen. The overall reaction is actually energy yielding. It yields one mole of ATP and two moles of NADH per mole of citric acid, and minimal growth is needed during production. This aspect makes fermentative production of citric acid a good candidate for the process of cellular immobilization.

Microbiological production of citric acid can be implemented by three techniques:

- Solid-state fermentation
- Liquid surface fermentation
- Submerged culture fermentation

In solid-state, or Koji, fermentation, *A. niger* is grown on moist wheat bran (70–80% water) and produces citric acid in 5–8 days. This process is practiced only in Japan and accounts for about one-fifth of Japanese citric acid production. In liquid surface, or shallow tray, fermentation, beet molasses (containing 48–52% sugar) or cane molasses of blackstrap (containing 52–57% sugar) or high test (containing 70–80% sugar) are introduced into a mixer. Dilute sulfuric acid is added to adjust the pH to about 6.0. Phosphorus, potassium, and nitrogen in the form of acids or salts are added as nutrients for proper mold growth and optimal citric acid production. The mix is then sterilized and finally diluted with water to a 15–20% sugar concentration. The medium flows by gravity into shallow aluminum pans or trays arranged in tiers in sterile chambers. Most chambers have provisions for regulation and control of temperature, relative humidity, and air circulation. Each tray holds about 400 L of solution at a depth of 76 mm. When the medium has cooled to about 30°C, it is inoculated with spores of *A. niger*. The tray fermentation requires 8–12 days. The pH drops to about 2 at the end of the fermentation, and the acid content varies from 10 to 20%. Some oxalic and gluconic acids are also formed. The temperature is maintained at 28–32°C during the fermentation. Sterile air is circulated through the chambers, and the relative humidity is controlled between 40 and 60%.

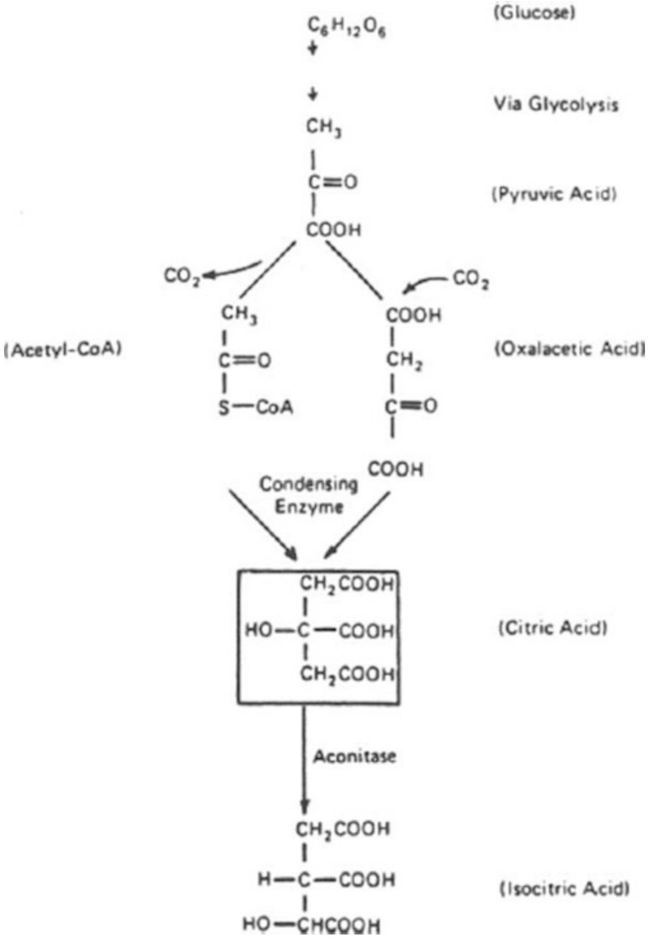


Fig. 30.15 Pathway leading to citric acid from glucose

Most newly constructed plants have adopted the submerged culture or deep fermentation process. The fermentation medium consists of sucrose (around 200 g/L) and mineral salts to provide a balanced supply of iron, zinc, copper, magnesium, manganese, and phosphate. The provision of a suitable culture medium is the most critical factor in obtaining a high yield of citric acid. The fermentation is carried out at 25–27°C. Oxygen is provided by bubbling air at a rate of 0.5–1.5 volumes of air/volume of solution/minute without mechanical agitation. It is generally accepted that the formation of pellets between 1 and 2 mm in diameter in the fermentation mash is most desirable. Pelleting reduces broth viscosity, increases oxygen transfer, and simplifies mycelium separation in the recovery scheme. The submerged fermentation has a time cycle of 6–9 days. The yield of citric acid on sugar varies from producer to producer but the theoretical maximum is 112% on sucrose. The liquid surface fermentation yield is high (90–95%) but the submerged culture fermentation is a bit lower. Reducing the formation of by-products, mainly oxalic acid, has resulted in improvements in the yield of the submerged culture process, nearly reaching those of the surface culture process.

The fermentation broth from the solid state, surface culture, or submerged culture process is treated similarly for recovery and refining of citric acid. Two recovery methods are used: precipitation and filtration, and extraction. A process flowsheet including the fermentation and refining section using the first method is shown in Fig. 30.16. The mycelium, which is initially filtered out of the fermentation liquor, may be used as fertilizer after proper weathering and processing. The clarified liquor flows to precipitating tanks fitted with stirrers where it is heated to a temperature of 80–90°C. The oxalic acid present is separated by preferential precipitation through the addition of a small amount of hydrated lime. The resulting calcium oxalate is purified separately in a manner similar to the process described for citric acid recovery.

Approximately one part of hydrated lime for every two parts of liquor is added slowly over a 1-h period while the temperature is raised to about 95°C. The precipitated calcium citrate is filtered on a vacuum filter, and the filtrate, free of citrate, is discarded as waste. The calcium citrate cake is moved to acidulation tanks, where it is acidified with dilute sulfuric acid. It is then filtered, and the citric acid mother liquor is decolorized by a charcoal treatment. The purified liquor is concentrated in a vacuum evaporator, run into a crystallizer where, upon cooling, citric acid crystallizes, generally in the form of the monohydrate. The resulting acid is of USP grade.

The extraction method treats the filtered fermentation liquor with a highly selective solvent, tri-*n*-butyl phosphate in kerosene, and then recovers free citric acid by counterextraction with water. The aqueous solution, which is further concentrated and crystallized, yields 92% citric acid with 8% soluble impurities.

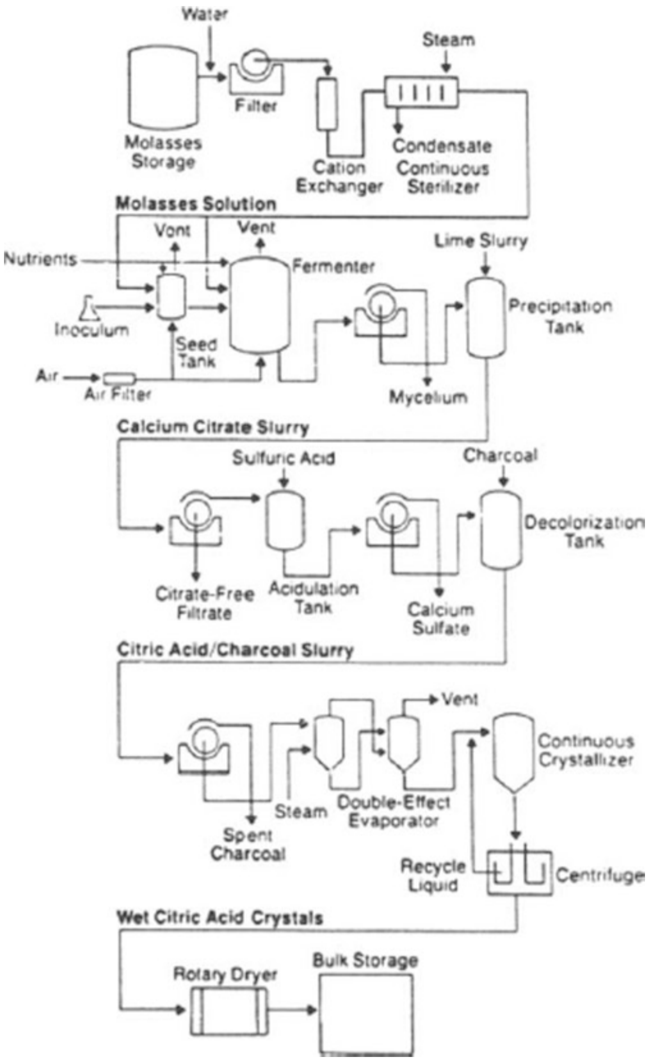

Fig. 30.16 Citric acid flow sheet

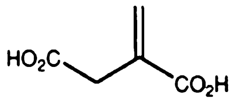
In the last two decades, the citric acid industry has seen some major changes in ownership and expansions. The worldwide production stands at about one million ton a year. The major producers include the Swiss-based Jungbunzlauer, La Citique Belge/Roche in Belgium, Bharat Starch Industries in India, and ADM, Cargill, and Tate & Lyle in the United States.

The list price of citric acid (anhydrous) has been in the range of 60–90 cents/lb, USP, 100-lb bags.

Itaconic acid



Itaconic acid (methylene succinic acid) is an unsaturated dibasic acid. It is a structurally substituted methacrylic acid, and therefore primarily used as a copolymer in acrylic or methacrylic resins. Because pure acrylic fibers are dye-resistant, it is necessary to include other components to make the fibers susceptible to dyes. An acrylic resin containing 5% itaconic acid offers superior properties in taking and holding printing inks and in bonding. In addition to its main application as a component of acrylic fibers, itaconic acid is used in detergents, food ingredients, and food shortenings.

Previously, itaconic acid was isolated from pyrolytic products of citric acid or produced by converting aconitic acid present in sugarcane juice. It is now produced on a commercial basis predominantly by direct fermentation of sugars. The biosynthesis of itaconic acid follows the metabolic sequence shown in Fig. 30.17.

Although both *Aspergillus itaconicus* and *Aspergillus terreus* are known producers of itaconic acid, the latter is superior and is used industrially with either surface (shallow-pan) or submerged (deep-tank) fermentation [35]. The medium contains a sugar source, corn steep liquor, ammonium sulfate, and mineral salts of calcium, zinc, magnesium, and copper. The fermentation, similar to that of citric acid, is very sensitive to concentrations of copper and iron. The fermentation is carried out at 39–42°C, pH of 2.0–4.0, and under vigorous agitation. Moderate, but continuous, aeration is critical. The batch cycle time is 3–6 days. The highest known product concentration is 180–200 g/L from a medium containing 30% sugar. Therefore, the yield of itaconic acid on sugar is typically 50–70%. The itaconic acid recovery scheme involves the following:

1. Acidification of itaconic precipitates, if present
2. Filtration to remove mycelium and other suspended solids
3. Activated carbon treatment (not necessary for industrial grade product)
4. Filtration to remove carbon
5. Evaporation and crystallization

If a high-purity acid is desired, further purification steps such as solvent extraction, ion exchange, and carbon decolorization are used.

The price of itaconic acid in 2002 was about $2/lb, and the world production is estimated to be about 20,000 t/year. The major producers include Cargill (using Pfizer technology) in the United States, San Yuan in Taiwan, Rhodia in France, and Merck in Germany.

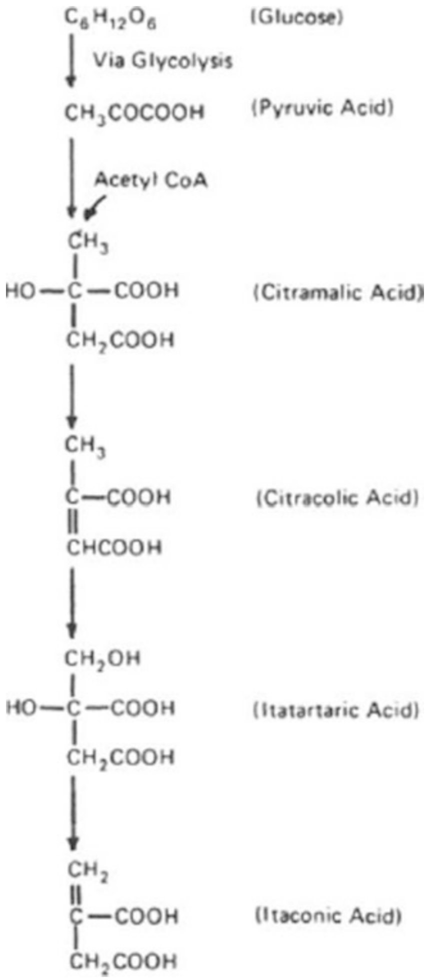


Fig. 30.17 Proposed metabolic sequence for biosynthesis of itaconic acid

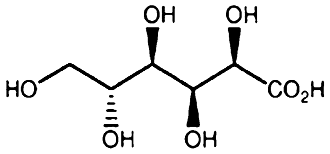
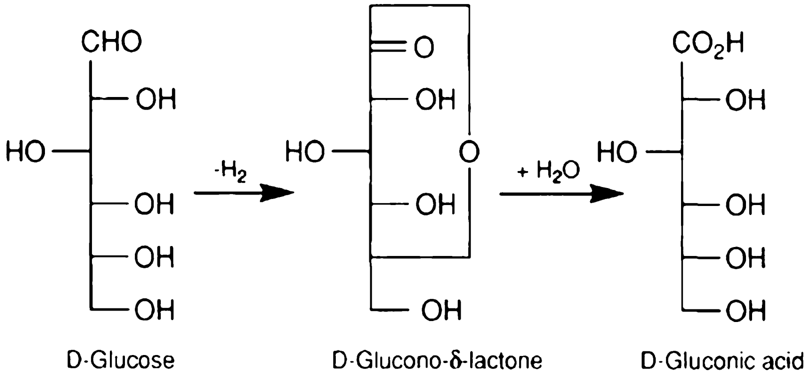
Gluconic acid. Gluconic acid is produced by the oxidation of the aldehyde group of glucose to a carboxylic acid.





Gluconic acid may be prepared from glucose by oxidation with a hypochlorite solution, by electrolysis of a solution of sugar containing a measured amount of bromine, or by fermentation/enzymatic conversion (glucose oxidase, catalase) of glucose by fungi or bacteria (U.S. Patent 5,897,995). For economic reasons, the biological methods are now preferred.

Gluconic acid is marketed in the form of a 50% aqueous solution, calcium gluconate, sodium gluconate, and glucono-δ-lactone. Gluconic acid finds use in metal pickling, as an acidulant in foods, as a protein coagulant in tofu (soybean curd) manufacture, as a calcium sequestrant in detergent formulations, in the pharmaceutical area in mineral (calcium and iron) supplements, and as a cement viscosity modifier in the construction area. Calcium gluconate is widely used for oral and intravenous therapy. Sodium gluconate, a sequestering agent in neutral or alkaline solutions, finds use in the cleansing of glassware. Glucono-δ-lactone is used as a food flavor and an acidulant in making cheese and tofu, baking powders, and effervescent products.

Commonly used organisms for gluconic acid fermentation are *A. niger* and *Gluconobacter suboxydans*. The larger volume production uses the fungal process. Most of the gluconic acid produced from the *Gluconobacter* process is marketed as glucono-δ-lactone.

During gluconic acid fermentation, glucose is first oxidized (or, more correctly, dehydrogenated) to glucono-δ-lactone. This is carried out by glucose oxidase. Hydrogen peroxide is also produced in this step, but is decomposed by catalase. The fermentation can be by either surface or submerged culture, the latter more generally practiced in industry. Horizontally rotating fermentors have also been used. Calcium gluconate fermentation, in which calcium carbonate is used for neutralization of the product, is limited to an initial glucose concentration of approximately 15% because of the low solubility of calcium gluconate in water (4% at 30°C). Neutralization by sodium hydroxide instead allows the use of up to 35% glucose in the medium.

The recovery of calcium gluconate from fermentation broth involves the following:

1. Filtration to remove mycelium and other suspended solids
2. Carbon treatment for decolorization
3. Filtration to remove carbon
4. Evaporation to obtain a 15–20% calcium gluconate solution
5. Crystallization at a temperature just above 0°C

In sodium gluconate fermentation, the medium also contains corn steep liquor, urea, magnesium sulfate, and some phosphates. The pH is controlled above 6.5 by addition of sodium hydroxide. One to 1.5 volumes of air per volume of solution per minute (vvm) are supplied for efficient oxygenation and a high back-pressure, up to 30 psig, is desirable. The fermentation cycle is 2–3 days. Continuous fermentation is used in Japan to convert a 35% glucose solution to sodium gluconate with a yield higher than 95%. The continuous process doubles the productivity of the usual batch system.

Sodium gluconate can be recovered from the fermentation filtrate by concentrating it to 42–45% solids, adjusting the pH to 7.5 with sodium hydroxide, followed by drum-drying. In glucono-δ-lactone fermentation, *G. suboxydans* converts a 10% glucose solution to glucono-δ-lactone and free gluconic acid in about 3 days. Approximately 40% of the gluconic acid is in the form of glucono-δ-lactone. Aqueous solutions of gluconic acid are in equilibrium with glucono-δ-lactone. Crystals that separate out of a supersaturated solution below 30°C are predominantly of free gluconic acid; from 30 to 70°C, the crystals are principally glucono-δ-lactone; and above 70°C, they are mainly of γ-lactone.

Sodium gluconate sells for 30–70 cents/lb, depending on the liquid or dry form. Dry sodium gluconate is the main form of gluconic acid/gluconate consumed in the United States. The world market of gluconic acids and salts is about 60,000 t/year. The major producers include Glucona

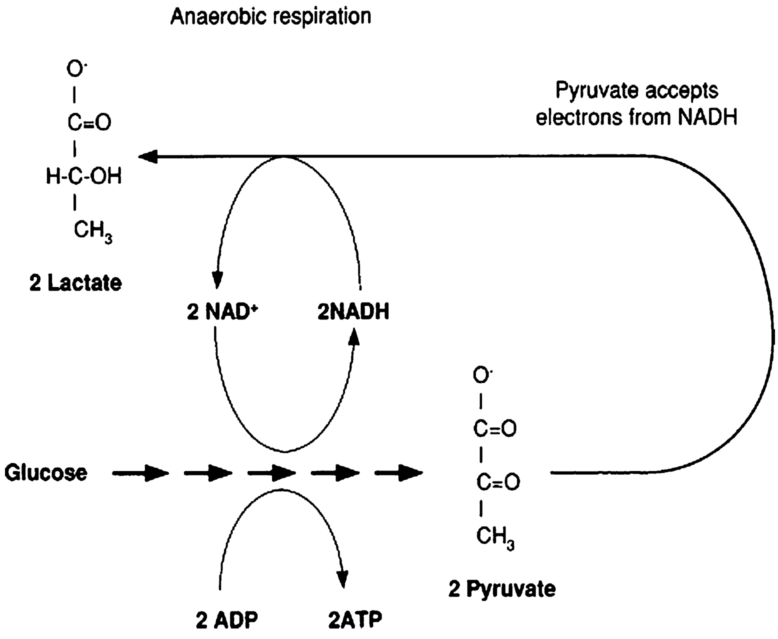


Fig. 30.18 Lactic acid from glucose fermentation

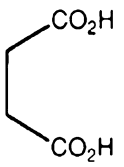
America (a subsidiary of Aveba B.A.) and PMP Fermentation Products (acquired by Fujisawa) in the United States; Benckister, Jungbunzlauer, and Roquette Freres in Europe; and Fujisawa and Kyowa Hakko in Japan. An isolated enzyme system (glucose oxidase-catalase) has recently become cost-competitive with the fermentation process and is therefore likely to expand its use.

Succinic acid

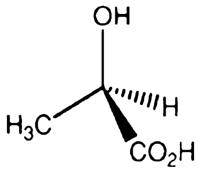


Succinic acid, as an intermediate in the chemical synthesis of 1,4-butanediol, tetrahydrofuran, and adipic acid, has a very large market potential [36]. It is a common intermediate in the metabolic pathway of several anaerobic microorganisms including *Anaerobiospirillum succiniproducens* and *Actinobacillus succinogenes.* However, succinate is produced by mixed-acid fermentations in low yields and concentrations along with several by-products. As the sole product of fermentation, it is possible to produce succinic acid at titers >100 g/L and yield of 1.2 moles per mole of glucose. In such a process, organisms use the phosphoenolpyruvate (PEP) carboxykinase pathway to make succinic acid. Other key enzymes include PEP carboxylase, malate dehydrogenase, fumarase, and fumarate dehydrogenase. Carbon dioxide concentration has been shown to regulate the levels of these enzymes for production of succinate. Carbon dioxide functions as an electron acceptor and modulates the flux of PEP.

An *E. coli* strain has also been engineered by overexpressing PEP carboxylase. Metabolic engineering of the strain was also performed in which genes encoding pyruvate:formate lyase and lactate dehydrogenase were inactivated. PEP flux was also increased through inactivation of the glucose-specific phosphotransferase system (PTS) system. Ideally, for minimizing salt formation in an acid fermentation, the pH should be lower than the pK_a. Otherwise, the conversion of the salt to the free acid adds significant costs in the final purification.

According to http://www.nrel.gov/docs/fy04osti/35523.pdf, there is a significant market opportunity for biobased C4 building block diacids. However, in order to be competitive with petrochemical-derived products, the fermentation cost needs to be below $0.25/lb. Although much progress has been made in the engineering of organisms for succinic acid production, at this point it remains commercially challenging.

Lactic acid



Lactic acid has been used as a food preservative and food-flavoring compound. Recent attention on lactic acid has been for its use in making polylactic acid (PLA), a biodegradable polymer. As a result, the market for lactic acid is rapidly growing. Under batch fermentation conditions, homolactic fermentative Lactic Acid Bacteria (LAB) make lactic acid as

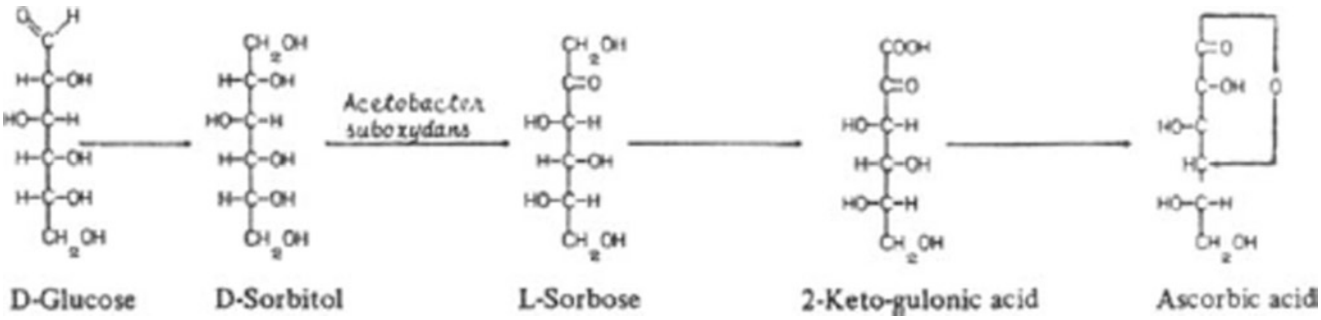


Fig. 30.19 Reactions leading to vitamin C from glucose

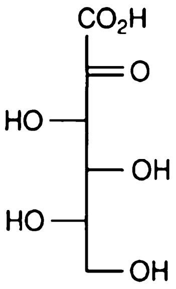
their endproduct. As shown in Fig. 30.18, 2 moles of lactate and 2 moles of ATP are formed per mole of glucose used. Although free lactic acid is preferred for most industrial processes, the anaerobic fermentation operates optimally at pH 5 where the salt of the acid is formed. To obtain lactic acid in its free form, the fermentation process must be carried out well below its pK_a of 3.87. This challenge has been met by cloning the bovine LDH gene into yeast, which has resulted in 1.19 mole lactate production per mole of glucose during fermentation at low pH. The fermentor titer reached is >100 g/L with a productivity of 0.8 g/L/h. A strain of *S. cerevisiae* overexpressing the lactate–proton symporter *JEN1* resulted in increased titer and yield.

Recovery of lactic acid is complicated by the high solubility of its salt. The traditional method of recovering calcium lactate is being replaced by membrane, electrodialysis, or ion-exchange purification methods. Producers such as Purac, Cargill, ADM, and Jiangxi sell lactic acid for $0.50–3.00 per kg depending on whether the product is industrial, feed, food, or pharma grade.

NatureWorks® LLC has set up a $300 million plant at Blair, NE, which is capable of producing about 140,000 t/year of polylactide polymers from corn sugar. It employs a fermentation process to produce two chiral isomers of lactic acid from glucose, which are then cracked to form three lactide isomers. The isomers are subsequently polymerized to polylactide.

2-Keto-L-gulonic acid



2-Keto-L-Gulonic acid (2-KLG) is the precursor for Vitamin C (L-Ascorbic acid). Vitamin C is used on a large scale as an antioxidant in food, animal feed, beverages, pharmaceutical formulations, and cosmetic applications. About one half of the vitamin C is used in vitamin supplements and multivitamin preparations, one quarter in food additives, 15% in beverages, and 10% in animal feed. When ascorbic acid is used in cosmetics, it is phosphorylated to prevent its oxidation.

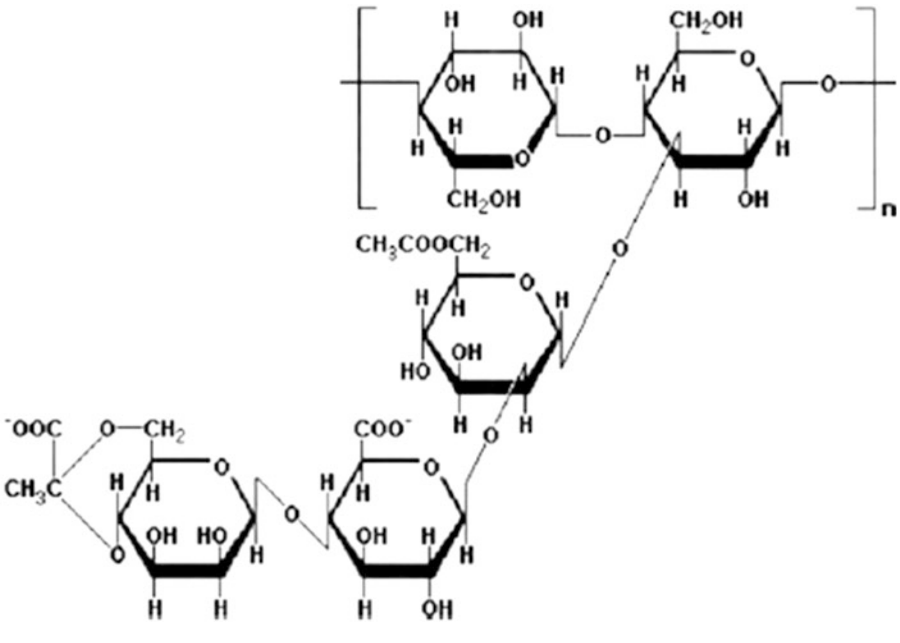
Figure 30.19 shows the reactions involved in the combined microbiological and chemical conversions of glucose, via sorbitol, to vitamin C, called the Reichstein and Grussner process. Sorbitol is made by catalytic hydrogenation of glucose and L-Sorbose is produced from sorbitol by the action of several species of bacteria, the most commonly used being *Acetobacter suboxydans*. Because this organism is very sensitive to nickel ions, it is important that the medium and fermentor be free of nickel. The medium normally consists of 100–200 g/L sorbitol, 2.5 g/L cornsteep liquor, and an antifoam agent such as soybean oil. The medium is sterilized and cooled to 30–35°C, about 2.5% inoculum is added, and the tank is aerated and sometimes stirred. This is the only step based on fermentation, and the step yield is 80–90% in 20–30 h. The chemical steps in the conversion of sorbose to ascorbic acid involve the preparation of the diacetone derivative, which is then oxidized, the acetone groups are removed, and the resultant 2-KLG is isomerized to the enediol with ring closure. It is believed that this chemical process currently operates at an overall yield of about 50% vitamin C on glucose.

Groups all around the world have pursued alternative vitamin C production technologies. A one-step fermentation process starting from glucose to produce 2-keto-L-gluconic acid was reported to be practiced in China, a microalgae process was developed in the United States and a two-stage fermentation process via the intermediate 2,5-diketo-D-gluconic acid (2,5-DKG) was developed in Japan. Genentech [37] succeeded in cloning the 2,5-DKG reductase gene from a *Corynebacter* sp. and expressing it in an *Erwina* sp. that naturally produces 2,5-DKG via the fermentative oxidation of glucose. The recombinant *Erwina* culture is thus capable of carrying out the complex oxidation and reduction steps to form 2-KLG in a single fermentation.

Genencor International, in partnership with Eastman Chemical Co. has developed such a single fermentation process using genetically engineered *Pantoea citrea*. To maximize the product yield on glucose, detailed analysis of the steps in the formation of 2-KLG was carried out. In the periplasm of this organism, glucose is first converted to gluconic acid by a membrane-bound PQQ-dependent glucose dehydrogenase. This is followed by the oxidation of gluconic acid to 2-keto-D-gluconate (2-KDG) by a cytochrome C coupled enzyme, gluconate dehydrogenase. In a third reaction, 2-KDG is further oxidized to 2,5-DKG by 2KDG dehydrogenase, another cytochrome C coupled enzyme. Purification, characterization, and determination of the enzyme structure of 2,5-DKG reductase have added significantly to the understanding and development of this production process.

The major manufacturers include DSM, BASF, and four Chinese producers, viz. Northeast Pharmaceutical, North China Pharmaceutical, Shijiazhong Pharmaceutical, and Jiangshan Pharmaceutical. The current world supply of ascorbic acid is more than 80,000 metric tons per year with annual revenues in excess of US $700 million.

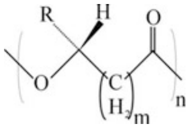
Xanthan gum



Xanthan gum is an anionic polymer of β-(1,4)-D-glucopyranose glucan with side chains of 1,3-α-D-mannopyranose and (1,2)-β-D-glucuronic acid residues [38]. It is produced naturally by bacteria to enable them to stick to plants. The negatively charged carboxyl groups on the side chains generate viscosity when the xanthan gum is mixed with water. The glucan backbone is protected by the side chains, thus making it relatively stable to acids, alkalis, and cellulase enzymes. Xanthan gum is used as a thickener, stabilizer, emulsifier, and foaming agent in products such as salad dressings, cosmetics, pharmaceuticals, paints, lubricants, and ice cream. Its key property is high viscosity at low shear and thinning character at high shear. Xanthan gum is not affected by ionic strength over a wide pH, shear or temperature range.

Xanthan gum is produced commercially via aerobic submerged fermentation of sugar by *Xanthomonas campestris*. Different strains or fermentation conditions produce differing degrees of acetylation, pyruvylation, and hence functionalities. The production strain is grown in medium containing carbohydrate, nitrogen, and salts. The production process of xanthan gum is energy intensive and costly, and product titer and productivity are relatively low due to high viscosity. In addition, the broth is difficult to filter due to cells in the broth. After fermentation, the broth is sterilized to inactivate cells; the product is precipitated or coagulated, separated by centrifuges, dried, and milled. About 20,000 t of xanthan are produced each year with a market value more than US $160 million.

Poly(3-hydroxyalkanoates)



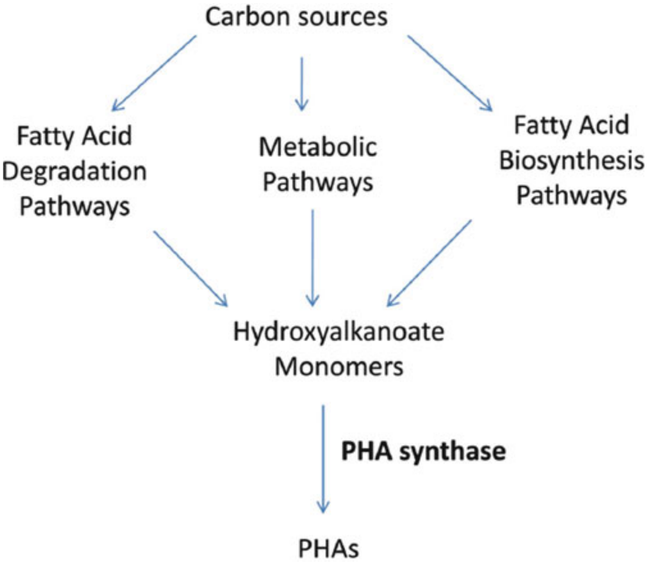


Fig. 30.20 Pathway for synthesis of poly(3-hydroxyalkanoates) using a variety of substrates

Among a wide variety of biobased polymers [39], poly(3-hydroxyalkanoates) (PHAs) also known as microbially produced polyesters are diverse in terms of constituents and biosynthetic pathways, and therefore desired as starting materials for a variety of conventional and thermo-plastics applications. Some microorganisms produce polyesters naturally, e.g., Ralstonia eutropha formally known as *Alcaligenes eutrophus*, a gram negative bacteria that produces PHAs as inclusion bodies or granules in the cytoplasm and serve as storage of carbon and energy. Natural organisms accumulate PHAs under excess carbon or some nutrient limitation, and use them later under carbon starvation. But engineered micro-organisms can accumulate up to 80–95% of the cell's dry weight, and large scale fermentors can grow >100 g/L dry cell weight. PHA is the most common polyester made in nature, and poly-3-hydroxybutyrate (PHB) was the first to be discovered. Other PHAs have since been discovered, including those containing hydroxyvalerate units, as in poly-3-hydroxyvalerate (PHV). Because the structure and monomeric composition of PHAs determine the applications for each type of polymer, a variety of polymers have been synthesized by co-feeding of various substrates or by metabolic engineering of the production organism (see Fig. 30.20).

Production organisms are fed carbon sources like glucose, sucrose, oils, propionic acid, etc. After fermentation, the cells are lysed, the cell debris is separated, and the PHA is extracted with a solvent, precipitated from water as powder, purified, and converted to pellets. Production of PHA could take up to 5 kg of raw material per kg product, and genetic improvements in microorganisms are necessary for higher PHA yield, use of cheaper feedstocks, and lower capital.

PHA commercial production has been considered by several companies like W. R. Grace, ICI, DSM, Metabolix, Monsanto, Proctor & Gamble (P&G), Kaneka, Meridian, Tianan, Tianjin, and others. According to P&G/Kaneka, PHA/PHB (Nodax^{TM}) production cost has to be <1.5 USD per kg for high volume applications, and alkaline digestibility and flushability are convenience factors of interest to the production of single-use consumer goods.

Alcohols

The organic chemicals that fall into this category and can be produced by fermentation include ethanol, 1,3-propanediol, butanol, acetone, 2,3-butanediol, and glycerol. Butanol and acetone have been produced industrially by fermentation, but currently for economic reasons, chemical synthesis is the manufacturing method of choice. However, as price and availability of ethylene and propylene as feedstocks for the synthetic processes become subjects of concern, there is a renewed interest in examining the fermentation processes. As the cost of crude oil continues to go up while the price of renewable resource such as agricultural crops remains relatively stable, there has been an increasing interest in producing chemical feedstocks from renewable resources by biological means.

1,3-Propanediol

1,3-Propanediol is a monomer with potential utility in the production of polyester fibers and in the manufacture of polyurethanes and cyclic compounds. A variety of chemical routes to 1,3-propanediol are known. For example, (1) ethylene oxide may be converted to 1,3-propanediol over a catalyst in the presence of phosphine, water, carbon monoxide, hydrogen, and an acid; (2) a catalytic solution phase hydration of acrolein followed by reduction; or (3) from glycerol, reacted in the presence of carbon monoxide and hydrogen over catalysts having atoms from group VIII of the periodic table. Although it is possible to generate 1,3-propanediol by these methods, they are capital intensive and/or generate waste streams that contain environmental pollutants.

The biological production of 1,3-propanediol from glycerol has been known for a number of years [11]. The use of natural organisms (e.g., enteric bacteria such as *K. pneumoniae*, *Citrobacter freundi*, and Clostridia, such as *C. butyricum*) to produce 1,3-propanediol from glycerol has been well studied. Continued optimization of the basic anaerobic glycerol fermentation process has produced promising results. A number of batch or fed-batch

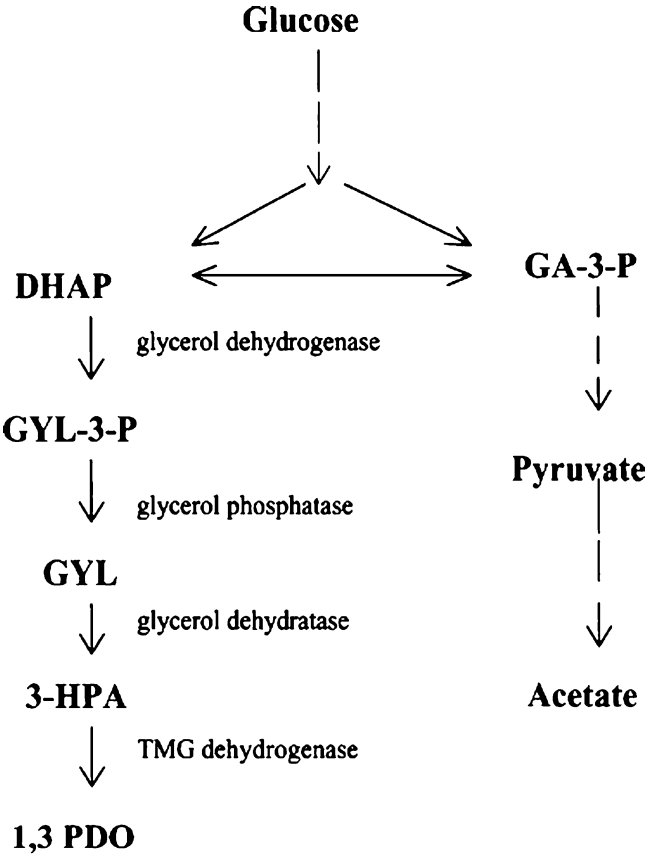

Fig. 30.21 1,3-PDO pathway from glucose

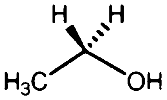
fermentations using *K. pneumoniae* or *C. butyricum* have produced titers of 50–75 g/L and a yield of 0.44–0.69 mol/mol 1,3-propanediol from glycerol. However, the complete conversion of glycerol to 1,3-propanediol is not possible due to the requirement of an additional reducing power in the form of NAD(P)H.

Neither the chemical nor the biological methods described earlier for the production of 1,3-propanediol are well suited for industrial scale. The chemical processes are energy intensive and the biological processes require the expensive starting material, glycerol. A more desirable process would be to develop a microorganism that would have the ability to convert basic carbon sources such as carbohydrates or sugars to the desired 1,3-propanediol. Such a single organism approach developed by Genencor International and DuPont overcomes this problem by generating reducing cofactors from the glucose conversion to CO_2. The ability to control both carbon and energy flow in the single organism allows for the more efficient use of the input carbon source.

As shown in Fig. 30.21, the conversion of glucose to 1,3-propanediol requires the combination of two natural pathways: glucose to glycerol and glycerol to 1,3-propanediol. The two enzymes involved in the conversion of glycerol to 1,3-propanediol have been cloned and characterized from several organisms, viz. *Klebsiella*, *Citrobacter*, and *Clostridium*. The first enzyme in the pathway is glycerol dehydratase. The dehydratase has been shown to undergo catalytic inactivation and requires the addition of a reactivation complex of two additional proteins. The second enzyme in the pathway is a NAD-linked tri-methylene glycol (TMG) dehydrogenase. Both of these enzymes have been cloned and expressed in *E. coli*. The pathways for the production of glycerol are found in the yeast, *S. cerevisiae* that produces glycerol from the glycolytic intermediate dihydroxyacetone-3-phosphate using two enzymes: dihydroxyacetone-3-phosphate dehydrogenase and glycerol-3-phosphate phosphatase. To construct a single organism to produce 1,3-propanediol from glucose, one could clone the glycerol pathway into a natural 1,3-propanediol producer, or the 1,3-propanediol pathway into a natural glycerol producer. Although either of these approaches seems simple and direct, there are problems involving natural regulation of the pathways. However, building both pathways into *E. coli* is advantageous as it is the most completely studied organism. It provides a rich set of genetic tools (sequenced genome, vectors, promoters, well-characterized metabolism, and physiology) and a large number of metabolic mutants that have been constructed and analyzed [40]. Moreover, *E. coli* has been used in large-scale fermentation for production of industrial and healthcare products, does not naturally overproduce glycerol or 1,3-propanediol, and thus has a strong likelihood of no natural regulation to overcome. Modifications of more than 70 *E. coli* genes were analyzed and the final production organism had 18 genes modified. Some of these genes were regulatory elements that indirectly affected the function of a few hundred other genes. The optimized strain of *E. coli* produced 135 g/L of 1,3-propanediol, at 3.5 g/L/h, and 51% weight yield on glucose.

The joint venture between DuPont and Tate & Lyle has demonstrated the large-scale feasibility to produce 1,3-propanediol by fermentation (bio-PDO^{TM}). The process uses the genetically engineered organism developed jointly by former Genencor and DuPont. The joint venture has announced that in 2006 they will commercially produce bio-PDO™ from corn to replace petrochemicals in the production of their polymer Sorona$^{®}$, for many end-use applications, including fibers. The bio-PDO™ will be produced at a new plant in Loudon, TN, USA. The bioprocess for making 1,3-propanediol is claimed to require 40% less capital and has a 25% lower operating cost than the chemical process for making the same product. Because of a different impurity profile, the polymer made from the biological-based 1,3-propanediol has improved properties and actually creates a superior product compared to the chemically based 1,3-propanediol (http://www.dupont.com/sorona/faqs.html).

Ethanol



Ethanol is a versatile chemical being used in industrial solvents, thinners, detergents, toiletries, cosmetics, and pharmaceuticals. It is also used as an intermediate for manufacturing other chemicals such as glycol ethers, ethyl chloride, amines, ethyl acetate, vinegar, and acetaldehyde. With the ever-increasing price and dwindling supply of crude oil, ethanol fermented from grains and other renewable organic resources is becoming an economical fuel supplement. The U.S. fermentation ethanol capacity is now about four billion gallons a year, a result of efforts by the ethanol industry to expand its use in fuels, as a replacement for the oxygenate, methyl *tert*-butyl ether.

Ethanol is produced by fermentation from sugar-containing materials such as grain products, fruits, molasses, whey, and sulfite waste liquor. Yeast, particularly strains of *S. cerevisiae*, is almost exclusively used in industrial ethanol fermentation. It tolerates ethanol concentrations up to about 20% (by volume), and under anaerobic conditions converts over 85% of the available carbohydrates to ethanol and carbon dioxide. Air or oxygen suppresses the formation of ethanol from sugar (the Pasteur effect). Under aerobic conditions, a major portion of the carbohydrates goes towards cell growth. Ethanol is formed via glycolysis (the Embden–Meyerhof–Parnas pathway). The overall reaction starting from glucose can be written as follows:

$$C_6H_{12}O_6 \rightarrow 2C_2H_5OH + 2CO_2 + 18\ \text{kcal}$$

The ethanol yield on glucose is thus 51% by weight. Because the carbohydrate is also used for cell growth and respiration, the overall yield of ethanol from total carbohydrate consumed is about 42–46 wt.% on a glucose equivalent basis.

Ethanol fermentation can be conducted on any carbohydrate-rich substrate. Molasses, which is the waste mother liquor that remains after the crystallization of sucrose in sugar mill operations, is widely used. Blackstrap molasses contains 35–40% sucrose and 15–20% invert sugars (glucose and fructose). High-test molasses contains 22–27% sucrose and 50–55% invert sugars. Most of the blackstrap molasses do not require the addition of other nutrients for ethanol fermentation. However, high-test molasses requires ammonium sulfate and other salts such as phosphates. In the molasses process, blackstrap or high-test molasses is charged into a mixing tank and diluted with warm water to give a sugar concentration of 15–20%. The pH is adjusted to 4–5, the mash pasteurized, cooled, and charged into fermentor tanks, and 1–5% yeast inoculum is added. The fermentation is carried out nonaseptically at 23–32°C. Antibiotics may be added to control possible bacterial contaminations. Because the overall reaction is exothermic, cooling is necessary. The fermentation takes 28–72 h to produce an ethanol concentration of 8–10%. Carbon dioxide normally is vented, but if it is to be recovered, then the vent gas is scrubbed with water to remove entrained ethanol and then purified using activated carbon. The bubbling due to carbon dioxide generation by fermentation could provide sufficient agitation for small tanks. Mechanical agitation may be necessary for large fermentors. The fermentation may be conducted batchwise or continuously, with or without recycling yeast. Although continuous fermentation and/or cell recycle can significantly improve productivity and thus reduce required capital investment, it may have only a limited impact on lowering product costs in as much as a significant portion of the total cost comes from raw materials.

Ethanol can also be produced by fermentation of starch, whey, sulfite waste liquor, cellulose, and hemicellulose. Potato or tapioca can also be converted to ethanol. Grain fermentations [41] require additional pretreatment because yeast cannot metabolize starch directly. The grain (corn, sorghum, barley, wheat, rice, or rye) is ground and heated in an aqueous slurry to gelatinize or solubilize the starch. Starch-liquefying enzymes (thermostable alpha amylase) are added in this step. The liquefied starch is then cooled to 60–65°C. Yeast is then added to carry out fermentation simultaneously with saccharification by amyloglucosidase (or glucoamylase). The subsequent fermentation and refining procedures are the same as those using molasses as raw materials.

The grain-based ethanol process, also called dry milling was developed and optimized for the beverage industry utilizing starch-based feedstock and energy-intensive processes. Such processes tend to produce some nonfermentable sugars during cooking of starch. Salts added for the needed pH adjustments of the enzymatic treatments. Both of these result in extra process costs. A granular starch hydrolyzing enzyme (GSHE) technology is likely to replace the traditional energy intensive process of liquefaction/saccharification (http://www.biorefineryworkshop.com/presentations/Dean.pdf). The GSHE is a new enzyme product to reduce energy usage for the production of inexpensive glucose from granular starch, which replaces the energy-intensive liquefaction/saccharification. The ethanol industry needs continued energy, cost, and conversion efficiency improvements. An ethanol production process that has the following key features is much desired.

- Energy savings—elimination of jet cooking
- Capacity increase—high solids and increased ethanol yield

- Reduction of yeast growth inhibitors—high glucose concentration, Maillard reaction products, and so on.
- Operational cost reduction—labor, time, and chemicals
- Value-added co-product, Dried Distiller's Grains and Solubles—higher protein content
- Process simplification—fewer unit operations

GSHE-like novel enzyme-processing technologies with reduced total operating cost will provide a dramatic acceleration in the timelines for the establishment of the biobased economy. This developing technology will also have a major positive impact on the life cycle costs of biobased products and address the growing concerns among policy makers and environmentalists.

The GSHE is a blend of enzymes with synergistic activity on granular starch. The key enzymes of the GSHE blend include acid stable alpha amylases and glucoamylases that "drill" holes in the starch granules. Thus the GSHE is capable of hydrolyzing insoluble granular (uncooked) starch into fermentable sugars by enabling depolymerization of starch to glucose without the need for the energy-intensive jet-cooking step, in a Simultaneous Saccharification and Fermentation (SSF) process for alcohol production. Genencor International has achieved high level of expression of these enzymes in industrial production strains resulting in an acceptable cost structure.

Research to improve ethanol fermentation has also focused on the development of a high solids, continuous feeding process as well as improved yeast strains. Other related developments include processes for the use of biomass feedstocks, such as cellulosic waste material [42–46]. The former Genencor and NREL collaboration funded by the U.S. DOE has (a) put in place the tools required for continual improvement of biomass-derived cellulases, (b) built a suite of enzymes with enhanced thermostability and improved specific performance at elevated temperatures, (c) developed an improved production strain for the enhanced cellulase components and demonstrated an enhanced production process. Therefore, plans are in place to provide a developmental product(s) in support of continued industry development.

Developments in genetic engineering have made possible the development of new organisms (yeasts and bacteria) that can survive in higher concentrations of ethanol, tolerate higher sugar concentrations, grow at higher temperatures, and utilize starch or cellulose feedstock directly (http://www.farmfoundation.org/projects/03-18_biofuels.pdf).

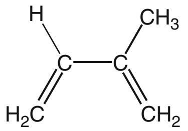
Ingram's [44] pathway engineering program has created a production organism patented by the University of Florida, with improved efficiency of ethanol production from C5 and C6 sugars (xylose, arabinose, galactose, mannose, glucose). Gelunol holds the rights to the patented engineered bacteria and is building a large-scale biomass-to-ethanol plant in Jennings, LA. The plant is expected to be operational in 2007 and will use bagasse waste from sugarcane to produce up to 30 million gallons a year of ethanol. According to the USDA and DOE, production of one billion ton of biomass per year is possible on a sustainable basis. This scale of biomass has the conversion potential of producing 100 billion gallons of ethanol per year.

In order to prevent the diversion of industrial alcohol to potable uses, it is denatured by the addition of some material that renders the treated alcohol unfit for use as a beverage. A fuel mixture such as 10% alcohol and 90% gasoline has become the most important use of fermentation ethanol. Ethanol from grain fermentations has been made competitive as a liquid fuel in the United States because of improvements in technology, especially in the area of efficient enzymes and energy usage in production plants, and various government subsidies designed to reduce the nation's dependence on imported foreign oil. Other countries in Europe as well as Brazil, India, and China also have substantial production of fermentation ethanol for use as fuel. In the United States, ADM, Tate & Lyle, and Cargill are the biggest among a large number of producers (for ethanol recovery, see "Recovery section").

Hydrocarbons

Hydrocarbons that can be produced by fermentation are many, from hydrogen and methane typically produced in anaerobic waste treatment, to ethylene and isoprene produced naturally by a variety of micro- and macro-organisms (plants, trees, animals). Very recent advancement of pathway engineering of isoprene and farnesene production systems has drawn significant attention.

Isoprene



Isoprene is an important commodity chemical used in a wide range of industrial applications ranging from the production of synthetic rubber for tires and coatings to use in adhesives and development of specialty elastomers. Styrene-isoprene-styrene block copolymers form an essential part of most hot melt pressure sensitive adhesive formulations and *cis*-polyisoprene or synthetic rubber is used in tire manufacture. All of the world's isoprene is produced from petroleum-derived feedstocks and is subject to volatility in pricing and supply linked to oil.

A first of its kind biobased process to produce isoprene (BioIsoprene™) from renewable raw materials is in

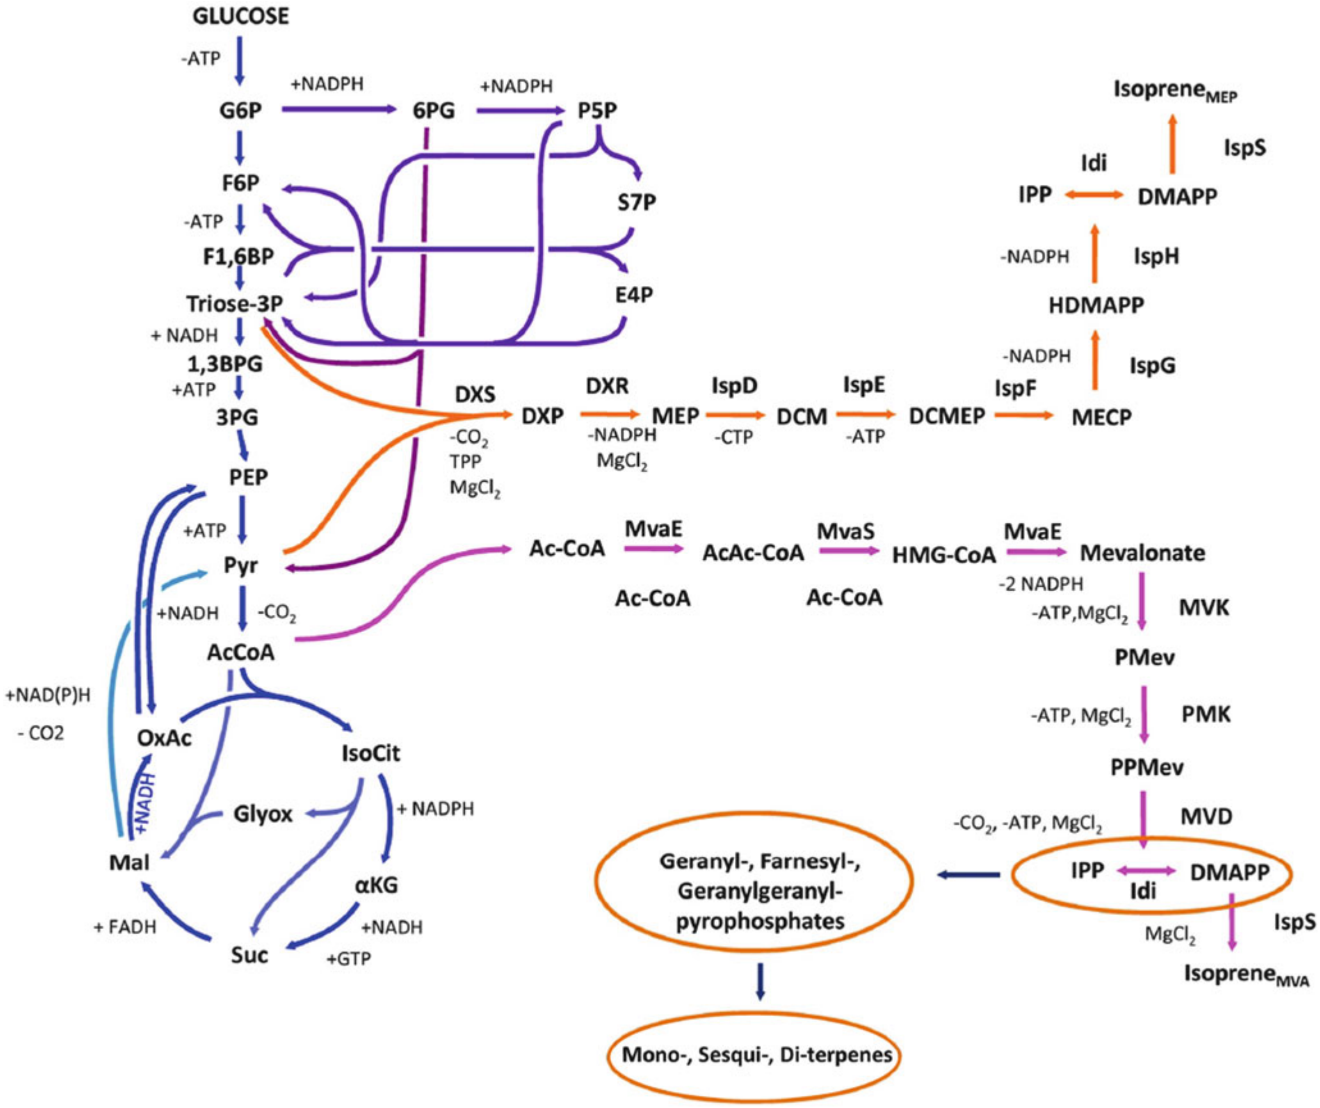


Fig. 30.22 Isoprene production pathways: mevalonic acid (MVA) and methyl erythritol phosphate (MEP)

development by former Genencor and The Goodyear Tire & Rubber Company. Production system for BioIsoprene™ is based on microbial fermentation of renewable sugars converted to dimethylallyl pyrophosphate (DMAPP), the key substrate of isoprene synthase, the key plant enzyme engineered into the production organism. DMAPP and its isoform, isoprenyl pyrophosphate (IPP), are essential compounds in all living organisms and are produced via one of two known pathways, the mevalonic acid (MVA) pathway present in eukaryotes and some prokaryotes, and the 5-methyl erythritol phosphate pathway (MEP, also known as deoxyxylulose phosphate [DXP] pathway) present in prokaryotes and plants [47] (Fig. 30.22). Carbon flux into both pathways stems from intermediates derived from sugar metabolism via central metabolism, acetyl-CoA for MVA; pyruvate and glyceraldehyde 3-phosphate for MEP. These pathways are amenable to molecular biology manipulations and metabolic pathway engineering in both prokaryotes (*E. coli*) and eukaryotes (*S. cerevisiae*). Both biosynthetic isoprenoid pathways, MEP and MVA, are being optimized towards this end. The key to successful process is engineering a microbial cell factory that is streamlined in physiology to drive sugar conversion through engineered biosynthetic pathways to produce isoprene at near theoretical yields. Unlike other biobased systems to produce biochemicals, BioIsoprene™ is produced as a gas-phase product and released into the off gas of the fermentor without any noticeable negative physical or inhibitory impacts on the production organism. The product comes out of the fermentor continuously in the gas phase and is recovered from the fermentation off gas in a continuous process. Current state-of-the-art technology has resulted in production, recovery, polymerization, and manufacture of tires with the isoprene component produced via fermentation. Polymer-grade BioIsoprene™ is recovered from the integrated process. Potential benefits of the gas-phase nature of the product include: (a) reduction and/or elimination of feedback inhibition by the isoprene product on further synthesis; (b) efficient recovery and purification of polymer-grade BioIsoprene™ from the fermentation; and (c) possibility to use crude, low cost feedstocks.

The development of BioIsoprene™ represents a major achievement for industrial biotechnology because it has the potential to enable production of isoprene from renewable raw materials to deliver commercial quantities of a basic C5 hydrocarbon that, in principle, can be used as a feedstock for a large number of value-added products. One of these products is a synthetic *cis*-polyisoprene (synthetic rubber), which for decades has been recognized as a suitable replacement for natural rubber in many applications. Additionally, there is potential for creating polyisoprenes with improved material properties. The BioIsoprene™ process offers a real possibility for obtaining the quantities of low-cost isoprene needed to produce a meaningful large-volume alternative to Hevea natural rubber and petroleum-derived isoprene.

BioIsoprene™ will have broader commercial applications beyond the biochemical uses of isoprene in synthetic rubber, adhesives, and specialty elastomers. As a C5 hydrocarbon, BioIsoprene™ has inherent fuel properties and represents a key biobased intermediate that can be converted to a drop-in transportation fuel additive using chemical catalysis to C10 and C15 biobased hydrocarbon fuels, thus addressing performance gasoline, jet fuel, and biodiesel markets.

Farnesene

Amyris has engineered yeasts that convert sugars into a hydrocarbon molecule called farnesene [48], a sesquiterpene which can be processed into cosmetics, lubricants, and diesel and jet fuel. If hydrogenated, the hydrocarbon can be turned into a diesel fuel that burns cleaner than conventional diesel. Amyris' process uses engineered yeast to convert sugar into beta-farnesene, in oil form, easy to separate from aqueous fermentation broth.

As shown in Isoprene production pathway (Fig. 30.22), farnesene, like many isoprenoids, is assembled using the five-carbon monomer IPP and its isomer DMAPP. IPP and DMAPP could also be condensed by IPP synthases into geranyl pyrophosphate (GPP, C10), farnesyl pyrophosphate (FPP, C15), or geranylgeranyl pyrophosphate (GGPP, C20). Terpene synthases convert these long chain pyrophosphate molecules into branched chain or cyclic alkenes, e.g., farnesene. Isoprenoid tailoring enzymes can then oxidize the alkenes into alcohols or reduce them to alkanes. Alternatively, isoprenyl phosphatases or IPP synthase mutants can generate long-chain alcohols such as farnesol, geraniol, and geranylgeraniol from GPP, FPP, or GGPP, respectively.

While the Amyris industrial synthetic biology platform can use a wide variety of feed stocks, their initial focus is on sugarcane due to its abundance, generally low cost, and favorable carbon footprint. That's why Amyris' initial production efforts are in Brazil, leveraging the infrastructure of existing sugar and ethanol mills. However, their success depends on increasing the sugar conversion efficiency (15–16% kg farnesene per kg sugar reported). Other success factors include productivity (less than 1 g/L/h reported), farnesene concentration in broth (about 100 g/L reported), and large-scale operation (200,000 L size fermentors reported).

Advanced biofuels

Ethanol has become a valuable additive to liquid transportation fuels. During 2010, 13 billion gallons were produced in the United States with most of this being fermented using grains as starting material. Ethanol provides high octane, but the energy density is only about 70% that of traditional gasoline. The hydroscopic property of ethanol also renders it difficult to transport in existing pipelines without resulting in corrosion. For these and other reasons, there has been increased interest in producing fuels besides ethanol from renewable resources [49, 50].

Higher Alcohols

Production of higher alcohols can be further broken out into two key groups: (1) fermentative pathways to isopropanol and *n*-butanol and (2) nonfermentative pathways to a larger diversity of branched chain alcohols.

Fermentative pathways to alcohols are typically based upon the acetone-butanol-ethanol (ABE) fermentation classically found in Clostridia. Acetone can be reduced in a single step to form isopropanol. For economic reasons, native production of these compounds in Clostridia is not currently practiced. But through synthetic biology and metabolic engineering, it has been possible to optimize heterologous pathways to maximize yield and productivity in industrial microorganisms. Considerable work has focused especially on production of butanol especially in *E. coli* and *S. cerevisiae*. Pathways for three different butanol species are shown in Fig. 30.23a. For *n*-butanol, two molecules of acetyl-CoA are condensed to form acetoacetyl-CoA, which then undergoes reduction and dehydration to generate *n*-butanol. 2-butanol is formed through acetolactate by decarboxylation, dehydration, and reduction. Isobutanol is formed by a nonfermentative pathway through 2-keto-isovalerate.

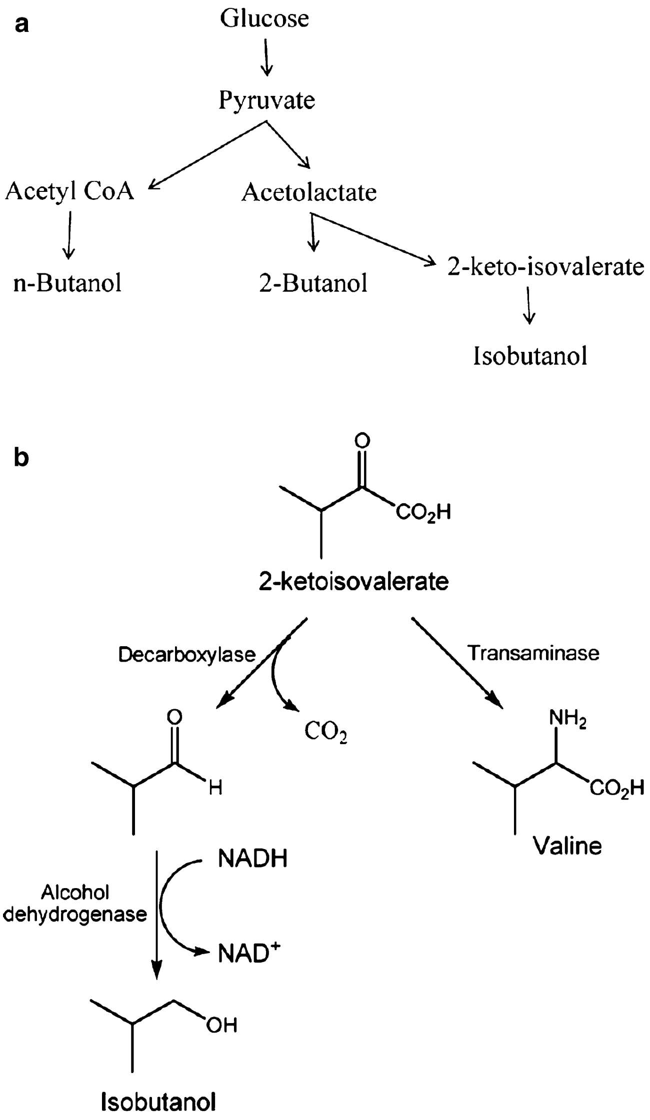

Fig. 30.23 (**a**) Pathways for three different butanol species, (**b**) pathway for the production of isobutanol

Nonfermentative pathways can result in a wider range of higher alcohols. The key steps in all these pathways are the decarboxylation of 2-keto acids and reduction of the resulting aldehyde to the corresponding alcohol. Many amino acid biosynthesis pathways have these 2-keto-acids as intermediates. As an example, 2-keto-isovalerate is the product of the penultimate step in valine biosynthesis. But instead of being transaminated to valine, it can also be decarboxylated and reduced to make isobutanol. This is shown in Fig. 30.23b. There is a wide range of alcohols that can be formed from these naturally occurring 2-keto acids. However, the range of alcohols that can be formed has been increased even further by engineering completely new pathways to make nonnatural 2-keto acids [51]. These then undergo the same decarboxylation and reduction to form alcohols. Once again, enzymes from the branched chain amino acid pathways were used. The leuABCD operon of *E. coli* acts upon 2-keto-isovalerate to add a carbon leading to 2-keto-isocaproate and then to leucine. Two enzymes were protein engineered to allow conversion of nonnative substrates. Making changes to leuA and 2-keto-isovalerate decarboxylase resulted in the formation of a large number of nonnative alcohols with carbon range of C5–C8. This work indicates that the types of molecules that can be produced are not limited by what is observed by native biosynthetic reactions.

Biodiesel Production

Biodiesel production from plant oils has been practiced. Natural triacylglycerols in oils undergo transesterification with methanol or ethanol to make fatty acid methyl and ethyl esters (FAME and FAEE). Think of modified diesel vehicles whose exhaust smells like French fries. However, the availability of plant oils limits the potential use as fuels. And the transesterification reaction can be costly. Acyltransferases can be used to perform the reaction in vivo by feeding fatty acids in strains making ethanol [52]. Conversely, deregulation of fatty acid biosynthesis has allowed for FAEE formation with alcohol feeding, but without fatty acid feeding [53]. It is only a matter of time before complete FAEE synthesis is made directly from carbohydrates.

Isoprenoid-based biofuels

Isoprenoids are naturally occurring hydrocarbons that carry out a number of biological functions. For instance, electron transport is mediated by ubiquinones and membrane structure and function are controlled by sterols [54]. Much of the recent work on the production of isoprenoids was initiated by the production of the antimalarial drug, artemisinin [55]. The key intermediates leading to all isoprenoids are the C5 isomers IPP and DMAPP. These are formed by two different pathways, the MVA pathway from acetyl-CoA and the MEP(DXP) pathway from pyruvate and glyceraldehye-3-phosphate. These can be joined together in many ways by terpene synthases to generate C10, C15, and higher hydrocarbons. Phosphatases can directly convert many of these compounds to fuel-like molecules.

Carbon sources for biofuels production

Simple sugars have been the starting point for first-generation ethanol production. Sucrose from sugarcane has driven Brazilian production while starch from grains has been enzymatically converted to glucose in the rest of the world. However, this typically uses only a portion of the plant material for incorporation into product. Agricultural residues or dedicated energy crops could greatly increase the amount of available substrate for conversion to biofuels. But the use of these lignocellulosic sources is not without issues [56]. The presence of lignin, a heterogeneous polymer of aromatic alcohols, can interfere with the hydrolysis of the desired carbohydrates. A large number of pretreatment processes have been developed to separate or modify the lignin to make the carbohydrates more accessible. Pretreatments are also required to modify the structure of recalcitrant cellulose to make it more amenable to enzymatic digestion. These processes include physical, thermal, and chemical treatments. Cellulose is then converted to fermentable glucose, just as in the starch-based processes. The final component of lignocelluloses is hemicelluloses. Hemicellulose is another heterogeneous polymer made up of a number of different sugar monomers. The most abundant of these is xylose. Different from six-carbon glucose, xylose is a five-carbon sugar that is metabolized by different pathways than glucose. Metabolic engineering has been employed extensively to combine simultaneous fermentation of both hexoses and pentoses to ethanol in a variety of organisms including *Zymomonas mobilis* [57], *S. cerevisiae* [58], and *E. coli* [59]. These strains are still being improved and in addition to ethanol, can be the starting point for the generation of advanced biofuels. Adding new pathway elements, modifying transport mechanisms, and alleviating native control hierarchy have all been utilized in the building of these strains.

Next generation processes: fuels from carbon dioxide

The use of sucrose from sugarcane, starch from corn, and even lignocellulosic biomass are all examples of utilizing chemical energy produced by photosynthetic organisms from solar energy and CO_2. Producing advanced biofuels directly from these photosynthetic organisms could ultimately result in the largest reduction of atmospheric CO_2 [60]. The most advanced systems are those producing biodiesel directly from photosynthetic microalgae. Some strains can generate lipids, used as energy storage compounds, at nearly 40% of the total dry biomass. These lipids can be extracted and undergo the same transesterification process as from plant-derived oils.

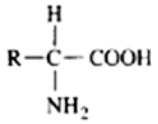
Photosynthetic organisms such as microalgae generate energy and reducing power from light. Photons are captured by specialized light harvesting complex proteins and the energy is used to split water into protons, electrons, and oxygen. Electrons are passed along an electron transport chain and eventually to NADPH. Protons are released across an organelle membrane creating a proton gradient used to generate ATP. These biological energy compounds are then used in the Calvin cycle to fix CO_2. CO_2 is added to ribulose-1,5-bis-phosphate, which is then split into two molecules of 3-phosphoglycerate, a key 3-carbon metabolic intermediate.

Metabolic engineering approaches are being applied to microalgae just as they have been applied to other organisms to generate biofuels. Here, focus has been in two main areas: (1) increasing oil production and (2) increasing photosynthetic efficiency. Most probably nonintuitive, reducing the amount of light harvesting complex proteins has led to increases in photosynthetic efficiency.

Photosynthetic organisms lead to a new problem in large-scale production. In order to function, the culture needs both abundant light and CO_2. Open ponds are one obvious choice for cultivation. However, closed bioreactor designs have numerous advantages over open ponds. These include, among others, high surface area per unit volume, ability to keep out contaminating organisms, and the more efficient use of water.

Amino Acids

Amino acids, in general, can be represented by the formula:



$$R-\overset{\displaystyle H}{\underset{\displaystyle NH_2}{\overset{|}{\underset{|}{C}}}}-COOH$$

Because the amino group is on the α-carbon, the amino acids with this general formula are known as α-amino acids. The α-carbon atom becomes asymmetric when R is not an H atom. Naturally occurring amino acids have an L-configuration. Amino acids are the building blocks of proteins, and the elementary composition of most proteins is similar; the approximate percentages are:

$$C = 50 - 55, \quad N = 15 - 18,$$

$$H = 6 - 8, \quad S = 0 - 4, \quad O = 20 - 23$$

Table 30.4 gives the structure of R, molecular weight, and elementary composition of each of the 20 amino acids commonly found in proteins.

Of the natural amino acids, only methionine is manufactured chemically as the racemic mixture. All other natural types are produced by fermentation as the L-enantiomer. Commercially, the most common amino acids manufactured are the L-forms of glutamic acid, mostly mono-sodium glutamate (MSG), lysine, phenylalanine, aspartic acid, threonine, tryptophan, arginine, citrulline, glutamine, histidine, isoleucine, leucine, ornithine, proline, tyrosine, and cysteine [61]. The biological methods vary (e.g., fermentation, extraction from natural sources, and enzymatic synthesis). Amino acids obtained from purified proteins are derived from chemical or enzymatic hydrolysis. They can also be isolated from industrial by-products; extracted from plant or animal tissues; or synthesized by

Table 30.4 Twenty common amino acids

Amino acids	R⁻	Elemental Composition (%wt.) M.W.	C	H	O	N	S
Alanine	$CH_3\text{—}$	89	40	8	36	16	0
Arginine	 $H_2N\text{—}\underset{\underset{NH}{\|}}{C}\text{—}NH\text{—}CH_2\text{—}CH_2\text{—}$	174	41	8	18	32	0
Asparagine	 $H_2N\text{—}\underset{\underset{O}{\|}}{C}\text{—}CH_2\text{—}$	132	36	6	36	21	0
Aspartic acid	 $HO\text{—}\underset{\underset{O}{\|}}{C}\text{—}CH_2\text{—}$	133	36	5	48	11	0
Cysteine	$HS\text{—}CH_2\text{—}$	121	30	6	26	12	26
Glutamic acid	 $HO\text{—}\underset{\underset{O}{\|}}{C}\text{—}CH_2\text{—}CH_2\text{—}$	147	41	6	44	10	0
Glutamine	 $H_2N\text{—}\underset{\underset{O}{\|}}{C}\text{—}CH_2\text{—}CH_2\text{—}$	146	41	7	33	19	0
Glycine	$H\text{—}$	75	32	7	43	19	0
Histidine		155	46	6	21	27	0
Isoleucine	 $CH_3\text{—}CH_2\text{—}\underset{\underset{CH_3}{\vert}}{CH}\text{—}$	131	55	10	24	11	0
Leucine	 $CH_3\text{—}\underset{\underset{CH_3}{\vert}}{CH}\text{—}CH_2\text{—}$	131	55	10	24	11	0
Lysine	$H_2N\text{—}CH_2\text{—}CH_2\text{—}CH_2\text{—}$	146	49	10	22	19	0
Methionine	$CH_3\text{—}S\text{—}CH_2\text{—}CH_2\text{—}$	149	40	7	22	9	2
Phenylalanine		165	66	7	19	8	0
Proline		115	52	8	27	12	0
Serine	$HOCH_2\text{—}$	105	34	7	46	13	0
Threonine	 $CH_3\text{—}\underset{\underset{OH}{\vert}}{CH}\text{—}$	119	40	8	40	12	0
Tryptophan		204	65	6	16	14	0
Tyrosine		181	60	6	26	8	0
Valine	 $CH_3\underset{\underset{CH_3}{\vert}}{CH}\text{—}$	117	51	9	12	27	0

organic, enzymatic, or microbiological means. All these methods yield the L-isomer.

Alanine and aspartic acid are produced commercially utilizing enzymes. In the case of alanine, the process of decarboxylation of aspartic acid by the aspartate decarboxylase from *Pseudomonas dacunhae* is commercialized. The annual world production of alanine is about 200 t. Aspartic acid is produced commercially by condensing fumarate and ammonia using aspartase from *E. coli*. This process has been made more convenient with an enzyme immobilization technique. Aspartic acid is used primarily as a raw material with phenylalanine to produce aspartame, a noncaloric sweetener. Production and sales of aspartame have increased rapidly since its introduction in 1981. Tyrosine, valine, leucine, isoleucine, serine, threonine, arginine, glutamine, proline, histidine, citrulline, L-dopa, homoserine, ornithine, cysteine, tryptophan, and phenylalanine also can be produced by enzymatic methods.

The worldwide amino acids market amounts to about \$5 billion. MSG and the animal feed additives, methionine and lysine, account for about 75% of this sales value. The other amino acids are used as precursors in pharmaceuticals, food additives, and animal feed. The worldwide demand for glutamic acid is about 800,000 t/year, 300,000 t/year for methionine, and 500,000 t/year for lysine. Other significant amino acids such as aspartic acid, phenylalanine, threonine, and glycine, each have a worldwide market of about 10,000–20,000 t/year. Tryptophan and cysteine command a global market in the thousands of tons as well.

Glutamic acid. MSG is an important flavor enhancer for natural and processed foods. It is also good for protecting the flavor and color of preserved foods and suppressing off-flavors. Glutamic acid is not an essential amino acid. However, it has some pharmaceutical uses and also improves the growth of pigs.

A number of glutamic acid-producing bacteria are known, for example,

- *Corynebacterium glutamicum* (synonym *Micrococcus glutamicus*)
- *Brevibacterium flavum*
- *Brevibacterium divaricatum*

Among them, *C. glutamicum* is used most commonly in the industry. Kyowa Hakko has recently completed a genome map of its glutamic acid producing organism, and hopes to improve glutamic acid fermentation efficiency and create a next-generation production system through pathway engineering.

The fermentation medium contains a carbon source (glucose or molasses), a nitrogen source (urea, ammonium sulfate, corn steep liquor, or soy hydrolyzate), mineral salts to supply potassium, phosphorus, magnesium, iron, and manganese, and less than 5 μg of biotin per liter depending upon the strain. The biotin requirement is the major controlling factor in the fermentation. When too much biotin is supplied for optimal growth, the organism produces lactic acid. Under conditions of suboptimal growth, glutamic acid is excreted. The metabolic pathway involved in the biosynthesis of glutamic acid from glucose limits α-ketoglutarate dehydrogenase activity, which is a notable phenotype of glutamic acid overproducing microorganisms.

The fermentation is conducted aerobically in tanks with k_La value in 300 mmol O_2/L/h/atm range. If aeration is not adequate, lactic acid is produced, and the yield of glutamic acid is poor. If aeration occurs in excess, even more lactic acid in addition to some α-ketoglutaric acid is produced. The fermentation temperature is 28–33°C, and the optimal pH is 7–8. Continuous feeding of liquid or gaseous ammonia controls pH and supplies ammonium ions to the fermentation. The fermentation cycle is 24–48 h, and the final concentration of glutamic acid is about 120–150 g/L. The overall yield of glutamic acid on sugar is about 65% on a weight basis. A portion of sugar is used for cellular growth; otherwise glutamic acid yield on sugar is 86% according to the equation:

$$C_{12}H_{22}O_{11} + 2NH_3 + 3O_2 \rightarrow 2C_5H_9O_4N + 2CO_2 + 5H_2O$$

For recovery of glutamic acid after fermentation, the broth is clarified by adding acid to pH 3.4, heating to 87°C, holding for a sufficient time to coagulate suspended solids, and filtering the coagulated solids. The clarified broth is concentrated by evaporation followed by glutamic acid crystallization. Other recovery schemes such as membrane filtration or ion-exchange can be used.

MSG sells for about \$2/kg, and glutamic acid (99.5% pure) for about \$4/kg. The major manufacturers of these are Ajinomoto, Asahi Foods, Kyowa Hakko, Takeda (Japan), Orsan (France), Biacor (Italy), Cheil Sugar, Mi-Won (S. Korea), and Tung Hai Fermentation Industry, Ve Wong (Taiwan).

Lysine. Lysine, biologically active in its L-configuration, is an essential amino acid in human and animal nutrition. The richest sources of lysine are animal proteins such as meat and poultry, but it is also found in dairy products, eggs, and beans. On the other hand, cereal grains, such as corn, wheat, and rice, are usually low in lysine. For applications in human food, lysine in its salt forms can be added to cookies and bread, and in solution it can be used to soak rice. As most animal feed rations are based on corn and other grains, supplementing the feedstuffs with lysine (plus methionine) significantly improves their nutritional value for breeding poultry and pigs.

A fermentation process for producing lysine was made possible by using mutants of *C. glutamicum* or *B. flavum.* Both auxotrophic and regulatory mutants have been obtained for overproduction of lysine. Figure 30.24 shows the biosynthetic pathway of lysine and its metabolic controls in *C. glutamicum.*

Molasses was the most common carbon source until being replaced by glucose for reasons of easier downstream processing. Sufficient amounts (over 30 μg/L) of biotin must be included in the medium to prevent the excretion of glutamic acid. This biotin requirement was previously met by using molasses as the carbon source and must now be added exogenously. The fermentation runs at temperatures of about 28–33°C and pH 6–8. High aeration is desirable. The final product concentration is around 100–140 g/L, and the fermentation time is 48–72 h. The yield of lysine on carbohydrate is about 40–50%. The formation of lysine from sucrose can be represented as follows:

$$C_{12}H_{22}O_{11} + 2NH_3 + 5O_2 \rightarrow C_6H_{14}O_2N_2 + 6CO_2 + 7H_2O$$

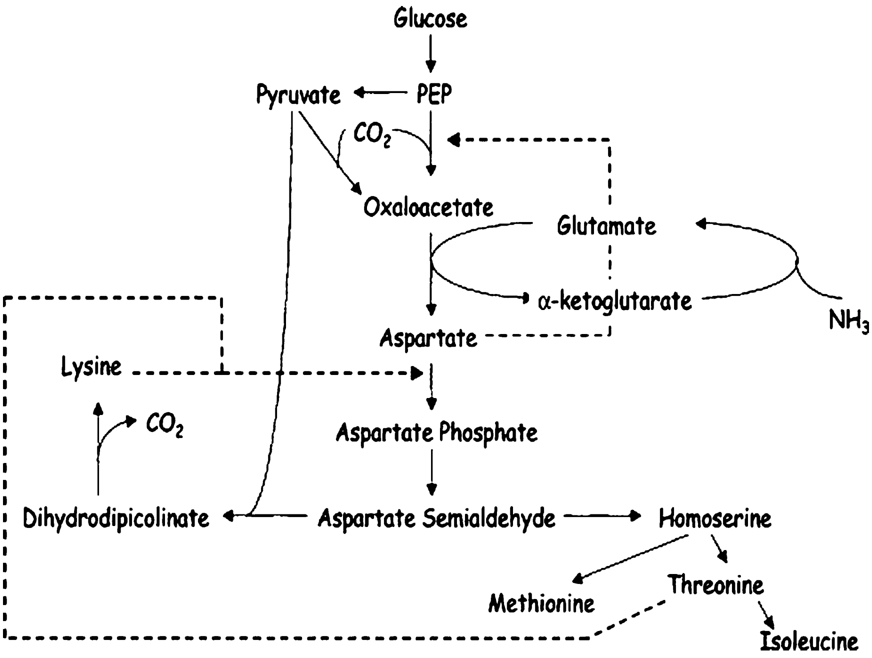


Fig. 30.24 Lysine biosynthesis from glucose in *Corynebacteria*

Ion-exchange resins are used for isolation of lysine from fermentation broths. The eluted lysine is then crystallized from water. The most common commercial form of lysine used in animal feed is 98% lysine monohydrochloride. For lower purity, the entire fermentation broth may be evaporated and syrup or the dried product is used as an animal feed supplement.

Standard commercial food-grade lysine (as 98.5% lysine monohydrochloride) is about $5/kg, and lysine as a feed supplement is about $2/kg. The major producers include Ajinomoto and Kyowa Hakko of Japan, Sewon and Chiel Sugar of South Korea, and ADM, BioKyowa (a subsidiary of Kyowa Hakko), Heartland Lysine (a subsidiary of Ajinomoto), and Degussa (formerly joint venture of Cargill and Degussa in the United States). China's Global Bio-Chem has been increasingly selling protein–lysine (protein with enhanced lysine content), as well. The world demand for lysine is expected to increase continually. In fact, the increasing ethanol fermentation capacity for bioethanol production provides an opportunity for increased lysine production. Distillers' Dried Grains (DDG), a by-product of ethanol fermentation used as a protein source in animal feeds, is deficient in lysine and other essential amino acids. Therefore, it needs to be supplemented with lysine for full-value use.

Aromatic amino acids. The aromatic amino acids, phenylalanine and tryptophan, provide some of the first examples of chemical production using microorganisms through the use of pathway engineering [62, 63]. Intermediates in the aromatic amino acid pathway can also be used as precursors to other biosyntheses with genes recruited from different organisms. Examples include catechol, adipic acid, shikimic, and quinic acids. In general, the aromatic pathway illustrates the potential of multiple product opportunities from one pathway and provides a great leveraging factor with respect to technical and commercial development costs.

Initially, work on the aromatic amino acid pathway of *E. coli* was focused on the construction of a strain for the overproduction of natural amino acids (phenylalanine, tryptophan, tyrosine). These efforts have focused on:

1. Cloning and optimization of complete primary aromatic pathway with an emphasis on removal of transcriptional and allosteric regulation, that is, removal of rate-limiting steps.
2. Enhancement of carbon flux to the aromatic pathway through modification of gene activities within central metabolism.

For the aromatic pathway (Fig. 30.25), the critical control points are the condensation of PEP and erythrose-4-phosphate to 3-deoxy-D-arabinoheptulosonate 7-phosphate, DAHP, by DAHP synthase. For tryptophan, the formation of anthranilic acid from chorismic acid by anthranilate synthase is the second critical control point. The transcriptional regulation was overcome through the use of alternative promoters and allosteric regulation was circumvented by the classical technique of selection for feedback-resistant mutants using toxic analogues of the repressing compounds.

For tryptophan production in *E. coli*, the natural regulation controlling production of tyrosine and phenylalanine was

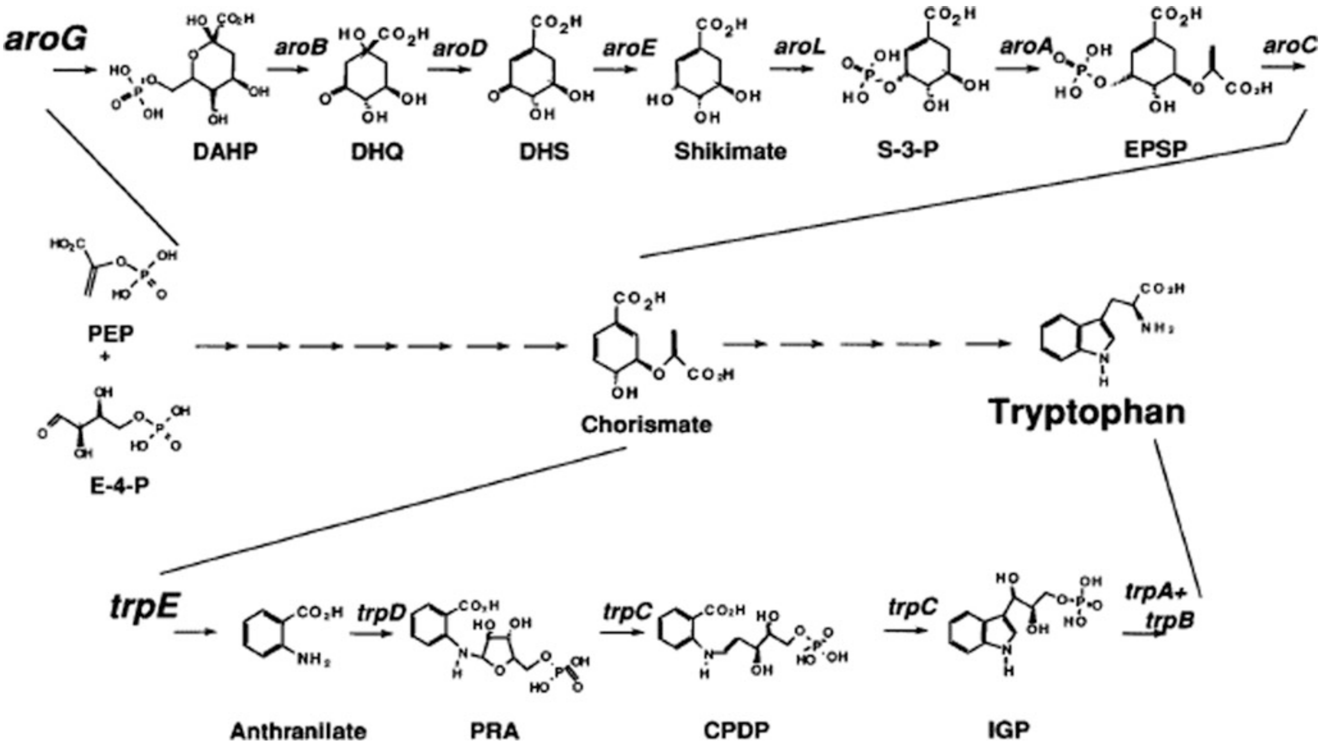

Fig. 30.25 *Escherichia coli* aromatic pathway to tryptophan

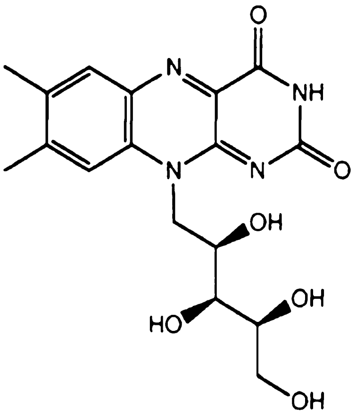
sufficient to keep carbon flowing specifically to tryptophan. This eliminated the need for addition of auxotrophic compounds to the growth medium. The major industrial producers of tryptophan are ADM, Kwoya Hakko, and Ajinomoto.

The same could not be said for the construction of a strain for the overproduction of phenylalanine. Here the control mechanisms for tyrosine were not sufficient to keep a significant amount of carbon from being diverted. However, instead of using an auxotrophic strain, a technology was developed to keep the gene for chorismate mutase and prephenate dehydrogenase present during the growth phase of the fermentation and then have it excised from the chromosome during the production phase. Due to the sweetener Aspartame, the market for phenylalanine has expanded to 10,000 metric tons per year with an average price of $10 per kg. The major producers are Nutrasweet and Ajinomoto.

Vitamins and Neutraceuticals

In the commercial market for vitamins, the most significant are ascorbic acid (Vitamin C), the D group (D2, D3, ergosterol), folic acid, and alpha-tocopherol (Vitamin E). The next important group of vitamins is biotin, cyanocobalamin (B_{12}), inositol, pantothenic acid, and riboflavin (B_2). Microorganisms can synthesize many vitamins of medical importance. Vitamin B_2 (riboflavin) and vitamin B_{12} (cyanocobalamin) are products of fermentation. Vitamin C (ascorbic acid) precursor, 2-keto-L-gulonic acid (2-KLG) is produced microbiologically as well as chemically as discussed in the “Organic Acids and Polymers” section.

Riboflavin. Riboflavin is used as a dietary supplement in both human food and animal feed. The yellow-orange riboflavin crystals are only sparingly soluble in water. To include riboflavin in water-soluble formulations, sodium riboflavin-5′-phosphate is used.



The first organism employed primarily for riboflavin production was *Clostridium acetobutylicum*, the anaerobic bacterium used for the microbial production of acetone and butanol. Riboflavin was purely a by-product and was found in the dried stillage residues in amounts ranging from 40 to 70 µg/g of dried fermentation solids. Later investigations disclosed that riboflavin could be produced by yeast such as *Candida flareri* or *C. guilliermondi*, and the yield was as high as 200 mg/L.

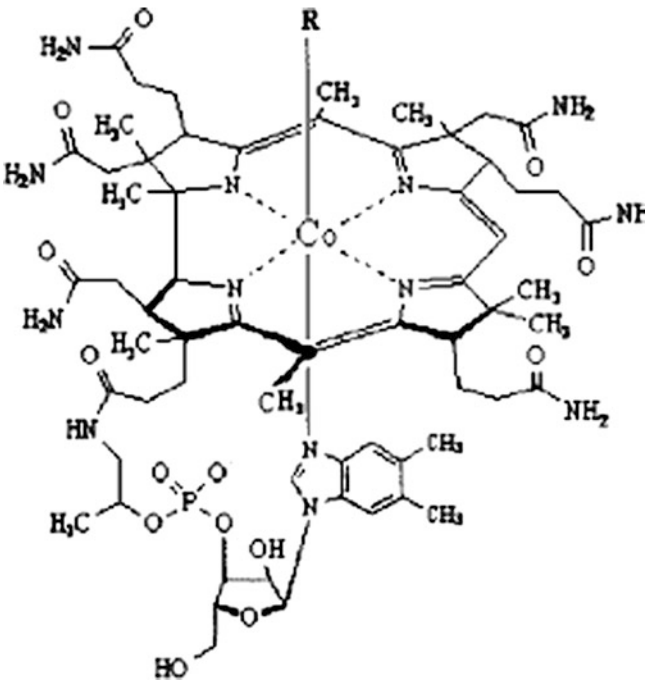
Other studies on a fungus, *Eremothecium ashbyii*, and a closely related organism known as *Ashbya gossypii* resulted in the production of much larger amounts of riboflavin. Yields as high as 10–15 g/L were possible. Then, major fermentation strain and process improvements were made with the *A. gossypii* strain. The fermentation lasts 8–10 days. Cell growth occurs in the first 2 days, and enzymes catalyzing riboflavin synthesis are formed during the growth period. Glycine and edible oil stimulate the formation of riboflavin, but they are not its precursors. The additions of carbohydrate and oil permit the overproduction of riboflavin [64]. The riboflavin carbon yield is about 50% on carbohydrate and about 100% on oil.

Upon completion of the fermentation, the solids are dried to a crude product for animal feed supplement or processed to an USP-grade product. In either case, the pH of the fermented medium is adjusted to pH 4.5. For the feed-grade product, the broth is concentrated to about 30% solids and dried on double-drum driers.

When a crystalline product is required, the fermented broth is heated for 1 h at 121°C to solubilize the riboflavin. Insoluble matter is removed by centrifugation, and riboflavin recovered by conversion to the less soluble form. The precipitated riboflavin is then dissolved in water, polar solvents, or an alkaline solution, oxidized by aeration, and recovered by recrystallization from the aqueous or polar solvent solution or by acidification of the alkaline solution.

The major producers of riboflavin include DSM and BASF. There have been significant improvements in both of the production processes. DSM opened a new riboflavin production facility in Grenzach, Germany in 2000, based on a fermentation process with a genetically modified *B. subtilis*. On the other hand, BASF, working with the University of Salamanca, Spain, engineered an improved *A. gossipii* that produces a larger amount of enzymes for riboflavin synthesis, and increased its production capacity by 20% at its Ludwigshafen facility without capital investment. The annual production of riboflavin by ADM, BASF, and DSM is about 4,000 metric ton. The feed-grade product sells for about \$30/kg and the USP-grade product \$50/kg.

Cyanocobalamin



Vitamin B_{12}, cyanocobalamin, is an important biologically active compound. It serves as a hematopoietic factor in mammals and as a growth factor for many microbial and animal species. Its markets are divided into pharmaceutical (96–98% pure) and animal feed (80% pure) applications. All vitamin B_{12} is now made commercially by fermentation [65].

Spent liquors from streptomycin and other antibiotic fermentations contain appreciable amounts of vitamin B_{12}. Bacterial strains producing high amounts have been specially selected for commercial production. Today vitamin B_{12} is obtained from fermentations using selected strains of *Propionibacterium* or *Pseudomonas* cultures. A full chemical synthesis process for vitamin B_{12} is known. However, it requires some 70 steps and for all practical purposes is of little value.

The *Pseudomonas denitrificans* strain is most often used for commercial production of vitamin B_{12} [66, 67]. It requires medium containing sucrose, yeast extract, and several metallic salts. Dimethylbenzimidazole (10–25 mg/L) and cobaltous nitrate (40–200 mg/L) must be supplemented at the start of the culture in order to enhance vitamin production. Betaine (tri-methyl glycine) stimulates the biosynthesis of vitamin B_{12}, even though the organism does not metabolize it. Similarly, choline also has favorable effects, either by activating some biosynthetic steps or altering the membrane permeability. Glutamic acid, on the other hand, stimulates cellular growth. Because of high betaine and glutamic acid contents, beet molasses (60–120 g/L) is preferentially used in industrial fermentations of vitamin B_{12}. The fermentation is conducted with aeration and agitation. Optimal temperature is about 28°C and pH near 7.0. The yield reported in the literature was 59 mg/L in 1971, using a *Pseudomonas* strain. A yield of 200 mg/L was reported for vitamin B_{12} fermentations using *Propionibacteria* in 1974. It is believed that yields of vitamin B_{12} have been significantly improved since then.

About 80% of the vitamin produced is outside the cells and 20% inside the cells. For recovery, the whole broth is heated at 80–120°C for 10–30 min at pH 6.5–8.5 and treated with cyanide or thiocyanate to obtain cyanocobalamin. B_{12} isolation can then be accomplished by adsorption on a cation-exchange resin, such as Amberlite IRC 50. Extraction can also be done by using phenol or cresol alone or in a mixture with benzene, butanol, carbon tetrachloride, or chloroform; or separation by precipitation or crystallization upon evaporation with appropriate diluents such as cresol or tannic acid. Using the extraction method, 98% pure cyanocobalamin can be obtained with a 75% yield. The total world market for cyanocobalamin is estimated to be in excess of 10,000 kg/year and sells for about $25/g. The leading producers include DSM, Wockhardt, and Merck.

Docosahexaenoic and arachidonic acids. Docosahexaenoic acid, DHA, is a long-chain polyunsaturated omega-3 (22:6 ω3) fatty acid whereas arachidonic acid, ARA, is a long-chain polyunsaturated omega-6 (20:4 ω6) fatty acid. Both DHA and ARA are found in human milk and are important nutrients in infant development, and especially for brain development. DHA is a major structural and functional fatty acid in the gray matter of the brain, the retina of the eye, and the heart cell membranes. DHA can be obtained through the diet in foods such as fatty fish (accumulated via natural algae) and organ meat. ARA is the principal omega-6 fatty acid found in the brain as well. Adults obtain ARA readily from the diet in foods such as meat, eggs, and milk. The DHA- and ARA-rich oil can also be used in supplements and functional foods for older children and adults for improvement in cardiovascular health.

Martek (http://www.martekbio.com) and DSM have developed processes to produce oils rich in DHA and ARA. The DHA is extracted from fermented microalgae (*Cryptecodinium cohnii*) and the ARA is extracted from soil fungus (*Mortierelle alpina*). In the DHA production process, the microalgae are grown in fermentors (80,000–260,000 L scale). The cell mass is then harvested by centrifugation, and the concentrated cell mass is spray-dried. The dry cell mass is then broken down into smaller particles and extracted by a solvent for the oil-containing DHA. The solvent is then evaporated from the oil, leaving crude oil. The crude oil is refined, bleached, and deodorized to cleanse it of any impurities. The final product is rich in DHA. Likewise, DSM ferments the fungus, and extracts the crude ARA oil by the DHA downstream type process. Crude oils can be extracted with the traditional hexane extraction method or with new solvents such as isopropanol or supercritical CO_2. The final cell mass, total fermentation time, and the lipid content of the organism are very important for the economic feasibility, as these factors largely determine the productivity. Media components such as the amount of sugars and nitrogen have a significant effect on growth and lipid accumulation.

Table 30.5 Examples of natural antibiotics and producing organisms

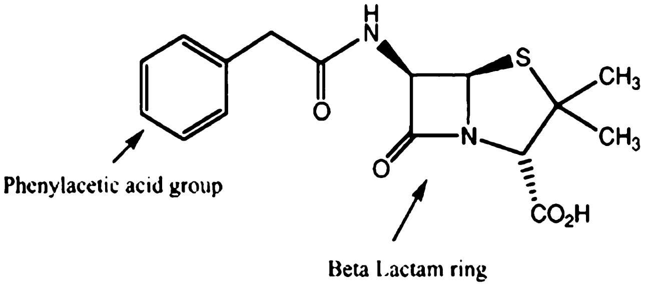
Natural antibiotic	Producing organism
Amphotericin B	*Streptomyces nodosus*
Bleomycin	*Streptomyces verticillus*
Cephalosporin	*Cephalosporium* sp.
Erythromycin A	*Saccharopolyspora erythraea*
Gentamycin	*Micromonospora purpurea*
Lovastatin	*Aspergillus terreus*
Neomycin	*Streptomyces fradiae*
Penicillin G	*Pencillium chrysogenum*
Spiramycin	*Streptomyces ambofaciens*
Tetracycline	*Streptomyces aureofaciens*
Vancomycin	*Streptomyces orientalis*

The market for DHA, ARA, and other essential neutraceuticals used in dairy, beverages, cereals, and breads, is multibillion dollars and growing as the health benefits are determined for prenatal to elderly care.

Antibiotics

Since the early 1940s, an intensive search for new and useful antibiotics has taken place throughout the world. More than 10,000 antibiotics have been discovered from microbial sources [68–73]. *Streptomyces* spp., filamentous fungi, nonactinomycete bacteria, and non-Streptomycete strains of actinomycetales are major sources of antibiotics, examples of which are listed in Table 30.5. Of the antibiotics in clinical use, 50% are produced by microbial fermentation and others by a combination of microbial synthesis and subsequent modification.

Penicillins



Penicillin G

Table 30.6 Structural formulae of natural penicillins

Formula	Type of penicillin	*Side chain R substitutions*
(G) Benzyl	(X) *p*-Hydroxybenzyl	(F) 2-Pentenyl	$CH_3—CH_2—CH{=}CH—CH_2—$
(Dihydro F) *n*-Pentyl	$CH_3—CH_2—CH_2—CH_2—CH_2—$
(K) *n*-Heptyl	$CH_3—CH_2—CH_2—CH_2—CH_2—CH_2—CH_2—$
(V) Phenoxy	
The original mold observed and preserved by Alexander Fleming was a strain of *P. notatum*, a common laboratory contaminant. Later, cultures of *P. chrysogenum* were found to be better producers of penicillin, and the present industrial strains have been derived from this species. The original strains produced the antibiotic only by surface fermentation methods and in very low yields. Improved media and productive strains under submerged aerobic fermentation conditions led to dramatic yield increases. Subsequent improvements, principally in culture selection and mutation, further improved yields, reaching 20–30 g/L.

Table 30.6 gives the structural formulae of the "natural penicillins," which are comprised of several closely related structures with aliphatic and aromatic substitutions to the common nucleus. The early impure product contained mixtures of these penicillins; however, penicillin G has become the preferred type and the crystalline product of commerce. Phenylacetic acid or its derivatives are used as precursors in the fermentation medium to enhance penicillin biosynthesis.

Nonpigmented mutants of *P. chrysogenum*, for example, Wisconsin 49-133 derivatives, are universally employed in the industrial process. The desired culture is propagated from a laboratory stock in small flasks and transferred to seed tanks. A typical production medium is as shown below.

Components	Grams/liter
Corn steep liquor	30
Lactose	30
Glucose	5.0
$NaNO_3$	3.0
$MgSO_4$	0.25
$ZnSO_4$	0.044
Phenyl acetamide (precursor)	0.05
$CaCO_3$	3.0

The medium is sterilized, cooled to 24°C, and inoculated. After 24-h seed growth, larger fermentors are seeded. Sterile air is sparged through the tank, at about one volume per volume per minute. The time of the production stage varies from 60 to 200 h.

For recovery, the broth is clarified by means of rotary vacuum filters. The penicillin, being acidic, is extracted from the aqueous phase into a solvent, such as methyl isobutyl ketone or amyl acetate, at a pH of 2.5 by means of a continuous countercurrent extractor, such as a Podbielniak. The penicillin is then re-extracted with an aqueous alkaline solution or a buffer at a pH of 6.5–7.0. About 90% recovery yield is typical at this step. The aqueous solution is chilled, acidified, and extracted again with a solvent, such as ether or chloroform. Finally, penicillin is re-extracted into water at a pH of 6.5–7.0 by titration with a solution of base. The base used depends on which salt of penicillin is desired. The popular forms are sodium or potassium salts. A typical flow sheet for antibiotic recovery is shown in Fig. 30.6.

Cephalosporins. Microbiological processes for production of cephalosporin C resemble in many respects those used for penicillin production. Special strains of *Cephalosporium* have been selected that produce more cephalosporin C and less cephalosporin N than the parent culture. The growth of these strains in certain special fermentation media has resulted in higher antibiotic titers. Even with these improvements in processing, the antibiotic concentration, averaging 10–20 g/L, is much lower than those reported for the penicillins.

Table 30.7 Structure of clinically important tetracyclines

	R_1	R_2	R_3	R_4
Tetracycline	H	OH	CH_3	H
7-Chlortetracycline (Aureomycin®)	H	OH	CH_3	Cl
5-Oxytetracycline (Terramycin®)	OH	OH	CH_3	H
6-Demethyl-7-chlortetracycline (Declomycin®)	H	OH	H	Cl
6-Deoxy-5-oxytetracycline (Vibramycin®)	OH	H	CH_3	H
6-Methylene-6-deoxyl-6-demethyl-5-oxytetracycline (Rondomycin®)	OH	H	CH_2	H

Tetracyclines. In 1948, a broad-spectrum antibiotic, chlortetracycline (Aureomycin), was introduced by the Lederle Laboratories, a Division of American Cyanamid Company. This antibiotic is produced by *Streptomyces aureofaciens* when grown under submerged aerobic conditions on media composed of sugar, corn steep liquor, and mineral salts. The crystalline compound has a golden yellow color, which suggested the trade name. A related antibiotic, oxytetracycline (Terramycin), a product of *Streptomyces rimousus*, is produced by Pfizer Inc. It is chemically and biologically similar to chlortetracycline. Independent research by both companies eventually provided the structure of these two important chemotherapeutic agents. Both the compounds may be regarded as derivatives of a nucleus known as tetracycline. Their structures along with those of other clinically important tetracyclines are given in Table 30.7. Tetracycline can also be produced by fermentation of *S. aureofaciens* under special conditions, such as chloride starvation or by use of special strains of the organism that fail to halogenate efficiently. Tetracycline possesses many of the chemotherapeutic properties of chlortetracycline and oxytetracycline. Mutations of tetracycline-producing organisms have led to other tetracycline analogues, of which 6-demethyl-7-chlortetracycline (Declomycin) has clinical use. Chemical modifications of oxytetracycline have generated two other useful members of the family, known as Vibramycin and Rondomycin. Tetracyclines are active in vivo against numerous gram-positive and gram-negative organisms, and some of the pathogenic Rickettsiae and large viruses.

Dramatic price reduction has come with improved production. For instance, a million-unit vial of penicillin (1,667 units = 1 mg of potassium penicillin G) had a wholesale price of \$200 in 1943. Today, a million units of potassium penicillin G sell for as little as \$0.50 or approximately \$20/kg of free acid. Cephalosporins sell for around \$250/kg. Tetracyclines, used as animal feed supplements, sell for about \$60/kg. The antibiotic market is over \$12 billion, and volume continues to increase simultaneous with price drop. Cephalosporins, macrolides, penicillins, quinolones, and tetracyclines account for the majority of the sales of antibiotics.

In the last 20 years, it has become evident that the contribution of microorganisms does not have to be limited to the realm of infectious diseases. Metabolites of microorganisms have been found to have many other interesting therapeutic applications. Particularly as our understanding of disease processes at the biochemical and genetic levels becomes more advanced, enzymes or receptors have increasingly served as specific targets for therapeutic intervention. Recombinant DNA technology, in particular, has helped to produce reagents as tools for the development of practical and high-throughput screening methodologies based on mechanism of action. Automation and miniaturization have also allowed a rapid increase in the throughput of the screening process.

Several of these bioactive natural products have been successfully developed as therapeutics for clinical use. For example, Cyclosporin A is a fungal decapeptide principally used to suppress immune rejection in organ transplant patients. Mevinolin and compatin both control cholesterol synthesis in human. The search for enzyme- or receptor-targeted microbial products does not limit itself to medical use. Several commercially important "antibiotics" such as Nikkomycin and Avermectin have been found for agricultural applications in recent years.

Biopharmaceuticals

The term "biopharmaceuticals" has been generally accepted to distinguish the large molecule pharmaceuticals (mainly proteins) that have emerged as a result of the modern "biotechnology" from the traditional small molecule drugs.

Table 30.8 Examples of biopharmaceutical products, applications, and manufacturers

Biopharma product	Application	Companies
Insulin	Diabetes	Eli Lilly, Novo Nordisk
Erythropoietin	Anemia	Amgen, Johnson & Johnson
Human growth hormone	Growth deficiency	Genentech, Pharmacia
Interferon α	Hepatitis	Schering, Roche
Interferon β	Multiple sclerosis	Chiron, Biogen
Factor VIII	Hemophilia	Bayer
Tissue Plasminogen Activator	Blood clot	Genentech
Glucocerebrosidase	Gaucher's disease	Genzyme
Therapeutic antibodies	Cancer	Glaxo, Amgen, Genentech
GCSF	White blood cell	Amgen, Sankyo

Biopharmaceuticals that are industrially produced by microbial (bacterial or yeast) fermentation include insulin, human growth hormone, hepatitis B surface antigen vaccine, alpha interferon, beta interferon, gamma interferon, granulocyte colony stimulating factor, and interleukin-2. Table 30.8 lists some of the major biopharma products, some of which are produced by mammalian cell culture.

Insulin is the first human biopharmaceutical product that was commercialized using the recombinant DNA technology. Its fermentative expression in *E. coli*, downstream recovery, and purification serves as a good example for the large-scale production of recombinant proteins. Insulin, given its rather small size, is expressed as N-terminal extended proinsulin using the *trp* promoter. The fermentation is carried out at about 37°C and near neutral pH. It is a fast, aerobic fermentation. The *trp* operon is turned on when the fermentation runs out of its natural repressor, tryptophan. The chimeric protein as it is expressed accumulates very rapidly inside the cells as insoluble aggregates (inclusion or refractile bodies). The formation of inclusion bodies prevents proteolysis and facilitates product recovery. The recombinant *E. coli* fermentation usually runs for 18–24 h. At the end of fermentation, the inclusion bodies account for about 10–30% of total dry cell mass. Following purification from the inclusion bodies, the C-peptide is removed from proinsulin using trypsin and carboxypeptidase, and the properly folded and cleaved insulin is purified further. Fermentatively or microbially produced recombinant proteins can also be expressed as soluble proteins inside the cells or secreted outside the cells.

The biopharmaceuticals sales are about $45 billion and represent 10% of the total pharma market. Today, 25% of new drugs are biopharmaceuticals. Since the introduction of insulin over 25 years ago, 160 biopharma products, ranging from proteins, monoclonal antibodies, and nucleic acid-based products, have been approved for use. In 2004 alone, 12 new biopharmaceuticals have been approved, of which only 3 are produced by microbial fermentation, as cell culture is the preferred method for production of biopharma drugs.

Drug development, in general, is a slow, lengthy, and expensive process, requiring an average investment of $0.8 billion over 12–15 years for discovery, development, preclinical testing, Phase I, II, and III trials, and FDA approval prior to marketing. Given the complications of biopharma drug discovery and development, microbial fermentation and biocatalysis may aid in introducing rapid and innovative processes to produce potential drug candidates. It may thus be worth exploring the possibility of producing biopharmaceuticals by microbial fermentation and demonstrating that they can be made reproducibly to meet the right purity, concentration, and dose at the required market cost and volume targets.

Enzymes

Microorganisms used for production of enzymes range from prokaryotic systems including both the gram-negative and gram-positive bacteria to eukaryotic systems such as yeasts and fungi. For most of the history of enzymes, their production has occurred predominantly in strains known to make the enzyme of interest [30, 74–77]. Thus, many different types of microorganisms have been employed to make enzymes for different types of uses, as discussed in Chap. 31.

For example, an alkaline protease naturally secreted by *Bacillus licheniformis* to break down proteinaceous substrates, resulted in one of the first commercially produced enzymes, Subtilisin Carlsberg, for use in detergents. Similarly, α-amylase was produced from *B. licheniformis* because it naturally secretes a highly thermo-stable α-amylase capable of breaking down starch to more easily digestible oligosaccharides. Strains of *Bacillus* have been some of the workhorse strains for enzyme production for decades, based mainly upon their ability to overproduce subtilisin and α-amylase. Those strains and the promoters of these genes are also used to express other enzymes, wild type and engineered.

Glucoamylase, which completely breaks down oligosaccharides to glucose, is produced by strains of the fungal genus, *Aspergillus*. Strains that overproduce glucoamylase have been isolated over the years. Another carbohydrase, an acid lignocell enzyme complex, found in the fungus *Trichoderma*, is capable of breaking down cellulosic substrates to glucose, similar to the starch-degrading enzymes. This particular application has turned out to be much more challenging to commercialize but has found applications in treatment of textiles, feed, and food. New programs initiated by the U.S. Department of Energy have helped improve the expression and activity of the lignocell enzyme complex.

One of the enzymes that has been used on a large scale is glucose/xylose isomerase, which catalyzes the rearrangement of glucose to fructose, to yield a product with a sweet taste like sucrose. The enzyme is present in *Streptomyces* spp. as well as a few other organisms. Once again, the native host strain has been improved for production of glucose isomerase.

Future: Biorefineries

Biorefineries integrate biobased industries/processing facilities that utilize mostly plant materials as feedstocks to produce food, feed, fuel, chemicals, materials, and intermediates for making varieties of products. Fermentative processes discussed here and biocatalysis discussed in Chap. 31 can be applied for a wide variety of processes where renewable resource-based materials are used and produced. Bioprocesses are continually becoming more efficient through better understanding and controlling of metabolic pathways. Today, industrial biotechnology companies such as DuPont Industrial Biosciences and Novozymes sell enzymes produced via microbial fermentation processes for a wide variety of bioprocessing applications. Chemical producers are seeking new and renewable feedstocks as well as environmentally friendly and sustainable production processes, in the face of escalating nonrenewable raw material prices. In addition, there is a need for development of interesting new chemistry and products. Major chemical companies—including Dow Chemical, DuPont, BASF, Degussa, and Celanese—have invested heavily to explore these opportunities, often through alliances with small technology firms that offer specific expertise (http://pubs.acs.org/email/cen/html/060804150713.html). However, most products made today are relatively low-volume, high-value types, for example, drugs and specialty chemicals. Only a few products, such as ethanol, are produced by fermentation at a million-ton scale per year.

Improvements in fermentation organisms and processes will have to be achieved in order to raise productivity and conversion efficiency and lower production costs (http://www.nrel.gov/docs/fy04osti/35523.pdf). Enzymatic processing is also expected to play a major role in refining biofeedstocks into sugars, protein, oil, and other by-products. Such advances alone will enable the vision of biorefineries to become a reality. Analogous to conventional refineries, progress in three areas will be key for the successful development of biorefineries: low energy milling of biofeedstocks to its components, efficient bioconversion of mixed sugars to products, and the utilization of by-products. These improvements will require integration of all major areas of industrial biotechnology: novel enzymes and microorganisms, functional genomics, pathway engineering, protein engineering, biomaterial development, bioprocess design, product development, and applications.

Acknowledgment The subject of biotechnology first appeared in an earlier edition of this *Handbook* as a chapter titled “Industrial Fermentation: Principles, Processes and Product,” written by Dr. Arthur E. Humphrey of Lehigh University. In later editions he was joined first by Dr. S. Edward Lee and then by Dr. Lewis Ho, both of Pfizer. Chaps. 30 and 31 in this edition are an outgrowth of that earlier work, some of which is used in the new chapters. Grateful acknowledgment of this use is made to the authors of that work.

Industrial Enzymes and Biocatalysis

Joseph C. McAuliffe

Introduction

All life processes, whether plant, animal, or microbial, depend upon a complex network of enzyme-catalyzed chemical reactions for cellular growth and maintenance [1, 2]. As catalysts, enzymes facilitate reactions by enabling alternate reaction mechanisms with lower activation energy, but in no way modify the thermodynamic equilibrium constant or the free energy change of a chemical transformation. They generate enormous kinetic rate accelerations, often exceeding factors of 10^{12}-fold relative to the rate of the uncatalyzed reaction. Enzymes are capable of performing many different chemistries, can be produced on a large scale, and typically operate at ambient temperatures and near neutral pH [3–5]. These attributes have captured the attention of generations of scientists and engineers alike and enabled the dramatic growth of the enzyme industry over the past century.

All commercial enzymes are proteins, which are assembled in living cells from a combination of the 20 naturally occurring amino acids, according to specific sequences defined by genes within the cell's DNA. Additional structural features are often present, such as carbohydrates, metal ions, and coenzymes which influence both the physical and catalytic properties of enzymes. The biosynthesis of a given enzyme is typically subject to several layers of cellular regulation and control; however, these controls can often be genetically or environmentally manipulated when overproduction of an enzyme is desired.

Enzymes have been used quite extensively as industrial catalysts and the current trend toward green, more sustainable processes is driving strong growth of this industry [5–9]. They possess the following attributes;

1. They are specific in action, and thus minimize the occurrence of undesirable side reactions
2. They are relatively inexpensive and can perform under mild conditions
3. They are effective for chemical conversions (biocatalysis)
4. They can be produced on a large scale by fermentation from common sugars and other renewable substrates
5. They can be modified and improved to suit a particular application
6. They are safe and acceptable for applications in food processes and medicinal treatments
7. They are effective over a wide range of concentrations

Over 3,000 different enzymes have been isolated and characterized, although less than 100 have ever been used in industrial applications. Enzymes are often named according to the substrate they act upon, for example, cellulose degrading enzymes are called cellulases and those that degrade starch, a mixture of amylase and amylopectin, are referred to as amylases. Many individual enzymes also have common names such as subtilisin, a family of serine proteases, and the digestive proteases chymotrypsin, rennin, and pepsin. Another example is lysozyme, a glycosidase that hydrolyzes peptidoglycan, a key component of bacterial cell walls. Enzymes that act upon polymeric substrates are also described according to their site of action—polysaccharide-degrading enzymes that act within the polymer chain are referred to as endoglycosidases and those that remove sugar units from the termini of the substrate as exoglycosidases. A description of the system used to formally classify enzymes is given later in the chapter. Commonly used industrial enzyme classes, their substrates, and products are listed in Table 31.1.

The world market for industrial enzymes exceeded \$US3.5 billion/year in 2010 and was growing at a rate of 5–8% per annum (Fig. 31.1) [10]. Over 50% of the sales come from proteolytic enzymes for use by the detergent, dairy, and leather industries [11]. The carbohydrases, mainly the amylases, isomerases, pectinases, cellulases, and hemicellulases, used in baking, brewing, fuel ethanol, starch, and textiles industries, represent nearly 40% of the total

Table 31.1 Properties of industrial enzymes

Enzyme class	Substrate	Products
Amylase	α-1,4 Glycosidic bonds in starch	Maltodextrins, maltose, glucose
Catalase	Hydrogen peroxide	Water and oxygen
Cellulase	β-1,4 Glycosidic bonds in cellulose	Cellooligosacchardies, cellobiose
Glucoamylase	Nonreducing terminal α-1,4/6 glycosidic bonds in starch	D-Glucose
Glucose isomerase	D-Glucose	D-Fructose
Glucose oxidase	D-Glucose	D-Gluconolactone
Hemicellulase	β-1,4 Glycosidic bonds in hemicellulose	Oligo- and disaccharides, xylose
Lipase	Fatty acid esters	Fatty acids, glycerol
Pectinase	Pectin	Pectin oligosaccharides
Phospholipase	Phospholipids	Fatty acids, glycerol phosphate
Phytase	Inositol phosphate esters (phytate)	Inositol, phosphate
Protease	Peptide bonds in proteins	Peptides, amino acids
Pullulanase	α-1,6 Glycosidic bonds in amylopectin	Amylose

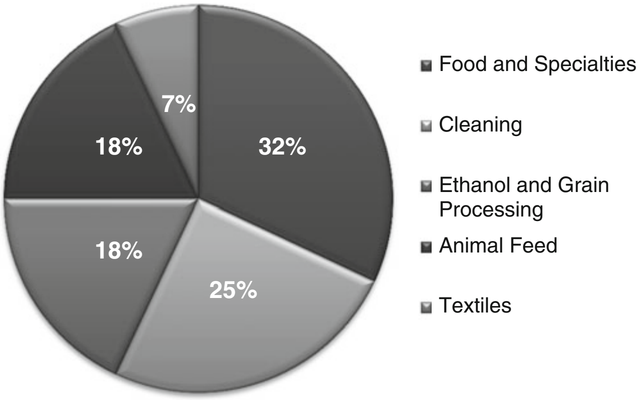

Fig. 31.1 Uses of industrial enzymes

enzyme market [12]. Lipases, phytases, oxidoreductases, and other highly specialized enzymes make up the remainder of total enzyme sales. While markets have matured in North America and Western Europe, regions including Latin America and Asia are still experiencing strong growth driven by demand from the animal feed, textiles, detergent, and grain processing industries. The major worldwide enzyme producers are Novozymes A/S and Genencor, now part of DuPont.

A multitude of non-industrial uses for enzymes have also been developed [13]. Although the total volume of enzyme protein for specialty uses is relatively small, the global market was estimated to exceed $2.5 billion by 2011 [14]. Enzymes used for analytical, clinical, and research purposes include glucose oxidase, hexokinases, pyruvate kinase, uricase, glucose-6-phosphate dehydrogenase, amino acid oxidase, aminopeptidase, and others. Restriction enzymes, endonucleases, and oligonucleotide polymerases are essential tools in Molecular biology and Forensic analysis. Glycosyltransferases and other carbohydrate-modifying enzymes are also routinely employed as tools for carbohydrate research [15]. Another growing application for enzymes is in the field of industrial biocatalysis, whereby enzymes are used for chemical and pharmaceutical manufacture, often displacing traditional chemical catalysts [5, 13, 16–18].

The first section of this chapter outlines the history of the enzyme industry, the general properties of enzymes (classification, structure, catalysis, and kinetics), and the methods used for enzyme discovery and optimization. The second section of the chapter describes the production and applications of industrial enzymes, with a focus on those of greatest commercial importance. The application of biocatalysis in industry is covered in the third section, with an emphasis on the processes employed and the resulting products. The interested reader can find more detailed information in the books and reviews cited throughout the text.

Industrial Enzymes: General Properties

History of Enzyme Use

The history of enzyme use dates back to ancient times and many cultures applied enzymes from various natural sources for the production of beverages, foods, and textiles [2, 5]. It was not until the nineteenth century that the basic nature of enzymes was investigated and their specific actions characterized. Diastase, an amylase mixture prepared from germinating barley, was described by Anselme Payen and Jean-François Persoz in 1833. Soon after, in 1835, Theodor Schwann isolated the digestive enzyme pepsin. As early as 1836, the Swedish chemist Jöns Jacob Berzelius speculated that thousands of catalytic processes took place in every organism and hypothesized that “catalytic bodies” were responsible. A mixture of protease and carbohydrases derived from solid-phase cultures of the fungus *Aspergillus oryzae* was developed in 1894 by Jokichi Takamine and is still sold under the brand name Takadiastase.

The name "enzyme" itself was coined in 1878 by Wilhelm Kühne, derived from the Greek term meaning "in yeast." Subsequent work by Emil Fischer beginning in 1894 led to a better understanding of enzymatic action, particularly the concept of substrate specificity. Further studies by Eduard Buchner demonstrated alcoholic fermentation in a cell-free system and he postulated that enzymes were responsible, although this theory was not widely accepted at first [19]. The protein nature of enzymes was demonstrated by James B. Sumner in 1926 through the crystallization of urease, a contribution for which he received the 1946 Nobel Prize [20]. The precise structure of enzymes and proteins in general remained elusive until 1965 when the 3D structure of lysozyme was finally deduced by Phillips and coworkers through X-ray crystallography [21].

Despite an incomplete understanding of enzymes, there was considerable use of crude enzyme preparations before 1950, primarily those derived from animal sources. Applications included cheese-making, leather production, brewing, cleaning, and the manufacture of malt extract. The primary limitation to the further development of enzymes was the inability to produce them on a large scale. This began to change after the mid-part of the twentieth century through the implementation of fermentation-based processes for the manufacture of bacterial amylases and proteases.

The development of large scale processes for the production of glucoamylase and proteases had significant impact within the starch processing and detergent industries, respectively. The ability to formulate enzymes and minimize sensitization of workers in enzyme production was another important development in the early 1970s, meeting a challenge which had significantly impeded the expansion of the enzyme industry. The advent of gene engineering in the late 1970s and early 1980s heralded an expansion of enzyme technologies that continues to this day. The first recombinant industrial enzyme product, a subtilisin protease variant, was marketed by Genencor International, Inc. in 1988 [22]. Additional engineered enzyme products were developed in the 1990s, as well as improved means to discover, engineer, and produce enzymes. In the last decade, the ability to rapidly sequence DNA and information technologies such as Bioinformatics have provided new tools for enzyme development. Powerful analytical methodologies including mass spectrometry, nuclear magnetic spectroscopy (NMR), and X-ray crystallography are now routinely used to solve enzyme structures and analyze the mechanisms underlying enzymatic catalysis [23]. The ability to design enzymes de novo is not yet routine, although some examples have been reported and further developments are highly likely.

The number of applications for enzymes has steadily expanded over the past 40 years and enzymes have gained wide use in the detergent, textiles, grain-processing, animal feed, pulp and paper, fuel ethanol, and chemical industries [5–10]. In addition to the economic benefits that enzymes offer, the need for clean and more sustainable industrial processes will inevitably stimulate new technologies for enzyme development and application.

Enzyme Structure and Properties

Enzymes are complex, three dimensional macromolecules that contain the chemical environment necessary to catalyze a particular reaction mechanism, in addition to possessing a template function that limits the set of possible substrates and the resulting products [3, 4]. All enzymes contain a defined region within their structure, known as the active site, where catalysis takes place. Each enzyme class catalyzes a specific reaction or a group of reactions with certain common characteristics. Many enzymes possess the ability to catalyze reactions with very high stereoselectivity in that they favor the production of only one of two possible stereoisomers. As macromolecules, enzymes can lose their catalytic properties when subjected to agents such as heat, strong acids or bases, organic solvents, or other conditions that break non-covalent bonds, a process called denaturation. Some enzymes can withstand quite extreme conditions, for example, temperatures exceeding 120°C and pH values of less than 1 [24]. The ability of an enzyme to turn over a substrate is referred to as enzyme activity. The activity of an enzyme is a function of the intrinsic nature of the enzyme itself, as well as environmental factors such as substrate concentration, temperature, and pH. All enzymes exhibit optima with regard to pH and temperature. Outside of these optimal regions, enzymes become less efficient and can undergo irreversible denaturation. Enzyme activity can be measured using an enzyme assay, where the concentrations of substrates and/or products are determined after a given period (end-point assays) or as a function of time (kinetic enzyme assays) [25].

All proteins, including enzymes, consist of a linear sequence of amino acids, referred to as the primary sequence. The N-terminal of the sequence possesses a free α-amino group, and the C-terminus contains a free α-carboxylic acid function. A typical enzyme is composed of several hundred amino acid residues with molecular weights in the 20–100 kDa range. The smallest enzyme yet described is 4-oxalocrotonate tautomerase, consisting of only 62 amino acids, whereas the large eukaryotic fatty acid synthase complex is composed of over 2,500 amino acid residues [26, 27]. Commercial enzymes such as proteases, amylases, cellulases, and lipases typically consist of 200–500 amino acids.

A key feature of enzymes and proteins in general is the ability to fold into more complex structures. It is the primary sequence of an enzyme that determines the 3-dimensional

Fig. 31.2 Ribbon diagram of a protease

structure of an enzyme, although the protein folding process is complex and not yet fully understood [28]. Secondary structure refers to features such as alpha-helices, beta-sheets, and random coils which are defined by hydrogen bonding between different amino acid residues in the primary sequence. The identity and order of amino acids defines the secondary structural features. These secondary features fold further to form the tertiary structure of an enzyme, which is stabilized by a combination of both non-covalent (hydrogen, ionic, and hydrophobic bonds) and covalent bonds (disulfide bridges). The tertiary structure of an enzyme can be depicted in several ways, the most common being a ribbon diagram where the orientation of the amino acid backbone is represented, but amino acid side chains are omitted for clarity. A ribbon diagram of a protease is depicted in Fig. 31.2. Space filling models where all atoms are depicted are also common, particularly when visualizing the active site and other binding regions of an enzyme. Quaternary structure refers to complexes formed from two or more fully folded proteins. Such complexes can take the form of dimers, trimers, and higher order assemblies. These complexes can be formed from many sub-units of the same enzyme (e.g., homodimers and trimers) or several different molecules (e.g., heterodimers, trimers, tetramers, etc.). Many enzymes are catalytically inactive in monomer form and only express activity in quaternary complexes. Protein and enzyme structural hierarchy is depicted in Fig. 31.3.

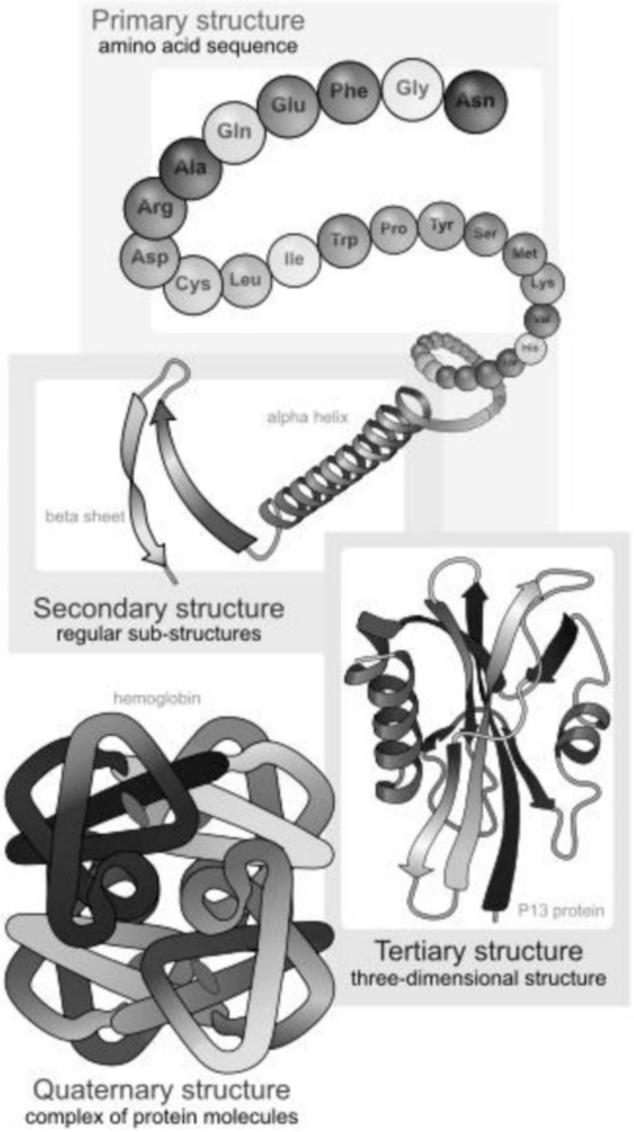

Fig. 31.3 Protein and enzyme structural hierarchy

Many enzymes contain additional structural features beyond the amino acids that define the primary structure. These elements are called posttranslational modifications resulting from subsequent processing following the biosynthesis of the primary sequence. The two most common types of posttranslational modifications are phosphorylation and glycosylation with mono- and oligosaccharides. Glycosylation is of particular interest as the carbohydrate chains can account for a large proportion of an enzyme's molecular weight. Glycosylation is described as either O-linked (serine and threonine residues) or N-linked (asparagine and glutamine residues) depending on whether the glycan chain is attached to the protein backbone through oxygen or nitrogen, respectively. Enzymes made in fungal hosts such as *A. oryzae*, *A. niger,* and *Trichoderma reesei* are often glycosylated, in contrast to those produced in bacterial cells. Enzymes often contain additional structural elements

Table 31.2 The six families of enzymes that comprise the enzyme classification system

Group	Reaction catalyzed	Examples
EC 1: Oxidoreductases	Transfer or removal of electrons or their equivalents from one substrate to another	Glucose oxidase, catalase, laccases
EC 2: Transferases	Transfer of a functional group from one substrate to another (e.g., acyl, methyl, amino, glycosyl, etc.)	Transaminases, acyltransferases, glycosyltransferases
EC 3: Hydrolases	Breaking of chemical bonds by addition of water to form two products	Proteases, amylases, cellulases
EC 4: Lyases	Non-hydrolytic scission of a substrate to form two products	Decarboxylases, aldolases, carbonic anhydrase
EC 5: Isomerases	Rearrangement of substrate molecular structure	Xylose isomerase, amino acid racemases
EC 6: Ligases	Formation of a product from two substrate molecules	DNA ligase, aminoacyl-tRNA synthetases

including metal ions, phosphate and fatty acid esters, and organic cofactors (coenzymes) like heme, cobalamin, and flavin adenine nucleotide. In many instances, these modifications have regulatory or catalytic functions.

The primary structure of an enzyme can be determined by a process known as sequencing, with Edman degradation being the most widely used technique. Mass spectrometry is now used routinely to determine the amino acid sequence of an enzyme, as well as modifications to the amino acid backbone [29]. Several analytical techniques are used to determine enzyme 3-dimensonal structure, including circular dichroism for secondary structure and X-ray crystallography for tertiary and quaternary structure. NMR is also an invaluable tool in enzyme structure determination and can be used to observe enzyme dynamics [30].

Enzyme Classification

Enzyme nomenclature is defined according to the Enzyme Commission number (EC number), first developed in 1955 at the International Congress of Biochemistry in Brussels. The system is based upon the nature of the reaction that the enzymes catalyze, as opposed to structural or other characteristics. There are six major groupings within the EC system, each of which contains many subtypes. Enzymes that perform hydrolysis reactions (EC 3) such as proteases, amylases, lipases, and cellulases dominate the current markets for industrial enzymes, although examples from each of the other classes have also been commercialized, particularly in the area of biocatalysis (oxidoreductases, lyases, isomerases) and diagnostics (oxidoreductases, ligases). Table 31.2 summarizes the EC classes and the reactions they catalyze. The EC number is also referred to as the IUBMB (International Union of Biochemistry and Molecular Biology) number. The IUBMB periodically updates enzyme nomenclature and lists the corresponding CAS number for each IUBMB number. More detailed information can be found at the International Union of Biochemistry and Molecular Biology enzyme nomenclature website (www.chem.qmul.ac.uk/iubmb/enzyme) and the ExplorEnz database (www.enzyme-database.org).

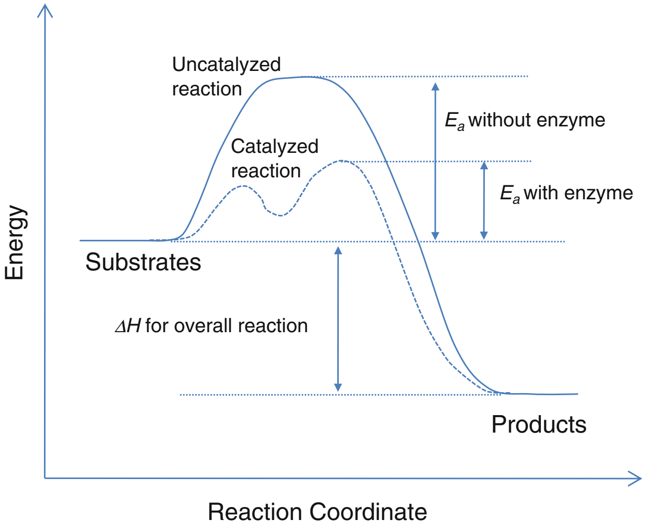

Fig. 31.4 A comparison of the reaction coordinates of a catalyzed vs. an uncatalyzed reaction. A catalyst provides an alternate reaction pathway with lower activation energy

Enzyme Catalysis and Kinetics

The basic principle by which enzymes and chemical catalysts in general operate is their ability to lower the activation energy (E_a or $\Delta G^{\ddagger}$) for a chemical reaction by altering the reaction coordinate, thus facilitating the rate at which the conversion of substrates to products proceeds [31]. Lowering of the activation energy does not change the equilibrium position of a reaction and accelerates both the forward and reverse directions of a chemical reaction (Fig. 31.4).

The relation between activation energy, temperature, and reaction rate is defined by the Arrhenius equation (31.1) where R is the universal gas constant, T is temperature in

Kelvin, k is the reaction rate coefficient, and A refers to the frequency factor. The equation demonstrates why catalysts can produce dramatic rate accelerations. For example, an enzyme that lowers the activation energy of a reaction by 10 kJ/mol at 25°C leads to a rate increase of around 50-fold, whereas a 40 kJ/mol reduction in E_a gives a rate acceleration of 10^7 fold [32].

$$k = Ae^{-(E_a/RT)} \tag{31.1}$$

Reaction rates tend to increase with temperature and enzyme catalyzed reactions are no different, exhibiting a rate increase of approximately twofold for every 10°C rise in temperature. The physical stability of an enzyme is also related to temperature, a concept known as thermostability. Thus, enzymes display temperature optima with regard to their activity. Some enzymes have broad temperature optima, while others display maximal activity over narrower ranges of temperature. Enzymes from animal sources typically have optimal temperatures around 37°C, whereas those from microbial sources have widely varying optima, often correlating to the environment from which the source organism was isolated.

The action of enzymes can be divided into three distinct events—initial substrate recognition, followed by enzymatic catalysis and subsequent product release. The binding of a substrate to an enzyme is often highly specific and the nature of this event was first explained through the lock and key model, developed by Emil Fisher in 1894, which held that the structures of the substrate and enzyme were both rigid and complementary, such that similar but different substrates would not bind with the same affinity, relative to the preferred substrate. The induced fit model was put forward by Koshland in 1958 to overcome the shortcomings of the earlier theory and proposed that the conformations of both enzyme and substrate adapt upon binding in order to produce an enzyme/substrate complex that undergoes catalytic conversion to an enzyme/product complex. This model more readily explains how an enzyme is able to produce and stabilize the transition state that lies between a substrate and the resulting product during the catalytic process.

A number of theories have been proposed to explain how an enzyme lowers the activation energy for a chemical reaction and the topic is still the subject of much debate [33]. A common view is that enzymes stabilize the transition state of a reaction, thereby reducing the free energy of this state and promoting the rate of the reaction. Enzymes accomplish this through non-covalent interactions including hydrogen-bonds, Van der Waals, and electrostatic interactions. This hypothesis is supported by the observation that compounds designed to mimic transition states are often extremely potent enzyme inhibitors with far greater affinity for the enzyme relative to either the substrate or products of the enzyme. For example, Acarbose, a nitrogen-containing pseudo-tetrasaccharide, has a K_d for glucoamylase of 10^{-12} M, far below that of maltotetraose, a substrate for this enzyme [34].

Enzymes also promote reactions through the assistance of chemical functionalities present within the active site that participate in the reaction by acting as acids, bases, nucleophiles, and counter ions. Such catalytic residues consist of amino acid side chains or elements within cofactors. Examples include carboxylic acid groups from glutamic and aspartic acid that participate in glycosidic bond cleavage by glycosidases, serine, histidine, and aspartic acid that comprise the catalytic triad of proteases and the nicotinamide groups from the soluble redox cofactors NADH and NADPH. Metal ions are also commonly employed by enzymes to perform some of the more demanding feats of chemical catalysis, for example, zinc-containing metalloproteases, iron-based oxygenases, and molybdenum nitrogenases [35].

Yet another means by which enzymes promote reactions is through conformational changes of the protein which increases strain on bonds within the substrate and bring catalytic residues into close proximity to the substrate [36]. Such conformational changes can be induced through substrate binding or from the different vibrational modes of the protein itself. The role of enzyme dynamics in catalysis is a topic of current interest, as is quantum tunneling, whereby a proton or electron transfer event occurs at rates faster than one would predict from the known activation energy by tunneling through the energy barrier instead [37]. The enzyme aromatic amine oxidase is thought to utilize quantum tunneling to oxidize tryptamine.

Enzyme Kinetics

The kinetic parameters for a free enzyme in solution are readily derived using the Michaelis–Menten approach describing pseudo-steady-state conversions [4, 38]. Consider (31.2) representing the conversion of a substrate S into a product P, catalyzed by an enzyme E. The rate of formation of an enzyme/substrate complex, ES, is denoted as k_1, the reverse reaction by k_{-1}, and the rate of subsequent conversion to the free product by k_2.

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \mathrm{ES} \xrightarrow{k_2} E + P \tag{31.2}$$

The Michaelis constant K_m under steady-state conditions is defined as follows:

$$(k_{-1} + k_2)/k_1 = K_m \tag{31.3}$$

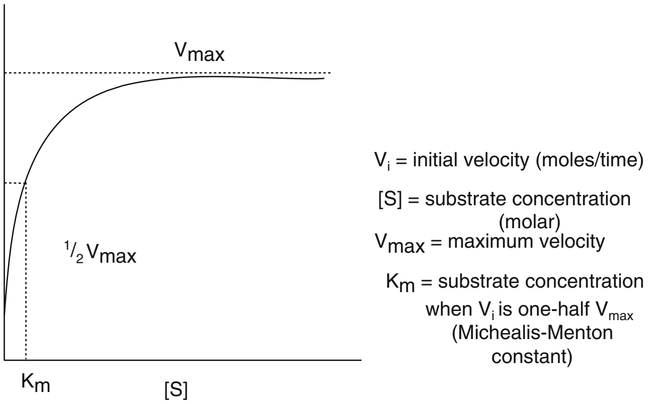

Fig. 31.5 Enzyme velocity vs. substrate concentration

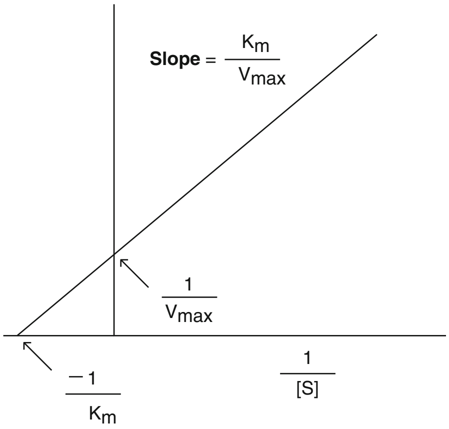

Fig. 31.6 A Lineweaver–Burke plot

The term k_{cat} can be substituted for k_2 and is referred to as the turnover number of an enzyme (units of s^{-1}). The expression $k_{\text{cat}}/k_{\text{m}}$ is widely used as a measure of the catalytic efficiency of an enzyme and is termed the specificity constant or turnover number. Where $[S] \gg K_{\text{m}}$, one can assume that all enzyme is bound to substrate (i.e., $[E_0] = [\text{ES}]$). Under these conditions, the maximal velocity of the reaction $V_{\max}$ is a function of k_2, represented in (31.4), where E_0 is the initial enzyme concentration.

$$V_{\max} = k_2[E_0] \tag{31.4}$$

From this one can derive an expression for the velocity of an enzyme catalyzed reaction as a function of the substrate concentration $[S]$, termed the Michaelis–Menten equation (31.5):

$$v = V_{\max}[S]/(K_{\text{m}} + [S]) \tag{31.5}$$

This relationship can be graphically represented by plotting reaction velocity vs. substrate concentration (Fig. 31.5) or alternately as a double reciprocal plot known as a Lineweaver–Burk plot (Fig. 31.6) where the x-intercept is $-1/K_{\text{m}}$, the y-intercept is $1/v_{\max}$, and the slope $K_{\text{m}}/V_{\max}$.

Although the Michaelis-Menten approach provides a useful approximation of enzyme kinetics, there are many situations in which the relation of reaction velocity to substrate concentration is more complex and cannot be adequately modeled using the Michaelis-Menten approach. In many instances, the substrate is a heterogeneous material, such as starch or biomass. There may be other enzymes present, resulting in synergistic effects. Many enzymes possess additional sites other than the active site where molecules can bind and alter activity, a phenomenon known as allosteric regulation. Allosteric regulation can either enhance or decrease enzyme activity and is a common form of regulation observed in metabolic networks.

Enzyme Inhibition

Enzyme inhibitors may also modulate the activity of the enzyme, altering the observed kinetic behavior of the system. An enzyme inhibitor is defined as a substance that can bind to an enzyme and reduce the catalytic rate. There are two overall types of enzyme inhibition—reversible and irreversible inhibition. Irreversible enzyme inhibitors often react with an enzyme forming a covalent enzyme-inhibitor complex. Fluorophosphonate nerve agents (e.g., sarin) are examples of irreversible inhibitors that can react with serine proteases and acetylcholine esterases. Suicide inhibitors are a type of irreversible enzyme inhibitor that is converted into the reactive form through the action of the enzyme they act upon.

In the case of reversible inhibitors, the formation of an enzyme inhibitor complex [EI] is conceptually similar to the enzyme-substrate complex [ES]. The inhibition constant K_{i} is used to describe the affinity of an inhibitor for an enzyme. Weak inhibitors have K_{i} values in the millimolar range and above, whereas potent inhibitors can inhibit enzymes on a stoichiometric (1:1) basis and have subnanomolar K_{i} values. Enzyme inhibitors can be both small and large molecules and can bind at the active site, substrate binding sites, or allosteric sites. Several types of enzyme inhibition are known and are summarized in Table 31.3. Examining the profile of Lineweaver-Burk plots at different inhibitor concentrations is a common means to determine the mode of inhibition.

Reversible enzyme inhibitors are often used to prevent unwanted enzymatic reactions, such as autoproteolysis in protease concentrates. Enzyme inhibitors can also be used to enhance the thermostability of enzyme formulations, provided the inhibitor is not so potent as to reduce the activity of the enzyme under use conditions in the presence of substrate [39].

Table 31.3 Different modes of reversible enzyme inhibition

Inhibition mode	Description	Effect
Competitive inhibition	Inhibitor and substrate compete for the active site of the enzyme	• K_m increases • V_{max} unchanged
Noncompetitive inhibition	Inhibitor binds elsewhere to the enzyme and does not compete with the substrate	• K_m unchanged • V_{max} decreases
Uncompetitive inhibition	Inhibitor only binds to enzyme-substrate complex. Relatively uncommon	• K_m decreases • V_{max} decreases
Mixed inhibition	A combination of competitive and uncompetitive inhibition	• K_m increases • V_{max} decreases

Enzyme Discovery and Engineering

When a suitable enzyme for a desired application is not available, it becomes necessary to develop a new or improved enzyme. Traditionally, this has been done by screening living microorganisms from either environmental samples or culture collections. With the recent advances in molecular biology and the explosion of genomic sequences, it is possible to isolate novel enzymes through genetic engineering of existing molecules, environmental gene screening, or by genomic database mining [40–43].

The classic method for discovering new enzymes involves screening environmental isolates and culture collections. This process was used very successfully as far back as the 1950s for the discovery of antibiotics such as penicillins and streptomycin. The technique involves examination and screening of thousands of isolates from a diverse array of environments such as soil, plant, and aquatic samples. The limiting factor in this process is the throughput capabilities. A significant investment in time is required to cultivate and screen the organisms, of which many will not have the desired activity. However, one can significantly enhance this process by subjecting an environmental sample to some selective pressure that will enrich for the desired activity. An example of this would be to take a soil sample and then provide a particular compound as the sole carbon source. This would enrich for organisms that are capable of breaking down the compound and using it as a carbon source. Another approach would be to select environmental conditions that would mimic the conditions of the biotransformation. Environments such as the hot springs, mud pots, and fumaroles found in Yellowstone National Park reach temperatures over 80°C and pH values lower than 3. Organisms such as *Sulfolobus solfataricus* that grow optimally at 80°C and pH 3 will also express extracellular enzymes that work optimally at these conditions. In addition, one the most famous research enzymes, Taq Polymerase, came from an organism, *Thermus aquaticus*, isolated from Yellowstone National Park.

One of the limitations of screening environmental isolates is the cultivation of the organisms. In a single gram of soil, more than 10^8 microbes may be present, the majority of which cannot be cultivated. It is clear from molecular ecological studies that traditional cultivation techniques only capture a fraction, usually less than 1%, of the available diversity. To overcome this, direct cloning of DNA from environmental samples enables an unbiased representation of the microbial diversity. The collective genomes of all microorganisms in a given environment is known as the "metagenome" [44]. Briefly, this involves the isolation of DNA from environmental samples and subsequent cloning into plasmids or bacterial artificial chromosome (BAC). The plasmid libraries can then be screened for the desired activity. A comparison to the traditional screening method is shown in Fig. 31.7. For example, Knietsch et al. incubated environmental samples in the presence of glycerol or propanediol to enrich for organisms and activities that would oxidize short-chain polyols or reduce the corresponding carbonyls [45]. Total DNA was isolated from the samples and approximately 100,000 *Escherichia coli* strains were screened for the desired activity. In total, 16 strains were isolated that stably expressed the desired activity and a number of novel genes were identified that encoded alcohol dehydrogenases and putative oxidoreductases.

A third approach to isolate novel enzymes is via genomic database mining. Genomic database mining is defined as the process of finding and extracting useful information from raw DNA sequence data sets. With the explosion of genomic sequencing, there is a wealth of information available to the researcher. The whole genomes of over 1,200 organisms can be found in databases such as ERGO (http://ergo.integratedgenomics.com) and NCBI (http://www.ncbi.nlm.nih.gov/genome). All three domains of life are represented, bacteria, archaea, and eukaryota, as well as viruses and various organelles (Table 31.4).

With the protein sequence of a molecule that has been characterized biochemically, one can easily identify a large number of sequence homologues in completed genomes. Genes of interest can be identified through BLAST analyses

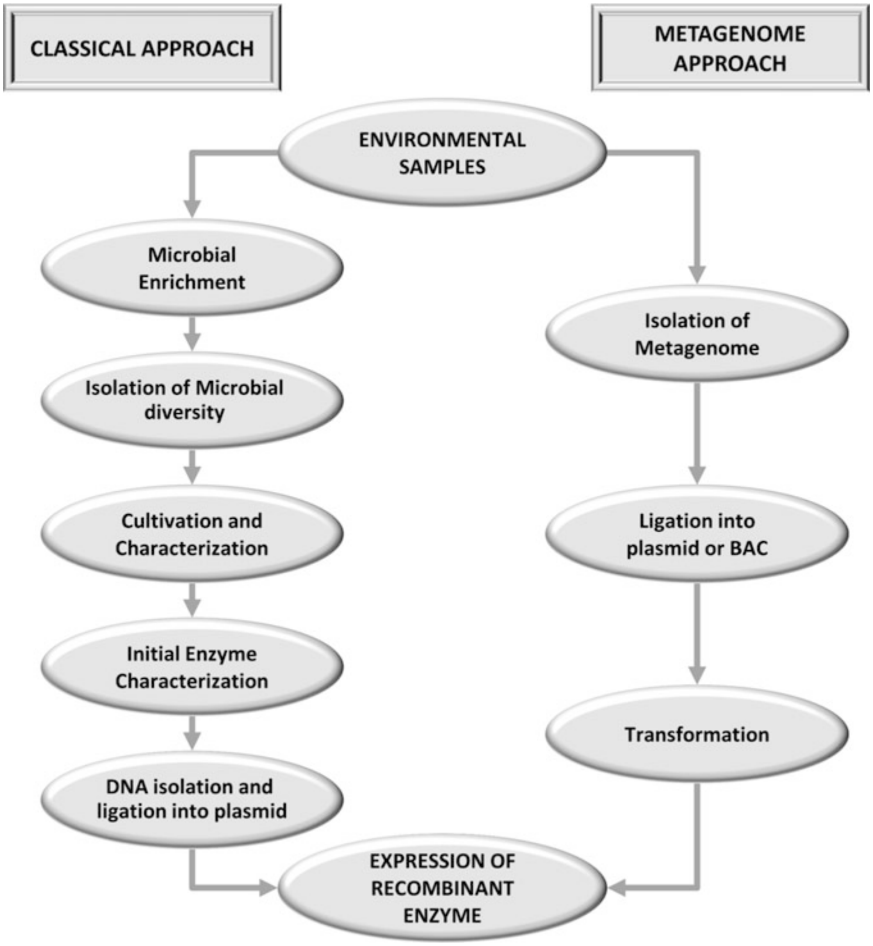

Fig. 31.7 Processes for the isolation, screening, and expression of enzymes

Table 31.4 Number of genomes available in ERGO and NCBI (2011)

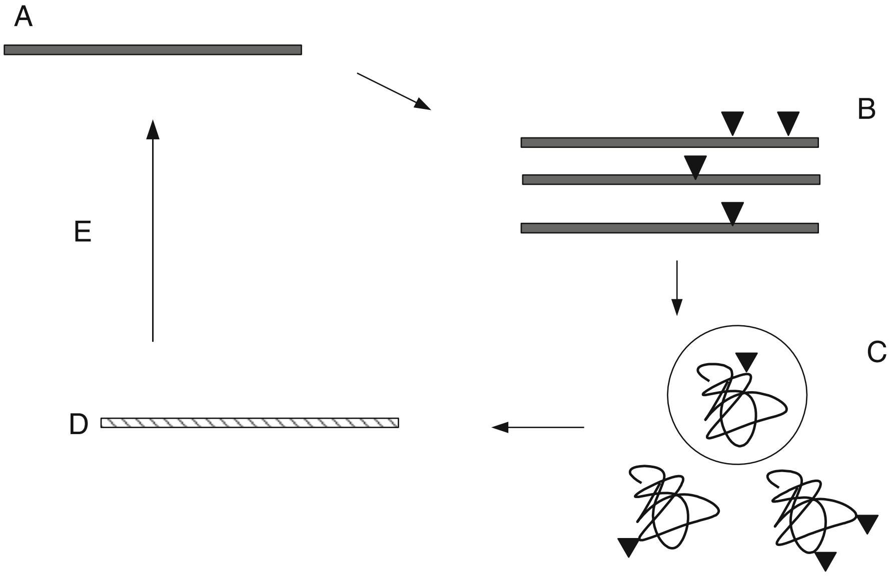
	ERGO	NCBI
All genomes	1,218	980
Bacteria	792	607
Archaea	49	44
Viral	241	213
Eukarya	136	116

of completely sequenced genomes. In addition, putative biocatalysts can be analyzed for known motifs using ScanProsite (http://ca.expasy.org/tools/scanprosite), the presence of signal peptides using SignalP (http://www.cbs.dtu.dk/services/SignalP/), and genomic organization using the STRING analysis method (http://string.embl.de), for possible enzyme–gene relationships. An example of this was done with the identification of proteases in the hyperthermophiles [46]. Initial efforts to assess the extent and variety of proteases in hyperthermophiles by biochemical methods significantly underestimated this biocatalytic feature. With the benefit of genome sequence data, it is clear that the proteolytic genotypes of these organisms are more expansive than can be inferred from biochemical analyses with over 30 proteases/peptidases identified in each genome.

The last approach involves engineering of an existing enzyme [47]. Molecular biology, high-throughput screening, and other analytical methods have made it possible to redesign and improve wild-type enzymes through the generation and screening of enzyme variant libraries. Site-directed mutagenesis is the method of choice for assessing the role of individual amino acids in the enzymes' catalytic mechanism or stability. A high-resolution crystal structure or a model based on the structure of a related protein is necessary to identify the residues to mutate. Using this technique, the amino acid of interest is either deleted or altered to another amino acid of choice. Subsequent biochemical analyses will yield information about the residues' role in the protein. This method has been an important tool in determining protein structure–function relationships and elucidation of catalytic and protein stabilization mechanisms.

Whereas site-directed mutagenesis is a technique that focuses on changing very specific residues based on the protein structure, directed evolution and gene shuffling

Fig. 31.8 Error-prone PCR for directed evolution of enzymes: (**a**) gene of interest; (**b**) error-prone PCR generating diversity; (**c**) expression of variants and characterization; (**d**) selection of variant with improved trait; (**e**) variant then serves as template for subsequent rounds of evolution



take a more global approach. An advantage of these methods is the limited knowledge of the proteins structure and mechanism that is required. The discovery of error-prone PCR was an important breakthrough in enzyme-variant generation. The mutation frequency of the error-prone PCR can be controlled at two levels, the reaction conditions and the choice of polymerase. An overview of this method is shown in Fig. 31.8.

Another method for generating diversity is gene shuffling. Using this method, one can start with either a single gene or a family of related genes. In the first case, error-prone PCR is carried out and the diversity of the library can be further increased through gene shuffling (Fig. 31.9a). The other alternative is to use multiple genes from various sources with significant levels of identity, usually >70% (Fig. 31.9b). In both cases, the genes of interest are fragmented by a DNAse treatment and then allowed to reassemble via recombination thereby generating a library of variants.

Industrial Enzymes: Properties and Applications

The global market for industrial enzymes is dominated by hydrolases from the EC 3 family, namely α-amylases, glucoamylases, proteases, cellulases, and lipases. Altogether they account for over 85% of the total sales of enzymes. In recent years, additional enzymes have shown strong sales growth, including phytase, an animal feed additive for increasing the bioavailability of phosphorous, laccase for the biobleaching of denim, phospholipases for edible oil production, and xylanases for biomass degradation. Applications of the industrially important enzymes are listed in Table 31.5, along with their microbial sources and commercial applications [6].

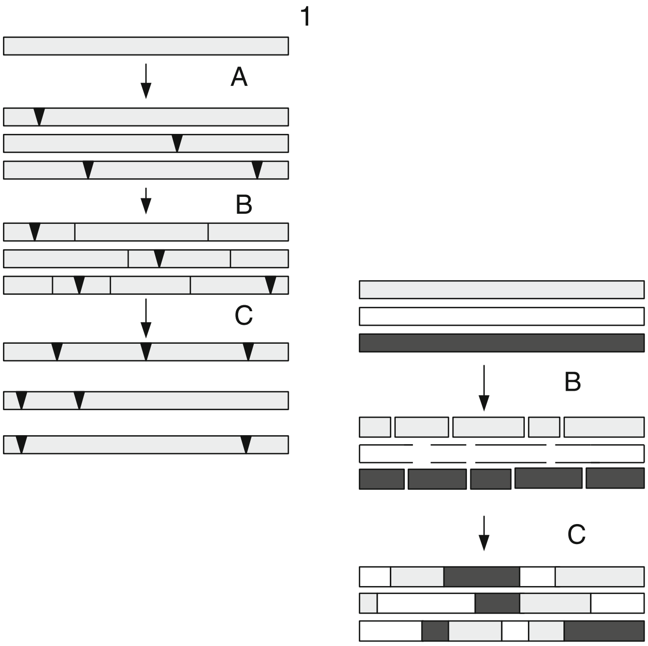


Fig. 31.9 Gene shuffling using a single gene (1) or a family of genes (2): (**a**) error-prone PCR generating diversity; (**b**) DNAse treatment; (**c**) homologous recombination of fragments and generation of diversity

Industrial enzymes are either extracted from natural sources (animal, plant, microbial) or manufactured though large-scale microbial fermentation processes. The latter method is responsible for the majority of the enzyme protein produced per year, accounting for over 85% of the total [48]. Submerged fermentation is the dominant fermentation technique, although solid state fermentation is still used for the production of some enzymes [49]. The advent of recombinant DNA technology has had a great influence on the production of enzymes for industrial purposes, both through improvements in the molecules themselves as well as the microbial hosts used in their production. The majority of technical enzymes are now produced in recombinant systems. This has offered many advantages to enzyme users. For instance, the price of enzymes has dropped significantly, while the purity of enzymes has increased overall. The improvement in purity was mainly achieved by the absence of enzymatic side activities, which has enabled much better control of enzyme activity in the industrial environment. General methods for the production, recovery, and formulation of enzymes by fermentation processes are covered in detail within the preceding chapter on Industrial Biotechnology (Chap. 30).

Despite the dominance of large-scale microbial fermentation processes for enzyme manufacture, many commercially relevant enzymes are still isolated from natural sources for both cost reasons, as well as consumer preference. The protease chymosin (rennin), used in cheese-making, is derived from rennet, a substance isolated from calf-stomach lining. While recombinant versions of chymosin expressed in microorganisms are available at lower cost, the demand for the animal-derived product remains strong, especially in Europe. Other animal-derived enzymes include lysozyme, derived from hen egg whites and the digestive aid Pancreatin, a mixture of amylase, lipase, and protease, manufactured from either cow or pig pancreatic extracts.

Plant-derived enzymes also have an important niche in the marketplace. For example, the cysteine proteases papain (papaya latex), ficin (fig latex), and bromelein (pineapple stalks) have been used as meat tenderizers, for contact lens cleaning, and as digestive aids. In the case of papain, latex from papaya trees is collected and dried, resulting in a crude extract. Further purification involves steps including extraction with water, reducing and chelating agents, salt precipitation, and solvent extraction. Highly pure material can be obtained through affinity purification using an immobilized substrate to isolate the enzyme from background components, although this form of purification is often rather costly. In recent years the FDA has restricted the use of papain for topical applications due to the risk of hypersensitivity and potential allergenicity. Malted barley is another important plant source of enzymes providing both α- and β-amylase, as well as β-glucanase, which are used on a very large scale for brewing and food applications. Lipoxygenase, an enzyme that oxidizes fatty acids, is isolated from soy beans. Production of industrial enzymes in recombinant plant systems has generated much interest, as well as controversy in recent years. While this mode of production has the potential to produce large volumes of enzymes directly from carbon dioxide and sunlight, there are concerns about contamination of non-GMO crops with enzyme-producing strains [50].

The major classes of industrial enzymes are discussed below, in addition to emerging enzymes of interest. Further information can be found in the reviews cited early in each section.

Proteases

Proteolytic enzymes (EC 3.4) are by far the most important of the commercially available industrial enzymes having found widespread use for laundry, automatic dishwashing, baking, diary, textiles manufacture, and other applications [11]. These enzymes, being essential parts of the metabolic system of most living organisms, can be isolated from innumerable sources. They can be divided into two overall categories—exoproteases (i.e., peptidases) that hydrolyze terminal peptide bonds releasing free amino acids, and endopeptidases that hydrolyze internal peptide bonds and convert proteins into smaller peptides. Proteases are also classified according to their catalytic mechanism, these subtypes are listed below;

- Serine proteases (EC 3.4.21)
- Cysteine proteases (EC 3.4.22)
- Aspartic acid proteases (EC 3.4.23)
- Metalloproteases (EC 3.4.24)

This classification is determined by amino acid sequence and through reactivity toward inhibitors that act on particular amino acid residues in the active site region of the enzyme. The serine proteases are widely distributed among microbes. The enzymes have a reactive serine residue in the active site and are generally inhibited by diisopropylfluorophosphate (DFP) or phenylmethylsulfonyl fluoride (PMSF). They are generally active at neutral and alkaline pH. The best-known serine proteases are the subtilisins, a large family of alkaline endoproteases which are the dominant enzymes used in cleaning applications owing to their wide temperature optima, broad substrate specificity, and resistance to denaturation by surfactants and other chemicals [51].

The occurrence of cysteine proteases is also widespread, occurring in both prokaryotes and eukaryotes. Examples include the plant-derived proteases papain and bromelein. These proteases are sensitive to sulfhydryl reagents, such as TLCK (tosyl lysyl chloromethyl ketone) and iodoacetic acid. Aspartic proteases are widely distributed among molds, including *Aspergillus*, *Penicillium*, and *Rhizopus*, but are less commonly found in bacteria and protozoa. They have their maximal activity at low pH, around 3–4. Many of the aspartic proteases are unstable above neutral pH and are not found in cultures growing at neutral or alkaline pH. Most

Table 31.5 Applications of industrial enzymes

Enzyme function	Origin	Applications
1. Oxidoreductases		
Glucose oxidase	*Aspergillus niger*	Increase gluten strength Improve shelf life Preserve milk Indirect enzymatic bleaching Tooth paste
Hexose oxidase	*Chondrus crispus*	Increase gluten strength
Laccase	*Trametes versicolor*, *Coprinus cinereus*	Prevent backstaining in enzymatic denim stone washing Pulp bleaching Cork treatment
Catalase	*Aspergillus niger*	Shelf life improvement of food Milk preservation Hydrogen peroxide removal
Peroxidase, lactoperoxidase	*Phanerochaete chrysosporium*	Dough improvement Milk preservation
Lipoxygenase	*Plants*	Whitening of breadcrumb
2. Transferases		
Transglutaminase	*Bacillus circulans*	Texture improvement in yoghurt and whipped cream Strength improvement of bread dough
Dextransucrase	*Leuconostoc mesenteroides*	Production of isomalto-oligosaccharide beer
3. Hydrolases		
α-Amylase	*Bacillus* sp.	Cleaning (laundry and automatic dish detergent) Baking (antistaling) Brewing (mashing, fermentation) Sweetneers Fuel ethanol Textiles processing
Cellulase	*Aspergillus* sp., *Trichoderma reesei*	Cotton finishing and depilling Biomass processing Pulp and paper Laundry detergent
Xylanase	*Bacillus* sp., *Aspergillus* sp., *Trichoderma reesei*	Baking (dough strengthening) Animal feed Lignocellulosic biomass processing Textiles processing
Protease (subtilisin)	*Bacillus* sp.	Cleaning (laundry and automatic dish detergent) Animal feed (improved digestibility) Leather production (soaking, bating, dehairing)
Protease (other)	Animal, plant and microbial sources	Cheese manufacture (Chymosin) Brewing Digestive aids
Lipase		Cleaning (removal of greasy soils) Paper and pulp (pitch removal) Biodiesel production Food applications (food oil production)
Pectin methylesterase	*Aspergillus* sp.	Apple and red berry juice pressing Citrus fruit peeling
Phytase	*Aspergillus* sp.	Mashing Releasing of phosphate from phytic acid in animal feed
Pullulanase	*Aerobacter aerogenes*, *Bacillus licheniformis*	Increase fermentability of starch worts or syrups
β-Amylase	Barley, *Bacillus cereus*	Mashing Fruit juice production
Glucoamylase, amyloglucosidase	*Aspergillus niger*	Apple juice production
		Mashing
		Hydrolysis of maltooligosaccharides
		Tooth paste

(continued)

Table 31.5 (continued)

Enzyme function	Origin	Applications
4. Lyases		
α-Acetolacetate decarboxylase	*Bacillus brevis*	Brewing (diacetyl removal)
Pectate lyase	*Aspergillus* sp.	Cotton scouring
Pectin lyase	*Aspergillus* sp.	Apple and red berry juice production Citrus fruit peeling
5. Isomerases		
Xylose isomerase	*Streptomyces* sp.	High fructose corn syrup production

aspartic proteases are sensitive to epoxy and diazoketone compounds. The pepsin-like aspartic proteases have been used commercially in processes such as soybean protein hydrolysis, and the rennin-like aspartic proteases have been used for clotting milk in a manner similar to animal rennins. The rennin-like proteases from *Mucor* and *Endothia* species have commercial applications in the manufacturing of cheese. The metalloproteases have pH optima between 5 and 9 and are sensitive to metal-chelating agents such as EDTA. Metalloproteases are widespread and most of the bacterial and fungal metalloproteases contain zinc. Calcium is required to stabilize their protein structure. The best-known metalloprotease is thermolysin produced by *Bacillus thermoproteolyticus*.

Protease Applications

Microbial proteases with widely different properties are produced commercially. *Bacillus* proteases, however, represent more than 95% of the sale of all proteases [52]. The most important use of *Bacillus* proteases is in detergents for both laundry and automatic dish (ADW) applications. Proteinaceous dirt often precipitates on clothes and it coagulates during the normal washing process. Similarly, protein soils can be difficult to remove from dishware and eating utensils through chemical-based detergents alone. The addition of proteolytic enzymes to the detergent cleaves such proteinaceous stains into soluble peptides, thus facilitating stain removal.

The alkaline serine protease of *Bacillus licheniformis*, also known as Subtilisin Carlsberg, (EC 3.4.21.62), a 274 amino acid protein, was the first protease to find widespread use in both nonionic and anionic detergents [53]. It readily dissolves proteins by cleavage of peptide bonds in a non-specific manner and is sold under the Trademark Alcalase® by Novozymes. It may be used at temperatures up to 65°C, and its pH optimum is close to 9.0, the pH normally used in washing fluids. Additional proteases have also been developed for solid and liquid detergents, including both wild-type and engineered enzymes, at both neutral and alkaline pH ranges. The serine protease Subtilisin Novo (BPN′) from *Bacillus amyloliquefaciens* has also found application as a detergent enzyme, crude versions of which contain a substantial content of α-amylase. An engineered version of BPN′ was developed by Genencor in 1984 by replacement of a methionine residue (Met 222) with amino acid residues less prone to oxidation by bleach (Ser, Ala and Leu) [22]. The subtilisins from other *Bacillus* species are also found in many commercial products, including *B. lentus*, *B. clausii*, *B. halodurans,* and *B. alcalophilus*. Commercially available products include Savinase® (Novozymes), Purafect® (Genencor), and Properase® (Genencor) [6].

Sales of proteases were small and relatively unimportant until about 1965. Since then, the use of proteases in detergents has enabled rapid expansion of the enzyme industry as a whole. However, allergic symptoms were discovered in some workers handling enzymes in detergent factories in 1971. The public, particularly in the United States, was alarmed, and proteases were taken out of most detergents. It was later found that every risk could be eliminated with proper precautions in handling by using proteases in liquid form or by encapsulating the enzymes.

Proteases are also used in the leather industry for soaking, bating, and dehairing processes [54]. Their use has enabled reductions in the amounts of hazardous chemicals including sodium sulfide used by the industry. The alkaline protease from *B. amyloliquefaciens* is used alone or in combination with sulfide for hide treatment and dewooling. A protease from an alkalophilic *Bacillus* sp. is successfully used for dehairing of ox hides in combination with lime, apparently because the enzyme is stable at pH as high as 12. Serine proteases are also used for wool scouring, a process which involves the removal of the scales naturally present on wool fibers, thus reducing the tendency of wool garments to shrink upon washing.

In the brewing industry, there is a development toward substitution of malted grain with unmalted barley and exogenous enzymes, including α-amylase, β-glucanase, and proteases of microbial and plant origin. The neutral protease from *B. amyloliquefaciens* and the thermostable neutral protease *Bacillus subtilis var. thermoproteolyticus* have been used by brewers successfully to hydrolyze barley proteins into amino acids and peptides in order to reduce foaming and haze in the finished product. The choice of enzyme and the condition applied are important as the production of certain peptides can impart undesirable flavors that should be avoided. The use of carbohydrases in brewing is covered in the "Amylases" section below.

Proteases are used in many food applications, primarily baking and cheese manufacture, as digestive aids and in the preparation of protein hydrolyzates, such as those derived from soybean protein. These proteases are derived from a range of different organisms, including *Bacillus subtilus*, *Streptomyces griseus*, *Aspergillus niger*, *Aspergillus flavusoryzae*, *Mucor miehei, and Mucor pusillus.*

Rennin, an aspartyl protease mentioned earlier, is found in the fourth stomach of nursing calves. Because of a decline in veal consumption and an increased demand for cheese, the dairy industry found it difficult to obtain sufficient quantities of this enzyme from natural sources. The increasing market for rennin (around $100 million/year) provided the necessary incentive for commercializing a recombinant DNA-derived chymosin. Prochymosin, the self-processing precursor of chymosin, was expressed in *E. coli* as an insoluble, refractile protein aggregate. The cells were lysed, and the insoluble prochymosin mass was isolated by centrifugation. The prochymosin was solubilized by 8 M urea with high pH treatment, renatured, and activated, and then chymosin was purified by ion exchange chromatography. The recombinant *E. coli* chymosin is no longer commercially available. Today recombinant chymosin is produced in the microorganisms *Kluyveromyces lactis*, *A. niger,* and *T. reesei*. These organisms secrete prochymosin. After prochymosin is separated from the cell broth, a pH drop induces the autocatalytic cleavage of prochymosin, which yields the active chymosin. This process is much cheaper than the former downstream processing from *E. coli* fermentations.

In addition to the recombinant chymosin, several coagulants for cheese-making are available from microbial origin. These are endoproteases from *Rhizomucor miehei*, *Rhizomucor pussilus*, and incidentally the plant-derived endothiapepsin from *Cryphonectria parasitica.*

Protease Production

The protease fermentation of *Bacillus* bacteria takes place under strictly contained conditions in conventional equipment for submerged fermentations. The aeration rate is about 1 vvm (volume of air per volume of medium per minute). Vigorous agitation is used to improve air distribution and oxygen transfer. The fermentation temperature is around 37°C, and the time cycle is 2–4 days. The composition of the fermentation medium is important to the yields of protease. Proteins of many different sources are used in commercial media. Carbohydrates are used as an energy source. The C/N ratio is important to the success of the process. Protein should be present in high concentration, and carbohydrate must not be in excess. A convenient way of obtaining this is to conduct fed-batch fermentation, feeding carbohydrate during the run and maintaining the carbohydrate concentration below 1%. Continuous fermentation of protease on a commercial scale is currently not practiced. The recovery and finishing of *Bacillus* protease involves the following steps.

1. Cooling to about 4°C to prevent microbial spoilage.
2. Precipitating undesirable salts using flocculants or filter aids.
3. Removing particles by centrifugation or filtration.
4. Removing pigments and odors with activated carbon treatment.
5. Concentration by ultrafiltration to product an ultrafiltered concentrate (UFC).
6. Sterile filtration to reduce microbial contamination.
7. Addition of formulation chemicals in order to produce a stabilized concentrate.
8. If a solid protease product is desired then granulation technologies are used.

Most, if not all, proteases are now produced on an industrial scale using genetically engineered organisms that overexpress either the wild-type enzymes (through homologous expression or self-cloning) or variants that have been obtained through protein engineering. The major reason for using the genetically engineered organisms is to reduce production cost. The overexpressing Bacilli can secrete proteases into the fermentation broth in very high yields. The secreted protease becomes the dominant protein in the broth. This greatly facilitates and reduces the cost of downstream processing and purification.

Amylases

The commercial importance of amylolytic enzymes is now well established and has driven significant expansion in the grain processing and fuel ethanol industries [55–58]. Amylases are also used in combination with proteases for cleaning applications. These enzymes catalyze the hydrolytic reactions of amylose (unbranched starch), amylopectin (branched starch), glycogen (animal starch), and related glucose polymers. Amylases, according to their difference in modes of action, can be divided into;

1. α-Amylase (EC 3.2.2.1), an endoglycosidase, hydrolyzes α-1,4-linkages randomly to yield a mixture of oligosaccharides, maltose, and glucose
2. β-Amylase (EC 3.2.1.2), an exoglycosidase, cleaves successive maltose units from the nonreducing end of starch

3. G4-amylase (EC 3.2.1.60), an exoglycosidase, hydrolyzes maltotetraose (G4) units from the non-reducing ends of starch
4. Glucoamylase (or amyloglucosidase) (EC 3.2.1.3) sequentially liberates glucose units from the non-reducing termini of amylose and amylopectin
5. The debranching enzymes such as pullulanase (EC 3.2.1.41) attacks the α-1,6-linkages at the branching point of amylopectin

The properties of amylases listed above have led to their use in many applications, including;

1. To produce grain syrup, glucose syrup, liquid glucose, and crystalline glucose
2. To produce high-fructose corn syrup (HFCS) in combination with glucose isomerase
3. To solubilize and saccharify starch for ethanol production in brewing, distilling, and fuel industries
4. To modify the viscosity of starch used in coating printing papers
5. To remove starch sizes applied to cotton thread before weaving in the textiles industry
6. To produce maltose-containing syrups in brewing and baking industries
7. To reduce the viscosity of sugar syrups used in various food and sugar products
8. As a component in digestive aids
9. To remove starch stains on clothes/dishes

α-Amylase is produced commercially by using both fungal and bacterial species. Fungal amylase has relatively low heat stability and its major application is in the baking industry to supplement the variable activity of amylase present in wheat flour. Bacterial amylases are much more heat stable and it is used in brewing, starch degradation, alcohol, textiles, and detergent industries. The organisms commonly used for the commercial production of α-amylase include:

Fungi
  Aspergillus oryzae
  Trichoderma reesei
Bacteria
  Bacillus subtilis
  Bacillus licheniformis
  Bacillus amyloliquefaciens

A. oryzae can be grown in either semisolid or submerged culture. In semisolid culture, it produces several enzymes, primarily α-amylase, glucoamylase, lactase, and protease. In submerged culture, the production of α-amylase is increased and the formation of other enzymes becomes minimal. The use of this fungal amylase in the baking industry speeds up the yeast (*Saccharomyces carlsbergenis*) fermentation; produces stiffer, more stable dough; and improves the texture, porosity, digestibility, and shelf life of bread. The fungal α-amylase delivers its optimal activity at pH 5–7 and at 50–55°C.

In the last decade, both protein engineering and recombinant DNA technology have been used to improve the thermostability of amylases by increasing the negative charges at its calcium-binding site and to improve the enzyme's resistance to oxidative compounds present in bleach containing detergents by substituting the oxidation-sensitive methionine residue with leucine. Genencor and Novozymes market their improved enzymes under the trade names of PuraStar® OxAm and Duramyl®, respectively.

Amylase Production

Different amylase-producing organisms may require different fermentation conditions for optimal enzyme production. When *B. subtilis* is used, the fermentation medium may contain starch, cornsteep liquor, yeast, phosphate, and some mineral salts. The amylase treatment on starch is often short to prevent the significant accumulation of glucose, which is inhibitory to the *Bacillus* amylase fermentation. The fermentation is run at neutral pH and at around 35°C. Care must be taken to prevent contamination by unwanted microorganisms. The time cycle is about 48 h. Whole mash may be used directly for starch liquefaction and saccharification or the mash may be processed to produce liquid or crystal enzyme preparation with high purity. The processing, involving filtration or centrifugation of the bacterial fermentation broth, presents a challenge to the recovery plant. Pretreatment with coagulating or flocculating agents is often needed. The amylase produced by this *Bacillus* strain is relatively unstable, but the addition of calcium chloride improves the stability.

Fungal glucoamylase, an exoglucosidase, drives the further degradation of starch following initial solubilization by α-amylase (often of a bacterial origin). Both *A. niger* and increasingly *T. reesei* are used for the production of glucoamylase. The fungal fermentation starts with a medium containing 25–30% starch and around 10% cornsteep liquor. Incremental or continuous feeding of concentrated nutrients may be used to circumvent the problems caused by a concentrated initial medium. The fermentation pH is about 4 and temperature around 28°C. The fermentation has a high oxygen demand. High oxygen tension, however, inhibits enzyme production. Levels of dissolved oxygen (DO) that approach zero are not atypical in this fermentation. After the completion of the fermentation in 4–5 days, the fermentor mash is cooled and filtered to remove cells and insoluble matters. *Trans*-glucosidase may be removed using clay, destroyed preferentially using proteases at certain pHs and temperatures, or inactivated by magnesium oxide. Contamination of glucoamylase by the transglucosidase activity may result in the loss of 5–10% of glucose to isomaltose and panose by a reversion process. These reversion products also impede the crystallization of glucose.

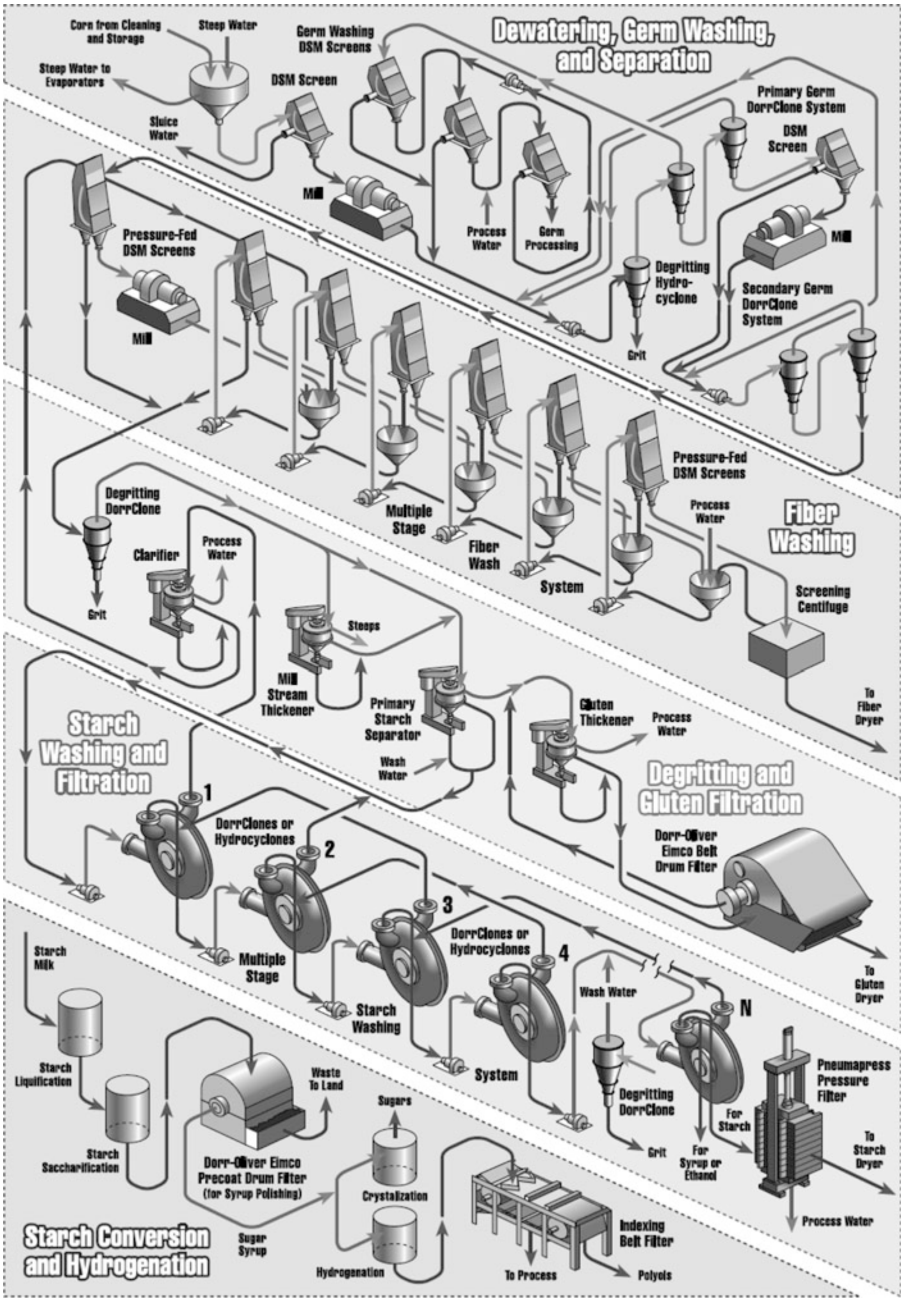

Fig. 31.10 Flowsheet of wet corn milling process (Copyright FLSmidth Co. and reproduced with permission)

Amylases in Wet and Dry Milling Processes

The enzymatic hydrolysis of starch to glucose has long since superseded the acid hydrolysis route using hydrochloric acid. The enzymatic process produces fewer side products, does not involve a corrosive acid, and allows the use of less pure starch products whose protein contaminants would, upon acid hydrolysis, give amino acids and browning reactions. Fungal glucoamylase in combination with bacterial α-amylase makes a complete enzymatic mixture for hydrolysis of starch to glucose. Corn is the dominant source of starch in the United States and is processed by either wet or dry milling processes to produce ethanol, starch, dextrins, corn syrup, glucose, and fructose syrups, in addition to byproducts of significant value such as corn oil and dry distillers grains and solubles (DDGS), a protein-rich animal feed [59].

Corn wet milling involves initial separation of the grain kernel into the germ, fiber, protein, and starch components prior to fermentation. The corn wet milling process is depicted in Fig. 31.10. Liquefaction of starch to form maltodextrins is aided by the action of bacterial α-amylase, whereas fungal glucoamylases are used in order to saccharify maltodextrins to glucose. Prior to liquefaction, granular starch is gelatinized by heat treatment at temperatures of up

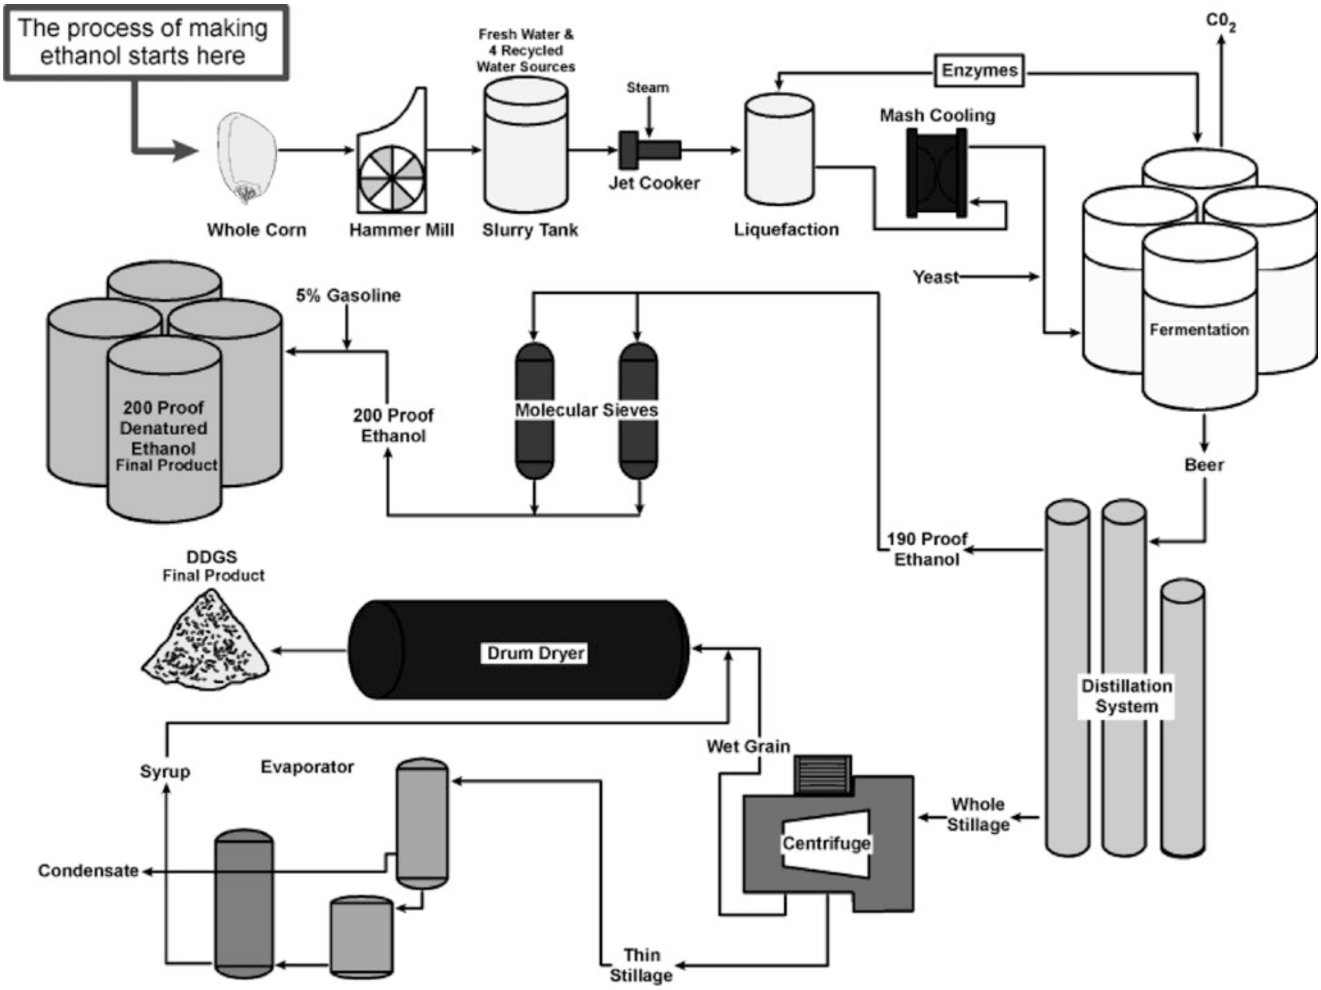

Fig. 31.11 Overview of a corn dry-milling process

to 108°C for 5 min in the presence of a thermostable amylase. The α-amylase from *B. amyloliquefaciens* functions at pH 5.5–7 and 90°C and α-amylase from *B. licheniformis* functions at pH 5.5–9 and temperatures as high as 110°C. In the subsequent saccharification process, an appropriate amount of fungal glucoamylase is added to the thinned starch (30–50% dry substance) with stirring at 55–60°C and pH 4–5 for 48–72 h. This achieves a final DE (dextrose equivalents) of about 97, with about 94% of the dry weight being glucose. The equilibrium concentrations of the saccharides formed by resynthesis limit the maximum degree of hydrolysis obtainable. Because the activity of glucoamylase toward the branching points (the α-1,6-linkages) is low, it may be advantageous to use a debranching enzyme such as pullulanase early in the hydrolysis process.

Dry milling of corn is the dominant means by which corn is converted into bioethanol (Fig. 31.11) and delivers improved process economics relative to corn wet milling. The process begins with the grinding of whole corn into flour in a hammer mill. This flour is slurried, the pH adjusted to around 5.8, and treated at 80–90°C with α-amylase for 30–45 min in order to reduce viscosity. This slurry is then gelatinized and liquefied in a similar manner to the corn wet milling process. Simultaneous saccharification and fermentation (SSF) combines the conversion of maltodextrins to glucose by glucoamylase and fermentation to ethanol. The yeast *Saccharomyces cerevisiae* is typically used, the fermentation period lasting from 48 to 72 h. Following fermentation, the spent mash (referred to as "beer") is distilled to produce 95% (190 proof) ethanol which is further dried and ultimately blended into gasoline.

Enzymes for the processing of granular starch directly to glucose at lower temperatures (<50°C) have been developed, for example, Stargen™ (Genencor) and BPX (Novozymes). The Granular starch hydrolysis (GSH) process eliminates the cooking step and combines the liquefaction, SSF steps, further streamlining the overall economics of corn drymilling.

Amylases are widely used in cleaning products, primarily laundry and automatic dish-washing detergents. The ability

Table 31.6 Glucose isomerase (GI) producing microorganisms[a]

Microorganism	Patent assignee	Yield (GIU)
Arthrobacter sp.	R. J. Reynolds	4,720
NRRL-B-3728		4,440
Streptomyces welmorensis	Standard Brands	4,640/g
Mutant-1		7,540/g
Mutant-2		6,680/g

Bacillus coagulans	Novo	Not known

[a] 1 GIU ~ The amount of enzyme which converts 1 mmol glucose to fructose/minute

to hydrolyze starch in food soils greatly boosts the ability of the detergent to remove stains. Many amylases are active at the high pH values and temperatures that some applications demand. In addition, detergent amylases must be resistant to proteolysis and bleaches. Typical dosing levels in the wash are in the 0.1–5 ppm range. In recent years, much effort has gone into developing amylases and other detergent enzymes that operate with improved efficiency at lower temperatures, allowing energy savings.

Glucose Isomerase

Starch degradation using α-amylase and glucoamylase produces corn syrup with glucose concentrations of up to 94% on a dry weight basis. The glucose can then be isomerized to a mixture of glucose and fructose by glucose isomerase (GI), an enzyme present in many microorganisms [60]. The product, known as HFCS, has become the dominant sweetener used in food and beverages, displacing fructose syrups derived from the action of invertase on sucrose. Industrial production of HFCS represents one of the largest biocatalytic processes in current practice and is discussed further in the third section of this chapter.

Many organisms are glucose isomerase producers. Most of them produce xylose isomerase with low specificity and glucose can be an alternative substrate for the enzyme. Table 31.6 lists microorganisms used industrially for glucose isomerase production, along with their reported yields. The desirable application conditions of glucose isomerase are pH 7.0–8.0 and 65°C. Glucose isomerase fermentation typically has a cycle time of about 2 days. The fermentation conditions vary from producer to producer. Many glucose isomerase-producing organisms require xylose and cobalt for full enzyme induction. Xylose is too rare and expensive to be used in commercial fermentation processes and cobalt ions remaining in the spent fermentation medium constitute a serious environmental hazard. However, mutants that do not require xylose and cobalt have been obtained for commercial production of glucose isomerase.

Almost every known glucose isomerase is an intracellular enzyme and can only be extracted from the cells in relatively low concentrations, so it is expensive to use this enzyme as a soluble and “once only” enzyme. Immobilized enzyme/cell technology is the key scientific advance that has made the use of glucose isomerase for HFCS production a commercial success. Improved mutants of GI are still actively sought, particularly those with altered pH optima and increased temperature resistance.

Cellulases

Cellulases (EC 3.2.1) are a large group of enzymes that find use in many industrial applications [61]. Cellulose is a homopolymer of glucose monomers, which are linked by β-1,4 bonds. The difference of the linkages distinguishes cellulose from starch and determines the difference in macroscopic properties of these two natural polymers. Starch functions as energy storage in the form of glucose and is consequently used by humans as a food ingredient, whereas cellulose is a structural polymer, which is used for production of paper and textiles. Cellulases can be separated into three distinct groups: the endo-1,4-β-glucanases (EC 3.1.2.4), which catalyze the hydrolytic cleavage within the cellulose polymers; the exo-1,4-β-glucanases (cellobiohydrolases, EC 3.2.1.91), which attack the polymer from the ends releasing cellobiose; and the β-glucanases (EC 3.2.1.21), which catalyze the hydrolysis of cellobiose into glucose monomers.

Cellulases are found in fungi and bacteria. Of commercial interest are fungal enzymes from *Aspergillus* sp. or *T. reesei* and a few bacterial enzymes. They are either used as a multicomponent, which contain all enzyme types and are found in *T. reesei* (*Hypocrea jecorina*), or as a monocomponent enzyme product, which consists of only one of the three types of enzymes. The multicomponent enzyme preparations can be produced from a selected cellulose overproducing strain of the wild-type organism, whereas the monocomponent cellulases are mainly produced in recombinant production systems.

Currently, the main use of cellulases is in the textiles, paper, and laundry detergent industries. In textiles applications, cellulases are used to change the appearance of the fabric by enzymatic removal of cellulose fibrils at the surface and in the so-called stone-washing process of denim jeans, which gives them the aged look. In the paper industry, cellulases are used as process aids, where they increase the efficiency of the papermaking process by saving energy or allowing higher machine speed. The properties of the paper can also be influenced by cellulose usage. As detergent ingredients, cellulases assist in the cleaning process and can maintain the new look of the washed textiles by removing pills or micro fibrils from the surface of cellulose-based garments.

Hemicellulases

Hemicellulases are a diverse set of enzymes that degrade mixed polysaccharides present in plant derived biomass, known collectively as hemicelluloses [62, 63]. Hemicellulose polymers comprise a variety of different sugars, principally 5-carbon sugars (xylose, arabinose), 6-carbon sugars (mannose, galactose), and uronic acids (galacturonic and glucuronic acids). They also contain ester linkages with organic acids such as acetic and ferulic acids, or with alcohols, for example, methyl esters of galacturonic acid. Accordingly, the hemicellulases span a range of different enzyme activities capable of cleaving both glycosidic and ester bonds. Hemicellulases are widely distributed in the microbial world and are found in bacteria, fungi, and yeasts from many environments. Some more common hemicellulases are listed below. A more comprehensive account on hemicellulases can be found in Chap. 33 on Biomass Conversion in this volume and the references cited within.

- α-L-Arabinofuranosidase (EC 3.2.1.55)
- Endo-α-1,5-arabinase (EC 3.2.1.99)
- α-Galactosidase (EC 3.2.1.22)
- Endo-galactanase (3.2.1.89)
- α-Glucuronidase (EC 3.2.1.139)
- Endo-β-1,4-mannanases (EC 3.2.1.78)
- Exo-β-1,4-mannanases (EC 3.2.1.25)
- Endo-β-1,4-xylanases (EC 3.2.1.8)
- Exo-β-1,4-xylanases (EC 3.2.1.37)
- Acetyl xylan esterase (EC 3.1.1.72)
- Ferulic acid esterase (EC 3.1.1.73)

Hemicelluloses, like xylan, arabinogalactan, or glucomannan, are part of many natural materials from plant origin and have a variety of uses. Consequently, xylanases, glucomannanases, and mannanases find use in many technical applications, for example, as detergent additives, for flour processing in baking, as animal feed additives, as well as in the textiles and pulp and paper industry.

The pectins are a related but distinct class of plant polysaccharide composed of poly-β-1,4-galactouronic acid chains with varying degrees of methyl ester functionality. Four different enzyme classes help degrade pectin and are referred to collectively as "pectinases" [64]. They are pectate lyase (4.2.2.2), pectin lyase (EC 4.2.2.10), polygalacturonase (EC 3.2.1.15), and pectin methylesterases (EC 3.1.1.11). The predominant use of pectinases is for the clarification of fruit juices by hydrolysis of haze-forming pectins. Pectate lyase is also used for cotton scouring by modifying pectin within the cotton structure and enhancing the subsequent washing steps. Another textiles application for which hemicellulases are used is for desizing of fabric.

Lignocellulose Degradation

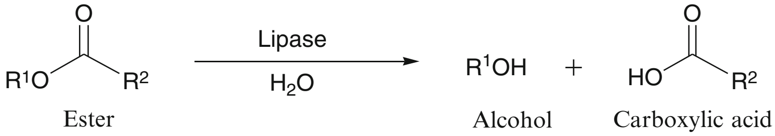
The use of cellulase/hemicellulase blends for conversion of lignocellulosic biomass into fermentable sugars for the production of ethanol and other chemicals promises to greatly expand the market for these enzymes [65]. The quest for economic processes for the utilization of cellulosic biomass has faced many challenges, for example, the cost of and amount of the enzymes required to carry out the process. As much as 100-fold more native cellulase protein (as compared to amylase protein for breakdown of starch) is required for conversion of pretreated substrate (e.g., corn stover) to fermentable sugars. In addition, chemical or thermal pretreatment of cellulosic biomass is needed in order to enable subsequent enzymatic hydrolysis of polysaccharides. Despite these hurdles, much progress has been made in recent years through intensive research programs conducted by government, industry, and academic institutions and have led to the construction of several pilot and demonstration plants, primarily for ethanol production. These efforts have led to identification of new enzymes for biomass degradation, enzymes with greater thermostability, and the optimization of the ratios of the components in enzyme blends.

One strategy to minimize ethanol production cost is to run simultaneous SSF, which utilizes ethanologens engineered to operate in high-temperature environments. Ideally, the fermentation organism has ability to utilize C5 sugars derived from the hemicellulose component, with acceptable productivities in the presence of numerous byproducts of the biomass pretreatment process, leading to lower overall production costs [66]. Several enzyme products designed specifically for biomass processing are now commercially available, for example, the Accellerase™ product line from Genencor.

Lipases and Esterases

Lipases (EC 3.1.1.3) and esterases (EC 3.1.1.1) are enzymes that catalyze the hydrolytic cleavage of ester bonds (Fig. 31.12), but differ in their substrate spectrum. Lipases have the special capability to catalyze the hydrolysis of water-insoluble substrates such as fats and lipids. Like many other enzyme-

Fig. 31.12 Lipases and esterases catalyze the hydrolysis of ester bonds



catalyzed reactions, the ester hydrolysis is a reversible process, which allows using lipases and other esterases for the synthesis of esters. The use of lipases and esterases as biocatalysts is described in the Industrial Biocatalysis section of this chapter.

True lipases show the interfacial activation phenomenon in their catalytic activity pattern. At low concentration of water-insoluble substrates, lipases are almost inactive, and the hydrolytic activity does not increase linearly. At a certain substrate concentration, however, the hydrolytic activity of lipases increases rapidly and the lipase kinetics resembles "normal" enzyme kinetics. This boost in activity is related to the formation of water-insoluble substrate aggregates such as micelles or another second phase. Only when this second phase is present, do lipases become fully active. This interfacial activation is caused by a large conformational change in the 3D structure of the lipases. In their water-soluble form, the active site is covered by a lid, which prevents the substrates from reaching it. At the lipid/water interface, the lid is opened and the active site is accessible to the substrates. In addition, the now accessible area is mainly hydrophobic, which gives the open-form lipase the shape and behavior of conventional surfactant molecules with a hydrophilic and a hydrophobic moiety in one single molecule.

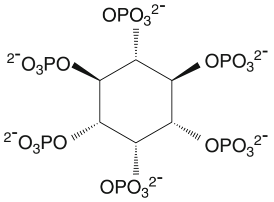
Lipases are found in a wide variety of bacteria, yeasts, and filamentous fungi. Due to their unique properties, lipases are used in all applications where lipids are modified or need to be removed [67]. In the detergent industry, lipases are added to laundry detergents for the removal of fat-containing stains. In the paper industry, lipases remove fatty pitches from paper in the manufacturing process. These pitches stem from remaining resin of the wood chips.

In the food industry, lipases are used in lipid modification processes. In these processes, the texture, digestibility, or physical properties of natural lipids are modified by lipase-catalyzed transesterification reactions with lipids other than the original fatty acids. In the baking industry, lipases are used to influence the quality of bread through modification of the wheat flour lipids. Finally, lipases are used for flavor enhancement of cheese in the dairy industry. The phospholipases (EC 3.1.1.4) related class of enzymes which act upon phospholipids such as lecithin [68]. The major use of these enzymes is for degumming of vegetable oils, for egg processing, and in the baking industry.

A new industrial application for lipases has been developed in the field of renewable energy. Lipases are used for methylation of plant oils such as rapeseed oil. The resulting methylated oils (biodiesel) are used as a replacement or supplement for fossil fuel-derived diesel. As of today, the costs of the biocatalyst, however, prevent its commercial application and chemical processes such as saponification of fats with sodium methoxide is currently preferred.

Phytase

Phytases are a class of phosphate ester hydrolase (a phosphatase) that act upon phytic acid (phytate, myo-inositol-1,2,3,4,5,6-hexakisphosphate), the dominant form of phosphate in plant feedstuffs, including cereal grains and oil seeds. The use of phytases as additives in feed for monogastric animals has expanded greatly in recent years. They increase the bioavailability of phosphate, thus enhancing animal growth while reducing the amount of phosphate that would otherwise end up in the environment [69].



Phytate (myo-inositol-1,2,3,4,5,6-hexakisphosphate)

Most commonly used in swine and poultry feed, phytases also increase the bioavailability of other minerals (calcium, magnesium, iron, and zinc) and nutrients (amino acids, proteins) by hydrolysis of complexes with phytate (phytin) that tend to sequester these nutrients.

Phytases are found in many organisms where their functions include phosphate metabolism and the modulation of inositol phosphate regulatory metabolites. Phytases are characterized according to the position at which they initially remove phosphate from phytic acid. Plant phytases (EC 3.1.3.26) remove phosphate from the 4- and 6-positions of phytic acid, whereas those from microbial sources (EC 3.1.3.8) such as *Aspergillus* species tend to remove phosphate from the 3-position. There are exceptions to these rules, for example, phytases from *E. coli*, *Buttiauxella* and *Peniophora* sp. act at the 6-position of phytate. Both acid- and alkaline-phytases have been described. Those from microbial sources usually belong in the former category with pH optima in the 4.5–6.5 range. Phytases expressed in eukaryotic organisms are typically glycosylated, a feature than has been found to confer stability by reducing the protein aggregation at elevated temperatures. There are four different types of phytase, listed in Table 31.7.

Table 31.7 The four known phytase families

Phytase family	Description	Example
Histidine acid phytases (HAP)	• Largest class of phytase • Concensus active site motif is Arg–His–Gly–Arg–X-Pro • Two-step catalytic mechanism	*Aspergillus niger* HAP *Escherichia coli* HAP
Beta-propeller phytases (BPP)	• Structure resembles a six-bladed propeller • Degrades phytate in soil and water	*Bacillus subtilis* phytase C *Pedobacter nyackensis* phytase
Purple acid phytases (PAP)	• Metalloenzyme first isolated from the cotyledons of germinating soybeans • Also present in other cereal grains	Soybean (*Glycine max*) PAP Barley (*H. vulgare*) PAP
Protein tyrosine phosphatase-like phytase (PTP)	• Isolated from microorganisms present in ruminant guts • Concensus sequence of His–Cys–(X)5–Arg	*S. rumanatium* PTP

Bacterial and fungal phytases are most readily produced at scale and possess the activity and stabilities required for an industrial product. Nonetheless, most wild-type phytases have temperature optima in the 40–60°C range and considerable activity is lost at the elevated temperatures (>90°C) attained in the steam pelleting process used to manufacture feed pellets. Ideally, a phytase product must retain at least 80% of the initial activity upon transient exposure to temperatures of 90°C or greater. For this reason, both protective enzyme granulation technologies and phytases engineered for greater thermostability have been developed to minimize loss of activity during the feed pelleting process. Commercial Phytase products include Phyzyme® XP (Danisco), Ronozyme® (DSM), and Natuphos™ (BASF).

Phytases have also found application in the starch processing industry where they are used to reduce the levels of phytate derived from corn and other feedstocks. Enzyme blends containing both α-amylase and phytase are commercially available. Reduction of phytate in the starch liquefaction process has numerous benefits including;

- Ethanol yield improvement
- Removal of phytate-mediated inhibition of α-amylases
- Viscosity reduction during liquefaction
- Release of inositol, a yeast nutrient
- Production of low-phytate, high phosphate DDGS for animal feed

Overall the market for phytase is poised for further growth, particularly in Asia and other developing regions, driven by demand for meat and need to minimize the associated effects on the environment.

Oxidoreductases

Oxidoreductases (EC family 1) are enzymes that add or remove electrons from a substrate. Cofactors are usually required to assist electron transfer and a stoichiometric electron donor or acceptor is always needed. Applications for oxidoreductases have been limited in comparison to the hydrolases, but have grown substantially in recent years [70]. Oxidases using oxygen as a terminal electron acceptor have found the greatest application, whereas those that require an electron source are still restricted in their practical application. Oxidoreductases of particular prominence are discussed below.

Glucose oxidase (EC 1.1.3.4) converts D-glucose into D-gluconolactone utilizing molecular oxygen (O_2) as the ultimate electron acceptor and producing hydrogen peroxide in the process [71]. This enzyme is used for scavenging traces of oxygen in food products, generation of hydrogen peroxide as a preservative, and for the detection of glucose in body fluids. While the later application does not consume a large amount of enzyme by weight, it forms the basis of modern glucose meters used by diabetics and others to monitor blood glucose levels. Glucose oxidase is commonly used in conjunction with catalase (EC 1.11.1.6), an oxidoreductase that converts hydrogen peroxide into oxygen and water [72]. Catalase is also used to decompose excess hydrogen peroxide in textiles bleaching applications.

Laccases (EC 1.10.3.2) are a class of copper-containing oxidases that transfer electrons from phenolic substrates to oxygen, producing water in the process [73]. The phenolic substrates are also known as mediators and can remove electrons from a wide array of substrates including lignin and dyes. Laccases occur in plants, bacteria, and fungi and have a characteristic blue color in their pure form. Commercial applications include bleaching of indigo in denim manufacture, decolorization of dyes in wastewater, and for degradation of lignocellulosic biomass [74].

Emerging Industrial Enzymes

New applications for established classes of industrial enzymes such as proteases and amylases are developed every year [6]. By contrast, products based upon new classes of enzyme are less common, although there is great potential for new enzymes that enable chemistries which cannot be performed under mild conditions. Some examples are discussed below.

Organophosphate hydrolase (OPH) (EC 3.1.8.1) and organophosphorous acid anhydrolases (OPAA) (EC

3.1.8.2) are enzymes that detoxify organophosphorous compounds including pesticides (e.g. paraxon, parathion, malathion) and chemical warfare agents (e.g., sarin, soman, tabun) [75]. These enzymes are being assessed for use by primary responders to counter chemical agents, although even larger potential lies in dealing with organophosphate pesticide contamination in agriculture.

Asparaginase (EC 3.5.1.1) is an enzyme that converts the amino acid asparagine to aspartic acid and ammonia by hydrolysis of the side-chain amide functionality. This class of enzyme is used to reduce the formation of acrylamide, a neurotoxic compound, in starchy foods such as French fries, by treatment of the foodstuff prior to cooking [76]. Products containing asparaginase are sold under the tradenames Acrylaway® and PreventASe™.

A bacterial arylesterase capable of peracid formation under aqueous conditions was developed by Genencor for biobleaching applications and is currently sold under the tradename PrimaGreen® EcoWhite. This enzyme has a unique active site configuration which disfavors hydrolysis of esters and readily performs both perhydrolysis and acyltransfer reactions [77]. The enzyme is formulated with propylene glycol diacetate and catalyzes the formation of peracetic acid in the presence of dilute aqueous hydrogen peroxide.

Section III: Industrial Biocatalysis

The use of enzymes for the synthesis of bulk and fine chemicals represents a somewhat specialized application relative to their wider industrial uses. Nonetheless, biocatalysis is becoming increasingly relevant within the chemical industry for the production of a wide range of materials (see Table 31.8) [5, 16–18]. Broadly defined, a biocatalytic process involves the acceleration of a chemical reaction by a biologically derived catalyst. In practice, the biocatalysts concerned are invariably enzymes and are used in a variety of forms. These include whole cell preparations, crude protein extracts, enzyme mixtures, and highly purified enzymes—both soluble and immobilized. The products of biocatalytic processes are as varied, ranging from the synthesis of fine chemicals and pharmaceuticals to polymer precursors, flavor, fragrances, foodstuffs, and fuels. The common theme is that the use of a biocatalyst has either lowered the cost of production or facilitated the development of a new product.

Biocatalysts often enable one to perform chemical transformations with greater selectivity or under milder conditions than might be achieved through conventional chemical means [78]. Large reductions in waste streams have been achieved in many instances. The term “bioconversion” has also been used in order to distinguish biocatalytic processes involving the transformation of a defined starting material into specific products using either isolated enzymes or resting cells. Despite the widespread recognition of the potential advantages of biocatalysis, the number of large-scale industrial processes is still relatively limited. A summary of the products of these processes is listed in Table 31.9.

The use of biocatalysis for the production of chemicals started to receive serious interest in the 1960s with the development of immobilized aminoacylases for the production of chirally pure amino acids by Tanabe Seigaku of Japan, as well as the application of penicillin acylase for the production of 6-aminopenicillanic acid (6-APA), a key intermediate in the production of semi-synthetic antibiotics. The production of HFCS began in 1968 with implementation of a batch process using whole cells originally developed by Takasaki et al. [79]. The industrial production of HFCS remains as the largest bioconversion worldwide. These applications coincided with the growing use of proteases for cleaning and significant improvements in the production

Table 31.8 Comparison of biocatalysis to chemical synthesis for chemical production

• Advantages	Disadvantages
• Mild reaction conditions	• Low volumetric productivity
• Aqueous medium	• Substrate solubility issues
• Highly stereo-, regio-, and chemoselective	• Unwanted reactions with impure preparations
• Unique and varied chemistry	• Restricted set of substrates
• Environmentally friendly	• Costly recovery of products
• High catalytic efficiency	• Poor operational stability
• Ability to fine tune catalysts	• Long development cycles

Table 31.9 Examples of products made through the application of biocatalysis

Scale (t/year)	10	$>10^2$	$>10^3$	$>10^4$	$>10^5$
Product	Glycidylbutyrate Butyl glucosides Styrene oxides Oligosaccharides	D-Pantothenic acid L-Malic acid L-Methionine L-Valine *R*-mandelic acid L-Carnitine	Aspartame L-Aspartate Cyclodextrins (*S*)-CPA	6-APA Cocoa butter Acrylamide	HFCS

(S)-CPA (*S*)-chloropropionic; *6-APA* 6-aminopenicillanic acid; *HFCS* high fructose corn syrup

Table 31.10 Enzyme classes used in biocatalysis

Enzyme	Reactions catalyzed
Lipases	Ester formation and hydrolysis
Proteases	Ester and amide hydrolysis, peptide synthesis
Esterases	Ester hydrolysis
Aminoacylases	Amide formation and hydrolysis
Acyltransferases	O- and N-acylation
Epoxide hydrolases	Hydrolysis of epoxides
Phosphoesterases	Hydrolysis of phosphate esters
Glycosidases	Glycoside hydrolysis/formation
Oxygenases	Hydroxylation, dihydroxylation, epoxidation
Glycosyltransferases	Glycosyl transfer
Nitrilases	Nitrile hydrolysis
Oxynitrilases	Cyanohydrin formation
Oxidoreductases	Reduction of aldehydes, ketones, and enolates
Aldolases	Aldol reactions (C–C bond formation)
Isomerases	Isomerization of carbohydrates, racemization, and epimerization

and isolation of industrial enzymes. The advent of recombinant DNA technology in the 1970s was followed by the development of the powerful PCR reaction for DNA amplification in 1984 by Kary Mullis while working at Cetus Corporation. Aside from revolutionizing biomedicine, these and other technologies have led to the ability to alter and improve many wild-type enzymes to the point that new bioconversions are now economically feasible.

The majority of industrial biocatalytic processes involve the use of hydrolytic enzymes including proteases, transaminases, glycosidases, aminoacylases, and lipases as well as several additional enzyme classes (Table 31.10) [80]. In some instances, hydrolytic enzymes can be used to drive the reverse reaction as in the formation of ester bonds through the use of lipases. In contrast, oxidases and other enzymes requiring movement of electrons commonly rely on the supply of a cofactor that may need to be recycled for practical application. These processes are typically limited to those involving respiring cells capable of regenerating such cofactors, or through the supply of a stoichiometric electron donor/acceptor, for example, hydrogen peroxide or oxygen. An emerging application of redox enzymes is in diagnostics and other sensitive analytical devices where direct electronic detection of a chemical reaction is possible.

One of the greatest hurdles for the application of biocatalysis is the need to operate processes under conditions that can differ dramatically from those in which the enzymes evolved. Many techniques are used in order to preserve catalytic activity and minimize the costs associated with the biocatalyst. In cases where the cost of the biocatalyst is a concern, an enzyme might be immobilized and used in a packed column or a fluidized bed reactor so as to enable reuse. Here also the enzyme must be stable for extended periods and may even be used under nonaqueous conditions and elevated temperatures. Recombinant technology has revolutionized the applications of biocatalysts through the ability to modify existing proteins. When combined with high-throughput screening and other analytical methods, it is now possible to redesign and improve wild-type enzymes such that they can be used in areas not previously possible. Coupled with these advances are those in the large-scale production and recovery of industrial enzymes, in addition to improvements in formulation and stabilization of enzymes.

The following sections focus on the elements of industrial biocatalysis, including the definition of a biocatalytic process, rendering, biocatalysts into immobilized forms, and performing bioconversions using whole cells. Key issues relating to the design of bioreactors are highlighted and several larger-scale bioconversions are discussed in further detail, followed by some emerging trends in biocatalysis.

Biocatalytic Processes

The nature of a biocatalyst often defines its utility for industrial bioconversions and determines the conditions under which it can be used. For example, the biocatalyst must be stable enough for practical application and of sufficiently low cost so as not to affect the overall economics of the process. Biocatalysts come in many forms including highly purified enzymes, enzyme mixtures, and whole cells. The form used is often related to cost and performance considerations. Although a crude enzyme preparation might be relatively cheap, the presence of additional enzyme activities might affect the purity and yield of the product. Similarly, the need for cofactor recycling might weigh against the use of a purified enzyme in favor of a respiring whole cell. Another important factor relates to the exquisite selectivity of many enzymes. This has both advantages and disadvantages in that a particular enzyme might be too narrow in its substrate preference to allow the use of unnatural substrates, thus limiting the potential application of that enzyme. Interestingly, some enzymes demonstrate broad substrate selectivity while retaining a high degree of stereoselectivity. A case in point is the lipase B isolated from *Candida antarctica* [81]. Despite the fact that this enzyme was isolated from a psychrophilic organism (cold-adapted), it demonstrates a high degree of thermostability, being functional at over 80°C, especially in an immobilized form. Another enzyme displaying broad specificity is rabbit muscle aldolase, useful for the formation of C–C bonds [82]. Selection and development of the right biocatalyst for a given transformation is often the key for successful commercialization of a biocatalytic conversion.

Immobilized Enzymes

There has been considerable effort directed toward the immobilization of both enzymes and whole cells in a wide array of formats [83, 84]. Initial attempts to immobilize enzymes on naturally derived supports such as charcoal were conducted early in the twentieth century and eventually led to the development of more robust biocatalysts immobilized on synthetic resins by the mid-1950s. Immobilization often confers a number of advantages relative to the free biocatalyst including ease of removal from the process stream, potential for reuse, improvements in stability, favorable alterations in kinetic parameters, suitability for continuous production, and in some cases the ability to operate in organic solvents. The focus of this section is on the immobilization of enzymes; however, many of the same principles apply to whole cells, the primary difference being the fact that immobilized cells are often less stable than individual enzymes and may contain additional undesired enzyme activities.

Immobilization needs to improve the performance of an enzyme enough to offset the costs associated with the procedure. Such gains can be measured in terms of improvement in the total amount of product produced per unit of enzyme, an increase in the rates and volumetric efficiency of a bioconversion, improvement in the ease of removing the biocatalyst, or through the enabling of new applications for a given enzyme. It is often the case, however, that the cheapest immobilization methods suffer from a number of drawbacks including lack of both enzymatic and mechanical stability, leaching of the enzyme, fouling of the support, and limited enzymatic activity. The many methods for producing immobilized enzymes can be divided into these subcategories:

1. Adsorption to a matrix such as carbon, chitin, diatomaceous earth, and ion exchange resins
2. Crosslinking enzyme crystals and whole cells with gluteraldehyde and other agents
3. Gel entrapment in silica sol-gels, alginate, and protein matrices
4. Covalent attachment to resins and other carriers
5. Encapsulation within a membrane or liposome

Many factors influence the catalytic efficiency and kinetics of an immobilized enzyme. The immobilization process itself can lead to loss of enzymatic activity through incomplete capture of the enzyme or through denaturation of the enzyme protein. Such denaturation may arise from the action of reagents used in the immobilization process, for example, the use of carbodiimides during covalent immobilization methods, or through partial unfolding of the protein upon contact with hydrophobic surfaces such as those encountered in the adsorption of enzymes onto polymeric resins. Immobilized enzymes often demonstrate dramatic improvements in stability over free enzymes, especially in organic solvents or at elevated temperatures. This is particularly the case where enzymes have been attached to a solid support through multipoint covalent attachment or entrapped within a rigid matrix. In such instances, the potential for loss of activity through unfolding of the enzyme is reduced.

Kinetics of immobilized enzymes. Another major factor in the performance of immobilized enzymes is the effect of the matrix on mass transport of substrates and products [85]. Hindered access to the active site of an immobilized enzyme can affect the kinetic parameters in several ways. The effective concentration of substrates and products is also affected by the chemistry of the matrix, especially with regard to the respective partition coefficients between the bulk solution and the matrix. Immobilization of an enzyme typically reduces the rate of diffusion of a substrate to the active site of an enzyme and increases the apparent K_m while reducing V_{max}. The nature of the mass transfer effect depends on the fashion in which the enzyme is immobilized. Enzymes immobilized on the surface of a carrier will experience external mass transfer limitations between the bulk solution and the surface, whereas those entrapped within a porous matrix are also affected by internal mass transfer limitations due to the reduction in the rate of diffusion of substrate and products through the matrix.

The effect of diffusional limitations is given by the Damköhler number D_a, defined as the maximal rate of reaction divided by the maximal rate of diffusion:

$$D_a = V_{max}/k_L[S_b] \tag{31.6}$$

where $D_a \gg 1$ diffusion limits the observed rate, whereas when $D_a \ll 1$ the reaction rate is limiting. The effectiveness factor η is commonly used to assess the effect of immobilization on a given enzyme and is defined as the ratio of the rate with diffusional limitation vs. the rate without diffusional limitation. The relationship is a function of bulk substrate concentration β, defined as $[S]/K_M$ in addition to the ratio of the bulk substrate concentration $[S_R]$ to that within the matrix $[S_r]$. Thus, the rate of reaction within a matrix r_s is given by the modified Michaelis–Menten equation:

$$Rs = \eta(V_{max}[S]/K_m + [S]) \tag{31.7}$$

Current methods for large-scale immobilization. Although there are numerous methods for enzyme immobilization described in the scientific literature, relatively few methods have been successfully applied on an industrial scale. By volume the largest process is the immobilization of glucose isomerase for the production of HFCS. Several methods have been used, summarized below:

- Adsorption to polyethylenimine (PEI) treated alumina, followed by gluteraldehyde cross-linking (UOP, 1981)

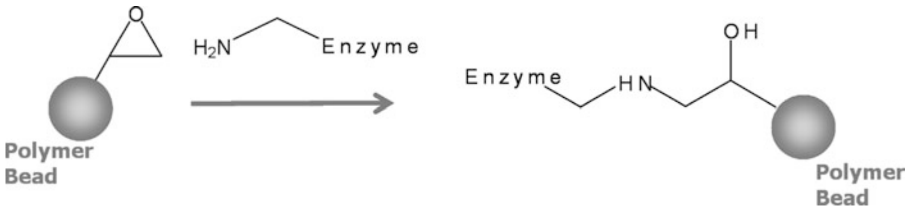


Fig. 31.13 Covalent attachment of enzymes to oxirane-functional polymeric beads (Courtesy of M. Elizabeth Miller and Rohm and Haas)

- Adsorption onto anion exchange resins (e.g., DEAE-cellulose/TiO_2 based resin)
- Cross-linking of lysed cells with gluteraldehyde followed by extrusion
- Incorporation into clay/PEI/gluteraldehyde cross-linked matrix, mechanical formation of granules

Over 500 t of immobilized GI are produced per annum, the majority through the incorporation of GI into a porous clay-based composite. The largest producer is Genencor. The process begins with a whole-cell lysate derived from GI fermentation to which is added PEI, bentonite clay, and diatomaceous earth, followed by cross-linking with gluteraldehyde. The resulting flocculant solid is filtered and pressed to remove excess water. Particles are fashioned mechanically by extrusion and dried in a fluidized bed dryer. The resulting immobilized GI is extremely stable, with a half-life of over 1 year when used in a packed bed reactor at temperatures of over 60°C. One kilogram of immobilized GI is sufficient to produce 20,000 kg of HFCS.

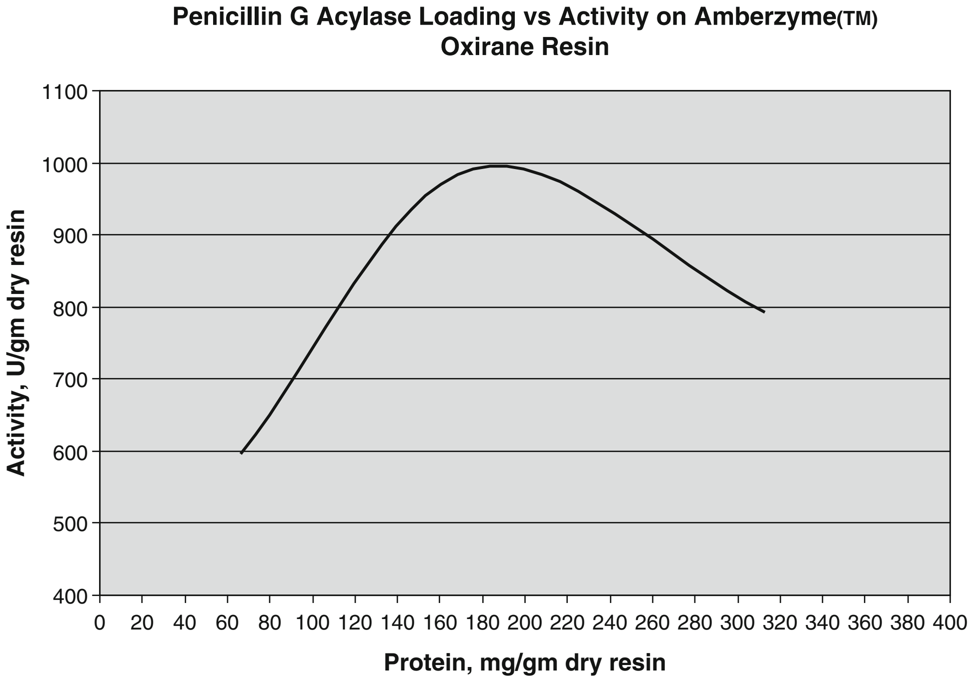
Another method for large-scale immobilization of lipases involves the formation of silica granulates, a technology developed by Novozymes A/S (Denmark) with the aim of producing a low-cost immobilized lipase for transesterification of food oils [86]. This process involves initial coating of a silicate powder with a crude lipase solution, followed by addition of a binding agent and mechanical granulation. The resulting granulates are typically 100–300 μm in diameter and are best suited to nonaqueous biocatalysis. A process for the transesterification of food oils based on a silica granulate containing *Thermomyces lanuginosa* lipase, Lipozyme TL-IM, was developed in a joint venture between Novozymes and ADM and has produced transesterified oils in the United States since 2002. The process itself uses a portable packed bed reactor operating at temperatures well below that required for chemical transesterification. Another advantage of the bioprocess is the fact that that product does not need to be purified by extraction with water as is necessary in the traditional chemical process.

A considerable number of industrial bioconversions utilize covalently immobilized biocatalysts. Examples include Penicillin acylases V and G, aminoacylases, and aspartase. In some cases the biocatalyst is immobilized through cross-linking and in others the catalyst is captured by a reactive resin [87]. Covalent immobilization often leads to extremely stable catalysts with high potential for reuse and exhibiting minimal leaching of enzyme during operating conditions. A variety of both organic and inorganic supports has been used, typically modified with a reactive functional group. The oxirane-based acrylic resins Eupergit C® (Röhm GmbH, Germany) and more recently Amberzyme™ (Rohm and Haas, USA) have proven to be versatile carriers for many enzymes. Attachment of an enzyme to an oxirane resin involves agitating a solution of the enzyme with the resin at approximately pH 8 for 12–24 h, followed by washing to remove non-covalently bound material (Fig. 31.13). The absence of amine-containing buffers (e.g., TRIS) or impurities is an important requirement for achieving high enzyme loading on the resin. The total activity of enzyme-functional beads is proportional to the amount of enzyme bound up to a certain point, past which the specific activity falls, most likely due to mass transport limitations. This effect is depicted in Fig. 31.14.

Adsorption of enzymes to various polymeric resins is a straightforward means for immobilization. Zwitterionic molecules such as proteins can bind to both anionic and cationic ion exchange resins. Hydrophobic macroporous resins are also useful for immobilizing many enzymes, particularly lipases. For example, an immobilized form of *Candida antarctica* lipase B (CAL-B) on acrylic resin has been sold for many years under the name, Novozyme® 435 (N435). The enzyme is produced in a modified *Aspergillus* organism by submerged fermentation and is subsequently adsorbed onto a macroporous acrylic resin. Once immobilized, the enzyme is very robust and ideally suited to reactions in organic media where it has been widely used by the research community. Several pilot-scale processes have been developed based upon this catalyst including the production of sugar-based surfactants through the solvent-free esterification of ethyl glucoside with long-chain fatty acids. N435 has also been used for the synthesis of chiral alcohols, amines, and carboxylic acids. The use of this biocatalyst for the synthesis of biodegradable polyesters was developed by Baxenden (United Kingdom) and scaled to 2 t per annum. The cost and limited availability of this catalyst is one of the limiting factors in the wider use of CAL-B in polymer synthesis.

The last decade has seen great progress in materials science, an example being the development of practical methods for the synthesis of a great variety of mesoporous

Fig. 31.14 Relationship between Penicillin G Acylase loading level and on-bead enzyme activity using Amberzyme™ Oxirane resin: loadings at higher challenge levels (Courtesy of M. Elizabeth Miller and Rohm and Haas)



solids and nanoparticles. A number of researchers have used these materials as substrates for enzyme immobilization [88]. Advantages of nanomaterials for enzyme immobilization include very high surface areas, narrow size distributions, and the ability to tailor surface chemistries for optimal enzyme activity. Nanomaterials have also been designed to facilitate electron transport between electrodes and redox active proteins.

Enzymes can also be immobilized using techniques that mimic natural processes for the biosynthesis of inorganic materials [89]. One strategy employs a templating molecule capable of precipitating an inorganic solid like silica (SiO_2) from a soluble precursor—sodium silicate being one example. An enzyme can be premixed with the templating molecule, or even covalently attached to a templating agent. Addition of the enzyme/template solution to an inorganic precursor results in the rapid formation of a colloidal coprecipitate consisting of the enzyme, the template, and the inorganic matrix (Fig. 31.15). A portion of the enzyme becomes entrapped within the composite matrix, often retaining high catalytic activity. The solid can be filtered and dried, or spray-dried directly. An application of this technology has been to formulate improved anti-fouling paints for ship hulls as an alternative to toxic tin-based coatings [90].

Whole-Cell Biocatalysis

Whole-cell biocatalysis is a productive and practical style of conducting biocatalytic reactions [91]. Such reactions, as implied by the term, are done with structurally intact cells. Usually, viable respiring cells are used, but not exclusively. There are many reasons why a whole-cell reaction might be preferred to a cell-free reaction using crude or purified enzymes. Often, whole-cell biotransformations use enzymes, which are not normally excreted into the growth medium. Quite often these enzymes, which are normally intracellular, are unstable outside of the cell and quickly lose activity making them unsuitable for reactions without further stabilization work. Thus, the specific productivity or total turnovers per mole of catalyst may be severely compromised compared to that seen when used in the whole cell due to inactivation of the enzyme in the reaction conditions.

Whole-cell biocatalytic reactions are most often used when the biotransformation to be conducted requires the input of energy. In biological systems this usually takes the form of reduced pyrimidine nucleotides or ATP, but can be many of a number of reduced cofactors or modified reaction components. Using the whole cell allows the technologist to take advantage of the intact, preformed cellular machinery to efficiently provide the required cofactors or components. In order to provide the energy to catalyze these reactions, a source of reducing power is usually required. The co-oxidation of an oxidizable substrate such as glucose or ethanol can provide this energy. The partitioning of the enzymes inside the cells from the bulk medium of the reaction also can be advantageous to let the cellular machinery keep the reaction medium around the enzymes constant and allow for the accumulation, removal, or in other respects processing of the reaction products (see Fig. 31.16). Many techniques exist for the in situ removal of reaction products or side products using whole cells [92]. This task is often

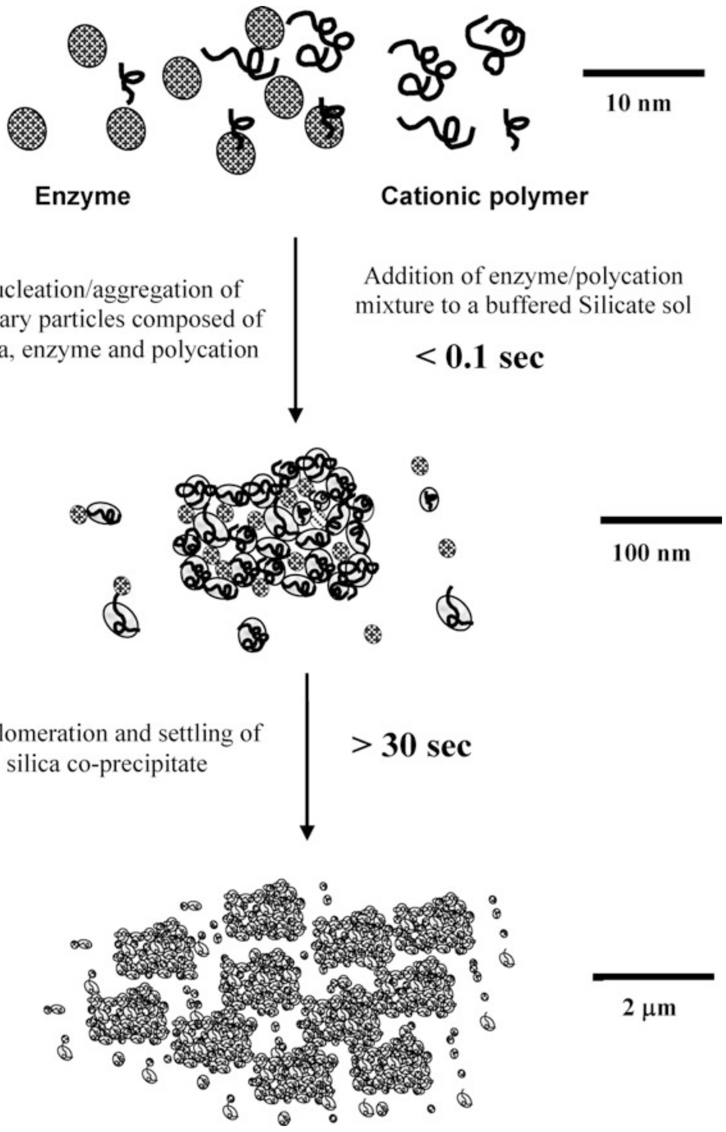


Fig. 31.15 A template-driven silicate coprecipitation process results in the formation of a active enzyme/template/silica coprecipitate

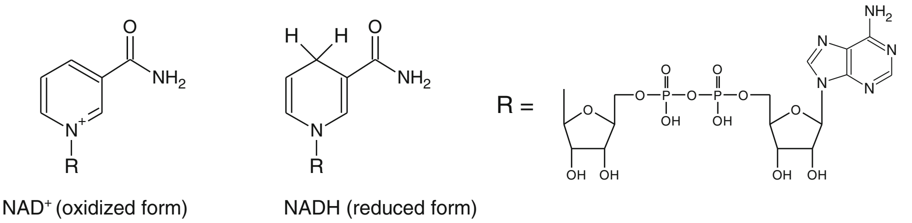

Fig. 31.16 Oxidized and reduced forms of nicotinamide adenine dinucleotide

more difficult with cell-free reactions unless the catalyst is immobilized or in some other way partitioned from the bulk reaction medium.

Another major factor when considering whole-cell vs. cell-free reactions is the overall reaction kinetics. Some enzymatic reactions utilize a complex multicomponent enzyme system. Reconstitution of the crude or purified enzyme components are not usually as effective in vitro as they are when they remain in the intracellular milieu. Whole cells have often been called “little bags of enzymes.” Although this is an oversimplification, it is a useful concept to consider. Whole cells sequester the enzyme components in a small but concentrated form, which is usually optimal for high efficiency. Whole cells also contain co-factors, including the systems that recycle them and control pH and ionic strength. Altogether these factors combine to make whole cells a very useful form for the presentation and use of sensitive enzyme catalysts.

A practical point of using whole-cell biocatalysts is their inherent ease of preparation, use, and removal. There is a variety of growth considerations, as with any fermentation, but the major ones with respect to the use in biotransformations surround the induction of the enzyme(s) of interest and the repression of enzymes which might compete with the desired process or degrade the desired catalyst. Generally, a medium can be used in which the cells can be used directly after growth for the biotransformation. Some consideration needs to be given to the extraction of the product with respect to the growth medium. Often medium components from rich media used for fermentations can interfere with recovery or extraction procedures. The effort required to reduce the complexity of the medium, to one as defined as possible, is usually worth the trouble. Having the resulting growth medium as much like water as possible simplifies downstream work. If the cells must be removed from the growth medium and resuspended in a different biotransformation medium, they can be removed by centrifugation or the medium exchanged by microfiltration. Once the biotransformation is complete, the catalyst can be removed by centrifugation or filtration. Concentrating the medium after the biotransformation by removal of water will enhance many recovery processes. The concentration of the medium salts in this process often makes extraction much more efficient.

Although there are many advantages to the use of whole cells for biotransformations, there are certain limitations that must be considered. One consideration is the transport of substrates and products across the cell membrane. In life, the cell membrane is a proton-tight barrier to the rest of the world. It is generally impermeable to charged molecules and to water, but may have permeability to hydrophobic molecules. Often cells have specific transport systems that move compounds in and out as the cell needs them. In order for a whole-cell biotransformation to proceed, the substrate of interest must be transported across the cell membrane to the active enzyme or enzyme system. The same issues exist, of course, for the reaction product. Although it is not generally an issue, for biotransformations where the substrate is not transported but enters the cell by passive diffusion, mass transport must be considered. A simple dilution of the cell density can demonstrate if this is a problem if the rate is not proportional with cell density. Another limitation, which may be observed, is the nonspecific metabolism of the substrate or product by other enzymes in the cell. It is not uncommon to find a small percentage of the substrate or product oxidized or reduced by enzymes not in the desired pathway or reaction. This can sometimes be addressed by genetic techniques or by growth conditions. The commercial-scale use of whole-cell biocatalysts is typically limited to cells produced on-site and transferred under containment to the process vessel given the biosafety and economic issues inherent to transporting live microbes in large quantities.

A variation on the whole-cell biotransformation theme is the use of permeabilized cells. Whole cells can be rendered permeable to small molecules yet remain essentially intact by contacting them for a short time with low concentrations of solvents. This process has the effect of making “holes” in the cellular membrane while leaving enough of the cell membrane and cell wall intact to still contain the enzymes and other macromolecules. The permeabilized cells can then be treated much like immobilized enzymes. This technique is especially useful when transport issues are found to be limiting the reaction.

A related topic appropriate to this discussion is the use of solvents in whole-cell or permeabilized cell biotransformations. Solvents can be added to increase the solubility of substrates in the reaction medium. The specific solvent and concentration must be empirically determined and can be highly variable. Solvents, in low concentration, can serve as a source of energy for reactions requiring reducing equivalents. In such cases the solvents may serve to both supply energy and help solubilize the substrate. Although not generally considered a solvent, the use of a second nonmiscible liquid such as vegetable oil or hexadecane can be used in many whole-cell biotransformations to “buffer” the concentration of substrates and products with respect to the aqueous phase. Two liquid phase reactions can dramatically increase the yield obtainable from a specific biotransformation.

Bioreactor Configurations

The manner in which a bioconversion is performed is dictated by the nature of the biocatalyst, the chemistry involved, and process economics [93]. The overall aims of a bioconversion are the same as for any process, to maximize the production of a given material at the lowest overall cost. In some cases, this might mean maximizing the volumetric productivity (Qp in units of mol m^3/s) of the reactor. Alternately, it might be most important to enable the more efficient recovery through maximizing the ratio of desired to undesired products. If the cost of the biocatalyst is limiting then the catalyst productivity (P_{cat}) must be maximized, a function of the intrinsic activity of the catalyst itself and the fashion in which it is used.

A variety of reactor configurations has been developed for both batch and plug-flow modes of operation. Bioconversions, involving the transformation of a defined substrate into a product, are typically less demanding than fermentations involving growing cells where many additional factors such as oxygenation, feed rate, and the supply of trace nutrients may need to be tightly monitored. Nonetheless, the implementation of bioconversions, particularly larger scale operations, requires a considerable degree of engineering. Important factors that must be considered when selecting a

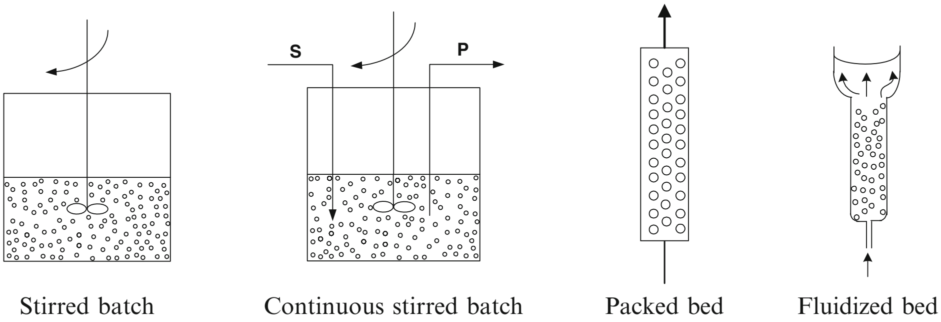

Fig. 31.17 Bioreactor configurations

reactor configuration for performing a given bioconversion include:

- Nature and solubility of substrates and products
- Form of the biocatalyst (whole cells, soluble or immobilized enzymes)
- Cost of biocatalyst relative to the overall process
- Kinetic parameters of the biocatalyst
- Substrate/product equilibrium
- Degree of product or substrate inhibition of the biocatalyst
- Operational stability of biocatalyst
- Product recovery

The bioreactor configurations in common use are illustrated in Fig. 31.17.

Batch reactors. The majority of smaller-scale bioprocesses are carried out in batch mode. A key advantage of many batch reactors is the ability to run a range of different bioconversions with the one piece of equipment. The main disadvantage is the downtime required for emptying and recycling the reactor and cases where product inhibition of the biocatalyst is significant. The simplest configuration involves the use of a stirred vessel containing the biocatalyst to which one or more substrates (S_t concentration) are added resulting in conversion to the desired product(s) over a given time. The required batch time (T_b) of such a system is a function of the kinetic parameters of the biocatalyst (K_m, V_{max}), the catalytic density (maximum enzyme activity per volume), and the initial substrate concentration (S_o), represented in the equation below.

$$(S_o - S_t) - K_m \ln(S_t/S_o) = \text{Catalytic density} \cdot T_b \quad (31.8)$$

In some cases, continuous extraction of products allows extended operation and high volumetric efficiency. Reactors run in this mode are referred to as continuous-stirred batch reactors (CSBR). In this case, the bioconversion is run under approximately steady-state conditions where the position of reaction equilibrium lies toward the products of the conversion. In this case the concentration of product (proportional to $S_i - S_o$) at a given reactor residence time becomes a function of both the flow rate (Q) into the reactor and reactor volume, in addition to the factors discussed above for batch mode reactors (i.e., catalyst parameters and density, inlet substrate concentration S_i, and outlet substrate concentration S_o).

$$\begin{aligned} Q \cdot (S_i \cdot S_o) &= V_{max} \cdot S_o/(K_m + S_o) \\ &= (\text{Catalytic density} \cdot \text{Reactor volume}) \\ &\quad \cdot S_o/(K_m + S_o) \end{aligned} \quad (31.9)$$

Another favorable aspect of stirred batch reactors is the fact that they are compatible with most forms of a biocatalyst. The biocatalyst may be soluble, immobilized, or a whole-cell preparation; in the latter case a bioconversion might be performed in the same vessel used to culture the organism. Recovery of the biocatalyst is sometimes possible, typically when the enzyme is immobilized or confined within a semi-permeable membrane. The latter configuration is often referred to as a membrane reactor. An example is the hollow fiber reactor where enzymes or whole cells are partitioned within permeable fibers that allow the passage of substrates and products but retain the catalyst. A hollow-fiber reactor can be operated in conjunction with the stirred tank and operated in batch or continuous mode. A tubular reactor configuration consisting of hollow fibers is also useful for continuous plug-flow mode operation.

Plug-flow bioreactors. Continuous bioconversions can also be carried out using so-called “plug-flow” reactors where a substrate is converted to a product by passage through a biocatalyst in immobilized form. The packed-bed bioreactor is the most common, although fluidized-bed bioreactors are also used. The principle advantages of packed-bed reactors are the greatly increased catalytic density relative to batch reactors allowing for compact designs and suitability for continuous production. There are several technical issues that need to be addressed before a given bioprocess can be performed in this fashion. The catalyst must be immobilized in a form compatible with a packed-bed format, usually immobilized on rigid particles that enable optimal fluid flow through the bed. The particles must be strong enough to support their own weight and also resist fouling by

Table 31.11 Process metrics for the glucose isomerase process

Parameter	Batch soluble	Batch immobilized	Continuous immobilized
Reactor volume (m^3)	1,100	1,100	15

impurities such as particulates in the substrate. The rate of the conversion dictates the required bed thickness, or alternatively, the need for recycling in order to drive a conversion to completion. In this case, the concentration of product (proportional to $S_i - S_o$) at a given reactor residence time (T_p) becomes a function of both the flow rate (Q) into the reactor and reactor volume in addition to the factors discussed above for batch mode reactors (i.e., catalyst parameters and density, inlet substrate concentration S_i, and outlet substrate concentration S_o).

$$(S_i - S_o) - K_m \cdot \ln(S_o/S_i) = \text{Catalytic density}$$

$$T_p = \text{Catalytic density}\cdot(\text{Reactor volume/flow rate}) \qquad (31.10)$$

Continuous bioconversions using packed-bed reactors are particularly well suited for high-volume bioprocesses including HFCS and enzymatic transesterification of fats and oils. As shown in Table 31.11 for an HFCS production reactor using Glucose isomerase, PFR is advantageous in terms of short residence time critical for minimum color formation, high productivity, and low cost. An overall summary of the relative advantages and disadvantages of different bioreactor configuration is listed in Table 31.12.

Recovery of products often dictates the fashion in which a bioconversion is carried out. Liquid/liquid two-phase systems have proven useful, particularly when substrates of low water solubility are used. In these cases it is often possible to operate the reactor in continuous mode by removing and recycling the phase containing the products. The mode of product recovery depends on the nature of the product and the medium in which it is dissolved, in most cases water. Distillation can be used for product recovery in some instances, whereas extraction using a solvent might be used for nonpolar products. In many cases the removal of water from dilute solutions of product can add considerable cost to a bioprocess. For this reason there has been widespread interest in the use of solvents other than water for biocatalysis, discussed below.

Table 31.12 Comparison of bioreactor configurations

Configuration	Advantages	Disadvantages
Stirred batch	• Simple versatile format • Compatible with most biocatalyst forms	• Low catalytic density • Downtime between cycles
Continuous-stirred batch	• Higher volumetric efficiency • Continuous production	• Incomplete conversion to product
Packed bed	• High catalytic density • Extended operation	• Biocatalyst must be immobilized in compatible form
Fluidized bed	Resistance to blockage	Lower catalytic density
Membrane	Compatible with soluble enzymes	Membrane fouling

Nonaqueous Biocatalysis

Enzymes are, for the most part, soluble in water and not obviously suited for use in organic solvents. Many enzymes are denatured by exposure to solvents and still others require water as part of their catalytic action. Prior to 1980, there were several reports of biocatalysis in solvents; however, it was Klibanov and co-workers in the 1980s who first clearly demonstrated the potential of biocatalysis in organic media [94–96]. The use of such media, typically organic solvents, has greatly expanded the scope of biocatalysis for several reasons:

- Ability to use substrates with low water solubility
- Modulation of enzyme regio- and enantioselectivity
- Improved product yields in some cases
- Improved product recovery
- Enhanced biocatalyst stability
- Prevention of microbial contamination

Hydrolytic enzymes such as lipases and proteases catalyze readily reversible reactions and will often promote reverse hydrolysis at reduced water activities. Water can be removed with desiccants, as an azeotrope with a solvent or through application of a vacuum. Lipases have proven particularly useful in this regard, allowing the formation of esters from alcohols and either free carboxylic acids or esters.

An example is the synthesis of fatty acid esters in hexane from fatty acids and alcohols, a reaction catalyzed by many lipases including Porcine pancreatic lipase (PPL), *P. alcaligenes* lipase (LIPOMAX^{TM}, Genencor), CAL-B (N435, Novozymes), and *Candida rugosa* lipase (Amano

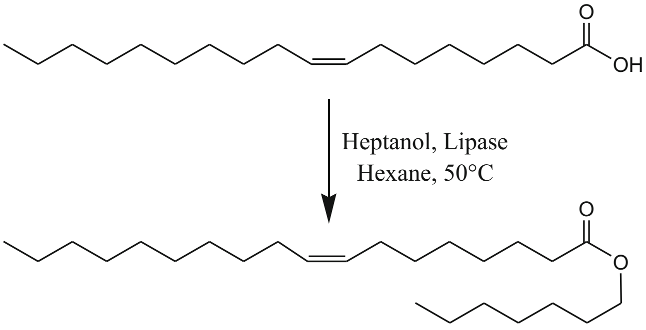

Fig. 31.18 Lipase-mediated ester formation

AYS, Amano) among others (Fig. 31.18). Many other classes of enzyme have also been used in organic solvents such as acyltransferases, glycosidases, dehydrogenases, oxidases, and dehalogenases, for the most part on the laboratory scale. Another major advantage of nonaqueous biocatalysis is the greatly expanded set of possible substrates, particularly those of low or negligible solubility in water. Examples of such compounds include long-chain fatty acids and ester derivatives, steroids, aromatic compounds, and many pharmaceutical intermediates. Several texts have been dedicated to the topic of synthetic biocatalysis, for example, the comprehensive handbook edited by Drauz and Waldmann [97].

A wide variety of organic solvents have been used to conduct bioconversions including nonpolar solvents such as isooctane, *n*-hexane, and toluene, in addition to methanol, acetone, and other water-miscible solvents. Dipolar aprotic solvents dimethylformamide (DMF) and dimethylsulfoxide (DMSO) are also compatible with many enzymes and are often used to enhance the solubility of substrates in combination with a nonpolar solvent. Tertiary alcohols such as *t*-butanol and *t*-amyl alcohol have been used for many lipase-mediated esterifications as sterically hindered tertiary alcohols are not typically good substrates for most enzymes. It should be noted that the presence of small amounts of water is essential for the effective use of most biocatalysts in organic solvents. In some cases an enzyme may only require a monolayer of water molecules on its surface in order to operate. In other cases there may need to be enough water to form reverse micelles where the biocatalyst is contained within a predominantly aqueous environment. The amount of water needed for maximal enzyme performance is usually cited in terms of water activity (A_w). Some enzymes (class “A”) operate efficiently at low water activities and become less efficient at catalyzing certain reactions such as ester formation at high A_w. Other enzymes will operate most efficiently at high water activities (class “B”). The enzyme activity as a function of water activity for these two classes of enzyme is represented graphically in Fig. 31.19.

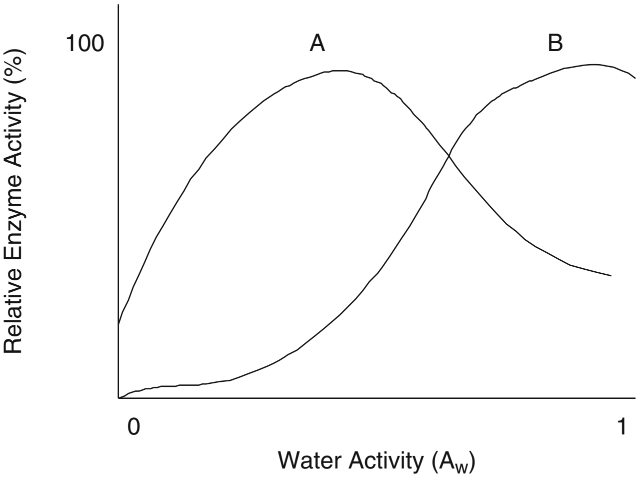

Fig. 31.19 Enzyme activity vs. water activity plot

Few industrially important bioprocesses are carried out exclusively in organic solvents. Two-phase systems are more common, however, consisting of a water-immiscible solvent that allows adequate dissolution of substrates and products and an aqueous phase containing the biocatalyst [98].

Products of Biocatalysis

Although numerous chemicals have been produced at a pilot scale using biocatalysis, there are only a modest number of materials produced at the ton scale or greater [99]. Some materials such as fructose syrup, acrylamide, and aspartame are produced on a large scale (>1,000 t/year), whereas others, including most pharmaceutical intermediates, are manufactured at considerably smaller volumes. A summary of some current products produced through biocatalytic processes is given in Table 31.13.

High-fructose corn syrup. Glucose isomerase (GI) is used for the large-scale isomerization of glucose syrups produced from the enzymatic hydrolysis of corn starch (Fig. 31.20). The product, commonly known as HFCS, typically contains 42% fructose, 50% glucose, 6% maltose, and 2% maltotriose. Fructose, the monosaccharide commonly called fruit sugar, is about 50% sweeter than sucrose, the disaccharide familiarly known as table sugar.

Annual production of HFCS amounts to over ten million tons, selling at around 30 cents/lb for the 42% grade (HFCS-42). HFCS is also available in the form of 55% syrup (HFCS-55), 90% syrup (HFCS-90), or as 99% pure crystalline fructose. The lowest grade, HFCS-42, is 15–20% cheaper than liquid invert sugar on a dry weight basis and is predominantly used in soft drinks. The baking industry ranks as the second largest user. Combining HFCS-42 and

Table 31.13 Selected products of industrial biocatalysis

Product	Biocatalyst	Substrate	Application
Food stuffs			
High-fructose corn syrup	Glucose isomerase	Corn syrup (glucose)	Sweetener
Aspartame	Thermolysin	L-Aspartic acid + D, L-phenylalanine	Artificial sweetener
L-Aspartic acid	Ammonia lyase	Fumaric acid + NH_3	Amino acid, aspartame precursor
L-Carnitine	Agrobacterium	γ-Butyrobetaine	Dietary supplement
L-Methionine	L-Aminoacylase	*N*-Acetyl-DL-methionine	Supplement
Pharmaceuticals			
7-ACA	D-amino acid oxidase and glutaric acid acylase	Cephalosporin C salt	Intermediate for semisynthetic antibiotics
Cephalexin	Penicillin acylase	7-Amino-deacetyoxy-cephalosporanic acid	Antibiotics
6-APA	Penicillin G acylase	Penicillin G	Intermediate for semisynthetic antibiotics
(*S*)-Naproxen	Lipase	(*RS*)-Naproxen ethyl ester	Drug
Isosorbide 2-acetate	Lipase	Isosorbide diacetate	Intermediate
(2*R*, 3*S*)-4-methoxy phenylmethyl glycidate	Lipase	Racemic 4-methoxy-phenylmethyl glycidate	Intermediate
L-Valine	Aminopeptidase	DL-Valinamide	Intermediate
Ethyl (*S*)-4-chloro-3-hydroxybutyrate	Carbonyl reductase	Ethyl acetoacetate	Statin intermediate
Chemicals			
Acrylamide	Nitrile hydratase	Acrylonitrile	Monomer
Cyclodextrins	Glucosyltransferase	Amylose	Formulation aid
Nicotinamide	Nitrile hydratase	3-Cyanopyridine	Vitamin precursor
(*S*)-2-Chloro-propionic acid	Dehalogenase	(RS)-2-Chloro-propionic acid	Intermediate for herbicides
(*S*)-2-Glycidyl-butyrate	Lipase	(RS)-Glycidyl-butyrate	Chemical intermediate
(*S*)-2-Methoxyisopropyl amine	Acylase	(RS)-2-Methoxyiso-propylamine	Herbicide intermediate

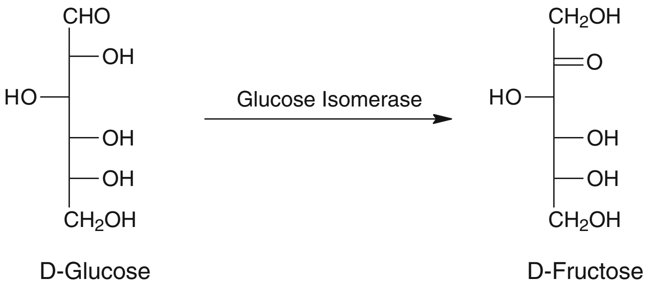

Fig. 31.20 Isomerization of D-glucose to D-fructose catalyzed by glucose isomerase

HFCS-90 gives HFCS-55, which has about the same degree of sweetness as sucrose. It is used as a sweetener and flavor enhancer in fruit-flavored soft drinks. Fructose enhances flavors, whereas sucrose masks them. Because the molecular weight of fructose is approximately half that of sucrose, a smaller amount of it is needed to sweeten a product to desired levels, and sweetener calories in the product can be reduced by about one third. The major use of HFCS-90 is in dietetic foods and drinks. Crystalline fructose of over 99% purity is obtained by drying the 90% pure HFCS. Pure fructose is about 70% sweeter than sucrose, and as an essentially pure sweetener, fructose allows the full taste of product flavors to develop. It has also found uses in low calorie foods and drinks. The amount of HFCS consumed per capita has risen dramatically in the last 30 years and there is some controversy about the possible health effects of high level consumption [100].

In many industrial cases, whole microbial cells containing GI are immobilized by physical means such as entrapment or encapsulation in polymeric materials or by chemical methods such as intermolecular cross-linking with gluteraldehyde or covalent binding with diazotized diamino compounds. Commercially, soluble glucose isomerase is also immobilized on DEAE-cellulose. The immobilized glucose isomerase can usually be used for over 1,000 h at a temperature of around 65°C. When the column enzyme activity decreases, the flow rate of the incoming glucose syrup can be adjusted so that the conversion of glucose to fructose is maintained constant.

Acrylamide. One of the largest scale industrial bioconversions is the process for the bioconversion of acrylonitrile to acrylamide, which is used in coagulants for water treatment, soil conditioners, paper treatment, adhesives, paints, and secondary oil recovery [101]. The worldwide production volume for the bioconversion process is in the tens of thousands of tons per year range. The reaction is a hydration of a nitrile to an amide and has traditionally been done by either a sulfuric acid or a copper-catalyzed

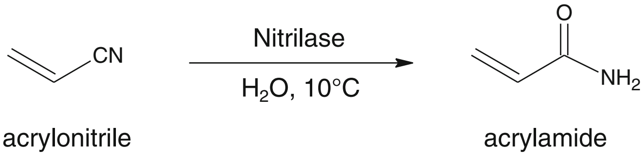

Fig. 31.21 Enzymatic conversion of acrylonitrile to acrylamide

hydration process. These processes are rapidly being phased out and replaced with a bioconversion process that has increased volumetric productivity, higher energy efficiency, decreased costs, and lower environmental impact.

The commercial bioconversion process employs the enzyme nitrile hydratase, which catalyzes the same reaction as the chemical process (Fig. 31.21). The bioconversion process was introduced using wild-type cells of *Rhodococcus* or *Pseudomonas*, which were grown under selective conditions for optimal enzyme induction and repression of unwanted side activities. These biocatalysts have since been replaced with recombinant cells expressing nitrile hydratase. The process consists of growing and immobilizing the whole-cell biocatalyst and then reacting them with aqueous acrylonitrile, which is fed incrementally. When the reaction is complete, the biocatalyst is recovered and the acrylamide solution is used as is. The bioconversion process runs at 10°C compared to 70°C for the copper-catalyzed process, is able to convert 100% of the acrylonitrile fed compared to 80%, and achieves 50% concentration of product compared to 30% concentration. Thus, the bioconversion process does not have to recycle the reaction to complete the hydration and the final liquor does not have to be concentrated as most of the commercial acrylamide is sold as a 50% solution.

It should be noted that this elegant example of replacing a chemical catalyst with a biocatalyst that has higher efficiency, lower costs, and is environmentally friendly did not happen overnight. It was first introduced in 1985 and has become progressively improved to the currently described state. That caveat being said, the current availability of biotechnological tools would today probably be fivefold shorter. The ability to identify and manipulate the enzyme, select the improved catalyst, and express it in a variety of host organisms has improved significantly in the last 20 years.

Semi-synthetic antibiotics. In 1959, Batchelor and coworkers in the Beecham Research Laboratories in England discovered that the penicillin nucleus, 6-APA, accumulated during fermentation when side chain precursors were omitted. This 6-APA could be used for the chemical synthesis of entirely new types of penicillin by coupling with new side chains. Shortly thereafter, several sources of penicillin amidase were found that would cleave the phenylacetyl side chain from penicillin G, thus producing a more economical source of 6-APA. A vast number of "synthetic penicillins" have been generated, and a few have achieved clinical importance [102]. Several objectives were sought:

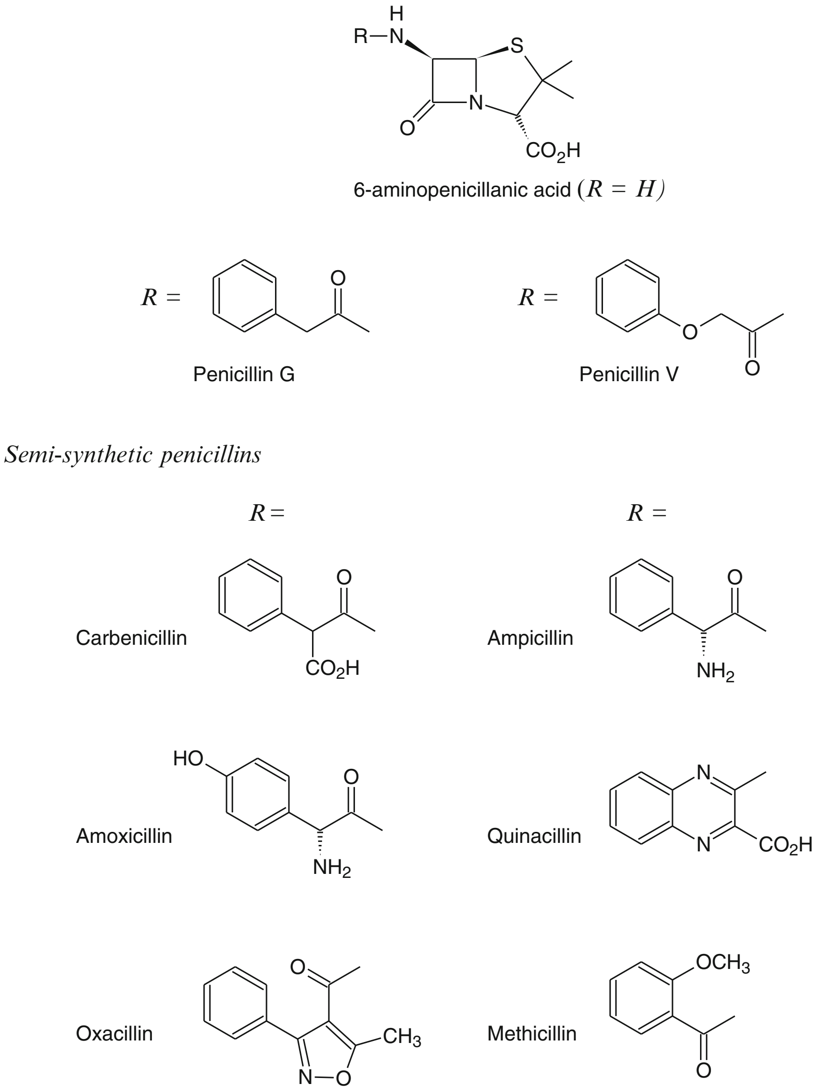
1. To broaden the inherent utility of penicillin to include gram-negative pathogens not inhibited by the natural penicillins
2. To improve its stability and absorption
3. To increase resistance to penicillinase producing pathogens
4. To decrease allergenicity
5. To improve other factors pertinent to clinical use

The broad objectives have been achieved with varying degrees of success. Table 31.14 shows the structures of some of the semisynthetic penicillin that have become important chemotherapeutics.

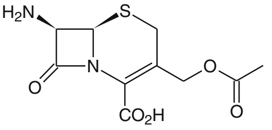
The natural penicillins, primarily G and V, have a relatively narrow spectrum. They act mostly on gram-positive organisms. The fact that proper selection of precursors could lead to new variations in the penicillin side chain offered the first source of synthetic penicillins. Penicillin V, derived from a phenoxyacetic acid precursor, attracted clinical use because of its greater acid tolerance, which made it more useful in oral administration. Also, the widespread use of penicillin eventually led to a clinical problem of penicillin-resistant staphylococci and streptococci. Resistance for the most part involved the penicillin-destroying enzyme, penicillinase, which attacked the beta-lactam structure of the 6-APA nucleus. Semisynthetic penicillins such as ampicillin and carbenicillin have a broader spectrum. Some, such as methicillin, oraficillin, and oxacillin, are resistant to penicillinase. In 1984, Beecham introduced Augmentin, which was the first combination formulation of a penicillin (amoxicillin) and a penicillinase inhibitor (clavulanic acid). Worldwide production of semisynthetic penicillins is currently around 10,000 t/year, the major producers are Smith Kline Beecham, DSM, Pfizer, and Toyo Jozo.

As in the penicillin studies, the chemotherapeutic properties of cephalosporin C can also be improved through synthetic modification of the 7-aminocephalosporanic acid (7-ACA) nucleus. Several semi-synthetic cephalosporins have been produced and are used clinically. The leading agents in this category include cefaclor (first-generation cephalosporin, developed by Lilly), cefoxitin (second-generation, by Merck), cefuroxime axetil (oral form, second-generation, by Glaxo), and ceftriaxone (third-generation, by Roche). Large-scale enzymatic removal of the 6-acyl side chain of penicillins is widely used in the commercial production of both 6-APA and the ring-expanded analogue, 7-aminodesacetoxycephalosporanic acid (7-ADCA). Two enzymes are used commercially, Penicillin acylases G and V. Penicillin G acylase is used in most cases, originally isolated from various sources

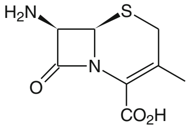
Table 31.14 Structural formulae of natural and semisynthetic penicillins



including *E. coli*, *Bacillus megaterium*, and *Streptomyces lavendulae*. Penicillium acylase V, used to a lesser extent, is derived from organisms including *Beijerinckia indica var. Penicillium*, *Fusarium* sp., and *Pseudomonas acidovorans*. Bacterial acylases have also been found that cleave the 7-acyl side chain of cephalosporin C to form 7-ACA.



7-aminocephalosporanic acid
(7-ACA)



7-aminodesacetoxycephalosporanic acid
(7-ADCA)

Immobilized forms of penicillin amidases and acylases have replaced whole-cell biocatalysts for the production of 6-APA and 7-ACA as they can be reused many times, in some cases for over 1,000 cycles. Another major advantage is the purity of the enzyme, lacking the β-lactamase contaminants often present in whole cells. The productivity of these biocatalysts exceeds 2,000 kg product/kg catalyst. A typical process for the production of 6-APA employs immobilized penicillin G acylase covalently attached to a macroporous resin. The process can be run in either batch or continuous modes. The pH of the reaction must be maintained at a value between 7.5 and 8 and requires continuous adjustment to compensate for the drop caused by the phenylacetic acid generated during the course of the reaction. Recycle reactors have been used, as they allow both pH control and the use of packed bed reactors containing the immobilized catalyst. The enzymatic process is cheaper, although not greatly so, than the older chemical route to

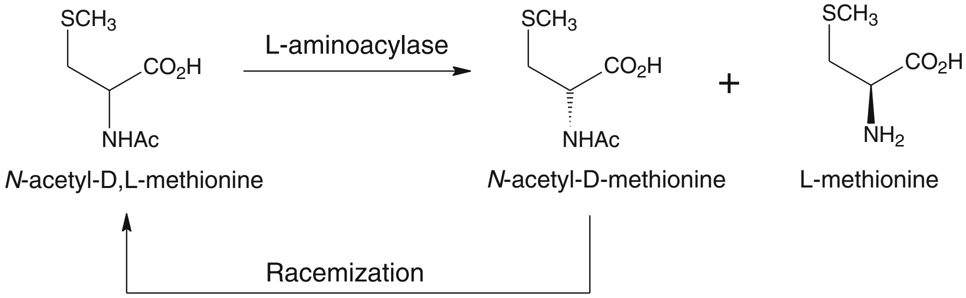


Fig. 31.22 Chiral resolution of racemic *N*-acetyl-DL-methionine

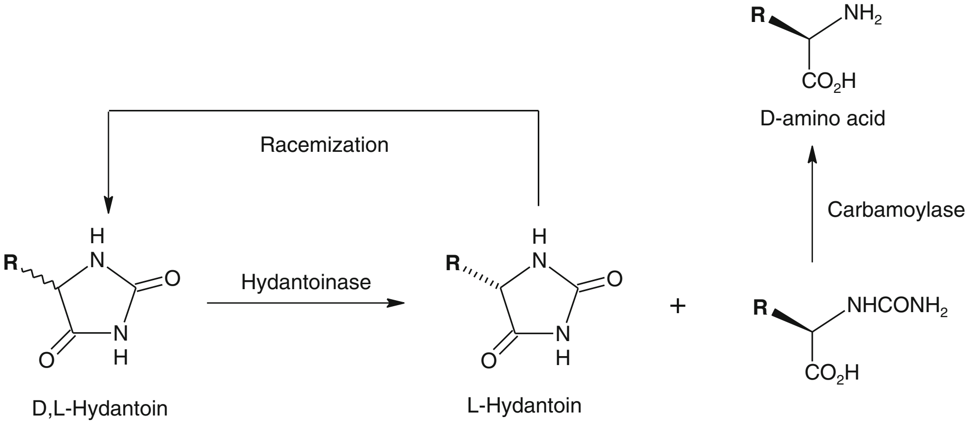

Fig. 31.23 Hydantoinase/carbamoylase process for the production of D-amino acids

6-APA, although it produces far less waste and doesn't require hazardous chemicals such as trimethylsilyl chloride. The biological production of 7-ACA, developed by Hoechst and currently practiced by Biochemie, is another excellent example of the waste reductions possible through implementation of a bioprocess, in this case from 31 to 0.3 kg per kg of product. Overall, the discovery and the development of penicillin and cephalosporin acylases greatly accelerated the commercialization of many semi-synthetic penicillins and cephalosporins and highlight the utility of biocatalysis for the selective modification of complex molecules.

Amino acids. Amino acids are produced by both fermentation and biocatalysis for use in animal feed, fertilizer, as flavor enhancers, dietary supplements, and in pharmaceutical manufacture [103]. By volume, the most important products are L-lysine, L-methionine, L-threonine, and L-tryptophan, most of which are produced by fermentation. Biocatalysis still plays an important role in amino acid supply and has been used to synthesize both L- and D-amino acids, including a variety of nonnatural analogues. The major producers are Degussa, Tanabe Seiyaku, and Kyowa Hakko.

Several enzyme classes have been used to synthesize amino acids, listed below;

- Aminoacylases
- Hydantoinases
- Amidases
- Dehydrogenases
- Racemases
- Lactamases
- Lyases

Aminoacylases (EC 3.5.1.14) were first used for the production of both D- and L-amino acids in the mid-1950s in batch mode processes to effect the selective deacetylation of chemically synthesized racemic *N*-acetyl-DL-amino acids. The most widely used enzyme was derived from *A. oryzae*, selective for the L-isomer. The technology was further developed by Chibata and coworkers at Tanabe to the point where the aminoacylase was immobilized to an ion-exchange resin and used in a packed-bed reactor allowing continuous production [104]. More recently, D-aminoacylases have been isolated and used for the synthesis of D-amino acids. In most schemes, the unwanted isomers are racemized chemically under forcing conditions (pH <3, >80°C) or, alternatively, with a racemase enzyme and subsequently recycled. Examples of amino acids produced through this process include L-methionine, L-valine, L-phenylalanine, and L-tryptophan. The immobilized enzyme is quite stable with a half-life of over 1 month at 50°C. When the total activity of the reactor drops, more of the enzyme can be added to the carrier. Productivity of the continuous process ranges from 70 to over 200 t/year for a 1,000-L column and is approximately 40% less costly than the older batch process. Figure 31.22 depicts the chiral resolution of racemic *N*-acetyl D, L-methionine.

Another widely adopted route to chirally pure amino acids is the hydantoin route. The enzyme hydantoinase

Fig. 31.24 Synthesis of L-*tert*-leucine is carried out using a cofactor recycle process using formic acid as the stoichiometric hydrogen donor

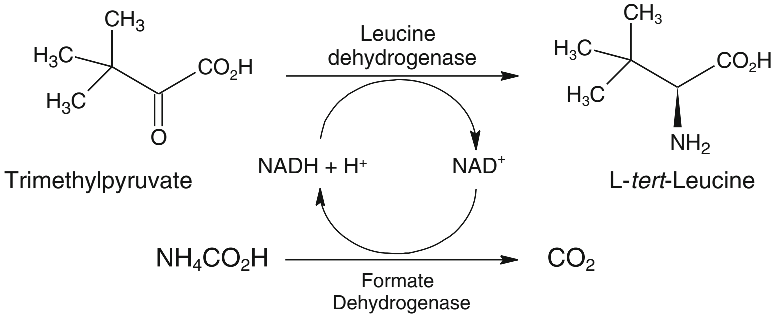

Fig. 31.25 Synthesis of L-lysine from DL-α-amino-ε-caprolactam

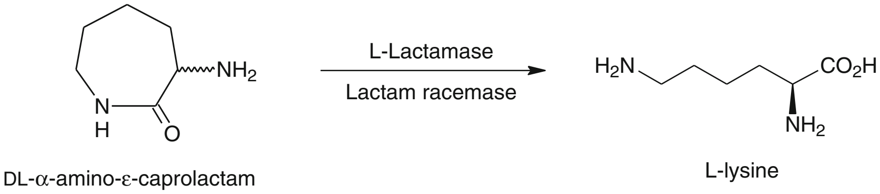

allows the selective hydrolysis of L-hydantoins to form a carbamoyl amino acid that is subsequently converted to the free-L-amino acid by carbamoylase (Fig. 31.23). An advantage of this process is the fact that racemization of hydantoins is far more facile than for *N*-acetyl amino acids. This process has been used for many years for the large-scale production (>1,000 t/year) of both D-phenylglycine and 4-hydroxy-D-phenylglycine, used in the synthesis of semi-synthetic antibiotics.

Dehydrogenases are also used for amino acid production, albeit on a far smaller scale. An example is the unnatural amino acid L-*tert*-leucine, manufactured by Evonik (formerly Degussa), used as an intermediate for the manufacture of peptidomimetic drugs such as HIV protease inhibitors. The route used to synthesize this material is noteworthy in that it employs Leucine dehydrogenase, a redox enzyme with cofactor regeneration driven by the decomposition of ammonium formate, in turn catalyzed by formate dehydrogenase (Fig. 31.24). The cofactor in this case is NADH modified with polyethyleneglycol (NADH-PEG) so as to increase its molecular weight and allow retention within a membrane reactor. Total cofactor recycle efficiency is very high at over 125,000 cycles. This elegant approach has also been used to produce other unusual amino acids including β-amino acids.

L-Aspartic acid is used in production of aspartame, in pharmaceuticals, and as a food additive. A bioprocess for the production of this amino acid was first commercialized in 1973 by Tanabe Seiyaku Co. (Japan) and involves the stereoselective addition of ammonia to fumarate catalyzed by L-aspartate ammonia lyase (Aspartase, EC 4.3.1.1). L-Aspartic acid was originally produced by fermentation; however, more recent processes use whole *E. coli* cells immobilized within either an acrylamide or cross-linked polysaccharide matrix. In this case the immobilized cell-based catalyst is far more stable than immobilized forms of the isolated enzyme, with an operational lifetime of over 120 days. The process is typically run in a continuous fashion with recovery of the L-aspartic acid readily achieved through crystallization. The major producers are Tanabe Seiyaku Co. and Kyowa Hakko Co. with a combined production of over 10,000 t per annum.

A similar process is also used for the production of L-malic acid from fumarate, in this case using a hydratase enzyme derived from *Brevibacterium ammoniagenes.* Another variation of the Tanabe technology involves the synthesis of L-alanine from L-aspartic acid through the use of immobilized whole cells (*Pastilla dacunae*) containing aspartate-decarboxylase.

L-Lysine is produced on an enormous scale, over 500,000 t/year, mostly through fermentation using genetically modified organisms. A biocatalytic route was also used to produce L-lysine, the most popular being the Toray process where chiral resolution of DL-α-amino-ε-caprolactam was achieved using a combination of a lactamase selective for the L-lactam and a DL-racemase (Fig. 31.25). A blend of whole-cell biocatalyst strains was used, consisting of *Cryptococcus laurentii* (L-ACL lactamase) and *Achromobacter obae* (ACL racemase). Yields of close to 100% are realized with productivities of over 100 g/L/day. At its peak, this process produced over 10,000 t of L-lysine per year.

Aspartame. Aspartame is a high-intensity sweetener (200-fold that of sucrose) consisting of L-aspartyl-L-phenylalanine methyl ester (L-Asp-L-Phe-OMe). Around 10,000 t are produced per annum, mostly by a chemical process owned by Nutrasweet Corp. Holland Sweetener Company (a DSM/Tosoh joint venture) uses the protease thermolysin (EC

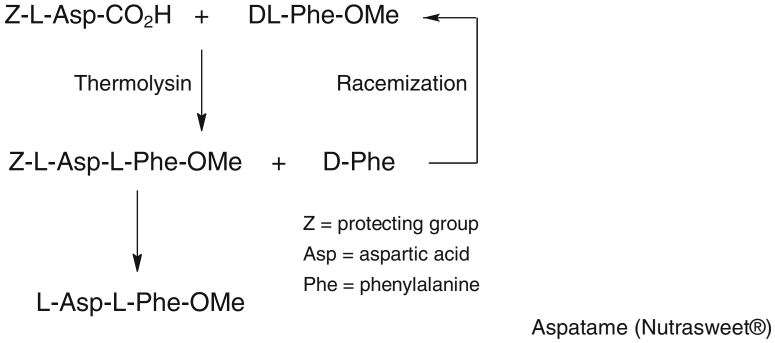

Fig. 31.26 Thermolysin-mediated synthesis of aspartame

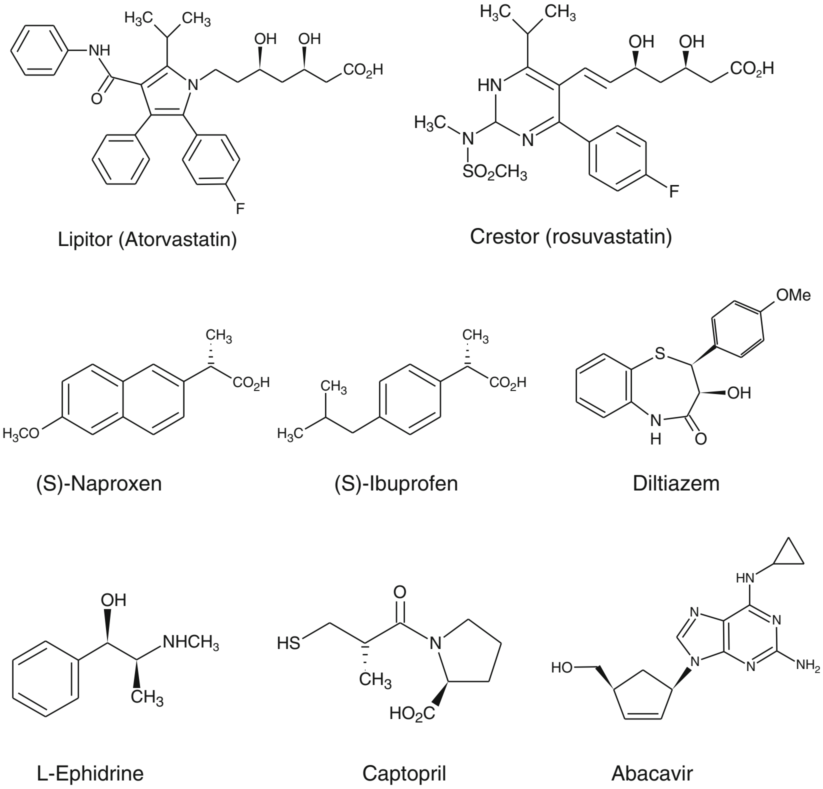

Fig. 31.27 Examples of pharmaceuticals synthesized using biocatalysis

3.4.24.27) to synthesize aspartame from a chemically protected L-aspartic acid derivative (Z-L-Asp) and racemic phenylalanine methyl ester (DL-Phe-OMe). The enzyme only accepts L-phenylalanine-OMe and the unused D-isomer can be isolated, racemized, and recycled. This process is depicted in Fig. 31.26.

Chiral pharmaceutical intermediates. The use of biocatalysis for producing chirally pure pharmaceuticals is now an accepted technology that complements alternative chemical and physical methods [105, 106]. The size of the world market for single enantiomer drugs, over $225 billion in 2005, offers plenty of incentive to develop competitive biocatalytic routes for key intermediates [107]. The market for chiral intermediates themselves, although far smaller, is still considerable and was projected to rise from over $7 billion in 2002 to over $15 billion by 2012 [108]. The majority of these intermediates are generated through traditional chiral pool resolution, 35% by asymmetric chemical synthesis and 15% through the application of biocatalysis (Fig. 31.27) [109]. The number of biocatalytic processes is increasing as more traditional chemical companies begin to view enzymes more as reagents than exotic materials. In most cases biocatalysis is one of many options for the synthesis of given material and must demonstrate economic benefits in order to be adopted.

One of the inherent advantages of enzymes is the ability to discriminate between stereoisomers, often generating products with enatiomeric excesses (i.e., of over 98%). Judicious application of biocatalysis can also reduce the number of chemical steps needed to synthesize certain drugs, leading to hybrid chemoenzymatic processes with lower costs and less waste. The range of enzymes used in

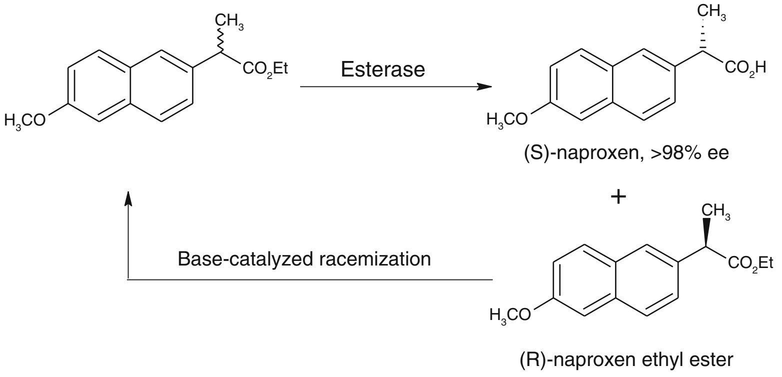

Fig. 31.28 Dynamic chiral resolution of naproxen ethyl ester

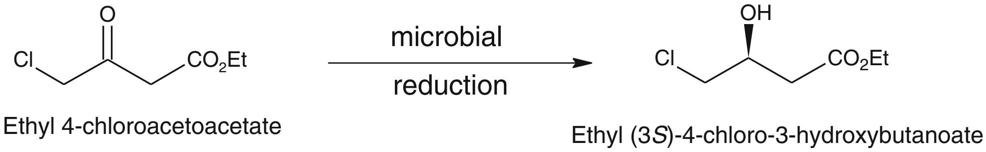

Fig. 31.29 Synthesis of ethyl (3*S*)-4-chloro-3-hydroxybutanoate (ECHB) from ethyl-4-chloroacetoacetate through whole-cell microbial reduction

the synthesis of chiral intermediates has expanded beyond esterases and acylases and now includes oxidoreductases, glycosyltransferases, and C–C bond-forming enzymes (e.g., aldolases). A number of excellent reviews and books have been dedicated to the application of biocatalysis in the production of pharmaceuticals and should be consulted for detailed information [105–111]. A few examples of the use of biocatalysis are discussed below.

Naproxen and ibuprofen are nonsteroidal antiinflammatory drugs (NSAIDs) widely available as OTC medications. In both cases the active (*S*)-enantiomer is far more potent. Selective hydrolysis of racemic esters of these drugs enables the production of both (*S*)-naproxen and (*S*)-ibuprofen. A number of bioroutes have been developed for the synthesis of these drugs. Most commercial processes are based on the selective hydrolysis of racemic esters performed by lipases and esterases, although the selective hydrolysis of nitriles with nitrilases has also been used. One such process for (*S*)-naproxen, was developed by Chirotech using a recombinant esterase, generates titers of around 150 g/L in a batch-mode process. Recovery of the (*R*)-ester is readily achieved by centrifugation and is subsequently racemized by base treatment and returned to the reactor (Fig. 31.28).

The blockbuster anti-cholesterol agents Lipitor® (atorvastatin) and Crestor® (rosuvastatin) generated combined sales of over $15 billion in 2010. Several companies have developed improved biocatalytic methods for the synthesis of ethyl (*S*)-4-chloro-3-hydroxybutyrate (ECHB), a key intermediate for these drugs [112]. One popular route to ECHB involves selective reduction of ethyl 4-chloroacetoacetate with a whole-cell biocatalyst (Fig. 31.29). Daicel Chemical Industries of Japan produces over 100 t/year of ECHB using two enzymes coexpressed in *E. coli* to carry out this reduction. An NADH-dependant carbonyl reductase, originally isolated from *Kluyveromyces aestuarii*, and an engineered formate dehydrogenase dehydrogenose from *Mycobacterium vaccae* resulted in ECHB yields of nearly 50 g/L/h. Alternative biocatalytic routes have been developed by DowPharma in collaboration with Verenium (formerly Diversa), and also by Codexis.

Diltiazem, a benzothiazepin used widely for the treatment of high blood pressure, is derived from a *p*-methoxyphenyl-substituted glycidyl ester with two stereocenters. Lipase-mediated resolution is used to obtain the desired (2*R*, 3*S*)-ester. Both DSM and Sepracor have commercialized processes for this intermediate using lipases including those from *C. rugosa* and *Serratia marcesens*. A typical process is run in a membrane reactor using a two-phase solvent/water mixture. The unwanted isomer is hydrolyzed to a carboxylic acid that subsequently decomposes to an aldehyde and CO_2 (Fig. 31.30). The addition of bisulfite to the reactor prevents inhibition of the lipase by complexing with the aldehyde byproduct and allowing extraction into the aqueous phase.

A number of other important drug intermediates are produced at scale (>1,000 kg/year) by biocatalysis including

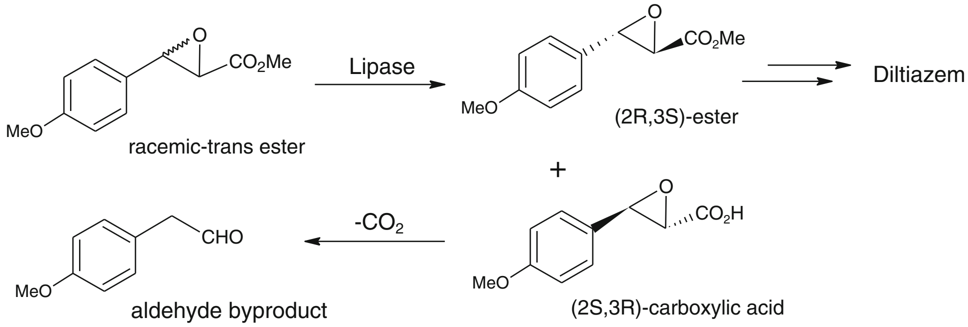

Fig. 31.30 Lipase-mediated synthesis of the key intermediate for Diltiazem

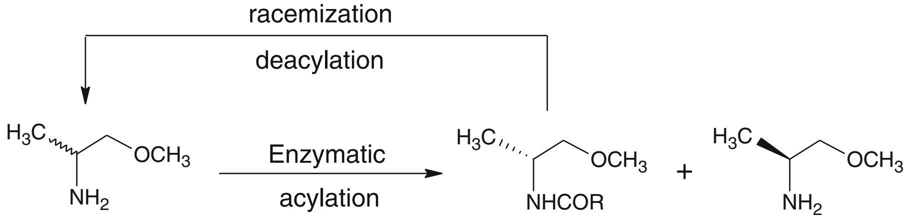

Fig. 31.31 Chiral resolution of 2-methoxyisopropylamine

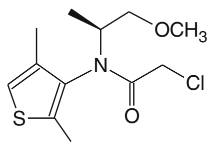
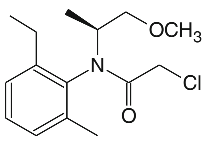
D-phenylglycine and D-(*p*-hydroxyphenyl)glycine for antibiotics, nicotinamide, 6-hydoxynicotinic acid, (*R*)-glycidol, and D-pantothenic acid. Many fine chemical companies have developed a biocatalysis capability such as Avecia (now a part of Nitto Denko Corp.) and Lonza to address the growing market for chiral intermediates. Others specialize in the development of novel biocatalysts of use for fine chemical synthesis.

Herbicides. Herbicides are used in great quantities globally, accounting for over $18 billion in sales in 2009. A number of herbicides are produced as racemates and, as is the case for many pharmaceuticals, one enantiomer is often more potent than the other. Examples include Frontier, produced by BASF, and Metolochlor, a Syngenta product. The active enantiomer, (*S*)-metolachlor, was introduced in 1999. BASF introduced Outlook^{TM}, the *S*-enantiomer of Frontier, in 2001.



Outlook®



(S)-Metolochlor

Whereas (*S*)-metolochlor is produced chemically by asymmetric hydrogenation, a biocatalytic route is employed by BASF for the production of (*S*)-methoxyisopropylamine on the multithousand-ton scale per annum. Resolution of racemic methoxyisopropylamine is achieved through selective enzymatic acylation of the unwanted (*R*)-isomer. This amide is then separated, racemized, and recycled (Fig. 31.31). A similar approach is used by BASF to produce a range of additional chiral amines as part of the ChiPros® portfolio.

Another chiral small molecule, (*S*)-2-chloropropionic acid (S-CPA), is a key intermediate in the synthesis of the 2-phenoxypropionic acid class of herbicides, including Fusilade (Avecia) and Mecoprop (BASF). Kinetic resolution of racemic CPA is performed with a whole-cell biocatalyst expressing a dehalogenase enzyme selective for the (*R*)-enantiomer and producing (*S*)-lactic acid, itself a useful byproduct. The S-CPA is extracted with a solvent following removal of the biocatalyst by filtration. Removal of the solvent by distillation gives crude S-CPA, which can be further purified. The process was developed by Avecia (purchased by Dr. Reddy's Laboratories in 2005) and produces over 2,000 t per annum.

Carbohydrates. Aside from starch processing and the production of HFCS, there are few biocatalytic processes currently employed for the large-scale synthesis of carbohydrates [113, 114]. A number of carbohydrates are, however, produced on the smaller scale. They include monosaccharides such as xylitol, L-sorbose, and sialic acid, alkyl glycosides, sugar fatty acid esters, cyclodextrins, and oligosaccharides including gluco-, galacto-, and fructooligosaccharides. Many of these processes involve the formation of a glycosidic bond, the carbohydrate version of an acetal or ketal. Three types of enzyme are used for glycoside formation, depicted in Fig. 31.32.

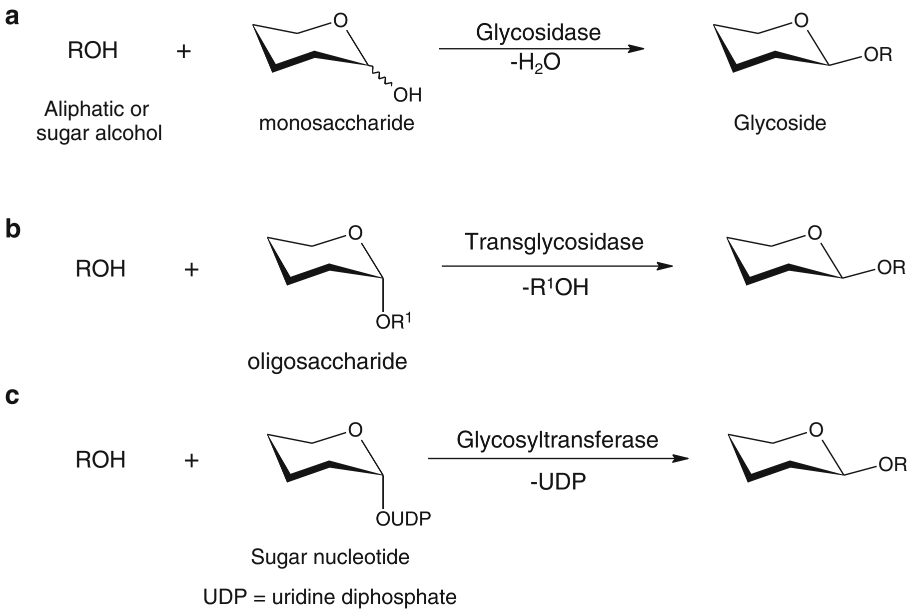


Fig. 31.32 Formation of glycosides using (**a**) a glycosidase and a free sugar; (**b**) a transglycosidase and a glycoside; (**c**) a glycosyltransferase and a sugar nucleotide

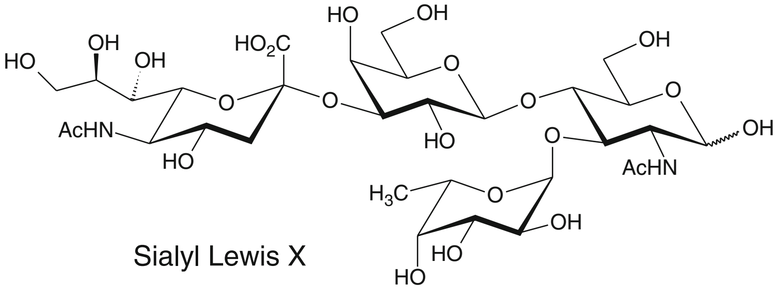
Glycosidases typically hydrolyze glycosidic bonds, but can be made to work in reverse under certain conditions. An example is the β-glucosidase from sweet almonds, which can form glycosides from free (unactivated) sugars and aliphatic alcohols. Transglycosidases are used to interconvert glycosides. Many glycosidases also have transglycosidase activity. The industrial production of butyl-α-D-glucoside involves the transglycosylation of maltose with butyl alcohol in a two-phase system employing the α-transglucosidase from *A. niger* [115].

Glycosyltransferases are the most specific of the enzymes used to form glycosidic bonds and have also been used to synthesize complex oligosaccharides in a far more direct fashion than is possible by chemical means alone. One disadvantage of glycosyltransferases is the need for activated sugar nucleotide donors, such as UDP-glucose (UDP = uridine diphosphate). Recent progress in the practical application of glycosyltransferases has been made possible through the commercial availability of recombinant enzymes and elegant schemes for the in situ regeneration of sugar nucleotide donors using cheaper energy sources such as phosphenolpyruvate.

For example, production of a complex pentasaccharide, Sialyl Lewis X (SLe^x), was achieved on the multikilogram scale by Cytel Corporation using technology developed by Wong and Whitesides whereby all of the required sugar nucleotides were regenerated in a multienzyme scheme [116]. This molecule was originally identified as a possible therapeutic agent for the prevention of reperfusion injury following heart attacks. Although this drug ultimately failed in clinical trials, the technology has since been used in the production of carbohydrates for infant formula, as anti-infectives, and for the production of glycosylated therapeutic proteins.

Future Trends in Biocatalysis

Biocatalysts. Continued discovery of new enzymes and microorganisms will further drive the development of biocatalysis by both enabling new chemistries and lowering the cost of existing technologies. It has been estimated that over 98% of the microbial diversity in Earth remains untapped. The potential of this resource cannot be underestimated. For example, the discovery of extremophilic bacteria



Sialyl Lewis X

existing at temperatures exceeding 120°C and extreme pH values has already led to the development of thermostable enzymes for a variety of applications, of particular note the PCR reaction conducted with DNA polymerases. Libraries of enzymes derived from extremophiles are now commercially available. Table 31.15 lists different classes of extremophiles from which useful enzymes have been derived. Further information on extremophiles and their potential utility for biocatalysis can be found in the reviews by Kumar et al. [117] and Gomes and Steiner [118].

Enzyme engineering will increasingly drive the development of robust enzymes tailored to specific bioprocesses. The strategies used for improving the stability of enzymes will continue to focus on the generation and screening of libraries of mutants produced by random or targeted amino acid substitutions; however, alternative approaches also include the rational design of stabilizing protein motifs (e.g., salt bridges) and even the incorporation of unnatural amino acid analogues [119]. A case in point is the passive incorporation of fluorinated analogues such as hexafluoroisoleucine into proteins by Tirrel and coworkers combined with the observation that fluorinated amino acids can stabilize protein folds in some instances [120]. The ability to design enzymes from unrelated proteins is another long-term goal. Similarly, computational design of enzymes from first principles has great promise, although the field is still in its infancy [121, 122]. Improved production methods for enzymes useful for biocatalysis will also enable the commercialization of many currently uneconomical processes. Gains are also to be expected from refinement of methods used for enzyme immobilization and bioreactor design. The development of improved supports for enzyme immobilization through the application of nanotechnology has particular promise through the enhancement of stability and productivity of immobilized enzymes.

Table 31.15 Classification of extremophiles

Class	Optimal environment
Thermophile	Temperatures above 60°C
Hyperthermophile	Temperatures above 80°C
Psychrophile	Temperatures below 15°C
Halophile	Ionic strength >2 M
Acidophile	pH values below 3
Alkaliphile	pH values over 9
Radiophile	Radioactive environments
Xerophile	Low-water conditions
Piezophile	Pressures-over 100 MPa

Novel media for biocatalysis. The development of novel media in which to conduct biocatalytic transformations has been subject to investigation for almost as long as biocatalysis itself, with greatest focus on the use of organic solvents. In recent years several new directions have gained attention. In particular, the use of ionic liquids (Fig. 31.33) and supercritical carbon dioxide ($scCO_2$) have extended the range of conditions under which biocatalytic processes can be applied, primarily through allowing the solubilization of substrates under conditions amenable to enzymatic catalysis and/or facilitating the isolation of products from the reaction medium [123–126]. The desire to reduce waste generation and eliminate the need for volatile and potentially flammable solvents is also spurring the development of novel media for biocatalysis.

Ionic liquids based on salts of alkylimidazoles and pyridines have been used for the synthesis of esters of ascorbic acid and other sugars on the laboratory scale and show particular advantage in their ability to dissolve otherwise incompatible substrates. One of the key features of these solvents is their extremely low vapor pressures and excellent ability to dissolve both polar and nonpolar materials. Reactions can be run under vacuum allowing the removal of volatile byproducts such as water and enable one to shift the equilibrium of a reaction towards product formation, as in the case of reverse hydrolysis used for the formation of esters, glycosides, and peptide bonds. Product recovery can be facilitated through continuous extraction or phase separation allowing recycling of the solvent. The ability to alter the nature of both the cation and anion of ionic liquids independently affords a degree of tunability, a useful property when attempting to optimize a bioprocess. To date, bioprocesses in ionic liquids have predominantly employed lipases; however, other classes of enzyme such as proteases and glycosidases can also be used. Baker's yeast and other whole-cell biocatalysts have also been used successfully for enantioselective reductions in ionic liquids.

Supercritical fluids (SCFs) and in particular $scCO_2$ have also been shown to provide a unique medium in which to perform biocatalytic transformations. The ability to perform biocatalysis in a SCF was first demonstrated in 1985 by several groups. There are several advantages to the use of

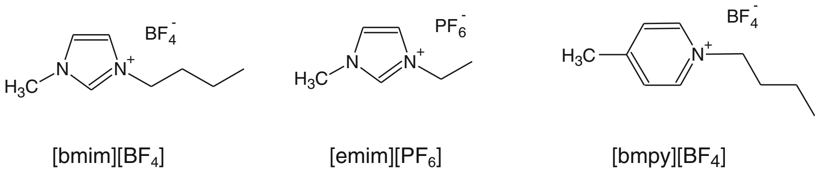


Fig. 31.33 Structures of some ionic liquids

Table 31.16 Critical points of solvents useful for biocatalysis

Solvent	Critical temp (°C)	Critical pressure (MPa)
Carbon dioxide	31.1	7.4
Fluoroform	25.9	4.8
Ethane	32.3	4.9
Sulfur hexafluoride	46	3.8
Ethylene	9.3	5.0

SCFs, as well as some drawbacks that need to be addressed if large-scale processes are to be developed.

Advantages:

- Improved solvation of nonpolar materials
- Improved mass transfer relative to water and other liquids
- Ability to modulate solvent properties through pressure changes
- Ability to remove solvent by depressurization
- Nontoxic and environmentally friendly
- Ease of product recovery

Disadvantages:

- Not compatible with all enzymes
- Need for specialized equipment
- Cosolvents often needed
- Water activity often important
- No large-scale processes developed to date

The conditions under which CO_2 becomes supercritical are mild (Table 31.16) and compatible with many, but not all enzymes. Other SCFs aside from $scCO_2$ have also been used to conduct bioconversions, for example, trifluoromethane, ethane, and propane.

In some cases an enzyme that performs poorly in $scCO_2$ will exhibit greatly improved activity in an alternative SCF. An example is the increased activity of subtilisin in supercritical propane and propane/CO_2 mixtures as compared to $scCO_2$ alone. A particularly interesting property of SCFs is the ability to dramatically alter the solvent properties (e.g., dielectric constant) through changes in temperature and pressure. Increases in pressure can enhance enzyme activity in some cases. Enzyme activity in SCFs is also markedly affected by water activity, as is the case in organic media, and the presence of small amounts of water is often essential for effective catalysis. Lipases are particularly suitable for supercritical biocatalysis and are often used in immobilized form owing to increased stability and ease of handling. Other enzymes have also been employed including proteases, oxidases, and glycosidases. The use of whole cells in supercritical CO_2 has also been reported. Matsuda et al. in 2001 employed the bacterium *B. megaterium* to catalyze the carboxylation of pyrrole at rates exceeding those possible in water [127].

Often a cosolvent is used in order to solubilize particularly polar substrates such as sugars and amino acids. Surfactants or additional solvents may also allow adequate solvation of enzymes. In some cases two-phase systems can be used to conduct bioconversion. For example, Reetz et al. employed both SCFs and ionic liquids in a semi-continuous process for the esterification of alcohols where the enzyme resided in the IL phase and $scCO_2$ enabled substrate solvation and product removal [128].

Products. Biocatalysis will increasingly be used for the production of bulk chemicals including fuels, polymers, and other large-volume materials. Much of this development will be driven by large chemical manufacturers, many of whom have invested heavily in the development of in-house biocatalysis capabilities. Examples include BASF, Dupont, Celanese, DSM, Dow Corning, Lonza, and Evonik. The major factor driving this investment is the realization that in many instances bioprocesses can improve productivity, lower costs, and reduce waste streams. The production and modification of bulk polymers holds particular promise as enzymes may enable the production of polymeric architectures that are not readily made through purely chemical routes, for example, polyesters derived from sugars and other polyols [129].

Production of fine chemicals and active pharmaceutical ingredients (APIs) will also continue to benefit from the judicious application of biocatalysis, in many cases as part of multistep synthetic schemes. Of particular relevance is the increasing demand for chirally pure pharmaceuticals, driven by concerns about the unwanted side-effects often associated with racemic drugs. Another growth area is likely to be the production of biologically active carbohydrates, traditionally requiring complex and expensive chemistries for production, to be used as pharmaceuticals, in infant formula, and as nutritional supplements.

Continued development of the biorefinery concept should eventually lead to sources of renewable materials at costs competitive with those from petrochemical sources through the effective utilization of biomass from various sources (cellulosic, agricultural waste, garbage, vegetable oils). Many of these materials will be amenable to further modification through biocatalytic processes, for example, the production of biodiesel using lipases and fatty acids. Industrial enzymes overall should also see increased use in medicine as diagnostics and as components in biosensors and other devices.

Summary and Conclusion

Enzymes are currently applied across many industries and are used as processing aids, incorporated into consumer products, and used in biocatalysis for chemical production. The global market for industrial enzymes will continue to expand as enzymes find their way into new markets and attract greater interest from the chemical industry at large. Several factors will contribute to this growth:

- Improved knowledge of enzyme mechanisms
- Reduction in the production costs of industrial enzymes
- Improved means for enzyme immobilization and bioprocess engineering
- Novel schemes for cofactor recycling
- Advances in metabolic engineering of whole microorganisms
- Greater awareness of the environmental benefits of enzyme technology

Ultimately, the distinction between biological and chemical catalysis may become less distinct as technologies for modified enzymes, enzyme mimetics, and chemoenzymatic catalysis advance [130]. In the meantime, however, it is clear that further application of enzyme technology within industry will greatly benefit society in the twenty-first century.

Industrial Production of Therapeutic Proteins: Cell Lines, Cell Culture, and Purification

32

Marie M. Zhu, Michael Mollet, and Rene S. Hubert

The biotechnology and pharmaceutical industries have seen a recent surge in the development of biological drug products manufactured from engineered mammalian cell lines. Since the hugely successful launch of human tissue plasminogen activator in 1987 and erythropoietin in 1988, the biopharmaceutical market has grown immensely. Global sales in 2003 exceeded US $30 billion [1]. Currently, a total of 108 biotherapeutics are approved and available to patients (Table 32.1). In addition, 324 medically related, biotechnology-derived medicines for nearly 150 diseases are in clinical trials or under review by the US Food and Drug Administration [2]. These biopharmaceutical candidates promise to bring more and better treatments to patients. Compared to small molecule drugs, biotherapeutics show exquisite specificity with fewer off-target interactions and improved safety profiles. Protein engineering technologies have advanced to create protein drugs with improved efficacy, specificity, stability, pharmacokinetics, and solubility. Strategies that have been employed to implement these changes include mutagenesis, recombination, and other directed evolution methods, as well as rational design and structure-based computational approaches [3–7]. These advanced protein engineering technologies are creating novel drug designs and clever treatment strategies that are fuelling the biopharmaceutical market growth.

Currently, 60–70% of all biotherapeutics based on recombinant proteins are produced in cultivated mammalian cells [8]. Mammalian systems are often preferred over other hosts, such as bacteria, plants, and yeast, because of their capability for proper protein folding, assembly, and posttranslational modification. The quality and efficacy of a protein can thus be enhanced when expressed in mammalian cells. With the recent expansion in the biotherapeutics market, the demand for proteins derived from mammalian cells continues to grow, and the biopharmaceutical industry is faced with the challenge of efficiently producing these proteins in large quantity. To keep up with demand while driving manufacturing costs down, mammalian cell production expectations are rising every year, with product titers reaching 4 g of protein/L of culture [8]. The high yields obtained today are the result of combined efforts made in improving host cells, expression vectors, screening methods, medium development, and process development. In this chapter, we outline the common methods applied to mammalian cell line development and describe the typical industrial processes used in cell culture and purification for the production of recombinant proteins. Recent advances in this field are also presented.

Cells Used For Industrial Production

This section focuses on the generation of engineered mammalian cell lines that stably produce therapeutic proteins. Hybridomas, transient expression systems, and insect and bacterial cell line development are outside the scope of this section. The commonly used cell lines, expression systems and vectors, as well as cell banking and stability are described.

Host Cell Lines

Mammalian cell lines commonly used to manufacture therapeutic proteins include NS0 mouse myeloma, baby hamster kidney (BHK), and Chinese hamster ovary (CHO) derived lines such as CHO-S, CHO-K1, CHODUXB11, and CHO-DG44. The latter two cell lines are engineered to have single or double knockout mutations, respectively, for the dihydrofolate reductase (DHFR) gene. NS0 and CHO cell lines are also available with the glutamine synthetase gene

Table 32.1 Approved biotechnology products

Trade name	Proper name	Manufacturer	Approval Date	Application	Cell type
Abbokinase	Urokinase	Abbott Laboratories	10/2002	Lysis of acute massive pulmonary emboli	Human neonatal kidney
Actimmune	Interferon gamma-1b	InterMune Pharmaceuticals	12/1990	Chronic granulomatous disease/osteopetrosis	NA
Activase	Alteplase recombinant	Genentech	11/1987	Acute myocardial infarction/acute massive pulmonary embolism/ischemic stroke	CHO
AcuTect	Tc-99 m apcitide	Berlex	1998	Scintigraphic imaging of acute venous thrombosis	NA
Adagen	Injection pegademase	Enzon	1990	Severe combined immunodeficiency disease	NA
Aldurazyme	Laronidase	Biomarin	4/2003	Hurler and Hurler–Scheie forms of mucopoly saccharidosis I	CHO
Alferon N injection	Interferon alfa-n3	Hemispherx Biopharma	10/1989	Genital warts	NA
Amevive	Alefacept	BiogenIdec	1/2003	Moderate to severe chronic plaque psoriasis	CHO
Apligraf	Graftskin	Novo Novartis	5/1998	Venous leg ulcers	NA
Aranesp	Darbepoetin alfa	Amgen	9/2001	Anemia associated with chronic renal failure/ chemotherapy-induced anemia	CHO
Argatroban	–	GlaxoSmithKline	6/2000	Heparin-induced thrombocytopenia syndrome	NA
Avastin	Bevacizumab	Genentech	2/2004	Metastatic colorectal cancer	CHO
Avonex	Interferon beta-1a	BiogenIdec	5/1996	Multiple sclerosis	CHO
BeneFIX	Human factor IX	Wyeth	2/1997	Hemophilia B	CHO
Betaseron	Interferon beta-1b	Chiron/Berlex	7/1993	Multiple sclerosis	E. coli
Bexxar	Tositumomab and Iodine I-131 tositumomab	Corixa	6/2003	CD20 positive, follicular, non-Hodgkin's lymphoma	Mammalian cells
BioTropin	Human growth factor	Bio General - Technology	5/1995	Growth hormone deficiency in children	NA
Botox	Botulinum toxin type A	Allergan	4/2002	Cervical dystonia/moderate to severe glabellar lines	C. botulinum
Campath	Alemtuzumab	Millennium/Ilex	5/2001	B-cell chronic lymphocytic leukemia	CHO
Carticel	cultured Autologous chondrocytes	Genzyme	8/1997	Symptomatic cartilaginous defects of the femoral condyle	Human cartilage
CEA-Scan	Arcitumomab	Immunomedics	6/1996	Imaging agent for detection of colorectal carcinoma	NA
Cerezyme	Imiglucerase for injection	Genzyme	5/1994	Type 1 Gaucher disease	CHO
Comvax	Haemophilus b conjugate	Merck	10/1996	Vaccination against both invasive haemophilus influenzae b and hepatitis B	S. cerevisiae
DACS SC	Stem cell enrichment device	Dendreon	9/1999	Rescue therapy following high-dose chemotherapy	NA
Elitek	Rasburicase	Sanofi-Synthelabo	7/2002	Management of plasma uric acid levels in patients with leukemia, lymphoma, and solid tumor malignancies	S. cerevisiae
Enbrel	Etanercept	Amgen	11/1998	Moderately to severely active rheumatoid arthritis/ polyarticular course juvenile rheumatoid arthritis/ psoriasis	CHO
Engerix-B	Hepatitis vaccine B	GlaxoSmithKline	8/1989	Hepatitis B	S. cerevisiae; CHO
Epogen	Epoetin alfa	Amgen	6/1989	Multiple types of anemia	CHO
Erbitux	Cetuximab	ImClone Systems	2/2004	Advanced colorectal cancer	NS0
Fabrazyme	Agalsidase beta	Genzyme	4/2003	Fabry disease	CHO
Follistim	Follicle-stimulating hormone	Organon	9/1997	Infertility	CHO

knocked out. Stable cell lines are generated by integrating the genes that encode the desired proteins into the genome of one of the above host cell lines. The CHO-DHFR system uses a plasmid that contains a variety of promoters driving the production of the genes for the proteins and dihydrofolate reductase, which acts as a selectable marker. Amplified expression can be achieved by applying methotrexate, the selective agent for dihydrofolate reductase. The NS0-GS and CHO-GS systems use a vector containing the glutamine synthetase gene, which functions as the selection marker. This type of system can be amplified to boost expression levels by using methionine sulphoximine. In addition to being engineered for selection, host cells have also been genetically constructed by inserting growth factor genes, anti-apoptosis genes, and cell cycle control genes to generate superior production hosts [9].

Expression Systems

The goal of cell line development is to engineer cells to express a large amount of a recombinant protein and to stably maintain this level of production for many cell doublings. The basic schema is:

1. Generate plasmid expressing recombinant protein.
2. Introduce plasmid into cell.
3. Identify cell line expressing high levels of recombinant protein.
4. Select cell line maintaining high levels of expression through scale-up and bioreactor processes.

Plasmids. The plasmid contains all genetic elements necessary for the expression of recombinant protein and for the selection of the cells generating the desired product. For stable cell lines, the plasmids must integrate into transcriptionally active chromosomal regions. The vector promoter elements drive the expression of recombinant protein. The strong cytomegalo virus (CMV) promoter is in general use, although the weaker simian virus 40 (SV40) and rouse sarcoma virus (RSV) promoters are also used. Recently, the strong promoter, CHO-EF1 (CHEF1) [10] has been generating CHO cell lines with high production levels. The inclusion of a chimeric intron in the primary transcript leads to higher stable expression of recombinant protein through enhanced transport and processing of the mRNA from the nucleus into the cytoplasm where it is translated [11, 12].

To allow the selection of cells expressing the desired protein, the plasmid also contains selectable markers such as the *neo* gene generating aminoglycoside 3-phosphotransferase (APH 3 II) for G418 geneticin resistance, the *hph* phosphotransferase gene for hygromycin resistance, the *Sh ble* gene for zeocin resistance, or puromycin N-acetyl-transferase encoded by the *pac* gene for puromycin resistance. Selection can also occur using a complementation gene such as DHFR or GS, which can be included in plasmids when using DHFR-negative or GS-negative cell lines, such as CHO-DG44 and NS0-GS, respectively. The use of an internal ribosomal entry site (IRES) element can facilitate the coexpression of selectable markers and protein product when integrated into the genome [13]. This system generates a single transcript accessible to ribosomes at two locations just prior to the start site of each gene. The fact that the selectable marker and the product gene are under the control of a single promoter, which generates one transcript, is likely to improve cell line stability. Elements such as matrix attached regions (MARs) [14, 15] and ubiquitous

chromatin opening elements (UCOEs) [16] can also be included in plasmids, as they are known to generate transcriptionally active genomic environments once integrated into the cell genome.

DNA delivery. Several methods are in use for introducing plasmid DNA into cells. $Ca_2(PO4)_2$ precipitation is the earliest method, but has been surpassed by the more convenient and consistent lipid-base reagents (lipofectamine, fugene, transfectin) and electroporation [17]. Polyethyleneimine (PEI) [18] is a low-cost alternative DNA delivery method. Retroviral transduction has a long history for inserting DNA into cells, but use for manufacturing is only now emerging (Gala Biotech, Middleton, Wisconsin). Transfection efficiencies can vary from 5 to 100% depending on cell line and DNA delivery method. CHO cells can achieve 5–40% with $Ca_2(PO4)_2$, 20–60% with lipids, and 100% with retroviral transduction.

Amplification systems. The DHFR and GS amplification systems have successfully generated manufacturing cell lines with high protein titers (Lonza, Basel, Switzerland) [19, 20]. These systems employ a DHFR or GS cell line that is transfected with the plasmid encoding product of interest along with DHFR or GS, respectively. The use of methotrexate and methionine sulphoximine results in chromosomal amplification events that increase the DHFR or GS gene copy number, respectively, to overcome the drug toxicity. The gene encoding the product of interest is usually coamplified with the DHFR or GS genes as they are inserted into the genome in the same locations. Tenfold or greater improvements in expression can be achieved with this amplification system. The DHFR amplification system has the potential to experience the loss of transgene copy number [21–23], so stability studies are especially important to characterize cell lines derived from drug-induced genomic amplification approaches.

Sequential transfection. A simple approach to boosting expression is to repeat the transfection on previously transfected cells but with selectable markers not used in the first transfection. Xoma (Berkeley, CA), Sunol Molecular (Miramar, FL), and ICOS (Bothell, WA) have used this approach successfully. Fivefold or greater improvements in expression can be achieved in a single sequential transfection. ICOS reports the added advantage of balancing heavy and light chain ratios to improve the secretion and expression of recombinant monoclonal antibodies.

Table 32.2 summarizes expression systems that are currently used in the biotechnology industry for generating stable cell lines. Before one makes a decision as to which expression system is preferred, it is important to evaluate all aspects including productivity and time needed for cell line development, as well as potential license fee and cost.

Identifying High-Expressing Cells

For industrial cell line development, moderate to high-throughput methods are needed to identify the cells expressing the highest levels of the protein pharmaceutical. Typically, the cells are grown in selective or amplifying environments in several 96-well plates. For secreted proteins, enzyme-linked immunosorbant assays (ELISA) on conditioned media can identify the cells expressing the highest protein levels. AlphaScreen™ (Perkin-Elmer, Boston, MA) is a recent homogeneous assay that is well suited for high-throughput quantification of protein production. The Guava Inc. (Hayward, CA) personal cell analyzer (PCA) economically and conveniently generates fluorescence-activated cell sorting-like (FACS) expression profiles of cells with moderate throughput in 96-well microtiter plates. Using Guava PCA, clonal populations and cells with the highest average productivity can be identified.

A critical element of generating stable cell lines is identifying clonal populations of expressing cells. Pools of expressing cells tend to express lower levels of desired protein; they can drift to lower expression levels, and are more difficult to adapt to serum-free suspension. Limited dilution methods have been used for years whereas FACS sorting of live cells has also proven successful. FACS can be used to simultaneously clone and enrich for the highest expressing cells [24]. Recent automated approaches for identifying clones include picking high-expressing colonies in semisolid media (Genetix, New Milton, UK) and enriching for high-expressing cells by laser ablation of low and nonproducing clones (Cyntellect, San Diego, CA).

Cell Banking

A stock of cells must be preserved to ensure continuity for research, development, and manufacturing production programs. For a small research program, only a small number of frozen vials may be needed. However, to continue to supply a cell line for the manufacture of therapeutic proteins, it is usually best to prepare two-tiered cell banks: a master cell bank (MCB) and working cell banks (WCB). A single cell line demonstrating suitable expression levels and stability is used to generate an MCB, and a WCB is derived from one vial of the MCB. Each MCB and WCB usually includes 100–300 vials. As a WCB is depleted during manufacturing runs, another frozen vial of MCB is used to generate a new WCB.

Making cell banks involves the process of cryopreserving cells. During cryopreservation, cells can be damaged by the formation of intracellular ice crystals or by osmotic effects that occur with decreased water content. To minimize cell damage, the rate of freezing must be controlled and cryoprotectants must be used. Dimethylsulfoxide (DMSO) at 7.5–10% is routinely used as a cryoprotectant. In some cases, a low percentage of fetal calf serum or serum albumin is added to the freezing medium. However, when freezing cell lines for the production of therapeutic proteins, it is generally preferable to eliminate any animal-derived material to minimize the risk of disease transmission from animal to human. To control the rate of freezing, Nalgene Cryo freezing containers (Nalge Company, Rochester, NY) are routinely used in making small cell banks, whereas programmable controlled-rate cell freezers are needed for large cell banks.

Cell Stability

The properties of a cell line are likely to change during a long period of continuous passage. For example, cell lines can lose their expression and can generate undesired proteins clipped from the product. Therefore, it is critical to characterize the cells to ensure consistency for large-scale production and to guarantee that the properties of the protein derived from the cells are maintained. For a production cell line, an acceptable level of stability of the desired characteristics must be established and a maximum passage number must be defined so that comparison of the cells' characteristics can be made after low and extensive passages. Tests such as peptide mapping, amino acid sequencing, DNA fingerprinting, and determination of gene copy number and phenotype markers must be conducted to ensure the cells' genetic stability. In addition, productivity and product identity must be examined to assess the stability of the cell line. A good production cell line should be able to maintain its productivity and product quality through the many generations required to reach the end of large-scale production. In most instances, stability retained for 50 generations will satisfy the rigors of large-scale manufacturing.

Media

Mammalian cell culture is the most important source of therapeutic proteins and monoclonal antibodies. Just as mammalian cells are more complicated than most other microorganisms, the media required for their growth is also more complex. The extracellular medium must provide the same nutrients and growth factors that mammalian cells are exposed to in vivo in order for them to survive, proliferate, and differentiate. Serum contains many important components that support the growth of mammalian cells including growth factors, hormones, transport and binding proteins, attachment factors, protease inhibitors, and lipids. Serum was therefore commonly supplemented in the media in early mammalian cell culture and for large-scale production of therapeutic proteins and monoclonal antibodies in the 1980s. However, the use of serum in mammalian cell culture has many disadvantages: (1) it is a potential source of bacterial, mycoplasmal, and viral contamination; (2) it is the most expensive additive to cell culture media; (3) it has a high degree of batch variability, making production consistency difficult; (4) it contains a high concentration of proteins that can interfere with product recovery. In the early 1990s, these drawbacks, especially the serious concern about the risk of transferring diseases from animal to human, led to an important regulatory-driven trend to eliminate serum and animal-derived components from mammalian cell growth media. This trend sparked an industry-wide interest in developing serum-free media.

Commercial Serum-Free Media

Many new medium companies formed in the early 1990s. Today, more than a decade later, the medium development industry has matured. Currently, a variety of serum-free (SF)

Table 32.3 Examples of commercial serum-free media

Media	Type of medium	Cell type	Applied vendor
CD CHO	PF and CD	CHO	Invitrogen

media are available commercially. Table 32.3 lists some SF media produced in the United States. Many of these media are also made in powder form to facilitate use in large-scale production. As listed in Table 32.3, there are different types of SF media, which can be categorized into protein-free (PF), chemical-defined (CD), and animal component-free (ACF) media. The relationships among these different types of media are illustrated in Fig. 32.1.

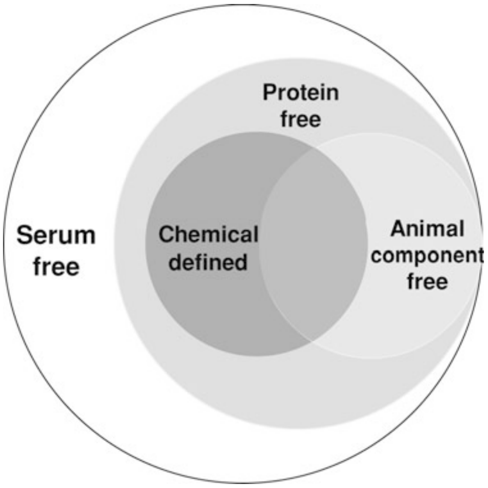

Fig. 32.1 Relationships among serum-free, protein-free, chemical defined and animal component-free media

SF, PF, ACF, and CD media tend to be highly specific to one cell type and sometimes even to one particular cell line. It is not uncommon that a different optimal medium is required for a particular cell line. Developing SF, PF, ACF, or CD media requires considerable experience and expertise and can be very time-consuming. One approach is to start with a commercially available SF medium and add necessary nutrients to optimize growth and production for a particular cell type. This approach can shorten the time-line needed for in-house medium development.

However, using commercial media has two major drawbacks: commercial SF media are expensive, which can lead to a high cost of goods for large-scale production; the composition of a commercial SF medium is proprietary to the medium company and the buyer will not know its formulation. This makes it difficult to gain full knowledge about the growth and production characteristics of your cell line. To fully understand the metabolism and characteristics of your cell line, there is no substitute for developing your own media.

Approaches for Serum-Free Medium Development

Medium development is part of the process of cell culture optimization. It can be very complicated and time consuming, and will require expertise and resources. In this section, we outline the common and novel methods used for SF medium development. Details of each strategy can be found in the referenced literature.

In the early 1980s, efforts were initiated to eliminate serum or animal-derived components from the culture media used to produce human therapeutics. At that time, different strategies were recommended for the development of SF media:

1. Limiting factor method: [25] Starting with an existing formulation, the serum concentration is lowered until cell growth becomes limited; then the concentration of each component of the medium is optimized until cell growth recovers.
2. Synthetic method: [26] A variety of growth factors is added to the existing basal media to replace the serum's functions.

The last decade saw the development of many new genomic and automated screening tools. These advancements, as well as an improved understanding of mammalian cell culture, allowed novel concepts and approaches to be applied to the development of SF and CD media. Some representative strategies are briefly summarized below.

1. Rational design: [27] This method uses four complementary methods, including component titration (CT), media blending (MB), spent media analysis (SMA), and automated screening (AS), to achieve the best SF culture medium in the shortest timeline. An example of how to use this strategy is outlined in Fig. 32.2.
2. Factorial design: [28–30] This method identifies key growth factors in a lean basal medium by performing experiments using a full factorial matrix. It allows calculating the maximum number of interaction effects and gives insights into growth factor biology.
3. Genomic tools: [31] This method takes advantage of select genomic (microarrayor PCR-based approaches) and proteomic (antibody array analysis) tools to identify the receptors for growth factors, hormones, cytokines, and other components of cell signaling pathways expressed by a culture of interest.

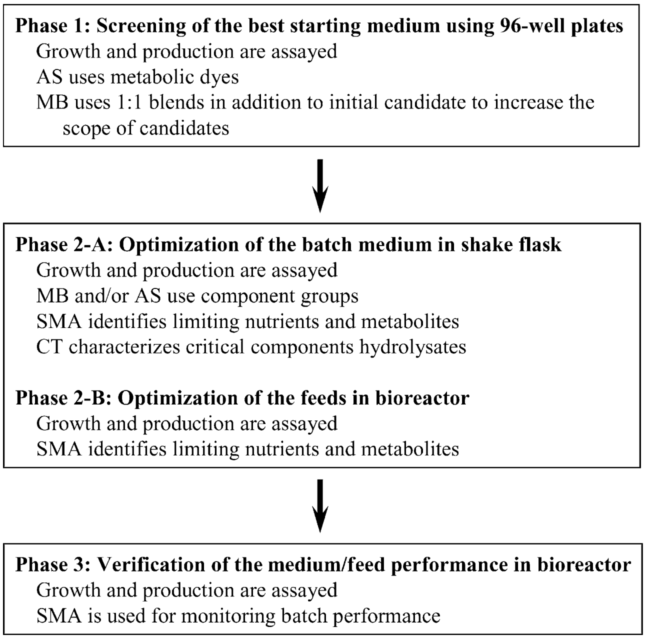

Fig. 32.2 Procedure of using rational design

Serum-Free Adaptation

In most cases, cells are grown in a serum-containing environment during the early stages of cell line development, such as transfection and selection. Once an SF medium with a good nutrient balance is chosen, the next step is to adapt cells to SF growth. Two adaptation strategies, sequential adaptation and starve/save adaptation, are described.

Sequential Adaptation. This method weans cells off serum gradually (e.g., from 10 to 5% to 2.5 to 1.25% to 0.5 to 0.1%) until the serum is completely removed. This strategy is conservative and easy to follow, and therefore commonly used in the biotechnology industry. A drawback is that it takes a relatively long time (up to 6 months) before achieving a full SF adaptation. A typical protocol includes these steps:

1. Grow the cells in a targeted SF medium containing 10% serum and split the cells until the same doubling time is achieved as in the old serum-containing medium.
2. Reduce the serum concentration to 5% and continue to split the cells until a relatively consistent doubling time is achieved. Reduce the serum concentration to 2.5% and repeat the process.
3. Transfer the cells to the medium containing 1.25% serum. At this level of serum, it will be more difficult for the cells to adapt. The cells may become stressed and show diminished survival. It is therefore wise to maintain the cells at the previous serum concentration while spliting them to a lower serum concentration.
4. Continue to reduce the serum to 0.5, 0.25, 0.1, and 0% by repeating step 3. At the low serum concentrations, seeding the cells at a high cell density (5×10^5 cells/mL) will facilitate adaptation. This can be achieved by centrifuging the cells out from the medium containing the current serum concentration and resuspending them into a

smaller volume of medium containing a lower serum concentration.

5. Once the cells are able to survive and grow in an SF medium with a high seeding density, split them several times at a lower density (2 × 10^5 cells/mL) to ensure that the cells are truly adapted.

Starve and save adaptation. This method uses an SF medium to starve the cells of components contained in serum, thereby selecting for adaptable cells. Switching to a serum-containing medium then saves the cells that became stressed during starvation. This process is repeated allowing selection and adaptation to continue until full SF adaptation is achieved. The advantage of this method is its effectiveness in selection, so it usually only takes 4–6 weeks to achieve the goal [32]. The following steps are used.

1. Define an SF medium and a serum-containing medium that have exactly the same formulation except for the serum.
2. Grow cells in the serum-containing medium to reach a high cell density.
3. Split and grow the cells in the SF medium, monitoring changes in cell density and viability.
4. When cell viability drops to about 50%, save the cells by transferring them back to the serum-containing medium.
5. Switch back to the SF medium to further select the cells and repeat steps 3–5 until the cells grow successfully in the SF medium.

Bioreactor Systems

Many therapeutic proteins are produced using genetically modified mammalian cells, as described in the preceding sections. This section describes the basic design and function of bioreactors used for suspended mammalian cell culture. Bioreactors should provide a sterile environment, adequate mixing, ease of operation, and control of temperature, pH, and dissolved oxygen. Traditionally, these requirements were met using glass or stainless steel stirred-tank systems. At production scale, therapeutic proteins are primarily produced in stirred-tank bioreactors. However, single-use, disposable systems such as the Wave bioreactor are gaining acceptance for certain applications.

Stirred-Tank Systems

Stirred-tank bioreactors are generally glass or stainless steel tanks with an impeller to provide mixing. Air or oxygen is usually bubbled through the media to supply oxygen to the cells. An example of a stirred-tank bioreactor is depicted in Fig. 32.3. Sterility is obviously an important issue in mammalian cell culture, and therefore stirred-tank systems require extensive cleaning and autoclaving. A significant portion of the labor involved with operating these systems is related to cleaning and sterilizing.

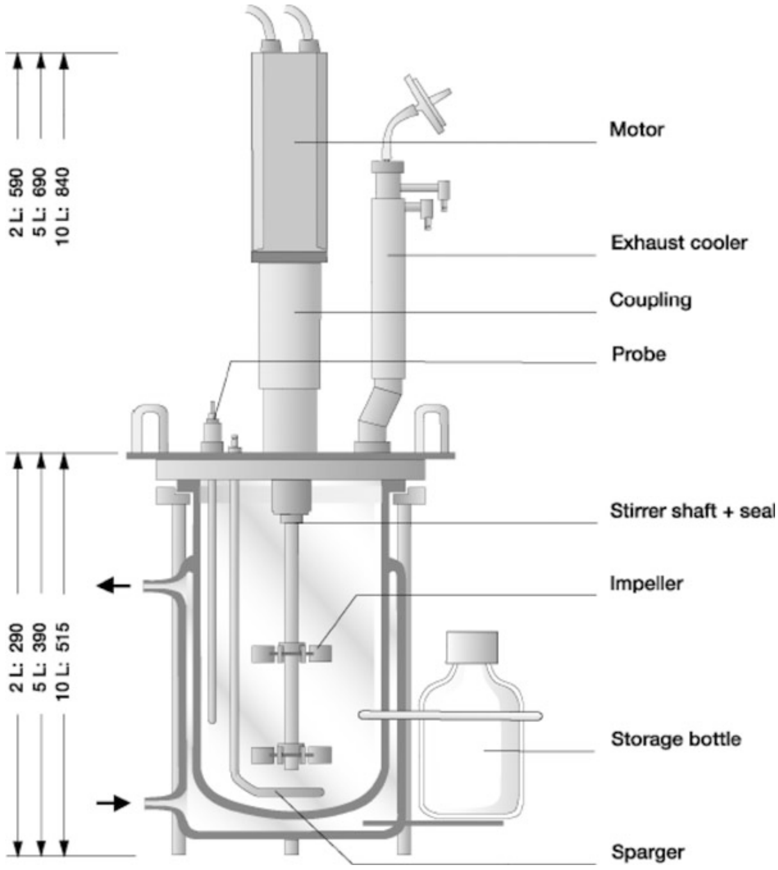

Fig. 32.3 Standard bench-scale, water-jacketed stirred tank bioreactor (Permission of Sartorius BBI Systems Inc.)

Mixing in stirred-tank bioreactors. Adequate mixing is essential to suspend the cells and to facilitate heat and mass transfer. Historically, however, due to concerns regarding mammalian cells' sensitivity to hydrodynamic stress, most stirred-tank bioreactors were agitated just enough to keep the cells in suspension [33]. This low level of mixing can result in large concentration gradients of pH, oxygen, and other nutrients. Ozturk demonstrated this experimentally by adding base to a poorly mixed bioreactor [34]. The base was added to the top of the bioreactor, and because of poor mixing, a high pH region was created at the top. The cells in this region ruptured, forming a "snowball" of cellular debris in the vicinity of the base inlet.

Proper impeller selection and sizing will improve mixing. Generally, the diameter of the impeller should be approximately one-third to one-half of the tank diameter. The lowest impeller should produce a radial flow pattern to aid in gas dispersion, and the upper impeller(s) should produce axial flow to eliminate "zones of mixing." Paddle or Rushton impellers produce radial flow, and hydrofoils and pitched blade impellers produce axial flow. Retrofitting existing bioreactors with different impellers, however, may prove difficult because the motor driving the impellers may not produce enough torque to turn them. Adequate baffling will also improve mixing; baffles prevent solid body rotation and vortex formation [35].

Aeration. Oxygen can be introduced to the culture in many different ways. Membrane aeration provides efficient oxygen transfer with minimum shear damage to the mammalian cells and minimal foaming. However, due to the design complexity and the difficulty involved in cleaning and sterilizing membrane reactors, membrane aeration has limited utility in large-scale bioreactor systems. Sparger aeration offers high oxygen transfer rates and is widely used in both bench and production-scale bioreactors. Because oxygen is only sparingly soluble in water, a large surface area is needed to maximize diffusion of oxygen into the cell culture media. Frit spargers with micropores provide a large surface area for diffusion, but this type of sparger can cause foaming problems at large scale. Traditional large-hole-ring spargers reduce foaming and are therefore often used in production-scale stirred-tank bioreactors [36].

Biosensors. Sensors are required to adequately monitor bioreactor performance. Ideally, one would like to have online sensors to minimize the number of samples to be taken from the bioreactor and to automate the bioreactor process. Most bioreactors have autoclavable pH and dissolved oxygen (DO) electrodes as online sensors, and use offline detectors to measure other critical parameters such as glucose and glutamine concentration, cell density, and carbon dioxide partial pressure (pCO_2). An online fiber-optic-based pCO_2 sensor is commercially available and appears to be robust [37]. Probes are also commercially available that determine viable cell density by measuring the capacitance of a cell suspension. Data from perfusion and batch cultures indicate that these probes are reasonably accurate at cell concentrations greater than 0.5×10^6 cells/mL [38, 39].

All of the aforementioned biosensors are designed for a standard stirred-tank bioreactor; they will not work with small-scale vessels such as shake flasks. Small noninvasive sensors have been developed to measure DO and pCO_2 inside shake and T-flasks [40, 41]. A DO or pCO_2 detecting "patch" is placed in the flask and this patch contains an oxygen or carbon dioxide luminescent dye. The color shifts of these dyes are detected using an external fluorometer.

Disposable Bioreactors

One of the major drawbacks of the stirred-tank bioreactors is the difficulty of cleaning and sterilizing the vessels. Disposable bioreactors are now commercially available that are based on the use of presterile plastic bags. The sterile bag is partially filled with cell culture media and is then pressurized with a mixture of carbon dioxide and air. The bag is placed on a platform that rocks back and forth creating waves inside the bag. The wave motion provides sufficient mixing and gas transfer to easily support cell growth of over 20×10^6 cells/mL [42]. Currently, wave bags are available in sizes up to 500 L culture volume and have been proven for the good manufacturing practice (GMP) production of human therapeutics. Wave bioreactors have been primarily used as batch culture for inoculum preparation and transient production; however, internal perfusion filters can be applied, allowing the option of use for high-density perfusion culture.

Modes of Bioreactor Operation

Industrial mammalian cell culture can be divided into three primary modes of operation: batch, fed-batch, and perfusion. Each mode of operation has its attributes and drawbacks, which are described in detail below.

Batch. Batch culture is the simplest of the three modes to operate. Cells are inoculated into media, and with the exception of agitation, temperature, pH, and DO control, essentially left alone for 3–5 days; no additional nutrients or media are added. Batch processes are easy to operate and require the least optimization effort of the three modes. However, cell densities and protein titer are significantly lower for batch processes, typically less than 5 × 10^6 cells/mL and 0.5 g/L, respectively [43]. Also, some protein products are degraded in the media during the batch process.

Fed-Batch. Fed-batch processes start out as batch cultures; after a few days of growth—when a crucial nutrient is depleted—a concentrated solution of nutrients is added to the media. Fed-batch cultures persist for one to two weeks and may produce high cell density and product titers, typically greater than 10 × 10^6 cells/mL and 1.5 g/L, respectively [43].However, one needs to optimize the contents of the feed solution as well as the feeding strategy. Similar to batch cultures, fragile proteins may be degraded during the course of the culture.

Perfusion. Perfusion cultures can be considered continuous cultures. Broth is continually removed from the bioreactor, the cells are separated using a cell retention device, the cells are returned to the bioreactor, and the supernatant is collected for later protein purification. There is a variety of cell retention devices available, including spin filters, acoustic separators, continuous centrifuges, and gravity settlers. Spin filters and, to a lesser extent, acoustic settlers are the two most commonly used cell retention devices for large-scale perfusion cultures [44]. Perfusion cultures usually last many weeks, but require a longer time for process optimization, and more effort in bioreactor operation than either batch or fed-batch cultures. The increased effort is primarily due to continuous feeding/harvesting and fouling of the cell retention devices. The cell densities attained in perfusion cultures are usually on the order of 50 × 10^6 cells/mL, and the product titer, in most cases, is lower than that from fed-batch culture. However, the volumetric productivity is typically ten times that of fed-batch cultures. Because broth is continually removed from the bioreactor, fragile proteins can be separated immediately from cell proteases and other components that can cause degradation of the product.

Cell Culture Process and Control

Mammalian cell culture processes must be tightly controlled to attain acceptable cell density and maximize product titer. Slight deviations in pH, temperature, nutrient, or catabolite concentrations can cause irreparable damage to the cells. This section covers the effects of pH, shear stress, catabolite, and carbon dioxide accumulation on cell growth and product formation, and discusses the importance of controlling glucose and glutamine concentrations in fed-batch and perfusion cultures. A brief discussion of scale-up heuristics in mammalian cell culture is also included.

Table 32.4 General control parameter set points for mammalian cell culture

Control parameter	Optimal range
Temperature	37°C
pH	7.0–7.4
Osmolality	280–320 mOsm/kg
O_2 demand	0.5–2 mM/h

Process Parameters

General parameter values. The optimal pH range for mammalian cell growth is 7.0–7.4, which is typically maintained using carbon dioxide and sodium bicarbonate. The optimal osmolality of the media is between 280 and 320 mOsm/kg. In general, mammalian cells achieve high cell densities most quickly with the temperature set to 37°C; however, a lower temperature may be advantageous in some cases for extending cell life, thereby increasing product titer. The oxygen demand for mammalian cells is 0.5–2 mM/h and is one of the more critical control parameters in cell culture. The optimal ranges of common control parameters in cell culture are summarized in Table 32.4.

Mitigating Effects of Physical and Chemical Stress

Shear Stress. Because mammalian cells lack a cell wall and are larger than bacteria, they are more susceptible to hydrodynamic forces, or shear stress. Several studies have investigated the effects of shear stress on mammalian cells [45–48]. Many indicate that the action of the impeller alone does not decrease the viability of suspension-adapted mammalian cells [46, 48, 49]. Some bioprocess engineers in industry have seen a few cell lines that appear to be less robust, and anecdotally might have been damaged by the impeller. However, bubble rupture does cause sufficient hydrodynamic force to kill all the cells attached to the bubble [48]. The effects of bubble rupture can be greatly reduced by the addition of surfactants, such as Pluronic F-68. Pluronic F-68 renders cell-bubble adhesion thermodynamically unfavorable, so the cells do not adhere to bubbles [50]. However, Pluronic F-68 offers very little shear protection; cells rupture at the same level of hydrodynamic force regardless of the Pluronic F-68 concentration [51]. Cells attached to microcarriers, however, are very susceptible to shear stress and can quite easily be removed and killed by the action of the impeller [47].

pH Perturbations. As mentioned earlier, significant pH gradients within the bioreactor are common, due to

Table 32.5 Effects of shear force, pH deviation, and accumulation of lactate, ammonia, and carbon dioxide on cell culture

Stress	Cause	Effects	Possible solution
Shear force	Bubble rupture, impeller	Decreased viability	Add surfactants such as Pluronic F-68
pH deviations	Inadequate mixing	Decreased growth rate, viability	Increase agitation/aeration rate; optimize vessel configuration
Lactate accumulation	High glucose concentration	Decreased growth rate, increased glucose/glutamine consumption	Optimize feed strategy/media to reduce (glucose)
Ammonia accumulation	Metabolism/deamination of glutamine	Apoptosis, decreased growth rate, altered glycosylation	Optimize feed strategy/media to reduce (glutamine); use cell line with GS system
CO_2 accumulation	Cellular respiration, sparged gas component	Decreased growth and protein production	Increase agitation/aeration rate; optimize vessel configuration

inadequate mixing. Cell lysis occurs at extreme pH; however, even moderate deviations from the optimal pH may be detrimental. Osman and coworkers found that pH values greater than 8.0 or less than 7.0 cause a considerable decrease in cell viability and a reduced culture time [52]. Antibody titers increased when the pH set point was reduced from 7.2–7.3 to 7.0 [52, 53]. The best way to eliminate deviations from optimal pH is to improve mixing (reduce the mixing time); this can be achieved by increasing the agitation or aeration rate, adding baffles, or optimizing the impeller design or placement.

Catabolite accumulation. Several byproducts of cellular metabolism accumulate during the course of a bioreactor run. Many of these catabolites, such as lactate, ammonia, and carbon dioxide, are detrimental to cell growth and protein production. Lactate is a product of glycolysis and lactate accumulation greater than 2 g/L tends to inhibit cell growth and increase glucose and glutamine consumption [54, 55]. Lao and Toth pointed out the difficulty in completely decoupling the effects of lactate accumulation from the effects of increased osmolality (osmolality increases with increasing lactate concentration) [54]. The effects of lactate accumulation can be mitigated by keeping glucose levels low, which can be achieved by optimizing media composition and feeding strategies.

In cell culture, ammonia is produced as a cellular metabolite and is converted from glutamine in the media through deamination. Less than 20 mM ammonia inhibits cell growth, induces apoptosis, and alters glycosylation in certain cell lines [56–58]. The primary method of reducing ammonia concentrations in fed-batch and perfusion cultures is to optimize feeding strategies. In addition, cell lines containing the glutamine synthesis gene (GS systems) can be used to eliminate ammonia production; in GS systems, the cells are able to synthesize glutamine based on need. A recent report shows that substituting glutamine with pyruvate can greatly reduce ammonia production [57].

Carbon dioxide is a product of cellular respiration. In mammalian cell culture, carbon dioxide and sodium bicarbonate are normally used to control bioreactor pH. Elevated partial pressure of carbon dioxide (pCO_2) hinders cell growth and protein production [59–61]. As with lactate accumulation, the effect of elevated pCO_2 is difficult to completely decouple from the effect of elevated osmolality [60, 61]. Generally, one can reduce pCO_2 by increasing the volumetric mass-transfer coefficient (kLa), typically by increasing the sparge rate and/or the agitation rate. Mostafa and Gu were able to reduce pCO_2 in a 1,000 L culture and nearly double the titer by increasing the sparge rate and using an open pipe instead of a sparger [62]. Table 32.5 summarizes the effects of shear force, pH deviation, and accumulation of lactate, ammonia, and carbon dioxide on cell culture and lists methods to minimize these effects.

Temperature shifts. Culture temperature is one of the primary control parameters in mammalian cell culture. As stated previously, most mammalian cells grow optimally at 37°C. However, reducing the temperature set point slows cellular growth rate and metabolism, extends the period of high cell viability, arrests cells in the G0/G1 phase of the cycle, and possibly reduces intracellular protease activity [63–66]. By decreasing the temperature to 31–33°C, the period with high cell viability is extended for several days, leading to higher product titers. Fox et al. [65] and Bollati-Fogolin et al. [66] reaped the benefits of a cooler temperature without excessively extending culture time by shifting from 37 to 32 or 33°C, respectively. The temperature shift occurred toward the end of the cells' exponential growth phase, approximately 3–4 days after inoculation in a batch culture. Different cell lines and culture conditions may have different optimal time points for the temperature shift. However, finding the optimal time point is important and worth investing the time required. Operating cell cultures at a reduced temperature will most likely increase production of the target protein, but to avoid substantially increasing the culture time, the culture is generally started at 37°C, and then decreased to 31–33°C at a predetermined time point.

Fed-Batch Process Control and Optimization

In general, fed-batch cultures are initially operated in batch mode; when a key nutrient(s) is exhausted, a solution containing the nutrient(s) is added to the media. As mentioned earlier, the feed solution and feeding strategy should be optimized. A common approach is to use partial concentrates (i.e., 10×) of the basal media as the feed solution; typically most of the salts found in the basal media are not included in the feed solution. The bioreactor is sampled at regular intervals and when one or more of the key nutrients (usually glucose and/or glutamine) is below a certain concentration, a precise amount of feed solution is added to raise the nutrient concentration up to its set point. A useful rule for choosing the nutrient set point concentrations is to provide enough nutrients to support cell growth and production while avoiding the formation of toxic levels of catabolites due to excess feeding. Another method is to determine which of the media's several nutrients become depleted during the culture and add those particular nutrients to the bioreactor independently [67]. Wong et al. selected glutamine and glucose as key control nutrients, and used two feed solutions (glucose and glutamine solutions) to maintain them at specified concentrations [68]. Using this strategy, they maximized cell viability and density while decreasing accumulation of lactate and other catabolites.

Perfusion Process Control and Optimization

In perfusion bioreactors, supernatant is removed from the bioreactor at certain times, the cells are separated from the supernatant, the supernatant is harvested, and the cells are returned to the bioreactor. Perfusion bioreactors can be operated in a variety of modes. The simplest mode is to consistently remove a certain amount of broth each day (i.e., one bioreactor volume/day) and replace with fresh media. This mode is relatively easy to control. However, as the cell density increases, the required nutrient level may not be met. Also, the protein product tends to become diluted in the collected supernatant [34, 38]. Another mode of perfusion operation is to remove relatively small volumes of media at a time and replace the volume with a concentrated solution of nutrients. This mode is similar to fed-batch bioreactors. One might think of this as a perfusion/fed-batch hybrid, and as with fed-batch bioreactors, considerable effort goes into determining the optimal nutrient set point concentrations and the feeding strategy. Sophisticated analysis and control schemes have been developed for this type of perfusion bioreactor [69, 70]. A third mode of perfusion bioreactor operation attempts to maintain a pseudo-steady-state cell concentration, after an initial growth period. Dowd and coworkers employed an online cell density meter and were able to maintain a relatively constant cell concentration by altering the perfusion rate, the amount of media removed from the bioreactor [38]. This mode of perfusion reduces the frequency of sampling and analysis required to uphold a set nutrient concentration, but requires a well-characterized online cell density probe and a well-calibrated pump control scheme.

Scale-Up of Mammalian Cell Bioreactors

When scaling up a process to large scale, it is important to maintain the same physical and chemical conditions as in small scale. The chemical conditions include pH, oxygen level, concentration of medium components, and concentrations of toxic metabolites; these must be monitored and controlled to keep the cells in the proper physiological environment. The physical conditions include the bioreactor configuration and the power provided to the bioreactor. In scale-up, it is critical to preserve a similar geometrical configuration of the bioreactor in order to facilitate duplication of mixing patterns.

Impellers are an important physical component in a stirred bioreactor; they convert electronic energy to hydrodynamic motion and generate the turbulence required to keep the cells in suspension and achieve good mass transfer. At large scale, efficient oxygen delivery and carbon dioxide stripping become increasingly difficult due to poor mixing. At the same time, the energy generated at the tip of the impeller blades must be limited, as certain cell lines can be damaged by the elevated shear force. Therefore, to achieve good mixing and minimize possible damage of the cells from high shear force, one must determine the proper impeller shape, ratio of impeller to vessel diameter, and impeller tip speed.

The mixing time as well as the oxygen and carbon dioxide mass transfer rates can be correlated to the power per unit volume of the reactor, also known as the average or overall energy dissipation rate [71]. Maintaining constant power per unit volume is a commonly used scale-up strategy because of its simplicity. Other strategies include keeping the average shear force experienced by the cells constant, or keeping the maximal shear force constant (the shear force experienced by the cells when passing the impeller tip).

In addition to scale-up models, scale-down models are widely used to establish the operating ranges of critical large-scale process variables [72, 73]. Conducting the many experiments required to define a validated range for

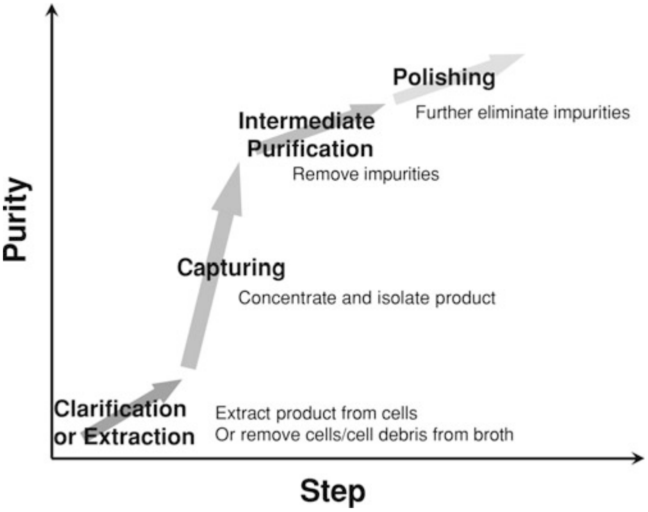

Fig. 32.4 General strategies for protein purification (Permission of Amersham Biosciences, GE Healthcare)

each parameter is not feasible at large scale. A scale-down model based on an existing large-scale process therefore becomes an efficient and economic tool in reaching this goal.

Purification Process

The process of purification, also called "downstream processing," depends on the product and the degree of purification required [74]. Current strategies used for purification of therapeutic proteins generally involve these steps: (1) sample preparation (clarification or extraction), (2) product capture (product concentration), (3) intermediate purification (removal of bulk impurities), and (4) polishing (removal of trace impurities) as shown in Fig. 32.4.

Microbial cells such as *E. coli* and yeast are limited in their ability to make glycoproteins or correctly structured glycoproteins. Therefore, therapeutic proteins (including monoclonal antibodies) that require glycosylation for their biological activity are often produced via cultivation of mammalian cells. Compared to microbial fermentation, mammalian cell culture generates complex broths with a variety of impurities. Typical impurities found in culture broths include:

1. Host cells and cell debris
2. Host cell protein (HCP) and DNA released by the cells
3. Aggregated proteins or cleaved proteins produced by the cells
4. Medium additives (such as serum and protein used to support cell growth)

These impurities pose risks for the safety of proteins used as therapeutics and must be removed to a final concentration below their target limit. In addition, the product stream contacts materials such as filters and resins. Extractables, such as leachates from protein A resins, can pose an immunogenic risk to the patient and must be eliminated [75]. Finally, adventitious agents such as viruses and bacterial pathogens or related contaminants such as endotoxins can lead to serious problems with the safety of the protein preparation and therefore must be minimized. Table 32.6 lists concentrations for the above impurities that are generally considered acceptable in a final protein product [76].

Table 32.6 Concentrations of impurities generally acceptable in final protein product

Impurity	Concentration in final product
Cell debris	0
Host cell protein and serum	<0.1–10 mg/L
Aggregated/cleaved proteins	Various
DNA	10 ng/dose
Leachates	0.1–10 mg/L
Virus pathogens	$<10^{-6}$/dose
Endotoxins	0.25 EU/mL

This section describes some general processes used for protein purification, including methods and tools currently employed by the bioseparation industry to achieve clarification, capture, and removal of impurities.

Generic Processes

As shown in Fig. 32.3, each purification step has different goals. The purification problems associated with a particular step will greatly depend on the properties of the starting material. Thus, the goal of a purification step will vary according to its position in the process.

Chromatography is one of the most important tools in protein purification. Chromatographic purification techniques include affinity chromatography (AC), ion exchange chromatography (IEX), hydrophobic interaction chromatography (HIC), and gel filtration (GF). These techniques separate proteins according to differences in specific protein properties. The protein property used for separation, the attributes of each technique, and its suitability for different purification steps are summarized in Table 32.7.

Selection of the purification strategy will depend on the specific properties of the sample and the required level of purification. Due to the widely differing properties of proteins, a final purification strategy that is most suitable for one protein may be unsuitable for another. A logical combination of chromatographic steps can usually achieve the final goal of protein purification. Figure 32.5 shows two flow diagrams commonly used for the purification of proteins expressed by mammalian cells.

Table 32.7 Attributes and purification suitability of chromatographic techniques (Permission of Amersham Biosciences, GE Healthcare)

Technique	Protein property	Main attributes	Capture	Intermediate Purification	Polishing
Affinity chromatography (AC)	Ligand specificity	High capacity High resolution High speed	+ + +	+ + +	+ +
Ion exchange chromatography (IEX)	Charge	High capacity High resolution High speed	+ + +	+ + +	+ + +
Hydrophobic interaction chromatography (HIC)	Hydrophobicity	High capacity High resolution High speed	+ +	+ + +	+
Gel filtration (GF)	Size and shape	Low capacity High resolution	–	+	+ + +

+ + + = highly suitable; + + = very suitable; + = suitable; – = not suitable

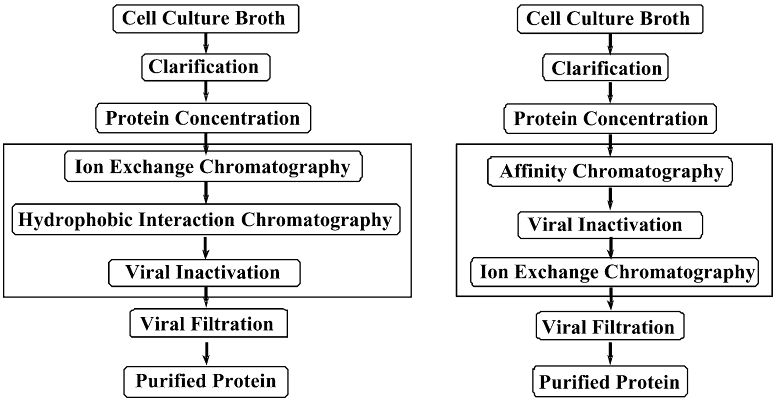

Fig. 32.5 Flow diagrams for protein purification

Clarification of Broth

For proteins secreted into broth, the first objectives after cell culture are to remove cell mass and debris, to reduce processing volume, and to bring the product to a stable holding point for further purification steps.

At bench-scale purification, a two-step operation of depth filtration followed by sterile filtration (or centrifugation followed by sterile filtration) can efficiently remove large particles, colloidal particles, and bacteria. At industrial scale, however, the clarification step is usually completed by three stages in series as shown in Fig. 32.6.

Centrifuges can function in batch-mode and continuous mode. Batch-mode works well for laboratory-scale processes, whereas continuous-mode can handle larger volumes and is thus conducive to large-scale processes. Both depth and tangential flow filtration are commonly used in the clarification. For large-scale purifications, depth filters may have volume and throughput limitations. Tangential flow filtration becomes a better choice when processing large harvest volumes.

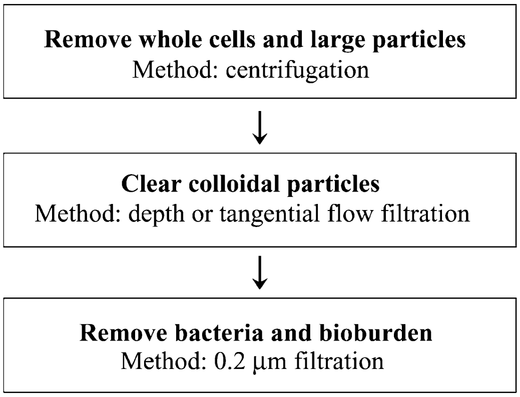

Fig. 32.6 Procedures for broth clarification at large scale

Capture of Product

The goal in the capture step is to concentrate and isolate a protein product. This step is usually accomplished with ion exchange or affinity chromatography. Ion exchange separates protein molecules based on interactions between charged side chains on the protein surface and oppositely charged groups, such as ammonium or sulfate, covalently linked to the chromatography matrix. The charge characteristics of a protein can be altered by changing the pH of the separation. Based on the charge differences of a targeted protein and other impurities, conditions at the capture step are selected to maximally bind the targeted protein and minimally bind the impurities to achieve isolation of the product. Ion exchange is probably the most frequently used chromatographic technique for the separation and purification of proteins. It offers many advantages such as high capacity, long resin lifetime, and low cost. Its operation is relatively simple and easy to control. A major disadvantage is that it usually only leads to moderate purity [77].

Affinity chromatography separates proteins based on a reversible interaction between a protein and a specific ligand coupled to a chromatography matrix. One of the most important attributes of this method is its excellent selectivity. As a result, affinity purification offers immense time savings over less selective multistep procedures. A single-step operation with affinity chromatography can achieve purification levels on the order of several thousandfold with high yield. The most successful example of affinity chromatography in protein purification is the use of Protein A to capture monoclonal antibodies. One-step purification with Protein A not only results in high yields of targeted antibodies, but also removes bulk contaminants such as host cell protein, DNA, and virus, leading to purity greater than 95%. Another advantage of using Protein A is that it works for multiple antibodies. Major disadvantages are: (1) high cost, (2) cleaning and sanitization difficulties, and (3) ligand leakage.

There are many different types of Protein A affinity media: MabSelect™ (GE Healthcare, Chalfont St. Giles, UK) and PROSEP Ultra (Millipore, Billerica, MA) are the two most commonly used at production scale. Recently, GE Healthcare released a new type of Protein A called MabSelect SuRe™. This latest MabSelect resin is resistant to deterioration from cleaning and sanitization-in-place with 0.1–0.5 NaOH.

Removal of Impurities

Although the capture step dramatically enriches a targeted protein and removes some impurities, bulk impurities such as host cell protein, DNA, endotoxin, virus, and leaching ligand remain in the eluted pool. Additional procedures are needed to eliminate these impurities.

Depending on the required level of purity, the step used for removing impurities can be a single or multiple-step chromatography operation. Table 32.8 summarizes chromatographic methods that can be used to remove impurities following the capture step [76, 78–80].

Table 32.8 Chromatography methods used to remove impurities

Impurity	Methods used to remove impurity
Host cell protein	AEX, CEX, HIC, AC
Aggregated/cleaved proteins	CEX, HIC
DNA	AEX, CEX, HIC, AC
Leachates	AEX, CEX, HIC
Virus pathogens	AEX, CEX, HIC, AC
Endotoxins	AEX, CXE, AC

For monoclonal antibody purification in which Protein A is primarily used for protein capture, cation and anion exchange chromatography are employed to reduce the remaining impurities [81]. Because the majority of monoclonal antibodies have a pI greater than 7 and predominating impurities (HCP and protein A leachates) have pIs lower than 7, cation exchange can retain the product and allow the impurities to flow through. Anion exchange can be employed as a noproduct-binding step to remove residual DNA and endotoxin. In this mode, the trace impurities will be retained on the column and the antibody will flow through. This step typically clears 2–5 logs endotoxin and 3–5 logs DNA [76].

Separation by HIC is based on the reversible interaction between a protein and the hydrophobic surface of chromatographic medium. This interaction is enhanced by high ionic strength buffers. Thus, HIC usually follows an ion exchange step where a high salt buffer is used for elution. It can be used to remove impurities such as host cell protein, DNA, and virus. However, at production scale, it is not as widely used as IEX.

Gel filtration separates proteins based on size and shape and can also be applied to remove the trace impurities. However, because this method is usually very slow, its application is often limited to bench or pilot scale.

In addition to chromatography, membrane filters have also proven to be effective in removing virus and endotoxin. For example, application of Sartobind™ membrane adsorbers made by Sartorius (Goettingen, Germany) results in up to 5 logs reduction of endotoxin. The Ultipor® VR grade DV50 membrane by Pall Corporation (East Hills, NY) demonstrated a greater than 7 log clearance in removal of retroviruses [82].

Strategies for Scaling Up Purification Processes

The great demand for high-quality therapeutic proteins requires efficient manufacturing processes, both upstream and downstream. When bioreactors are scaled up from bench to pilot to production scale (10,000–20,000 L), downstream processes must be scaled up accordingly. Equally complicated as upstream processes, scale-up of downstream processes requires more than simply increasing the size and volume of the laboratory equipment. The use of larger piping dimensions, larger filters, different types of pumps, and larger dead volumes can introduce variation to the large-scale process. We've limited our description here to common strategies used by the industry to scale up chromatographic columns.

Scale-up of affinity chromatography [78]

1. Prior to scale-up, different protein A resins should be screened. To achieve high production rate, defined as the amount of protein purified per unit time and per unit column volume, a resin must have a high dynamic binding capacity and be able to operate at low back-pressures.
2. Before scale-up, the column volume based on the required binding capacity must be calculated and the optimum bed height that allows high flow rates and high dynamic capacities must be determined.
3. During scale-up, the residence time, which is equal to the bed height divided by the linear velocity of the fluid, must be kept constant.
4. The operation flow rate should not exceed 70% of the maximum flow rate specified by the resin's vendor.

Scale-up of ion exchange column [78].

1. Prior to scale-up, screen resins to obtain those that offer a long lifetime, lot-to-lot consistency, and long-term availability.
2. During scale-up, the column volume should be increased by keeping the height of the resin bed constant and increasing the column diameter.
3. During scale-up, the total load of protein per unit of resin should be the same and the linear flow rate should be identical.
4. Scale-up usually involves two steps: the first step results in an increase of 50- to 100-fold, from laboratory to pilot scale; the second step results in an increase of 10- to 50-fold, from pilot scale to full production scale [83].

An Introduction to Biomass and the Biorefinery

What Is Biomass?

In its simplest terms, biomass is all the plant matter found on our planet. Biomass is produced directly by photosynthesis, the fundamental engine of life on earth. Plant photosynthesis uses energy from the sun to combine carbon dioxide from the atmosphere with water to produce organic plant matter. More inclusive definitions are possible. For example, animal products and waste can be included in the definition of biomass. Animals, like plants, are renewable; but animals clearly are one step removed from the direct use of sunlight. Using animal rather than plant material thus leads to substantially less efficient use of our planet's ultimate renewable resource, the sun. So, we emphasize plant matter in our definition of biomass. It is the photosynthetic capability of plants to utilize carbon dioxide from the atmosphere that leads to its designation as a "carbon neutral" fuel, meaning that it does not introduce new carbon into the atmosphere. In reality—as discussed later in the description of life cycle assessments of biomass use—we find that biomass fuels are not quite carbon neutral, because somewhere in the life cycle of their production, conversion, and distribution, some fossil energy carbon is released.

Few people understand the scale of energy and organic matter captured by photosynthesis in the form of biomass on the planet. Consider, for example, that the sun sends 3×10^{24} J of energy per year to our planet [1]. On average, over the entire globe, plant photosynthesis captures only 0.1% of the solar energy bombarding our world, storing 3×10^{21} J of energy in biomass annually. How does that compare with world energy production? The U.S. Department of Energy (DOE) estimates that, in 2000, global primary energy production in the form of oil, coal, natural gas, nuclear power, hydroelectric power, and other forms (including a small amount of renewable energy) was 400 quadrillion Btus annually or 4.2×10^{20} J/year [2]. Thus, energy stored in biomass each year worldwide is seven times greater than humankind's annual energy production. Can we expect to tap all of this energy to meet the ever-growing demand for energy? Could we be taking much greater advantage of this renewable source of organics and stored energy?

The Structure and Composition of Biomass

Why, then, isn't biomass the major source of our energy supply? The answer is that—in comparison to the relatively recent discovery and use of fossil energy sources—biomass

has proved more difficult or at least more costly to convert into convenient forms of energy. Thus, although biomass has a very long history as humankind's first primary source of energy, it has tended to find its most important use in modern times as a source of higher-value (societally and economically) food and fiber products.

There are, of course, many forms of biomass. In modern agriculture, many crops are grown for the starch, sugars, protein, natural oils, and fiber they contain. Sugars from sugarcane are used today in Brazil to produce fuel ethanol [3]. They were also the primary source of fermentable sugars in the United States until molasses became too costly [4]. In the United States today, ethanol made from sugars derived from starch in corn is the largest source of renewable transportation fuel. Starch consists of glucose molecules strung together by α-glycosidic linkages. These linkages occur in chains of α-1,4 linkages with branches formed as a result of α-1,6-linkages (see Fig. 33.1). The ability to release sugars from starch is common to many animals, including humans. It is thus no surprise that starch was the first major carbohydrate biopolymer to be used for energy production other than combustion. Indeed, the use of enzymes to biologically release sugars from starch is one of the earliest examples of modern industrial enzyme technology. It stands as an example of how biotechnology might be used to process other forms of biomass [5].

To foster a new bioindustry, we need to turn to less used—but more abundant—forms of biomass. This means focusing on the lignocellulosic components of the cell walls of all higher plants. Here we find highly complex material, both in chemical composition and structure. Plant cell walls are divided into two sections, the primary and the secondary cell walls [6]. The primary cell wall, which provides structure for expanding the cell is composed of the major polysaccharides and a group of basic glycoproteins, primarily extensins [7]. The predominant polysaccharide in the primary cell wall is cellulose; the second most abundant is hemicellulose; and the third is pectin. Because cellulose is made up only of β-(1,4)-linkages, it has a highly linear structure that encourages the formation of strong hydrogen bonds between chains of cellulose (see Fig. 33.2). The high level of hydrogen bonding among the chains makes it difficult to attack or depolymerize, either chemically or biologically. Once depolymerized, however, it is relatively easy to ferment, because it consists of the single sugar, glucose. Hemicelluloses, in contrast, are biopolymers of six- and five-carbon sugars that are almost always branched with a wide spectrum of substituents, including acetyl esters, uronic acids, sugars, hydroxycinnamic acids, and other moieties distributed along the backbone polysaccharide. The branched and amorphous nature of hemicellulose is vulnerable to degradation, but organisms in nature do not readily utilize some of its various sugars. Hemicelluloses are thought to hydrogen bond to cellulose, as well as to other hemicelluloses, which helps stabilize the cell wall matrix and renders the cell wall insoluble in water.

The secondary cell wall, produced after the cell has completed growing, also contains polysaccharides and is strengthened by polymeric lignin covalently cross-linking to hemicellulose [6]. Lignin is a high-energy content biopolymer rich in phenolic components. It provides structural integrity to plants. The combination of hemicellulose and lignin provide a protective sheath around the cellulose and this sheath must be modified or removed before efficient hydrolysis of cellulose can occur.

The picture of biomass sketched here offers important insights. The complex structure of lignocellulosic biomass provides protection and structural integrity to biomass. This makes things more difficult for industrial scientists and engineers seeking to convert biomass into useful forms of energy, chemicals, and products. On the other hand, the diversity of biomass composition offers opportunities for processing biomass into a wide range of new and existing chemicals. The challenge to the industrial processor is to develop sophisticated and robust approaches to optimizing the recovery and conversion of each component from this highly complex structure.

Converting Biomass into Energy and Other Products

Biological Versus Thermochemical Processing

The distinguishing feature of the various paths from biomass to useful energy is the choice of conversion technology. These technologies fall into two main categories: thermochemical and biochemical conversion. Thermochemical processing, as its name suggests, relies on heat and chemical catalysis to produce useful energy and products from biomass. Likewise, biochemical processing relies on biological organisms and biological catalysts to transform biomass into energy and products. They are complementary, rather than competing, technology paths that are part of an integrated scheme for making a wide range of fuels, products, heat, and power from biomass.

Thermochemical conversion of biomass. The simplest form of thermochemical conversion is direct combustion of biomass to produce heat and power. Direct combustion of biomass for electricity production in the United States currently supports more than 10,000 MW of generating capacity, with the majority of the biomass coming from landfill gas, municipal solid waste, and wood fuel [8]. The Energy Information Administration of the DOE estimates that 3 gigawatts of electric capacity could currently be supplied by biomass at prices competitive with coal-derived electricity [9]. Direct combustion of biomass in existing power plants is a very effective means of offsetting fossil energy use because it displaces conventional fossil fuels in electric generating stations on essentially a one-to-one basis.

At the heart of most advanced thermochemical conversion processes is the conversion of biomass into simple chemical intermediates in a process known as gasification, as shown in Fig. 33.3. Gasification is a process in which biomass is heated in the presence of air, oxygen, and/or steam to produce a gas mixture that can be used as an energy source itself or can be converted into a variety of fuels and products. Gasification dates back to the early 1800s. It has its roots in technology originally used for the production of gas from coal for lighting and heating [10]. There are many possible variations for the production of a gas mixture often referred to as a synthesis gas or "syngas." The core steps, however, are gas production in a gasification reactor, tar cracking (integrated or separate from the gasifier), and cleanup of the syngas. The clean syngas can then be used to generate power by direct combustion or in a gas turbine/combined cycle system or be synthesized to other fuels or products.

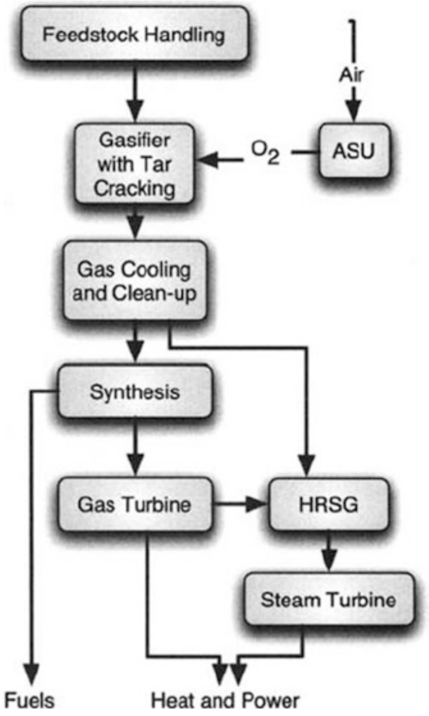

Fig. 33.3 General schematic of a process for thermochemical conversion of biomass to fuels, heat, and power. *ASU* Air Separation Unit; *HRSG* Heat Recovery Steam Generator

The severity of the conditions in this process affects the distribution of products, which can include pyrolysis oils, chars, and gases. The chemistry of gasification is relatively simple [11]. The key reaction that takes place in gasifiers is the "water gas shift" reaction. In this reaction, water (provided by steam) can combine with carbon to form carbon monoxide and hydrogen:

$$C + H_2O = CO + H_2$$

The carbon monoxide, hydrogen, and steam in the gasifier can then undergo more reaction to produce more hydrogen, carbon dioxide, and methane. The relative composition of the syngas will depend on the reactor conditions, choice of

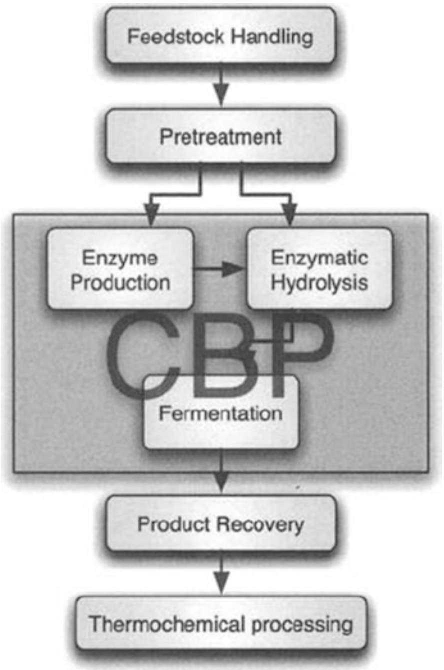

Fig. 33.4 General schematic of a biological process for converting lignocellulosic biomass to ethanol

catalysts, and the relative amounts of air, oxygen, and steam used. A wealth of chemistry is possible with this collection of simple compounds. Syngas can, therefore, serve as a platform for producing all sorts of fuels and other products. Syngas from coal, for example, is used to produce gasoline or diesel fuel products in large-scale commercial operations using so-called "Fischer–Tropsch" catalysts that can convert these simple compounds into hydrocarbons and oxygenates. Selection of conditions and catalysts in the water gas shift reaction also provides an opportunity to produce hydrogen from biomass for use in fuel cells [12].

Experience with biomass gasification, however, has been limited to heat and power generation. In the United States, the DOE helped to test gasification of wood, coupled with electricity generation, at a power plant in Vermont, successfully demonstrating this technology at the 200-t/day (5-MW) scale [13].

Biological conversion of biomass. Ethanol is typically the major fuel product of biological conversion. The basic steps of biological conversion are shown in Fig. 33.4. Lignocellulosic biomass can be converted into mixed-sugar solutions plus lignin-rich solid residues by the sequential use of thermochemical pretreatment and enzymatic saccharification. Sugars from hemicellulose and cellulose can then be fermented to ethanol for fuel production. Not shown in Fig. 33.4 is the possibility of biologically or chemically converting these sugars into other products.

There is a long and rich history of using acid and base catalysts to release the sugars found in cellulose and hemicellulose dating back to the discovery of wood sugars in the nineteenth century. The technology was commercialized during World War I in the United States, during World War II in Germany, and later in the twentieth century in the Soviet Union [14–34]. More advanced schemes for biological processing are under development today; however, they rely on this chemical hydrolysis step only as a pretreatment for removal of hemicellulose. Biologically mediated hydrolysis of cellulose is now viewed as the most selective and efficient means of hydrolyzing or depolymerizing the cellulose biopolymer to release its glucose sugar monomers. Many workers in the field agree that cellulose decrystallization and depolymerization are indeed the rate-limiting steps in the conversion of lignocellulosic biomass.

Removal of hemicellulose by dilute-acid pretreatment has been the classic means of rendering biomass more amenable to cellulase action [35]. In a hallmark study, Soltes and coworkers [36] showed that biomass with reduced acetylation responded significantly more favorably to cellulase action than did native biomass. Selig and co-workers more recently showed that enzymatic acetyl removal was effective in enhancing biomass hydrolysis after a variety of pretreatments. [679]. Although still controversial, there is some indication that biomass with reduced lignin content is also more readily hydrolyzed by cellulase action [37, 38]. At least one study has shown that lignin removal enhances enzymatic hemicellulose hydrolysis, the removal of which allows for greater hydrolysis of cellulose [680]. One key to understanding cellulase action on biomass is the fact that the structural and reactive chemical components of the substrate—primarily defined as acetyl and lignin contents—strongly affect enzyme access to cellulose. Another is that once cellulase component enzymes are available in sufficient ratio and concentration at the site of hydrolysis, the degree of cellulose crystallinity controls the hydrolytic rate [37, 39]. For the engineer seeking to improve this natural process, the key challenge is to make biomass depolymerization a more rapid and less costly conversion.

To be cost-effective, the process must use organisms capable of fermenting the full spectrum of five- and six-carbon sugars released from cellulose and hemicellulose. The advent of efficient genetically engineered organisms equipped with metabolic pathways to handle both types of sugars is an important improvement in the process that has occurred over the past decade or so [40–45]. The first generation of fuel ethanol technology for lignocellulosic biomass will include the production and use of enzymes for the hydrolysis of cellulose that work with these new versatile fermenting organisms. A future advance in the technology may involve the development of organisms capable of carrying out both the enzymatic hydrolysis of cellulose and the fermentation of the resulting sugars. This configuration—sometimes referred to as consolidated bioprocessing—would represent a

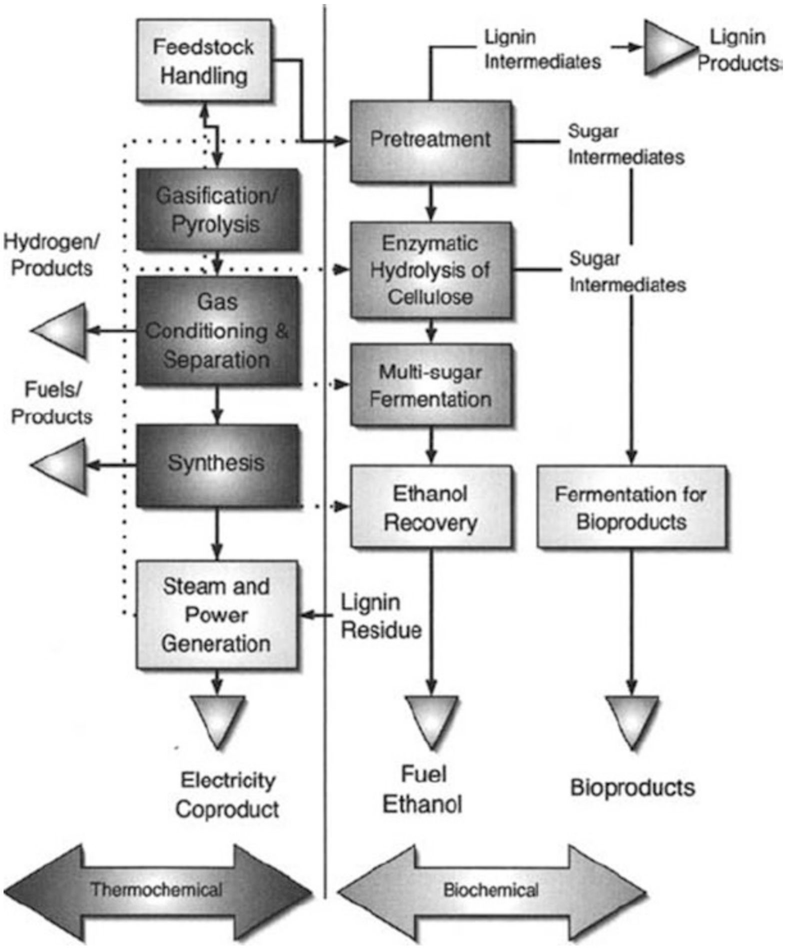

Fig. 33.5 General schematic of an ideal biorefinery combining biological and thermochemical processes for production of fuels, chemicals, heat, and power

significant step toward simplification and cost reduction of the process [46].

A purely standalone biological process is unlikely without significant improvement in both feedstock convertibility and microbial degradative and conversion capacity. Even after a combination of thermochemical pretreatment and biologicval conversion, there is a significant amount of residue left over after biological conversion of the carbohydrates. As shown in Fig. 33.4, this residue, containing mostly lignin, is usually sent to some form of thermochemical processing, even if that involves nothing more than direct combustion for production of heat, power, or both.

The Biorefinery

The integrated biorefinery is a conceptual framework that capitalizes on the synergies of integrating technologies from both biological and thermochemical process schemes. Furthermore, like the petroleum refinery, the biorefinery has the potential to combine production of low-volume, high-value products with high-volume, low-value fuels or energy production. The ideal biorefinery employs a combination of conversion technologies that maximizes the value of fuels, chemical, materials, and power made from biomass, as shown in Fig. 33.5.

The biorefinery should benefit from lessons learned during the evolution of modern-day petroleum refineries. These combine use of fluid catalytic cracking, thermal cracking, and hydrocracking technology to convert the higher-boiling-range fractions of crude oil into more useful lower-boiling-range products. Just as few petroleum refineries use all available conversion technologies, biorefineries too will use only those technology platforms that are most cost-effective for converting a certain type of biomass into a certain collection of desired endproducts.

Biomass, Fossil Energy Savings, and Greenhouse Gas Mitigation

The two most often touted benefits of biomass use are the ability to avoid the use of nonrenewable fossil energy resources and the concomitant ability to reduce net greenhouse gas generation, characteristics that can only be

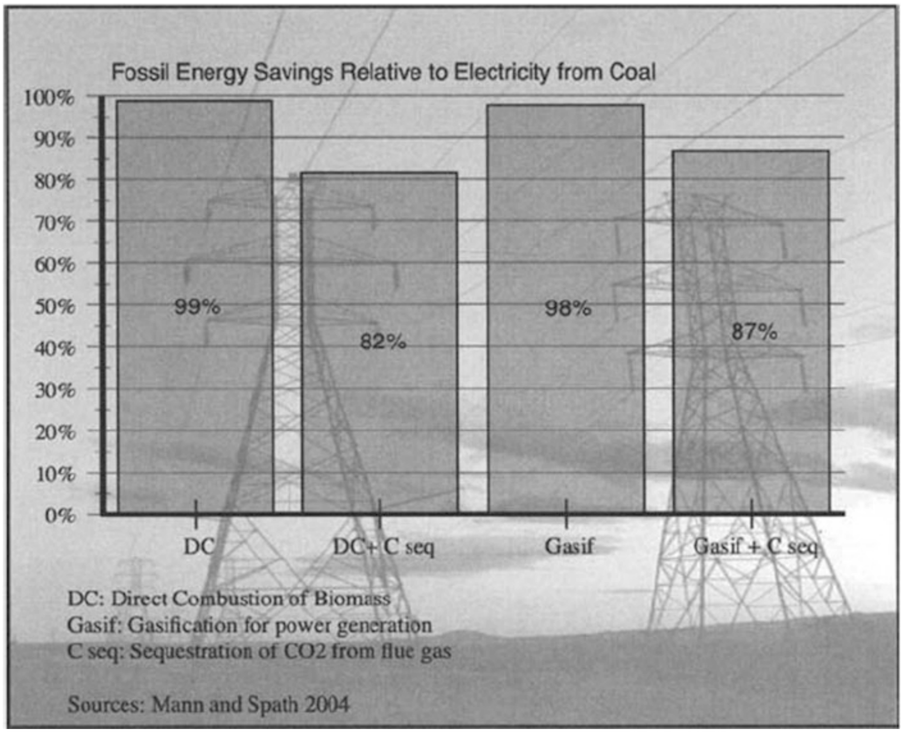

Fig. 33.6 Fossil energy savings for different biomass-to-power scenarios

assessed by using life-cycle assessment. Life-cycle assessment [47–52] is an analytical methodology for understanding the full impact of a given product or service on the environment and on the overall demand placed on our natural resources. In general, this involves looking at all of the stages of production and use of a product or service, from the first extraction of raw materials from the environment to the ultimate disposition of the product. For energy, this includes production and transport of a feedstock (whether that is coal, natural gas, oil, or biomass) to a conversion facility, conversion of the feedstock to a useful energy form, and distribution and use of the final energy product.

Life-Cycle Assessments of Biopower

Figure 33.6 summarizes the results of life-cycle assessments of the impact of various pathways for electricity generation from biomass on fossil energy requirements [53]. Direct combustion and gasification of biomass for power production provides 99 and 98% savings in fossil energy use, respectively, compared to combustion of coal for electricity generation. When carbon sequestration is added to either of these options, fossil energy savings are reduced because of the added energy demand for sequestering the carbon dioxide from the stack of the power plant. Greenhouse gas savings for these same technology options are also very good, often exceeding 100% reductions due to the effects sequestration of carbon in the soil that occurs when energy crops such as switchgrass are grown (see Fig. 33.7).

Life-Cycle Assessments of Biofuels

Figure 33.8 shows fossil-energy savings associated with the production of hydrogen, ethanol, and Fischer–Tropsch liquids from biomass. Savings range from 91 to 102%. Ethanol and Fischer–Tropsch fuels are both liquids that can be used in existing internal combustion engine vehicles, whereas hydrogen—which is a gaseous fuel—requires significant changes in vehicle technology, whether it is burned directly for power or used in a fuel cell. Furthermore, although the energy savings for hydrogen are comparable to the other two liquid fuels, these savings may be offset by higher energy requirements for distribution of hydrogen, which are not included in these energy balance calculations.

Estimates of greenhouse gas emissions for hydrogen and Fischer–Tropsch liquids made from biomass available. A number of estimates are available for have recently become ethanol made from biomass. These are shown in Fig. 33.9 for the use of E85 (a blend of ethanol, 85%, and gasoline, 15%) in a flexible fuel vehicle. The choice of feedstock can have a significant impact, with corn grain ethanol having the lowest benefits of those studied. The big difference between corn grain and the other biomass resources is that the former relies on fossil fuels to provide energy in the conversion facility, whereas the others make use of residual lignin from the biomass to meet all of the energy needs for conversion, with some left over for cogeneration of electricity.

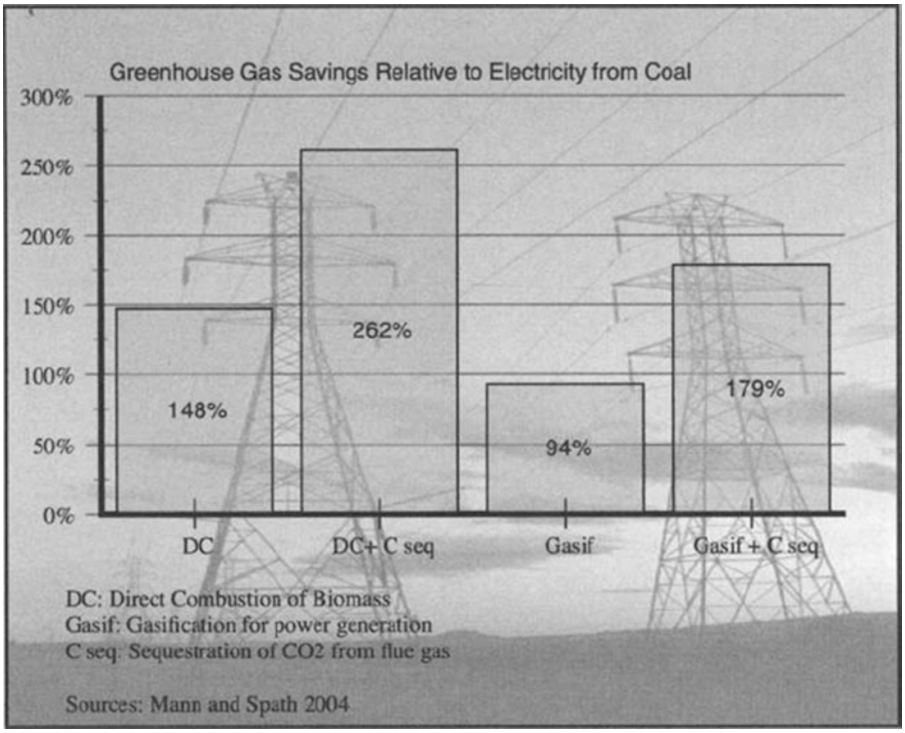

Fig. 33.7 Greenhouse gas savings for different biomass-to-power scenarios

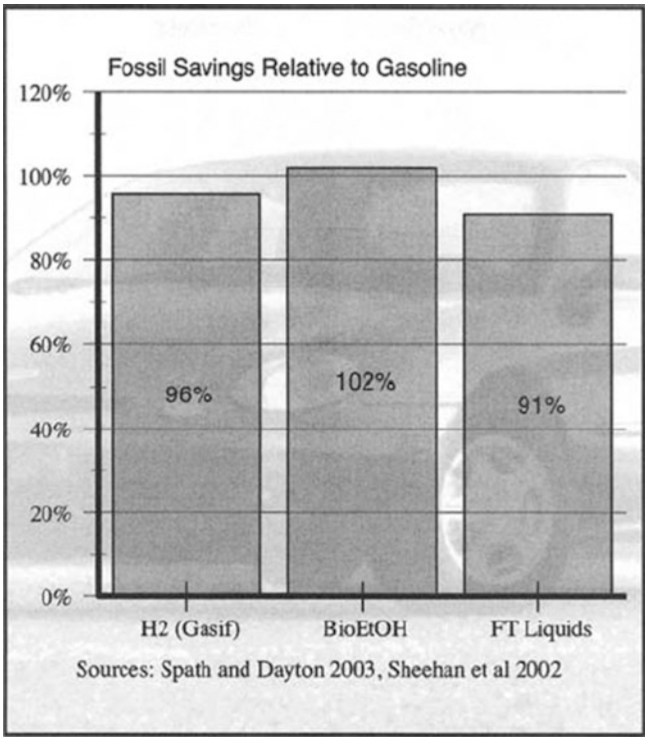

Fig. 33.8 Fossil energy savings for different biofuels

Cost Projections for Fuels and Power from Biomass

The Competitiveness of Biopower

Figure 33.10 compares the range and midpoint of costs for power production from coal and natural gas with the projected range and midpoint of costs of several biomass technology options [54]. As the numbers indicate, coal remains the lowest-cost option by far for producing electricity. Biomass technologies are from two to four times more costly and with predictions that coal prices are actually going to decline [55], this makes the prospects for competitive electricity generation from biomass a goal that will require advances in technology that have not, as yet, even been thought about, much less planned for.

The Competitiveness of Biofuels

Figure 33.11 provides a similar comparison for published estimates of the cost of transportation fuels made from biomass. None of these technologies is ready to compete with gasoline strictly on the basis of delivering energy to a vehicle. In the case of ethanol, the DOE has developed plans for reducing its cost to about $1.76 per gallon ethanol, or $2.62/gallon gasoline equivalent for 2012, which puts this

Fig. 33.11 Comparison of costs for gasoline and various biomass derived fuels for transportation new technology in a competitive range with ethanol made from corn grain. Recent published long-term (mature technology) estimates of the price that ethanol could reach are hard to find. In the early 1990s, the DOE published estimates for a best-case ethanol cost of $0.67 per gallon, or $8.4 per GJ. In 1996, Lynd reported a "best-parameter" case that brings ethanol cost down to $0.50 per gallon, or $6 per GJ, which is in line with gasoline's wholesale price [56]. These long-term projections show that it is possible for a bio-based fuel such as ethanol to approach parity with its fossil fuel counterpart, but that achieving such parity represents a significant stretch for the technology, with respect to its current or even potential cost.

Biomass as a Sustainable and Substantial Energy Source

Biomass as a Substantial Source of Energy: Balancing the Demands on Our Land

The estimates of global photosynthetic capacity described at the beginning of this chapter suggest that biomass could be a truly substantial source of renewable energy. The life-cycle assessments reported in this chapter also point to biomass as a highly sustainable source of energy.

The potential of biomass as a large source of fuels and chemicals, however, hinges on how much of the huge global capacity for biomass production can be harnessed for that purpose, after considering other demands placed on our land. And the question has been nothing if not controversial. Why? Because we recognize that the role land plays as the primary source of food and fiber is its most critical job for society. No other resource can provide us with food. So, when it comes to choosing between the use of land for producing food or energy, the choice is pretty obvious. Forget about the use of our land for providing energy to drive our cars and even to heat and light our homes, if it comes at the price of starvation.

Uncertainties of understanding sustainable management of our land, debates about what level of energy use is both adequate and sustainable for our society, and the unknown potential for future advances in science and technology all fuel controversy over the appropriate use of land. The public, policymakers, and even experts in energy find themselves bombarded with widely divergent perspectives. Here are just a few examples of the "pessimists":

- In 2002, a prominent collection of scientists wrote, "Biomass plantations can produce carbon-neutral fuels for power plants or transportation, but photosynthesis has too low a power density (~6 W/m^2) for biofuels to contribute significantly to climate stabilization." These researchers find the scale of our growing energy demand so daunting that they conclude that none of today's current options for renewable energy or energy efficiency are up to the task. They call for an unprecedented scientific effort to tackle what they call "the technology challenge of the century" [57].
- In 2002, a group of researchers led by David Pimentel dismissed biofuels for transportation outright because of their negative energy balance, and concluded that burning biomass for heat and power might achieve 5.28×10^{18} J/year worldwide by 2050. This represents, according to Pimentel's estimates, a 39% increase over current bioenergy production over five decades, and only 1.25% of world energy output in 2000.

Then, there are the optimists, exemplified below:

- In 2000, an ad hoc committee of leading scientists and engineers established by the National Research Council found that "there is enough unused biomass (in the United States) to satisfy all domestic demand for organic chemicals that can be made from biological resources. . .." Furthermore, the committee proposed a goal of ". . . eventually meeting over 90% of U.S. organic chemical consumption and up to 50% of U.S. liquid fuel needs with biobased products. . . " [58].
- Johansson et al. projected aggressive scenarios for a renewable energy-intensive economy in which 40% of direct fuel use (for everything except power generation) comes from renewables, mostly in the form of biomass, by 2050. Direct use of biofuels exceeds direct use of oil in their scenario [59].

Quantifying the controversial and uncertain factors that go into estimating biomass energy potential can shed light on these apparently contradictory findings. Lynd et al. [60] developed a generic equation to describe "*R*," the ratio of land required for meeting U.S. transportation energy demand with biofuels to the land available for biofuels production. A simplified version is shown below.

$$R = \frac{[\text{Energy Demand}] \times [\text{Land Required per Delivered Energy}]}{[\text{Total Land} - \text{Land Required for Food Production}]}$$

Accounting for all of the factors that go into energy demand (population, vehicle miles traveled per capita, vehicle efficiency) and land required for energy production (biomass land yields, biomass conversion yields, etc.), they found that the numerator in this equation can vary by a factor of 400 for a range of possible high and low values. The denominator can vary tenfold for a range of possible high and low values. This explains the wide diversity of conclusions that has been published regarding the potential for biomass to really affect our energy problem. More important, it points out the need for conducting more rigorous assessments of all these factors. Some of the factors involve social choices, whereas others involve prognostications on future technology developments.

In 2004, several new studies appeared that reconsidered the role of biomass in a future sustainable energy supply. Each has looked at some or all of the above factors, with an eye toward honing in on a more rational assessment of biomass energy supply potential. The Rocky Mountain Institute completed a major study seeking ways of eliminating the United States' dependence on oil. Among five major strategies that, taken together do just that, was an investment in research, development, and deployment of biofuels. They estimated that such a strategy could lead to a 25% reduction in our dependence on oil in the year 2025. This corresponds to around 57 billion gallons of gasoline equivalent supplied in the form of ethanol [61]. The Natural Resources Defense Council estimated in its recent assessment of biofuels that around 30% of total transportation energy demand could be met with ethanol from lignocellulosic biomass by 2050 [62]. This corresponds to about 130 billion gallons per of gasoline equivalent replaced with ethanol.

What sets these reports above others that have been published over the past two decades? First, the organizations themselves are different. They are both nongovernmental organizations (NGOs) that have never been particular advocates of biofuels. That is, they bring the perspective of a "disinterested party" to the table. Second, each looked at biofuels in a rational, future-oriented way. Third, they avoided the "single solution" trap so often found among technology advocates. Their results reflect this. Biomass comes forward as only part of the solution. Gone are the days of single energy solutions, or at least so it would seem from their analyses. Oil was indeed a one-time wonder.

$$R = \frac{[\text{Energy Demand}] \times [\text{Land Required per Delivered Energy}]}{[\text{Total Land} - \text{Land Required for Food Production}]}$$

Meanwhile, a third report has been issued in 2005 that looks at the potential supply of biomass from a different point of view. It comes from the U.S. Department of Energy's Office of the Biomass Program and from three offices within the U.S. Department of Agriculture (USDA). These are certainly not "disinterested parties." They are the key organizations in the federal government charged with looking at biomass and the role that agriculture can play in a sustainable energy future. So, it is not surprising that they turned the question of biomass supply on its head. Their starting question: are there a billion tons of biomass out there for conversion to energy and fuels? Or, put a little differently, could biomass replace 30% of today's petroleum demand? The motivation for the study was, quite simply, to see if we could prove that there is enough potential biomass to make energy companies and others take a second look at biomass. Figure 33.12 summarizes their findings. They found 1.3 billion tons of plant biomass for the taking each year, or around 80–100 billion gallons per year of gasoline equivalent, depending on the efficiency of the biomass-to-fuels conversion.

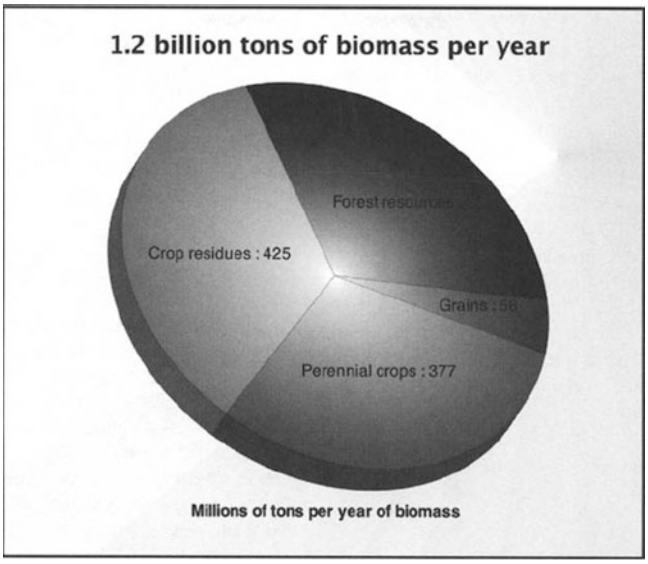

Fig. 33.12 Biomass feedstock potential finds from billion-ton vision study

What can we conclude thus far about the role that biomass can play as a substantial source for our future energy supply? It's worth aiming at. Competing with petroleum-derived energy is still a stretch, but there is still potential for improvement in the technology. As we move forward, we may find disappointments about biomass technology that force us to turn in other directions.

Microbial Bioethanol Production

The primary carbohydrate components of lignocellulosic biomass consist of D-glucose, D-xylose, L-arabinose, D-galactose, and D-mannose. Glucose (from cellulose) and xylose (from hemicellulose) are the two principal carbohydrates present in most biomass feedstocks. The levels of the minor carbohydrates L-arabinose, D-galactose, and D-mannose (also derived from hemicellulose) vary considerably with biomass type. Softwoods typically contain more galactose and mannose than hardwoods, whereas hardwoods, herbaceous plants, and agricultural residues generally contain higher levels of arabinose and xylose. In some herbaceous crops and agricultural residues, arabinose levels are high enough that conversion of arabinose (in addition to glucose and xylose) is required to achieve overall economic viability.

Ethanol Fermentation Schemes

Conversion efficiency and robust fermentation of mixed-sugar lignocellulose-derived hydrolysates are critical for

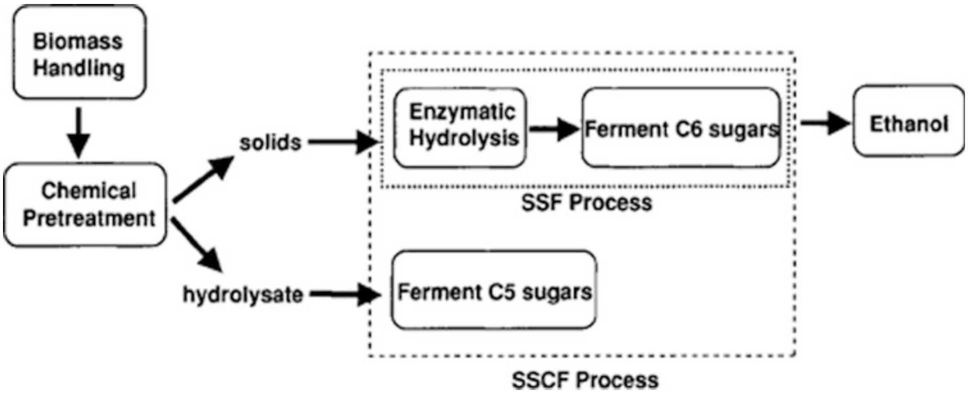

Fig. 33.13 Simultaneous saccharification fermentation (SSF) and simultaneous saccharification and co-fermentation (SSCF) concepts

producing ethanol at low cost to realize a commercially viable biorefinery. Biomass sugars are typically released by thermochemical pretreatment followed by enzymatic hydrolysis of chopped or milled biomass. The pretreated soluble fraction of biomass is called the "hydrolysate" and the hydrolysate containing the insoluble material is referred to as the "slurry." In diluted acid pretreatment, most of the hemicellulosic sugars (xylose, arabinose, galactose, and mannose) are solubilized; however, the glucose component remains in the solid form as cellulose, where it is later depolymerized by cellulases. This step is often combined with the subsequent microbial fermentation of the sugars to relieve the product inhibition of cellulases, the so-called simultaneous saccharification and fermentation (SSF) process. A process based on the fermentation of pentose sugars (derived from the hydrolysate) combined with the saccharification of cellulose and fermentation of glucose (derived from simultaneous enzymatic saccharification) is referred to as a simultaneous saccharification and cofermentation (SSCF; Fig. 33.13). To be successful, this scheme requires that the microorganisms are capable of fermenting hexose and pentose sugars equally well, though not necessarily simultaneously. Alternatively, a hybrid process with partial enzymatic hydrolysis (to obtain high cellulose hydrolysis rate by operating at high temperature) and co-fermentation may be used to achieve high overall conversion rates of biomass sugars to ethanol. Additionally, microorganisms are often susceptible to inhibitors, such as acetic acid, furfural, and phenolic compounds librated from lignocellulose during chemical pretreatment [63, 64]. Because of this, a detoxification step, such as the "over-lime process" is generally applied to reduce the toxicity of the hydrolysate. Alternatively, other adsorbants may be used or the microbes themselves can be adapted or engineered for increased tolerance to some of these inhibitors or the pretreatment process can be tweaked to minimize their production.

Although a number of microorganisms can efficiently ferment glucose to ethanol, only recently has conversion of the pentose sugars in the hemicellulosic fraction become feasible [65]. The few organisms that were known to utilize either D-xylose or L-arabinose typically grow slowly on pentoses and achieve relatively low ethanol yields and productivities [66]. Because of this, the identification and development of microorganisms capable of selectively converting D-glucose, D-xylose, and L-arabinose to ethanol at high yield has been the focus of extensive research during the past 10–15 years. In the past decade, the sophistication of molecular biology has grown tremendously and numerous attempts have been made to use recombinant DNA technologies to engineer superior microorganisms for bioethanol production. Only a few of these efforts have been provisionally successful and considerable work is yet to be done.

Metabolic Pathway Engineering

Metabolic pathway engineering is increasingly recognized as a powerful approach for developing microorganisms capable of efficiently converting biomass sugars to ethanol. In broad terms, superior ethanol-producing microorganisms can be developed by either of these metabolic engineering approaches:

1. Broadening the substrate range to include biomass sugars (e.g., xylose, arabinose, galactose, mannose) in strains exhibiting good product selectivity, but not capable of fermenting sugars other than glucose to ethanol
2. Increasing ethanol product selectivity in strains exhibiting broad substrate range

Of course, beyond these two basic approaches, significant metabolic engineering may also be required to stabilize "improved" strains or to enable such strains to achieve high ethanol yields and fermentation productivities.

Following the first approach, *Escherichia coli* and *Klebsiella oxytoca* have been engineered to be highly effective ethanol producers by introducing the genes for ethanol production from *Zymomonas mobilis* [67–69]. Extensive evaluation of these "ethanologenic" strains have been carried out, both in media containing pure sugars and in pretreatment hydrolysates derived from a variety of feedstocks [68–73].

The second approach, broadening the substrate utilization range of strains that are highly efficient ethanol producers, has been demonstrated by introducing the xylose assimilation and pentose phosphate pathway genes from *E. coli* into *Z. mobilis*. The result was an engineered *Z. mobilis* strain able to ferment xylose to ethanol at high yield [74–76]. An arabinose-fermenting *Z. mobilis* strain was also developed by introducing the arabinose assimilation and pentose phosphate pathway genes from *E. coli* into *Z. mobilis* [77].

More recently, a long-term effort to develop xylose-fermenting *Saccharomyces* sp. has also been successful. For example, xylose fermentation was reported for *Saccharomyces* strains transformed with the xylose reductase and xylitol dehydrogenase genes from *Pichia stipitis* (additionally, overexpression of native xylulokinase was found useful) [78, 79]. An effort to introduce xylose isomerase from *Pimicus* into *Saccharomyces cerevisiae* was also demonstrated [80–82]. Other noteworthy achievements in the metabolic engineering of superior ethanol producers include initial success in improving the performance of xylose-fermenting yeasts by optimizing the expression of genes encoding the xylose assimilation and ethanol production pathways [83, 84]. Successful transformation of the pentose-fermenting *Clostridium thermosaccharolyticum* has also been reported [85], providing a key tool for further developing this microorganism by altering product selectivity to favor ethanol production. Since the previous edition of this chapter, consolidated bioprocessing research has expanded dramatically, including metabolic and enzyme expression engineering of single microbes as well as cooperative multi-microbe systems. Furthermore, recombinant *E. coli*, *K. oxytoca*, *Z. mobilis*, and *Saccharomyces* were reported to be capable of anaerobically fermenting arabinose to ethanol [77, 86, 87], unlike the wild-type xylose-fermenting yeasts, such as *P. stipitis*. These yeasts can grow on arabinose aerobically, but cannot ferment arabinose anaerobically.

Performance Assessment

Efficiency of microorganisms for conversion of biomass to ethanol can be evaluated by three most critical performance factors: yield, productivity, and final product concentrations. Achieving high ethanol yield is the most important factor for the biorefinery, because the cost of feedstocks can be as high as 40% of the process cost [88]. Ethanol yield can be referred to either as metabolic yield or process yield. Metabolic yield is calculated as ethanol produced based on sugars consumed, which provides an indication whether microorganisms produce ethanol selectively. The maximum metabolic yields for both hexoses and pentoses are 0.51 g ethanol per gram sugars used. Formation of byproducts, such as lactic acid, glycerol, and acetic acid reduces the metabolic ethanol yield, consequently reduces process yield as well. Process yields calculated as "ethanol produced based on total sugars available" provides information not only how efficient the microorganisms can produce ethanol from the sugars, but also the degree to which the microorganisms are capable of utilizing all the sugars available. This parameter is especially important when considering high biomass sugar streams. Similarly, specific ethanol productivity, calculated as ethanol produced per gram of cell biomass per hour, reflects the effectiveness of the catalytic capability of cells. Volumetric ethanol productivity is used to reflect efficiency of the overall process. Kinetic parameters from various recombinant microorganisms have been summarized by Dien et al. [65].

Future Directions

Despite initial success in demonstrating microorganisms capable of fermenting biomass sugars, there is currently a dearth of fermentative microorganisms with the capability to efficiently convert all five biomass sugars in high ethanol yield and productivity under relevant industrial processing conditions. These processes demand robust performance at low pH and high temperature, as well as a high tolerance to ethanol. In most cases, the pentose utilization rate is at least several-fold lower than that of glucose. Therefore, the ethanol yield from pentoses is significantly lower compared to that of glucose [89].

Unlike the starch-based glucose streams, hydrolysates derived from lignocellulosic feedstocks can contain many toxic compounds that inhibit microbial growth and fermentation [88]. Improving our understanding of inhibition mechanisms and microbial physiology during hydrolysate fermentations will require full use of the advanced analytical and "omics" metabolic engineering and modeling tools recently made available. This approach will greatly enhance our capability to develop a new class of robust industrial microorganisms capable of efficiently and productively converting all biomass sugars to ethanol under "dirty" industrial processing conditions. Other important considerations for commercial viable microorganisms are hydrolysate tolerance and media requirements.

Futuristic process scenarios have been proposed that combine key process steps, thus reducing overall process complexity and cost. One notable example is the consolidated biomass processing (CBP) technology proposed by Zhang and Lynd [90] for the *Clostridium thermocellum* case. Their work reminds us that *C. thermocellum* hydrolyzes cellulose by a different mode of action compared to the classical mechanism associated with fungal-derived cellulases, the "cellulosome." Furthermore, for *C. thermocellum*, the bioenergetic benefits specific to growth on cellulose are result from the efficiency of oligosaccharide uptake combined with intracellular phosphorolytic cleavage of β-glucosidic bonds, another pathway not known in fungi. Zhang and Lynd believe that these benefits exceed the bioenergetic cost of cellulase synthesis, supporting the feasibility of anaerobic processing of cellulosic biomass without added saccharolytic enzymes. Another option for CBP is to enable yeast, already ethanologenic, to produce cellulases [91]. In this case, expression of some active and effective cellulases from yeast has proven challenging [92]; however, endoglucanases and beta-glucosidases appear more amenable to yeast processing [93].

Biomass Analysis and Compositional Variability

Introduction

The Importance of Reliable Compositional Methods for Biomass Analysis

The ability to rapidly and inexpensively obtain an accurate chemical composition of complex biomass feedstocks and biomass-derived materials is a key element in enabling commercialization of processes that convert biomass to fuels and valuable chemicals. Robust analytical methods are needed to improve our understanding of and our ability to economically control biomass conversion processes. Additional challenges face these processes because of the heterogeneity that is an inherent property of biomass. The chemical composition of a biomass feedstock varies as a function of many factors, including plant genetics, growth environment, harvesting method, and storage conditions. Many biomass conversion feedstocks are residues of another process. For example, bagasse is a byproduct of sugar production from sugarcane. In these situations, the varying efficiency in the original process can impart an additional source of compositional variance in biomass feedstocks. All of these sources of compositional variance are difficult if not impossible to control. However, the composition of a given feedstock can be measured at any point and that information can be used to adjust process conditions for optimal conversion or steady-state production. The rapid, inexpensive compositional analysis methods described in this chapter are examples of the types of new tools that will be needed for the commercialization of processes that convert biomass into fuels and valuable chemicals.

As illustrated in Fig. 33.14, biomass feedstocks can vary widely in the number of constituents and the concentration of each constituent. In biomass conversion processes, up to 20 constituents may need to be monitored to characterize the conversion of feedstock into a desired product or products. Standard wet chemical methods for the chemical characterization of biomass feedstocks and biomass-derived materials have been validated through the International Energy Agency and are available from the American Society for Testing and Materials (ASTM) [94]. In addition, the National Renewable Energy Laboratory [95] (NREL) has developed and validated a collection of standard laboratory analytical procedures specifically for the compositional analysis of biomass including, but going beyond those of the ASTM. These wet chemical methods of analysis are based on the fractionation of the biomass sample and the isolation of purified fractions that can be quantified using conventional analytical instruments [96]. These methods are primarily used in feedstock-specific portfolios containing analysis methods for each of the relevant constituents.

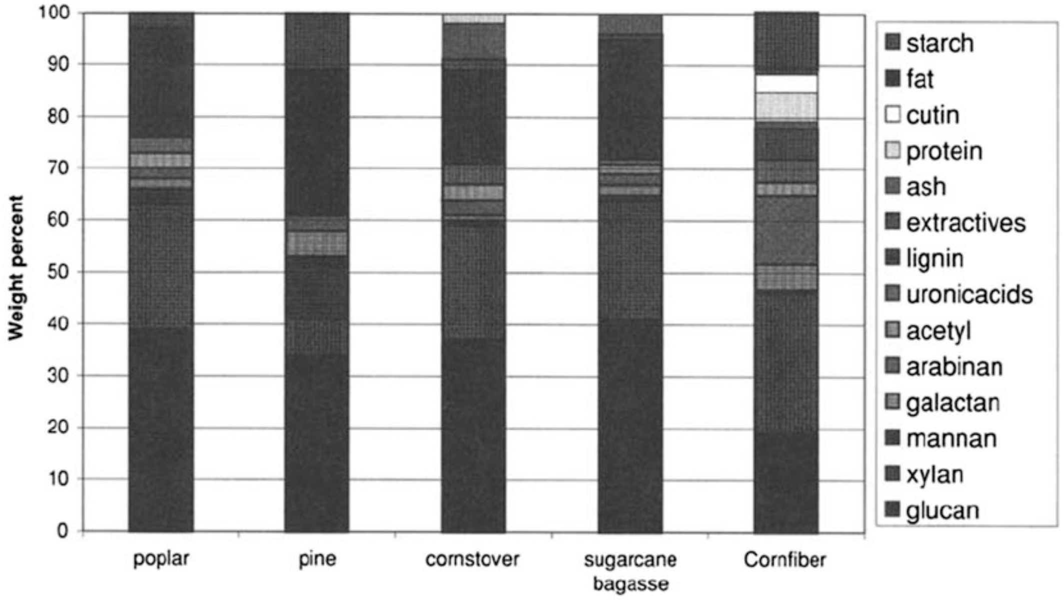

Fig. 33.14 Chemical composition of five commercial biomass feedstocks showing the variance in number and concentration of constituents

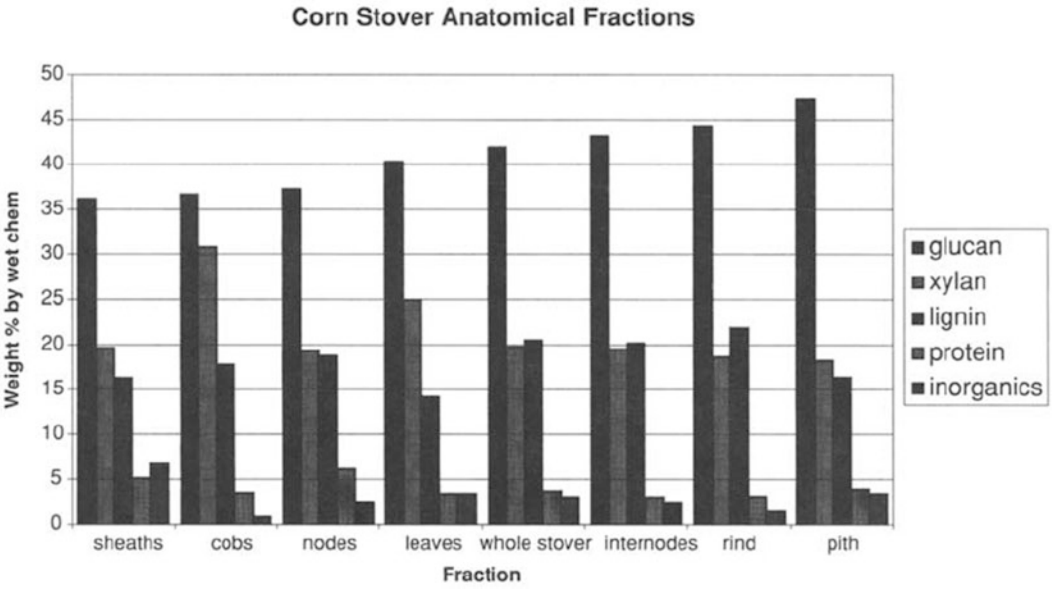

Fig. 33.15 Compositional variability of corn stover tissues from a single hybrid grown in a single field over a single growing season

In most cases, these portfolios enable the identification and quantification of greater than 95% of the dry mass of biomass feedstock and biomass-derived materials.

The Need for Accurate, Real-Time Biomass Analysis Methods

Standard wet chemical methods, although accurate and robust, are not applicable in a commercial setting, because they are very expensive (labor intensive) and cannot provide the analysis information in a timeframe useful for process control. For example, a complete analysis using standard wet chemical methods costs $800–$2,000 per sample and the results are typically not available for days, sometimes weeks. In contrast, new methods are being developed that can perform the same analysis for about $20 per sample and provide results in a timeframe relevant for process control, meaning that the information can be used to make the process adjustments necessary for steady-state production. One approach to reducing the time and cost of compositional analysis is the development of rapid analysis methods that use multivariate statistical analysis software to extract chemical information from easily obtained spectroscopic data. Rapid analysis methods match the precision and accuracy of their calibration methods, so the savings are obtained without loss of precision or accuracy [97]. New techniques, such as rapid analysis, are needed to provide analytical support for large-scale processes that convert biomass to fuels and chemicals.

Heterogeneity and Biomass Analysis

As stated above, plant cell walls are comprised of three-dimensional complexes of natural polymer matrices including cellulose, hemicellulose, lignin, and in some cases protein and silica. These polymer matrices are not uniformly distributed within the plant cell wall, and their relative concentrations change from one morphological region to another, reflecting physiological function. The difference in chemical composition between the tissues within a plant is, in nearly all cases, greater than the variation seen in any one tissue across the entire plant species. An example of this compositional variance is shown in Fig. 33.15 for corn stover from Pioneer 33J56. The concentration of five major constituents is shown for seven tissue types as well as an average composition for the whole plant. The various fractions are according to increasing glucan content. The independent variance of the concentration of various polymer constituents can easily be seen.

Much of the compositional variance in a feedstock can be explained in terms of varying proportions of the tissue types. These proportions can vary by variety, growth environment, harvesting method, and storage conditions. The differences in chemical composition imply structural differences that could also affect conversion efficiency. To understand biomass compositional variability and its implications, it is essential to appreciate the magnitude of variance in available feedstocks and to understand the controlling factors. Appreciating the sources of variance permits the formation of testable strategies for controlling or limiting the sources of variance. This strategy is particularly important in systems where process economics are driven primarily by product yield, as is the case for biomass conversion processes.

Sources of variance. It is well established in the agronomy literature that factors affecting plant characteristics and crop

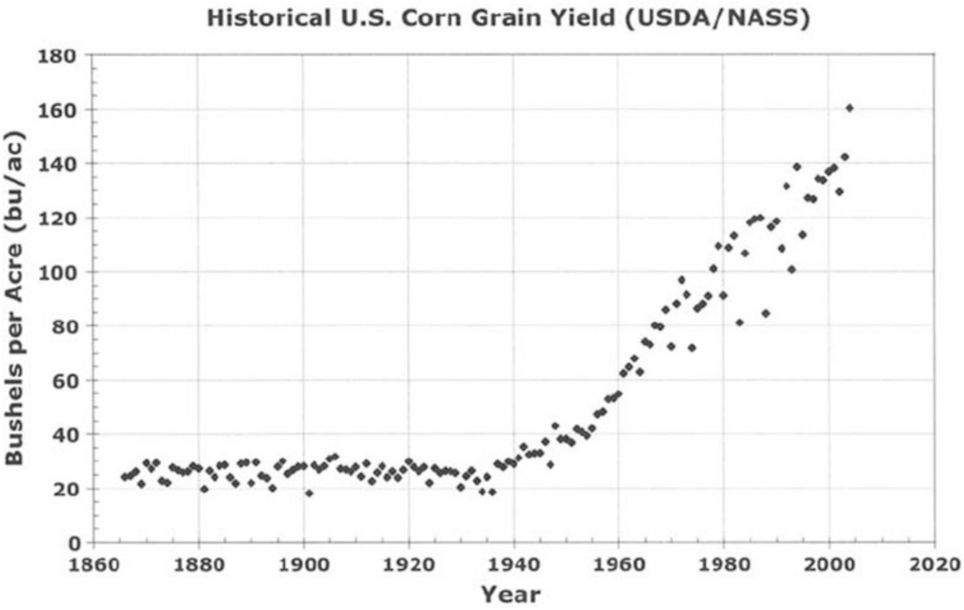

Fig. 33.16 Historical average U.S. corn gain yields in bushels/acre (data from USDA/NASS Web Site)

performance fall into three general categories: genetic, environmental, and interactions between these two classes. In other words, the phenotype (i.e., any measurable characteristic) of an individual plant is the product of its genotype (i.e., the complete set of genes inherited by an individual from its parents) as influenced by the environment in which that individual exists. For example, the same commercial hybrid varieties of corn often have statistically different yields when grown in different locations (i.e., environments). This may be due to differences between locations in weather patterns, soil types, agronomic practice, or other factors. Similarly, genetically distinct commercial hybrid varieties of corn grown in the same environment often have different grain yields (see results from the Wisconsin Corn Hybrid Trials [98] or the Minnesota Corn Variety Trials [99]). An interaction between these two broad classes of variables is said to occur when different genotypes respond in different ways to a change in environmental conditions.

Agricultural systems are notorious for their variability (e.g., harvest yield) from year to year, location to location, and variety to variety. Characteristics other than yield (e.g., plant height, pigmentation patterns, cell wall composition, nutritional quality, resistance to diseases, etc.) are also influenced by some combination of these and other factors. Each phenotype is most likely influenced by different combinations of genetic and environmental factors.

The analytical methods used to determine the composition of biomass materials are also a source of some variance in this kind of analysis. It must be determined whether variance due to sampling and measurement techniques is significant in light of variance from genetic and environmental sources.

Genetic Factors That May Contribute to Cell Wall Compositional Variability

Modern corn breeding dates back to the early 1900s with the work of Shull [100], East [101], and others. Increased grain yield (i.e., productivity) has long been the main objective of corn breeding programs in the United States and elsewhere. Corn breeding programs have produced remarkable results, evident in the historical corn grain yield data for the United States (available online from the USDA National Agricultural Statistics Service Web site [102]) and presented here as Fig. 33.16. It should be realized that the data in Fig. 33.16 reflect both genetic and agronomic improvements made in parallel.

Hallauer et al. [103] present a summary of 13 separate studies that attempt to estimate the fraction of observed corn grain yield improvement due to genetic gains. These estimates range widely (33–89%), but it is clear that genetics is responsible for a significant proportion of yield improvement during the past 100 years. The remaining fraction of yield gains is due to changes in cultural practice and crop management (e.g., fertilizer use, higher density of planting, pesticide availability and use, mechanized harvesting).

Peterson states [104], “Breeders’ efforts with maize have uncovered a highly heterogeneous genotype that can be manipulated in most directions to achieve the desired goal.” In addition to the overall goal of increased yield, this includes traits such as lodging (i.e., ability to stand), resistance to various biotic and abiotic stresses, male sterility, the angle at which leaves are held relative to the stalk, days to grain maturity, nitrogen-use efficiency, seed composition (i.e., starch, protein, and lipid content), and many others.

Studies relating to the genetic manipulation of nutritional quality (i.e., chemical composition) of corn grain are analogous to this discussion regarding manipulation of stover (i.e., cell wall) chemical composition. The following excellent example is used to illustrate what might be accomplished with regard to cell-wall composition using genetic techniques in maize.

The concentration of oil in the kernel varies widely in corn as a species, but corn belt inbred varieties range only from 2.5 to 5.5%. Commercial hybrids have an even narrower range, typically only 4–5%. An assortment of breeding strategies starting with out-crossing populations, in which the gene pool is broader than it is for inbred and hybrid cultivars, has altered the oil content of kernels from about 4% up to more than 21% over a series of selection cycles [105–108].

A similar story can be told regarding corn kernel protein content. Hybrid corn typically contains 8–11% protein, but considerable genetic variability for this trait exists in open-pollinated populations. In an experiment involving serial selection for both high and low protein content, mean protein content has been shifted more than 139% from the starting point mean value (a range of at least 20 standard deviations) [105–107]. At generation 70 (30 years ago!) in the Illinois Long-Term Selection Experiment, the Illinois High-Protein (IHP) line contained 26.1% protein and the Illinois Low-Protein (ILP) line contained 5.8% protein. These same lines were simultaneously the low-starch (44%) and high-starch (74.5%) lines, respectively [109]. Thus, at least in corn, selection for increased protein content in grain seems to occur mainly at the expense of starch.

Three plant genomes have now been completely sequenced, and several more are at various stages in the process. From DNA sequence data, it is estimated that the *Arabidopsis* genome contains around 25,500 genes [110]. The rice genome is estimated to contain somewhere between 32,000 and 55,000 genes [111, 112]. The *Populus trichocarpa* (black cottonwood), genome is estimated to contain about 58,000 genes [113]. To date, sequencing efforts in *Zea mays* (i.e., maize; corn) indicate that its genome also contains about 58,000 genes [114].

Cell wall biogenesis during cell growth and differentiation involves many different enzyme activities and perhaps several thousand genes. It has been estimated that 15% of the *Arabidopsis* genome (i.e., more than 3,800 genes) may be dedicated to cell-wall biogenesis and modification [115]. Although only a very few of these genes have been identified and characterized to date, several efforts are underway to do so (for example refs. [116–118]). Because multiple alleles (i.e., gene variants) probably exist for each of these genes, the possible number of permutations of genes that affect cell walls in a single species is truly enormous.

According to Carpita [115, 116], genes involved in plant cell-wall biogenesis fall into one of six functional categories:

- The synthesis of monomer building blocks of cell-wall polymers, such as nucleotide sugars and monolignols
- The biosynthesis of oligomers and polysaccharides at the plasma membrane and ER-Golgi apparatus (i.e., polysaccharide synthases and glycosyl transferases)
- The targeting and secretion of Golgiderived materials
- The assembly and architectural patterning of polymers (includes glycosyl hydrolases and structural proteins)
- The dynamic rearrangement of wall polymers during cell growth and differentiation (includes lignification)
- Signaling and response mechanisms

Although the metabolic pathways associated with the first category have been pretty well elucidated at this point, the enzymes involved in the second (cellulose synthases, some golgi-based synthases (e.g., mannans, xyloglucans, pectins) and third categories are largely uncharacterized. Likewise, most of the corresponding genes are also unknown. Significant progress has been made in some of these areas in recent years, however [119–123].

Once identified, those genetic factors that exert a large influence on cell-wall composition, cell-wall architecture, or biomass conversion process performance characteristics could become targets of a plant breeding strategy to manipulate these characteristics, while maintaining or increasing traditional crop yield or overall agronomics. To get the most from such a breeding program, it will be essential to monitor the effect of a wide range of environmental variables on genetic potential during the breeding process.

Environmental Factors That May Contribute to Variance

Environmental factors that affect plant phenotypes fall into two categories: namely, those that are at least partially under control of the farmer and those that are not. Factors that are largely not under human control include weather patterns (day length, solar flux, temperature, and precipitation), soil type and pH, and soil mineral content, and are not discussed further. A partial list of factors that can be addressed by the farmer include selection of hybrid variety, planting date, harvest date, tillage practice, irrigation, fertilizer types and amounts, pesticide and herbicide usage, and the strategy employed for harvesting, transporting, and storing crop residues. Soil pH is at least partially under control of the farmer. Producers commonly add lime to soil to make it less acidic. Which of these factors are most influential across the broadest range of situations with regard to stover compositional variability is an open question and will require multiyear, multilocation field trials to determine with confidence.

Most important are likely environmental factors associated with cultivation, crop management, and postharvest processes that can be controlled to some extent and on the other hand also have a large impact on the chemical composition, cell-wall architecture, or conversion processing behavior of plant biomass. These factors could form the basis of a testable strategy to decrease the variance associated with these characteristics.

Table 33.1 Confidence intervals for NREL and ASTM standard wet chemical methods

Constituent	Method variance absolute error 99% confidence
Glucan	1.5
Starch	1.0
Xylan	1.5
Arabinan	1.5
Mannan	1.5
Galactan	1.5
Uronic acids	1.5
Pection	1.5
O-acyl groups	0.5
Structural inorganic	0.5
Sucrose	1.5
Protein	1.0
Lignin	1.0
Ferulic acid esters	1.0
Extractives	1.0
Phytate	0.5
Cutin	1.5

Analytical Variance

A complete analysis characterizing greater than 95% of a biomass sample can require up to 30 independent measurements to report the concentration of 10–15 constituents. Table 33.1 shows the confidence intervals for the standard wet chemical methods used to characterize biomass feedstocks. The confidence interval of 1.5% for glucan means that when a value of 38% is reported for a biomass sample, there is a 98% probability that the "true" glucan concentration lies between 36.5 and 39.5%. Many of these values were determined in an international round robin evaluation of four biomass standard reference materials available from the National Institute of Standards Technology (NIST) [124].

Portfolio Methods

In the past, efforts were made to develop universal methods of analysis that could be used for any type of biomass or biomass-derived material [125]. These methods provide instruction for the various procedural steps, but they rarely discuss why a given step is included in the procedure. The assumption is made that all steps in a standard procedure will be followed as written without omission or amendments. When combined for a complete mass analysis, many analytical methods were compromised to the extent that they were adequate for most samples, but optimal for none. As the biomass conversion industry matures, the need for more accurate and precise methods will increase, as data generated from these methods will be used to evaluate a maturing state of technology for commercialization. In response to this need, newer methods of analysis are being developed in a modular fashion and designed to be incorporated into sample-specific portfolios capable of providing a customized total analysis of any biomass sample. In the portfolio, the individual constituent methods are independently validated relative to standard reference materials. These methods are then validated a second time when the results are combined to reconstruct the entire chemical composition of a biomass sample. Typical mass closures between 96 and 104% confirm that no major components have been overlooked and interferences between methods and double counting of materials are minimized.

Wet Chemical Methods

Within each portfolio, the sequence of application of the various analytical methods is critical, as many methods have been validated with the assumption that all prior steps have been followed. For feedstocks, the sequence is sample preparation, then removal of nonstructural materials through solvent extraction, followed by hydrolysis of the structural polymers to simple forms for chromatographic or spectroscopic analysis. In the past, many methods for biomass analysis have been "behavior based," meaning they define chemical structure based on solubility in certain solvent systems. The newest methods incorporate modern analytical instruments, which allow the various structural components to be measured and tracked based on chemical structure.

Before using biomass analysis methods, analysts are encouraged to review the literature that supports the standard methods [125]. Understanding the science behind the methods helps the analyst understand the ways that the various procedures are connected, the limits within which a step can be altered or modified, and the potential downstream consequences of omitting any given step. With this in mind, the following several paragraphs outline available information concerning the significance, implications, and limitations of each step in a complete characterization of biomass. More detail is available in the open literature and the text of the individual procedures.

Sample preparation. Sample preparation is an important but often overlooked part of biomass analysis. Biomass sample preparation must take several factors into account. The object of sample preparation is to enable the analysis to be done on a small scale while ensuring that the analysis of the small sample provides valid information about the larger bulk sample. Typically, biomass sample preparation includes drying, milling, sieving, and homogenizing. The overarching objective is usually obtaining a representative sample that can be analyzed on a reasonable scale.

Drying. Biomass feedstock samples can contain as much as 60% (w/w) water. If the biomass has been degraded in a manner that disrupts the ultrastructure of the plant (chemical treatment or enzymatic digestion), the moisture of the sample could be even higher. Water in a biomass sample, if high enough, can introduce errors during some of the analysis steps by diluting reagents. Moisture in samples can also cause sample fractionation during milling and sieving. Biomass samples with high moisture contents are still vulnerable to biological degradation and may not remain stable and uniform for the duration of a battery of tests. For these reasons, biomass samples are usually dried until the moisture content is less than 15%. Because some of the constituents are heat sensitive or volatile, certain protocols must be followed when drying a biomass sample for compositional analysis, to avoid sample loss or degradation. Air-drying is preferred if time, space, and ambient humidity will allow the sample to reach a moisture level below 15%. Drying the samples in a convection oven or vacuum oven where the temperature is not allowed to exceed 45°C is an acceptable alternative. When freezing does not cause collapse of the cellular structure of the biomass, samples can also be safely lyophilized, or freeze-dried. When drying biomass, one must also consider the end use of the material. If the material is to be used in enzyme hydrolysis or microbial conversion experiments, then the method of drying becomes doubly important. Complete removal of water or removal of water without structurally stabilizing the pore structure of the cell walls (as in lyophilization) can lead to a collapse of the cellulose microfibrillar network; a process referred to as "hornification". This process makes the cellulose more difficult to digest by cellulases and perhaps more difficult to disrupt by pretreatment catalysts. As it not easy to measure or prevent, the best way to deal with hornification is to dry the materials in as consistent and process-relevant manner as reasonably feasible.

Washing. If the biomass sample is contaminated with soil, the samples should be washed if possible before further processing. Soils vary considerably in chemical content and even a few weight percent of extraneous inorganic compounds can neutralize reagents, catalyze side reactions or affect subsequent analysis in ways that are difficult to observe or control. Washing may be as simple as agitation in clean demineralized water or may require small amounts of mild detergents to be effective. After washing, the sample must be carefully dried before analysis.

Milling. Size reduction is an important step in biomass analysis because standard methods are optimized and validated for materials with a specific particle size. The particle size will affect hydrolysis or digestion rates as well as rates of degradation and should be specified in any standard procedure. As a general rule, the sample to be analyzed should contain at least 100 particles of the biomass sample in order to be representative of the bulk material. For reasons described earlier for drying protocols, care must be taken during the milling process to avoid heating the biomass sample. This is particularly crucial if the biomass must be reduced to a fine powder. Cryo-mills, where the milling apparatus is submerged in liquid nitrogen, or mills that are jacketed for the circulation of cooling solutions are most suitable for milling in these situations. Knife mills such as the standard Thomas-Wiley Mill 4 (Thomas Scientific Model 3375E15 or equivalent) work well for most woody biomass samples. Less dense materials such as corn stalks or straws may be easier to feed into a hammer mill. Most knife and hammer mills will retain and reprocess materials until they pass through a screen of a particular particle size, allowing the user to specify the maximum particle size of the processed sample.

Sieving. All forms of chemical or thermal hydrolysis perform better when the particles are of a uniform size. For this reason, most standard procedures usually specify both a maximum and a minimum particle size. To accomplish this, the milled biomass is sieved through a set of standard screens. To prevent errors associated with incomplete hydrolysis, the oversized material is milled again until it passes through the largest screen. The material that passes through the larger screen but is retained on the fine mesh screen is of uniform particle size and can be used for compositional analysis. The material that passes through the fine mesh screen may be hydrolyzed too quickly leaving the hydrolysis products more susceptible to side reactions or degradation before analysis. Because the fine material cannot be reprocessed to increase particle size, this material must be discarded. The fine fraction should always be removed from the analysis if it has significantly higher ash content than the uniformly sized material. This elevated inorganic content may indicate the presence of non-biomass contaminants (typically soil).

The impact of extraneous inorganic matter on the analysis cannot be predicted. Most chemical analysis methods have been optimized for bark-free wood that has an ash content of less than 2%. These methods may not be applicable to herbaceous materials where structural silica can increase the ash content to more than 15% of the dry weight of the biomass. One potential problem with high ash samples is that inorganic materials, depending on their composition, may neutralize the sulfuric acid solutions used in the hydrolysis steps. The affect of pH changes on the hydrolysis of the carbohydrate polymers is unknown, but could result in incomplete hydrolysis of some carbohydrate structures. It is also possible that soil components such as iron and manganese could catalyze undesired side reactions, which produce products that would not be identified and quantified with the current analytical methods. However, although the impact of soil contamination cannot be easily determined, removal of the −80 mesh fraction can improve the chemical analysis by reducing the ash contents of samples to about the level of structural inorganics expected in that type of biomass. The fine material is weighed, reduced to ash to determine the percentage weight of inorganic material and then discarded. The analysis is performed only on the intermediate, uniformly sized material. The composition of the whole sample can be calculated by assuming that the biomass portion of the fines has the same chemical composition as the fraction that is analyzed. Although this assumption is not completely accurate, the precision gained by removing the fine material more than compensates for the error introduced by this assumption. If the sample has not been washed, removing the very fine material (less than 80 mesh) will remove most of the dirt entrained in the sample.

Making the particle size as uniform as possible also makes it easier for the analyst to select a small but reproducible sample for analysis. In some biomass samples, however, sieving to remove fine material chemically fractionates the sample. This is known to be true with wood that contains a significant amount of bark. The bark tends to granulate during milling and will preferentially be removed with the fines. The sample to be analyzed would then have an artificially low bark content relative to the original sample. A similar problem has been reported with some grasses where the friable pith material may be preferentially removed as fines. These samples should not be sieved for fines removal. Samples should be examined for soil contamination, and special care should be taken to select a representative particle size distribution for analysis.

Extractives Determination

Plants store nonstructural materials in their vessels and water transport channels that can interfere with accurate chemical compositional analysis. These materials are commonly known as extractives, which may give the impression that they are a single substance or at least a few closely related substances. This is not always the case. Extractable materials include gums, resins, pitch, waxes, sterols, flavonoids, tannins, terpenes, quinones, non-structural sugars, chlorophyll, and many other minor building block reserves that vary seasonally and by biomass type. Because extractives vary so much in chemical composition, their behavior during the slate of analyses required for a compositional characterization cannot be predicted. For this reason, non-structural components should always be removed prior to analysis for lignin or carbohydrates. Failure to remove these materials can cause several problems [124]. Some of the extractives may be insoluble in acid, will precipitate, and thus will be falsely counted as lignin. Because of changes in the physical properties of the extractives, the presence of some materials will limit access to the carbohydrate polymers. If extractable ash, starch, or protein is present in the biomass sample, separate measurements must be made to remove the contribution of this material from the extractives values and to report it more accurately in the correct constituent category. Recently, it has become more apparent that starch is not always efficiently or uniformly extracted by the standard extraction procedure. For samples suspected to be high in starch, such as green-harvested herbaceous material or biomass containing seeds, it is advisable to do a separate starch determination or to remove the starch with more aggressive protocols, such as amylase treatment. Care must be taken in this approach, as not all amylase are equal and some contain cellulase and/or hemicellulase activity. Several kits are available commercially to quantify or remove starch from biomass.

Carbohydrate Determination

Most analysis methods for the determination of carbohydrates in biomass incorporate a two-stage acid hydrolysis to separate individual polymers and hydrolyze them to simple compounds that can be readily analyzed by chromatographic or spectroscopic techniques. The first stage subjects the biomass sample to a concentrated acid that disrupts the noncovalent interactions between biomass polymers. A second, more dilute stage follows, which is optimized for complete polymer hydrolysis and minimized degradation of monomeric sugars. Failure to remove non-structural materials may result in incomplete hydrolysis of the more recalcitrant carbohydrate polymers, particularly glucans and galactans. Increasing the hydrolysis severity may result in excessive degradation of the accessible sugars. Hemicellulose sugars, especially xylans and arabinose, are the most susceptible to degradation if hydrolysis severity is increased. If non-structural sugars are present in the biomass, they should be removed and quantified during the extractive procedures. If both starch and cellulose are present, they will both contribute to the measured glucose concentration after hydrolysis. An independent starch measurement allows the two polymers to be accurately quantified. Some degradation of sugars is unavoidable in the two-stage hydrolysis methods. Carbohydrate standards of similar structure and concentration should be run in parallel to assess the magnitude of this degradation and correct the reported values for this loss if necessary. While monomer sugars are often included as “sugar recovery standards”, these do not represent the true course of degradation in the process, as most of the biomass sugars start as polymers, not simple sugars. Inclusion of pure cellulose and hemicellulose of known composition can also serve as a recovery standard. Structures such as uronic acids, ferulic acid esters, and *O*-acetyl groups are substituents on the hemicellulose polymers and should be included in a complete carbohydrate analysis.

Lignin Determination

Most lignin methods are still based on behavioral definitions: lignin is most often defined as the material insoluble in acid after hydrolysis of the carbohydrate fraction. This assumption is invalid for many biomass samples, particularly herbaceous materials where protein will condense with the lignin. Structural inorganics will also partition during acid hydrolysis with an irreproducible portion remaining in the acid-insoluble residue. Additional determinations must be made on the acid-insoluble residue to convert the gravimetric measurement into a valid lignin measurement. Failure to make these corrections results in falsely high mass closures, as protein and silica would be measured in more than one constituent category. In the two-stage hydrolysis, some acid-soluble lignin may be released into the hydrolysis liquor. An accurate lignin value includes a measurement of both acid-soluble and acid-insoluble lignin. Acid-soluble lignin is traditionally measured by UV/VIS spectroscopy. In these determinations, care should be taken to ensure that the measured absorbance is made in a concentration range where detector response is known to be linear and that an appropriate wavelength and absorptivity is selected. The references standard method portfolios include options for several biomass categories.

Protein Determination

To estimate crude protein content of biomass or other materials, the nitrogen content of the material is measured by Kjeldahl or combustion methods and multiplied by a conversion factor where:

$$\text{Protein}\,(\text{wt/wt\%}) = \text{Nitrogen}\,(\text{wt/wt\%}) \\ \times \text{Nitrogen-to-Protein Conversion Factor}$$

A nitrogen-to-protein conversion factor (*N*-factor) of 6.25 is commonly used for animal feeds and other materials. The practice of using 6.25 as an *N*-factor is based on an incorrect assumption that protein in a given material contains 16% nitrogen (100/16 = 6.25) [126].

The correct *N*-factor for protein found in herbaceous biomass will likely be different than 6.25. Yet, determining a perfectly accurate *N*-factor for the complex matrices of biomass feedstock and process samples may not be possible. The challenge is then to determine the most accurate *N*-factor possible for biomass feedstock and process samples. A strategy based on the consensus in the literature has been incorporated into the portfolio methods. These methods calculate the reasonable *N*-factor upper and lower limits for a given material. The limits are calculated using data from an amino acid (AA) analysis with multiple hydrolysis times and an accurate total nitrogen analysis substantially similar to the methods described by Mossé [127].

Other Feedstock Constituents

Validated standard analytical methods are available for a variety of minor constituents or constituents specific to a small class of biomass substrates, examples being pectin, cutin, and phytate. Inclusion of these methods into the analysis portfolio increases mass closure and allows tracking of minor constituents that may be concentrated during the biomass conversion process.

Degradation Products

The liquid portion of biomass-derived process samples may also contain carbohydrate degradation products, such as 5-(hydroxymethyl)-2-furaldehyde (HMF), levulinic acid, and furfural, as well as other components of interest, such as organic acids and sugar alcohols. Portfolio methods are available for the quantitative measurement of these degradation products and byproducts of polymer hydrolysis.

Reconstructing the Composition of the Original Biomass Sample

Following the multistep sequence of the portfolio methods, the constituents' values can be reported in many forms. Because biomass polymers incorporate one molecule of water in the hydrolysis of each monomer molecule, the carbohydrate content of a feedstock may be reported as the theoretical yield of monomeric sugars for the assessment of the conversion efficiency of a biomass process. More commonly, constituent values in solid samples are reported as percent dry weight on either an extractives-free basis or as-received basis. The composition of liquid samples is reported as concentrations in grams per liter for each constituent. Three additional measurements are required to reconstruct the composition of biomass process slurries: total slurry weight, liquor density, and fraction insoluble solids (FIS). The total slurry weight minus the weight of insoluble solids provides the weight of the liquid portion of the sample. Dividing by the density measurement converts this to volume. With the volume measurement, constituent concentrations can be converted to recovered weight for the determination of constituent and process mass closure.

Rapid analytical methods. One approach to industrial biomass analysis is to use published, standard methods to calibrate rapid, inexpensive spectroscopic techniques, which can then be used for feedstock and process analysis. Rapid analysis is a generic term for methods that couple traditional wet chemical methods of analysis with rapid, inexpensive spectroscopic techniques. The methods described here are often further classified as rapid biomass analysis methods. Although many spectroscopic techniques can be incorporated into rapid analysis methods, for biomass analysis, near infrared (NIR) spectroscopy has several advantages over alternate spectroscopic tools. Techniques have been developed for obtaining quality NIR spectra from bulk samples, minimizing the time and expense of sample preparation. Robust NIR instruments are commercially available for process analysis, process control, and field applications. Many of the industrial NIR techniques have been developed for use by the chemical, food processing, and agriculture industries and can be applied directly to the characterization of biomass.

Several steps are involved in rapid analysis method development. These include gathering appropriate calibration samples, chemical characterization of the calibration samples, developing spectroscopic methods for the rapid technique, projection-to-latent-structures (PLS) regression, validation of the PLS algorithm, and the development of QA/QC procedures [128].

Rapid analysis methods based on PLS multivariate modeling require calibration based on robust and accurate methods. The first step in developing a new method is to gather appropriate calibration data. Robust methods usually contain at least 100 well-characterized samples. Collecting and characterizing diverse and a good calibration set costs about $300,000. This is by far the most expensive and time-consuming step in method development. Calibration samples should have compositions similar to the samples to be analyzed. If possible, the calibration set should include samples that represent all known sources of compositional variance. The range of compositional variability within the calibration samples determines the validated calibration range for each constituent.

Quality spectroscopy is the second essential component of method development. The technique selected must contain information about the chemical composition of each sample. The spectroscopic method is the key to cost reduction and speed of analysis. In the next step of rapid analysis method development, multivariate analysis is used to identify spectroscopic patterns that correlate with compositional data. In the methods incorporated into work at the NREL, PLS models use whole NIR spectra collected from 400 to 2,500 nm. Equations are obtained that convert spectroscopic data directly into compositional information. In simplified terms, PLS analysis solves hundreds of equations in thousands of variables to obtain a linear equation that predicts compositional information from spectroscopic data. Multivariate analysis is designed for complex systems such as those found in biomass compositional analysis. These powerful mathematical techniques retain the precision and accuracy of the calibration data. It is important to note that PLS analysis can never be more accurate than the methods used to obtain the calibration data [97]. For this reason, the best and most accurate wet chemical techniques should be used for method calibrations, hence the large expense in setting up a calibration set. Once calibration is complete, compositional analysis becomes as fast and inexpensive as the spectroscopic method.

One of the major limitations of rapid analysis methods is that an answer is always provided and the user must determine the validity of the provided data. Robust QA/QC procedures are needed to assure that the rapid methods are appropriately applied to unknown samples [128].

In addition to significant savings in time and money for routine process samples, rapid analysis methods can be used to provide levels of information that were not previously available. For example, feedstock assessment and genetic studies require the screening of hundreds, sometimes thousands of samples. These studies would have been too costly to pursue without the savings in time and cost provided by rapid analysis methods. For example, approximately 200 samples can be analyzed from a bulk corn stover feedstock in 1 day at a cost of less than $4,000. This type of information has been used to develop protocols for the representative sampling of fields, bales, totes, and bags of feedstock. The ability to accurately sample a bulk feedstock and to analyze hundreds of samples for about $20 each provides a new tool that is being used to assess the compositional variability of corn stover in the United States as a function of variety, geographical location, harvest time, and collection method. Changes in feedstock composition during storage are also being monitored. With these larger data sets, feedstock composition can be more accurately reported as a range of expected normal values.

Application of Methods

Rapid, inexpensive biomass analysis can be useful at many stages of an industrial process. Rapid biomass analysis methods can characterize the feedstock as it enters the reactor. If necessary, rapid analysis can be used to guide feedstock blending. Chemical changes during the processing of biomass can provide feed-forward and feed-backward information that can be used to ensure that the process maintains a steady state in spite of the feedstock variability. Finally, process residues and products can be easily evaluated to assess overall process economics. As more samples are analyzed, information can be obtained about the composition of an “ideal feedstock.” Field-mobile instruments can be calibrated for use as purchasing tools. Buyers can obtain compositional information about a biomass feedstock at the point of purchase. Feedstocks can be assigned values based on quality. Young plants and perhaps even seeds can be evaluated (in breeding programs) and selected for desirable characteristics and production potential.

Biomass Process Monitoring and Improvement

The wet chemical and rapid analytical methods described above are being used on a daily basis in the U.S. Department of Energy’s Office of the Biomass Program. The methods are used primarily to keep track of chemical fractions of plant cell walls during biomass processing. Researchers use this capability to better characterize biomass conversion

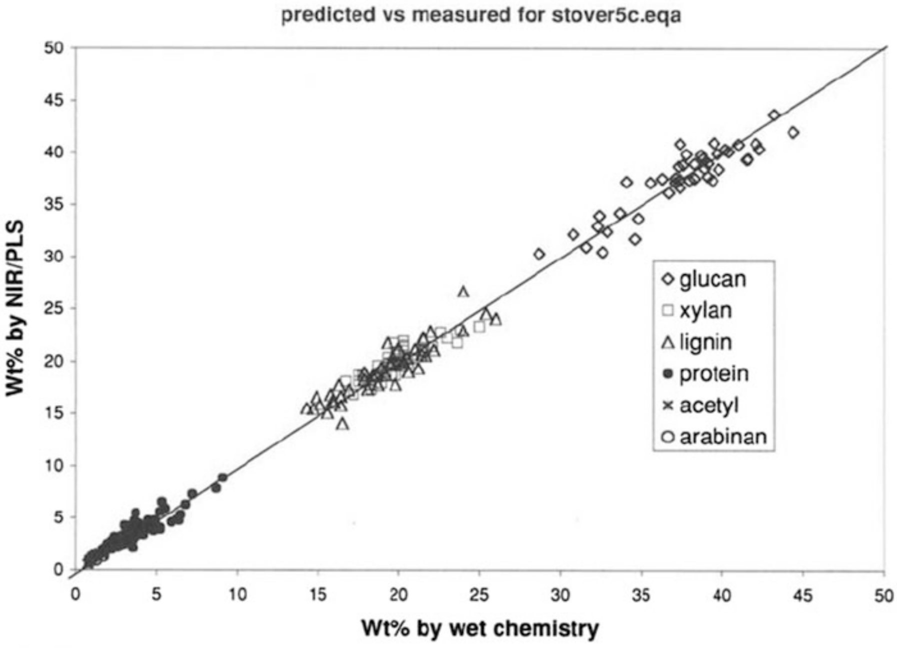

Fig. 33.17 Comparison of corns stover feedstock composition as determined by wet chemical and NIR/PLS method stover 5C

processes and to compare and evaluate alternate approaches to biomass conversion and their impact on overall process economics. Methods have been developed that are specific to and appropriate for determining the composition of raw biomass materials (e.g., corn stover, softwoods, and hardwoods [129]), as well as processing sorghum and other grasses, intermediates (e.g., dilute-acid pretreated hardwoods, softwoods, and corn stover [128]). The high cost of compositional analysis using traditional wet chemical methods was limiting the amount of information available for economic assessments and process optimization. The additional levels of information provided by rapid analysis methods increase the accuracy of technoeconomic models that guide research more efficiently toward the development of commercially viable process options for the conversion of biomass into fuels and valuable chemicals.

Survey of Corn Stover Compositional Diversity

The NREL's corn stover feedstock rapid analysis method has also been used extensively to assess the range of compositional variation present in corn stover from different varieties grown in different locations using a variety of crop management and harvesting strategies. In one study, university agronomy department researchers, agricultural biotechnology and seed companies, and individual farmers all provided stover samples. This was an example of an application that would not and could not have been undertaken using traditional wet chemical methods, because they are both too slow and too expensive. The resource limitations disappeared to a great extent with the development of the rapid analytical methods. This survey has provided indispensable information regarding the range of diversity of corn stover and its impact on biomass conversion process economics.

Using rapid analysis, the NREL has compiled large corn stover composition database. The database includes samples from 53 different locations in ten states (mostly U.S. corn belt) and more than 100 branded hybrids from 22 seed companies. Individual samples typically represent about 10–20 stalks of the same variety collected from the same field and grown during the 2001 season. Stalks were collected by hand after grain harvest was completed, dried to less than 20% moisture at less than 50°C, and shipped to NREL. Stover samples in this survey do not include cobs. Samples were milled using a rotary knife mill (Wiley Mill) to pass a $\frac{1}{4}$-in. screen prior to NIR spectroscopy.

The NIR spectrometer used for method development and sample analysis was a Foss NIR Systems Model 6500 Forage Analyzer with a sample transport module and a standard reflectance detector array. The transport module moves the sample compartment up and down during data collection, thereby allowing a more representative spectrum to be obtained from bulky heterogeneous samples. The reflectance array uses two silicon detectors to monitor visible light from 400 to 850 nm and four lead-sulfide detectors to monitor NIR light from 850 to 2,500 nm. Natural product sample compartment cells in 1/4-cup and 1-cup sizes were used as sample holders in the transport module. This instrument has a maximum resolution of 2 nm.

A key step in the application of rapid analysis methods is the collection of high quality NIR spectra. To minimize the effect of water in the biomass spectra, each sample was air-

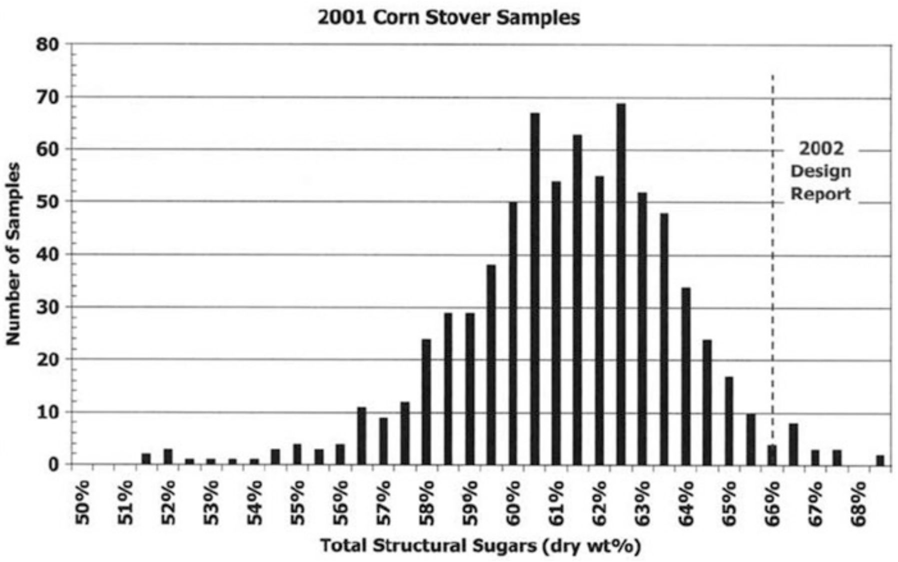

Fig. 33.18 Distribution of total structural sugars content among 738 hybrid corn stover samples collected in 2002

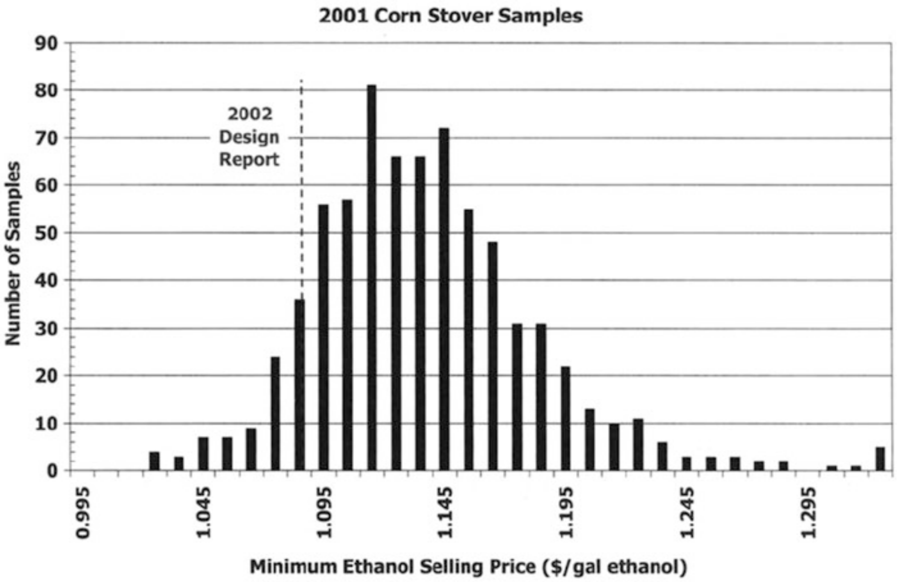

Fig. 33.19 Effect of feedstock composition on minimum ethanol selling price (MESP)

dried to less than 10% moisture prior to NIR spectroscopic analysis. Spectroscopic techniques were used that enable a high quality, reproducible, and representative NIR reflectance spectrum to be obtained. For each sample, a total of 35 spectra were collected and averaged to compensate for sample heterogeneity. Each calibration sample was subsampled three times. Sample cells were emptied and repacked between subsamples. Instrument reproducibility tests demonstrated that the reproducibility limits of the NIR spectrometer contributed less than 0.1% to the absolute prediction errors in the rapid analysis method.

NIR data were converted to compositions using the "stover 5c" rapid analytical method developed at NREL [129]. The ability of the stover 5C methods to accurately measure the composition of corn stover feedstock is shown in Fig. 33.17, where the composition, as determined by NIR/PLS, is compared to measurement of the same samples using standard wet chemical methods.

Improvements in the wet chemical calibration methods and the incorporation of additional calibration samples are continuously improving these rapid biomass analysis methods. In the future, information on these samples of corn stover can be updated using improved methods by reevaluation of their stored electronic spectra.

Figure 33.18 summarizes the results of compositional analysis by showing the distribution of values for total

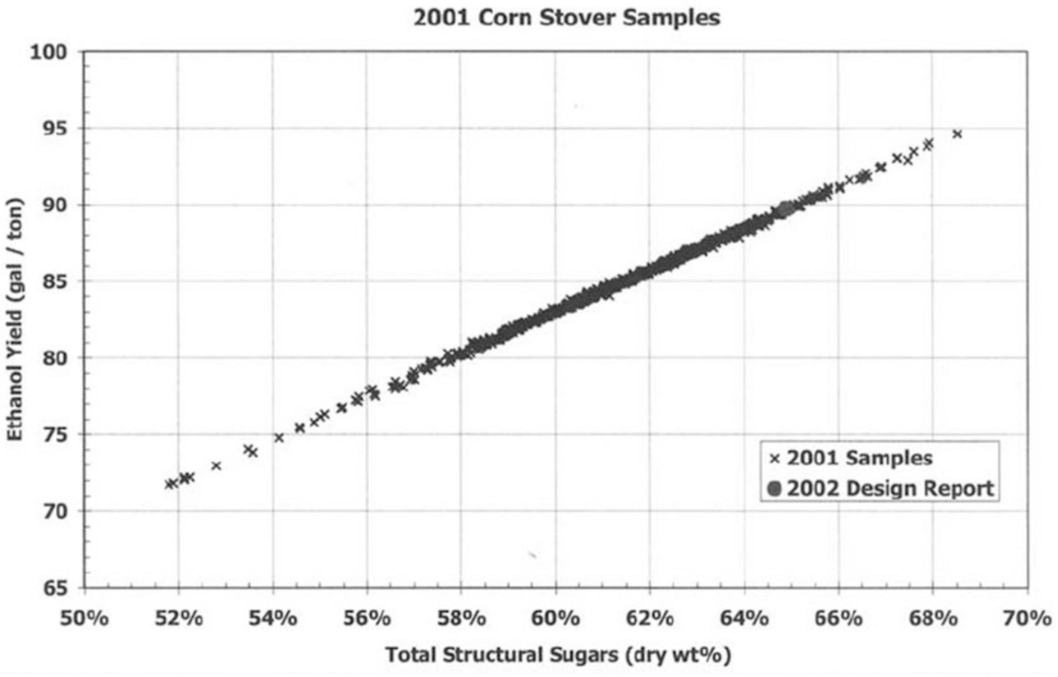

Fig. 33.20 Relationship between carbohydrate content of feedstock and ethanol yield per ton of input material.

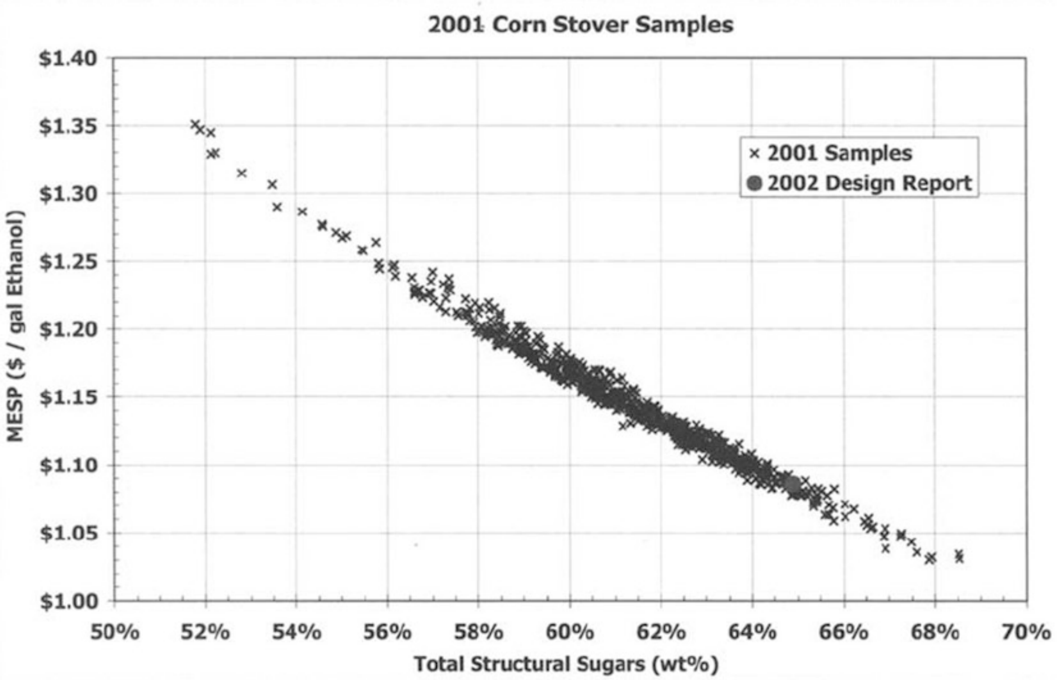

Fig. 33.21 Effect of feedstock composition on minimum ethanol selling price (MESP).

structural sugars (not including uronic acids) as a frequency histogram. Note both the normal distribution and the wide range of values. This same kind of normal distribution with a broad range is echoed by each of the individual major constituents of corn stover (i.e., glucan, xylan, lignin, protein, structural inorganics) across the population of 738 samples (data not shown). The dotted line in Fig. 33.18 indicates the composition of the corn stover used for process modeling efforts in the technoeconomic model by Aden et al. [130]. The fact that the composition assumed for process modeling efforts now appears somewhat optimistic in light of these results has caused subsequent modeling efforts to reconsider the feedstock composition assumptions.

Compositional variability can have a significant impact on biomass conversion process economics. The large effect (i.e., at least $0.30/gal ethanol) of observed compositional diversity on process economics is shown in Fig. 33.19 and is primarily due to the fact that the maximum theoretical product yield is proportional to feedstock carbohydrate content (Fig. 33.20) [131]. Yield is the major economic driver for the technoeconomic model used to assess the economic impact of composition on minimum product selling price [130], as can be seen from the data in Fig. 33.21.

Genetic Screening and Cell-Wall Genomics

The identification and characterization of genes involved in cell wall biogenesis can be approached using either a traditional genetic screening or a reverse genetics strategy. Both approaches are currently being used [116–118].

A forward genetics approach requires the availability of a relatively inexpensive, high-throughput method to assess the phenotype of individuals in a population. In the case of visible phenotypes, this only requires a person to inspect a large number of plants to identify unusual individuals to capture the genetic variants of interest. In the case of chemical phenotypes this is somewhat more difficult, but certainly possible. Chemical screens have been performed previously to find mutations in genes that affect important metabolic pathways and result in accumulation of abnormal branching patterns in starch [132], altered seed protein composition [133], abnormal fatty acids accumulating in storage or membrane lipids [134], or abnormal cell wall composition [135, 136].

Near-infrared spectroscopy has been employed as a high throughput screening tool to collect chemical information from plant tissue in a large genetic screen of a genomewide, transposon mutagenized collection of corn mutants [116, 137]. Recently, direct measurement of genetic, environmental, and other factors effects on biomass recalcitrance have been undertaken by the three DOE funded Bioenergy Research Centers (BRCs). The Bioenergy Science Center has developed a high throughput biomass recalcitrance screening pipeline which screens thousands of biomass samples for differences in pretreatability, enzyme digestibility, and glucan, xylan, and lignin content and composition. As the biomass in this pipeline is treated as near as practical to larger scale processes, the results are directly applicable to current large-scale biomass conversion schemes. In contrast, the Joint Bioenergy Institute uses ionic liquids to completely solubilize the biomass, removing structural and steric considerations from the assay and focusing on understanding the functionality of ionic liquids in large-scale biomass conversion. Similarly, the third BRC, the Great Lakes Bioenergy Research Center, utilizes a high-throughput, small-scale ball mill system to "pretreat" the biomass samples by reducing them to fine powder. This process reduces or eliminates the structural contributions of the cell wall to recalcitrance, but allows screening of the variations in chemistry between large sample numbers.

Future Applications

One of the long-term goals of rapid biomass analysis method development is the generation of robust methods for online and atline process monitoring and control. Because each method is feedstock, process, and sample specific, the achievement of this goal will require a significant long-term effort and considerable financial resources. One step in this direction is the development of automated and robotic methods of wet-chemical analysis that improve sample analysis throughput and decrease the cost of obtaining accurate calibration data.

The development of rapid biomass analysis methods is limited within the DOE program to feedstocks and processes currently used in program demonstration projects and industrial partnerships. Methods for other potential feedstock materials such as wheat straw, switch-grass, sorghum, or alfalfa could be developed if sufficient need and resources are identified.

Summary and Conclusions

Accurate, reliable, precise, and inexpensive methods for determining the composition of biomass at various stages during a conversion process are essential to effectively monitor the progress of the thermochemical and biochemical processes. This information enables the comparison of various process options and enables intelligent decision making in evaluating process options for maximizing product yield while minimizing capital and operating costs. Eventually, with the development of feedback and feedforward loops, a commercial biomass conversion process can be monitored and controlled by a set of automated processes. The availability of more realistic information concerning sources of variability in commercial biomass conversion processes minimizes investment risk and increases the realistic probability of achieving success in the DOE goals in establishing commercial biomass conversion industries in the United States.

Table 33.2 Major cellulase enzyme

IUBMB EC No.	Common name	Activity
Oligomer hydrolase		
EC 3.2.1.21	β-Glucosidase	Hydrolysis of terminal, nonreducing β-D-glucose residues with release of β-D-glucose
Exo-depolymerases		
EC 3.2.1.74	Glucan 1,4-β-glucosidase	Hydrolysis of 1,4-linkages in 1,4-β-D-glucans, to remove successive glucose units
EC 3.2.1.91	Cellulose 1,4-β-cellobiosidase	Hydrolysis of 1,4-β-D-glucosidic linkages in cellulose and celloteraose, releasing cellobiose from the nonreducing ends of the chains
Endo-depolymerase		
EC 3.2.1.4	Cellulose	Endohydrolysis of 1,4-β-D-glucosidic linkages in cellulose, lichenin, and cereal β-D-glucans

Biocatalysts for Biomass Deconstruction

Summary of Plant Cell Wall Structure

Plant cell walls are composed primarily of cellulose, hemicellulose, lignins, and pectins. These give structural rigidity and strength to the plant, deter pathogens, and retain extracellular water. Cellulose, a highly crystalline, insoluble polymer of β-(1,4)-cellobiose, comprises about 50% of the plant biomass. Although cellulose does not degrade easily, it will hydrolyze to glucose by the synergistic action of three distinct classes of enzymes: endoglucanases, exoglucanases, and cellobiases [138, 139]. In contrast with the insoluble linear cellulose homopolymer, hemicelluloses are water- or base-soluble heteropolymers, comprised of a variety of branched and substituted polysaccharides. In addition to providing water retention and structural reinforcement, hemicelluloses act as cross-linking agents.

It is worth noting that although hemicelluloses are considered soluble in their native form in vivo, extraction can result in significant debranching, often rendering them insoluble in water. Recently, Gatenholm and Tenkanen assembled a collection on properties, uses, and examinations of various hemicelluloses, both in industrial and basic science applications [140]. The complex structure of hemicelluloses has dictated an accordingly diverse array of hemicellulases. Generally, each structural feature in hemicellulose has an associated enzyme that can hydrolyze or modify this feature. Pectins are acidic polysaccharides that retain large amounts of water and act as an adhesive between adjacent plant cells, and, along with lignin, comprise much of the middle lamella. Although pectin may be found to some extent in most plant cell walls, it is a minor component in most tissues (fruits being the most notable exception), and its degradation is not covered here. For reviews on biodegradation by and commercial uses of pectinases, see articles by Galante and Formantici, Hoondal et al., Kashyap et al., Lebeda et al., and Naidu and Panda [141–145]. Lignin, by contrast, is a heterogeneous polymer of phenyl propanoid units containing various phenolic derivatives. Lignin is often thought of as the binder that cements the cell wall components together. Enzymatic degradation of lignin is still somewhat controversial, with various hydrolytic and oxidative mechanisms proposed. Many papers have been published on white rot degradation of lignin in recent years, however, the authors are unaware of a unified complete mechanism of lignin degradation, and an overview is not attempted here. Several reviews have, however, covered selected areas including lignin degradation by mycorrhizal fungi, dye decolorization by white rot fungi, lignin biodegradation in compost, applications in pulp and paper and ruminant feed, and the emerging molecular genetics of ligninolytic fungi [146–152].

Enzymatic Hydrolysis of Plant Cell Wall Components

The complex nature and interconnectivity of plant cell wall polymers preclude straightforward enzymatic digestion. There are dozens of enzyme families involved in plant cell wall hydrolysis, including cellulases, hemicellulases, pectinases, and lignin-modifying enzymes. The Nomenclature Committee of the International Union of Biochemistry and Molecular Biology (IUBMB) has classified cellulases and hemicellulases, like all enzymes, into different classes based on activity. Tables 33.2 and 33.3, compiled from the IUBMB enzyme nomenclature database (http://www.chem.qmul.ac.uk/iubmb/enzyme/), list the IUBMB enzyme classifications for cellulases and hemicellulases [153].

Synergy is a major factor in degradation efficiency, making measurement of these activities difficult, to say the least. The biomass degrading enzyme system, encompassing cellulases, hemicellulases, pectinases, lignin-modifying enzymes, and other accessory activities, is far too complex to be covered in detail in this general overview. The American Chemical Society (ACS) has covered much of this work in the ACS Symposium series including applications to lignocellulosics, fiber processing, pulp and paper, biomass

Table 33.3 Enzyme classes involved in hydrolysis of hemicelluloses

IUBMB EC No.	Common name	Activity
Debranching enzymes		
EC 3.1.1.6	Acetylesterase	An acetic ester + H_2O = an alcohol + acetate
EC 3.1.1.72	Acetylxylan esterase	Deacetylation of xylans and xylo-oligosaccharides
EC 3.1.1.73	Feruloyl esterase	feruloyl-polysaccharide + H_2O = ferulate + polysaccharide
EC 3.2.1.131	Xylan α-1,2-glucuronosidase	Hydrolysis of α-D-1,2-(4-*O*-methyl)glucuronosyl links in the main chain of hardwood xylans
EC 3.2.1.139	α-Glucuronidase	An α-D-glucuronoside + H_2O = an alcohol + D-glucuronate
EC 3.2.1.55	α-*N*-arabinofuranosidase	Hydrolysis of terminal non-reducing α-L-arabinofuranoside residues in α-L-arabinosides
Oligomer hydrolases		
EC 3.2.1.22	α-Galactosidase	Hydrolysis of terminal, nonreducing α-D-galactose residues in α-D-galactosides, including galactose oligosaccharides, galactomannans and galactohydrolase
EC 3.2.1.23	β-Galactosidase	Hydrolysis of terminal nonreducing β-D-galactose residues in β-D-galactosides
EC 3.2.1.25	β-Mannosidase	Hydrolysis of terminal, nonreducing β-D-mannose residues in β-D-mannosides
Exo-depolymerases		
EC 3.2.1.100	Mannan 1,4-mannobiosidase	Hydrolysis of 1,4-β-D-mannoside linkages in 1,4-β-D-mannans, to remove successive mannobiose residues from non-reducing ends
EC 3.2.1.145	Galactan 1,3-β-galactosidase	Hydrolysis of terminal, non-reducing β-D-galactose residues in (1,3)-β-D-galactopyranans
EC 3.2.1.37	Xylan 1,4-β-xylosidase	Hydrolysis of 1,4-β-D-xylans, to remove successive D-xylose residues from the non-reducing termini
EC 3.2.1.58	Glucan 1,3-β-glucosidase	Successive hydrolysis of β-D-glucose units from the nonreducing ends of 1,3-β-D-glucans, releasing α-glucose
EC 3.2.1.72	Xylan 1,3-β-xylosidase	Hydrolysis of successive xylose residues from the nonreducing termini of 1,3-β-D-xylans
Endo-depolymerases		
EC 3.2.1.101	Mannan endo-1,6-α-mannosidase	Random hydrolysis of 1,6-α-D-mannosidic linkages in unbranched 1,6-mannans
EC 3.2.1.136	Glucuronoarabinoxylan endo-1,4-β-xylanase	Endohydrolysis of 1,4-β-D-xylosyl links in some glucuronoarbinoxylans
EC 3.2.1.151	Xyloglucan-specific endo-β-1,4-glucanase	xyloglucan + H_2O = xyloglucan oligosaccharides (endohydrolysis of 1,4-β-D-glucosidic linkages in xyloglucan)
EC 3.2.1.32	Xylan endo-1,3-β-xylosidase	Random hydrolysis of 1,3-β-D-glycosidic linkages in 1,3-β-D-xylans
EC 3.2.1.39	Glucan endo-1,3-β-D-glucosidase	Hydrolysis of 1,3-β-D-glucosidic linkages in 1,3-β-D-glucans
EC 3.2.1.6	Endo-1,3(4)-β-glucanase	Endohydrolysis of 1,3- or 1,4-linkages in β-D-glucans when the glucose residue whose reducing group is involved in the linkage to be hydrolyzed is itself substituted at C-3
EC 3.2.1.71	Glucan endo-1,2-β-glucosidase	Random hydrolysis of 1,2-glucosidic linkages in 1,2-β-D-glucans
EC 3.2.1.73	Lincheninase	Hydrolysis of 1,4-β-D-glucosidic linkages in β-D-glucans containing 1,3- and 1,4-bonds
EC 3.2.1.78	Mannan endo-1,4-β-mannosidase	Random hydrolysis of 1,4-β-D-manosidic linkages in mannas, galactomannans and glucomannans
EC 3.2.1.8	Endo-1,4-β-xylanase	Endohydrolysis of 1,4-β-D-xylosidic linkages in xylans
EC 3.2.1.89	Arabinogalactan endo-1,4-β-galactosidase	Endohydrolysis of 1,4-β-D-galactosidic linkages in arabinogalactans
EC 3.2.1.99	Arabinan endo-1,5-α-L-arabinosidase	Endohydrolysis of 1,5-α-arabinofuranosidic linkages in 1,5-arabinans

for fuels, biomass conversion, and general activities on insoluble carbohydrates [154–160]. Readers are encouraged to find details for specific applications in these proceedings. The burgeoning number of scientific informational databases accessible through the Internet has also helped greatly to clarify (to some extent) the confusing nature of these enzymes. Sites include general enzyme databases, such as ExPASy (http://us.expasy.org/, the server gateway to Swiss-Prot/TrEMBLE (http://us.expasy.org/sprot/) and ENZYME (http://us.expasy.org/enzyme/]) and BRENDA (http://www.brenda.uni-koeln.de), as well as databases devoted exclusively to carbohydrases, such as CAZy (http://afmb.cnrs-mrs.fr/CAZY/acc.html) [161–164].

Current literature describing the assaying of general cellulase activity (or of individual component enzymes) has broadened considerably since Mandels et al. [165] reported reducing sugar release and substrate weight loss as suitable cellulase assay methods. To some extent, and for appropriate substrates, these methods are still considered adequate. However, modern assays based on molecular weight (MW) analysis detected by high-performance liquid chromatography size-exclusion chromatography (HPLC-SEC), coupled enzymes, viscometry, hydrolysis of dyed or derivatized insoluble and soluble polymers, and hydrolysis of derivatized or labeled low-MW substrates, have greatly enhanced the understanding of these complex systems. Cellulose structure and physical disruption of cellulose microfibrils have also been examined using light, electron, and more recently, atomic force microscopy [166–173]. These types of "assay" are more useful when the properties of the cellulose fiber are in question, not when the goal is total hydrolysis. There has also been work using gel-permeation chromatography to characterize changes to cellulose structure by examining the products of cellulase action on wood fiber [174]. As with much of biotechnology today, high-throughput methods have also been developed to increase the speed and accuracy of cellulase assay [175]. Despite all of the assays, or perhaps because of them, workers in the field are reminded that only assays designed to measure the conversion of cellulose from the actual biomass substrates in question are ultimately valid performance measures.

Most enzymes have very specific requirements for tight substrate binding and precise transition-state formation, which usually leads to high catalytic turnover rates. However, even ideal catalytic sites must be "carried to the substrate" by the macromolecule within which it is housed. Enzymes are also large compared to the polysaccharide oligomers under attack, especially as the particular site of action may be buried in a heterocrystalline structure of mixed polysaccharides. The complexity of biomass, specifically in regard to hemicellulose structure, requires a high degree of coordination between degradative enzymes. Studies show correlations between the enzymatic digestibility of cellulose and the removal of hemicellulosic sugars and lignin, supporting the notion of close spatial relationships [35, 176]. Of further complication is that the actions of glycosyl hydrolases often change the chemical environment of the partially degraded substrate, which in turn affects the actions of other glycosyl hydrolases. For example, partly because of the substituents attached to the main chain, most hemicelluloses are quite water soluble in their native state. These side chains disrupt the water structure and help to solubilize the hemicellulose. Debranching enzymes that remove these substituents generally decrease substrate solubility, and in turn lower the polysaccharide's susceptibility to endo-acting hydrolases [177]. Thus, a xylan that has been subjected to acetyl xylan esterase is less susceptible to enzymatic degradation than a xylan subjected to a mixture of branching and debranching enzymes [178]. As the substituents are removed, xylan can become less soluble, forming aggregates that sterically hinder and finally block further degradation [179]. The endoxylanases, for example, cleave the main chain linkages and are often quite particular about the type of linkage, type of sugar, and presence or absence of nearby substituents [180]. An endoxylanase that cleaves β-(1,4) linkages will usually have no effect on β-(1,3) linkages. Also, an endoxylanase that cleaves main-chain linkages near an *O*-2 linked arabinose may have no effect on an open-chain xylan [181].

Cellulases

Ask an industrial biochemist about cellulases and *Trichoderma reesei* will invariably come up. A mesophilic filamentous fungus typically found growing on cellulosic biomass, *T. reesei* produces arguably the most studied cellulase system in the world. Early research began when fungus-laden U.S. Army accoutrements were sent from the jungles of south-east Asia to the U.S. Army Natick Research and Development Laboratories during the 1940s [182]. This research program, led by Drs. Elwyn Reese and Mary Mandels for 40 years, succeeded not only in providing the U.S. Army and allies with chemical agents useful for protecting cotton goods, but also demonstrated the biological nature of their decay. The work at Natick demonstrated that many genera and species of fungi produce cellulose-degrading proteins, and that *T. reesei* was especially effective at degrading cotton. The Natick labs went on to learn how to grow *Trichoderma*, induce cellulase production, and determine operational ranges of pH and temperature, as well as tolerance to cations, anions, metals, solvents, and biomass-derived toxic compounds [183]. Furthermore, internship opportunities at Natick during the 1950s and early 1960s served to train the leaders of the next generation of cellulase scientists. In the end, this was perhaps one of the most important contributions of the program.

Despite cellulose's simple linear glucose polymer structure, its hydrolysis requires the coordinated action of at least three different types of β-1,4-glucanases (Table 33.2).

Endoglucanases

Endo-β-1,4-glucanases (EC 3.2.1.4) cleave the cellulose strand randomly along its length, generating new chain-end sugars, one reducing and one nonreducing. Usually, these chains remain insoluble and are thought to remain embedded in the cellulose crystal. The new ends, however, when exposed to the bulk water/cellulose interface, become new recognition sites for exocellulases.

Exoglucanases

Exo-β-1,4-glucanases (EC 3.2.1.91) cleave cellobiosyl (β-1,4-glucose dimers) or glucosyl units endwise from cellulose, chains. Most fungal, and some bacterial cellulase, systems display two types of exoglucanases: reducing-end and nonreducing-end cleavers. Exocellulases are thought to act processively on cellulose chains, starting at one end and

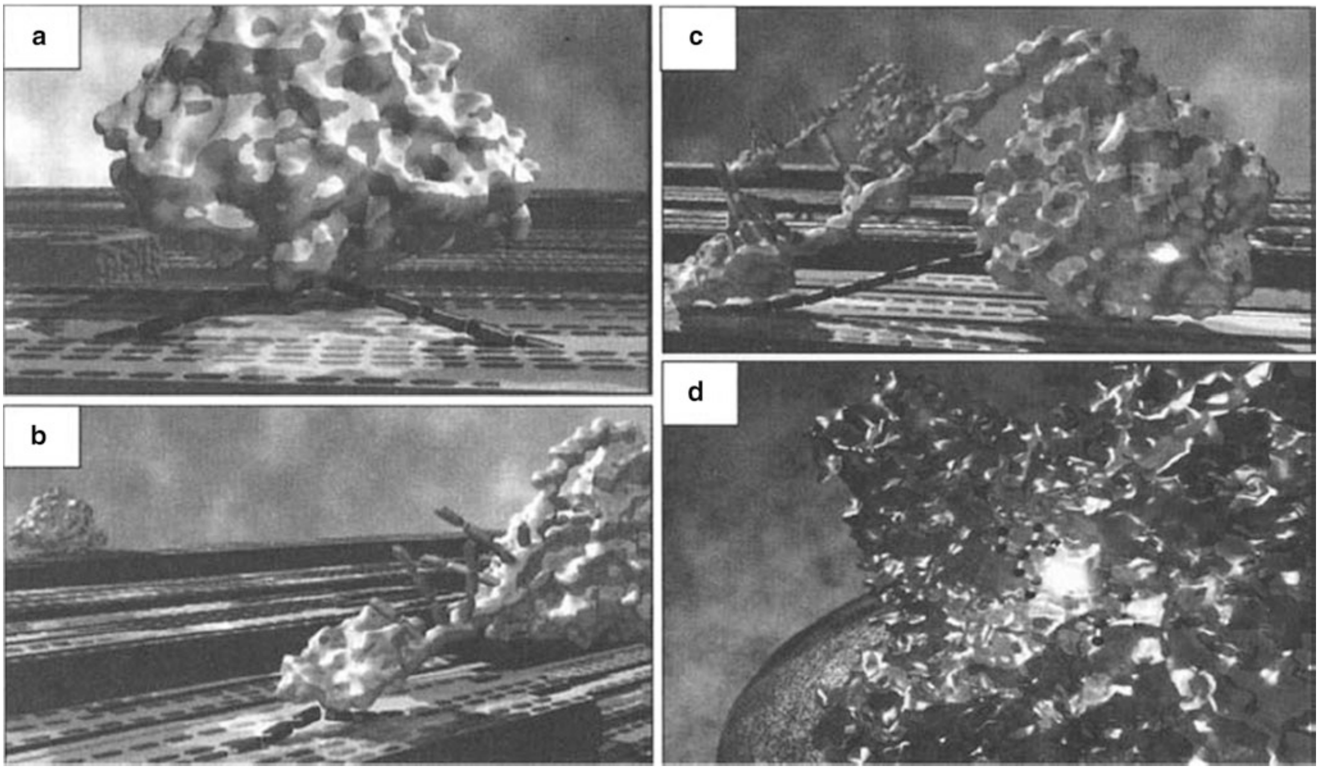

Fig. 33.22 Three enzyme activities in the degradation of cellulose: (**a**) endocellulase cel5A from *Acidothermus cellulolyticus*; (**b**) exocellulose cel7A from *Trichoderma reesei* finding an open reducing end; (**c**) cel7A processing along cellulose chain releasing cellobiose; and (**d**) bglA from *Bacillus polymyxa* hydrolyzing cellobiose

proceeding down the chain. The products are either cellobiose or glucose, and along with the reducing/nonreducing end-specificity, are specific to the enzyme in question.

Endoglucanases and β-Glucosidases

When endo-activity occurs close to a chain end in an amorphous region of the cellulose, the new cellulose oligomer may become dissociated from the larger structure. The degree of polymerization of the chain determines its solubility, ranging from highly soluble glucose dimer cellobiose to nearly insoluble cellohexaose. New soluble oligomers are usually acted upon by a third class of cellulases, the β-glucosidases (EC 3.2.1.21). This class acts primarily, if not exclusively, on soluble cello-oligomers, with decreasing specific activity as chain length increases. As their preferred substrate is cellobiose, they have also been termed cellobiases.

All three of these general activities are required for efficient and complete hydrolysis of cellulose to glucose. A conceptualized view of each typical cellulase action is shown in Fig. 33.22 [184]. The process is initiated by an endocellulase (in this case cel5A from *Acidothermus cellulolyticus*), which nicks the cellulose chain (Fig. 33.22a), exposing a new reducing and nonreducing chain end. Exocellulases (in this case the reducing-end specific cel7A from *T. reesei*) find these nicks (Fig. 33.22b) and feed the ends through their active sites, cleaving off products in a processive manner (Fig. 33.22c). If cellobiose is the product, as in the case of cel7A, then β-glucosidase hydrolyzes it to two glucose molecules (Fig. 33.22d).

Total Cellulase Activity Measurements

Each cellulase class has had its share of assay development. Assays that specifically measure each class are difficult to establish, as cross-reactivity between classes is greater than zero. However, there are assays that can be used to determine the relative ratios of these activities.

When using cellulases to degrade lignocellulosic material, total activity is usually the primary interest. The complexity of lignocellulose substrates and the huge heterogeneity in cellulase systems, however, create a quagmire for the cellulase enzymologist asked to determine the "activity" units of a particular cellulase. There are numerous methods for assaying cellulase activity, but most fall into one of three

Table 33.4 Specific activities of various *Trichoderma reesei* cellulase preparations

Source	Mix of component enzymes	Specific activity[a] (FPU/g protein)	References
Multifect GC[b]	Native	431	[675]

categories: sugar release (measured as reducing sugar), chain length reduction (measured by viscometry, light scattering, or size exclusion chromatography), and artificial substrate hydrolysis (measured by dye, chromophore, or fluorophore release).

The IUPAC Filter Paper Assay

In 1987, after significant effort, an international committee of cellulase researchers and the International Union of Pure and Applied Chemists (IUPAC) produced a procedure seeking to standardize cellulase activity measurements. This procedure uses microcrystalline cellulose and the dinitrosalicylic (DNS) acid method of Miller [185] to measure reducing sugars in the context of a highly specific assay protocol [186]. Because cellulose hydrolysis is nonlinear, the units were not defined as specific activity units per se (i.e., μmoles product/mg protein seconds), but rather as 4% hydrolysis of a 50-mg coupon of Whatman #1 filter paper, although many cellulase researchers have noted that after accounting for the addition of water to the glycosidic bond, the actual level of hydrolysis measured is 3.6% of the substrate. Regardless, the "filter paper unit" (FPU) was decreed the amount of enzyme that released 2.0 mg glucose from a 1.0 × 6.0 cm, 50-mg Whatman #1 test coupon after 60 min at 50°C. The dilution of enzyme required is converted, through a somewhat indirect procedure, to FPU per mL. For example, an undiluted cellulase preparation that yields exactly 2.0 mg glucose has 0.37 FPU/mL. This fractional unit is the lowest cellulase activity measurable with the IUPAC assay.

The IUPAC cellulase assay has significant limitations and merely serves as the best-defined method. Extrapolation of required glucose release from highly diluted or concentrated enzyme solutions is not permitted; assays must be conducted with enzyme dilutions that closely bracket the actual value. Cellulase solutions too dilute to release 2.0 mg glucose must either be concentrated to an appropriate level, or determined incapable of assay by the IUPAC method. For highest accuracy, every working solution made from an enzyme stock must be reanalyzed for activity, a condition that complicates most analytical procedures.

Cellulase activities of *T. reesei* broths are normally reported to lie between 400 and 600 FPU/g total protein [187]. Our work to assess the specific activities of *T. reesei* cellulase preparations has led us to the direct comparison of commercial cellulase products, typically highly selected *T. reesei* mutants, and reconstituted, purified cellulase enzymes (Table 33.4). Although the range of specific activities found from this internally consistent study generally agrees with the literature, our estimation of the maximal specific activity of reconstituted *T. reesei* cellulases is somewhat higher, 760 FPU/g protein. As some of the protein in commercial cellulases are comprised on non-active protein, this result is in line with an assay based on activity per gram of protein.

In fact, the activity of the native mixture of *T. reesei* cellulases (i.e., 10:20:60 for endoglucanase:cellobiohydrolase II:cellobiohydrolase I [EG I:CBH II:CBH I]) using reconstituted enzymes is about 10% less than that obtained with a mix higher in CBH II (Table 33.4). One should be aware that it is possible to find reports in the literature of *T. reesei* cellulases with specific activities greater than about 600 FPU/g protein. Considering these findings in view of recent studies of the magnitudes of possible inter- and intralaboratory errors in filter paper

[188] and protein assays [189], assay errors or inconsistencies are most likely responsible for most discrepancies in specific activity reported [190].

Variations on the filter paper assay have been developed. Irwin et al. have established a method for differentially measuring soluble and insoluble reducing sugars released from filter paper [191]. Ghose and the IUPAC committee also proposed a similar approach for measuring hemicellulases in 1987 [192]. This method relies on meeting a standard level of conversion of the xylan fraction in oat spelt xylan to xylose in a specified period of time under standard conditions. This latter method; however, is not often cited in the literature.

General Non-IUPAC Cellulases Assays

Many cellulase enzyme preparations are simply not concentrated enough to cause the required release of 2 mg glucose from the 50-mg filter paper sample in 60 min. If these samples cannot be concentrated accurately (which is often the case), traditional FPU cannot be measured. In such cases, however, the IUPAC committee recommends that the reducing sugar release per unit time be accepted as a "provisional" measure of enzyme activity. This is similar to the pseudo-initial rate approach often used in the decade previous to the IUPAC report to measure cellulase activity from a wide variety of substrates. These substrates may include filter paper [193], Avicel [194], de-waxed cotton [195], or phosphoric-acid-swollen cellulose (PSC) [196]. Methods based on the use of antibiotic disks [197] and turbidity development [198] also predated the IUPAC study. Because all three cellulase types generate new reducing ends, the most direct measurement of cellulase activity is the detection of new reducing ends in the cellulose chain. These methods are traditionally based on initial rate measurements introduced by Wood and McCrae [194].

The reducing sugars are typically measured by the Somogyi [199] and Nelson [200] procedures, which measure reduction of Cu^{2+} to Cu^{+} in alkaline solution, or by the dinitrosalisylic acid (DNS) assay, in which reducing sugars reduce DNS to 3-amino, 5-nitrosalicylic acid under alkaline conditions. Disodium 2,2′-bicinchoninate (BCA) can also be used to measure reducing sugars [201]. This reagent was found to be the best choice in a recent comparison of methods for the determination of endoglucanase activity [202]. The BCA method was highly sensitive, simple to perform, and directly gave the number of bonds broken, thus allowing for expression of endoglucanase activity in international units (μmol of β-1,4-glucosidic bonds hydrolyzed in 1 min during the initial period of hydrolysis).

Other methods used to measure cellulase activity include an automated filter paper assay for high throughput evaluation of cellulases [175], a diafiltration saccharification assay for minimization of product inhibition and high degree of digestion [203], measurement of cellulose size reduction by multiangle laser light scattering [202], use of dye release from various dyed substrates, and differential staining of cellulose digestion products [204–207].

Mathematical Modeling

A mathematical model has also been proposed for evaluating cellulase preparations. Sattler et al. [208] describe a relationship between hydrolysis extent, reaction time, and enzyme concentration. This procedure permits the effectiveness of different enzymes and of different pretreatment methods to be ranked. This method examines cellulose hydrolysis data collected from hyperbolic functions of substrate concentration vs. cellulase enzyme concentration at various timed incubations. The model is based on a double reciprocal plot of the relationship

$$(Y/C_o)^{-1} = (KC_o/Y_{\max})[E]^{-1} + (Y_{\max}/C_o)^{-1}$$

Y/C_o is the fraction of substrate hydrolyzed, $[E]$ is given in FPU/g substrate initially added, and $Y_{\max}/C_o$ is the fraction of substrate that could be maximally hydrolyzed at an infinite enzyme concentration. The y-axis intercept in the double reciprocal plot, $(Y_{\max}/C_o)^{-1}$, may be used to quantify the quality of the enzyme preparation. Ideally, an enzyme should have a high $Y_{\max}$ and a low value for $KC_o/Y_{\max}$. Adney et al. used this general method successfully to model the action of commercial *T. reesei* cellulase preparations on Sigmacell-50 [209]. Results from double reciprocal plots of enzyme activity, (percent conversion)$^{-1}$, vs. loading, (FPU/g cellulose)$^{-1}$, enabled extrapolation to infinite enzyme loading or maximal digestibility.

Endocellulase Activity Measurement

The "endo-1,4-β-glucanases" or 1,4-β-D-glucan 4-glucanohydrolases (EC 3.2.1.4), which act randomly on soluble and insoluble 1,4-β-glucan substrates, are commonly measured by detecting the decrease in viscosity or increase in reducing groups using carboxymethylcellulose (CMC) [202, 210, 211]. It is thought that the methyl groups limit activity of the exoglucanases while still permitting the endo-types to hydrolyze the chain interior, perhaps in regions with low side-chain density. Endoglucanases are also capable of hydrolyzing various polymeric, substituted substrates, such as Ostazin brilliant-red hydroxyethylcellulose (OBR-HEC) and azo-dyed and cross-linked HEC (AZCL-HEC), as well as the low-MW fluorogenic substrates, such as 4-methylumbelliferyl-cellobiose (MUC), 4-methylumbelliferyl-lactopyranoside (MUL), or 4-methylumbelliferyl-cellotriose (MU-G3). Although these substrates make it easy to measure activity, care should be taken in relating the measured activities to performance on biomass, as the two substrates are not equivalent.

Viscometric Assays

Viscometric approaches to cellulase measurement activities are important because other methods measure only the number of glycosidic bonds cleaved in a polymeric substrate. They do not provide any information about location in the substrate of the bonds cleaved. Viscometric methods measure a substantial change in a physical property of the substrate polymer, a very sensitive function of both the number and the location of the bonds cleaved [212–214]. For this reason, even though the recommended international units of carboxymethylcellulase are given in terms of glycosidic bonds cleaved, the most careful workers measure both bond cleavage (most often by measurement of sugar-reducing groups) and the change in solution viscosity as enzymatic hydrolysis proceeds. Vlasenko et al. [202] found the viscometric method to be simple to perform and highly sensitive for the internal bonds cleaved. However, this method does not account for the hydrolysis of CMC near the chain end and thus only allows for expression of endoglucanase activity in arbitrary viscometric units.

Activity Measurements

The "exo-1,4-β-D-glucanases" include both the 1,4-β-D-glucan glucohydrolases (EC 3.2.1.74), which liberate D-glucose from 1,4-β-D-glucans and hydrolyze D-cellobiose slowly, and 1,4-β-D-glucan cellobiohydrolase (EC 3.2.1.91), which liberates D-cellobiose from 1,4-β-glucans. Differentiation of these enzyme classes requires analytical techniques to distinguish glucose and cellobiose and is usually carried out by high-performance liquid chromatography (HPLC) or gas chromatography (GC). These enzymes can be further distinguished by their ability to liberate free sugars from either the reducing or nonreducing end of the cellulose chain [215, 216]. Synergy studies with enzymes of known orientation are usually used to determine chain-end preference given enzyme [191, 217, 218].

The process of detecting and verifying exoglucanases has long been controversial. If purified proteins are available, careful comparisons of reducing sugar yields and fluidity values from CMC hydrolysis as a function of enzyme concentration can be used to judge whether an enzyme is more EG-like or CBH-like. Of course, purified enzymes can also be further verified by analyzing the product from hydrolysis of a series of derivatized (i.e., radiolabeled, chromophoric, or fluorophoric) cello-oligomers [219, 220]. One class of these derivatives, cellobiosyl fluorides, has been reported to distinguish between CBH I and CBH II from *T. reesei* based on cleavage activity on the alpha and beta conformations of the cellobiosyl fluorides [221]. Claeyssens et al. also reported this type of rigorous analysis for fungal CBH I and CBH II [222]. Further specificities can be determined for proposed exoglucanases from analytical product evaluation by HPLC [223, 224]. This is a much more definitive method of distinguishing endo-from exo-acting cellulases.

In general, exoglucanases such as CBH I can be expected to hydrolyze the aryl-substrates MUC and MUL at the agluconic bond, but not the substituted soluble celluloses such as AZCL-HEC, OBR-HEC, and CMC [225]. Phosphoric acid swollen cellulose is also used as a substrate for exoglucanases; however, some endoglucanases will hydrolyze this cellulose form as well [224]. Analysis of activity on higher oligomeric derivatives has proven to be challenging, especially with EGs and CBH I [225]. Furthermore, because endoglucanases are highly synergistic with exo-acting glucanases, the presence of endoglucanases significantly complicates efforts to quantify exoglucanase activity and can be compensated for only by the separate purification and kinetic characterization of the endoglucanase. Attempts persist to link this synergy effect to the cellulose-binding module (CBM). There is some evidence that the CBM alone can have a synergistic effect on the activity of fungal cellulases, both exo- and endo-acting types [226–228].

β-Glucosidase Activity Measurements

The "β-D-glucosidases" or β-D-glucoside glucohydrolases (EC 3.2.1.21) act to release D-glucose units from cellobiose, soluble cellodextrins, and an array of glycosides. For cellobiose or cello-oligomers, this activity is usually measured and analyzed by HPLC or GC, or by direct spectrophotometric or fluorometric analysis of various chromogenic and fluorogenic analogues of cellobiose and cello-oligomers. β-D-glucosidase/cellobiase activities are usually determined according to the method of Wood [229] as aryl-β-glucosidase activity by the hydrolysis of *p*-nitrophenyl-β-D-glucopyranoside. The concentration of *p*-nitrophenol is determined from the absorbance at 410 nm under alkaline conditions induced by the addition of 1-2 volumes M Na_2CO_3. One unit of activity is defined as the amount of enzyme that catalyzes the cleavage of 1.0 μmol substrate per minute at 99°F (37°C). The temperature selection here seems somewhat arbitrary, as most cellulases have optimal activity at somewhat higher temperatures. If necessary, β-D-glucosidases can be distinguished from other cellulases by the relative differences in the initial rates for aryl-β-D-glucosides and cellobiose. Also, the unique and acute sensitivity of β-D-glucosidase to inhibition by gluconolactone provides a method to assess exoglucanase activity in mixed systems of these two enzymes. This approach is necessary because β-D-glucosidase cleaves the agluconic, as well as the holosidic bond of aryl-glucosides [230]. Note that a similar approach is often used to assay other aryl-glycosidases [231–233]. This practice is made possible by the availability of many *o*- and *p*-linked aryl-glycosides including (but not limited to) β-xylosides, β-mannosides, β-galactosides, and L-arabinofuranosides.

Hemicellulases

In contrast to cellulases, the hemicellulases encompass a much broader suite of activities. In addition to analogues versions of endo-, exo-, and glycosidase cellulase activities, multiple debranching activities are needed to handle the high complexity of the heterogeneous hemicelluloses (Table 33.3). The varied backbone composition of hemicelluloses also adds complexity. Xylans, xyloglucans, man-nans, and numerous other minor polysaccharide chains form the backbone for different hemicelluloses.

1. The endo-enzymes attack polysaccharide chains internally, with decreasing activity as chain length rises. Endoxylanases (EC 3.2.1.8) are specific for β-(1 → 4)-xylopyranose polymers, (i.e., the backbone of xylan) and others are specific for other hemicellulose polymers, such as mannan (endo-(1 → 4)-β-mannosidases, EC 3.2.1.78) or β-glucanases (endo-(1 → 3)-β-D-glucosidase, EC 3.2.1.39). As with endocellulases, these activities can be measured by viscometry or production of reducing sugar end groups on the appropriate hemicellulosic polymer.
2. The exo-enzymes act processively from either the reducing or nonreducing termini and again are specific to the type and length of the polymer. Some exo-acting enzymes have preferences for short chain substrates (DP 2–4), acting as cellobiase analogues, whereas others prefer larger substrates (DP > 4). Xylan (1 → 4)-β-xylosidase (EC 3.2.1.37), glucan (1 → 3)-β-glucosidase (EC 3.2.1.58), and mannan (1 → 4)-mannobiosidase (EC 3.2.1.100) are exo-acting enzymes specific for xylan, β-(1 → 3)-glucan, and mannan, respectively.
3. So-called "accessory" enzymes are also required for hydrolysis of hemicellulose in native plant tissue. These enzymes include a variety of acetyl xylan esterases (EC 3.1.1.72), acetyl esterases (EC 3.1.1.6), and esterases, such as feruloyl acid esterase (EC 3.1.1.73) [177], that hydrolyze lignin glycoside bonds. They also include classes for cleavage of specific hemicellulose side chains, such as α-L-arabinofuranose, glucuronic acid, and 4-*O*-methyl-glucuronic acid groups.

General Hemicellulase Assays

Xylan is the most predominant hemicellulose in most plant cell walls, comprising about $\frac{1}{4}$ to $\frac{1}{3}$ of total plant biomass [234]. Xylans function primarily by forming crosslinks between the other cell wall components, such as cellulose, lignin, other hemicelluloses, and pectin. The term "xylan" is a catch-all for polysaccharides that have β-(1 → 4)-D-xylopyranose backbones with a variety of side chains usually attached at the *O*-2 and *O*-3 positions, and include glucuronic acid, 4-*O*-methylglucuronic acid, L-arabinofuranose, xylose, and acetyl groups. The types and levels of side chains are dependent on the particular plant, with hardwoods having high acetyl and glucuronic acid moieties (glucuronoxylans) and grasses having mainly arabinofuranose and acetyl groups (arabinoxylan). Because of the complex nature of xylans, their enzymatic hydrolysis is intrinsically more complicated than that of most other plant polysaccharides. Typically, the polymer is debranched, either prior to, or in conjunction with, depolymerization of the backbone. Different debranching enzymes are required depending on the specific type of xylan being hydrolyzed. These include arabinofuranosidases, ferulic and coumaric acid esterases, acetyl and acetyl xylan esterases, glucuronidases, and xylosidases. Removal of these side chains synergistically enhances the rate of degradation by endoxylanase enzymes [177, 235–241].

Hemicellulose Debranching Enzymes

Debranching of the xylan backbone produces a wide variety of soluble low-molecular-weight compounds. Typically, these products are measured either by HPLC or GC. The difficulty in assaying these products is not so much in the detection as in obtaining the correct substrate for the enzyme. Most commercial xylan products are extracted by alkaline treatment, essentially hydrolyzing any ester linkages by saponification; that is, any acetyl-, coumaroyl-, or feruloyl esters are destroyed. Glycosidic side chains, such as arabinose or glucuronic acid are left intact, however, the polymer is typically insoluble. Enzyme studies using these substrates must be interpreted with caution, as the native esterified xylan is soluble. Extraction by DMSO or steam has been used to prepare "native" xylan, in which the esters are still intact and the polymer is soluble in water [242].

Arabinofuranosidases. α-L-arabinofuranosidases (EC 3.2.1.55) cleave α-L-arabinofuranosides from the arabinoxylan xylose backbone and have been shown to enhance the release of ferulic and coumaric acid from arabinoxylan, presumably through a preference for hydrolyzing phenolic acid substituted arabinose side chains [243]. In the context of hemicellulose hydrolysis, the activity most often reported is hydrolysis of the α-(1 → 2)-glycosidic linkage of the arabinofuranoside to the xylan backbone. Some of these enzymes have been shown, however, to cleave linear or branched α-(1 → 5)-linked arabinan side chains found in some pectins, resulting in some confusion regarding the specificity of this enzyme class [244–247]. Although most assays are carried out on extracted arabinoxylan, *p*-nitrophenyl-arabinofuranoside has also been used as a substrate [248–250].

Esterases. Acetyl esterase (EC 3.1.1.6) removes acetyl esters from acetylated xylose and short-chain xylo-oligomers. It's polymer-acting counterpart, acetyl xylan esterase (EC 3.1.1.72), has a similar activity, but prefers polymeric xylan [242]. In addition to acetate-specific enzyme detection kits, HPLC or GC analysis of acetate release from native extracted xylan and chemically acetylated xylan, colorimetric substrates, such as *p*-nitrophenol acetate and β-napthyl acetate, or the fluorometric substrate, 4-methylumbelliferyl acetate are also used to assay acetyl esterases [242, 251]. The third esterase, ferulic acid esterase (EC 3.1.1.73), hydrolyzes the ester bond between ferulic acid or coumaric acid and the arabinose side chain of arabinoxylan. Assays for this activity are usually carried out using starch-free wheat bran or cellulase-treated gramineous biomass as a substrate and monitoring ferulic or coumaric acid released by HPLC or TLC. When preparing enzyme-treated substrates, care must be taken to employ phenolic-acid-esterase-free cellulases [242]. Other substrates include methyl and ethyl esters of the phenolic acids, as well as finely ground plant biomass [238, 252, 253].

Glucuronidases. In hardwood xylans, xylan α-1,2-glucuronosidase (EC 3.2.1.131) and α-glucuronidase (EC 3.2.1.139) are involved in debranching the xylan backbone through removal of α-(1 → 2)-linked glucurono- and 4-*O*-methyl-glucuronosides [254–257]. Although relatively little work on these enzymes has been carried out, Tenkanen and Siika-aho reported synergy with endoxylanase utilizing deacetylated birch glucuronoxylan. The same report also demonstrated that acetylation interferes with glucuronidase activity and that higher activity was observed on soluble softwood 4-*O*-methylglucuronoxylan [255]. Such synergy has also been reported by others [240, 255, 258]. *Para*-nitrophenyl-α-D-glucuronide is used as a substrate for α-glucuronidase [259], whereas xylan α-1,2-glucuronosidase is specific for an α-(1 → 2)-linked glucuronoside. Some glucuronidases, including membrane-bound enzymes, have been found to prefer glucuronoxylo-oligomers as substrates [258, 260–262]. One report demonstrated the specific requirement for the 4-*O*-methyl group for efficient binding and positioning of the side chain in the enzyme active site [256].

Hemicellulose Depolymerization Enzymes

As noted for cellulases, hemicellulose depolymerizing enzymes are divided into three classes; endo-acting enzymes, exo-acting enzymes, and oligomer-hydrolyzing enzymes. Although mechanisms of hemicellulose hydrolysis have been steadily studied over the years, they have not received the attention given to cellulose hydrolysis. Despite this, a general pattern of degradation is beginning to emerge. Although there are specific examples of endo-acting enzymes requiring side chains for maximal activity [263], the majority of the endo-acting hemicellulose hydrolases tend to be more active on debranched or partially debranched hemicellulose, especially in the case of xylanases. The limitation on this increased activity is probably due to solubility analogues of the polysaccharides, which tend to become more insoluble as the debranching process continues. Decreasing chain length from the activity of endo-hemicellulases mollifies this, allowing the shorter, less substituted fragments to remain soluble. Exo-acting enzymes, which probably fall into reducing- and nonreducing-end-specific groups and oligomer-hydrolyzing enzymes, also require debranching as a precursor to maximal activity. Overall, a balance must be met among removing the branching side chains from the polysaccharide backbone, decreasing the average chain length, and hydrolyzing the oligomers into free monomers, all while maintaining enough solubility of the fragments to allow enzyme access. The concerted action of the various hemicellulase enzyme classes probably accounts for the high synergy observed when the enzymes are used in concert [240].

Xylanases. Depolymerization of the xylan backbone is mediated by endoxylanases with oligomers hydrolyzed by β-xylosidases. Structurally, the endoxylanases are divided into glycosyl hydrolase families 10 and 11. These enzyme families are similar in that they both depolymerize xylan via the Koshland-type, two-step catalysis that leaves products with retained stereochemistry of anomeric configuration. Family-10 enzymes typically yield lower molecular weight products (tetramers) than do family-11 enzymes (pentamers) [264]. This is likely a function of the difference in binding sites, with family-10 enzymes having a binding site that recognizes shorter oligosaccharides than do family-11 enzymes [257, 265]. Although these enzymes are active on native branched xylan, debranching may increase their activity [258, 266].

Assays for endoxylanases follow the same general patterns as endocellulase assays. Viscosity reduction, reducing sugar production, dye-release, solubilization, zymogram analysis, and colorimetric/fluorometric analogues are all used to determine endoxylanase activity [267–275]. DNS detection of reducing sugars from xylan is the most cited method. Endoxylanases tend to have a preference for polymers of a certain degree of polymerization (DP). Bray and Clarke reported a *Schizophyllum commune* endoxylanase with a preferred substrate DP of seven [276], whereas others reported enzymes exhibiting true endo-type activity, with decreasing activity at lower DPs [263, 277, 278].

There are numerous reports of β-xylosidases that cleave short chain xylo-oligomers to xylose. In these cases, product detection was typically carried out by direct HPLC analysis or hydrolysis of *p*-nitrophenyl-β-D-xylopyranoside [279–282].

Xyloglucanases. Xyloglucans are polysaccharide polymers composed of a linear backbone of β-(1 → 4) linked glucopyranose moieties with some monomers substituted with xylopyra-nose in an α-(1 → 6) linkage. The xylose side chains can in turn be substituted with one or more of the disaccharides α-(1 → 2)-L-fucosylpyranose-β-(1 → 2)-D-galactopyranose and α-(1 → 2)-L-galactopyranose-β-(1 → 2)-D-galactopyranose, with the fucose residues being found mainly in primary cell walls [283–288]. α-(1 → 2)-L-arabinofuranose has also been shown to be substituted onto either the main glucose chain or onto the xylose side groups [283, 289]. It has been shown that xyloglucans are acetylated through *O*-linkages to the arabinose or galactosyl side chains [283, 287, 289, 290]. Despite this side chain substitution, a specific acetylxyloglucan esterase has not been discovered.

There is an exo-acting enzyme that acts on the nonreducing end of xyloglucan oligomers. Oligoxyloglucan beta-glycosidase (EC 3.2.1.120) is produced by *Aspergillus oryzae* and removes an α-xylo-β-(1 → 6)-D-glucosyl dimer (isoprimverose) from the nonreducing end.

β-*Glucanases*. β-Glucan is a glucopyranose polymer containing either β-(1 → 3) or mixed β-(1 → 3), β-(1 → 4) linkages. The ratio of (1 → 4) to (1 → 3) linkages varies by species and gives specific properties to individual β-glucan polymers. Because of the differences in the linkages, different enzymes are required to cleave the two forms of β-glucan [291–296]. We now know that β-glucan can be degraded by glycosyl hydrolase family-12 enzymes (EC 3.2.1.4). Although these endo-acting enzymes are active on β-(1 → 4) glycosidic linkages, they are differentiated from other β-(1 → 4)-acting enzymes by the distinction of being able to hydrolyze the β-(1 → 4) linkages in mixed β-(1 → 3, 1 → 4)-linked polysaccharides. Glucan endo-1,3-beta-D-glucosidase (β-(1 → 3) glucanase) (EC 3.2.1.39) is an endo-acting glycosyl hydrolase that acts on β-(1 → 3) glucan, but has very limited activity on the mixed linkage β-glucan. Endo-1,3(4)-beta-glucanase) β-(1 → 3,1 → 4) glucanase) (EC 3.2.1.6), is also an endo-acting glycosyl hydrolase. There is an exo-acting glycosyl hydrolase that is active on β-(1 → 3) glucan. Glucan 1,3-beta-glucosidase (EC 3.2.1.58) acts by processively releasing glucose from β-(1 → 3) glucan from the nonreducing end. One interesting report utilized an enzyme-linked sorbant assay in microtiter plates coated with biotinylated β-glucan to determine activity [297].

Mannanases, *gluco- and galactomannanases*. Whereas mannan is characteristically described as a linear β-(1 → 4) mannopyranose polymer, galactomannan is composed of a polymeric β-(1 → 4) mannopyranosyl backbone highly substituted with β-(1 → 6) linked galactopyranose residues [298, 299]. The degree of substitution varies with source. Glucomannan, found mainly in the root of the konjac plant (*Amorphophallous konjac*) consists of a β-(1 → 4) linked mannopyranose and glucopyranose backbone in a ratio of 1.6:1 [300]. The backbone residues are substituted in a β-(1 → 3) linkage with several sugars and short oligosaccharides, as well as with *O*-linked acetyl groups about every 15 residues [301–303]. The structure, and hence the degradation, of mannan is very analogous to cellulose, both being linear β-(1 → 4) linked monosaccharide polymers [304]. Mannan, however, is found in only a few particular plants, notably in the endosperm of the ivory-nut from the Tagua palm (*Phytelephas macrocarpa*) and a few other plants [304]. In glucomannan and galactomannan, as with xylan, degradation requires both debranching and depolymerizing enzymes, which work in synergy [240]. There are two major types of galactomannan, differentiated mainly by the source and degrees of galactose substitution, locust bean gum, derived from the carob tree (*Ceratonia siliqua*), contains an average of 2,000 sugar residues, with a galactose about every 3.5-mannosyl residues. The other major commercial source is guar gum, from the seed of the leguminous shrub *Cyamopsis tetragonoloba*. Guar gum contains more galactose residues than locust bean gum, having a galactose every 1.5–2 mannose units, and is longer, with residue counts of around 10,000.

The enzymes involved in depolymerization of the mannans consist of β-mannanase (EC 3.2.1.78), the endo-acting enzyme, and β-mannosidase (EC 3.2.1.25), which produces mannose from the nonreducing end of the mannose chain [305–307]. Debranching of galactomannan is primarily carried out by α-D-galactosidase (EC 3.1.2.22) [308, 309]. Tenkanen and co-workers have also reported an acetyl glucomannan esterase active on the acetyl side chains in glucomannan [236, 310, 311]. There are little other data on specific debranching enzymes involved in degradation of glucomannan. Assays for mannan hydrolysis have been carried out using extracted polysaccharides as substrates, colorimetric analogues, and dyed polysaccharides. Dyed polysaccharides have been utilized to determine activities of cultures on various polysaccharides, both as activity screens and as quantitative measures. These substrates include both soluble and insoluble forms (dependent mainly on the properties of the native polysaccharides) and include azurine (azo-), Remazol Brilliant Blue (RBB), and Ostazin Brilliant Red (OBR), among others [312–315]. For azo-, RBB-, and OBR-linked substrates, clearing zones on Petri plate or acrylamide gel agar overlays indicate active colonies or protein bands [316–320]. The crosslinked version (AZCL-polysaccharides, Megazyme, Inc. Bray, Ireland) has also been used to screen for activity of various glycosyl hydrolases [321–323]. In the case of AZCL substrates, the result of activity is a blue halo surrounding active colonies or dye release into microtiter plate wells. The authors have used this technique extensively to screen both environmental samples and recombinant libraries for glycosyl hydrolase activities (Fig. 33.23).

Pectinases

In addition to cellulose and the hemicelluloses, pectins are a third class of polysaccharides found in the cell wall matrix of plant cells. Further information and good structural diagrams can be found in the recent review by Ridley et al. [324]. Found mainly between adjacent cell walls in the middle lamellae, pectins fall into three classes differentiated by their backbone structure and branching patterns [325, 326]. Homogalacturonan (xylogalacturonan) is comprised of α-(1 → 4)-linked galacturonic acid chains containing xylose side chains and makes up the smooth region of pectin [327]. Homogalacturonan is methylated through ester-linkages to the galacturonic acid residues. Once in place, pectin methyl esterases (EC 3.1.1.11) remove these side chains and allow formation of the gel matrix [328]. The rhamnogalacturonans make up the "hairy" region of pectin. In rhamnogalacturonan I, (RG I) the backbone chain is comprised of the disaccharide (→4)-α-D-galacturonic acid-α-(1 → 2)-α-L-rhamnopyranose-(1→). The rhamnose is typically substituted at the C-4 position with a branched chain of sugars made up of either galactose or arabinose or a combination of both and other sugars. The arabinose residues can be derivatized with ferulic acid. The galacturonic acid residues in the backbone are usually *O*-2 or *O*-3 acetylated and *O*-6 methylated. The structure and substitution patterns of RGI vary widely across plant species. Where the majority of the side chain is comprised of arabinose, the side chains are referred to as arabinans. These arabinans are predominantly α-(1 → 5) linked arabinofuranosyl residues substituted at either or both the *O*-2 and *O*-3 positions [326]. Side chains comprised of galactose residues are referred to as galactans. When these galactans are further substituted with arabinan chains, they are referred to as arabinogalactans [329]. In contrast to RG I, the structure of Rhamnogalacturonan II (RG II) is highly conserved across the plant kingdom [330]. It is comprised of 28 glycosyl residues, of which seven are found in the galacturonic acid backbone. The backbone is specifically branched at four points (designated A–D chains) with some unusual sugars such as 2-*O*-L-fucose and 3-deoxy-D-manno-2-octulosonic acid, aceric acid, and apiose [330]. The structures of each branch are known, although the exact point of attachment of branch D is still unclear.

As is apparent from the complex structure, there is a diverse enzyme suite required to hydrolyze pectin. As in hemicellulase systems, there are depolymerizing and debranching enzymes, mainly esterases, that act synergistically [315, 331]. The depolymerizing enzymes include both glycosyl hydrolases, which cleave glycosidic bonds by an acid–base catalysis mechanism, and polysaccharide lyases, which hydrolyze the glycosidic bond through a β-elimination mechanism, resulting in a double bond between the C-4 and C-5 of the new nonreducing end [315]. Reviews by Kashyap et al. and by Kennedy and Methacanon outline the pectinase enzymes in detail [143, 332]. Assay techniques involve the usual assortment of reducing sugar production, viscosity reduction, HPLC analysis, and dye release [315, 331, 333–338]. Ruthenium red staining in plates and zymograms have also been used [331]. Because of its solubility, pectin incorporated into plates can be detected by precipitation with hexadecyl-trimethyl-ammonium bromide, resulting in clear halos of hydrolysis around active colonies [339]. As with other polysaccharide degradation studies, structural determination of products has been carried out by nuclear magnetic resonance spectroscopy [333].

Chemical Catalysis for Biomass Deconstruction

Introduction

Deconstruction is a somewhat misleading term, in that it suggests processes exhibiting low selectivity or harsh conditions. To the contrary, *selective* biomass deconstruction can be a powerful tool for use within the biorefinery, as it provides both monomeric and polymeric materials for eventual conversion into final refinery outputs. Biomass deconstruction is a separation process highly analogous to petrochemical refining. In any process designed to convert a source of raw materials into products, the raw material almost always requires some form of preliminary upgrading in order to separate a complex mix of materials into individual streams of initial building blocks. The petrochemical industry "deconstructs" crude oil, using distillation to make mixed hydrocarbon streams for various fuel uses, or cracking (primarily using chemical catalysis) to prepare the industry's primary building blocks of ethylene, propylene, BTX, butenes, and methane for chemical uses [340].

The biorefinery is no different. Renewable raw materials are complex mixtures of different biopolymers, and chemical deconstruction processes (as differentiated from biochemical processes described earlier in this chapter) may be used to separate these biopolymers from one another. However, deconstruction processes optimized for the biorefinery offer more flexibility than those used in the petrochemical industry. The petrochemical industry tends to focus on refining processes that give low molecular weight (very roughly) (Fig. 33.24).

The wide range of different biomass materials can be somewhat daunting. However, biomass deconstruction processes greatly simplify this initial slate of raw material sources. Biomass provides three primary feedstocks: sugars, in the form of starch, cellulose, and hemicellulose; aromatics, in the form of lignin; and hydrocarbons, in the form of plant triglycerides. Further deconstruction of these polymers and oligomers leads to monomeric materials including individual sugars and related polyols such as glycerol from triglycerides, low molecular weight aromatics from lignin, and fatty acid hydrocarbons from triglycerides [341, 342]. Under proper conditions, deconstruction of the polymeric materials can also lead to structural modification of the monomeric units, leading to materials such as furfural, levulinic acid, and levoglucosan [343].

Chemical catalysis can play a key role in each of these deconstruction processes, promoting conversions of raw materials into individual polymers, and individual polymers into low-molecular-weight compounds. This section reviews examples of each type of process, showing how catalysis leads to core building blocks for the biorefinery, analogous to the initial building blocks manufactured by the petrochemical industry. Although highly important to overall biorefinery operation, further catalytic transformations of this initial set of building blocks to chemical products is not included in this discussion.

The selective deconstruction of biomass for biorefinery use is of particular importance when viewed in the context of biomass availability. Biomass is exceedingly abundant. A vast amount of renewable carbon is produced in the biosphere, as much as 170 × 10^9 metric tons is fixed annually. This amount could supply almost all domestic organic chemical needs, currently about 7–8% of our total nonrenewable energy and materials consumption [344–347]. When measured in energy terms, the amount of carbon synthesized is nearly ten times the world consumption [348]. Cellulose, the most abundant organic chemical on earth, has an annual production of about 90 × 10^9 metric tons [349–351]. Lignin production by the pulp and paper

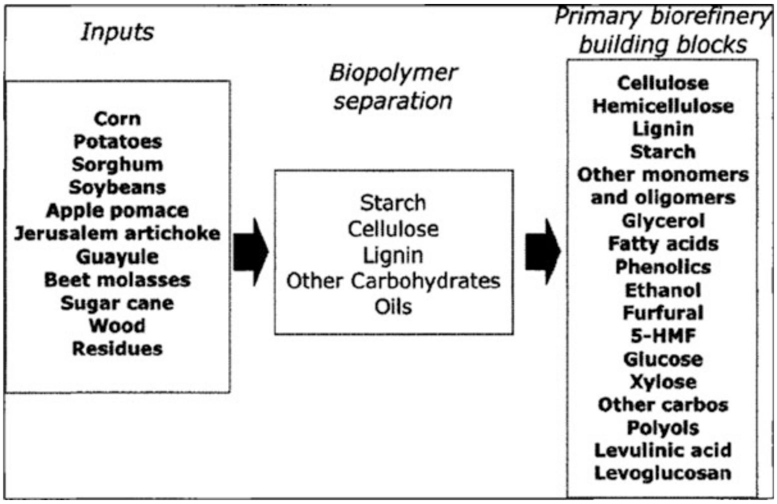

Fig. 33.24 Biomass deconstruction is a key step in its conversion to chemical products and fuels

industry is 30–50 × 10^6 metric tons/year [352]. The yearly availability of renewables is most important, inasmuch as—in contrast to petrochemicals—it makes this resource almost unlimited, if used in a sustainable manner. Some projections have world oil production peaking in the next 5–10 years [353, 354]. It is unlikely that demand will decrease in line with production. In the United States, energy consumption has increased by more than 28%—about 21 ekajoules (EJ)—during the last 25 years, with more than half of this energy growth—about 11 EJ—occurring during the last 6 years, indicating that other feedstock sources will be needed [355]. Chemical catalysis has been a key contributor to the success of the petrochemical industry, with more than 90% of all processes using some form of catalysis [356]. It is reasonable to assume that catalysis tailored for the specific features of biomass raw materials will play a similar role within the biorefinery, both to effectively and sustainably use this resource and to help address the growing needs of the world.

Scope of the Review

Chemical catalysis for processes leading to cellulose, hemicellulose, lignin, and their derivatives is an extremely broad topic. It is also somewhat hard to define for biomass. A number of different processes exist for separation of biomass into its constituent biopolymers. The corn wet mill produces carbohydrates as starch. The kraft process for pulping of wood produces carbohydrates as cellulose, and under certain conditions, isolable lignin. The kraft process itself is stoichiometric, but extensive research has been done on the use of catalytic amounts of additives to promote this and related separations [357]. Many other separation processes have been categorized under the term “pretreatment” [358–361] and are linked closely to the generation of fermentable sugars for fuel ethanol production, but can also provide polymeric materials for chemical use. Some pretreatments are solvolyses, which are technically noncatalytic. Yet the active component of the solvent (e.g., a proton) is not consumed within the molecular level mechanism, and serves to promote the reaction in a catalytic sense. Other systems are autocatalyzed through generation of a catalytically active species over the course of the separation. More recently, a new class of pretreatment has been getting more scrutiny. Ionic liquids, i.e. salts that are molten at "reasonable" temperatures, have shown the capacity for completely solubilizing biomass. Ionic liquids are being studied for several applications in biomass conversion including complete solubilization, swelling of fibers for increased digestibility, as a solvent system for increasing enzymatic digestion, and as a co-pretreatment in conjunction with other "standard" pretreatments.

The subsequent deconstruction of biopolymers into single, low-molecular-weight chemicals, allows the identification and definition of catalyst to become clearer. Chemical catalysis has been used to improve many of these processes, and several examples of these conversions are described below.

The options for practical operation of a biorefinery are also complex. Very broadly, the biorefinery will have the capability of deconstructing biomass into several categories of outputs including:

- Constituent polymers of biomass
- Oligomeric fractions of these polymers
- Monomers comprising these polymers or oligomers
- Individual chemicals from structural reorganization of other fractions

Ideally, biorefinery operation will be selective and flexible enough to switch among these categories depending on the needs of the market. Moreover, these categories could, in principle, be combined to provide diverse product profiles [362, 363]. In one instance, the biorefinery would provide cellulose, hemicellulose, and lignin. However, modification of conditions could further transform the initially produced carbohydrate polymers in situ, for example, hydrolyzing the hemicellulose to xylose, and then converting it to furfural. The Acetosolv process for the separation of wood is operated in this manner [364]. Pulping of wood with the Formacell process (pulping with HOAc/HCOOH mixtures) can produce cellulose, lignin, furfural, and 5-hydroxymethylfurfural (5-HMF) as primary products [365]. Thus the exact choice of operating mode and resulting product profile can be strictly dependent on the needs of the biorefinery operators.

Even with this potential variability in operation types, it is anticipated that the biorefinery industry will migrate toward a small group of easily produced primary building blocks from which a much larger group of final products will be derived. This approach would directly parallel the petrochemical industry, which uses seven primary building blocks for the eventual production of tens of thousands of marketplace products. The analogous group of primary building blocks for the biorefinery has not yet been defined, making the potential matrix of deconstruction processes and initial outputs complicated. Using carbohydrate polymers again as an example, hemicellulose, xylose, or furfural could each be a biorefinery primary building block as they are all linked by chemically catalyzed deconstruction processes.

In this section, we seek to identify materials that are the reasonable first structures to arise from biomass deconstruction, and to describe how chemically catalyzed processes are being developed for their production. For that reason, commercially practiced processes that use catalysis, such as the reduction of glucose to sorbitol, are mentioned only briefly or not at all. Chemical catalysis will certainly play an additional role in the further conversion of these initial building blocks into secondary intermediates or final marketplace products (e.g., oxidative conversion of levulinic acid into succinic acid), but such multistep possibilities are outside the scope of this discussion.

Separation of Biopolymers from Biomass Raw Materials

Biomass raw materials are made up primarily of the three biopolymers, cellulose, hemicellulose and lignin, and each of these materials finds use as a chemical feedstock. A wide variety of methods has been described for their separation and isolation. The paper industry describes these processes as pulping, whereas the biorefinery industry more normally refers to them as pretreatments. The goal in each case is the same: production of separate biopolymer streams for conversion to final product outputs. The uses of chemical grade cellulose are well known in industry and the literature and include cellophane and various cellulose esters and ethers [213]. Certain forms of lignin are also items of commerce [366]. Chemical catalysis of the following pretreatment/pulping processes has been examined to improve the initial separation of lignocellulosics into their constituent polymers.

Dilute Acid Pretreatments

Within the context of the biorefinery, the use of dilute acid is probably the most widely studied technology for the separation of the starting biomass raw material into its individual components. This process has been and continues to be extensively investigated, and the reader is referred to the many reviews available in the literature [88, 358–361, 367–373].

Solvent Separation Processes

Biomass separation based on the use of organic solvents ("organosolv" processes) offers more selective access to the biopolymeric constituents of renewable raw materials, as such operations normally give separate and high-quality process streams of cellulose, hemicellulose, and lignin. Several reviews on organosolv technology and the mechanism of separation are available [374–380]. Most examples of organosolv processes use volatile alcohols, such as methanol and ethanol, however, a huge variety of additional solvents has been employed, including 1,3-BDO, 1,4-BDO [381], ethylene glycol [382], glycerol [383], phenol [384], and organic acids under the names of Formacell, Milox, and Acetocell [385–390]. Attempts to commercialize organosolv technologies have also appeared as the Alcell, Organocell, or ASAM processes [380, 391–397]. Because these processes were primarily focused on new methods of producing cellulose pulp for the paper industry, their expense precluded commercialization. However, the selectivity of organosolv technology makes it well suited for the production of chemical building blocks from renewable raw materials.

In almost all organosolv processes, chemical catalysis plays a necessary role, as solvents alone do not function effectively for the separation of biomass [398]. The most commonly employed processes, based on the treatment of biomass with aqueous alcohols at elevated temperatures, are autocatalyzed. Acetic acid is generated during the separation process through hydrolysis of acetate groups present on the hemicellulose polymer [392, 399–401]. Alternatively, acid can be added to the separation medium prior to the process. Adding acid catalyst normally allows lower separation temperatures and milder conditions. Chemical catalysis has proven to be of particular importance for the organosolv separation of softwoods. Normally, softwoods are poor substrates in solvent-based processes. However, the addition of alkaline earth metals to alcohol separation processes has resulted in effective softwood separation [398, 402–404].

An example of an acid-catalyzed organosolv biomass separation is the clean fractionation (CF) process, developed at the NREL (Fig. 33.25) [405]. The process treats the biomass with a ternary mixture of methyl isobutyl ketone (MIBK), ethanol (EtOH), and water (H_2O) in the presence of sulfuric acid. The separation is carried out using a 16/34/50 ratio of MIBK/EtOH/H_2O for 56 min at 140°C in the presence of 0.025–0.2 M H_2SO_4 as standard conditions. The solvent mixture selectively dissolves the lignin and hemicellulose components, leaving the cellulose as an undissolved material that can be washed, fiberized, and further purified. The soluble fraction containing the lignin and hemicellulose is treated with water, causing a phase separation yielding an organic phase containing the lignin and an aqueous phase containing the hemicellulose. Solvent removal gives CF lignin in high yield as a shiny, brown, free-flowing powder exhibiting properties consistent with other organosolv lignins, and a generally lower-molecular-weight profile and greater solubility in polar organic solvents than other lignins. CF appears to be a very general process, and can be used for fractionation of a wide range of biomass feedstocks including corn stover, newsprint, bagasse, corn fiber, and rice straw.

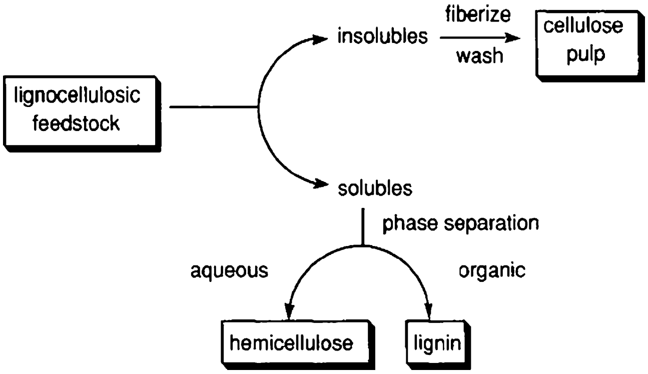

Fig. 33.25 The NREL clean fractionation process

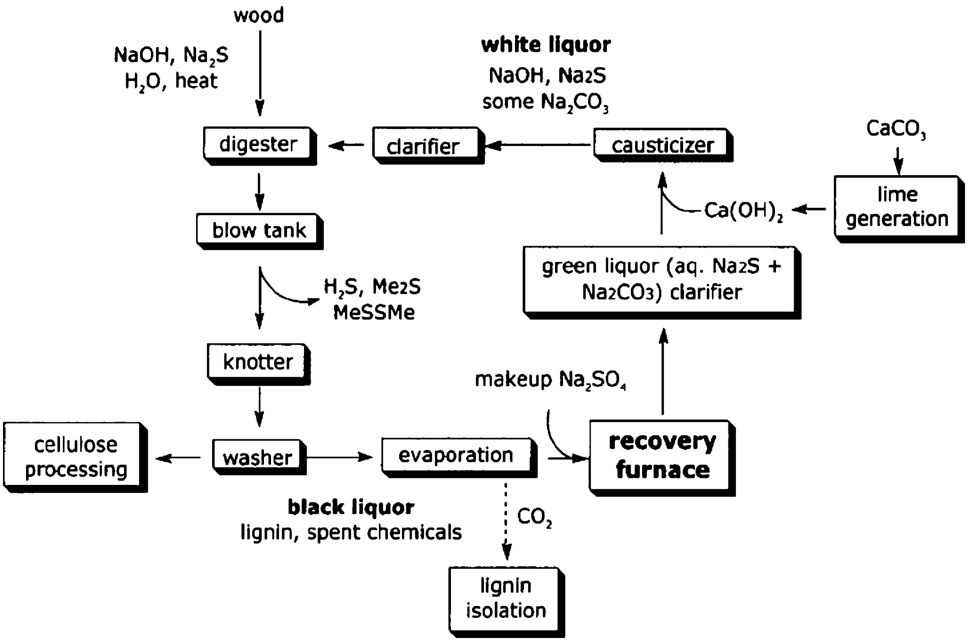

Fig. 33.26 Overview of the kraft process

Steam Explosion and Related Processes

The steam explosion process is a rapid and decades-old treatment process for lignocellulose that releases individual biomass components through steam impregnation under pressure, followed by a rapid pressure release. Steam explosion is carried out using high-pressure steam and short contact times [406–409]. This process has generally been used as a method for preparing cellulose pulp but can also serve as source of lignin. Alkaline extraction after explosion recovers more than 90% of the lignin when wood is used as the feedstock [410–414].

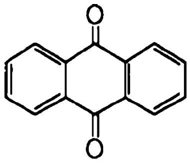
Catalysis of steam explosion processes has been carried out, primarily through the addition of acid [371, 373, 415, 416] or SO_2 to the separation. Added SO_2 has been shown to exhibit benefits in conversion yields and separation conditions [417, 418]. The characteristics of the oligosaccharides and lignin from these processes have been examined [410–414, 419].

The Kraft Process

Kraft pulping is the most widely used process in the world for separating cellulose from wood, but is not normally considered as a potential operating unit for biorefineries. Certainly for new construction, use of the kraft process would face considerable challenges, including the enormous capital cost of a new plant. Nonetheless, the existing infrastructure of the pulp and paper industry consumes more than 100 × 10^6 metric tons/year of wood, the majority of this with kraft technology, offering a possible opportunity for any underused capacity [103].

The process is conducted at the high pH in the presence of sodium sulfide, sodium hydrosulfide, and sodium hydroxide at 150–180°C for about 2 h (Fig. 33.26). Along with the primary cellulose product, the process generates a solution containing dissolved lignin, most of the wood's hemicelluloses, and spent pulping chemicals ("black liquor"). This solution is used in the kraft recovery boiler as a source of power for the mill and fuel for chemical recovery operations crucial to economic operation. The chemistry of pulping reactions has been the subject of much study, and summaries are available the literature [420–422].

The kraft process itself is stoichiometric, however, the process can be improved through the addition of catalytic amounts of anthraquinone (AQ, 1). The use of AQ in alkaline pulping processes has been widely examined by the industry [357, 423, 424].



1

As a catalyst, AQ offers a number of benefits, including an increase in pulping rate, a decrease in the amount of pulping chemicals used, a decrease in degradation of the cellulose during pulping, and improvement of cellulose bleaching processes. In the context of the biorefinery, these improvements lead to faster production and higher yield of a more easily purified cellulose biopolymer. AQ is typically added at levels of 0.05–0.1% based on the weight of raw wood feedstock used. Considerable mechanistic study has been performed to determine how AQ exerts these effects [425, 426].

Deconstruction of Biorefinery Raw Materials and Biopolymers to Monomeric Products

Initial separation of biomass raw materials can yield separate streams of biopolymers, each of which has potential utility as a product within the biorefinery. Further selective deconstruction processes can convert these biopolymers into their individual monomeric units, or to structurally rearranged materials. The following are examples of processes that have been improved through the use of chemical catalysis.

Polymeric Carbohydrate Hydrolysis Processes

The hydrolysis of polysaccharides into monomeric sugars is a well-studied process; its mechanism is still believed to be accurately described by the work of Saeman [427]. Its significance is linked to the production of fermentable sugars for ethanol manufacture. Many of these processes are based on acid catalysis and overlap closely the pretreatment methods described earlier [358, 359, 368]. Treatments with both concentrated and dilute acids are well known as methods for the hydrolysis of cellulose and hemicellulose, as is the use of organic dicarboxylic acids as alternative catalysts to mineral acids [428].

However, further cellulose deconstruction is considerably more difficult after acid hydrolysis. Commercial processes for acid hydrolysis of cellulose were known in the early part of the twentieth century [429]. The use of either low- or high-acid concentrations has disadvantages. At high concentrations, corrosion-resistant reactors and an effective acid recovery process are needed, raising the cost of the intermediate glucose. Dilute acid treatments minimize these problems, but a number of kinetic models indicate that the maximum conversion of cellulose to glucose under these conditions is 65–70% because subsequent degradation reactions of the glucose to HMF and levulinic acid take place. The modern biorefinery is learning to exploit this reaction manifold, because these “decomposition” products can be manufactured as the primary product of polysaccharide hydrolysis (see below).

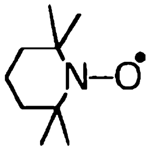
Carbohydrate Pyrolysis

Pyrolysis of C6 mono- and polysaccharides deconstructs the polymer chain forming either levoglucosan or levoglucosenone. In the presence of an acid catalyst (normally H_3PO_4), levoglucosenone is also formed in low yields (Fig. 33.27) [430–435]. The transformations are straightforward, but separation of these potential biorefinery building blocks is complicated by the formation of considerable amounts of tar. Nonetheless, attempts have been made to develop levoglucosan as a commercial product [343].

The formation of levoglucosan and levoglucosenone is found to be strongly dependent on the presence of catalytic amounts of various cations during pyrolysis. However, the literature is inconsistent regarding the effect of these cations. By varying the amount of acid catalyst used, Faix and coworkers were able to control the relative amount of the two products [436, 437]. Transition metal catalysts were also found to influence the course of the pyrolysis. Addition of Fe or Cu increased the yield of levoglucosan formation from wood or newsprint [438]. The presence of Ca ions also increased the yield of these products, whereas catalytic amounts of Na ions were found to decrease the pyrolysis yields [439]. In contrast, earlier work indicated that Li, K, and Ca ions all had a negative effect on the pyrolysis process [440].

Carbohydrate Oxidation

A considerable amount of recent work has focused on the oxidation of polymeric and monomeric carbohydrates in aqueous media. In the context of the biorefinery, these processes could be used for the preparation of oxidized carbohydrates as primary outputs of biomass deconstruction. Of particular interest are processes catalyzed with stable oxygencentered radicals such as the nitroxyl radical TEMPO (2) (2,2,6,6-tetramethylpiperidinoxyl) and using bleach as the stoichiometric oxidant.



TEMPO, **2**

The reaction appears to be well suited for selective conversion of biomass carbohydrates into their corresponding oxidized derivatives. This system serves to oxidize several polymeric carbohydrates including starches and pullulan [441–444]. More recent work has described the TEMPO-catalyzed introduction of carboxyl groups in native cellulose and its different morphological forms [445–447], cellulose derivatives [448], and the surface of cellulose nanocrystals [449]. The related biopolymer, chitin, also is oxidized under these conditions [450].

Under proper conditions, biomass deconstruction will generate streams of monomeric or oligomeric carbohydrates, with glucose and xylose (from cellulose/starch or hemicellulose, respectively) being the most likely initial feedstocks. Glucose oxidation in the presence of TEMPO and bleach has been used for the production of glucaric acids (see below) by selective, high-yield oxidation of the initial and terminal carbons of the starting sugar [451–454].

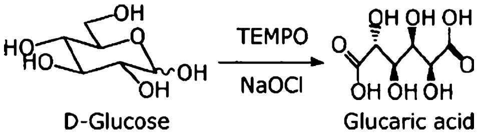


Fig. 33.27 Production of levoglucosan and levoglucosenone

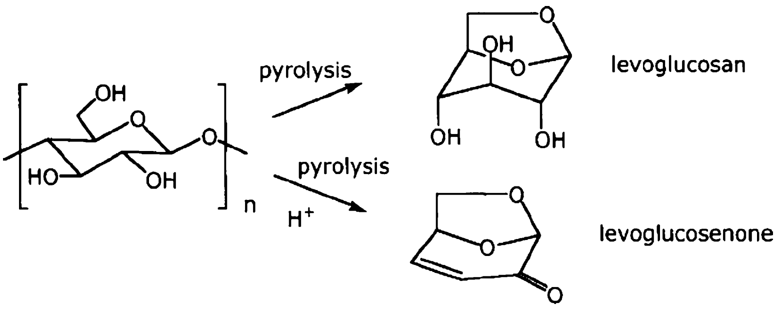


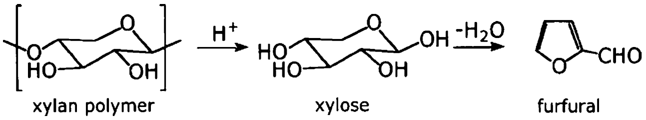
These materials can serve as novel polymer components in the production of new polyhydroxylated polyamides [455] and as starting points for the production of other biorefinery intermediates. Conventional processes for the conversion of sugars to aldaric acids use HNO_3 as the oxidizing agent. However, yields of aldaric acids using these processes are only fair, and the use of HNO_3 as the oxidant is potentially hazardous and environmentally unfriendly (NO_x emissions). Development of single-step biorefinery processes could make aldaric acids a useful primary building block of the biorefinery.

Other carbohydrates can also undergo selective, high-yield oxidation. For example, sucrose (the primary product of the sugar industry) converts into the corresponding tricarboxylic acid [456].

Carbohydrate Dehydration

The removal of water from initially formed biomass sugars is an important process for the production of primary biorefinery building blocks. Of particular interest are 5-HMF and levulinic acid (from the dehydration of glucose or other C6 sugars) and furfural (from xylose dehydration). Recent research has led to new catalytic processes for the production of each of these materials.

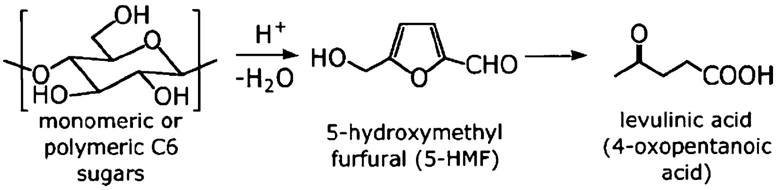
Furfural. Dehydration of xylose, available from biorefinery hemicellulose, leads to the production of furfural [457–459].



Although the process for furfural production has been known for decades and is applicable to most any C5-sugar-containing feedstock [460–463], it is not highly efficient, with commercial yields generally around 50% [464]. Current research is directed at improving the production of furfural from xylose or hemicellulose with new catalytic transformations. Improvement of process conditions for the standard H_2SO_4-catalyzed furfural production from the xylose in corn cobs was realized by use of HCl, leading to an 85% furfural yield [465]. A related process charges dry feedstock with catalytic gaseous HCl, minimizing decomposition reactions through a more rapid removal of furfural from the reactor [466].

The need to recover homogeneous acid catalysts in the production of furfural has spurred the investigation of acidic heterogeneous catalysts to promote the dehydration of C5 sugars. A relatively high conversion of xylose to furfural was reported using heterogeneous sulfonated mesoporous silicas [467]. Rapid removal of furfural from the reaction mixture using supercritical CO_2 has been examined as a method to improve furfural yields [468, 469]. Combining supercritical CO_2 extraction with xylose dehydration in the presence of sulfated titania and zirconia catalysts, led to high furfural yields at high xylose conversions [470]. Faujasite and mordenite catalysts have been examined as acid catalysts [471]. The presence of metal oxides has also been reported to improve furfural yield [461].

Levulinic acid. Dehydration of glucose or other monomeric and polymeric C6 sugars leads to the direct formation of levulinic acid (LA) as a potential primary building block for the biorefinery, and several reviews have described its potential commercial utility [472, 473]. The preparation of levulinic acid is not difficult, although the mechanism of its formation from carbohydrates is complex, and offers several alternative decomposition pathways (33.3) [474].



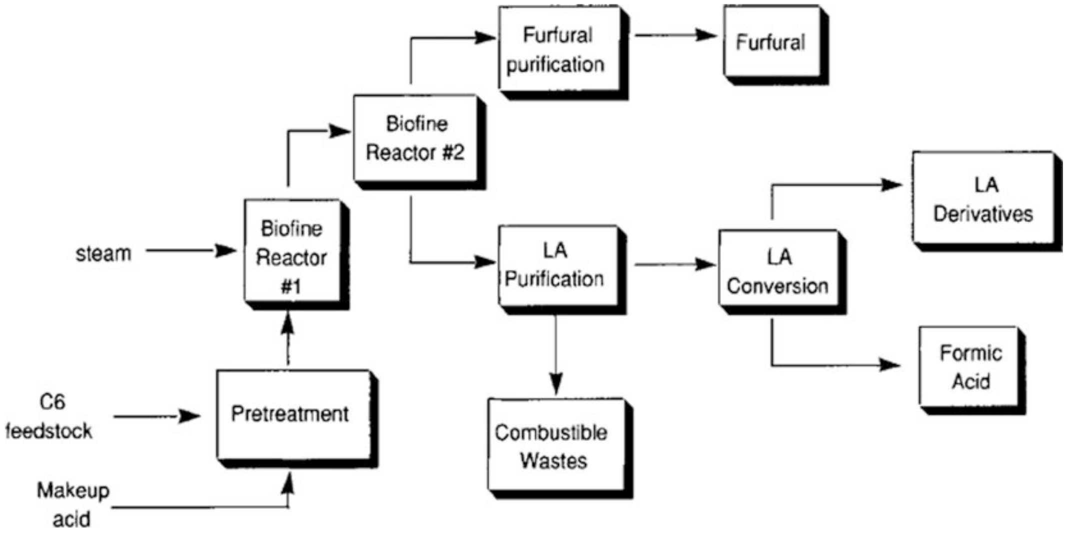


Fig. 33.28 The biofine process

Dehydration of glucose in the presence of microporous pillared clays has also been explored but, the selectivity to levulinic acid was low [475].

The most widely used approach for producing levulinic acid is the direct hydrolysis of biomass or carbohydrates, catalyzed by aqueous acid [473, 475–478]. However, this forms large amounts of side products and intractable materials, requiring an expensive separation that drives up its cost. Several years ago, a new process developed by the Biofine Corporation eliminated many of the existing production problems. The Biofine process also uses acid hydrolysis of carbohydrate sources (cellulose, starch, paper mill sludge, urban waste paper, agricultural residues, or paper fines) to produce LA, but in a novel, two-reactor system that minimizes sideproduct formation and associated separation problems (Fig. 33.28) [479, 480].

The process supplies carbohydrate-containing materials to a first reactor where they are briefly hydrolyzed at 210–230°C in the presence of mineral acid. This initial hydrolysis produces hydroxymethylfurfural, which is removed continuously and supplied to a second reactor. In the second reactor, the hydroxymethylfurfural is hydrolyzed further at 195–215°C for 15–30 min to produce levulinic acid, which is again continuously removed. The yield of LA is 75% or greater, based on the C6 content of the carbohydrate containing starting material, one of the highest reported. Two real strengths of this process are its relative insensitivity to the type of feedstock employed and the wide availability of feedstock sources. Any material containing C6 sugars will serve as a good starting material. The result is a cost-effective process, making it suitable as a starting material for a wide variety of products. Economic projections indicate that the LA production cost using this process could be as low as $0.08–$0.12/lb depending on the scale of the operation. This cost is consistent with the use of levulinic acid as a primary biorefinery building block.

5-HMF. Dehydration of C6 sugars also produces 5-HMF (shown above), which is an intermediate within the dehydration mechanism leading to levulinic acid. 5-HMF has been suggested as a potential primary building block for the biorefinery [481–483], but its relatively high instability and associated difficulties in its isolation have hindered its development.

Polymeric carbohydrates available from the biorefinery can serve as starting materials for 5-HMF. Recently, $LaCl_3$ has been used to catalyze the conversion of cellulose to 5-HMF (along with glucose, levulinic acid, and cellobiose) at elevated temperatures in water [484].

A primary reason for low yields of 5-HMF is its rapid conversion to levulinic acid in aqueous media. However, catalysis of the transformation with lanthanides has led to dramatic increases in the yield of 5-HMF. The effectiveness of different lanthanide cations has been surveyed [485, 486]. In nonaqueous solvents, such as DMSO, almost quantitative yields of 5-HMF have been reported [487]. Performing the dehydration in the presence of activated carbon (to adsorb the generated 5-HMF) has also been reported as effective [488].

Recent work has investigated the selective catalytic dehydration of fructose (available from corn starch) and related sugars such as glucose, sucrose, and inulin as a source of 5-HMF. Standard preparation of 5-HMF is carried out using aqueous acid catalysts [489–491]. The process can be improved by dehydrating the fructose with an Amberlyst catalyst in an ionic liquid as the reaction medium. Other solid acid catalysts have been reported [492–494]. Sub- and supercritical acetone has also been used as an alternative medium to improve 5-HMF production [495]. 5-HMF yields of 80% were reported under these conditions in comparison to control reaction yields of only 50% [496]. A number of heterogeneous catalysts have been used to promote this transformation [478]. The use of vanadyl phosphate doped with trivalent metal cations has been reported as effective for the production of 5-HMF in high yield without the formation of polymeric byproducts [497]. Niobium phosphate catalysts have also been investigated [498, 499], as well as acidic mordenites [500]. A mechanism for the catalytic reaction over zeolites has also been suggested [501].

Lignin Deconstruction

Deconstruction of lignin has been carried out for over a century, but in a largely nonselective manner. There is no doubt that lignin is widely available. It contributes as much as 30% to the weight of lignocellulosic biomass, making it second only to cellulose as a source of renewable carbon. Because lignocellulosic will be a major raw material source available to the biorefinery, isolation of sugars for use in one operating unit of the biorefinery guarantees a parallel lignin process stream. Moreover, the separation processes described earlier will provide separate carbohydrate and lignin components. Lignin's native structure (a complex network of oxygenated aromatic rings) certainly suggests that it could play a central role as a new chemical feedstock. But today's reality is that lignin is routinely relegated to very low value uses when considered as a biorefinery process stream. In the pulp and paper industry, the bulk of the removed lignin is used as a boiler fuel for chemical recovery. In other parts of the process, elegant bleaching sequences have been developed for the sole purpose of nonselectively converting residual lignin remaining with the cellulose into small, low-molecular-weight materials that are easily washed out [502]. Catalysis is playing a role in these processes [503–513]. Nonetheless, more selective catalytic lignin conversion processes continue to be examined [514].

General lignin oxidation processes. A vast amount of work has been done on lignin oxidation, primarily to understand and develop new pulp bleaching processes. More recently, the use of catalytic processes has been examined. If made selective, these types of processes could yield a broader family of lignin-derived primary building blocks. Because of the complexity of lignin's structure, much of the actual research has been carried out using lignin models. The oxidation of lignin models with HOOH in the presence of Co catalysts has been studied [515, 516].

Several more selective oxidation processes have been examined for the conversion of lignin to biorefinery building blocks. Oxidation of lignin residue from dilute acid pretreatment leads to a stream of mixed aromatic aldehydes [517]. Cu-catalyzed lignin oxidation with oxygen leads to the production of monomeric phenols [518]. Improved separation technology can allow effective use of these mixed streams within the biorefinery [519, 520]. Modeling has shown lignin conversion into quinones using cobalt and heteropolyacid catalysts [521–523]. and aromatic aldehydes with catalytic NO_2 in the presence of oxygen [524].

Phenol hydrogenation. In principle, appropriate lignin deconstruction processes will provide a stream of mixed phenols. Reduction of these phenols will leads to a new source of cyclic aliphatic alcohols of potential use in the manufacture of adipic acid derivatives. Several catalytic processes for these types of reductions have appeared for phenol and should be applicable to lignin-derived mixed phenols. Phenol itself is reduced to cyclohexanol in the presence of various heterogeneous catalysts based on Pd [525–530].

Vanillin. Catalytic oxidation of lignin has long been used as a source of vanillin. For the most part, yields in these processes tend to be very low, generally less than 10%. However, vanillin production can be used to provide a low-volume, high-value revenue stream within certain lignin-generating operations [531, 532]. The mechanism of the transformation has been reported [533–537].

Conclusions

Deconstruction of biomass raw materials offers the biorefinery access to a large number of both polymeric and monomeric primary building blocks. Biomass offers significant flexibility as to the product slate that various separation processes may realize. These materials, which are the biorefinery analogues to ethylene, propylene, BTX, and other building block chemicals of the petrochemical refinery, will serve as the platforms from which much larger families of products can be produced. Importantly, these processes also offer access to a wide range of new structures that can complement those currently available from the petrochemical industry. The challenge in using these materials will be development of appropriate technology tailored to accommodate these structures and facilitate their conversion into biorefinery intermediates and final products.

Thermochemical Biomass Conversion

Introduction

Biomass combustion has been a source of heat and light for thousands of years and is one of the oldest examples of thermochemical biomass conversion. More recently, biomass thermochemical conversion processes and technologies are receiving renewed attention as concerns about the sustainability of energy resources increase and mounting evidence of global climate change brought about

by fossil fuel consumption continues to be revealed. Advances in crop production and harvesting, collection, and use of biomass from thinning operations for improved forest health, and utilization of biomass residues can provide lower-cost biomass feedstocks. Integrating lower-cost feedstocks with advances in higher-efficiency biomass thermochemical conversion processes for the production of fuels, chemicals, and combined heat and power, provides a number of realizable social, economic, energy, and infrastructure security benefits for the future [11, 538, 539].

As defined above, biomass materials can be quite varied with a wide range of physical, fuel, and chemical properties. This variability in the inherent properties of biomass resources determines conversion technology options that are appropriate for specific applications.

Thermochemical conversion applications are generally fuel-flexible when it comes to variations in biomass composition. The main biomass fuel properties that affect the long-term technical and economic success of a thermochemical conversion process are moisture content, fixed carbon and volatiles content, impurity (S, N, Cl) concentrations, and ash content. Collectively, these properties affect the energy density of biomass fuels. The higher heating value of biomass on a dry and ash-free basis is typically around 8,000–9,000 Btu/lb (18.5–20 MJ/kg). High moisture and ash contents reduce the usable energy of biomass fuels proportionally. Therefore, from an energy perspective, maximum system efficiencies are possible with dry, low-ash biomass fuels. However, drying biomass can be costly and low-ash biomass resources are generally considered premium fuels that tend to be more expensive.

The bulk density of biomass feedstocks is also quite low compared to traditional fossil fuels. Lower bulk densities and lower energy densities translate into higher costs for feedstock preparation, handling, and transportation, putting biomass conversion technologies at an economic disadvantage in current energy markets. Consequently, biomass utilization is most advantageous when the feedstock is either a high-volume waste product of an existing system or is readily available in close proximity to the conversion plant. Examples of this can be found in the pulp and paper and wood products industries. In fact, the pulp and paper industry is the largest generator and consumer of biomass energy in the form of process heat and electricity produced from black liquor recovery boilers and bark/hog fuel boilers. Agricultural practices for grain production also provide the potential to use localized residues such as straws and stover in biomass thermochemical processes. In the future, dedicated energy crops such as switch-grass, poplar, and willow could potentially provide a renewable sustainable source of fuel for thermochemical conversion processes.

Important biomass fuel properties for thermochemical conversion processes are reported as proximate and ultimate analyses. The proximate and ultimate analyses for selected biomass feedstocks are presented in Table 33.5. For comparison, the analyses from two selected coal samples are also presented. Biomass generally has a lower energy density than coal, oils, and natural gas; it also has higher oxygen content. The higher volatiles and oxygen content of biomass translate into a higher reactivity compared to traditional fossil fuels. In terms of thermochemical conversions, this means that less severe process conditions (lower temperature and shorter residence time) are required for biomass-fueled systems. The chemical composition of biomass ash and the concentration of S, N, and Cl in the biomass can have detrimental impacts on long-term system operability and environmental performance.

Biomass can be used in thermochemical processes to produce heat and electricity, as with other renewable energy technologies. However, biomass resources are uniquely

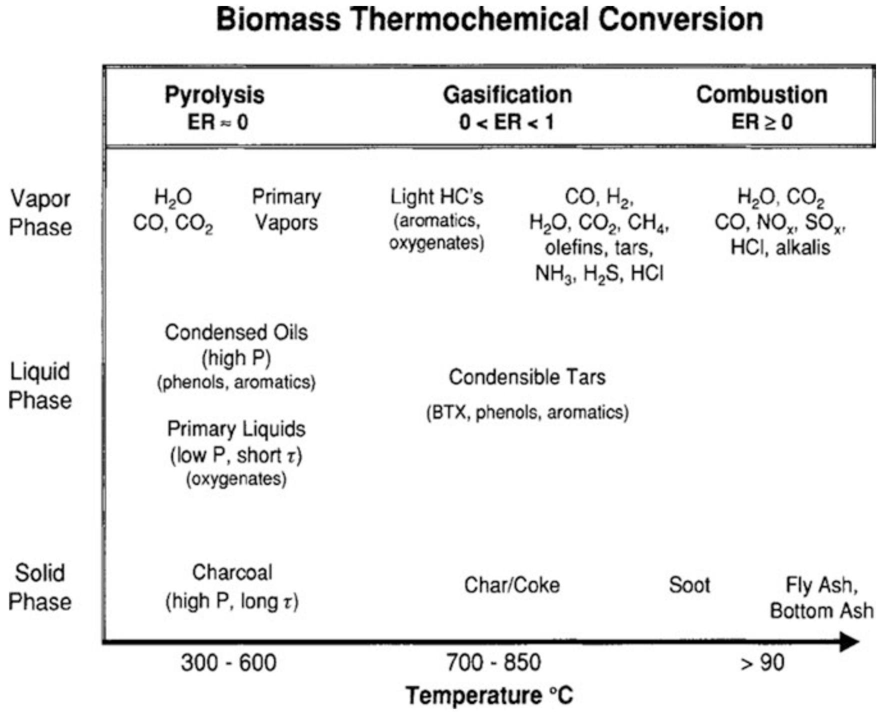

Fig. 33.29 General product composition as a function of process severity for biomass thermochemical processes

suited for conversion into liquid transportation fuels, chemicals, and materials. Thermochemical conversion of biomass into heat and power, transportation fuels, and chemical feedstocks is achieved by using one of three processes: pyrolysis, gasification, or combustion. All of these processes effectively use thermal energy to dehydrate, devolatilize, depolymerize, and oxidize, partially or completely, lignocellulosic materials to varying degrees. These thermochemical conversion processes are arranged in Fig. 33.29 in terms of process severity that can be considered a function of temperature and residence time. Increased temperature also correlates with increasing oxidation, especially for autothermal processes. Pressure does not necessarily affect process severity but can affect the product composition of thermochemical conversion.

Biomass pyrolysis is the thermal depolymerization of biomass at modest temperatures in the absence of added oxygen. The slate of products from biomass pyrolysis depends on the process temperature, pressure, and residence time of the liberated pyrolysis vapors [540–543]. Charcoal yields of up to 35% [544] can be achieved for slow pyrolysis at low temperature, high pressure, and long residence time. Flash pyrolysis is used to optimize the liquid products in an oil known as bio-crude or bio-oil [542]. High heating rates and short residence times enable rapid biomass pyrolysis while minimizing vapor cracking to optimize liquid product yields with up to 80% efficiency. Hydrothermal upgrading is a related process that produces a bio-oil product that converts wet biomass at high pressures into oxygenated hydrocarbons. Biomass liquefaction converts wet biomass feedstocks into liquid hydrocarbons at low temperatures in a high-pressure hydrogen environment.

Biomass gasification consists of several elementary steps that occur during the partial oxidation of biomass by a gasifying agent, generally air, oxygen, or steam. Initial heating of the biomass leads to evaporation of water. A further increase in temperature initiates biomass pyrolysis followed by the partial oxidation of pyrolysis vapors. The char remaining after a biomass particle is devolatilized is also gasified. The biomass gasification product gas is a low- to medium-energy content gas (depending on the gasifying agent), known as synthesis gas or syngas, that consists mainly of CO, H_2, CO_2, H_2O, N_2, CH_4, and other hydrocarbons. Minor components of the product gas include tars, sulfur and nitrogen oxides, alkali metals, and particulates. These minor components of the product gas potentially threaten the successful application of downstream syngas utilization processes. Gas composition and quality are dependent on a wide range of factors including feedstock composition, type of gasification reactor, gasification agents, stoichiometry, temperature, pressure, and the presence or lack of catalysts.

Biomass combustion systems range from very small-scale home heating applications (wood and pellet stoves) to small-scale commercial heating applications (furnaces and boilers) to modest-size biomass power plants (20–50 MW_e) to large-scale recovery boilers (400 MW_{th}) used in the pulp and paper industry. Direct biomass combustion systems can be used to generate process heat and electricity through traditional Rankine steam cycles at relatively

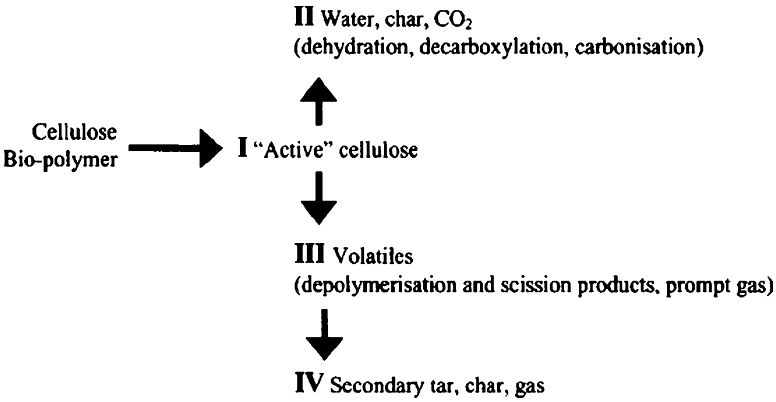

Fig. 33.30 Broido and Shafizadeh model for pyrolysis of cellulose

low (17–25%) thermal conversion efficiencies. Biomass can also be co-combusted with coal to take advantage of the high efficiency of large-scale pulverized-coal-fired power plants. Biomass combustion processes are generally feasible only if feed-stocks contain less than ~50% moisture.

Each of these thermochemical conversion processes has unique technical barriers and challenges that have been overcome with varying degrees of technical and economic success. The applications of these thermochemical conversion technologies are also in various stages of commercial application. For example, biomass combustion and biomass pyrolysis for production of a specific food additive are commercially practiced. Other technologies such as biomass gasification and use in integrated combined cycles for power production are in the demonstration stage. The technical details and challenges facing present and future application of these thermochemical biomass conversion processes are discussed in the following sections.

Pyrolysis

Pyrolysis as defined is a process of thermal decomposition occurring in the absence of oxygen. Pyrolysis of biomass is a complicated multistage reaction for which many pathways and mechanisms have been proposed [545–552]. The best known is the model developed by Broido and Shafizadeh [553, 554] for pyrolysis of cellulose that can be also applied, at least qualitatively, to whole biomass (Fig. 33.30).

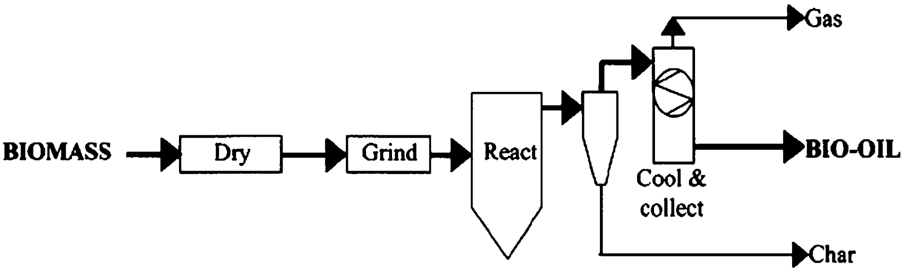
As shown in this model, pyrolysis of cellulose always results in solid, liquid, and gaseous products. However, the proportions of the product yields can change depending on the process conditions. The knowledge of thermodynamics and kinetics of the reaction pathways allows us to adjust the conditions to maximize the yield of desired products. Dehydration of cellulose is exothermic, whereas depolymerization and secondary vapor cracking are endothermic and have higher activation energy than dehydration. Therefore, lower process temperature and longer vapor residence times will favor the production of charcoal. High temperature and longer residence time will increase the biomass conversion to gas, and moderate temperature and short vapor residence time, necessary to minimize secondary cracking, are optimum for producing liquids. Table 33.6 provides data on the product distribution obtained by different modes of pyrolysis process.

Table 33.6 Modes of pyrolysis and typical products of wood pyrolysis

	Liquid (%)	Char (%)	Gas (%)
Fast pyrolysis Moderate temperature and short residence time, particularly vapor	75	12	13
Carbonization Low temperature and long residence time	30	35	35
Gasification High temperature and long residence times	5	10	85

Pyrolysis is always the first step in biomass thermochemical processes in which it is followed by total or partial oxidation of the primary products. Pyrolysis of biomass has been practiced for many thousand years to produce charcoal. In 1996, the world annual charcoal production was estimated at 100 million tons [544, 555]. Charcoal is a very important fuel in developing countries and is still a highly desired reductant in the metallurgical industry because of its low sulfur and mercury content. Large amounts of charcoal are also used to produce activated carbons extensively used for cleaning water and air. Charcoal is produced by a slow pyrolysis process occurring at temperature 350–450°C with low biomass heating rates (1–10°C/min). In most processes, part of the raw material is oxidized, using a limited air access, to provide heat for the process. Although charcoal formation reactions are slightly exothermic, heat is needed for drying biomass, which always contains moisture. Existing charcoal plants range from earth mound kilns to retorts operating in batch mode (cycles from 20 days to 24 h)

Fig. 33.31 Model for bio-oil production from biomass



to continuous shaft reactors having throughput up to 30 t/day. Depending on the production method, the yields of charcoal can vary from 10 to 35% based on dry wood. In the more developed processes (Degussa, Lambiotte, Lurgi) byproducts such as acetic acid, methanol, and other chemicals are also recovered. The technologies for producing charcoal have been reviewed in many textbooks [556] and a comprehensive review of the fundamentals of slow pyrolysis processes was recently published [544].

Fast Pyrolysis

Fast pyrolysis is one of the most recent renewable energy processes developed to maximize the production of the liquid product, bio-oil. It has achieved commercial status for production of chemicals and is very close to commercialization for the production of liquid fuels. Although related to the traditional slow pyrolysis processes for making charcoal, fast pyrolysis is carried out at a higher temperature (450–550°C) and with much higher biomass heating rates (100–1,000°C/s). As a result, biomass decomposes to generate mostly vapors, gases, and aerosols, and less charcoal. After cooling and condensation of the volatiles, a dark brown liquid is formed that has a heating value about half that of conventional fuel oil.

The essential features of a fast pyrolysis process are:

- Very high heating and heat transfer rates, usually requiring a finely ground biomass feed
- Carefully controlled pyrolysis reaction temperature of around 500°C in the vapor phase, with short vapor residence times of typically less than 2 s
- Rapid cooling of the pyrolysis vapors to give the bio-oil product

The main product, bio-oil, is obtained in yields of up to 75% wt on dry feed basis, together with byproduct char and gas, which are used within the process, so there are no waste streams. Several reviews on fast pyrolysis have been published in recent years that cover, the production, utilization, storage, and upgrading of biomass pyrolysis oils [540, 541, 543, 557–564].

A wide range of reactors such as bubbling and circulating fluidized beds, ablative, entrainment, rotating cone, auger, and vacuum have been operated. Fluidized beds were the most often used because of their ease of operation and ready scaleup. A typical bubbling fluidized-bed configuration presented in Fig. 33.31 uses the byproduct gas and char to provide the process heat. It also includes the necessary steps of drying the feed to less than 10% water to minimize the water in the product liquid oil, and grinding the feed to around 2 mm to supply sufficiently small particles to ensure rapid reaction.

Table 33.7 Typical properties of wood derived bio-oil

Physical property	Typical value
Moisture content	15–30%
pH	2.5
Specific gravity	1.20
Elemental analysis	
C	56.4%
H	6.2%
O	37.3%
N	0.1%
Ash	0.1%
HHV as produced (depends on moisture)	16–19 MJ/kg
Viscosity (at 40 °C and 25% water)	40–100 cp
Solids (char)	1%
Vacuum distillation residue	Up to 50%

Bio-oil from rapid pyrolysis is usually a dark brown, free-flowing liquid having a distinctive smoky odor. It has significantly different physical and chemical properties compared to the liquid from slow pyrolysis processes, which is more like a tar. Bio-oils are multicomponent mixtures comprised of different size molecules derived primarily from depolymerization and fragmentation reactions of the three key biomass building blocks: cellulose, hemicellulose, and lignin. Therefore, the elemental composition of bio-oil resembles that of biomass rather than that of petroleum oils. Basic properties of bio-oils are shown in Table 33.7. More detail on fuel-related characteristics is provided in the literature [565].

The single most abundant bio-oil component is water. The other major groups of compounds identified are hydroxyaldehydes, hydroxyketones, sugars, carboxylic acids, and phenolics. Most of the phenolic compounds are present as oligomers having a molecular weight ranging from 900 to 2,500. The presence of oxygen in many bio-oil components is the primary reason for differences in properties and behavior from those of fossil hydrocarbon fuels. Because of its high oxygen, bio-oil has an energy density (heating value) that is less than 50% of that for conventional fuel oils and it is also immiscible with hydrocarbon fuels. An even more important consequence of the organic oxygen in bio-oil is its limited stability.

Liquid bio-oil can be easily transported and stored. Czernik and Bridgwater reviewed the research on use of bio-oils for heat and power generation, showing that it is possible and usually only requires minor modifications of existing equipment [544]. Bio-oil has been successfully used as boiler fuel and also showed promise for diesel engines and gas turbines [543, 559, 565–578]. Upgrading bio-oil to a quality for liquid transportation fuels still poses several technical challenges and is not currently economically attractive [543, 558, 577, 579–582].

Slow Pyrolysis

For many centuries, wood slow-pyrolysis liquids were a major source of chemicals such as methanol, acetic acid, turpentine, and tars. At present, most of these compounds can be produced at a lower cost from other feedstocks derived from natural gas, crude oil, or coal. Though more than 300 compounds have been identified in wood fast pyrolysis oil, their amounts are small. Isolation of specific single compounds is seldom practical or economical, because it usually requires complex separation techniques. Some chemicals produced from the whole bio-oil or by its fractionation are already commercial products. Liquid smoke food flavoring is one example. A few others such as pyrolytic lignin as phenol replacement in resins and bio-oil-based slow-release fertilizer have a chance for short-term commercialization, especially in the context of a biorefinery based on a fast pyrolysis process. Commercialization of specialty chemicals such as glycolaldehyde or levoglucosan [583] from bio-oil requires more work to develop reliable low-cost separation procedures.

Gasification

Biomass gasification can effectively convert a very heterogeneous material into a consistent gaseous fuel intermediate for heating, industrial process applications, electricity generation, and liquid fuels production. Biomass gasification is a complex thermochemical process that consists of a number of elementary chemical reactions, beginning with the thermal decomposition of a lignocellulosic fuel followed by partial oxidation of the fuel with a gasifying agent, usually air, oxygen, or steam [584]. Volatile matter released as the biomass fuel is heated partially oxidizes to yield the combustion products H_2O and CO_2, plus heat to continue the endothermic gasification process. Water vaporizes and biomass pyrolysis continues as the fuel is heated. Thermal decomposition and partial oxidation of the pyrolysis vapors occur at higher temperatures, and yield a product gas composed of CO, CO_2, H_2O, H_2, CH_4, other gaseous hydrocarbons (including oxygenated hydrocarbons from some processes), tars, char, volatile inorganic constituents, and ash. A generalized reaction describing biomass gasification is as follows.

$$\begin{aligned}&\text{biomass} + O_2(\text{or } H_2O) \rightarrow CO, CO_2, H_2O, H_2, CH_4\\&\quad + \text{other hydrocarbons} \rightarrow \text{tar} + \text{char} + \text{ash}\\&\quad \rightarrow HCN + NH_3 + HCl + H_2S\\&\qquad + \text{other sulfur gases}\end{aligned} \tag{33.1}$$

The actual amount of CO, CO_2, H_2O, H_2, tars, and hydrocarbons depends on the partial oxidation of the volatile products, as shown in (33.2).

$$\begin{aligned}&C_nH_m + (n/2 + m/4)O_2\\&\quad \rightarrow nCO + (m/2)H_2O\end{aligned} \tag{33.2}$$

The char yield in a gasification process can be optimized to maximize carbon conversion or the char can be combusted to provide heat for the process. Char is partially oxidized or gasified according to the following reactions.

$$C + \frac{1}{2}O_2 \rightarrow CO \tag{33.3}$$

$$C + H_2O \rightarrow CO + H_2 \tag{33.4}$$

$$C + CO_2 \rightarrow 2CO\ (\text{Boudouard reaction}) \tag{33.5}$$

The gasification product gas composition, particularly the H_2/CO ratio, can be further adjusted by reforming and shift chemistry. Additional hydrogen is formed when CO reacts with excess water vapor according to the water–gas shift reaction.

$$CO + H_2O \leftrightarrow CO_2 + H_2 \tag{33.6}$$

Reforming the light hydrocarbons and tars formed during biomass gasification also produces hydrogen. Steam reforming and so-called dry or CO_2 reforming occur according to the following reactions and are usually promoted by the use of catalysts.

$$C_nH_m + nH_2O \rightarrow nCO + (n + m/2)H_2 \tag{33.7}$$

$$C_nH_m + nCO_2 \rightarrow (2n)CO + (m/2)H_2. \tag{33.8}$$

The actual biomass gasification product gas composition depends heavily on the gasification process, the gasifying agent, and the feedstock composition [585, 586].

Gasifier Reactor Designs

Four primary types of biomass gasification systems have been developed. These include fixed-bed reactors, bubbling fluidized-bed reactors, circulating fluidized-bed reactors, and entrained-flow reactors. Fixed-bed gasifiers can be classified primarily as updraft and downdraft [587]. Updraft gasifiers represent the oldest and simplest gasifiers. The updraft gasifier is a counterflow system where fuel is introduced into the top of the gasifier and flows downward and the gasifying medium is introduced below the grate and flows upwards through the reactor. Feed particle size needs to be controlled to maintain a uniform bed.

Char burns in the combustion zone at the bottom of the reactor, forming CO_2 and steam, which flow upward through the bed. Residual ash is removed from the bottom of the reactor at the grate. Operational problems can be avoided for feeds with low-melting-point ash by carefully controlling the temperature in the combustion zone or with fuel blending or additives to alter the ash chemistry on the grate.

The exothermic combustion reactions supply the energy to drive gasification, pyrolysis, and drying. Above the combustion zone is the reduction zone where CO_2 and H_2O are partially reduced to CO and H_2 according to reactions (33.4) and (33.5). The next area of the reactor is the pyrolysis zone where these gases are hot enough to devolatilize the biomass to produce pyrolysis products and residual char. At the top of the reactor the product gases and pyrolytic vapors dry the wet biomass. Product gases exit the gasifier at temperatures (typically 80–100°C) higher than the dew point of the product gas. A wide range of condensable tars and oils is produced in the pyrolysis zone. These can condense in transfer lines at the output of the gasifier. For this reason, updraft gasifiers are usually operated in a close-coupled mode to a furnace or boiler to produce steam or hot water.

In downdraft gasification, the gasifying medium and biomass fuel both flow in the same direction as the solid bed. This design tends to minimize tar and oil production. The fuel and pyrolytic gases and vapors move co-currently downward through the bed. The pyrolysis products pass through hot char (about 15% of the original feed) into a combustion zone where they mix with air and are thermally cracked and partially oxidized. The oxidizer concentration diminishes downstream of the combustion zone forming a reduction zone. The remaining hot char in the reduction zone reduces some of the combustion products, CO_2 and H_2O, to CO and H_2. The product gas exits the gasifier at fairly high temperature, around 700°C. Downdraft gasification systems typically have low overall thermal efficiency because of heat losses from the product gases, however, tar conversion is high, greater than 99%, and is a function of temperature, combustion efficiency, and channeling.

Downdraft and updraft gasifiers have the same general constraints on feed properties. The feed needs to have a fairly uniform particle size with few fines to maintain bed physical properties and minimize channeling. A low-ash feed with a high fusion temperature is also preferred to prevent slagging. Feed moisture content also needs to be less than about 20% to maintain the high temperatures required for tar cracking. A variation on the downdraft gasifier is the crossflow gasifier in which air is introduced tangentially at the bottom of the reactor. The principle of operation of the crossflow gasifier is the same as the downdraft gasifier.

Alternative gasifier designs are based on more complex reactor systems to maximize heat transfer and gas–solid interactions by introducing biomass into a moving bed of high-temperature solids [588]. In a gas–solid fluidized bed, a stream of gas passes upwards through a bed of selected free-flowing granular materials such as silica, olivine, limestone, dolomite, or alumina. A gas distribution manifold or series of sparge tubes [589–591] is used to maintain gas velocities high enough to freely circulate the widely separated solid particles so that the bed resembles a boiling liquid and has the physical properties of a fluid.

Above the bed in a fluidized-bed gasifier, the cross-sectional area of the reactor is increased to produce a disengaging zone where the superficial gas velocity is below fluidization velocity [592]. This allows the entrained sand particles to fall back down and maintain the bed inventory over time. This larger cross-sectional area zone, or freeboard, can be extended to obtain the total desired gas-phase residence time for complete devolatilization. Eroded bed material or fine char and ash particles that escape the reactor can be collected in a cyclone and either returned to the bed or removed from the system.

In a fluidized-bed gasifier, the oxidizer (air, oxygen, or steam) typically doubles as the fluidizing medium. Biomass can be introduced either on top of the bed or through an auger into the bed. In-bed feeding improves the conversion of fine particles that would otherwise be entrained in the fluidizing gas if they were introduced on top of the bed. As biomass is introduced into the bed, the organic pyrolysis vapors are released and partially oxidized in the bed. The exothermic combustion provides the heat to maintain the bed temperature around 800°C and to volatilize additional biomass. Bed temperature is governed by the desire to obtain complete devolatilization (95–99% carbon conversion) vs. the need to maintain the bed temperature below the ash-fusion temperature of the biomass ash.

As the gas flow in a bubbling fluidized bed is increased, a turbulent fluidized bed is formed. The gas bubbles become larger, larger voids are formed in the bed, and more solids are entrained in the exit gas flow. A circulating fluidized-bed system results if these solids are collected, separated from the gas, and returned to the bed through a continuous solids circulation loop. A circulating fluidized bed differs from a bubbling fluidized bed in that there is no distinct separation between the dense solids zone and the dilute solids zone. Circulating fluidized-bed densities are about 560 kg/m^3 compared to a bubbling-bed density of 720 kg/m [593]. To achieve the lower bed density, gas rates are increased from the 1.5–3.7 m^3/s of bubbling beds to about 9.1 m^3/s. The residence time of the solids in a circulating fluidized bed is determined by the solids circulation rate, the solids attrition rate, and the collection efficiency of the solids separation device.

Biomass-Gasification Product Gas

Various gasification technologies have been investigated for converting biomass into a gaseous fuel. The energy content of the gasification product gas ranges from 5 to 15 MJ/Nm^3 and is considered a low-to-medium energy-content gas compared to natural gas (35 MJ/Nm^3) [594, 595]. The relative amount of CO, CO_2, H_2O, H_2, and hydrocarbons depends on the stoichiometry of the gasification process and the selected gasification medium. The air/fuel ratio in a gasification process generally ranges from 0.2 to 0.35 and if steam is the gasifying agent, the steam/biomass ratio is around 1. If air is used as the gasifying agent, then roughly half of the product gas is N_2 [596].

Air-blown, or directly heated gasifiers, use the exothermic reaction between oxygen and organics to provide the heat necessary to devolatilize biomass and to convert residual carbon-rich chars. In these directly heated gasifiers, the heat to drive the process is generated internally within the gasifier. Thus, when air is used, the resulting product gas is diluted with nitrogen and typically has a dry-basis calorific value of about 5–6 MJ/Nm^3. The dry-basis calorific value of the product gas can be increased to 13–14 MJ/Nm^3 by using oxygen instead of air. Oxygen production is expensive, however, and its use has only been proposed for direct-heating gasification applications involving the production of synthesis gas where nitrogen is not permitted in downstream synthesis conversion operations. Oxygen typically costs \$40–\$60 per Mg and typically is used at the rate of 0.25–0.3 Mg/Mg of biomass, a cost equivalent to \$10–\$20 per Mg of biomass [597]. Indirectly heated gasifiers accomplish biomass heating and gasification through heat transfer from a hot solid or a heat transfer surface. Because air is not introduced into the gasifier, little nitrogen diluent is present and a medium calorific gas is produced; dry basis values of 18–20 MJ/Nm^3 are typical.

Gas phase impurities in syngas include NH_3, HCN, other nitrogen-containing gases, H_2S, other sulfur gases, HC1, alkali metals, organic hydrocarbons (tar), and particulates. The concentration of these non-syngas components strongly depends on the feedstock composition. Gasification of biomass containing high nitrogen and sulfur contents yields high levels of NH_3 and H_2S in the syngas stream. HCl concentration in biomass-derived syngas directly correlates with the chlorine content of the feedstock. Alkali metal, mostly potassium, in syngas is related to the alkali content in the biomass ash. Ash particles entrained in syngas affect the alkali metal content in syngas. The concentration of alkali vapors or aerosols in syngas depends on the ash chemistry of the selected biomass feedstock and the temperature of the gasification process.

The organic impurities in syngas range from low-molecular-weight hydrocarbons to high-molecular-weight polynuclear aromatic hydrocarbons. The lower-molecular-weight hydrocarbons can be used as fuel in gas turbines or engines, but are undesirable products in fuel cell applications and methanol synthesis. The higher-molecular-weight hydrocarbons are collectively known as “tar.” Tar yields in biomass-derived syngas can range from 0.1% (downdraft) to 20% (updraft) or greater (pyrolysis) in the product gases.

One issue associated with biomass gasifier tars is how they are defined. More often than not, tar is given an operational definition by those conducting biomass gasification research. An excellent report by Milne et al. [598] describes in detail the operational definitions of biomass gasification tars as published in the literature and provides a comprehensive survey of tar formation and conversion. For the most part, “tars” are considered to be the condensable fraction of the organic gasification products and are largely aromatic hydrocarbons, including benzene. The diversity in the operational definitions of “tars” usually comes from the variable product gas compositions required for a particular end-use application and how the “tars” are collected and analyzed. Tar sampling protocols are being developed [599–601] to help standardize the way tars are collected; however, these methods are not yet widely established.

Syngas Cleanup and Conditioning

Gas conditioning is a general term for removing the unwanted impurities from biomass-gasification product gas and generally involves an integrated, multistep approach that depends on the end use of the product gas [602–605]. For close-coupled gasifier-combustor systems, no gas cleanup is required. For gas-turbine power generation, the gas has to be free of particulates, tars, sulfur, and chlorine compounds, and of alkali metals to ensure the integrity of the turbine hot section [606–609]. Particulate removal to protect the turbine blades from erosion requires filtration technology, and the removal of tars ensures an even and less luminous combustion process (to avoid radiative heat transfer problems at the turbine). Alkali metal removal avoids deposition and corrosion of the turbine blade materials. Potassium and sodium levels must be reduced to less than 1 ppm to ensure long turbine blade and hot-section lifetimes. The tolerance to alkali metals is a function of the temperature of operation of the turbine inlet section. At very high temperatures (greater than 1,350°C) the level has to be less than about 25 ppb. The deposition and corrosion problems can be also addressed with turbine blade coatings, and it is likely that both coating and strengthening of components will be undertaken as well, as biomass power technology develops. For internal combustion use, it is necessary to cool the gas to ensure that a sufficient charge of energy can be put into each cylinder. Particular attention has to be given to both tar and particulate contents, to ensure that valves and cylinders are protected. Fuel-cell applications would require the gas to be mainly hydrogen without any significant sulfur or chloride contamination, to protect the electrodes. For synthesis operations such as methanol and hydrogen production, removal of particulates and contaminants such as H_2S is required to prevent poisoning of downstream catalysts.

Tar removal, conversion, or destruction is seen as one of the greatest technical challenges for the successful development of commercial advanced-gasification technologies [598]. Tars can condense in exit pipes and on particulate filters, leading to blockages and clogged filters. Tars also have varied impacts on other downstream processes. Tars can clog fuel lines and injectors in internal combustion engines. Luminous combustion and erosion from soot formation can occur in pressurized combined-cycle systems where the product gases are burned in a gas turbine. The product gas from an atmospheric-pressure gasification process needs to be compressed before it is burned in a gas turbine and tars can condense in the compressor or in the transfer lines as the product gas cools.

If the end use of the gas requires cooling to near ambient temperatures, it is possible to use wet scrubbing and filtration or other physical removal methods, to remove tars. Wet scrubbing is an effective gas-conditioning process that condenses the tars out of the product gas. This technology is available and can be optimized for tar removal. A disadvantage of wet scrubbing for product gas conditioning is the formation and accumulation of wastewater. This technique does not eliminate tars but merely transfers the problem from the gas phase to the condensed phase. Wastewater minimization and treatment are important considerations when wet scrubbing is used for tar removal. Also, when tar is removed from the product gas stream, its fuel value is lost and the overall efficiency of the integrated gasification process is reduced.

If the end use requires that the product gas remain at high temperature, at or slightly below the gasifier exit temperature, then some method of hot gas cleaning will be needed for tar elimination. Wet scrubbing is still an option, however, there will be a severe thermodynamic penalty from cooling and reheating the conditioned product gas, reducing the overall efficiency of the process. Hot gas conditioning eliminates tars by converting them into desired product gas components, thus retaining their chemical energy in the product gas and avoiding treatment of an additional waste stream. Thermal cracking is a hot gas conditioning option but it requires temperatures higher than typical gasifier exit temperatures (greater than 1,100°C) to achieve high conversion efficiencies. Increased temperatures for thermally cracking tars can come from adding oxygen to the process and consuming some of the product gas to provide additional heat. Thermal destruction of tars may also produce soot that is an unwanted impurity in the product gas stream.

An attractive hot gas conditioning method for tar destruction is catalytic steam reforming [610–615]. This technique offers several advantages: (1) catalyst reactor temperatures can be thermally integrated with the gasifier exit temperature, (2) the composition of the product gas can be catalytically adjusted, and (3) steam can be added to the catalyst reactor to ensure complete reforming of tars. Catalytic tar destruction has been studied for several decades [616–618] and a number of reviews have been written on biomass gasification hot gas cleanup [598, 615, 619]. Numerous catalysts have been tested for tar destruction activity at a broad range of scales. Novel catalyst formulations have been sought to increase the activity and lifetime of tar reforming catalysts. Different approaches for integrating catalytic tar destruction into biomass gasification systems have also been investigated.

Calcined dolomites are the most widely used nonmetallic catalysts for tar conversion in biomass gasification processes [620–625]. They are relatively inexpensive and are considered disposable. However, they are not very robust and quickly undergo attrition in fluidized-bed reactors. Consequently, dolomites find most use in fixed-bed catalytic reactors. Tar conversion efficiency is high when calcined dolomites are operated at high temperatures (900°C) with steam. Olivine, another naturally occurring mineral, has also demonstrated tar conversion activity similar to that of calcined dolomite. Olivine is a much more robust material than calcined dolomite and has been applied as a primary catalyst to reduce the output tar levels from fluidized-bed biomass gasifiers.

Commercial Ni catalysts are designed for use in fixed-bed applications and are not robust enough for fluidized-bed applications, and therefore are not useful as primary in-bed catalysts. These catalysts, however, have been extensively used for biomass-gasification tar conversion as secondary catalysts in separate fixed-bed reactors operated independently to optimize performance [626–628]. They have high tar-destruction activity with the added advantages of completely reforming methane and of promoting water–gas shift activity that allows the H_2:CO ratio of the product gas to be adjusted. Some studies have also shown that nickel catalyzes the reverse ammonia reaction, thus reducing the amount of NH_3 in gasification product gas.

A limitation of nickel catalyst use for hot gas conditioning of biomass gasification product gases is rapid deactivation, limiting catalyst lifetimes. Ni catalyst deactivation is caused by several factors. Sulfur, chlorine, and alkali metals, that may be present in gasification product gases, act as catalyst poisons. Coke formation on the catalyst surface can be substantial when tar levels in product gases are high. Coke can be removed by regenerating the catalyst, however, repeated high-temperature processing of nickel catalysts can lead to sintering, phase transformations, and volatilization of the nickel. Continued disposal of spent toxic Ni catalysts is not economical and poses an environmental hazard.

Using fixed dolomite guard beds to lower the input tar concentration can extend Ni catalyst lifetimes. Adding various promoters and support modifiers has been demonstrated to improve catalyst lifetime by reducing catalyst deactivation by coke formation, sulfur and chlorine poisoning, and sintering. Several novel, Ni-based catalyst formulations have been developed that show excellent tar reforming activity, improved mechanical properties for fluidized-bed applications, and enhanced lifetimes.

Hot gas conditioning using current or future commercially available catalysts offers the best solution for mitigating biomass gasification tars. Tars are eliminated, methane can be reformed if desired, and the H_2:CO ratio can be adjusted in a single step. The best currently available tar reforming process consists of a calcined-dolomite guard bed followed by a fixed-bed Ni-catalyst reforming reactor operating at about 800°C. Selection of the ideal Ni catalyst is somewhat premature. Commercially available steam reforming catalysts have been demonstrated, but several of the novel research catalysts appear to have the potential of longer lifetimes. This dual-bed hot gas-conditioning concept has been demonstrated and can be used to condition the product gas from any developing gasification process. A proprietary Ni-monolith catalyst has also shown considerable promise for biomass gasification tar destruction [614].

Biomass-Derived Syngas Utilization

Biomass gasification is a promising thermochemical conversion technique for producing electricity and liquid fuels for power generation because of the high efficiencies projected for integrated-gasification combined-cycle systems. Solid or gasified biomass can be burned as boiler fuel to generate electricity via the steam cycle. Biomass syngas can, however, also be used in diesel, internal combustion, or Stirling engines, in high-efficiency gas turbines, or in high-efficiency fuel cells, all with higher efficiency potential. All of these are suitable for even higher efficiency use with combined heat and power operation. Gasification also enables production of a wide range of fuels and chemicals, such as syngas, hydrogen, and liquid fuels or methanol, ethanol, and Fischer–Tropsch liquids using commercial processes developed in the petrochemical industry for the conversion of methane.

Integrated Gasification Combined Cycle

The integrated gasification combined cycle (IGCC) system has two main components, a high-efficiency gas turbine and a heat recovery steam generation system. This system uses heat from the turbine exhaust to raise steam and produce electricity in a traditional steam turbine section. Integrated biomass gasification combined cycle systems for electricity production have a number of potential advantages [606, 607, 629]. Projected process efficiencies are much higher than the direct combustion systems in commercial use today. In a co-generation application, overall system efficiencies can approach 85%, thus maximizing the conversion of biomass, a relatively low-energy-density fuel, to heat and power [630–633]. These process efficiencies are comparable to high efficiency large-scale pulverized coal systems, but can be achieved at a smaller scale of operation.

The increased efficiency in IGCC systems translates into environmental benefits because emissions per unit energy produced are lower. This includes CO, NO_x, SO_x, CO_2, and particulates. NO_x and SO_x emissions are inherently lower in biomass IGCC systems because biomass fuels tend to have low N and S contents to start with, and gas cleanup and conditioning in biomass gasification systems removes these impurities before the syngas is combusted in the gas turbine. The same is true for particulates. CO_2 emissions are effectively zero, because biomass is a renewable fuel.

Fuel Cell Applications

Fuel cell systems have the potential to substantially reduce air and water emissions associated with electricity production. In all fuel cell systems, hydrogen is consumed at the anode and water is produced at the cathode. The higher system efficiencies for fuel cells translate into enhanced fuel utilization and therefore reduced CO_2 emissions compared to lower efficiency systems. Fuel cell power plants will be capable of exceeding stringent present and future environmental regulations for particulates, NO_x, and SO_x emissions.

Without considering batteries and other chemical storage devices, there are effectively six types of primary or direct fuel cell technologies currently being developed: alkaline fuel cells (AFC), polymer electrolyte fuel cells (PEFCs), a specialized PEFC using methanol as the fuel called the direct methanol fuel cell, phosphoric acid fuel cells (PAFC), molten carbonate fuel cells (MCFCs), and solid oxide fuel cells (SOFC) [634–638]. These technologies are at various stages of commercialization and individual fuel cell systems have different applications [637]. The high cost of fuel cell systems ($1,000–$20,000/kW) is one of the more significant barriers to commercialization [635].

Integrated biomass gasification fuel cell systems have potential use for distributed and centralized power production.

Greater fuel flexibility and greater resistance to impurities makes developing high-temperature MCFC and SOFC systems the most likely technologies for future biomass applications. These systems are currently in various stages of development and demonstration, although MCFC systems are nearer to commercialization [639, 640]. Unlike PAFC systems, MCFCs can tolerate the high concentrations of CO that are produced in biomass gasification [634, 641, 642]. This eliminates the need for water–gas shifting and selective CO oxidation that would otherwise increase system costs and reduce overall efficiency. The higher operating temperatures of MCFC systems also provide an opportunity for co-generation or waste heat utilization that could improve overall system efficiency to about 85% (lower heating value) [643].

Syngas to Liquid Fuels

In its simplest from, syngas is composed of two diatomic molecules, CO and H_2 that provide the building blocks upon which an entire field of fuel science and technology is based [644–649]. Sabatier and Sanderens, who produced methane by passing CO and H_2 over Ni, Fe, and Co catalysts, discovered the synthesis of hydrocarbons from CO hydrogenation in 1902. At about the same time, the first commercial hydrogen from syngas produced from steam methane reforming was commercialized. Haber and Bosch discovered the synthesis of ammonia from H_2 and N_2 in 1910 and the first industrial ammonia synthesis plant was commissioned in 1913. The production of liquid hydrocarbons and oxygenates from syngas conversion over iron catalysts was discovered in 1923 by Fischer and Tropsch. Variations on this synthesis pathway were soon to follow for the selective production of methanol, mixed alcohols, and isosynthesis products. Another outgrowth of Fischer–Tropsch Synthesis (FTS) was the hydroformylation of olefins discovered in 1938. Many of the syngas conversion processes were developed in Germany during the First and Second World War at a time when natural resources were becoming scarce and alternative routes for hydrogen production, ammonia synthesis, and transportation fuels were a necessity.

Syngas composition, most importantly the H_2/CO ratio, varies as a function of production technology and feedstock. Steam methane reforming yields H_2/CO ratios of three to one whereas coal and biomass gasification yields ratios closer to unity or lower. Conversely, the required properties of the syngas are a function of the synthesis process. Fewer moles of product almost always occur when H_2 and CO are converted to fuels and chemicals. Consequently, syngas conversion processes are more thermodynamically favorable at higher H_2 and CO partial pressures. The optimum pressures depend on the specific synthesis process.

Catalytic syngas conversion processes are exothermic reactions generating large excesses of heat. This highlights the specific need for removing this heat of reaction to carefully control reaction temperatures to maintain optimized process conditions. Maximizing product yields, minimizing side or competing reactions, and maintaining catalyst integrity dictate optimum synthesis reaction temperatures.

Appropriate catalysts are necessary for all fuel and chemical synthesis. The basic concept of a catalytic reaction is that reactants adsorb onto the catalyst surface and rearrange and combine into products that desorb from the surface. One of the fundamental functional differences between various syngas synthesis catalysts is whether the adsorbed CO molecule dissociates on the catalyst surface. For FTS and higher alcohol synthesis, CO dissociation is a necessary reaction condition. For methanol synthesis the CO bond remains intact. Hydrogen has two roles in catalytic syngas synthesis reactions. In addition to being a reactant needed for CO hydrogenation, it is usually used to reduce the metalized synthesis catalysts and activate the metal surface.

Since the genesis of syngas conversion to fuels and chemicals, a tremendous amount of research and development has been devoted to optimizing product yields and process efficiencies. This includes the discovery of catalysts with optimized formulations containing the most active metals in combination with appropriate additives to improve activity and selectivity in a given process. Mechanistic studies have been conducted to interpret the fundamentals of specific conversion processes and measure the kinetic rates of key chemical reactions. Reactor design and engineering is another active research and development area of syngas conversion technology. Temperature control and stability in conversion reactors is a critical process parameter because of the large excess heat of reaction. To optimize commercial synthesis processes, detailed process engineering and integration are used with respect to heat integration and to syngas recycling to improve conversion efficiencies. Given the rich history of syngas conversion and the extensive research and development efforts devoted to this field of study, it is not surprising that a vast amount of literature is available that tracks the scientific and technological advances in syngas chemistry (see the Fischer–Tropsh Archive at www.fischer-tropsch.org). A summary of various catalytic syngas processes, including types of catalyst and reaction conditions, is shown in the “star” diagram in Fig. 33.32 [649]. This is by no means a comprehensive list of potential products, but identifies the available processes for utilizing syngas for producing fuels and chemicals.

Combustion

Biomass combustion is the most common and historically oldest method of extracting energy from biomass (other than food) either directly, in the form of heat and light from fire, or indirectly through use of this heat to produce steam that

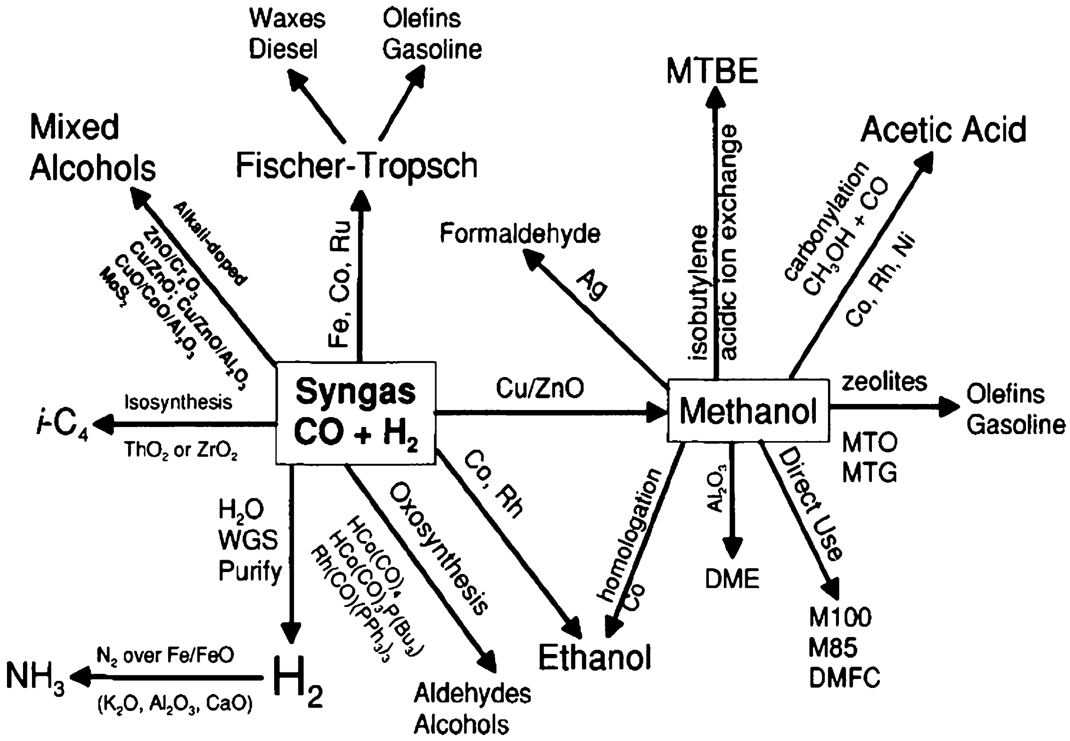


Fig. 33.32 Star diagram showing various high-pressure catalytic processes for converting syngas to fuels and chemicals

drives electricity-generating turbines. Biomass is the third largest global source of energy, accounting for 14% of annual global energy consumption [650]. The scale of biomass combustion systems ranges from residential heating and cooking applications to small-scale distributed energy production to large-scale centralized power production. Biomass use is very prominent in developing countries, particularly for distributed heat and power and for domestic heat, cooking, and light. Large-scale biomass power plants and industrial biomass utilization for heat and power supplant the residential and commercial biomass heating applications in developed countries.

The impetus for displacing fossil fuels with biomass in heat and power combustion systems is typically to reduce emissions of CO_2, and of NO_x, SO_x, and other air toxics, or to improve utilization of biomass residues and wastes. The threat of increased global warming has subjected the use of fossil fuels to increasing scrutiny in terms of greenhouse gas and pollutant emissions. Renewable and sustainable energy resources such as biomass can be combusted instead of coal to produce heat and power and help reduce the accumulation of greenhouse gases as carbon dioxide is consumed during plant growth. Also, on average, the sulfur content of biomass is lower than coal, so increasing the use of biomass power can reduce sulfur emissions from power production. The agricultural and wood products industries generate large quantities of biomass residues that could provide fuel for electricity production. Increasing the use of these waste biomass fuels could alleviate the burdens of waste disposal in the agricultural and wood products industries.

A number of biomass combustion technologies exist, including grate-fired and fluidized-bed processes [651]. The simplest biomass combustion systems are wood stoves and furnaces. These devices generate hot air that is used for heating residential and commercial buildings. Biomass boiler systems are more fuel flexible than the smaller furnaces and can be scaled to larger size and used to generate hot water or steam for heat and power applications. Larger-scale biomass boilers include pile burners in which biomass accumulates in a furnace and combustion air is fed from above and below the pile. This relatively simple design is fuel flexible but has low efficiency and poor combustion control, leading to relatively high emissions.

In grate-fired boilers, the biomass is fed in a thin layer, so it is evenly distributed over a sloped stationary, traveling, or vibrating grate. Improved control over the combustion process can be achieved with better carbon conversion. Fluidized-bed combustors are more complex systems, but offer much better control of combustion temperature, improved carbon conversion, and fuel flexibility. Using a boiler to produce both heat and electricity (co-generation) can improve the overall system efficiency to as much as 85%. Boiler efficiencies are affected by fuel moisture content, air–fuel ratio, excess air, combustion temperature, and biomass ash content.

Direct combustion to raise steam is used in all of the existing biomass generation plants in the United States today. Biopower is a commercially proven electricity-generating option in the United States and the following statistics for the use of biomass for electricity production can be found in the 2004 Energy Information Agency publications (www.eia.doe.gov). Renewable energy consumption in the United States in 2003 accounted for 6.2% of the nation's 98-quad total energy supply. The 2.9 quads of energy from biomass accounted for 47% of the renewable energy consumption. Biomass surpassed hydropower as the single largest renewable energy resource for the last several years. Of the total, nearly 90% of the biomass energy was consumed in the pulp and paper and forest products industry, three quarters of which was for process heat. Sixty percent of the electricity from biomass is produced from wood or wood wastes with the remaining 40% produced from landfill gas, municipal solid waste, and other biomass. Electricity production from biomass is being used and is expected to continue to be used as base load power in the existing electrical distribution system.

Today's biopower capacity is based on mature, direct-combustion boiler/steam turbine technology. The average size of biopower plants is 20 MW (the largest approach 100 MW) and the average efficiency from steam-turbine generators is 17–25%. The small plant sizes lead to higher capital cost per kilowatt-hour of power produced and the low electrical conversion efficiencies increase sensitivity to fluctuations in feedstock price [652].

All biomass energy systems suffer from the economic barrier associated with the energy cost of producing, transporting, and preparing the biomass feedstock. Significant progress has been made in this area, but to be truly economically competitive, new feedstocks and methods for their harvest and preparation must be developed. Harvesting, preparation, transportation, and feeding of a variety of biomass feedstocks suitable for power production must be demonstrated, and new methods developed for reducing costs and energy requirements must be verified. This will reduce the delivered cost of feedstock to the energy facility to a level more competitive with fossil fuels.

Technical barriers for biopower applications arise from the variability of biomass fuel compositions. The trace elements in biomass—N, Cl, K, Na, and ash—contribute to operational problems and pollutant emissions in biomass combustion systems [653–656]. The nitrogen content of biomass can vary considerably. Wood and wood wastes tend to have low nitrogen contents because hardwood and softwood trees are relatively slow growing and unfertilized. Agricultural residues and grasses tend to be faster growing and are fertilized and harvested on a yearly basis. Some agricultural residues such as alfalfa and soybeans have value as an animal feed because of their high protein (nitrogen) content. Variability in fuel-bound nitrogen (protein) in biomass leads to varying NO_x emissions in biomass combustion systems.

The chlorine content of biomass is generally a function of the soil conditions it is grown in and the amount of fertilizer applied during growth. Consequently, agricultural residues such as various stovers and straws can have high Cl levels. Subsequent HCl emissions during combustion can catalyze high- and low-temperature corrosion.

The major technical barrier associated with biomass combustion systems is the formation of tenacious deposits on heat transfer surfaces caused by the unique high-temperature chemistry of biomass ash. Many types of biomass used in combustion systems contain alkali metal species: sodium, potassium, and calcium. The ash content of woody biomass is quite low and not a problem. The ash content of agricultural residues such as wheat straw, rice straw, corn stover, and alfalfa stems can be quite high, on the order of 5% or up to 20% for rice straw and rice husks. The presence of alkali metals in conjunction with the high silica content of some biomass ashes can lead to molten ash at combustion temperatures [657–662]. In some cases, the K, Si, and Al contents are such that very low melting-point eutectic mixtures can form. The materials can be fluid at combustion temperatures, but form glasslike deposits on colder downstream surfaces such as heat exchanger tubes.

Ash deposition in biomass combustion systems has been the focus of numerous research efforts [653, 663]. The basic mechanism for deposit formation in biomass combustion systems starts with the vaporization of alkali metals, usually chlorides, in the combustor. Fly ash particles, which are predominantly silica, impact and stick to boiler tube surfaces. As the flue cools the alkali metal vapors and aerosols quench on the tube surfaces. When the ash chemistry approaches equilibrium on the surface and the deposit becomes molten, the likelihood increases that additional fly ash particles will stick, and deposits grow rapidly. Ash deposits can also accelerate the corrosion or erosion of the heat transfer surfaces. This greatly increases the maintenance requirements of the power plant often causing unscheduled plant interruptions and shutdown.

Co-firing

One solution to increasing biopower is to build dedicated biomass power plants. An alternative, lower capital cost option for increasing the use of biomass to produce electricity is to co-fire biomass and coal in existing coal-fired power plants. Coal-fired power plants are used to produce the majority of the electricity in the United States. If biomass were co-fired at low percentages in even a small number of coal-fired power plants, the use of biomass for power production would dramatically increase. Co-firing biomass and coal increases the use of sustainable fuels without the need for large capital investments while taking advantage of the high efficiencies obtainable in existing coal-fired power plants. Fuel diversity is another advantage of bio-mass/coal co-firing. Co-firing reduces the need for a constant supply of biomass that would be required in a dedicated biomass power plant. Co-firing biomass and coal is also a viable way to manage the increasing emissions of greenhouse gases and other pollutants from power-generating facilities.

Biomass and coal have fundamentally different fuel properties that can lead to benefits or deterrents to co-firing. For instance, biomass is a more volatile fuel than coal and has higher oxygen content. Coal, on the other hand, has more fixed carbon than biomass. Wood fuels tend to contain very little ash (on the order of 1% ash or less) and consequently increasing the ratio of wood in biomass/coal blends can reduce the amount of ash that needs to be disposed. A negative aspect of biomass is that it can contain more chlorine than coal. This is particularly true for some grasses, straws, and other agricultural residues.

Better environmental performance at a modest cost is one of the drivers for biomass/coal co-firing in utility boilers [664–667]. Biomass usually has lower sulfur content than coal, so co-firing reduces SO_x emissions because of displacement of sulfur in the fuel blend. Similar reductions are also observed for NO_x emissions, because the nitrogen content of the co-fired biomass fuels is generally lower than the nitrogen content of the coal. Initially, any change in NO_x emissions as a result of blending the biomass and coal can be attributed to changing the amount of nitrogen in the fuel blend.

The addition of biomass has been shown to reduce NO_x emissions in most commercial facilities, usually beyond the reductions expected because of a lower overall fuel-bound nitrogen content. The high volatiles content of biomass can effectively establish a fuel-rich zone early in the burner flame that can reduce NO_x emissions similar to fuel injection in flue gases (reburning) for NO_x reduction. Adding biomass can also reduce flame temperatures, leading to lower levels of thermal NO_x. The high moisture content of some biomass may also be effective for NO_x reduction at full-scale.

When biomass is co-fired with coal (even in small percentages), the alkali metals in biomass ash can alter the properties of the resulting mixed ash. This could have a significant impact on the coal plant's operating and maintenance costs or even operability. The addition of biomass to a coal-fired power plant can also nullify ash sales contracts for coal flyash. Biomass ash components in feedstocks may also reduce the long-term efficiency and effectiveness of certain (selective catalytic reduction, SCR) systems for the SCR of NO_x.

Fuel preparation and whether to premix the biomass and coal or introduce the two fuels separately into the boiler is another important issue that needs to be addressed for successful implementation of co-firing. Fuel handling of biomass in co-firing systems will need to be demonstrated with a variety of biomass feedstocks—such as switchgrass, willow, and energy cane—to take advantage of lower cost biomass residues and future energy crops.

Biomass co-firing is not a new technology; several utilities have taken advantage of opportunities and have or had been co-firing biomass for many years. One example is the AES (formerly NYSEG) Greenidge Station in Dresden, New York, that began co-firing tests in October 1994 [668]. The success of these tests led to the installation of a separate biomass preparation area in the fuel yard in early 1999, to separately feed biomass into the 108-MWe tangentially fired pulverized-coal unit. Another example is Steam Plant #2 at Tacoma Public Utilities' power plant in Tacoma, Washington. This plant was reconfigured in 1991 to co-fire coal, biomass, and refuse-derived fuels on a continuous basis in a 50-MWe atmospheric pressure fluidized-bed combustor. A third example is Northern States Power's King Station in Bayport, Minnesota. From 1987 through 1997, wood residues from the neighboring Anderson Window plant were continuously co-fired at a level of 5% (20 t/h) in a 550-MWe coal-fired cyclone boiler [668]. Co-firing was suspended at the King Station because Anderson Window found a higher value use for its wood residues, not for technical reasons.

Aside from these longer duration co-firing operations, several utilities have tested bio-mass/coal co-firing for short durations in utility boilers [669–673]. These various tests sought to systematically determine the impacts of biomass co-firing on such in-furnace parameters as boiler derating, boiler efficiency, emissions reductions, changes in fouling and slagging behavior, and corrosion. A number of demonstration projects are currently being funded to add to the knowledge base of utility-scale biomass/coal co-firing.

Several issues clearly remain regarding how blending biomass and coal will affect combustion performance, emissions, fouling and slagging propensities, corrosion, and ash salability. Nevertheless, several utilities have tested biomass/coal co-firing in utility boilers and the Electric Power Research Institute funded a study in 1997 to establish biomass co-firing guidelines [674].

Biotechnology in Agriculture and Processing

Human Survival Is Biotechnology

Biotechnology has been defined by various groups and broadly includes technologies that utilize living organisms or parts of biological systems. The nurture of man and animals, and provision of replenishable industrial materials, typically includes: (1) growing selected species or their genetic modifications; (2) harvest, preprocess storage, conversion into useful products, and protection until use; and (3) utilization or disposal of byproducts and wastes in the most beneficial or least-cost manner. Specific actions may be taken to suppress residual enzymes and contaminating microorganisms that could degrade product value. Also, *remediation* (restoration) of air and water used in processing to near-pristine condition often is mandated today.

The first *transgenic* (across genera) oilseed crops were planted in the United States and Canada in 1996 and were followed by rapid acreage expansion. Transgenic oilseeds generally do not require special processing unless they contain higher melting oils. In this chapter, the reader is first introduced to modern biology principles, and industry terms are presented throughout.

Human understanding of life processes, and competition between genera, continually broadens. Many biological reactions are catabolic and split large compounds into smaller units to obtain energy (carried by ATP, adenosine triphosphate) for heat, work, or reinvestment in syntheses and chemical structures for making required compounds. Plants are the original source of nutrients for man and animals. Microscopic plants, plankton, and larger members synthesize proteins, carbohydrates, lipids, and other compounds from inorganic elements and water, using ATP obtained from the sun by photosynthesis. In the process, carbon dioxide also is reduced to oxygen. Some products are used to build the plant's structures and maintain its functions, and others are stored in the seed as enzymes, proteins, and energy reserves (starches and lipids) for reproduction as new plants, or as sugars or starches in roots of perennials for later growth cycles. Humans rely on plants and animals, which consume plants (herbivores), or carnivores which eat other animals, for their food. Animals vary in their abilities to synthesize intermediate chemical structures needed for their development and life; generally, those lower in the food chain are more self-sufficient. As examples, amino acids are the building blocks of proteins and 11 are *dietary essential* (must be obtained from food) by humans; approximately 12–14 are dietary essential for economic animals (grown for meat or other food products), the exact needs varying with species, age, and physiological state. Carnivorous fish obtain long-chain highly unsaturated fatty acids in the wild by feeding on plankton eaters and often lose the ability to synthesize them directly. When grown in captivity, as in salmon farming, oils of plankton-eating fish are added to their feed. Diunsaturated linoleic acid and triunsaturated linolenic acid are considered dietary essential for humans. Also, longer-chain higher-unsaturated fish oils sometimes are prescribed for people with lipid metabolism deficiencies.

All organically made compounds, fossilized or not, were once synthesized by specific enzymes and pathways. They must remain degradable by enzymes of the same organism to perpetuate its life and by enzymes of other species for their nutrition and for biodegradation and carbon recycling. Life processes come to a halt if the laws of biochemistry and physical chemistry aren't satisfied. This chapter is limited to

---

This chapter was originally conceived and written by Dr. Lusas and appeared in the immediately preceding three editions.

lipids, but business and policy decisions about food, feed, and replenishable industrial raw materials also require holistic information about protein and carbohydrate technologies, about needs and preferences of biological users, and about human enterprises throughout the world.

Biotechnology has been implemented in two phases. Macro-biotechnology examples are commonplace and include agriculture, baking, and various fermentations. Implementation began about 10,000 years ago, even before written history, when humans initiated symbiotic relations with selected wild animals and plants to ensure a more reliable food supply than possible by hunting/fishing and gathering. Animals were refashioned through selection, protection, crossbreeding, and increase, to meet man's food, transportation, security, and compatibility needs. Higher-yielding seeds, which also were easier to dehull and process into food, were replanted for succeeding harvests. In time, the face of the earth's habitable lands was changed. Except in remote areas or designated refuges, humans: (1) eliminated wild animals dangerous to them and their protected crops and animals; (2) cleared lands and jungles for firewood, building materials, and growing additional crops, as the population increased; but (3) sometimes also destroyed arable land by over-grazing and erosion of uncovered top soil.

Biotechnology currently emphasizes microscale aspects that were not visible or envisioned until about 150 years ago, including: (1) microbes; (2) stereochemistry of reactions, molecular biology including transcription of genetic codes and translation for protein production, and cell multiplication; and (3) enzymes as catalysts. Humans came to only partially understand the nature of systems (animals, plants, insects, and soil) they handled in agriculture. Modern biotechnology must address needs of these systems, as well as those of people. Animals and plants must be healthy and adequately nourished, the pests (weeds and insects) controllable, the soil kept productive, and all must function in acceptable harmony if the quality of human life is to be sustained or improved as the population increases.

Histories of biotechnology progress in agriculture, genetics, medicine, pharmacy, industrial fermentations, food processing, and nutrition are reported in many books and on the Internet. Archeologists tell us the Babylonians brewed beer in 6000 BC, Egyptians baked yeast-leavened bread in 4000 BC, and other early cultures made wine and vinegar by fermentation and preserved cheeses by salt and acid. Sophisticated herbal medicines were developed. But, without scientific knowledge of why certain practices were successful, early progress through trial and error was earned slowly. Some of the less-mentioned milestones relevant to food production and utilization are described next.

Development of the microscope by Anton van Leeuwenhoek (1673) and others enabled man to see a new world of "microcreatures," including bacteria, yeasts, molds, blood cells, and spermatozoa, and microstructures such as muscle fibers and plant and seed tissues. This added credibility to later claims by Louis Pasteur and Robert Koch that microorganisms can spoil foods and cause disease at a time when many influential learned men still clung to theories of spontaneous generation of life.

Louis Pasteur (1863) invented a process to pasteurize wine by heating to inactivate microbes and prevent its turning sour from fermentation to acid. Nicolas Appert had already won a 12,000-franc prize from Napoleon I in 1809 by inventing a process for "canning" foods (actually packing precooked foods in glass bottles, sealing, and heating in boiling water). But, spoilage occurred frequently because few understood the roles of acidity or osmotic pressure in restricting microbial growth, problems of recontamination, or heating inactivation requirements for different bacteria, especially spore formers. The roles of bacteria and yeast in fermentations had been accepted when Eduard Buchner (1897) demonstrated that filtered extracts also could catalyze fermentation in the absence of intact yeast cells [1]. This led to modern enzymology where more efficient enzymes are extracted and purified from a variety of nontraditional sources, and more recently from "engineered" microorganisms that carry gene sequences from relatively unrelated species.

Genetic Messages

Gregor Mendel, an Austrian botanist and monk working with sweet pea plants, proposed that "factors" (units of information responsible for observable traits) are passed from one generation to the next (1866). But, his work essentially went unnoticed until rediscovered by several scientists in the early 1900s. Walther Flemming reported the discovery of chromosomes and mitosis in 1882. William Sutton (1902) announced that chromosomes are paired and may be the carriers of heredity. He named Mendel's factors "genes" and suggested they occur on chromosomes.

After observing meiosis, he developed the Chromosomal Theory of Heredity that gametes (egg and sperm cells) are haploid and carry only one of each pair of chromosomes from each parent in forming the new being (a diploid zygote) which then holds on to life as it best can. Details of genetics continued to develop. Alfred Hershey and Marsha Chase showed that deoxyribonucleic acid (DNA) is the genetic code carrier rather than proteins as was thought by some (1952). James Watson and Francis Crick proposed the double-stranded, complementary, antiparallel structure model for DNA (1953) [1].

Development of recombinant DNA techniques to produce engineered, genetically engineered (GE), or genetically modified organism (GMO) products is among the boldest achievements of cellular biologists. Paul Berg (1972) first demonstrated use of a selected enzyme to cut DNA strands into sections and reattach them to produce recombinant DNA molecules. In 1973, Stanley Cohen, Annie Chang, and Herbert Boyer announced splicing a viral DNA section with a bacterial DNA section to form a recombinant DNA molecule, which then was spliced into the DNA of a bacteria to produce the first *transgenic* (across genera) recombinant DNA organism. Herbert Boyer and Robert Swanson founded Gene tech, Incorporated, a biotechnology company dedicated to developing and marketing products based on recombinant DNA technology in 1976. It was the first company to receive US Food and Drug Administration (FDA) approval for marketing a genetically engineered drug (a form of human insulin produced by bacteria) in 1982, and since has developed many other products [1].

Research in genetic and protein structures created tremendous amounts of data. Fortunately, means to handle it also were being developed on another front. Norbert Wiener, a mathematician at the Massachusetts Institute of Technology and a founder of the science of cybernetics, published his book *Cybernetics; or, Control and Communication in the Animal and the Machine* in 1948 [2]. In this volume and its 1961 edition [3], Wiener, a specialist in communications and later in artificial intelligence [4], knew that messages degrade and can be fouled in retransmission and suggested that aging and diseases are analogous degradations of the genetic code. Realizing that a revolution in information handling was occurring, Wiener became concerned that cybernetics and automation not degrade the quality of life and published *Human Use of Human Beings: Cybernetics and Society* in 1954 [5]. It also was reissued posthumously in 1967 [6]. Cybernetics, and especially digital computing, have made the massive record keeping, data summarization, inventory handling, sequencing, scheduling, and control systems of today's business, government, and science possible. Complete amino acid sequences of proteins have been mapped, as well as genomes of microorganisms, plants, animals, and man. As medical research workers become interested in specific genetic traits or problems, or desire to investigate modified-protein drugs, they will more readily know where to locate the corresponding genes and structures.

Cell culture techniques, developed during research leading to transgenic DNA organisms, greatly assisted in the development of many nontransgenic *cultivars* (uniform subvarieties of a recognized genus and species) by selective cross-breeding of closely related germplasms.

Fatty acids in plants and animals typically are elongated during synthesis to chain lengths of 18 carbons by successive additions of two carbon units. The resulting product, stearic acid, is fully saturated, but has a melting point too high for most physiological reactions. Nature remedies this situation by also providing *desaturase* systems that enable organisms to introduce 1, 2, or 3 unsaturated bonds in the 18-carbon chain, thus lowering melting point of fatty acids and triglycerides. Melting points differ between fat deposit locations in animals, change seasonally in animal bodies, and vary with seed maturation temperatures of the same cultivar.

Stability of fatty acids against oxidation decreases as unsaturation increases, a prime example being tri-unsaturated 18-carbon linolenic acid in soybean oil. Biotechnologists developing soybean with greater oil stability have sought to do so by seeking germplasms with reduced desaturation for selective crossing, and by altering or suppressing expression of desaturation [7], to produce oils with reduced linolenic acid and increased oleic or stearic acid contents.

Water Activity

W.J. Scott, an Australian microbiologist, published a classic food science chapter "Water Relations of Food Spoilage Microorganisms" in 1957 [8]. He recognized that microorganisms compete with other solutes in mixed systems for water required for their metabolism and summarized ranges within which most bacteria, yeasts, and molds grow. However, water was not expressed as percent of system mass, but rather as *water activity* ($a_W = p/p_o$), where p is the vapor pressure of the solution (or product), and p_o is the vapor pressure of the pure solvent (water). Some prefer to use the term relative vapor pressure (RVP), which can be determined by measuring percent relative humidity in the headspace above a product that has equilibrated within its container and the relationship RVP = (percent ERH)/100. Water activity, osmotic pressure, lowering of freezing point, and rising of boiling point are colligative properties of solutions that follow Raoult's Law.

The guides indicated that relatively few bacteria grow at a_W below 0.91, few yeasts below 0.87, and few molds below 0.75–0.65 a_W and helped explain why many foods do not spoil even though they are not sterile. Microbial growth ability can be further reduced by increasing osmotic pressure by addition of soluble salts and sugars, lowering pH, use of microbial inhibitors, and reducing product temperatures. Exceptions to the guides exist, for example, halophilic bacteria tolerate high salt concentrations and osmophilic yeasts can grow on high sugar content products.

Food-induced diseases are mainly of two types: *food poisoning,* the effect of toxins produced during growth of a microorganism in the food before ingestion, and *infection,* resulting from food-borne microorganisms taking up residence in the body before doing their damage. Low a_W has been reported to inhibit production of toxins by various food-poisoning bacteria, even though the live organisms are present. However, some low a_W processed meats have been implicated as carriers of viable food infection bacteria, which apparently resume growth when a_W and temperature increase. Water activity can be controlled by: product formulation; drying fruits, vegetables, and meat; and by storing products like meats and fish in salt brines and fruit preserves in sugar syrups.

Over time, diagrams were developed relating water activity with: enzyme activity, dormancy of stored seed, loss of dry product crispness by moisture absorption, pigments and vitamins degradation, nonenzymatic browning, and fat oxidation. Response curves generally are not linear, and readers working with food or feed formulations are referred to the technical literature about their products.

Herbicide- and Insect-Resistant Oilseed Crops

Crop producers and processors were provided with powerful tools during the last four decades of biotechnology evolution. Seed producers can develop new cultivars by crossing two selected parents, or by *hybridization* (crossing two genetically diverse genotypes to obtain additional vigor). Generally, transgenic crops also are hybrids. The world's current major biotech oilseed crops are herbicide-tolerant (HT) soybean, corn, cotton, and canola (a type of rapeseed), and insect-resistant corn (maize) and cotton.

United States and European pharmaceutical and chemical companies have taken the lead in biotechnology, frequently by purchasing plant breeders and growers of planting seeds. Various producers offer transgenic crop seeds resistant to several herbicides. The Monsanto Company (St. Louis, MO) has often been among the first to get its products to the marketplace and is used as an example here. Roundup Ready® Soybean (planting seed) was introduced in the United States, and Roundup Ready Canola in Canada, in 1996. These transgenic crops are resistant to Roundup,® Monsanto's brand of glyphosate, a *nonselective* (broad-spectrum) herbicide for killing *weeds* (unwanted plants). A grower of a Roundup Ready crop needs to make fewer spray passes across the field, often with one herbicide, to control a season's weeds. Roundup Ready Cotton was commercialized in 1997 and Roundup Ready Corn in 1998. Monsanto introduced Bollgard® Cotton in 1996, and YieldGard® Corn in 1998. The Bollgard and YieldGard seeds included a gene sequence from the soil bacterium *Bacillus thurigiensis* var. kurstaki ("Btk") which enables the plant to make *systemic pesticides* toxic to larvae of specific insects. These compounds are known as plant-incorporated protectants (PIP) and formerly were called "plant pesticides"; the crops categorically are called "B.t."

By 2005, the Monsanto Company marketed: Roundup Ready Soybeans, Roundup Ready Canola, Roundup Ready Cotton, Roundup Ready Corn, and Roundup Ready Corn 2. Additional gene sequences from "Btk," which produce other PIP specific for other insect larvae, had been inserted into seeds, and Monsanto also offered: Bollgard Cotton for controlling tobacco budworm and pink bollworm, and high suppression of cotton bollworm; and Bollgard II® for control of tobacco budworm, pink bollworm, cotton bollworm, fall armyworm, cabbage and soybean loopers, and other secondary leaf- or fruit-feeding caterpillar pests in cotton. (It is ironic that none of the commercial B.t. cotton seeds control the cotton boll weevil, a long-time nemesis, but concurrent boll weevil eradication programs have made good progress toward this objective.) Monsanto's B.t. Corn line included: YieldGard Corn Borer®, effective against European corn borer, southwest corn borer, sugarcane borer, southern cornstalk borer, corn earworm, fall armyworm, and stalk borer; and YieldGard Rootworm®, effective against western, northern, and Mexican corn rootworm. In addition, YieldGard Plus® offered the protective properties of both YieldGard Corn Borer and YieldGard Rootworm®. The inclusion of two or more transgenic properties in a seed is known as "stacking." Other seeds offered include: YieldGard Corn Borer with Roundup Ready Corn; YieldGard Corn Borer with Roundup Ready Corn 2; YieldGard Rootworm with Roundup Ready Corn 2; YieldGard Plus® with Roundup Ready Corn 2; and Bollgard II with Roundup Ready Cotton. The Monsanto Company also licenses the use of Roundup Ready traits to other seed producers who offer their Roundup Ready lines in the marketplace. The growing of transgenic crops is approved variety-by-variety and state-by-state. The Monsanto Company sees its relation with growers as licensor-licensees of its technologies, rather than as traditional seller-buyers, and establishes licensor-monitoring rights before selling seed.

The *2005 Technology Use Guide*, downloaded from the Monsanto Company Web site, states that growers are required to sign a Monsanto Technology Stewardship Agreement to: (1) comply with all EPA (US Environmental Protection Agency) mandated Insect Resistance Management (IRM) requirements; (2) use all purchased seed with biotech traits for planting a single crop; and (3) sell harvested corn with biotech traits not yet approved by the European Union only to grain handlers who confirm their acceptance, or use that grain as on-farm feed. Finding an initial crop buyer is the grower's responsibility, and prior discussions with grain elevators and Monsanto seed dealers are encouraged.

Refuges (20% minimum to 50% of the total crop acreage) planted to the same crop (corn or cotton) with non-B.t. seed are required by the EPA as part of the IRM effort to slow development of B.t.-resistant insects. The concept is to provide an area for presumably B.t.-resistant insects escaping the B.t. crop area to mate with non-B.t.-resistant insects in an area where other insect control practices are used, and thus slow development of B.t.-resistant insects that survive to the following year. Options for refuge patterns and location are described, and growers must agree that Monsanto personnel or its agents will have access to monitor the transgenic crop and refuge areas.

Growers may use glyphosate herbicides, other than those designated by Monsanto, but only if they have been approved for use over Roundup Ready crops, and have been labeled for this use by all required governmental agencies.

If Monsanto suspects a grower may have planted saved seed containing a Monsanto genetic trait, it may request invoices or otherwise confirm that newly purchased seed has been planted. If information is not provided within 30 days, Monsanto may inspect and test all the grower's fields to determine if saved seed has been planted. Inspections are to be scheduled in advance at a reasonable time so the grower can be present if desired.

The US Department of Agriculture (USDA) has estimated that herbicide-tolerant (HT) soybeans reached 85% of total US soybean acreage and HT cotton reached 60% of total in 2004, whereas the HT share of corn reached 18% [9]. The ISAAA (International Service for the Acquisition of Agri-Biotech Applications) has reported that world cultivation of biotech crops increased 47-fold, from 1.7 million hectares (4.2 million acres) to 81.0 million hectares (1 ha = 2.47 acres) in the 9-year period 1996–2004, and was up by 20% from 2003. The number of countries growing 50,000 ha (123,500 acres) or more annually increased from the original United States and Canada to 14 in 2004, with the US still planting the most land (59% of global GMO plantings), followed by Argentina (20%), Canada (6%), Brazil (6%), China (5%), Paraguay (2%), India (1%), South Africa (1%), and Uruguay, Australia, Romania, Mexico, Spain, and The Philippines each planting less than 1%. Approximately 34% of the global biotech crop area in 2004 was in developing countries, with use in Southern Hemisphere developing countries increasing about three times more rapidly than northern industrial countries [10]. Growth in the five principal developing countries (China, India, Argentina, Brazil, and South Africa) portends significant changes in world food/feed trade patterns, which already are unfolding.

Concerns About Transgenic Crops

Benefits of biotech crops have not always materialized as expected. Introductions of many glyphosate-resistant transgenic crops have been met with complaints of "yield drag" in the initial years, with as much as 6–10% yield reduction for soybean compared to nontransgenic hybrids in test plots reported. Damage to root inoculants or nitrogen-fixing nodules by glyphosate and incomplete cleaning of mixed herbicide residues from weed sprayer tanks have been proposed as causes. However, problems seem to lessen in succeeding years, with no yield drag observed in glyphosate-resistant corn, and ~3% yield drag reported in more recent soybean tests. Yield is determined by genes other than those for glyphosate resistance and by adaptability of cultivars to specific soil conditions. It takes longer to optimize crops as the number of desired traits increases, and improved nontransgenic hybrids may be brought to market in shorter time. Soils differ in fertility, drainage, compacting, and temperature, and some growers chose several seed varieties for different soil conditions on the same farm. Reduced costs of tillage, including opportunities for drilling seed into no-tilled fields (nonplowed stubble of previous crops) and fewer trips across fields for herbicide application, are offset by higher seed costs in calculating overall costs of producing a crop. Economical justification of herbicide-tolerant crops seems confirmed by rapid increases in acres planted in the United States in recent years. Insect larvae carry fungi that produce mycotoxins in corn and cottonseed that can cause illness and death in economic animals and cancer in humans. Elimination of such problems also is welcomed, in addition to increased yields of B.t. crops protected against insect invasion.

Experience showed that some early visions of one-pass herbicide treatment of HT crops per season were overly optimistic. Various practices for controlling weeds are needed across the country, including an herbicide "burn down" of sprouted weeds before crop drilling, dealing with weeds that emerge at different times during the year and well into the growth of cotton, and control of perennial weeds and those resistant to glyphosate. Weed control practices must be tailored to local conditions, even though fewer applications may be required when planting glyphosate-resistant crops.

Many early skeptics predicted development of weed resistance to glyphosate and other herbicides used with HT crops, and insect resistance to PIP insecticides. But, resistance occurs as a natural adaptation for survival and has continuously led to the need for more powerful pest control methods in agriculture. Very strong weed resistance was experienced in growing HT canola in parts of Canada, also suggesting triple stacking of genetic resistance from exposures to previous sequences of herbicides. Canola itself, volunteering from previous plantings, could be a resistant super-weed if a locality switched to growing other crops. Various antibiotech concerns, and activist groups and their causes, can be found on the Internet. Glyphosate has been registered as an herbicide for nearly 30 years and is claimed to have attracted less resistance than other herbicides.

In early days of transgenic crop research, various scientific groups passed resolutions that extreme care should be taken to avoid biotech materials escaping into the environment. But, handling transgenic seeds in open fields by uninstructed personnel is far different than aseptic microbe transfers between test tubes in laboratories by trained technicians. Broad contamination of seed supplies and germplasm resources by transgenic sequences has become major concerns. Although unplanted borders around experimental and seed increase plots are recommended to reduce cross-contamination by wind-blown pollen, occasional winds may be stronger and pollinating insects may fly farther than expected. Floods can carry seed to other fields. Bulk seed can spill from trucks, sprout along roadways and fencerows, and the resulting plants pollinate related plants and later plantings. Inadequate cleaning of seed handling, storage, and transporting equipment can contaminate other crops (even at low levels of <0.5%) and spread transgenic seeds that eventually germinate and pollinate their own kind or wild relatives.

Protecting gene pools at *centers of diversity* (locales where a wild plant was first domesticated) from contamination by transgenic sequences has become a major concern among plant scientists. Farmers growing soybean for the organic foods market have difficulty finding planting seed uncontaminated by transgenic sequences and keeping the crop genetically uncontaminated during growth [11].

Concerns exist about potential gene flow problems arising from producing nonfood products such as industrial chemicals and pharmaceuticals in transgenic plants grown in open fields. The inability of current practices to keep such materials out of the food supply was demonstrated by the StarLink® corn incident. The EPA approved sale of StarLink, a B.t.-type corn developed by Aventis CropScience for animal consumption and industrial production of ethanol, in 1998. However, it was not approved for human consumption because of potential allergenic effects. In 2000, a coalition of environmentalists sent a collection of corn food products to a private laboratory and paid for its testing. In September, newspapers reported that StarLink corn was detected in taco shells sold in grocery stores, and Aventis suspended sales soon after. Although only about 0.4% of the United States corn crop had been planted to StarLink in the most popular of its 2-year cultivation, and much of the crop remained in feed channels, it had broadly contaminated the United States food corn supply and some export lots. Many corn-based foods were recalled because of concerns about contamination, and considerable unrest occurred throughout the food processing and exporting industries. Costs to Aventis for numerous analytical bills experienced by processors and traders holding corn in storage, and buying back the remaining StarLink corn and recalled products, reportedly, were approximately $100 million. No evidence was found that StarLink had produced an allergy reaction in any person. The EPA stopped granting split registrations for genetically engineered crops [12]. The concern is that far greater damages might occur if a more noxious chemical entered the food or feed supply through misplaced shipments of a common-looking transgenic crop.

The feasibility of producing plant made pharmaceuticals (PMPs) has been demonstrated with common crops such as corn in a practice sometimes called *biopharming* or simply *pharming*. Production of vaccines, pharmaceuticals, or their precursors in plants, rather than by animal cell culture or transgenic animals, has the advantage of avoiding potential transfer of bacterial or viral diseases. The need for greatly increased oversight in this emerging industry was demonstrated by the Prodigene incident in 2001. The company planted corn, genetically modified to produce pharmaceutical components, at various field sites. The following year, conventional soybean was grown at one of the sites. Seed from the previous year's experimental crop germinated as volunteers, and the corn plants were harvested with the soybean. Pieces of the transgenic corn plants were found with the soybean in elevators, and USDA inspectors quarantined 500,000 bushels of soybean [12]. The pharmaceuticals were in the corn plant trash and not in the soybean seed. It is difficult to predict what may have happened if commercial practices had run their course. If the soybean was extracted for oil, it may have been cleaned and the trash (including corn stalk pieces and any corn seed) sold for feed use. Depending on digestibility, the active compound may have entered the milk or meat supply. A public health disaster did not occur, but some feel the potential for misdirection of intended drugs has been demonstrated.

Over 85% of domestic foods are estimated to contain biotech crops. Whether, or how, to label GMO-containing foods has been an issue since their initial introduction. The EPA, which rules on safety and use of herbicides and pesticides, and the FDA, have adopted the *substantial equivalence* principle when granting approvals and look for closeness of similarities of genetically modified crops or foods with existing products based on chemical analyses. Acute toxicity and suspected allergenicity tests are run in initial screenings. European and some US scientists prefer multigeneration animal testing, reminiscent of earlier food additives approval practices, before release.

Attempts to tag EPA/FDA-registered GMO foods by product labeling have consistently been denied by the government and courts, apparently on the principle they cannot be identified as different from traditional crops because they already have been declared equivalent. Attempts to limit growing of GMO crops in specific areas also have failed, with state programs overruled as interfering with interstate commerce. The alternative of labeling nontransgenic products as “non-GMO” also has been denied on the principle they cannot be implied to be better.

Additionally, formulated non-GMO foods would have to carry the burden of ensuring that all ingredients were non-GMO, including cheeses, ice cream, and other products, which may contain dried nonfat milk solids from cows treated with recombinant bovine somatotropin (rBST). It would be extremely hard to track such products from originating farms to the point of formulation. Currently in the United States, organic foods, produced under certification programs, appear the most reliable non-GMO option (with non-GMO labeling not allowed). GMO products have been declared kosher for Jews and halal for Muslims, provided they do not contain genes from non-kosher or non-halal sources (e.g., pigs).

In Europe and other countries, contents of GMO ingredients are limited, or labeling may be required under the principle that the “right to know” what is in food is a citizen’s right. Domestic consumer activist groups initially strongly supported GMO labeling. The issue has become less vocal with the passing of years without recognized major health problems, but continues to be challenged as in current marketing of “natural hormone-free milk” and “organic” milk.

Still, diseases do not follow governmental decrees. The United States does not have mechanisms in place for specifically following food ingredients or additives approved by the FDA after they enter the marketplace as occurs with drugs. If chronic negative effects from long-term consumption of transgenic crops occurred across the broad population, they might not be attributed to the cause for years because hardly anyone is watching. The National Research Council has recognized needs for in-market follow-up of certain types of new foods [13] and has suggested legislation.

Drivers and Tools for the Future

The basic driver for the biotechnology evolution is rapid growth of the population and its needs. World population doubled (from 3 to 6 billion persons) between 1960 and 1999. In theory, this meant learning to grow as much food in 39 years as was learned during the first 10,000 years of agriculture. In practice, much more was accomplished, including increased life expectancy and improved health and living standards. A slowdown in population growth is expected. Currently, few forecasts venture beyond a world population of nine billion in 2043, still a sizeable increase. Significant quantities of easily accessed fossil energy (petroleum, gas, and coal) and minerals already have been exhausted. With high population densities, solutions to disposal of wastes can no longer be dilution in air, water, or landfills. But, waste disposal and air and water reclamation, by known means, are energy-intensive and place additional loads on resources. There seems to be little choice but to more completely harness recurring energy sources such as sunshine, wind, falling water, and possibly ocean tides and to produce more recyclable food, textiles, building materials, coatings, plastics, and moldable materials through applied biotechnology. Whereas in the past, chemical processing options often were chosen because they are faster, enzymatic routes are more likely in the future because they require less energy. But we must become better applied biophysical chemists to implement such changes.

Our tools include the already discussed abilities to tailor transgenic plants, animals, microorganisms, enzymes, and pharmaceuticals to our needs. We live at a time when communications and transportation are developing rapidly, and the most promising insurance for peace appears to be an international trade so interdependent that rational nations would hesitate before upsetting the balance and linkages by wars. Confidence in the rapidly globalized trade requires reliable trading standards, uniform analytical methods and quality control practices such as ISO 9001–2000 14001–2004, and appropriate enforcement by exporting nations.

The digital computer age has brought us sophisticated analytical instruments and computation abilities to delve even deeper into basic sciences. It also has enabled close monitoring and feedback control of processes, even in remote inhospitable atmospheres, to ensure that operations, and materials and products storage, are continuing as intended.

Government policies do not always turn out as expected. It long was common practice in some countries to direct uneducated workers to production agriculture and to hand operations in food processing. But modern crop and animal production facilities are capital-intensive and require skilled operators and knowledgeable supervisors. The same is true in crop, animal, and seafood processing, where machines and sorters never tire and prove more effective than hand laborers. Where sanitation is critical, quality usually improves as fewer hands touch the product. Whereas some governments in developing nations have sought to create manual jobs in processing foods for local consumption, traders, available alternate suppliers, and eventually consumers will decide what will be carried to the international marketplace.

Many industries have adopted integrated planning. It is a management by objective (MBO)-type technique, often without a name. Integrated pest management (IPM) has been one of the most successful examples. The term was introduced in 1967 by R.F. Smith and R. van den Bosch and formalized by the US National Academy of Sciences in1969 [14]. The initial objective was to find ways to reduce amounts of insecticides used on cotton. As it developed, implementation included: (1) an exhaustive review of the factors leading to application of insecticides, and opportunities for using other options; (2) removal of refuges such as crop stubbles, which protect insects during winter, and host plants in fencerows; (3) consideration of life cycles of beneficial insects, which prey on the species to be controlled by the insecticide; and (4) realization that major crop damage occurs only after several generations of insect build-up, and relatively little is accomplished by spraying early, except killing beneficial insects that would help in control. The solution is closely monitoring numbers of undesirable insects on the crop and delaying spraying until costs are warranted by benefits. Significant reductions occurred in amounts and costs of insecticides used in applying these simple concepts. The principle has caught on quickly. Today, IPM systems are also used to control insects in schools, libraries, museums of natural history, and operations. But the main principles, (1) review the holistic system and interactions between alternative options and (2) continue to monitor the problem closely, but take remedial action only when benefits warrant the costs, are applicable to other management situations. Such approaches have led to energy savings, reduction of waste disposal costs, improvement of oil yield and stability, and increased profits in the edible fats and oils industry.

Biotechnology Practices in Soybean Production and Processing

A brief summary of biotechnology practices in modern production of soybean and oil follows. Farmers select planting seeds, which have been produced by breeding, hybridization, or transgenic means already described. Most varieties grown are "daylight determinant," and flower and produce seed only when day lengths shorten to their optimum photoperiod. The United States has been divided into ten parallel regions for soybean, each about 100–150 miles wide in latitude. Local dealers stock seed of the maturity group appropriate for their region [15]. The soil is prepared by plowing-harrowing, or disk harrowing, for planting. In "no-till" planting, the seed is drilled into the stubble of the previous year's crop, but an herbicide "burn-down" is applied first if weeds are obvious before planting. Farmers typically inoculate the seed with commercial rhizobia inoculum (*Rhizobium* and *Bradyrhizobium* genera) if soybean has not been grown recently or to refresh inoculation. These bacteria establish a symbiotic relationship and create root nodules on the legume which convert atmospheric nitrogen to ammonia usable by the plant. Efforts to induce nitrogen-fixing nodulation in the grasses (specifically corn) have been unsuccessful, but inoculation has been extended to other legume crops.

Farmers also may deposit fertilizer near the seed when planting, or drill it in the previous fall. Depths of topsoil and moisture levels vary in fields in slightly rolling country. The effects often can be seen by aerial and infrared photography. Programs for mapping fertility levels within fields by global positioning systems (GPS), and adjusting rates of fertilizer application as planting–fertilizing equipment moves through the field, have become available. GPS is also used for variable-rate application of other chemicals [16] and for autoguidance of tractors across fields with four-inch precision in strip tilling and planting of close rows [17].

Plant nutrition, seasonal temperatures, and moisture availability affect final composition of soybean and yield/acre. Plants typically create the protein systems in their seed first and add energy reserves (oil in the case of soybean) later before maturing and dying. If the plant is lightly frosted before maturing of the oilseed, it may reinitiate growth and deposit additional chlorophyll in the seed. This compound is oil-soluble and a very strong light-catalyzed prooxidant, which reduces shelf life of bottled oil. Additional efforts must be made to remove chlorophyll by absorption with bleaching clays and silica gels during oil refining. During the summer, the farmer may decide to speculate on the soybean futures market and commit some of the expected crop at a guaranteed price to ensure recovery of at least critical expenses.

Harvest (combining) of soybean continues in some localities even after light snowfall, although quality (as monitored by free fatty acids increases) and market value decrease. Price is also discounted for water-mottled soybean. Whenever soybean is harvested, drying to the 0.65–0.75 a_W range puts it into a dormant state and maximizes the remaining storage life. Drying can occur at the farm, at elevators, or at a processor's holding facilities. Seeds continue to respire in the dormant state and must be aerated, the amount dependent on storage temperature.

By law, organic foods should not be made from transgenic seed. Organic growers cannot use chemical fertilizers, herbicides, or insecticides, but "organic pesticides" are available. Standards may exist about acceptable previous crops on the same soil. Precautions must be taken to ensure the crop is not contaminated with transgenic seed and is identity-preserved (IP) during trading and shipping. The Agricultural Marketing Service of USDA supervises organic foods as a marketing alternative and regulates the National Organic Program.

Although soybean is the world's major oil currently, it is the secondary product after feed meals and food proteins in percent of weight yield and value per bushel processed. Oil extraction processes should not degrade the more valuable protein fractions, which usually is not a problem with soybean processed to make feed protein meals. Enzymatic degradations during extraction and processing of oils can include: (1) a variety of lipases, which can cleave free fatty acids from triglycerides and reduce yield of saleable neutral oil; (2) phospholipases, which can render the phosphatides (lecithins) water-insoluble, difficult to remove when refining, and shorten oil frying life; and (3) two lipoxygenases which can cause off-flavors in refined oils. Maintaining the seed at low water activity, equivalent to about 10–11% during processing, is helpful in slowing enzyme activity. The ideal approach would be to inactivate the enzymes very early in soybean processing, and effectiveness of such processing already has been demonstrated in small extraction plants.

Enzymes have been used to assist oil extraction and in *degumming* (phosphatides removal), splitting fatty acids from trigly-cerides, *interesterification* (rearranging fatty acids on triglyceride molecules), and preparation of specialty oils. These processes are described later in this chapter.

Introduction to Lipids

Fats and oils predominantly *are triesters* (triglycerides, triacylglycerols, TAG) of glycerol and aliphatic fatty acids containing up to 22 carbon atoms. *Waxes are esters of long-chain fatty acids,* usually containing 24–28 carbon atoms, with long-chain primary alcohols (16–36 carbon atoms) or with alcohols of the steroid group [18].

Fats and oils are members of a broader group of chemical substances called *lipids*, which has been classified by the National Research Council into: (1) nonpolar lipids, including esters of fatty acids (triacylglycerols and cholesteryl esters) that are virtually insoluble in water, but soluble in most organic solvents and enter metabolic pathways only after hydrolysis; and (2) polar or amphipathic lipids, including fatty acids, cholesterol, sphingolipids, and glycerolphospholipids (mainly lecithins). The term phospholipids (phosphatides) includes lecithins and sphingomyelins [19]. Other minor natural compounds, also extracted by low-polarity organic solvents, include fat-soluble vitamins, colors, and flavors.

Fats and oils have major roles in human nutrition. They are concentrated dietary sources of energy, providing approximately 9 kcal/g when metabolized compared with 4 kcal/g for carbohydrates and proteins, and account for about 36% of domestic caloric intake per capita [19]. Dietary lipids also can provide essential molecular structures that are synthesized by the body into compounds required for selective functioning of cell membranes and regulation of life processes.

Fats and oils modify product texture in preparation of foods, serve as heat transfer media in food frying, carry flavors, colors, and oil-soluble vitamins, improve mouthfeel, provide a sensation of product richness, and induce satiety. They are used as energy sources in feeds for domesticated animals, and as components of many industrial products, including soaps and detergents, lubricants, plastics and protective coatings, and printing inks, and as carriers of pesticides for aerial spraying, for controlling grain dust, and as feedstocks for manufacturing chemicals. Considerable public interest has developed in the last two decades in replenishable biodegradable carbon sources and in liquid fuels such as biodiesel.

Recent Fats and Oils Industry Changes

Although many chemistry and processing principles have long been established, the industry has undergone major changes in the last three decades, with many starting in the mid-1980s. Rising costs of energy have led to more efficient equipment designs and to the installation of heat recapture systems throughout modern extraction plants and refineries. In the United States, Occupational Safety and Health Protection Agency (OSHA) regulations to prevent injuries and protect the health of workers have led to increased use of safety guards, dust collection systems with shrouding of equipment and improved ventilation, oversight of workers entering dangerous areas such as bins, and periodic checks for hearing loss. Redesigning and retrofitting the equipment was expensive. Process control computers became available concurrently in the early 1990s, and many companies chose instead to install robots in health- and safety-risk areas and to automate processes for operation from control rooms. The few people now seen on extraction plant and refinery floors are mainly repair and cleaning personnel, with hardly any “operators.” With computers making process adjustments, product quality, defined as “uniformity,” typically has improved.

Environmental Protection Agency (EPA) air emissions regulations have led to increased dust controls and to reduced solvent losses in extraction plants. Regulations on the discharge of polluting process streams into public waterways have led to containment and treatment where required of rain runoff from grain storage and processing properties and even from employee parking lots. Silica gel adsorption (modified caustic refining) processes have been developed to avoid production of waste waters in refining oils and problems associated with their disposal. Similar changes are being adopted at various rates throughout the world.

The effects of economic development loans and private investments in developing countries in the 1960–1990 era have matured and are changing the global fats and oils industry. World production of soybean has increased 7.5 times since 1960, with approximately 44% of the world’s crop now entering global trade as soybean, meal, and oil [20].

The growth of palm oil production has been even more spectacular. Hardly known as a crop after World War II, palm oil production increased nearly 21 times since 1960. World production of palm oil has surpassed that of soybean oil. Currently, the total world production of soybean oil is 42.00 million metric tons, whereas palm oil is 47.47 million metric tons (2010/2011). This has brought equatorial countries such as Malaysia and Indonesia into the group of leading edible oil producing and exporting nations. Establishment of trading rules, product definitions and standards, and analytical procedures for the erupting world market also has been part of the technical progress.

Strong competition in the world's oilseeds market, and concerns about the environment, have refocused interest in the United States on *nonfood-nonfeed uses* of crops, including biodegradable applications, renewable hydrocarbon sources, including liquid fuels, and *chemurgy,* the use of agricultural crops as chemicals feed stocks [21]. Nor is the United States alone in the current movement. Germany, Hungary, France, and other European countries, whose climates are too cold for raising soybean or oil palm but can raise rapeseed, recently have installed biodiesel production facilities.

AOCS, an Information Source

This chapter cannot summarize advances in all related technologies and concentrates on current major fats and oils extraction, refining, and utilization practices. The reader may need to browse the Internet for commercial information and computer-based technical abstract services for research reports. Much of the world's research on fats and oils processing and utilization is reported in the *Journal of the American Oil Chemists' Society* (*JAOCS*) published by the AOCS Press, an activity of AOCS (An International Society for the Science and Technology of Fats, Oils and Related Materials), Champaign, Illinois. The AOCS Press also publishes proceedings of selected Society conferences, a broad variety of related books, and the following journals: *INFORM*, a monthly business, news, and scientific publication addressed to professionals interested in the science and technology of fats and oils, surfactants, detergents, proteins, oleochemicals, and related substances; *Oil Mill Gazetteer,* a monthly news magazine for oil extraction and refining plants; *Lipids,* a monthly journal on basic chemistry and nutrition of lipids; *Journal of Surfactants and Detergents* (*JDS*)*,* a quarterly science and news journal on the practical and theoretical aspects of oleochemical and petrochemical surfactants, soaps, and detergents.

The Technical Services function of AOCS establishes, revises, and annually updates "AOCS Methods," the *Official Methods and Recommended Practices of the American Oil Chemists Society* [22] for fats, oils, and soap technology; *Spanish AOCS Methods,* a Spanish translation of the more commonly used AOCS Methods; and *Physical and Chemical Characteristics of Oils, Fats and Waxes.* Leaders of the methods development committees coordinate closely with AOAC International (formerly the Association of Official Analytical Chemists). AOCS Methods are recognized as "Official Methods" in US FDA activities and when litigation becomes necessary in industry trade. Additionally, the Technical Services function operates a Laboratory Proficiency Program (formerly the *Smalley Check Sample Program*) and oversees distribution and statistical analysis of 30 different series of basic laboratory quality assurance/quality control test samples. Certification as AOCS Approved Chemists, or as AOCS Certified Laboratories, and successful participation in the Laboratory Proficiency Program, is expected for industry arbitrators and referees.

Nutrition and Health Implications

Comments on fats and oils in nutrition and human and animal health are limited in this chapter, primarily because of frequent changes in advice given, but regulations are summarized. Three classes of foods exist: generally recognized as safe (GRAS) foods and ingredients, food additives, and food supplements. All are monitored by the FDA, but at different levels of review; meat products are monitored by the Federal Safety Inspection Service (FSIS) of the USDA. Within the FDA, foods are under the jurisdiction of the Center for Food Safety and Applied Nutrition (CFSAN), and animal feeds under the Center for Veterinary Medicine (CVM). Readers are referred to other authorities [23, 24], and FDA and USDA Web-sites, for more details about US food and feed regulatory systems.

The US government does not guarantee the safety of foods; it is the responsibility of respective manufacturers, and ultimately is enforced by torts litigation. USFDA-CFSAN decides whether a food or ingredient is listed as GRAS (useable without restriction), or as a food additive (useable in limited applications and amounts), on the basis of thorough review of applications and may request additional tests for proposed additives. *Food supplements* (vitamins, minerals, botanicals, plant extracts, etc.) may be marketed directly by the manufacturer, but the FDA has the power to check on underlying safety data and to remove unsafe products from the market. Food supplements also include *nutraceuticals, functional foods,* and *designer foods*—groups of products consumed for expected health benefits aside from nutrition and medication. These products became a major growth market in the last decade, but at times have been launched with limited documentation, and possibly knowledge about effectiveness. The FDA earlier held that food and drugs were separate classifications and did not allow health claims to be made for food products until the 1990s. Congressional legislation, including the Nutrition Labeling and Education Act of 1990, Dietary Supplement Health and Education Act of 1994, and the Food and Drug Administration Modernization Act of 1997, led to today's practices of allowing health claims, provided specific requirements are met [25].

A basic problem when considering food safety is the wide range of genetics, physiological ages, and individual health status in the United States population of nearly 300 million. Almost any product may prove adverse for an unpredictable portion of the population, especially if consumed in large quantities.

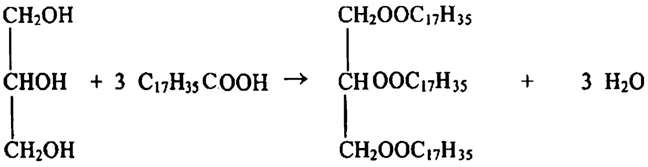
Many of the extraction, concentration, and purification techniques and equipment used in preparation of nutraceuticals originated in the vegetable oils and proteins processing industries. Byproduct streams often are further purified for this market.

Nomenclature and Molecular Structures

General

The choice of the term "oil" or "fat" usually is based on tradition and the physical state of the material. Generally, *oils* are liquid at ambient temperatures, and *fats* are semisolid mixtures of crystals in oil. *Fats* often are of animal origin (beef tallow, pork lard, and butter fat) or *hardened* (hydrogenated, interesterified, or thermally fractionated) vegetable oils, whereas oils are extracted from plant seeds or tissues or fish. In English-speaking countries outside the United States, oils liquid at room temperature sometimes are called *soft oils,* and those hard or pasty are called *hard oils*. Nutritionists generally use "fats" for solids or liquids.

Over 95% of the weight of most extracted/separated food fats are TAG (triacylglycerols or triglycerides) formed by the enzymatic combination of glycerol (a trihydric alcohol) with three fatty acids also yielding one molecule of water for each ester linkage:



$$\begin{array}{lcl} \begin{array}{l} CH_2OH \\ | \\ CHOH \\ | \\ CH_2OH \end{array} + 3\ C_{17}H_{35}COOH \rightarrow \begin{array}{l} CH_2OOC_{17}H_{35} \\ | \\ CHOOC_{17}H_{35} \\ | \\ CH_2OOC_{17}H_{35} \end{array} + 3\ H_2O \end{array}$$

Glycerol + 3 Stearic acids → Glycerol tristearate + 3 Water
(tristearin)

The reaction is reversible and favored by the presence of moisture and catalysts including lipases, alkalis, and alkaline metals. In the oleochemicals industry, TAG are split by high-pressure steam. Unassociated fatty acids are called free fatty acids or FFA.

Fatty Acids

Fatty acids are the building blocks of TAG. More than 90% of fatty acids have an even number of carbon atoms and are in aliphatic chains ranging from 4 to 22 carbons in length. The major fatty acid synthesis pathway is production of stearic acid (18 carbons) after which separate desaturase systems introduce 1, 2, or 3 unsaturated (double) bonds. Additional enzymes become active in elongating the chain as needed. Shorter fatty acids also are produced. Trace amounts of odd-number carbon fatty acids are found in most fats and also have been synthesized for research purposes. Microorganisms frequently produce odd-number carbon fatty acids, with heptadecenoic (17 carbon) acid a major component of *Candida tropicalis* yeast fat. Up to 8% C_{17} fatty acids have been found in milk and meat fats of ruminants (cattle, sheep, goats) and are of rumen microbe origin.

The names of common fatty acids under several conventions, carbon numbers, and selected properties are shown in Table 34.1. The common (trivial) names of some fatty acids are of long standing and often indicate the initial source studied. As examples: butyric acid is a major component of butter flavor; the 6, 8, and 10 saturated fatty acids have been called the *goaty acids* because they impart the characteristic flavors of goat and sheep milks and their cheeses. The terms *olein* and *stearin* were applied to the liquid and solid fractions, respectively, of tallow separated by pressing in early manufacture of oleomargarine and compounded shortenings. The iodine value (IV) is an indicator of the unsaturation of a fatty acid or fat/oil. It is determined by AOCS Method Tg 1a-64 or Cd 1–25, respectively: the higher the IV, the more unsaturated the fat and the lower the melting point.

Fatty acids sometimes are designated by the number of carbon atoms in the chain, followed by a colon with additional numbers indicating the number of double bonds. In the 18-carbon series, C18:0, C18:1, C18:2, and C18:3 represent *stearic, oleic, linoleic*, and *linolenic* acids, respectively. One- or two-letter abbreviations sometimes are used, with these acids designated as St, O, L, and Ln, respectively.

Under the most common convention, fatty acids are named on the basis of the number of carbon atoms, starting with the terminal carboxyl (-COOH) carbon as number "1."

Table 34.1 Names and characteristics of some important fatty acids

Carbon atoms and abbreviations	Common name	Symbol	Systematic name	Melting point (°C)	Iodine value	Common sources
Saturated fatty acids						
3:0	Propionic	–	Propanoic	−20.8	–	Bacterial fermentation
4:0	Butyric	B	Butanoic	−7.9	–	Milk fats
5:0	Valeric	–	Pentanoic	−33.8	–	Bacterial fermentation
5:0	Isovaleric	–	3-Methylbutanoic	−51.0	–	Dolphin and porpoise fats
6:0	Caproic	H	Hexanoic	−3.4	–	Milk fats, some seed oils
8:0	Caprylic	OC	Octanoic	16.7	–	Milk fats, *Palmae* seed oils
10:0	Capric	D	Decanoic	31.6	–	Sheep and goat milk, palm seed oils, sperm head oil
12:0	Lauric	La	Dodecanoic	44.2	–	Coconut oil
14:0	Myristic	M	Tetradecanoic	54.4	–	Palm and coconut oils
16:0	Palmitic	P	Hexadecanoic	62.9	–	Palm oil, most oilseeds and animal fats
18:0	Stearic	St	Octadecanoic	69.6	–	Animal fats
19:0	Tuberculostearic	–	10-Methylstearic	11.0	–	Tubercle bacillus lipids
20:0	Arachidic	Ad	Eicosanoic	75.4	–	Some animal fats
22:0	Behenic	–	Docosanoic	81.0	–	Peanut and various other seed oils
24:0	Lignoceric	–	Tetracosanoic	84.2	–	Minor amounts in some seed oils
26:0	Cerotic	–	Hexacosanoic	87.8	–	Plant waxes
28:0	Montanic	–	Octacosanoic	90.9	–	Beeswax and other waxes
30:0	Mellisic	–	Triacontanoic	93.6	–	Beeswax and other waxes
Unsaturated fatty acids						
10:1	Caproleic	–	9-Decenoic	–	149.1	Milk fats
10:2	Stillingic	–	2,4-Decadienoic	–	–	*Stillingia* oil
12:1	Lauroleic	–	2-Dodecenoic	–	128.0	Butterfat
14:1	Myristoleic	–	9-Tetradecenoic	18.5	112.1	Some feed fats, milk fats
16:1 (*n*–7)	Palmitoleic	–	9-Hexadecenoic	0.5	99.8	Many fats and marine oils
16:3	Hiragonic	–	6,10,14-Hexadecatrienoic	–	–	Sardine oil
17:1	–	–	9-Heptadecenoic	14.0	–	*Candida tropicallis* yeast
18:1 (t-oleic)	Elaidic	–	9-Octadecenoic	43.7	–	Butterfat
18:1 (*n*–9)	Oleic		9-Octadecenoic	16.3	89.9	Almost all fats and oils
18:1	Petroselinic	–	6-Octadecenoic	30–33	–	Parsley seed oil
18:1 (*n*–7)	Vaccenic	–	11-Octadecenoic	44.0	–	Butterfat, seed oils
18:2 (*n*–6)	Linoleic	Lo	9,12-Octadecadienoic	−6.5	181.0	Most vegetable oils
18:3 (*n*–6)	(gamma) Linolenic	–	6,9,12-Octadecatrienoic	–	–	(Omega-6); Evening primrose, borage, vegetable oils
18:3(*t*)	Eleostearic	–	9,11,13-Octadecatrienoic	–	–	Tung oil
18:3 (*n*-3)	(alpha)Linolenic	Ln	9,12,15-Octadecatrienoic	−12.8	273.5	(Omega-3); Linseed, soybean, canola, other vegetable oils
20:1	Gadoleic	–	11-Eicosenoic	23–24	81.8	Some fish oils
20:3 (*n*–9)	Eicosatrienoic		5,8,11-Eicosatrienoic	–	–	Brain phospholipids
20:3 (*n*–6)	Dihomo-γ linolenic		8,11,14-Eicosatrienoic	–	–	Shark liver oil
20:5 (*n*–3)	EPA		5,8,11,14,17-Eicosapentanoic	−33.5	75.0	Fish, plants
22:1	Erucic	E	13-Docosenoic	34	–	Rapeseed oil
22:2			13,16-Docosadienoic	–	–	
22:5 (*n*–3)	DPA		7,10,13,16,19-Docosapentaneoic	–	–	Fish oils
22:6 (*n*–3)	DHA		4,7,10,13,16,19-Docosahexaenoic	–	–	Cooler climate fish oils
Fatty acids of more unusual structure						
18	Chaulmoogric	–	13,(2-Cyclopentenyl) tridecanoic	68.5	90.5	*Chaulmoogra* oil
18	Malvalic	–	8,9-Methylene-8-heptadecenoic	–	–	*Malvaceae* seeds, cottonseed
18	Ricinoleic	–	12-Hydroxy-9-octadecenoic	5.5	86.0	Castor oil
18	Vernolic	–	12,13-Epoxy-9-octadecenoic	30–31	–	Some *Compositae* seeds
19	Sterculic	–	9,10-Methylene-9-octadecenoic	–	–	*Sterculiaceae* seeds, cottonseed

(continued)

Table 34.1 (continued)

Carbon atoms and abbreviations	Common name	Symbol	Systematic name	Melting point (°C)	Iodine value	Common sources
20	Arachidonic	–	5,8,11,14-Eicosatetraenoic	−49.5	333.5	Lard
20	–	–	5,8,11,14,17-Eicosapentaenoic	–	–	Some fish oil
20	Lesquerolic	–	14-Hydroxy-11-Eicosenoic	–	–	*Lesquerella* seed oil
22	–	–	4,7,10,13,16,19-Docosahexaenoic	–	–	Some fish oil

The terminal letter *e* of the respective alkane hydrocarbon is replaced with *oic* to indicate an acid; thus:

$CH_3CH_2CH_2CH_2CH_2CH_2CH_2CH_3$

Octane

8 7 6 5 4 3 2 1

$CH_3CH_2CH_2CH_2CH_2CH_2CH_2COOH$

Octanoic acid

The suffix *dioic is* used if the acid contains two carboxyl groups.

Occasionally in the literature, the carboxyl unit is regarded as a group substituted for hydrogen. In this case, the number 1 location is moved one position away from the reactive end, and the suffix *carboxylic* acid is added:

5 4 3 2 1

$CH_3CH_2CH_2CH_2CH_2COOH$

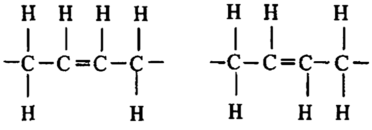
1 - Pentanecarboxylic acid

(hexanoic acid)

(caproic acid)

A double bond between two carbon atoms indicates the site, and possibly type, of hydrogen unsaturation. When double bonds are present, the suffix *anoic* is changed to *enoic, dienoic*, or *trienoic* to indicate the number of bonds. The location of the first carbon in the double bond is indicated by a number preceding the systemic name. Under International Union of Pure and Applied Chemistry (IUPAC) convention, stearic, oleic, linoleic, and linolenic acids are called octadecanoic, 9-octadecenoic, 9,12-octadecadienoic, and 9,12,15-octadecatrienoic acids, respectively.

The 3D geometric configuration of hydrogens at double bonds is indicated on paper by the Latin prefixes *cis* (both hydrogens on one side) and *trans* (hydrogens across from each other). Linoleic acid, with the *cis* configuration in both double bonds, is called *cis*-9, *cis*-12-octadecadienoic acid. Most fatty acids occur in nature in the *cis* form. Oleic acid is in the *cis* configuration and the corresponding *trans* form is called elaidic acid.



cis ***trans***

Increasing the number of double bonds lowers the melting point of the fatty acid from its fully or partially saturated form. Double bonds also are the sites of oxidation initiation on free fatty acids and within triacylglycerols. Creating a *trans* bond by hydrogenation increases the melting point, but not as much as full saturation.

Locations of the double bonds, and especially the last double bond in long-chain polyunsaturated fatty acids, are of special interest. Whereas chemists traditionally count with the carboxyl carbon (-COOH) assigned number “1,” biochemists and nutritionists assign number “1” to the methyl carbon (CH_3^-). Thus, linoleic acid (9,12-octadecadienoic acid), known as C18:2 to a chemist, carries the same trivial name for biochemists but is known as C 18:2 ω-6 or C 18:2 *n*-6 with *omega* or *n* signifying “count from the methyl carbon.” From a nutrition viewpoint, four families of fatty acids (*n*-7, *n*-9, *n*-6, and *n*-3) exist. Members of the *n*-7 and *n*-9 families generally are synthesized by each species as needed, but members of the *n*-6 and *n*-3 families may be dietary essential either because the species is unable to synthesize the fatty acid, or metabolic mechanisms are impaired in specific individuals. Plants, including plankton, are the ultimate source of dietary essential fatty acids (EFAs). Humans and most animals are considered to require linoleic and linolenic acids (C 18:2*n*-6 and C 18:3*n*-3, respectively). Fish vary by species, with carnivorous members like the salmonoids (salmon and trout) requiring EPA (C20:5*n*-3;5,8,11,14,17-eicosapentaenoic acid) and DHA (C22:6*n*-3;4,7,10,13,16,19-docosahexaenoic acid) when raised in captivity [26].

Contents of individual fatty acids in the fat of a species can vary by over 100%. Table 34.2 summarizes general fatty acids contents of the major edible fats and oils, and Table 34.3 does likewise for industrial fats and oils.

On a global basis for all species, oils produced in the tropics are more completely saturated and have the highest

melting points, with melting points decreasing with distance from the equator (in north and south latitudes). Many dietary fatty acids are transposed from plant or plankton feed sources to body tissues, and fish oils from the Arctic and Antarctic species generally melt at lower temperatures than those from the tropics. Many oilseed species are *daylight determinate;* that is, they require a specific number of hours of sunlight to blossom and produce seed. Thus, a plant

grown from seed adapted to another latitude may sprout and produce much foliage, but not flower and produce seed. Earlier soybean and sesame varieties were mainly light determinate, but indeterminate varieties also exist now.

Each oil has its unique properties and history, as demonstrated by sunflower seed. Sunflowers generally are indeterminate, with the same seed productive in the prairie provinces of Canada and in Mexico. When polyunsaturated oils were promoted in the 1960s and 1970s, United States processors of table oils (for salads and light cooking) purchased only sunflower seed grown north of the 39th parallel in the United States and Canada to maximize the polyunsaturated fatty acids (PUFA) content of their products. Fall seed maturation temperatures in the Northern climates are lower, resulting in higher PUFA and lower monounsaturates (oleic) contents than sunflower seed maturing at the same time in Texas. However, the higher oleic acid oil of Texas seed is less susceptible to oxidation and produces deep-fried foods and snacks with longer shelf lives. If growers in areas of Texas, capable of raising two crops annually, want to produce high-polyunsaturated oil, they merely have to time their second planting for seed to mature in the cooler winter months [27, 28].

Several important changes occurred in the early 1980s. First, oil processors realized that a significant market existed for high-stability oils and began seeking higher oleic acid content oils. Second, the medical community and nutritionists realized that, although PUFA do not cause cancer, they might promote growth of existing cancer cells more than monounsaturated fatty acid (oleic). Emphasis was changed from encouraging consumption of polyunsaturated vegetable oils to reducing fat intake in general, with recommendations that no more than 30% of dietary calories come from fats, of which no more than 10% are saturated (animal, tropical, or hydrogenated) fats [19], with some nutritionists believing that PUFA also be no more than 10%, essentially leaving at least 10% for monounsaturated fat.

The world's traditional monounsaturated fat is olive oil (~70% oleic acid), historically consumed in countries surrounding the Mediterranean Sea, thus the term *Mediterranean Diet*. However, olive oil is expensive and too limited in supply to satisfy the growing popularity of high-oleic acid oils. Thus, US table oil processors turned to importing high-oleic acid content canola oil from Canada. A mid-oleic sunflower seed oil (~65% oleic acid), grown in the northern states, was introduced to the fried foods industry in 2000. High oleic acid varieties of safflower and peanut have been introduced, and a transgenic high-oleic acid soybean was patented in late 2001. Two nontransgenic lines of high-oleic acid sunflowers, containing 80–82 and 90–92% oleic acid, were developed in the early 1980s, and their oils were marketed as feedstock for oleochemicals production. The venture was not commercially successful. Interest in nontraditional fats/oils sources, including newly domesticated crops, forest oilseeds, bacteria, yeasts, molds, and algae, has increased in recent years. The reader may consult the references and later publications for unusual fatty acids and their occurrence in various sources [29, 30].

Triacylglycerols

Glycerol esterified with one, two, or three fatty acids is found in nature and can be made commercially. The designations monoacylgly-cerol, diacylglycerol, and triacylglycerol (TAG), respectively, now are encouraged in the scientific literature, but the older mono-, di-, and triglyceride terminology is used in commerce. As the number of fatty esters on the glycerin "backbone" decreases, the compound becomes more polar and functionally effective as a surfactant. Mono- and diacylglycerols are further described throughout this chapter.

Triacylglycerols are named in various ways. For example, unsaturated fatty acids sometimes are indicated as U and the saturated as S. If glycerol is completely esterified with stearic acid, the resulting monoacid TAG may be designated as SSS, or, more descriptively as StStSt, tristearin, tristearoylglycerol, or glycerol tristearate.

If more than one species of fatty acid is present, its relative location on the glycerol may be important to its functionality, enzyme susceptibility, and oxidation stability of the fat/oil. Several conventions have been developed to specify arrangements of fatty acids on the glycerol molecule (if known). To avoid confusion from inversion of the 1 and 3 carbon positions, hierarchies have been established to designate the number 1 carbon under the R/S (*rectus-sinisturs*) system [31] and the *sn* (stereospecific numbering) system [32]. In the R/S system, the longest chain fatty acid is assigned to the 1 position, the second longest to 2, and the shortest to 3.

If the positions of fatty acids on the TAG molecule are known, the *sn* system is preferred for identifying their locations: *sn* immediately before the word glycerol, as in 1-stearoyl-2-oleoyl-3-myristoyl-*sn*-glycerol, identifies the respective fatty acids in the 1, 2, and 3 positions; the term *rac* (racemic mixture), as in *rac*-StOM, identifies the middle acid in the 2-glycerol position and the remaining fatty acids are equally divided between the *sn*-1 and *sn*-3 positions; and the term β, as in β-StOM, identifies the middle acid in the 2-glycerol position, but distribution of the other two acids is unknown [33]. Despite international efforts to standardize chemical terminology and abbreviations, a variety is still used, especially in *cis* and *trans* notations.

Table 34.4 Relative rates of oxidation and hydrogenation of fatty acid chains ([a]Modified from Beckman [34])

Fatty acid	Iodine value	Relative oxidation rate	Relative hydrogenation rate
Stearic (18:0)	0	1	0
Oleic (9*cis*-18:1)	90	10	1
Linoleic (9*cis*, 12*cis*-19:2)	181	100	20
Linolenic (9*cis*, 12*cis*, 15*cis*-18:3)	274	150	40

Oxidation

As shown in Table 34.4, oxidation and hydrogenation reactivity of a fatty acid, in free form or as part of a TAG, increases with the number of double bonds [34]. Oxidation of fatty acids and TAG (aldehyde formation, breakdown into shorter chains, and crosslinking to form polymers) is initiated at double-bond sites. However, linoleic acid, C18:2 *n*-6, does not decompose into a mixture of C9, C3, and C6 compounds. Instead, as the molecule starts degrading, positions of the double bonds migrate and provide many opportunities for splitting. Over 250 different breakdown compounds have been found [33, 35–38]. Part of the confusion about oxidation reactions is related to the type present, with light-induced photosensitized singlet oxygen oxidation the fastest [39]. For this reason, removal of photo-sensitizers such as chlorophylls and porphyrins during refining and use of oil is extremely important.

The extent of prior oxidative activity in a fat sample may be estimated by the following tests: Peroxide Value (PV), a titrametric method (AOCS Method Cd 8–53); thiobarbituric acid test (TBA), which measures the presence of malonaldehyde; Anisidine Value-Totox; Kreis test; oxirane test; total and volatile carbonyl compounds content; chromatographic analysis; ultraviolet spectroscopy; fluorescence; and especially organoleptic evaluation. However, the resulting peroxides are unstable and decompose. Peroxide values are not cumulative and, alone, are not always indicative of the extent of earlier oxidation. An oil sample may be starting to degrade or may already have passed through a serious oxidation cycle; thus, age and history of the sample should be considered in forming a conclusion.

Predisposition (susceptibility) to oxidation can be estimated for oils and fats by the Active Oxygen Method (AOM) and Oil Stability Index (OSI) for oils and fats and by the Schall oven test or the oxygen bomb method for fat-containing products. The stability of triglycerides formerly was determined by the AOM (AOCS Method, Cd 12–93), in which heated air was bubbled through a heated liquid sample of the oil or fat, and the number of hours for the sample to reach 100 milliequivalents (meq) of peroxide was recorded. The AOM procedure was put in *surplus status* (still legal but not preferred) in 1997 and the focus then shifted to the Oil Stability Index (OSI) (AOCS Method, Cd 12b-92). However, AOM is still used in product and purchase specifications and in reports. In the OSI procedure, heated air is bubbled through heated liquid triglycerides and is scrubbed on exiting in a bath of deionized water, whose conductivity is continuously monitored spectrophotometrically. Absorption of polar degradation products is noticed immediately. Whereas the AOM method determines the time for the triglyceride to reach a specific level of oxidation (100 meq peroxide value), OSI determines the *induction period* (time required to exhaust the antioxidant properties), but not oxidation progress in the oil. OSI values always are lower (less time) than AOM values.

Biohydrogenation and Conjugated Linoleic Acids

Rumen microorganisms, in cattle, sheep, and other ruminants, hydrolyze exposed TAG in feeds and metabolize the glycerol. The unsaturated FFA are especially toxic to microorganisms and are *biohydrogenated* by enzymes in microbial cell walls to prevent permeation into their cells, possibly by raising their melting points above rumen temperature. Although polyunsaturated fatty acids can be reduced to stearic acid, rumen hydrogenation often is incomplete. It yields products such as monounsaturated vaccenic acid (*trans*-11-octadecenoic acid; *trans*-11 C18:1) and conjugated linoleic acids (CLA) in which the methylene carbon in the C9 through C13 (—C═C—C—C═C—) sequence of linoleic acid is eliminated to form a *conjugated sequence* of double bonds (—C═C—C═C—). The conjugated sequence can appear in many positional isomers along the 18-carbon chain, usually between carbons C6 and C14, resulting in a variety of CLA. Two of the CLA, 9 *cis*-11 *trans*-18:2 (rumenic acid), and 10 *trans*-12 *cis*-octadecadienoic acid have shown physiological activity: the 9,11-*ct* CLA isomer displaying antimutagenic properties, and the 10,12-*tc* CLA isomer displaying antifat deposit and cholesterol-modulating properties [40, 41].

Although more research is needed to document consistent modes of action, capsules containing CLA produced by microbial fermentation are sold as food supplements. CLA in ruminant products are considered natural, and levels of up to 1.5% of the fat in beef and 6% of the fat in cheeses made from spring pasture milk have been reported.

Vaccenic acid and CLA conjugation were once thought not to exist in plant oils, but with improved analytical instruments and methods, are increasingly reported, especially in spices. Conjugation also is an early step in chemical hydrogenation and in initiation of oxidative degradation of fats and oils. Recent research further supports that the majority (78%) of c9,t11-CLA in cow's milk is produced exogenously from body fat vaccenic acid in the mammary gland by *delta*-9 desaturase [42].

Recently, in 2008, the United States Food and Drug Administration (FDA) approved CLA containing conjugated *cis* and *trans* double bonds as a food ingredient. The announcement states that CLA is generally regarded as safe for use in foods. This clears the way for CLA, to be used as an ingredient in foods and beverages sold in the United States.

Fatty Acid and Triacylglycerol Melting Characteristics

Body temperatures are approximately 37°C/98.6°F for humans; 38.5–39.5°C/101–103°F for domestic animals; and 40.5–41.5°C/105–107°F for poultry. As shown in Table 34.1, the longest saturated fatty acid that is fluid at these temperatures is caproic (C10:0). All longer saturated fatty acids must be accompanied by lower melting unsaturated fatty acids as in a TAG structure to be fluid. The C18 oleic acid (*c*-9-octadecenoic acid) has a melting point of 16.3°C, the *trans* isomer elaidic acid (*t*-9-octadecenoic acid) melts at 43.7°C, and the biohydrogenated product *trans*-vaccenic acid (*t*-11-octacedenoic acid) melts at 44°C [40].

Fat digestion and absorption in mammals occur in the small intestine and mainly consist of emulsification of TAG by bile salts, lecithin, and agitation, followed by pancreatic lipase cleavage at the 1,3 positions to produce free fatty acids and 2-monoglycerides. These are carried by the bile to surfaces of the microvilli, where they are absorbed through the membranes into the intestinal lymph. While passing through the intestinal epithelial cells, the fatty acids and monoglycerides are resynthesized into new TAG that are transported, mainly in lymph chylomicrons, through the thoracic lymph duct which empties into the circulatory blood [43]. (Although the free fatty acids may be rearranged onto new TAG, fatty acids in the 2-position remain as before.) Animals have various mechanisms for ferrying fatty acids during absorption at the small intestine, and moving fatty acids and triglycerides through their circulatory systems. Readers interested in details are referred to books on medical physiology.

The positioning of fatty acids on the triglyceride chain follows several patterns. If unsaturated fatty acids are limited in availability, nature tends to place them in the number 2 position to obtain the lowest melting point for a plant's triglycerides. If more plentiful, the preferred positions will be 2 and 1 or 3 or both [44]. In contrast, saturated fatty acids are more likely to be in the 2 position in fats of warm-blooded animals, with palmitic acid in the 2 position in (pork) lard as an example.

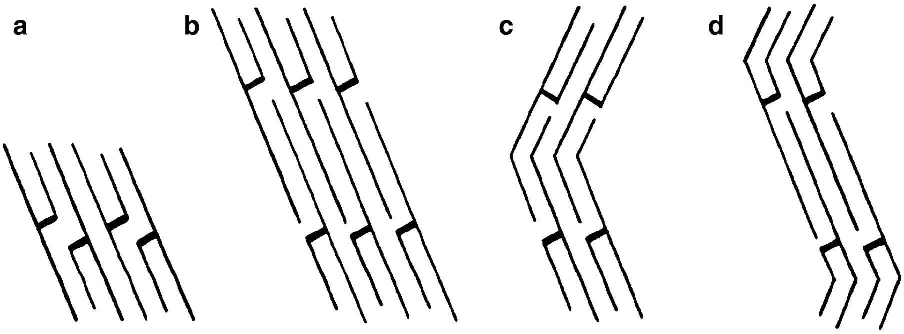

Fig. 34.1 Drawings of two- and three-chain triacylglycerol layers: (**a**) saturated monoacid SSS-type; (**b**) saturated symmetrical PSP-type where 2 chain differs from 1 and 3 chains in length; (**c**) symmetrical POP-type where 2 chain is unsaturated; and (**d**) symmetrical OPO-type where 1 and 3 chains are unsaturated. Crystals grow in bilayer units

Factors affecting the melting points of specific fat samples include: the types of fatty acids present (lengths of the fatty acids chains, number and location of *cis* and *trans* double bonds in the chains), location of specific fatty acids on the glycerol, compatibility of the different TAG in the mixture, and types of crystals present. Melting points increase with chain length. *Trans* fatty acids always have higher melting points than their *cis* counterparts for any chain length. Where only one double bond exists in a fatty acid, as in C18:1, the melting point is lower if it is located after an odd-number carbon than an even-number carbon, and also if the double bond is located near the middle of the chain as compared with a location at either end [45]. Compatibility of mixed fats from different sources can be a factor. For example, the melting points of multifatty acid TAG, consisting primarily of 16–18 carbon fatty acids, generally rise smoothly with increased content of higher melting fats. However, when TAG with 12–16 carbon fatty acid fats (from coconut and palm kernel oils) are added, concentration-related eutectic points and incompatibility (miscibility gaps) may occur [46–48]. Chemical interesterification of natural fat usually raises its melting point.

Polymorphism and Crystal Types

Polymorphism means "many bodies." Having determined the melting point of tristearin in 1849, Heintz continued to heat the capillary and witnessed: resolidification, a second melting point at a higher temperature, and resolidification and a third melting point for the same sample. Duffy confirmed the principle and reported three melting points, at approximately 52, 64, and 70°C in 1853. Later, five and even seven crystal forms were reported for some fatty acids and mono- and mixed-acid TAG, depending on the heating and cooling history of the sample [49].

As fatty acids or TAG cool, Gibbs free energy ($G = H - TS$) decreases by reduction of both enthalpy (H) and entropy (S, the degree of disorder). At decreased S, fatty acid chains assume pole-like structures that are less co-repulsive and pack more tightly into crystal lattices. It is widely accepted that, to participate in a crystal structure, TAG assume an "h" configuration (also called two-legged chair or tuning fork). This can be envisioned in our gravity-oriented world by assuming that each ester linkage acts as a hinge. If the glycerol number 2 carbon chain is held upright at the methyl end, the number 3 carbon chain hangs directly beneath it forming the back and one leg of the chair, and the number 1 carbon chain juts out at a right angle and curves downward to form the second leg [48, 50–54]. In order to save space, half of the chairs are packed upside down to form a palisade-like structure. A stack of two such structures forms a bilayer whose outer surfaces, consisting of methyl groups, display low inter-attraction. This helps explain why TAG crystals are relatively flat, grow rapidly in length and less rapidly in width by adding parallel chair structures, and grow slowly in thickness by adding additional bilayers.

Within each layer, the chair backs and legs can be further envisioned to act as a vertical loose palisade of knobby-surfaced posts. (Although the hydrocarbon chains have stiffened into pole shape, the carbon atoms are not positioned as beads on a tight string, but rather in sawtooth-like fashion with carbon–carbon bonds of 112°.) The poles can slide behind each other to obtain tighter packing with lowered free energy and can be tilted in two directions to allow the sawtooth-configured carbon atoms on adjacent chains to slip by each other and pack even more tightly. Furthermore, all the vertical units in one layer can be tilted at an opposing angle to the units in the other layer.

As shown in Fig. 34.1, if the three fatty acids in the TAG are saturated and approximately of the same length, each of the layers in the fat bilayer will be approximately two fatty acid chains in height. If the fatty acid on the number 2 glycerol carbon is appreciably shorter than those on the 1 and 3 carbons, each of the layers will be three chains thick. If the TAG is symmetrical, with the 2 position glycerol carbon or both the 1 and 3 carbons unsaturated, the layer will be three chains long but with a zigzag configuration to accommodate the *cis* configuration.

On rapid chilling, a glass (vitreous, γ) form occurs, which can change into a α or β' form as activation energy becomes available. The form showing the least amount of crystalline

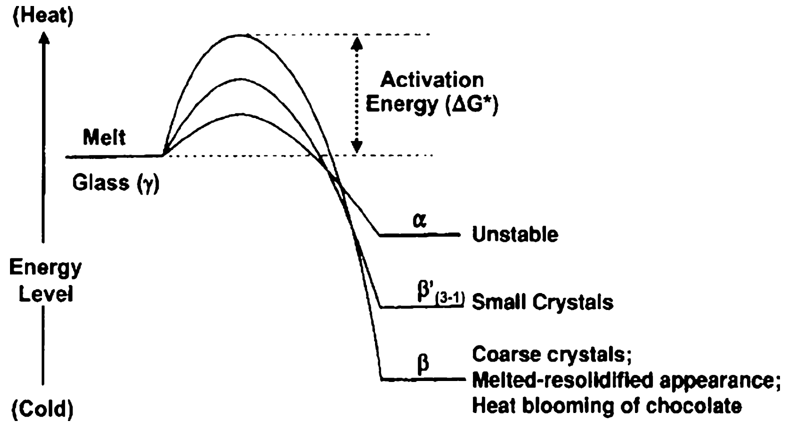

Fig. 34.2 Gibbs energy relationships of polymorphs of a triglyceride. (Modified from Sato [53] pp. 227–263)

order for a TAG, as determined by X-ray diffraction and infrared spectroscopy, is called the *alpha* (α) form. The most compact crystalline form, with the lowest free energy and the highest melting point, is called the *beta* (β) form. One or more intermediate *beta* prime (β') forms also may exist and are indicated as β'_3, β'_2, and β'_1 as the crystal progresses to tighter packing, a lower free energy state, and an increased melting point. When a TAG is cooled very slowly and without mixing, it preferentially assumes the β crystal form. But the tight packing of crystals requires time for alignment and may be thwarted by increased viscosity as the fat/oil mixture cools.

The free energy relationships between the different crystal forms are depicted in Fig. 34.2. Although the β crystal form has the lowest free energy G, induction of its formation requires the highest activation energy ΔG. Differential scanning calorimetry (DSC) often is used to follow free energy changes as fats melt and change between their polymorphic forms. Left to itself, a fat will seek its lowest thermodynamic free energy crystal state.

The formation of β crystals may intentionally be encouraged or hindered, depending on the processing application. The α crystals are relatively unstable, and commercial interest is primarily placed on the differences between the β' and β forms. Generally, β' crystals are smaller (about 0.5–2.0 μm diameter in shortening, and 5–10 μm in margarine [55]), whereas β crystals can grow as large as 20–30 μm. When the objective is to thermally fractionate fats by crystallization, production of the β form is encouraged by carefully controlling temperatures (to not shock the fat into a semi-stable β' form), gentle stirring, and nuclei seeding. The smaller β' crystals have smoother mouthfeel, minimize oiling from margarine, and entrap more air in creaming cake batters. Their production is intentionally encouraged by formulating mixtures of natural or preprocessed fats, by the inclusion of emulsifiers to interfere with crystal growth, and by rapid agitation during plasticizing of the margarine or shortening.

Figure 34.2 also helps explain the mechanisms of defects appearing in fatty products. If a fat that has been conditioned into a stable β' fine crystal form is suddenly exposed to thermal shock and then left unattended, the energy may activate it to settle into the lower energy, coarse β crystal form. Thus, chocolate bars, left to melt and cool several times in an automobile during the summer, turn coarse in texture and mousy in color.

An awareness of crystal packing characteristics and polymorphism helps one to understand incompatibility problems of different fats. Crystal formation has specific demands, and individual crystals in mixed systems each consists of only one species of TAG. However, surfactants and other molecules can act as impurities and interrupt crystal growth. Different TAG are considered compatible when they co-crystallize as separate crystals under the same conditions without the formation of a eutectic.

Other Lipids

Many minor lipids are extracted by nonpolar solvents along with FFA and TAG. Although present in small quantities, they must be removed in refining and sometimes are isolated and purified for medicinal and other uses.

Waxes

Waxes are fatty acid esters of alcohols and are formed by the general reaction:

$$\underset{\text{Alcohol}}{CH_3(CH_2)_nCH_2OH} + \underset{\text{Fatty acid}}{CH_3(CH_2)_nCOOH} \rightarrow$$

$$\underset{\text{Wax ester}}{CH_3(CH_2)_nCH_2COOCH_2(CH_2)CH_3} + \underset{\text{Water}}{H_2O}$$

Table 34.5 Sources and compositions of natural waxes

Type	Melting point (°C)	Main components
Animal waxes		
Beeswax	64	Myricyl palmitate
Chinese	82–84	Isoheptacosyl isoheptacosanoate, ceryl lignocerate
Shellac	81–82	Ceryl lignocerate, ceryl cerotate
Spermaceti	–	Cetyl palmitate
Wool (anhydrous lanolin)	36–42	Cholesteryl estolidic esters, alcohol esters of iso- and anteiso acids
Mineral waxes		
Montan	86	Tricontanyl esters of C_{28-30} acids
Petroleum waxes		
Microcrystalline	71–88	Hydrocarbons (490–800 molecular weights)
Paraffin	54–57	Hydrocarbons (350–420 molecular weights)
Vegetable waxes		
Bayberry	43–48	Trimyristin, tristearin
Candelilla	70–80	C_{29-33} hydrocarbons, simple esters and lactones
Carnauba	80–85	Esters of C_{26-30} alcohols and C_{26-30} ω-hydroxy acids
Esparto	69–81	Hydrocarbons, esters of C_{26-32} acids and alcohols
Japan	51–62	Tripalmitin
Jojoba (a liquid wax)	11–12	Docosenyl eicosanoate
Ouricury	79–85	Myricyl cerotate and hydroxycerotate
Sugarcane	79–81	Myricyl palmitate stigmasteryl palmitate

A major role of waxes in nature is the protection of plant tissues. Examples include coating upper surfaces of leaves to reduce dehydration by the sun and protecting seeds against moisture loss during storage. Minor quantities of waxes are always present in oils extracted by solvents. Waxes extracted from seed hulls cause cloudiness in refrigerated sunflower seed oil and failure of the 5.5-h cold test at 0°C. Sunflower seed oil may be dewaxed by first degumming or miscella refining to remove the natural emulsifier lecithin, which limits the growth of wax crystals, and then winterizing (chilling and filtering) the oil or its *miscella* (oil in its extraction solvent) [56, 57]. With the improvement of dehulling equipment, some sunflower seed processors remove the hulls before extraction. Extracted rice bran, a relatively recent development in the United States, contains waxes with potential commercial promise. Methyl and ethyl fatty acids esters, used as liquid fuels, solvents, and in other applications, also are "waxes" of short-chain alcohols; these are described later.

Waxes are common forms of high-energy storage, in the oils of fish and other marine animals. The major lipids of commercial whale oil consist of approximately 65% waxes and 35% TAG. The lipids of Australian orange roughy (*Hoplostethus atlanticus*) and dory fish oils are 97.1 and 90.9% wax esters, respectively [58]. Essentially all the oil in jojoba (*Simmondsia chiensis*) seed is in wax form. Whale and jojoba oils have been valued for stability in cosmetics and heavy-duty lubrication applications.

Extraction processes for waxes vary in sophistication, from: boiling crushed leaves and berries and skimming the oil (as in the regulated production of Candelilla wax a substitute for hard carnauba wax from *Euphorbia antisyphilitica* in the Big Bend area of Texas and Mexico); to screw pressing seeds such as jojoba; to direct solvent extraction. Cold-pressed jojoba oil is preferred for cosmetics because of concern about other lipids that might be extracted in solvent processes. Oil remaining in the meal has been recovered by secondary hexane extraction for industrial uses. Waxes are susceptible to hydrolysis by nonspecific lipases and are at least partially digestible. They may be hydrogenated or sulfurized into solid forms. The compositions of significant commercial waxes from natural sources are given in Table 34.5.

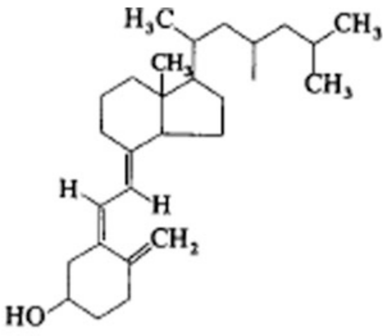
Terpenes

Terpenes are condensation products of the five-carbon *isoprene* (2-methyl-1,3-butadiene) and are extractable by nonpolar solvents. They are classified according to the number of isoprene units: two units, *monoterpenes*; three units, *sesquiterpenes*; four units, diterpenes; six units, triterpenes; eight units, tetraterpenes; and *polyterpenes*. Terpenes may be linear or cyclic. Taken together, this class of compounds includes major essential oils (used in perfume and flavorings), fat-soluble colors, fat-soluble vitamins, and steroids. A saw-toothlike shorthand form often is used to depict the longer chains.

Examples of monoterpenes include the linear aldehyde citral, which is found in many essential oils, and the (*cis*) alcohol *geraniol,* a major component of oil of geranium. Cyclic monoterpenes include limonene, menthol, pinene, camphor, and carvone, major components of lemon oil, mint oil, turpentine, camphor oil, and caraway oil, respectively. Sesquiterpenes include farnesol, a component of rose oil, and bisabolene, a component of Bisabol myrrh. The diterpenes include phytol, a component of chlorophyll, and vitamin A, which is one half of the tetraterpene *β*-carotene. The triterpenes include squalene, a precursor of cholesterol. Examples of tetraterpenes are the oil-soluble: carotenoid plant pigments; xanthophylls, including the yellow pigments lutein in plant leaves and *zeaxanthin in* corn (*Zea mays*); capsanthin, the red pigment in red peppers (*Capsicum annuum*); lycopene, the red coloring of tomatoes (*Lycopersicum esculentum*); and *β*-carotene, a yellow-orange pigment that is the precursor of vitamin A. Bixin, from the seedpods of *Bixa orellana*, is the yellow-orange pigment in annatto food color. It is considered to be a form of carotene oxidized to remove both six-membered end rings. Polyterpenes include gutta, natural water repellant and electrical insulating material from *Palaquium gutta*, and natural rubbers with molecular weights of up to 1.2 million daltons obtained from the latex of the *Hevea brasiliensis* tree and from rubber-filled cells in the branches and roots of the guayule shrub (*Parthenium argentatum*).

Sterols

Structures of selected sterols are summarized in Fig. 34.3. Cholesterol is synthesized from lanosterol, which consists of six isoprene units. Cholesterol is a powerful emulsifier and intermediate for synthesizing other steroids and compounds in animals. It participates in multiple ways in fatty acids and



Vitamin D_3

Vitamin K_3

TGA transport and is monitored as a major index of arterial and general health. Other important (animal) zöosterols include ergosterol, a precursor of vitamin D required to avoid rickets in children. The ability of certain plant-origin phytosterols to reduce blood cholesterol levels, including low-density lipoproteins (LDL), was discovered in the 1950s and reconfirmed many times. Pine tree "tall" oil, a byproduct of papermaking, is a rich source for commercial preparations. In recent years, selected phytosterols have been approved as food additives and have been included in specialty margarines and spreads. Stanol homologues differ from sterols by saturation at the 5 position, to yield cholestanol instead of cholesterol, and sitostanol instead of *β*-sitosterol. Commercial phytosterol preparations are mixtures of *β*-sitosterol, sitostanol, campesterol, and campestanols. Free sterols have limited solubility in fat, and stanols are hardly soluble; thus, they are converted to fatty acid esters for use in formulated foods. Bennecol®, a table spread, developed by the Raisio Group in Finland and approved as GRAS by the FDA for the United States market in 1999, is an example of a plant sterol/stanol application. The FDA requires that a product provides at least 1.3 g/day of plant sterol esters or 3.4 g/day of plant stanol esters in use to qualify for a cholesterol-lowering health claim [59–61].

Frying studies have shown that phytosterols with double bonds at the 24–28 position in the ethylidene side chain (Δ^5-avenasterol, Δ^7-avenasterol, fucosterol, citrostadienol, and vernosterol) act as chemical antipolymerizers on the surface of frying oils and prolonged frying life. However, stigmasterol, *β*-sitosterol, spinasterol, lanosterol, ergosterol, and cholesterol are either ineffective or slightly increase polymerization [62–65].

Fat-Soluble Vitamins

The fat-soluble vitamins include: vitamin A (retinol), a colorless compound resulting from cleavage of *β*-carotene, vitamin D_3 (cholecalciferol), a steroid, and vitamins E and K (tocopherols and menadione and their derivatives, respectively), which consist of isoprene and phenolic-quinone components.

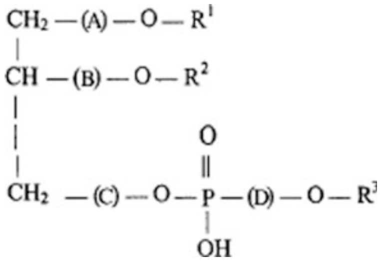
The carotenoids generally are highly susceptible to oxidation. Only selected members (xanthophylls, *β*-carotene, and bixin) are extracted for food coloring. They are used in products such as butter, margarine, and cheese, where exposure to oxygen and light is limited. The more stable yellow-orange pigments (lutein and xanthophylls) are extracted from alfalfa and marigold blossoms for use as poultry feed additives to increase the yellow color in egg yolks and in skins of broilers. Much of the world's *β*-carotene is produced synthetically and is increasingly obtained from (red) palm oil. There is current controversy whether lycopene, the red pigment of tomatoes, has antioxidant properties in the human body.

"Vitamin E" is a generic term for tocopherols and tocotrienols recovered from condensed deodorizer or physical refiner distillates. In earlier years, wheat germ oil was a major source. Structures of tocopherol and tocotrienol isomers are identical except for the presence of double bonds at positions 3′, 7′, and 11′ in the side chain of tocotrienols. The R_1, R_2, and R_3 positions are occupied by CH_3, CH_3, and CH_3, respectively, in the *alpha* (α) isomers; CH_3, H, and CH_3 in the *beta* (*β*) isomers; H, CH_3, CH_3 in the *gamma* (*γ*) isomers; and H, H, and CH_3 in the *delta* (δ) isomers. As shown in Table 34.6, tocopherols are the primary tocols in soybean, corn, olive, and sunflower seed oils, and tocotrienols are primary in wheat, rice bran, and palm oils. During chill fractionation, tocotrienols in palm oil concentrate in the olein (liquid) phase. The greatest vitamin E activity is shown by α-tocopherol—the commercial "vitamin E"—with lesser activities shown by other tocopherol and tocotrienol isomers. However, when used as antioxidants, the *gamma* and *delta* isomers often have proven more effective in protecting vegetable oils against oxidation. Intensive research continues on potentials of tocols for avoiding or curing various diseases, with considerable focus on diseases of aging.

Oils from the livers of cod and other fish species were early sources of vitamin D_3; also, ergosterol was irradiated by ultraviolet light to produce vitamin D_2. Currently, most of the commercial vitamin D is produced synthetically. Commercial vitamin E is recovered from deodorizer condensates from plants refining palm and other oils, including soybean.

Phosphatides

Phosphatides are natural emulsifiers with the following structures [66].



where

R^1 = fatty acid.

R^2 = fatty acid, or the phosphatidyl group in the 2 position.

When R^3 is one of the following, the phosphatide is named:

Fig. 34.3 Structures of selected sterols. Sources: animal—lanosterol, cholesterol, and ergosterol (also microbial); plant—all others. (From Warner [65], pp. 37–49, With permission)

$R^3 = C_6H_6–(OH)_6$	diacylphosphatidyl inositol
$R^3 = H$	diacylphosphatidic acid

and preceded by names of the two fatty acids if relevant.

In the pharmaceutical industry, the word *lecithin* is synonymous with phosphatidyl choline. However, the entire or modified mixture is sold as lecithin in food supplement capsules, and for food, feed, and industrial uses. Soybean oil phosphatides consist of 29–39% diacylphosphatidyl choline, 20–26% diacylphosphatidyl ethanolamine, 13–17% diacylphosphatidyl inositol, 5.9–6.3% diacylphosphatidyl serine, and 5–9% diacylphosphatidic acid [66].

The phosphatides have polar and nonpolar sites and generally act as water-in-oil emulsifiers. They are extracted by solvents with the oil, but preferentially will absorb available water, form gums, and precipitate. Commercial lecithin is produced by *water degumming* (precipitation from oil with ion exchange-treated water) as explained later.

Phosphatides precipitate on hydration during the storage of oils, foul bleaching earths, poison hydrogenation catalysts, and cause darkening of the oil during deodorization/physical refining and also if it is used in frying applications. Their removal is desirable, but requires close supervision to preserve oil yields. Four lipases are able to hydrolyze phosphatides. Phospholipase A cleaves fatty acids at the "A" position; phospholipase B (also called "A2") cleaves fatty acids at the "B" position; phospholipase C cleaves the phosphatidyl chain next to carbon "C;" and phospholipase D cleaves between the phosphate structure and choline, ethanolamine, serine, or inositol. Cleaving by phospholipase D and dissociation of the phosphorous group expose two negatively charged sites, which can complex with divalent cations (mainly calcium and magnesium, but also including iron, copper, and others) present in soybean tissue during solvent extraction. As a result, the phosphatide becomes nonhydratable.

The production of nonhydratable phosphatides (NHP) by phospholipase D can be minimized by heat inactivation of the enzyme by expanders/extruders while preparing seed for solvent extraction, by heating briefly to more than 112°C/235°F. However, some NHP are unavoidable, especially in wet fall seasons when high moisture seed may begin to sprout. Unless the NHP content is extremely high, they can be changed to the hydrated form by treating the crude oil with acidic chelating agents (*acid degumming*) to withdraw the divalent cations as described later. In the last two decades, several companies have introduced *enzyme degumming*. In these processes, usually a position 1 lipase is introduced to hydrolyze the R^1 fatty acid. This leaves the 1 position attractive to water and renders the phosphatide hydratable again.

The enzymatic degumming process is very robust and versatile. Using this process increases oil yields and reduces phosphorus content to a greater extent. The method is suitable for edible oil and biodiesel processing. Recently in 2010, Varenium has marketed their two Purifine PLC products for the degumming process.

Fats and Oils Sources and Consumption

Production

Global production and export estimates for fats and oils for 2003/2004 are shown in Table 34.7. Approximately 39% of the world's production of vegetable oils, and an additional 20% of oilseeds grown, enter international trade [20, 67]. Records of estimated production, imports, and exports are kept, country by country, by the Foreign Agriculture Service (FAS) of the US Department of Agriculture, and *Oilseeds World*, a publication in Hamburg, Germany.

The leading producers of the major oilseeds, in decreasing order, are *Soybean*: the United States, Brazil, Argentina, China, and Paraguay; *Rapeseed/Canola:* China, the

MMT million metric tons

European Union, Canada, India, and Eastern Europe; *Sunflower seed:* the former Soviet Union 12, Argentina, European Union, Eastern Europe, China, and the United States; *Peanut/Groundnut:* China, India, and the United States; and *Cottonseed:* China, the United States, India, Pakistan, the former Soviet Union 12, and Brazil.

Soybean oil is the world's largest supply of *visible* (separated) fats, accounting for approximately 29.8%. Palm, rapeseed/ canola, and sunflower seed follow it, and peanut oils in tonnages produced. The production of palm oil has been increasing and now accounts for 28.8% of the world's supply; added to the 3.4% palm kernel oil produced, the palm crop provides 32.2% of total oil supply. With oil palm plantings still to mature in various tropical countries, palm oil production alone is expected to bypass soybean oil within the next several years. However, palm oil generally is the lowest cost edible fat available and accounts for 54.7% of the world's exported oils. Thus, it is one of the more economical and easier acquired oils.

Currently, the United States is the world's leader in soybean production (35.2%), followed by Brazil (32.7%), Argentina (17.9%), and China (8%). Approximately 34% of the world's soybean meal (for animal feed), 29% of the oil (mainly in degummed form), and 34% of the world's soybean seed (mainly for overseas extraction) enter global trade. The United States exports 36% of its soybean crop in seed form, 12% of its processed meal, and 3% of its soybean oil. In contrast, Brazil exports 35, 65, and 48%, and Argentina exports 20, 98, and 98%, respectively. The latter two nations each surpass the United States in tonnage of meal and oil exports. This results partially from increasingly more of the domestic crop retained in the United States to supply the local population's needs. Also, larger tariffs were imposed on seed exports than on meal or oil in Brazil and Argentina in the 1970s and 1980s to encourage development of domestic oils extraction industries; these strategies appear to have been successful. Because of population growth, China now imports more soybean than is produced internally [20].

Rendered beef, pork, poultry, and other animal fats are not well reported internationally, and global statistics are unreliable. Total production of fats in the United States by the rendering industry for 2000 is estimated at 4.18 million metric tons [68]. Outputs of all rendering facilities captive to integrated broiler operations might not be included. Of the amount reported, 76% is inedible tallows and greases, 18% is edible beef or mutton tallows, and 6% is edible pork lard.

Fish oils are not well reported either, with annual estimates at about 1.3 million metric tons from sustainable (sea catch) fisheries. Production has ranged by as much as 50% between years, depending on availability of fish.

Changes in Sources

The maturing of nations as raw materials suppliers follows a sequence. Centuries ago, bands of marauders attacked villages to steal crops after harvest. Later, countries conquered neighboring lands for "a place in the sun" for their growing populations. With improvements in transportation and discovery of the New World, followed by Africa and Australia, it no longer was necessary to relocate large populations. Colonies could be established to supply the "mother country" with raw agricultural materials in addition to minerals and fossil fuels. As local education improved, colonies typically declared their independence, but the new countries needed something to trade for goods they were unable to produce themselves.

The oils of ancient times were olive and sesame oil in the Mediterranean basin, rapeseed and animal fats in Europe, and coconut (copra) oils in the tropics. Cottonseed was the world's first new oil of the Industrial Revolution age

Table 34.8 Gross composition of major undehulled oilseeds

Crop/Source	Moisture (%)	Protein (%)	Fat (EE) (%)	Crude fiber (%)	Ash (%)	Oil: co-products ratio

EE ether extraction method.

(early 1800s) and became the dominant US oil after the Civil War (from the latter 1860s until the mid-1930s). But, cottonseed oil is a byproduct of growing cotton fiber, and edible oil and animal feed requirements of the world's growing populations soon exceeded supplies of this crop. Solvent extractors, invented in Germany in the early 1920s, maximized oil recovery and produced animal feed protein meals with less heat damage. As European demands grew for a closer and more reliable source of soybean than had been available from the Manchuria area of China since 1910, soybean export opportunities opened for the United States. Many of continental Europe's oil mills were demolished during World War II, placing the United States in the position of major soybean seed, oil, and meal supplier to the world. In 1960, the United States grew and traded about 60% of the world's soybean. China grew about 32% of the world soybean crop and supplied about 19% of the trade, but soon decreased as a world supplier because of its own population growth. The poultry broiler industry became global about 1960. Its large requirements for feed protein, best supplied by soybean meal, contributed to increasing world soybean production by 7.5 times in the succeeding 40 years.

Although slightly more than four tons of meal is produced for each ton of oil, the sheer volume of the meal business has co-produced enough soybean oil to keep it the world's major oil until now. Much of the production and processing technology was developed by the United States and European nations. In time, roads, canals, and port systems, crop production, and processing infrastructures in South America were funded as economic development programs by the World Bank, Regional Banks, and by private investors. The position of "lowest cost producer of soybean and soybean oil" has passed from the United States to South American countries. Brazil has opened its sub-Amazon basin to soybean growing, an area four to five times larger than available in the United States, and has developed varieties acclimated to the climate and day length. Its production of soybean is expected to surpass the United States in the near future. China also has developed salt-tolerant varieties that will grow in its coastal regions. At the same time, economic assistance and private investment in Southeast Asia and tropical countries have led to production of palm oils at prices lower than soybean oil.

The appearance of Asian soybean rust (*Phakopsora pachyrhizi)*, first of South America and in the United States in 2004, is a cause for concern. This fungus has potential for greatly reducing soybean yields per acre and could become a critical factor in world protein and oil supplies. No other crop is as capable of producing protein as soybean, essentially resulting in a monoculture. The Unites States has maintained a wheat rust response program for nearly half a century, continuously developing rust-resistant varieties for replacement as needed. Fortunately, biotechnology has provided even better tools for newer programs.

Many factors dictate which oilseed species will be grown and/or imported into a country. Climate and local demand for high-protein feed meals are leading factors. Cool weather and short growing seasons have essentially limited Canada, Northern Europe, and the former European Russian republics to growing rapeseed/canola or sunflower seed. Some European countries grow and export seed or oil of canola, but import soybean for their edible oil and animal feeding industries. Insect problems were important factors in selecting crops before modern insecticides and IPM systems became available. Devastation of the southeastern United States cotton crop by the boll weevil led to the introduction of large-scale peanut growing in the early 1900s.

As shown in Table 34.8, the oil content of row crop oilseeds varies from about 19% for soybean to 43% for sunflower seed, and 41–45% for rapeseed/canola. More feed co-products always are produced than oils, with a ratio 4:1 in the case of soybean. Soybean meal is the major feed protein source for production of poultry, currently the leading domestic and global meat source, and in the rapidly developing aquaculture industries.

The relative availability of fat- and oil-bearing byproducts of other current agri-businesses is an additional consideration in types and amounts of oilseeds grown. Because only about 12% of the return to cotton farmers comes from the seed, the domestic supply of cottonseed for crushing is dictated by world demand and the price of cotton and is hardly affected by price of cottonseed oil. Corn oil has become the second major oil in the United States due to large quantities of corn germ provided by rapid growth of the domestic corn sweetener and ethanol industries. There is sufficient processing of rice in the United States now to warrant two rice bran oil extraction plants, with quantities of stabilized rice bran also shipped to Japan. Beef, pork, and poultry packing operations always produce fatty tissues for rendering into inedible tallow, lard, chicken fat, and meals used in animal feeds. Generally, fats/oils from co-products of other local processing industries must clear the market first, at whatever price they can get, before growing or importing of significant quantities of high-oil content crops becomes economically attractive.

Consumption

The world's current production of edible oils is estimated at about 101 million metric tons, and an increase of ~2.5 million metric tons is needed annually to meet the needs of the growing population. Average per capita consumption of fats/oils is difficult to determine from gross disappearance figures because these materials also are used in animal feeds and industrial applications. Generally, consumption is related to personal income and local availability, but once fats are introduced into the diet, their priority among food expenditures remains high. The annual consumption of oils is estimated at 10.4 kg per person for the world and ranges from 27.2, 42.9, and 29.3 kg for the United States, Belgium, and West Germany, respectively, to 13.1, 4.7, and 5.9 kg, respectively, for Egypt, China, and India.

About 60% of the total fat consumed domestically is "invisible," in meat, poultry, fish, dairy products, eggs, and prepared foods. The visible 40% is used primarily in the form of salad and in-home cooking oils, shortenings, and margarine. From 1965 to 1990, average domestic consumption of fat decreased from 50.7 to 32.5 kg per capita for men 19–50 years of age and 30.3 to 23.4 kg/year for women.

Since 1990, consumption increased to 36.9 kg/year for men and 23.7 for women in 1995 [69]. Approximately two thirds of visible fats available per capita in 1940 were from animal sources. The use of vegetable source fats has grown significantly, accounting for about two thirds of the visible fats consumed in 1965, and 90% in 1985 [70]. More recent data have shown that fat consumption per capita has not deceased in grams per day intake, but has decreased as a percentage of total diet with the average caloric intake increasing.

At times, the public acts indifferently regarding caloric intake. In the mid-1990s, various low-fat or nonfat snack foods were introduced, requiring different processing machinery, techniques, and flavoring technologies. Although promising at first, sales of these products showed a decline in 1997 [71]. The Procter & Gamble Company developed olestra (Olean™) during a 28-year period (1968–1996) before the FDA approved its use as a frying oil in *savory snacks* (salty chips, crackers, and tortilla chips) and spent several hundred million dollars in the process. Olean™ is a polyester of sucrose and 6 to 8 fatty acids, which is nondigestible by human lipases, and thus noncaloric. However, public interest shifted from snacks promoted as "healthy" to indulgence in salty, traditional-flavor, higher fat content products [72]. Many of the newer snack products were withdrawn from the marketplace. Digestive tract upsets also found in earlier evaluations of other nondigestable fats were again reported among Olean consumers.

Extraction of Fats and Oils

Basic Processes

By trial and error over the centuries, man has learned five basic skills in handling oilseeds:

1. *Preservation of seed by natural or artificial drying* and cooling to a dormant state before storage, with protection from insects and rodents. Generally among oilseeds, sprouting enzymes become active once seeds rise above 75% relative humidity (RH). Rise in free fatty acid (FFA) content signals need for early processing.
2. *Removal of trash and hulls*, by stamping, threshing, disk hullers, cracking rolls, and other devices, followed by winnowing, sieving, or aspiration to separate kernels ("meats") from hulls and chaff.
3. *Freeing the oil*, by pounding seed with rocks, mortar, and pestle-type grinders (which later became human, beast, water, or electric-driven ghanis); use of vertical stone/iron wheels known as "edge rollers" to crush the seed; cracking and flaking rolls; and, more recently, expanders/extruders.
4. *Heating the seed to increase oil recovery*. This was first interpreted as denaturation, making the protein matrix brittle to surrender the oil on pressing. Later, it was recognized that concurrent inactivation of enzymes also arrests development of various types of degradations.
5. *Separation of oil* from crushed seed by: draining; squeezing cooked mash in cloths by lever, wedge, or hydraulic presses; continuous screw presses, or by solvent extractors.

Initially, various societies used plant oils for medicinal and cosmetic purposes. Later, they were used for lighting and, as extraction and refining techniques improved, for food. Crude techniques are still used in remote areas.

Screw Press Operations

Continuous screw presses are used: (1) for extracting fats and oils in small operations where investment capital or supplies of raw materials are limited and installation of a solvent extraction plant is impractical; (2) to partially defat high-oil content seeds for easier handling in subsequent solvent extraction or hard pressing; and (3) for extraction of animal flesh and bones, fish, and fleshy-type oilseeds such as palm fruit, olives, and copra (dried coconut "meat") and oilseeds. These machines have been generically referred to as "expellers," but the Expeller® trademark belongs to Anderson International Corporation, Cleveland, OH, successor to the company founded by Valerius D. Anderson who patented the first continuous screw press in 1899.

The main principle in *hard pressing* is to preheat (cook and dry) prepared seed and animal materials to the point where cell walls become brittle and rupture readily on pressing. Generally, seed is dehulled, tempered, flaked, and cooked (dehydrated) to low moisture (3–4%) before hard pressing. Screw presses used for hard pressing row crop oilseeds (soybean, cottonseed, rapeseed/canola, sunflower seed, and peanut) typically include two stages: the second stage, operating at higher pressure, further extracts oil remaining after first stage pressing (Fig. 34.4). Approximately 4–5% oil is left in oilseed meals. Single-stage continuous screw presses typically are used in rendering operations and in pressing palm fruit and olives, which leave bone or hard seed pieces in the press cake. Approximately 9–12% fat is left in meat and bone, and fish, meals, and 5–6% oil in oilseed meals. High temperatures partially destroy the dietary essential amino acid lysine and reduce nutritional quality and economic value of protein feed meals. Milder *wet processing* techniques have been developed for meat and fish meals.

Generally, oils from press operations go to a settling tank. A layer of foam may be skimmed off; the *midfraction* (oil) is filtered and sent to refining, and the settled solids (*foots*) are spread over the stock going to the screwpress. Pressed oils benefit from cooling to less than 42°C/11°F as soon as possible to slow oxidation and setting of color.

The traditional practice in processing high-oil row crop oilseeds (containing over 25% oil, such as canola/rapeseed, sunflower, peanut, safflower, and corn germ) was to reduce the oil content to less than 18% using lighter duty *prepresses*, break up the press cake, and finish with solvent extraction. Such operations are called *prepress-solvent extraction*. Cottonseed also was prepressed in earlier years. Expanders with oil removal cages (Fig. 34.11, to be described in more detail later) are used to reduce oil content to less than 20% and are replacing prepresses in high-oil content seed extraction plants. Modified discharge heads are used on expanders to enhance hard pressing.

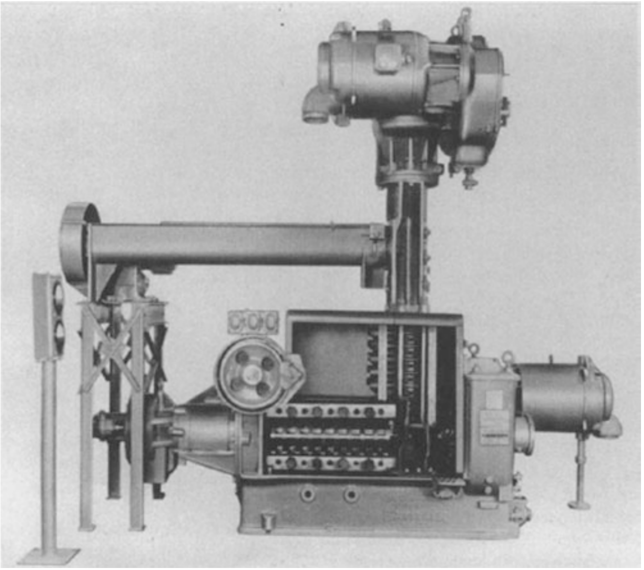

Fig. 34.4 Anderson Expeller® Press, model 55 in. TDMS.™ Note elevated conditioner carrying product from *left* to *right* across *top* of press; vertical screw first-stage press section (*right* side); higher pressure second-stage press screw section carrying product from *right* to *left*. Some hard presses have both stages on one shaft. (Courtesy of Anderson International Corp., Cleveland, OH)

Most oilseeds contain excessive fat for extensive animal feeding. "Scalping" oilseeds such as cottonseed and soybean by preheating and partially pressing to about 9–12% residual oil (which is sold) is becoming popular among large animal feeders, feed manufacturers, and farmer cooperatives. Toxic components, such as trypsin inhibitor (in soybean) and gossypol (in cottonseed), are partially inactivated, and the meals are improved for feeding selected animals.

Decanters and Centrifuges

Two major types of centrifugal separators are used in press-type oil/fat extractions and *wet rendering:* horizontal decanters and vertical stacked conical disk centrifuges. A drawing of a decanter, which separates solids and liquids, is shown in Fig. 34.5. Decanters are built with different internal designs depending on the solid–liquid ratio to be separated and operate at ~2,500–3,000 × gravity (*g*). When properly operated, a "dry" solids phase and a liquid phase of two immiscible liquids (aqueous matter and oil) are discharged.

A cut-away of a three-phase stacked-disk centrifuge is shown in Fig. 34.6 [16]. These are vertical separators, operating at ~6,000 × *g*, which employ a spinning bowl and set of conical stacked disks. Centrifuges are used

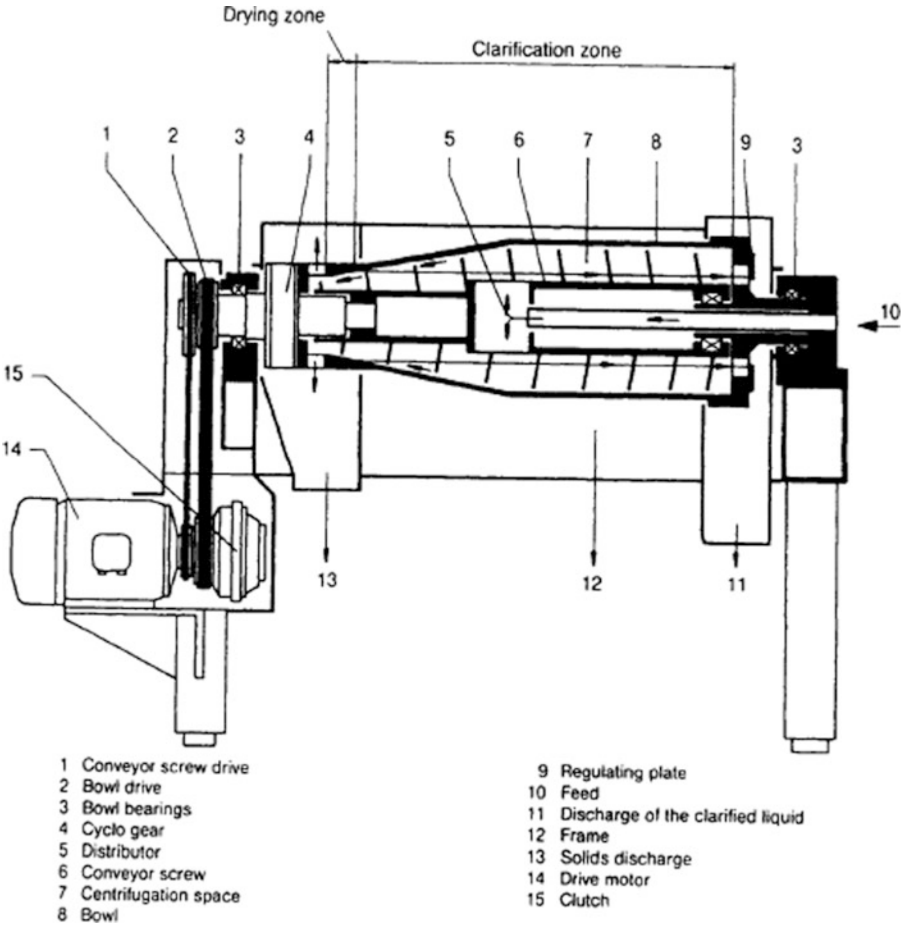

Fig. 34.5 Schematic drawing of Westfalia Model CA 450 Continuous Clarifier Decanter. (Courtesy of GEA Westfalia Separator Company, Northvale, NJ)

primarily in three-phase mode to separate the liquid portion into two immiscible phases and a fine solids (*sludge*) fraction. They are not meant to handle significant amounts of coarse solids. The material to be separated enters the spinning bowl at the bottom through a hollow spindle and is discharged under the lower plates to be thrown against the side of the bowl by centrifugal action. Continual arrival of fresh liquid forces the earlier liquid into the plates, with the heavier aqueous phase remaining at the outside of the bowl, and the oil phase moving into the center. In the past decade, both major manufacturers of centrifuges in the western world have introduced systems for adjusting the aqueous: oil phase ratios exiting their machines while running. The solids, collected at the outer extremities of the bowl, are allowed to escape as heavy slurries by momentarily lowering the bottom of the bowl on a timed *desludging cycle*.

Olive Oil

Traditionally, oil was extracted from fruit of the olive tree, *Olea europea*, by crushing cleaned, ripe olives, including the seed, using stone “edge rollers” or metal grinders; milling by mixing the paste while heating to coalesce the oil droplets; and shrouding it in press cloths or mats for squeezing in lever, wedge, mechanical screw, or hydraulic presses. Next, the *must* (oily liquids escaping the press) was centrifuged to separate the oil and aqueous phases. Lower quality secondary oils were obtained by reworking and repressing the pomace, or by drying it for solvent extraction. Modern olive oil extraction plants: crush the olives and seed using hammer mills; mix the paste while heating; and separate the must from pomace using decanters. The must is heated and separated by disk centrifuges. The solids may be reextracted several times. Some olive oil plants now use bladder presses, similar to those for crushing grapes in making wine, to remove the highest quality oil. Virgin oils are separated by pressing, and usually are usable after filtration. Pomaces are dried and their remaining oil extracted by solvent. Some operations use the desolventized extracted pomaces to fuel steam boilers for the plant [73–75].

Coconut Oil

Coconuts, from the *Cocas nucifera* palm, are dehusked before cracking the nut to drain away the coconut water. Then, the flesh is separated from the adhering shell and dried, raising the oil content from approximately 30% in

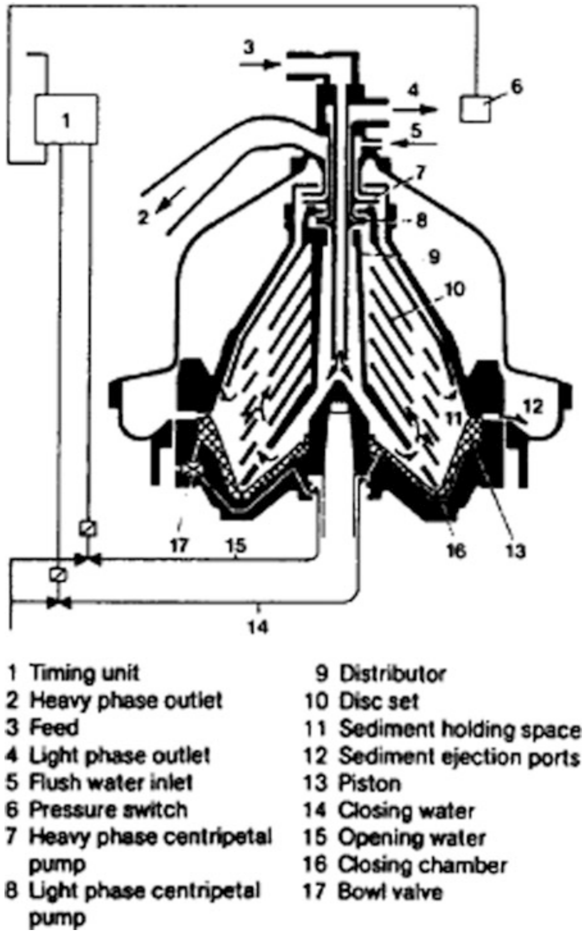

Fig. 34.6 Schematic drawing of Westfalia Model RSA refining separator with self-cleaning bowl. (Courtesy of GEA Westfalia Separator Company, Northvale, NJ)

the "meat" to 50–65% in the resulting copra. Considerable amounts of copra are prepared by hand and sun-dried to supplement family income in tropical countries. Centralized coconut mechanical husking and dehulling facilities, which dry the coconut meat using heat generated from burning the husks, offer advantages of improved moisture control and reduced mold spoilage and aflatoxin problems and are increasing in number. In the oil extraction process, copra is: (1) cleaned by shaker screens to remove trash; (2) size-reduced by hammer or attrition mills, or fluted roller mills; (3) optionally flaked; (4) additionally dried if necessary; and (5) hard pressed or prepress-solvent extracted [76]. Specially designed expanders have been applied to preparing copra for coconut oil extraction.

Palm Oil

Two distinctly different types of oils are produced from the fruit of the Southeast Asia and African oil palm, *Elaeis guineensis*, and its hybrids with the South and Central American palm, *Elaeis oleifera*. Palm oil is obtained from the red-orange fleshy part of the fruit, which resembles an oversized olive about the size of a small chicken egg. Palm kernel oil is derived from the kernel within the nut. Well over 98% of the fatty acids in palm oil belong to the C16 and C18 palmitic-stearic group, whereas approximately 64% of the fatty acids in palm kernel oil consist of the C12 and C14 lauric group.

A palm tree produces 10–15 fresh fruit bunches throughout the year, weighing 5–23 kg (10–50 lb) each. The bunches are cut from the tree with knives attached to long poles and are transported to the oil mill, sometimes by a small-gauge railroad. Although palm fruits somewhat resemble olives, they have a very strong lipase enzyme which is deactivated first by steaming the bunches at about 40 psig for 50–75 min. This also loosens the fruits on the stalk, which are freed in thresher drums and passed through a digester to convert the fleshy pulp to mash. Then, the mash is pressed by twin-screw or hydraulic presses to yield red crude oil. The nuts are dried, shells cracked, and the kernels separated and bagged or bulk-stored for sale and/or solvent extraction in a fashion similar to the processing of row crop oilseeds [77].

Animal Fats and Fish Oils

Extraction of Lards and Tallows

A variety of methods, old and new, is used for extracting animal fats [78]. The method used depends on the required properties of the edible or inedible nonfat product produced and the age of the facility since construction or its last modernization. In recent years, continuous processes generally have replaced batch processes for edible and inedible rendering to take advantage of heat recapture systems, economies and reduction of worker safety problems through automation, and the ability to minimize discharge of offensive odors. Modern edible and inedible rendering plants located near urban areas often are under negative pressure, and the building and processing equipment operate under slight vacuum. Steam vapors from processing are condensed, and air taken into the building is water-scrubbed before return to the atmosphere. Edible and inedible animal fats and fish oils may be subjected to refinery processes similar in principle to those of vegetable oils. Industrial fats often are split by high-pressure steam into fatty acids for further processing by the oleochemicals industry [79].

Edible products for human consumption are processed under federal or state inspection in facilities separate from inedible rendering plants. In the United States, construction of the processing area and designs of equipment selected are previewed and approved before startup by the Food Safety

Inspection Service of the USDA. Only raw materials passed by FSIS inspectors may be used. They may be chilled or frozen and shipped in refrigerated trucks or railroad cars under FSIS seal to the edible rendering facility. On-duty FSIS (or state) inspectors monitor the rendering operation. Edible rendering plants are limited to one species in the United States, and mixing fat of different species is not permitted [80].

Edible beef tallow is produced from the fat of cattle (*Bos taurus*). A counterpart, produced from sheep (*Ovis aries*), is known as mutton tallow. Lard is rendered from the fatty tissue of pigs (*Sus scrofa*). Edible chicken fat is rendered in some countries [81]. Essentially, three methods are used for separation of fat from animal tissues. In older *batch wet rendering* processes, an autoclave is filled with precut raw material, closed, and steam is injected to raise the temperature to about 140°C/280°F. After heating for 2–3 h, the pressure is slowly reduced to atmospheric to avoid emulsification. After a settling period, the free fat is drained from the autoclave; the cracklings are pressed by single-screw machines and sent to drying. Indirect heating is used in *batch dry rendering*. A reactor, equipped with a rotating agitator, and jacket at 6–7 bar (88–103 psi), liberates the fat in 1.5–2 h. On discharge, the fat is drained and the cracklings are pressed. Where batch-type cage presses are still used in other countries, the cake is formed in the shape of large wheels, sometimes called *greaves*.

Much of the edible rendering industry has adopted continuous *wet rendering*, in which the minced raw material is heated first to 60°C/140°F, and then to 90°C/195°F, in an airtight melting section within minutes. The heated material then is separated into solid and liquid fractions by mechanical horizontal decanters (Fig. 34.5) or dewatering screw presses, and the oil is separated from the aqueous portion (stick water) and fines by a three-phase disk-type centrifuge (Fig. 34.6). The pure fat is flash-dried and cooled to approximately 12°C/20°F above melting point by passing through a tube-in-shell or plate heat exchanger before storage and shipping [82].

Lower heating temperatures are used when producing partially defatted beef fatty tissue (PDBFT), or similar edible products of other species, used in making processed meats, including frankfurters. Fatty tissues and trimmings are ground and heated to 43°C/110°F in a mixing tank to melt the fat but still retain the heat-setting properties of the tissues for later use. The slurry is passed through a disintegrator to rupture the fat cells, and then through a horizontal decanter for separation into solid and liquid phases. The solids are cooled for packaging and used in making processed meats. The liquid is heated to 93°C/200°F to coagulate proteins and passed through a desludging disk-type centrifuge to "polish" the oil by separating the stick water and removing any solids [83].

Higher heat treatments, using open cooking kettles, produce darker and more strongly flavored fats and cracklings, also usable as edible food ingredients, which are preferred in specific applications. But, for the most part, bland edible animal fats are preferred and may later be neutralized (alkali refined), bleached, hydrogenated, deodorized, rearranged (interesterified), and fractionated in ways similar to vegetable oils before incorporation into margarines/spreads and shortenings, or used for frying [84].

Inedible Animal Products

Inedible animal products include viscera and inedible parts, carcass parts condemned by inspectors, fatty trimmings from butcher shops, outdated fresh and processed meats, and dead animals that have been skinned. They may be rendered by wet or dry batch processes. In modern rendering, the flesh and bones are ground or chipped, heated to denature the protein and release the aqueous and fat fractions. Next, the slurry is passed through a decanter or dewatering press to separate the solids from the liquid which is further heated to reduce viscosity in separating fat, stick water, and sludge. The meat/bone fraction is dried, reaching high temperatures specified by the federal government to destroy pathogenic bacteria. The solids then are pulverized by hammer mills and sieved for animal feed use, with the separated large pieces recycled to the grinders. Inedible renders, sometimes called *the original recyclers*, play an increasingly significant function as the world wrestles with problems of biodegradable waste disposal.

Restaurant Greases

Used frying oils typically are processed in separate inedible systems. Restaurants and large commercial fryers dump their spent oils into on-site bins, equipped with steam heating coils provided by the grease processor. Pilferage of grease has been a problem in the industry, and covers on the bins are kept locked. The collector may attach a steam line to heating tubes in the bin to melt the fat if required; then, it is pumped to a tank on the collection truck. An exchange of fats occurs between the oil and the product during frying. For example, the used grease may contain substantial quantities of chicken fat from frying. At the processing plant, the liquid grease is heated to 100°C/212°F and flashed into an evaporator flash chamber operating at 82–85°C/180–185°F and 21 in. mercury vacuum to remove the moisture. Next, the dried grease is passed through a decanter to remove any solids and partially cooled before storage [85]. Some inedible renderers also provide services for pumping restaurant and grocery store grease traps. These fats are segregated for handling in separate processing facilities and sold in separate markets.

Table 34.9 Specifications or typical analyses of edible and industrial/feeding animal fats (Compiled from: NRA [80])

Grades	Titre min (°C)	FFA max (%)	FAC[a] color max	Moist. max (%)	Iodine value max	Saturated (%)	Fatty acids distribution unsaturated (%)	Linoleic (%)
Edible[b]

Animal Fat Specifications, Production, and Utilization

Specifications, or typical analyses, of edible, industrial, and feed animal fats are shown in Table 34.9 [80, 86]. Much emphasis is placed on Titer, the solidification temperature of fatty acids in a saponified sample of the fat or oil (AOCS Method Cc 12–59). Feed ingredients in the United States may not be as aesthetically attractive as food ingredients, but are required to pass the same toxicology standards.

Rendering produced an estimated 4.18 million metric tons of animal fats in the United States in 2000 [87]. Of this amount, approximately 18 and 6% were edible tallow and lard, respectively, and 41 and 35% were inedible tallow and grease. Approximately 15 and 34% of the edible tallow and lard, respectively, and 37% of the inedible tallow and grease were exported. Of the inedible tallow and grease used in the United States, an estimated 75% was used as animal feed, 16% was converted to fatty acids by the oleochemicals industry, 4% was used in soaps, and 3% in lubricants. Inedible animal fats are the lowest cost domestic fat sources. Their market price per pound sometimes is less than fuel oil, and rendering plants have chosen to burn them as fuels. In 2001, animal fats were included with vegetable oils for federally supported trials of biodiesel fuel.

Fish Oils

Raw materials for producing fish oils include: (1) *pelagic-type* (surface feeding) fish pursued for reduction to meal and oil; (2) waste products produced at facilities that process edible fish; and occasionally (3) *by-catch species* also netted with the primary catch. The type of processing used depends on geographic location, species of fish normally taken in the area, and whether done at an on-shore plant or a factory ship. As in continuous wet rendering, whole fish or trimmings are ground, cooked, pressed, or decanted to yield solids and liquid, and the liquid fraction then centrifuged into stick water and oil [88, 89]. A significant fish protein industry, using trawlers for netting and mother ships for processing, has developed in Alaska. Local fish species have low oil content, and most of the oil produced is used on board to power steam boilers and engines [90]. Dried animal meals and fish-meals do not contain natural antioxidants, and it is common practice to preserve their fat by using synthetic antioxidants. This is especially important in fish meals, where rapid polymerization can generate sufficient heat to cause spontaneous combustion of stored meals.

Fish oils may be alkali-refined, bleached, hydrogenated, deodorized, and used in making margarine/spreads, other food products, and nutraceuticals. Direct food uses are approved, but seldom made in the United States. Because fish oil contains fatty acids with three or more double bonds, it readily polymerizes in the presence of air and is a major drying oil used for coatings. This property is further enhanced by *kettle bodying* (heating and mixing while bubbling in air). The fatty acid compositions of different fish oils, processing, and uses are presented by Bimbo [91], and Bimbo and Crowther [88]. Nonfood uses include animal feeds, fish attractants and lures, automotive gaskets, caulking compounds, ceramic deflocculants, core oils, fatty acids, fatty acid chemicals, fermentation substrates, fire retardants, fuel oil, illuminating oil, insecticidal preparations, leather tanning, lubricants and greases, mold-release agents, mushroom culture, oilfield chemicals, oiled fabrics, ore flotation, plasticizers, polyurethane lures, pressed wood fiber boards, printing inks, protective coatings, refractory compounds, rubber compounds, rust proofing, soaps, specialty chemicals, and tin-plating oils.

Feeding Animal and Marine Fats

Animal and marine fats provide approximately 2.5 times more calories per unit dry weight than carbohydrates or proteins, but are lower priced. Digestive tract capacities limit growth of broilers and turkeys and productivity of laying hens, and these animals respond well to high-energy diets, another name for fat-containing feeds. This also is true, to a lesser degree, for pigs and fish. However, high intakes of oil can disrupt normal function of rumens, and various bypass techniques are used in feeding cattle. The most common has been to hydrogenate fatty acids to melting points above rumen temperatures. Because of concerns about bovine spongiform encephalitis (BSE or "mad cow disease"), feeding of mammalian meat meals to ruminant animals has been outlawed in the United States and much of Europe, but these restrictions do not apply to feeding of tallows and greases. Concerns also exist about potential crossover of BSE to cats, and ruminant meat and bone meals are avoided in formulating dry cat foods.

Special needs must be addressed in pet foods. The lower melting point animal fats (choice white greases) are more appealing in odor than the tallows. However, lower melting fats can wick into and disfigure paper packaging. Solutions have included using the higher titer fats, including nonpermeable plastic layers in multiwall bags, laminating fat barriers onto paper, and filling into plastic bags. Some foods for guard duty and sled working dogs, and some fish feeds, require 30–40% fat content. However, high-fat formulas do not extrude easily even on modern machinery. Solutions have included using twin-screw extruders, which convey better than single-screw machines, the inclusion of full-fat soybean meal where the oil still is bound within its natural matrix, and enrobing the products with fat after extrusion and drying.

In addition to increasing caloric density and feed palatability, and improving appearance, feed efficiency, and reducing feed costs, feeding of animal, marine, and vegetable fats can:

1. Provide needed molecular structures through dietary EFAs and phospholipids
2. Increase blood glycogen levels and endurance in working animals such as horses and sled dogs.
3. Lower the heat of reaction during digestion and metabolism, thus increasing tolerance of heat by large animals during summertime or in tropical areas.
4. Prevent dermatitis and improve the appearance of skin and hair–an important effect of polyunsaturated fatty acids.
5. Carry fat-soluble vitamins and natural color compounds, for example, yellow pigments to improve the color of egg yolks; red and orange colors for feeding salmon.
6. Prevent segregation of mixed feeds.
7. Lubricate feed-processing machinery.
8. Bind heat-sensitive flavorings, vitamins, medications, "instant gravy mixes" to pet foods and feeds after extrusion and drying.
9. Reduce dustiness of feeds and improving animal health [86].

Row Crop Oilseeds Processing

Extraction Plants

The term *row crop* in this chapter generally means annual crops that are grown in rows. Their seeds have many similarities in extraction and oils processing and often can be handled in the same facilities if provision is made for differences in dehulling requirements. As a group, these oils contain appreciable amounts of phosphatides, which must be

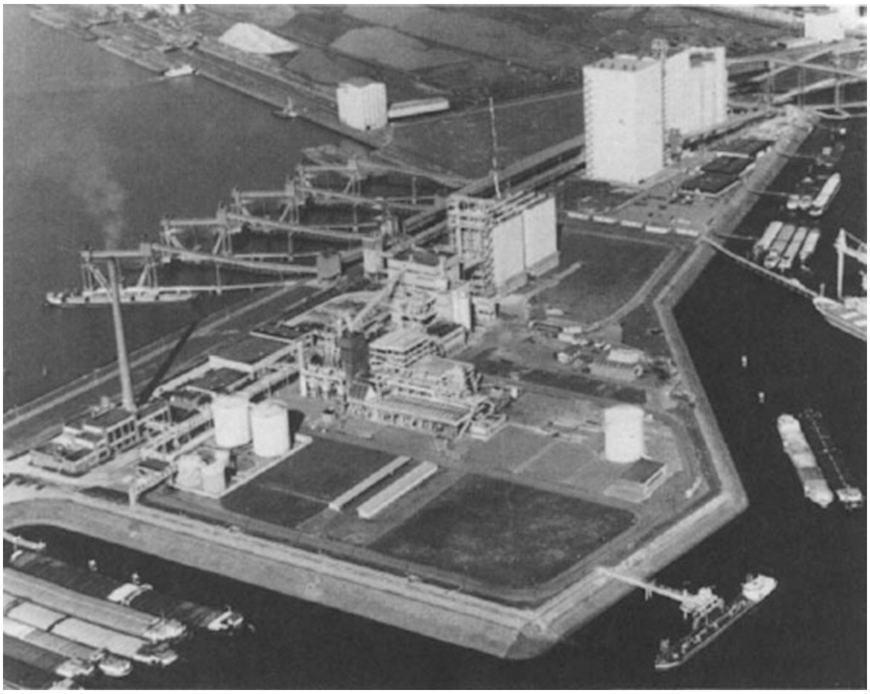

Fig. 34.7 Photograph of an operating soybean extraction plant. (Courtesy of Archer Daniels Midland Company, Decatur, IL)

removed, and are not as readily processed by physical refining as tree seed pulp crops such as palm and olive oils; instead, they must be prepared for lower temperature deodorization.

Concerns about marketing the meal (accounting for 65–75% of returns per bushel of soybean grown), and disposal of refinery byproducts, have reshaped the domestic soybean processing industry in the last 20 years. Soybean extraction plants now are located close to domestic meal feeding markets, and/or on major barge waterways and railways to reduce transportation costs to export facilities. Byproducts of refining are difficult to handle, and their production exceeds market demands. The major oil processors now generally locate extraction plants and oil refineries on the same property to enable spraying and drying surplus gums (crude lecithins) and soapstock on the meal for sale as animal feed. Independent edible oil refineries have almost disappeared, although refineries already associated with an extraction operation may purchase crude oils from other sources.

Economies of scale have led to minimum capacities of about 2,000–3,000 metric tons per day for new United States regional soybean extraction plants, and larger facilities (4,000–6,000 t per day) for soybean plants that pool some of their output for export. At the United States average yield of 38 bushels/acre, each 1,000 metric tons per day solvent plant capacity requires the output of 966.65 acres/day, or 338,328 acres/year (136,975 ha). A 2750 metric tons per day plant would use the soybean crop of 930,402 acres/year (376,681 ha). An extraction plant of this size will support a 500 t per/day refinery. Regional plants are smaller than export plants because accumulating this much soybean, in competition with other processors, can be difficult in some areas of the United States.

The largest solvent extractors can process 8,000 and 10,000 metric tons of soybean per day and are used primarily for the international trade. Two large extractors are used in the world's largest oilseed extraction plant in Argentina, reported to process 16,000 metric tons of soybean per day. Installations typically include: (1) facilities for unloading railroad cars, barges, or ships; (2) storage for at least several weeks' supply of seed, solvent, meal, and crude oil; (3) seed cleaning, preparation, oil extraction, and meal desolventizing equipment; (4) an on-site oil refinery; (5) repair and maintenance shops; (6) a quality control laboratory; and (7) offices and locker rooms for supervisors and workers. A photo of an operating soybean extraction seaport plant is shown in Fig. 34.7.

Seed Preparation for Extraction

A general flow sheet for direct solvent extraction of many row crop oilseeds is shown in Fig. 34.8. Initial quality of the seed and its preparation for extraction have the most effect on yield of extracted oil, subsequent required refinery operations, and yields of (saleable) *neutral oil*. Freshly harvested seed should be cleaned of trash, which may become ignited during drying, or harbor moisture that accelerates seed heating in storage. Oils of most good quality, dry, row crop seeds contain 0.5–0.75% FFA (AOCS Method Aa 6–38, Ac 5–41) with up to twice this range often accepted in trading without discounts. Rising pile temperature and FFA signals seed deterioration. The maximum moisture content for holding seed for long periods without spoilage varies with storage temperature and ranges from 8 to 13% among species. It is inversely related to the oil content, because less protein and carbohydrate is available to compete for water in high-oil seeds; however, the optimum relative humidity for storage is constant at about 65–70% for all seeds. If not adequately cleaned before storage, the seed should be completely cleaned before further processing to prevent clogging and damage of equipment. The processing system should be well equipped with magnets to arrest tramp metal that arrives with the seed or that is shed by equipment. Electronic metal detectors now are being installed as occurrence of stainless steel tramp metal increases.

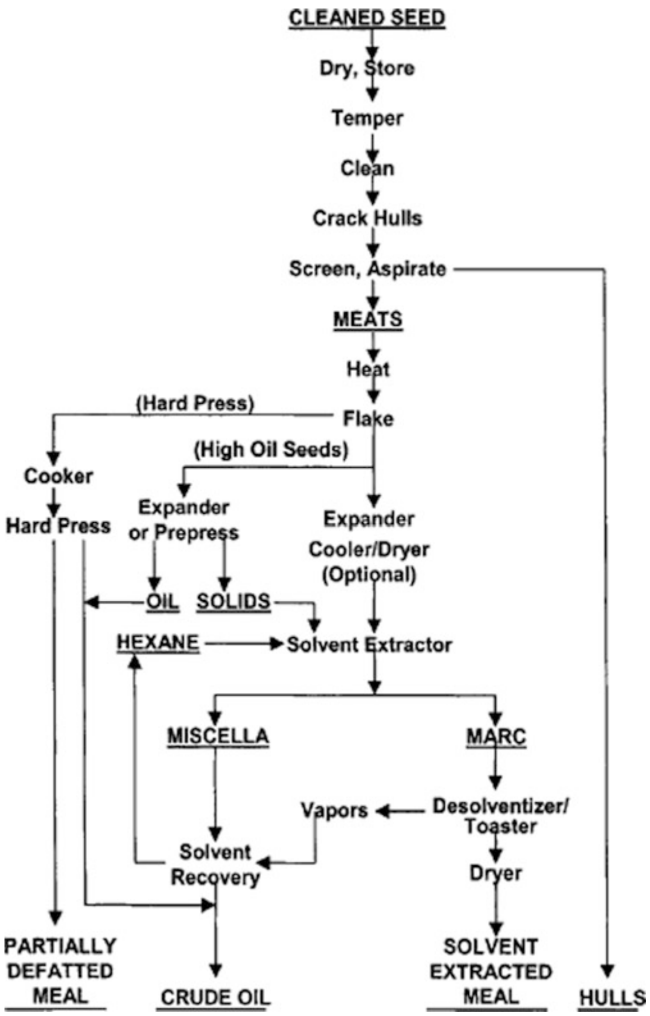

Fig. 34.8 General flow sheet for extraction of row, crop oilseeds

Oilseeds do not have fat cells like those of animals for storing fats. Instead, oil is stored in microscopic globules throughout the cells of dicotyledonous oilseeds, or in corn germ or rice bran. Yields and processing costs are highly dependent on the effectiveness of preextraction operations to disrupt cells and free the oil for recovery. Operations differ among various oilseeds, mainly in techniques of dehulling. Traditional processes have heated soybean and let it stand (temper) for several days to loosen the hull (Fig. 34.9) [92]. They are being replaced by hot dehulling systems which loosen the hull and crack the seed in one operation immediately before flaking and extraction (Fig. 34.10). Avoiding a second heating step saves energy.

Hulls are removed in a two-step process, called *dehulling* or *decortication*, in which seed is first cracked, and the hulls removed by screening and/or aspiration to obtain "meats" for processing. The major objective of removing the hulls is reduction of fiber content in meals for feeding poultry and swine, resulting in increased protein content and reduction of volume of material sent to the extractor. Partial retention of hulls in the meats was required earlier to improve traction in screwpressing operations, but hulls are no longer required with availability of expanders equipped with oil drainage cages. It is common practice either to leave sufficient hulls with the meats to just surpass minimum protein guarantees of meals, or to adjust high protein meals to industry trading standards

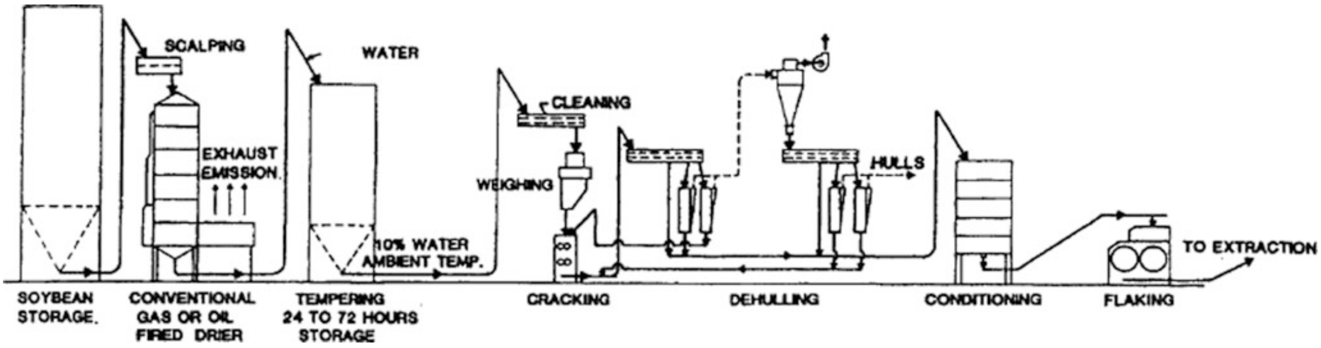

Fig. 34.9 Preparation system for conventional dehulling and flaking of soybeans. (From Moore [92], 141A–144A, With permission)

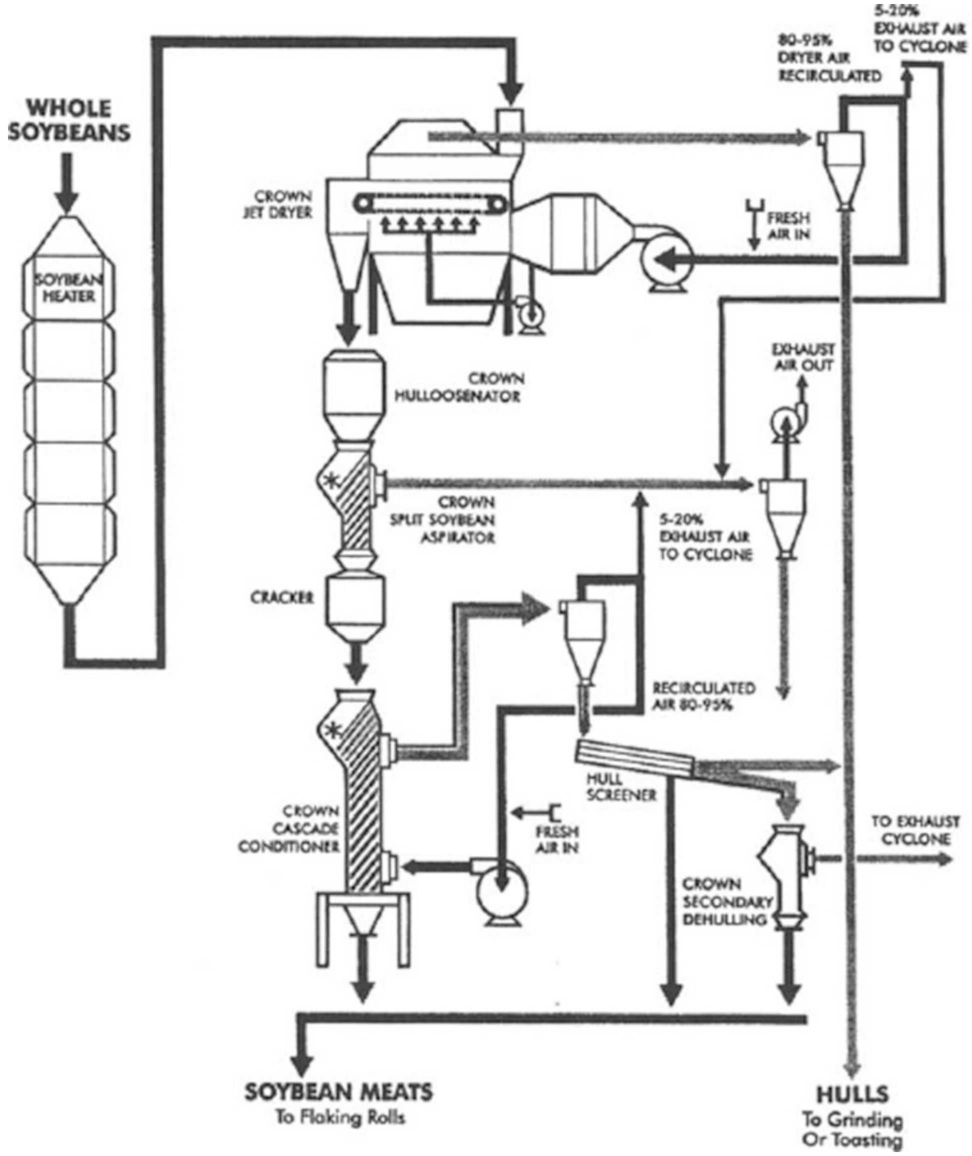

Fig. 34.10 Patented crown iron works hot dehulling system for soybean. (Courtesy of Crown Iron Works Company, Minneapolis, MN)

by adding back hulls after extraction. Currently, dehulled (low fiber) soybean meal trades at 48% protein, nondehulled soybean meal at 44%, cottonseed meal at 41%, and dehulled sunflower seed meal at 42% protein.

The meats are heated by steam injection to soften and increase the moisture content for plasticizing if needed in flaking. Cookers and heaters, used in the oilseeds processing industry, often are shallow circular ring-cooker pans with sweep arms in a multi-stack design, as shown in Fig. 34.16. In earlier processes, seed was heated to about 74°C/165°F before flaking to about 0.3-mm (0.012-in.) thickness. Now, it is realized that *phospholipases*, enzymes that make the phospholipids nonhydratable and more difficult to remove from the oil by water degumming, are highly active at this temperature, and seeds preferably are heated to less than 57°C/135°F or higher than 85°C/185 F to avoid the range of maximum phospholipase activity. Often, the flakes next pass through an expander for rapid heating to 105–121°C/220–250°F for homo-genization and shaping into collets.

Before the mid-1980s, processing concepts were based on classification of oilseeds into two groups. Meats containing over 30% oil on a dehulled or as-processed basis, including rapeseed/canola, oil-type sunflower seed, peanut, safflower seed, and copra, were considered *high-oil seeds*. Typically,

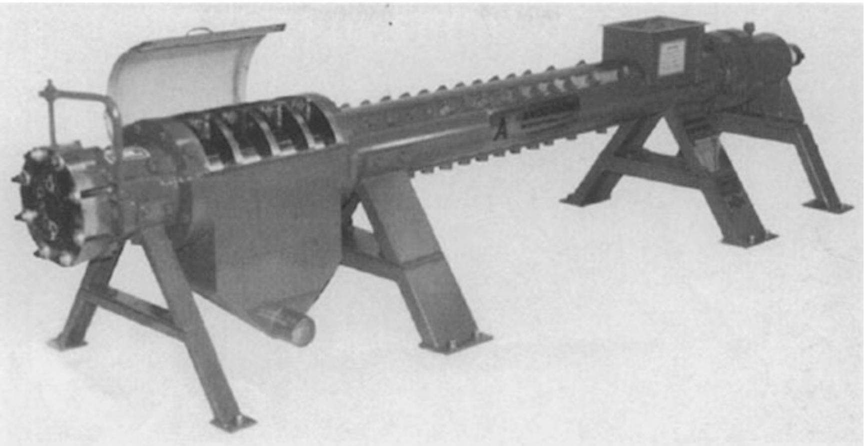

Fig. 34.11 Anderson International Corp. Hivex-Series-Expander™ with oil drainage section for preparing extraction collets from high-oil-content seeds. (Courtesy of Anderson International Corp, Cleveland, OH)

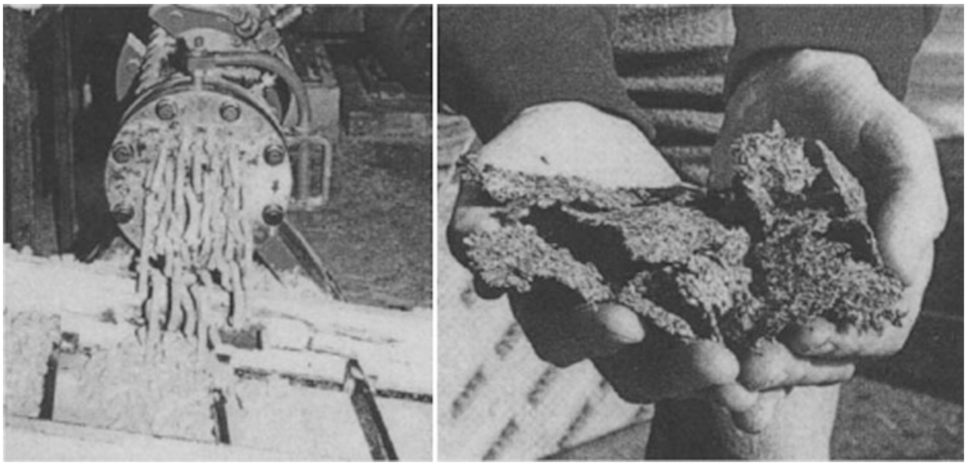

Fig. 34.12 *Left*: Soybean collets for extraction exiting die plate head, Solvex™ expander; strands break into random lengths. *Right*: Puff sheets made by hydraulically positioned cone choke head on expander. (Courtesy of Anderson International Corp., Cleveland, OH)

these seeds were dehulled (shredded in the case of copra); heated, flaked, and hard pressed, leaving 4–6% residual oil in the meal. Processors desiring to recover additional oil would first prepress high-oil seeds to 15–18% oil content using lighter-duty screw presses, and then solvent extract the press cake to less than 1% residual oil content; this process is called *prepress-solvent extraction*. Hard pressing was considered too inefficient for low-oil content seeds such as soybean unless nearby markets were available for the oil-rich meal. Soybean typically has been direct solvent extracted to less than 0.75% residual oil content. Cottonseed was extracted originally by hard press, later by prepress-solvent extraction, and now mainly by expander-direct solvent extraction techniques.

Introduction of the expander, a high-shear extruder with an interrupted-flight screw, in the mid-1980s revolutionized oilseed extraction practices. Essentially all solvent-extracted cottonseed and approximately 70% of domestic soybean tonnage now are processed with expanders. The expander heats, homogenizes, and shapes seeds or flakes into porous collets (pellets) that are more dense (weigh more per unit volume) than flakes, but are more rapidly extracted, approximately doubling the throughput of continuous solvent extractors. In effect, solvent extraction is changed from a diffusion process to a leaching process. Even though the expander homogenizes the seed, prior flaking still enhances oil recovery, but can be done at 0.5-mm (0.020-in.) thickness instead of the typical 0.3 mm (0.012 in.). The flakes or collets are cooled, with some drying occurring, to about 6°C/10°F below the boiling point of the solvent before entering the extractor. Collets also drain more completely than flakes, greatly reducing steam costs for desolventizing the extracted meal.

The Anderson International Company of Cleveland, Ohio, has patented an expander with a drainage cage (Fig. 34.11) to reduce the oil content of high-oil seeds to less than 20%, thus enabling the production of collets for direct solvent extraction from completely dehulled seeds such as sunflower seed and peanut. Replacement of the die plate (Fig. 34.12) with a hydraulically operated cone discharge head in the mid-1990s solved many of the problems first experienced in using oil-drainage cage-equipped expanders.

Introduction of the expander has enabled extraction plants to handle additional seed species, with purchase of only minimal cleaning and dehulling equipment where needed.

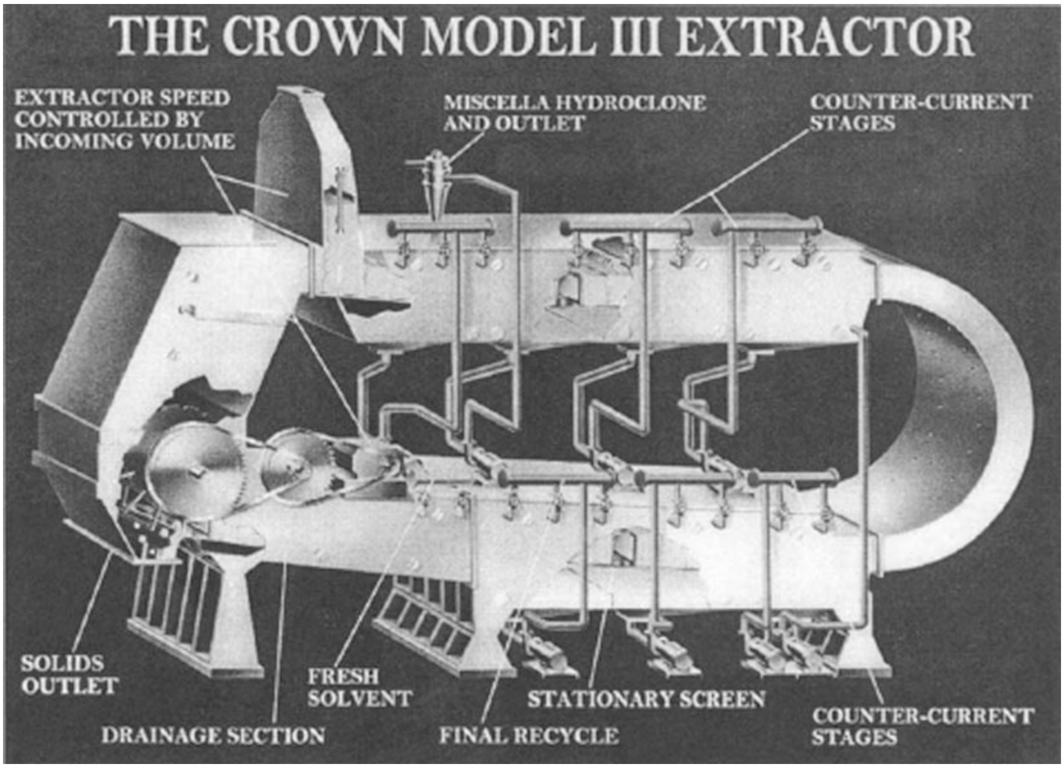

Fig. 34.13 Rectangular loop-type continuous countercurrent solvent extractor. (Courtesy of Crown Iron Works Company, Minneapolis, MN)

Prepress-solvent extraction facilities are being replaced by expander-direct solvent extraction equipment, leaving two basic extraction processes in modern large volume oilseed extraction plants: expander-direct solvent extraction, and hard press for applications where seed supplies are limited, or other considerations do not warrant construction of solvent extraction plants or the expense of skilled personnel and additional safety precautions for their operation. Hydraulic cage presses still are used in processing industrial crops such as castor seed, and for edible oils in developing countries.

Solvent Extractors

Hardly any batch-type oilseed solvent extractors remain. Three of the more popular types currently manufactured include: (1) *shallow bed-type* extractors, where a 0.5–1.5 m thick layer of collets or flakes is pulled across a linear screen and extracted by drenching with a countercurrent flowing miscella consisting of solvent and solubilized oil (Fig. 34.13); (2) *diffusion belt type*, where deeper beds of collets or flakes are conveyed on a woven mesh or folding-pan belt while drenched in countercurrent fashion with miscella (Fig. 34.14); and (3) *deep bed-type* which are constructed as carousels with pie-shaped cells that are filled with collets or flakes (~3 m deep), and extracted in countercurrent flowing fashion by drenching with miscella. *Marc* (wet extracted flakes/collets) dropping doors and moving parts have been eliminated in the newer carousel models, and the cells are revolved across a fixed screen (Fig. 34.15). Shallow bed extractors are built in capacities of up to 8,000 metric tons per day, and carousel-type extractors at up to 10,000 metric tons per day.

Solvents

Many solvents have been proposed for extracting oilseeds, but later found ineffective; others were used for a period, but disallowed because of health concerns about residues in food and feed products, or worker exposure [93]. All extraction solvents approved currently are flammable. Most commercial oil extraction currently is with hexane, a mixture of petroleum refinery fractions with a boiling point of 65–68°C/145–155°F, that consists of at least 60% *n*-hexane, with the balance being short-chain homologues and branched compounds. Some plants are using isohexane, which boils at a lower temperature. The US-EPA raised many concerns about extraction solvents in the late 1980s and 1990s. The FDA's position that *n*-hexane is a neurotoxin was put aside after industry-sponsored research showed the problem does not exist in mixed solvent systems [94]. The EPA also raised concerns that discharged volatile organic compounds (VOC) are contributors to ozone production [95]. A major solvent

containment program was instituted and resulted in domestic extraction plants reducing hexane losses from as high as more than 1 gal per ton of seed extracted to 0.25 gal, with some plants reducing losses to less than 0.16 gal per ton seed processed. Extraction solvents are highly flammable, and plants are built, equipped, and operated under Standard 36 of NFPA International, formerly known as the National Fire Prevention Association [96]. Additional worker exposure limits, safety practices, and training are established by the Occupational Safety & Health Administration (OSHA) of the US Department of Labor.

A major project added to the information about isopropyl alcohol (IPA) from earlier trials [97, 98] and showed it can be as effective an extraction solvent as hexane [99]. However, because of high retrofitting costs, IPA is not likely to be implemented while hexane-type hydrocarbons are allowed.

Batch extraction of vegetable oils with high-pressure CO_2 (carbon dioxide) in a critical state (at pressures required for maintaining a liquid phase) was heavily researched in the 1980s [100]. A continuous process has recently been commercialized in which CO_2 is injected into the barrel of a modified screw press (HIPLEX®, High pressure liquid extraction, Crown Iron Works, Harburg-Freudenberger, personal communication). Soy meals produced using this equipment maintain high protein solubility, with PDI's (protein dispersibility index) >70%, and a residual oil context <4%. This technology is being implemented where markets for food application demand "organic" labeling of ingredients and high protein solubility is a functional necessity for the product. Eighteen 400 metric ton/day critical propane extraction plants were processing soybeans in China in 2002. But, domestic critical propane demonstration lines have experienced safety problems. A critical CO_2 extraction laboratory instrument, for rapid analysis of fat content in seed and meals, has been marketed domestically since the mid-1990s.

Desolventizing-Toasting

The extracted, drained marc contains approximately 25% hexane holdup in soybean collets and 33% in flakes, which is vaporized in a desolventizer-toaster (DT) under vacuum. Some DTs have cooling sections, but separate dryer-coolers (DCs) often are used in large installations. Steam is sparged into the marc as the heat source for volatilizing the solvent. The condensate must be removed subsequently by drying. The moist "toasting" operation destroys enzymes and antigrowth factors such as trypsin inhibitors and hemagglutinins in soybean [101] and reduces meal protein solubility and digestibility by rumen microorganisms, thus improving rumen by-pass or escape in feeding cattle and sheep. Figure 34.16 shows a cutaway drawing of a Crown/Schumacher design desolventizer-toaster-dryer-cooler (DTDC) line. The drained marc enters at the top of a stack of circular trays and is mixed by sweep arms and pushed to fall through slots to lower trays. The bottoms of the initial trays also are steam jacketed. As the marc progresses downwards, it encounters rising steam and solvent vapors and is "toasted" by moist heat. The steam provides heat for vaporizing the solvent, but leaves condensate. The solvent-water vapors, drawn off at the top of the DT, are condensed and the solvent recovered. The desolventized flakes or collets continue to work down through the trays where they are dried by hot air and then cooled by ambient air.

Miscella Refining

In processing most oilseeds, hexane is stripped from the miscella by distillation to produce a crude oil that subsequently is alkali or physically refined. However, gossypol and other pigments become extremely difficult to *bleach* if left in warm cottonseed oil for more than a few days. It is normal practice for cottonseed oil mills to send their crude oil immediately to an alkali refinery or to operate an on-site miscella refinery, where phosphatides, FFA, and color pigments are removed by alkali treatment of the oil-extraction solvent mixture. Cooling the crude oil as produced, until refining, also slows *fixing* of color.

In the process, miscella leaves the extractor at about 30–35% oil and is concentrated to approximately 65% oil by evaporation. The FFA in the concentrate then is reacted with alkali (sodium hydroxide solution) to produce soaps that are removed with other water-soluble compounds by centrifugation. Next, the solvent is removed from the miscella-refined oil by further evaporation, and the soapstock is spread on the meal in the DT to recover its solvent. Hexane vapors from the miscella and the DT are condensed, and the solvent is recycled to the extractor for reuse. The non-condensable gases are passed through a mineral oil stripper to recover the last traces of hexane.

Refining of Vegetable Fats and Oils

Technically, *refining* means alkali neutralization of FFA in the oil. But over time, all postextraction processing of oils has become known as *refining*, and the facility in which it is conducted a *refinery*. Conversions of the resulting ingredients into margarines and spreads, and bottling oils, often are done at different locations or companies. The objectives in refining and processing edible fats and oils include: removal of FFA, phospholipids (*gums*), oxidation products, color and off flavor/odor compounds, and toxic substances to produce light-colored, bland products with long shelf lives; obtaining a mixture of TAG with the desired solids content profiles over the temperature range of product use; and preparation and storage of semi-solid products with desired textures. A flow sheet for refining and processing fats and oils is shown in Fig. 34.17. Refining procedures reliably purify oils extracted from cottonseed, peanut, and corn germ that have been contaminated with (water-soluble) mycotoxins or pesticides, but the resulting meals may have to be destroyed, used as fertilizer, or further treated to inactivate aflatoxins.

Oil Receiving and Handling

Maximizing yields of saleable oil requires even more detailed analyses and attention to lot-to-lot differences during refining than in preparing oilseed lots for extraction. Using soybean oil as an example, the first priority on receiving a shipment, or the output of an adjoining extraction plant, is to characterize the overall quality of the oil and determine what needs to be done to prepare it for market. The responsibilities of the refinery may include preparing freshly extracted oil ready for sale as *Crude Degummed Soybean Oil, Once Refined Soybean Oil,* or *Fully Refined Soybean Oil* for export under National Oil Processors Association (NOPA) Trading Rules [102], or other agreements made with the buyer.

To prevent hydration and precipitation of phosphatides during storage and shipping, the phosphorous content of crude soybean oil must be reduced to less than 0.02% (200 ppm) before entering the trade. This usually is accomplished by water degumming.

If the refinery purchases soybean oils for processing, one of the first tasks is to check composition of the received oil against the contract (usually NOPA Trading Rules), in as much as this determines the final price paid:

- *Flash point* (indicator of residual extraction solvent)—AOCS Method Cc 9c-95(97) (>250°F)
- *Unsaponifiable matter*—Method Ca 6a-40(97) (<1.5%)
- *Free fatty acids* (FFA), as oleic—AOCS Method Ca 5a-40(97) (<0.75%)
- *Moisture and volatile matter* (M&V)—AOCS Method Ca 2d-25(97) and insoluble impurities—AOCS Method Ca 3a-46(97) (<0.3%)
- *Phosphorous*—AOCS Method Ca 12-55(97) (<0.02%)

Additionally, the analytical laboratory estimates how much saleable oil can be produced from the lot, usually by neutral oil and loss (NOL) analysis (AOCS Method Ca 9f-57). In this procedure, a solvent-diluted sample of the oil is poured over a column packed with activated alumina (aluminum oxide). After evaporation of the solvent, the weight percentage of the oil that passed through the column is considered *neutral oil,* and the weight of oil retained is the "loss." The analyst may run a *bleach test* (AOCS Method Cc 83–63) or a *refining test* (AOCS Method Ca 9d-52, seldom used currently) if concerns exist about reducing the color of the oil to an acceptable range.

Phosphatides Degumming, Lecithin Uses

Phosphatides are essentially removed in modern oil processing to minimize fouling the bleaching earth, poisoning hydrogenation catalysts, and darkening the oil color by heat during deodorization and deep fat frying. Phosphatide contents

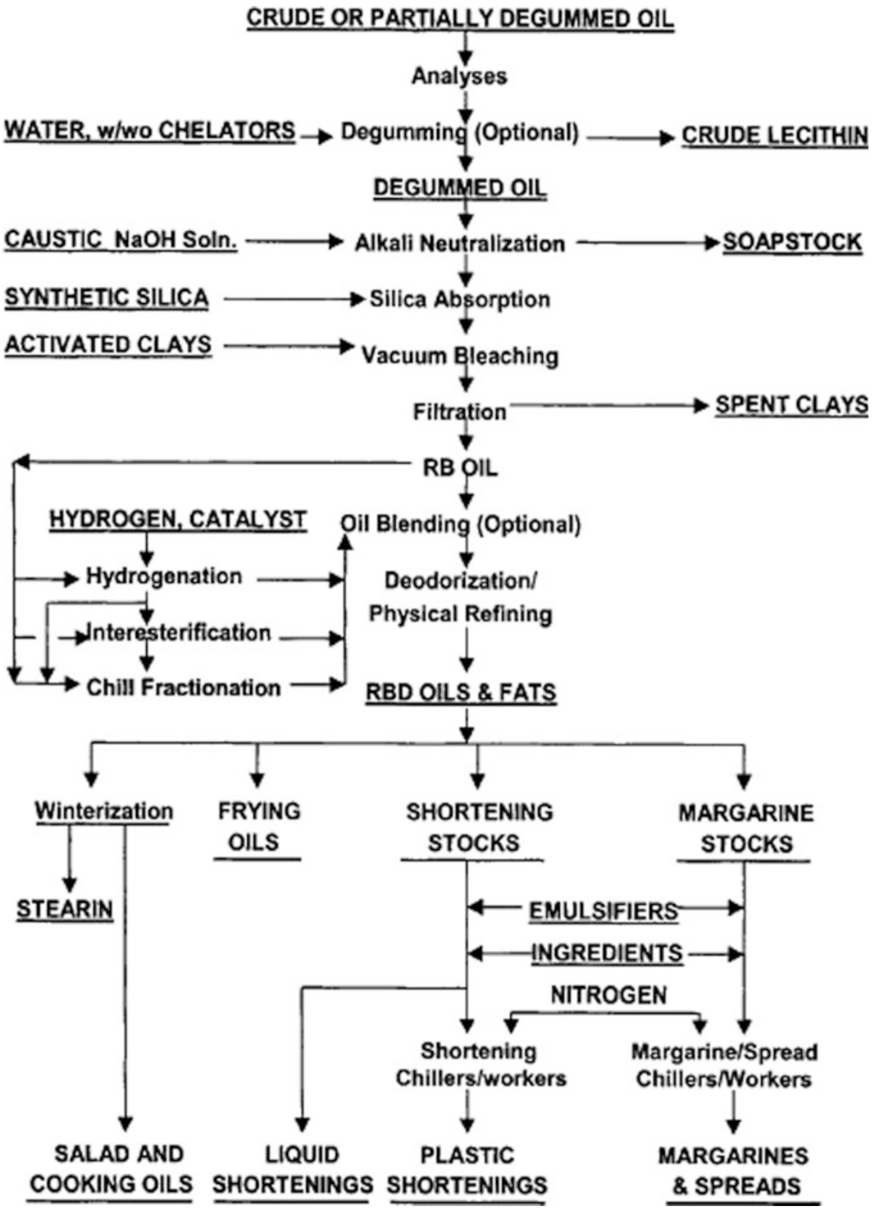

Fig. 34.17 Composite flow sheet of oils and fats refining and processing

of common vegetable oils are shown in Table 34.10. Soy, corn, and canola phosphatides are separated in North America, and some of the former Soviet Union countries separate sunflower seed phosphatides. For soybean oil, the relationship between phosphatide and phosphorous content is:

$$[\text{phosphatide } (\%) \times 10^4]/31.7 = \text{phosphorous ppm}$$

If lecithin is saved at the refinery, the hydratable phosphatides are separated by simple *water degumming* (hydration with deionized water, followed by centrifugation). However, some of the phosphatides will have been converted to NHP by enzyme action. In this case, a chelating agent (phosphoric acid usually because of lower cost) is added to the alkali in the FFA neutralization step to return the NHP to hydratable form. Palm oil has very low phosphatide levels and is physically refined after acid degumming and bleaching. The addition of chelating acids to crude row crop oils before alkali refining results in removal of hydrated phosphatides with the centrifuged soapstock, but viscosity is high and appreciable losses of neutral oil can occur by occlusion. Thus, many soybean oil refineries, without markets for crude lecithin, still run preliminary degumming operations and spread the gums with the later removed soapstock over the desolventized marc for drying in the dryer-cooler and sale as part of the soybean meal [103].

Commercial lecithin is produced by water degumming (precipitation from oil with ion-exchange treated water), separation by stacked disk centrifuge, and vacuum drying to less than 1% moisture content. Crude lecithins contain

Table 34.10 Phosphatide contents of common vegetable oil (From: Farr [103], With permission)

Type of oil	Phosphatide content As (%)	As Phosphorous[a] (ppm)
Soybean	1.0–3.0	311–940
Corn	0.7–0.9	220–280
Safflower	0.4–0.6	130–290
Sunflower	0.5–0.9	160–290
Peanut	0.3–0.4	95–190
Canola (super degummed)	0.16	50
Canola (crude)	1.0–3.0	311–940

[a] Phosphorous calculated as: [phosphatede (%) × 10^4]/31.7 = phosphorous (ppm)

70–72% acetone insolubles (AI) and are standardized to 62–64% and an acid value of 30 by addition of oil and fatty acids before sale. Crude lecithins may be treated with acetone to obtain free-flowing powders with 95–98% AI. Lecithin can be additionally purified, bleached, fractionated, hydrogenated, hydroxylated, acetylated, sulfonated, and halogenated [104]. One domestic company makes 13 kinds of lecithin for food uses alone.

Food applications of lecithins include: emulsification, wetting and dispersing agents, modification of baking properties, pan release agents, viscosity reduction of melted chocolate, anti-spattering agents in margarine, antioxidant effects, and nutritional supplements. Feed uses include wetting and dispersing agents in calf starters, and nutritional supplementation. Choline is a recognized vitamin, and inositol has been found essential in feeding some species of fish. Industrial uses include: emulsification and dispersion of active agents in pesticides, dispersing agents and stabilizers in paints and magnetic tapes, softening agents and penetrants for leather, and softening and lubrication of textiles. Cosmetic uses include: foam stabilizers and emollients in hair care, and emulsification, emollient, refitting and wetting agents in skin care. Pharmaceutical applications include: emulsifiers in parentoral nutrition, carriers and softening agents in suppositories, and emulsification and penetration improvement in cremes and lotions [105].

Some natural NHP always are present in crude oil, but development of additional NHP during seed extraction can be minimized by heat inactivation of phospholipases as explained earlier. In preparation for degumming, a tank large enough to supply the refinery with uniform oil feed stock for a suitable period of time is filled and mixed. Samples are taken for FFA, calcium, and magnesium analyses. Earlier practices of adding an amount of water equal to the weight of the phosphatides have been defined more precisely, and:

$$\text{added water} = (\text{ppm } P \times 3.17 \times 10^{-4}) \times 0.7$$

is recommended. The amount of phosphoric acid used is:

$$H_3PO_4 = [(Ca + Mg)/2] \times 10$$

with all components expressed in ppm.

The phosphoric acid and water are added to the warmed (65°C/150°F) crude oil stream, pass through a high-shear mixer, and are pumped to the stirred hydration tank. Details of the process, using an Alfa Laval (Lund, Sweden) PX-90 centrifuge rated at 33,000 kg/h for degumming, are shown in Fig. 34.18 [7]. After degumming, the crude oil is vacuum dried to <0.3% moisture and volatiles content and cooled to 50°C/120°F for storage or shipment. But, this step can be omitted if the oil is refined immediately [103].

The objective in acid degumming is to chelate the calcium and magnesium ions and render the nonhydratable phosphatide forms hydratable. In addition to phosphoric acid, citric and malic acids are effective, as well as ethylenediaminetetraacetic acid (EDTA). Acid-treated phosphatides are not used for production of commercial lecithins. Extensive reviews on oil degumming have been prepared [106, 107]. Lurgi, a German equipment manufacturer, has developed an EnzyMax™ process that cleaves the NHP with a phospholipase B at the triglyceride's second carbon to produce a lysophosphatide that is insoluble in oil and is removed by centrifuging [108].

In earlier times, the NHP content was determined by analyzing a water degummed sample for phosphorous, but the procedure took too long for commercial use. In reality, phosphorous is only a marker and loss of hydration actually results from the presence of divalent cations, primarily calcium and magnesium. Refineries now use induction coupled plasma (ICP) spectrographs for analyzing divalent cations content rapidly in aspirated crude oil and adjust the amount of phosphoric acid used for each "day tank lot" of analyzed oil. ICP units cost in the range of $75,000–125,000, but, reportedly, pay for themselves through increased oil yields in as little as 6 months in mid-size (500 t/day) refineries.

The crude oil from which gums are taken for lecithin production still contains non-hydratable phosphatides, but can be treated with a chelating agent before alkali neutralization and will be removed with the soapstock by centrifugation. Provision must be made for the added acid in calculating the amount of neutralizing alkali added.

Alkali Neutralization

The elimination of neutralized oil wash water is the major breakthrough of the decade in oils refining, with *modified caustic refining* or *silica refining* processes still being optimized. Phosphatides are removed by degumming, as already described, and FFA in the crude oil is still

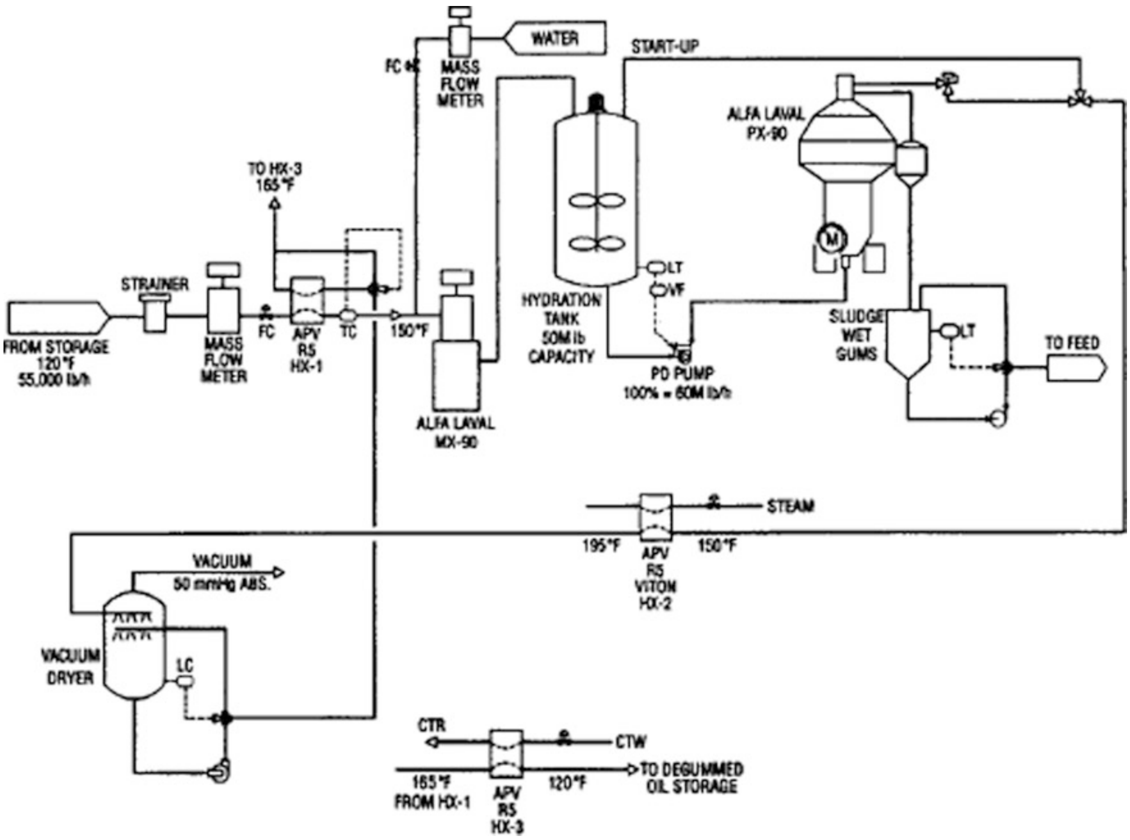

Fig. 34.18 low sheet of a modern water or acid degumming line. (From Farr [103], With permission)

neutralized with sodium hydroxide (*caustic*) solution (20–50°Be for cottonseed oil, and 16–24°Be for soybean, sunflower, safflower, peanut, and corn *oils*). But, the refinery then has the choice of water-washing the oil after removal of soapstock, or adsorbing the residual soaps on silica hydrogel before bleaching, thus eliminating problems of disposing the wash water. Process demonstration by the W. R. Grace Company began in 1986, with increasing growth in the commercial use of Trisyl™ in the 1990s. Several silica hydrogel suppliers now exist [103].

Two major processes have been used for alkali neutralization of FFA in row crop oils: the *long mix* and the *short mix*. The short mix process evolved in Europe, runs at a higher temperature, and reportedly is effective with a number of oils. The long mix process was developed in the United States and has been championed for refining soybean oil. It respects the principle that chemical reactions occur more rapidly and are harder to control, at higher temperatures (van't Hoff rule that the speed of reaction doubles with each 10°C rise in temperature). Traditionally, the long-mix process starts with crude soybean oil at ambient temperature, uses a low-concentration caustic solution, and has a mixer retention time of 15 min after which the oil–caustic mixture is heated to 70°C/160°F to reduce its viscosity before centrifuging. In the short-mix process, crude oil is heated to 90°C/194°F, mixed with high-concentration caustic solution for 1 min and centrifuged [109]. The throughput per hour of both systems is the same because the additional volume for the holding time is built into the long mix line.

A flow chart of a long mix neutralization process is shown in Fig. 34.19. The recommended retention time for soybean oil in this system is 6 min and was shortened by a major improvement in caustic–oil retention mixers developed by the Alfa Laval Company, Tumba, Sweden, in the mid-1990s [103].

The amount of caustic treat to be added for neutralization of soybean oil is calculated as:

$$\begin{aligned}\text{percent treat} = {} & [(\text{factor} \times \text{percent FFA}) \\ & + (\text{percent excess})/\text{percent NaOH}] \times 100\end{aligned}$$

where factor = 0.142, NaOH is determined from the 20°Be of the caustic solution, and percent excess is selected from the following ranges based on experience in the specific refinery: degummed soybean oil, 0.01–0.05; nondegummed soybean oil, 0.15–0.25. Continuing with Fig. 34.19, soybean oil from storage is adjusted to 38°C/100°F, passed through strainers, mixed with the treat in the rapid mixer, held in the retention mixers for 6 min, heated to 60°C/140°F, and passed through the primary (first) centrifuge [103]. The soapstock is returned to the extraction plant with surplus

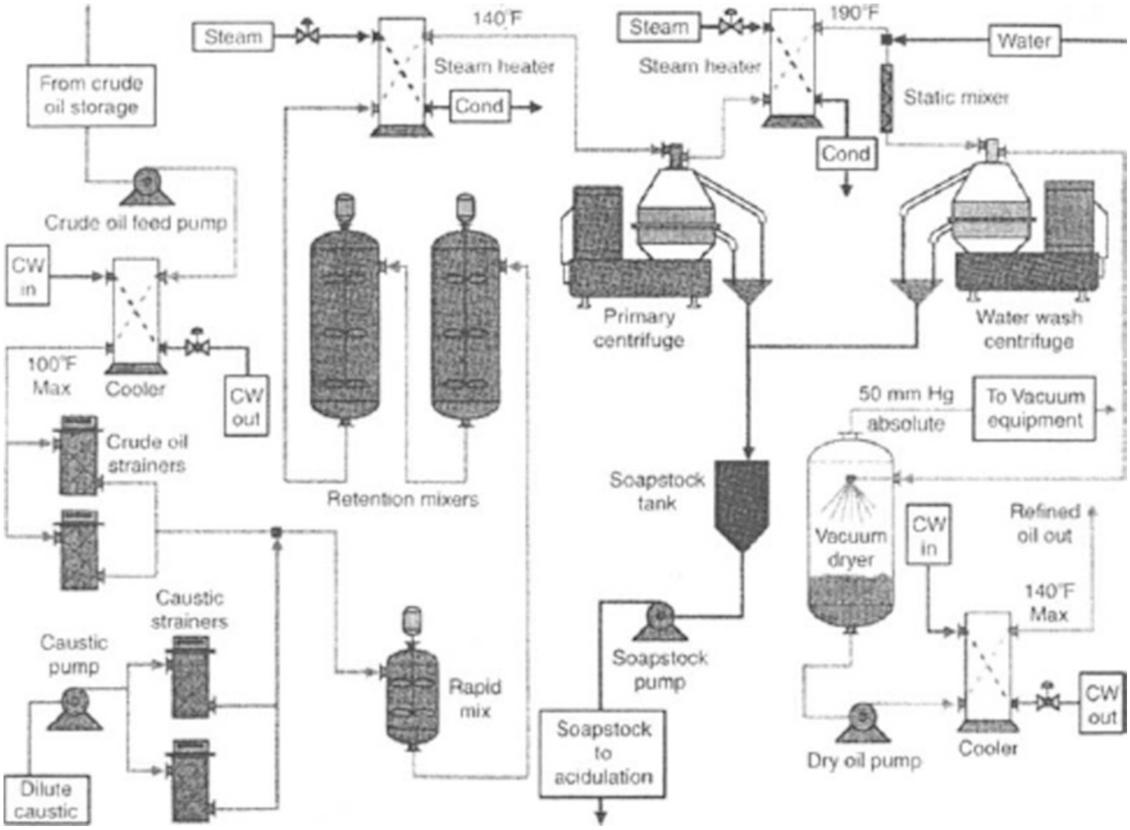

Fig. 34.19 Flow sheet of continuous refining of soybean oil (long mix process) with water wash option. (From Farr [103], With permission)

or acid-degummed phosphatides to be spread over the meal before the dryer-cooler. The refinery then can water wash and vacuum dry the oil by traditional methods, or treat it by silica gel adsorption. If a water wash is used, the oil is heated to 88°C/190°F with 12–15% soft water, held in an agitated tank for ~0.5 h, and centrifuged to produce an oil with <20 ppm soap. The soap can be reduced to "0" by addition of a small amount of phosphoric acid in the water-wash retention tank. The oil is next sprayed into a drying tank at 50 mmHg absolute [103].

Sodium silicate neutralization also has shown promise as a potential commercial method. The resulting soaps form a granular agglomerate, which can be removed by filtration to produce oil containing less than 100-ppm soaps. Thus, the costs of purchasing and maintaining primary and water-wash centrifuges and wash water disposal are avoided. The filtered oil can be treated with neutral or activated clays to remove color, peroxides, residual phosphatides, and soaps to produce oils with FFA fatty acids contents of less than 0.05% and "0" PV (*peroxide value*) [110]. The method has been patented and is being evaluated commercially.

Various researchers have reported on attempts to remove fatty acids from oils by ultrafiltration membranes. In the absence of membranes that can withstand extraction solvents, success generally has been limited. However, progress has been made on membrane degumming [111].

Silica Gel Adsorption

Silica hydrogels are very effective in removing phosphatides, residual soaps, and metal ions (all poisonous to hydrogenation catalysts), thus reducing the amount of bleaching clay required (by 50–75%) and leaving its function primarily to remove chlorophyll and secondary oxidation products. By eliminating soapy wash water, water discharged from refineries is reduced by ~50% in volume and has much lower biological oxidative demand (BOD). Additionally, cost and expenses of a second washing centrifuge are avoided [103].

The method of using silica hydrogel has changed during perfection of the process. Variations in procedure exist, but silica hydrogel can accept oil from the centrifuge at 0.2–0.4% water content. The currently recommended process consists of blending the silica hydrogel with oil directly from the soap removal centrifuge, with minimum, if any, drying of the oil. Silica hydrogel then is removed by filtration before mixing the oil with the bleaching earth [103].

Bleaching

Bleaching originally was a process for reducing color in oils, but the name has become a misnomer of this industry. Although limited color reduction occurs during the process, the major reduction of red and yellow colors occurs during the high heat of the deodorization process. The current practical function of bleaching is to remove chlorophyll and oxidation-degraded compounds and prepare the oil for hydrogenation or interesterification by scavenging the remaining soaps, phosphatides, and minerals that would poison the catalyst. Several authors have reviewed the theory and practical aspects of bleaching [112–114].

Bleaching earths are made from naturally occurring minerals, including palygorskite—also known as attapulgite, sepiolite, bentonite, and montmorillonite—and other minerals belonging to the aluminum silicate family. They may be used as such, but typically are preactivated by treatment with hydrochloric or sulfuric acids which: increase absorption by increasing surface area several fold; provide acid centers with catalytic properties; and impart ion-exchange properties to the clay. These properties are important in adsorbing various undesirable impurities in the oil, and in rendering complex organic structures adsorbable. In addition to adsorbing phosphatides and soaps, the process also removes pesticides, polycyclic aromatic hydrocarbons, *trans* and conjugated fatty acids, dimers, and polymers. Activated earths also provide a catalytic surface for breaking down peroxides. Decomposition is an exothermic reaction, with the heat apparently enhancing the *press effect* in color reduction of carotenoids in the filter press. The cation exchange property of the activated earth is credited with removing magnesium from the center of the chlorophyll complex and arresting its activity as a pro-oxidant. Cation exchange also is used for the removal of heavy trace metal pro-oxidants such as iron and copper, and for removing trace nickel in postbleaching of hydrogenated oil [114]. Although peroxides content is reduced, *p*-Anisidine Value (AV; AOCS Method Cs 18–90) increases. The AV is believed to estimate aldehydes (2-alkenals and 2,4-dienals) in animal and vegetable oils with the potential for later breakdown.

Bleaching clay load (typically 0.1–2.0%) and operating temperatures depend on the type and quality of oil processed [114]. Modern bleaching processes are conducted under vacuum (50 mmHg) to minimize later oil oxidation, and subsequent nitrogen blanketing of the oil during shipping and storage is recommended.

Close coupling of the refining and bleaching operations is highly recommended, especially when using the modified caustic refining or silica refining processes [103]. Because of the high level of unsaturated oils and peroxides in spent bleaching earth, it is very susceptible to spontaneous combustion unless quenched with water. Disposal in landfills is becoming increasingly difficult. Spreading spent bleaching clay on soybean meal for animal feeding is done in limited quantities, but caution should be taken because, by absorbing pesticides and mycotoxins, bleaching is one of the two safety valves in processing oils. The other is collection of volatile pesticides in the condensed deodorizer distillate.

Oils and Fats Modification

If processing proceeded next through deodorization, the resulting product would be liquid and known as “RBD oil” (refined, bleached, deodorized), and suitable for cooking and table use. However, consumers often want: oils that remain crystal clear when stored in household refrigerators; fat solids for an array of products such as butter-, ghee-, and lard-replacement spreads; air-entrapping shortenings for making tender, light-textured cakes; brittle or soft fats for toppings and frostings; cocoa butter replacements and substitutes; prolonged and prolonged bottled oil and frying lives; and fresh flavor in fried cereal-based snacks and nuts. Various techniques are used to craft fats with temperature-solids profiles such as the selected shortenings shown in Fig. 34.20 [115] from liquid oils. Modification processes include thermal fractionation, hydrogenation, and interesterification usually done before deodorization. Thermal fractionation and hydrogenation can use well-purified RB oil. Interesterification requires RBD oil with low FFA content. Hydrogenated and interesterified oils are postbleached and deodorized.

Solid Fat Index/Solid Fat Content

Two systems are used to characterize solids content of temperature-profiled fats. The Solid Fat Index (SFI) (AOCS Method AOCS Method Cd 10–57) uses dilatometers and was developed in the United States. It is the older method and is effective for fats containing up to 50% solids at 10°C/50°F. The Solid Fat Content (SFC) (AOCS Method Cd 16–81) uses pulsed nuclear magnetic resonance (NMR) techniques to quantify crystalization. It was developed more recently to accommodate palm oil and its products and is used in most other countries. SFC is effective for solids contents up to 95%; however, additional care in sample tempering may be required at the upper solids limits for either SFI or SFC. In both methods, a sample of the fat is completely melted to destroy its crystal memory, then chilled to 0°C to set the crystals. Readings are then taken at selected temperatures (10°C/50°F, 21.1°C/70°F, 26.7°C/80°F, 33.3°C/92°F, 37.8°C/100°F, and 40°C/104°F) to develop SFI or SFC curves. In some industries, five-point or three-point readings are taken; readings also may be made

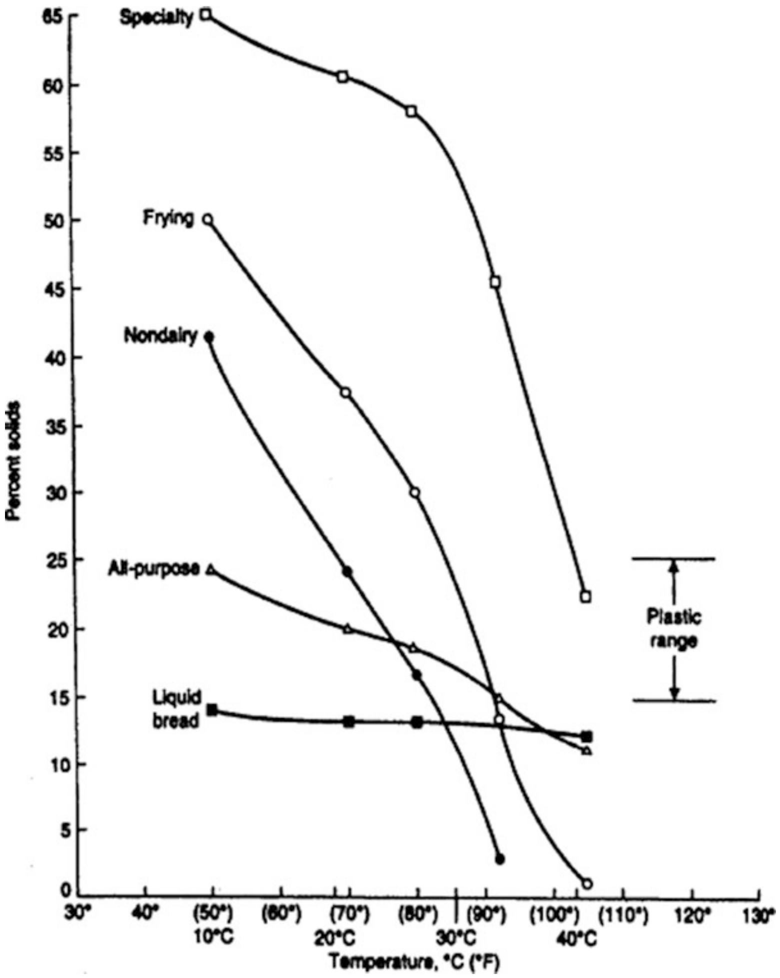

Fig. 34.20 Solids–temperature curves for various types of shortenings. (From O'Brien [115], With permission)

at higher temperatures. SFI and SFC give similar, but not identical results. A recent comparison of the two methods concluded that SFC reads higher at lower temperatures (10 and 21.1°C), but similar to SFI at higher temperatures [116]. The following equations for converting SFC of fats to SFI, with correlation coefficients, R^2, of 0.98–0.99 were offered: Commercial spreads:

$$\mathrm{SFI} = 1.98 + (0.72 \times \mathrm{SFC}) - (0.035 \times \mathrm{temp.})$$

Base stocks:

$$\mathrm{SFI} = 40.94 + (1.22 \times \mathrm{SFC}) + (1.03 \times \mathrm{temp.})$$

Bends (base stocks/liquid oil):

$$\mathrm{SFI} = 0.94 + (0.82 \times \mathrm{SFC}) + (0.02 \times \mathrm{temp.}) + (0.02 \times \mathrm{percent})$$

Profiles of margarine and table spread fats are shown later. Information available from SFI/SFC profiles includes solids contents at removal from most refrigerators (10°C/50°F), in typical kitchens (21.1–26.5°C/70–80°F), and at body temperature (37.8°C/100°F). The Steepness of the profile indicates relative effects of temperature change on fat firmness.

Melting properties of fats in the mouth are important. Generally, consumers can detect a greasy characteristic if more than 3% solids remain in spreads at mouth temperatures, or if more than 5–6% fat solids remain in baked, fried, and snack foods. Thus, doughnuts and bakery products are best eaten while warm to avoid greasy mouthfeel. The fried snack foods industry must choose between these alternatives: (1) snacks fried in oil may impart a cloudy appearance to see-through panels in the package, feel oily when picked up by the fingers, and stain clothing if dropped. (This is expected in long-time favorites such as corn chips, but may not be acceptable in newly introduced snacks.); and (2) Processors who want a "dry feeling" on pickup of the snack may select a fat that is solid at room temperature, but melts rapidly in the mouth to avoid the greasy sensation. Some snacks leave a greasy lining in the mouth if they are eaten at the same time the consumer drinks a cold soda pop. A fat, such as the one marked "Nondairy" in Fig. 34.20, could be used in coffee whiteners.

Another important factor is *plastic range*. Generally, 15–25% solids at ambient temperature are considered acceptable for working a fat-containing product (dough) without it becoming too oily to handle. Doughs containing the “all-purpose shortening” shown in Fig. 34.20 can be machined over a wide range of temperatures in a warm bakery. Stick margarines often are compounded to be softer and easier to spread than butter when taken from the refrigerator, to remain firmer at kitchen temperatures, and to melt completely without greasy mouthfeel when eaten. Soft (*tub*) margarine is ready to spread as taken from the refrigerator.

Thermal Fractionation

The simplest type of thermal fractionation is *winterization* for cosmetic reasons to obtain salad and cooking oils that remain clear when stored in the refrigerator. The oil is chilled in tanks with slow mixing to crystallize the higher melting point waxes, or TAG which are natural or produced by light hydrogenation to delay oxidation of the oil. A filter aid is added to assist filtration. After separation of the liquid (*olein*), the filtering apparatus is heated to melt and recover the fat solids (*stearin*), which can be used in compounding shortenings and other products [117]. The resulting oil is known as RBWD (refined, bleached, winterized, deodorized) and is expected to pass the “cold test” (AOCS Method CC 11–53) by resisting clouding for 5.5 h at 0°C. Shallow unstirred tanks in cool rooms were used for crystallization in earlier days. The rooms became warmer as crystallization progressed, demonstrating it as an exothermic reaction, and oils will readily assume the more compact crystal forms provided they are able to shed the energy as heat.

Thermal fractionation technology is most developed in the palm oil industry, where most oils are fractionated before sales. Solids profiles of stearins that have been fractionated from crude palm oil by chilling to different temperatures are shown in Fig. 34.21 [118]. Thermal fractionation and double fractionation can be useful tools in obtaining fat fractions with the specific desired characteristics (Fig. 34.22) [119].

Three major techniques are used in fractionation. In *dry fractionation,* oil is chilled with slow stirring and often seeded with crystals from an earlier batch. The resulting mixture can be quite viscous and present difficulties in draining oil from the crystals during filtration. In *solvent fractionation,* chilling and crystalization of oil occurs in a solvent, often acetone. The viscosity of the liquid phase is greatly reduced, resulting in easier separation and improved purity of crystals. Solvent fraction must be conducted in explosion-proof facilities. In *detergent fractionation,* a surfactant is added to the chill-crystallized oil–fat mixture and greatly improves drainage [77, 120]. Significant progress in recent years in dry fractionation technology has greatly simplified processing and reduced problems of handling solvents and byproduct streams [121]. A variation of the detergent fractionation principle has been used in dewaxing sunflower seed oil. Advantage is taken of the soap content (1,000–2,000 ppm) and 3–4% water remaining in un-washed alkalineutralized oil. After alkali neutralization, sunflower seed oil is pumped from the primary centrifuge directly to a heat exchanger for crystallization. The oil is held at 5–7°C/41–45°F for about 4 h for crystal growth, then heated by heat exchanger to 12–15°C/54–59°F, centrifuged to remove the wax crystals along with some water and soaps, washed with hot water, and centrifuged [122].

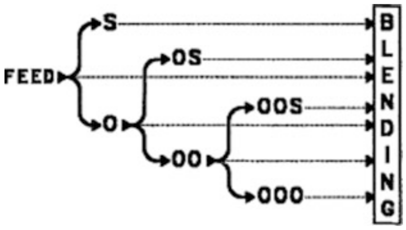

Fig. 34.22 Fat fractions from cascade fractionation. (From Tirtiaux [106], With permission)

Until the mid-1980s, continuous-belt vacuum filters mainly were used for separating oleins from stearins.

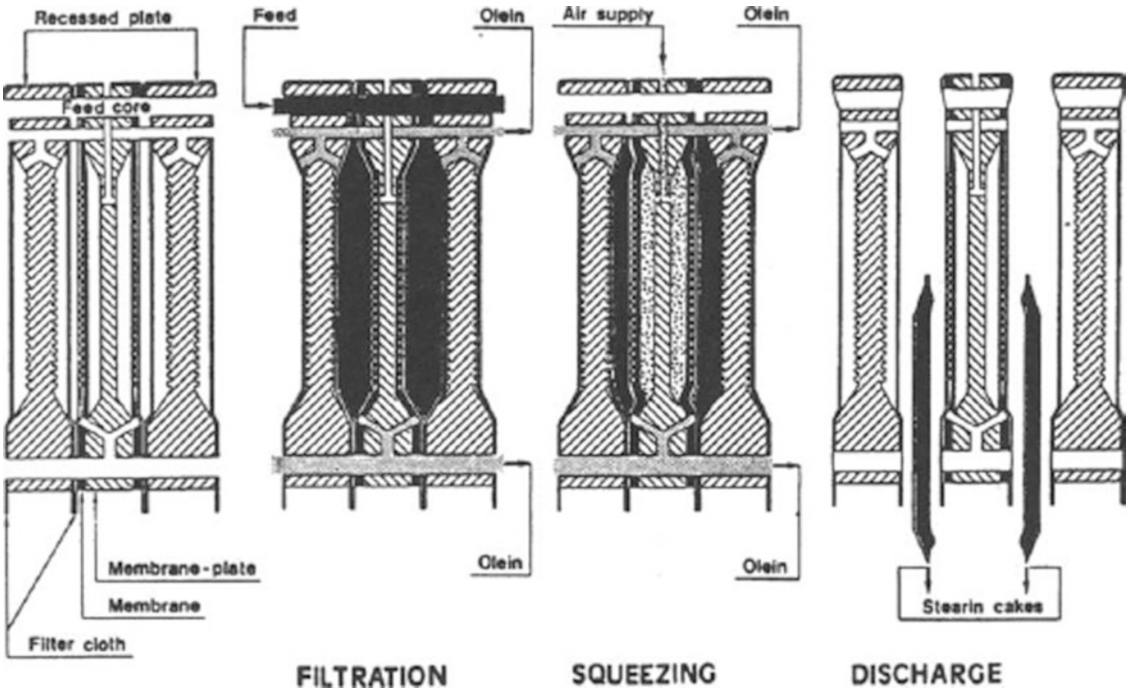

Fig. 34.23 Principle of membrane-type filtration of olein and stearin. (From Tirtiaux [106], With permission)

These are expensive and complex machines, requiring controlled temperatures in various sections and clearing of the belt for the subsequent filtration cycle. Simpler membrane filters have gained in popularity. As shown in Fig. 34.23, the active members resemble a plate and frame filter. Each cavity is lined on both sides with "membrane" filter stock, between which the crystal–oil mixture is pumped. Initially, free oil escapes through the filter stock, until the cavity is filled with crystals. Addition of the oil–crystals slurry is then stopped, and compressed air applied between the membrane and the frame to squeeze oil out from the enclosed crystal mass. When completed, the frames open, allowing the crystal cake to fall into a take-away screw. The frames then reclose, and the cycle is repeated. Stearins produced by membrane filters contain significantly less free oil than those from vacuum belt filters [119].

Oil is an effective solvent for higher temperature melting TAG, and results of thermal fractionation of common fats can be surprising. An example is milk fat (butterfat), which on extensive study has yielded 123 fractions melting as high at 54°C/129°F. Many tropical countries allow inclusion of up to 5% high melting hydrogenated fats in chocolate to raise the melting point and prevent blooming (loss of sheen, paling of color, and development of coarse crystals) resulting from repeated melting and resolidification. This also is a problem during the summer months in temperate countries. However, the latter countries often prohibit inclusion of fats other than cocoa butter in chocolate. The problem has been reduced in milk chocolate by adding high melting fractionated milk fat. Milk fat also has been used in higher-priced shortbread cookies, laminated pastries, and other bakery products where it provides a shortening effect, but doesn't melt and appear greasy.

Hydrogenation

Hydrogenation is the catalytically assisted addition of hydrogen to carbon–carbon double bonds. Its main uses are to increase fryer life of oils and shelf life of table oils and bakery products and to create solids for making shortenings, margarines and spreads, and various confectionery and specialty products. Many process reviews have been published [124–131].

Food technologists prefer to minimize the C18:3 content of oils to improve fryer and bottled oil shelf lives by reducing oxidation tendencies (Table 34.4). This has been partially accomplished by applying selective breeding and biotechnology to oilseeds, but the GMO products still are in the introductory phase. Because small amounts of linoleic (C18:2) and linolenic (C18:3) fatty acids are dietary essential, it is not desirable to eliminate them completely. For many applications, soybean and canola oils are partially stabilized against oxidation by (light) *brush hydrogenation*.

Selectivity, the tendency of the catalyst or process to remove one type of bond in favor of another, has several meanings in hydrogenation catalysts. *Preferential* or

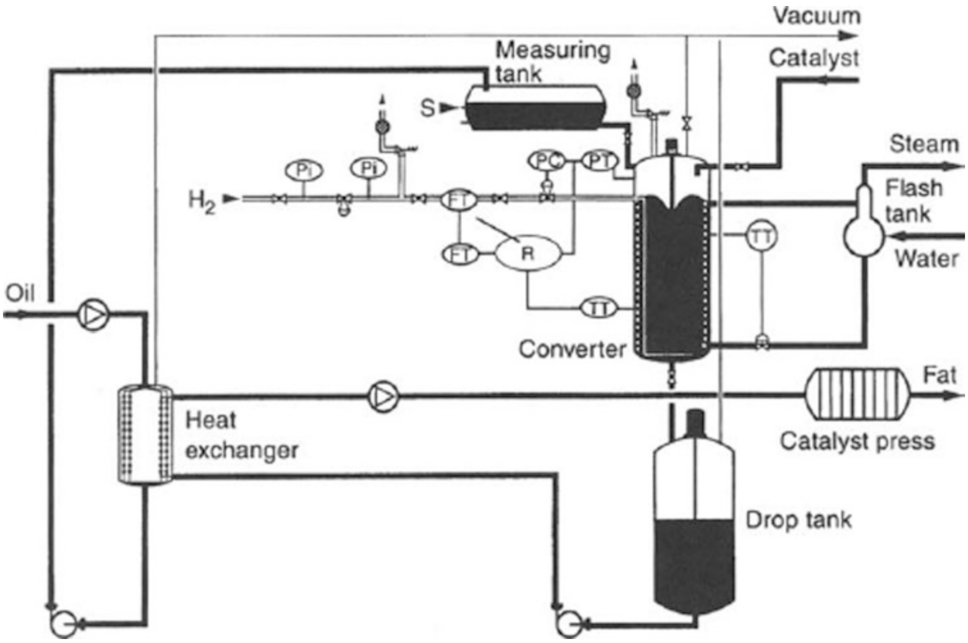

Fig. 34.24 Hydrogenation line. (From Hastert [130], With permission)

saturate selectivity indicates a focus on saturating a specific bond, for example, the C18:3 bond of linolenic acid to form C18:2 linoleic acid. Preferential selectivity is estimated from the following kinetic relationships:

$$C18:3 \xrightarrow{k_1} C18:2 \xrightarrow{k_2} C18:1 \xrightarrow{k_3} C18:0$$

with linolenic selectivity ratio (SR) defined as SR $1 = k_1/k_2$ and linoleic selectivity as SR $2 = k_2/k_3$. Linolenic acid selectivity for nickel catalysts varies from 2 to 3 and is as high as 6 for copper-based catalysts. Better control of linoleic selectivity, with SR 1 varying from 3 to 4 to 60, is achievable by the choice of catalysts, catalyst poisons, and reaction conditions. This gives the operator greater flexibility in establishing melting behavior and stability of the hydrogenated product [125].

Trans isomer selectivity is less directed and favors formation of *trans* bonds. Catalysts vary in selectivity, with performance greatly affected by catalyst dosage, effectiveness of mixing, temperature, and hydrogen pressure in the reactor. Bonds become conjugated during hydrogenation, but not all atoms fall back neatly into their former positions after the process. The new types of TAG produced increase diversity, which is desirable in controlling later crystallization processes. The production of *trans* (partially saturated) bonds is intentional and can be partially controlled [129].

Hydrogenation is conducted in hardening plants (Fig. 34.24). The *converter* is a pressurized reaction tank, equipped with a highspeed mixer and assisting baffles, means for adding and removing the oil, a gas distributor, a means to add catalyst, and heating and cooling coils. The hardening plant additionally has means for premeasuring and heating the oil, a drop tank, heat exchangers, and a catalyst filter. Purities of the oil and hydrogen affect the life of the catalyst, typically a thin film of nickel on an inert carrier [130].

In brush hydrogenation of soybean oil selective catalysts: (1) reduce IV by 15–25 to ~115 units; (2) produce ~15% *trans* isomers; (3) reduce C18:3 content to 3% maximum; and (4) increase C18:0 content by ~1% [131].

In preparing margarine bases, selective catalysts reduce IV to ~70 and produce about 50% *trans* isomers. Selective or nonselective catalysts used in preparing shortening bases reduce IV to ~75 and produce about 35% *trans* isomers. A high-activity catalyst is used in producing stearin flakes; the IV is reduced to ~5–10 with hardly any *trans* isomers remaining. The flakes are scraped off the surface of a chilled roll, or beadlets can be produced using a shot tower with chilled air.

Maintaining high levels of polyunsaturates is desirable in producing coating fats. A sulfided nickel catalyst is used to reduce IV to ~70 and produce about 65% *trans* isomers with production of saturates (C18:0) minimized to 2–4% increase [131].

Factors affecting the hydrogenation reaction include reactor design, purity of feedstock and hydrogen, operating conditions, and choice and efficiency of the catalyst. Operating conditions include hydrogen pressure, reaction temperature, catalyst dosage, and agitation. Because *trans* formation is indicative of incomplete saturation, conditions that favor keeping the catalyst covered with hydrogen favor saturate selectivity. Progress in the hydrogenation process typically is monitored online by refractive index, calibrated to IV for each process and product [131].

Production of temperature-profiled fat products, such as margarines/spreads and shortenings, often includes preparation of four to six base stocks hydrogenated to different IVs (Fig. 34.25), which are blended with oil and hardstocks to obtain the desired temperature-fat solids profile [132].

An example of broadening the plastic range (15–25% fat solids) of two base stocks by addition of hardstocks is shown in Fig. 34.26. By itself, the 80 IV base stock is in the 15–25% solids (machinable) range only between the temperatures of 10 and 20°C. But, by addition of 8% (5 IV) hardstock, the range was broadened to ~30°C. Addition of 12% hardstock to the 85 IV base stock broadened its working range from ~10–12 to 38°C, which is more typical of bakery operating temperatures [124].

Interesterification

Interesterification (INES) is the exchange of acyl radicals between an ester and an acid (*acidolysis*), an ester and an alcohol (*alcoholysis*), or an ester and an ester (*transesterification*) and can be random, directed, or enzymatic. The process has been called *intraesterification* if an exchange of positions occurs within the same molecule, and *randomization* if exchange occurs between molecules [44, 48]. The principles can be used to position fatty acids on molecules with hydroxyl sites to produce monoglycerides (emulsifiers), fatty acid methyl esters (FAME) for analytical purposes, liquid fuels such as methyl soyate (biodiesel), specialty fats such as medium chain triglycerides (MCT), and sugar-ester noncaloric fat substitutes such as Olean™.

n native; *r* randomized

Research publications exist from at least as early as 1852, and United States patents from 1939 [133].

The basic acidolysis reaction is:

$$R^1COOR^2 + R^3COOH \rightarrow R^3COOR^2 + R^1COOH$$

The alcoholysis reaction is:

$$RCOOR^1 + R^2OH \rightarrow RCOOR^2 + R^1OH$$

with methyl alcohol used for preparing FAME when determining the fatty acids components of TAG, and in making much of the biodiesel. Ethanol and other alcohols, up to four carbons in length (butanol), also have been used [44].

Glycerolysis has been used to prepare mono- and diglyceride emulsifiers by reacting TAG with an excess of glycerol [44].

Standard “mono- and diglyceride” products contain 40–50% monoglycerides, whose content can be raised to 53% without distillation. Distilled monoglycerides contain a minimum of 90% α-monoglycerides [44].

In the *sucrosolysis* preparation of Olean™, the generic name for Proctor & Gamble Company’s olestra, six to eight fatty acids, selected for functionality purposes, are positioned on sucrose. Although many noncaloric fats are limited or nondigestible, they are made from traditional vegetable oils. Akoh has summarized uses of these and similar products [134].

Except for enzyme-directed processes to place certain fatty acids in specific positions on TAG, such as production of coating fats, cocoa butter substitutes, or reduced-calorie fats [135], the majority of esterification processes are randomizations.

As mentioned earlier, nature arranges the fatty acids in plant oils to achieve the lowest melting point. The abbreviations S and U, for saturated and unsaturated fatty acids, respectively, also are used in indicating their prevalence on TAG: thus S_3, S_2U, SU_2, and U_3. Distributions of these combinations in nature and in randomized products are shown in Table 34.11 [48, 136]. The literature indicates that stability against oxidation often is reduced by withdrawing the unsaturated fatty acids from the *sn*-2 position [44]. Randomization always raises the melting point, more so for vegetable oils than for animal fats, with an increase of 8.5°C for soybean oil. S_3 TAG hardly exists in natural vegetable oils, with only low concentrations occurring in animal fats. However, some are formed during randomization.

Directed randomization is a specific technique that precipitates S_3 and S_2U TAG as formed, depending on operating temperatures chosen. Removal of saturated fatty acids from cottonseed oil has been demonstrated recently

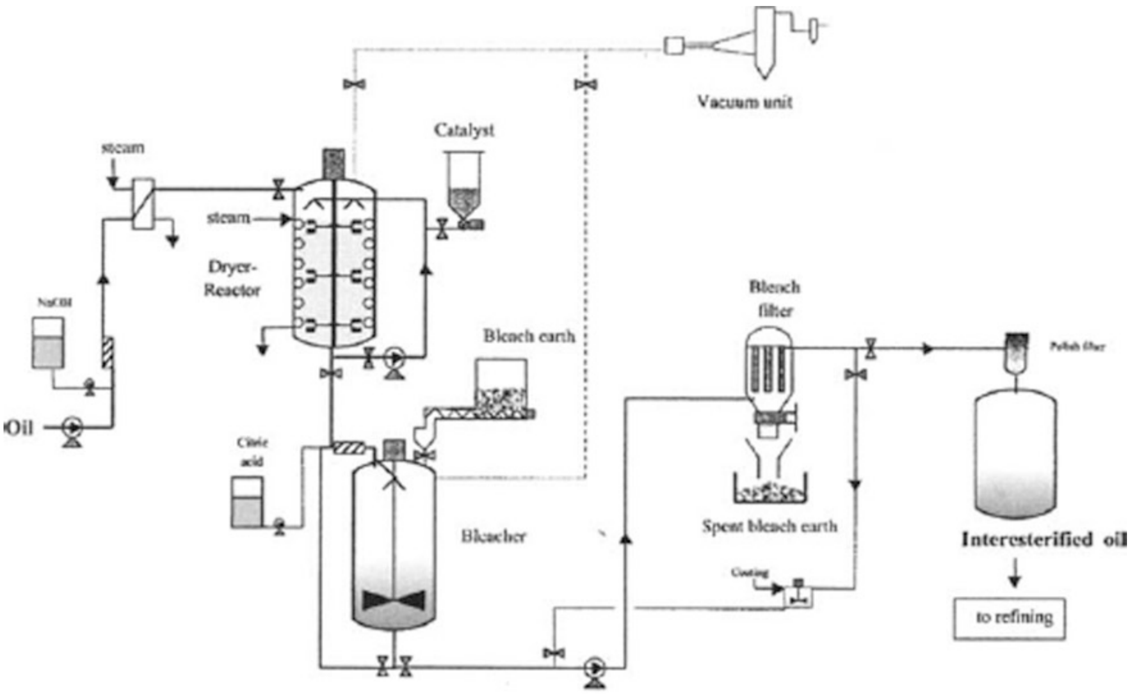

Fig. 34.27 Semi-continuous (chemical) interesterification line with postbleaching. (Courtesy of Desmet Ballestra Oils and Fats, Brussels, Belgium)

[137]. Directed randomization can be used to modify either the olein or stearin fractions.

A flow sheet for a semi-continuous interesterification line with postbleaching ability is shown in Fig. 34.27. The oil must be degummed, well-refined (<0.05% FFA), and free from peroxides and moisture that causes production of soaps. Palm oil stearin and completely saturated (<5 IV) C18 hydrogenated fats generally are *trans* free and may be used as part of the feed. Reactions are run under vacuum, and oil is best stored under nitrogen between processes [44].

A variety of catalysts is available, including alkali metals, alkoxides, alkali hydroxides, sodium hydroxide and glycerol mixtures, metal soaps, and metal hydrides [44]. Alkaline hydroxides (KOH or NaOH) in combination with glycerol were used in earlier days because of their low cost [138]. Currently, sodium methylate and sodium ethylate are popular because of their efficiency. Rozendaal has proposed that the actual interesterification catalyst is a sodium derivative of a diacylglycerol, activated during the process [139].

The oil is loaded into the reactor, shown with both an agitator and a pumped circulation-spray loop, and heated under vacuum (110–130°C) to reduce water and peroxide contents. Next, the oil is cooled to 70–90°C and the catalyst is added as dry powder at 0.05–0.15% or suspended in dry oil. Randomization requires about 30 min, with an additional 15–30 min allowed for completion. After the reaction is complete, the batch is transferred to a postbleacher where the process is arrested by inactivating the catalyst by addition of water or an (phosphoric or citric) acid solution. Bleaching earth added to absorb the inactivated catalyst and soaps removed by filtration and the oil sent to blending or deodorization. Losses from the formation of FFA and FAME are ~10 times the catalyst weight, with an additional 0.5–1.0% lost in the formation of mono- and diglycerides, for a total of 1.5–2.0%. Continuous processes also are available. Interesterification progress can be monitored by online ultraviolet (UV) spectrophotometry and completion of the process by melting point determination and other measurements [44].

The main objective in interesterification is to produce solids free from *trans* fatty acids for later use in compounded fat products. The final fat, or a series of base stocks, can be made for future blending. Randomization can improve the functionality of a fat, as shown for lard in.

Figure 34.28. Natural lard is within the 15–25% solids plastic range between 9 and 24°C; by randomizing, the temperature range is moved to 0–17°C; both conditions greatly restrict its use. But, by directed interesterification, the machinable range is moved to the more acceptable ranges of 0–32°C. In contrast, natural cocoa butter (Fig. 34.29) is almost brittle at 26°C, melts rapidly by taking energy from the tongue, causes a pleasant cooling sensation in the mouth, and is completely liquid with good palate "cleanup" at 35°C. Randomizing destroys these properties, changing the fat into a softer mass, which does not completely melt below 56°C [48].

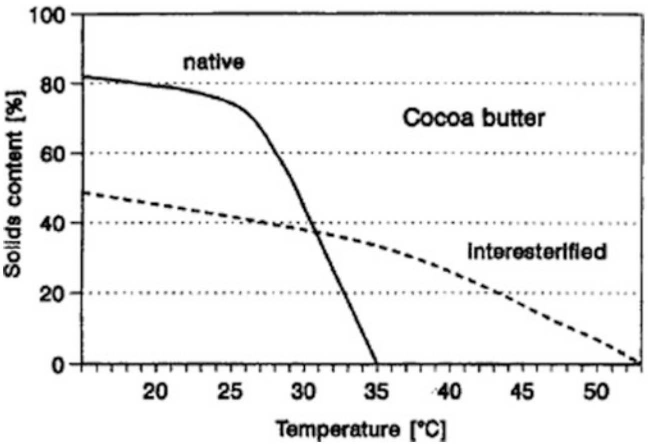

Fig. 34.29 Solids content of natural and randomized (interesterified) cocoa butter.(From Bockish [48], With permission)

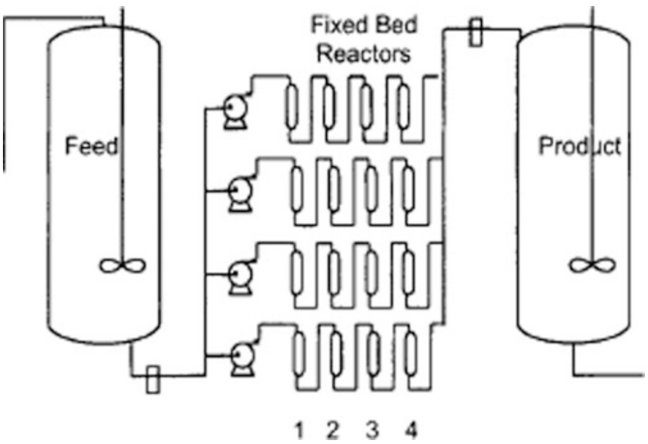

Fig. 34.30 Schematic drawing of multiple enzyme reactor system for enzymatic interesterification of *trans*-free margarine and shortening oils. (Courtesy of Novozymes A.S, Bagsvaerd, Denmark)

Interesterification is being pursued on the basis that *trans* production during hydrogenation increases the melting points of TAG and fatty acids, increases blood cholesterol levels, and increases atherosclerosis (plaque deposits in arteries) and coronary heart disease (CHD) incidence. However, considerable documentation also shows that the presence of saturated fatty acids (primarily palmitic, and to a lesser degree myristic and stearic) at the TAG *sn*-2 position strongly favors atherogenesis. Pork lard contains 70% of its palmitic fatty acid in the *sn*-2 position, whereas only 17% of the palmitic acid in beef tallow is in this position. Lard is considered more atherogenic to laboratory animals than tallow; randomization reduces this propety. However, atherogenicity of tallow is increased by randomization. Levels of saturated fatty acids at the *sn*-2 position are very low in natural vegetable oils, but are increased by randomization, with accompanying atherogenesis in feeding trials [140, 141]. Skepticism exists that switching to interesterification as a means of generating fat solids will reduce health concerns about hypercholesterolemic and atherogenic effects of fats.

Enzyme interesterification is rapidly becoming popular and has the advantage of selection of TAG positions at which fatty acids are interchanged. When 1,3 lipases are used, the current fatty acid at 2-position remains in place, avoiding transposition with saturated fatty acids. A simple way to conduct enzyme interesterification is by contracting for a fixed-bed reactor service. The supplier assists in installing the process and takes responsibility for providing portable reactor beds charged with specified 1,3-lipases to treat established quantities of oil. A schematic of a multiple enzyme reactor system is shown in Fig. 34.30. The freshest reactor is connected to the tank receiving the product and is preceded by a sequence of increasingly used reactors back to the most spent reactor connected to the feed tank. As spent reactors are retired, they are moved forward from positions “4” toward “1.” In this fashion, full use is made of remaining enzyme activity as feed flows through the system. The partially exhausted reactors filter the least processed feed and intercept competitive inhibitors that otherwise could reduce performance of fresh reactors. The reactors are shipped between supplier and user by truck. Large facilities can repack reactors in house [142].

Deodorization/Physical Refining

Deodorization is the final step in the production of RBD oils and modified fats. The process is called *deodorization* if most of the FFA is removed by alkali neutralization as with row crop (“soft”) oils, and *physical refining* if, by omitting alkali neutralization, the FFA are left in the oil for removal by steam distillation as with palm oil. Thorough degumming and bleaching must first be done before physical refining of all oils.

The volatile peroxides, other oxidation decomposition products, and odiferous compounds form reduced-boiling point azeotropes with water in the steam, at high temperatures, 250–260°C/482–500°F, and very low absolute pressures (~3 mbar). This is above the smoke point of soybean oil, but below the flash point, and oxygen must be excluded. Considerable heat bleaching of yellow–red carotenoids also occurs at this temperature. Typically: the deodorization process requires 20–40 min after come-up time, uses 0.5–2.0% sparged steam (the higher level if tocopherols are recovered), operates at between 2 and 4 mbar, and produces a product with about 0.03–0.05% FFA [143].

Historically, the standard deodorizer held 60,000 lb of oil (one railroad tank car). Except for refineries making only a few kinds of oil, as for export, building of continuous deodorizers slowed with the advent of just-in-time (JIT) delivery, supplier self-certification, and customers buying on the basis of their projected production schedules. This has led to development of improved batch-continuous systems, which are designed to handle many batches of different oil blends per day, with minimum cross-contamination and delays for process.

For many years, deodorizers (operating at above 270°C/520°F) were heated by several types of mineral oil-like thermal fluids which, in turn, could be heated in direct-fire furnaces at 315°C/600°F in plumbing and coils at 3.2 bar (46 psig). During the 1970s, some consumer health problems in Europe were ascribed to leakage of thermal fluids into oils during deodorization. As a result, the European market required that the local and imported oils industry shift to using high-pressure steam generators, operating at ~80 bar (1,150 psig) to provide a temperature of 295°C/560°F. Soon, other import countries also started adopting European standards. This essentially meant that heating coils and jackets of deodorizers, owned by suppliers wanting to sell oil in Europe, had to be rebuilt or new deodorizers and high-pressure steam generators purchased [144].

Deodorizers are built in many vertical and horizontal designs [143–145]. They typically are located outdoors and look like multistory plumbed silos or petroleum refinery reactors. A drawing of a modern deodorizer is shown in Fig. 34.31. The components have been gathered into one shell to take advantage of heat recovery opportunities, and the temperature gradient within the vessel gradually decreases from top to bottom. As with all manufacturers, improved designs are continuously evolving. The unit is operated at lower temperatures, 220–235°C/428–455°F, and a deeper vacuum (2 mbar) to minimize *trans* and polymer formation and loss of valuable minor components such as tocopherols. The supporting high-pressure steam boiler and vacuum system (typically a four-phase steam-jet ejector with barometric condensers, mechanical liquid ring vacuum pumps, or dry "ice" condensing system) is not shown. In the deodorization process, a well-prepared pre-warmed RB oil is passed through a deaerator to remove dissolved air, then heated in an exchanger by oil exiting from the deodorization stage. It is additionally heated by steam coils and passes into the deodorization tray, where it is deodorized by sparged steam. Next it passes through a heat recovery exchanger, heating the incoming oil. After partial cooling, citric acid (20–50 ppm) in solution is added to sequester iron or copper that may be picked up later by the oil. The oil is still hot and under vacuum, and the moisture flashes off. Then, the oil is cooled and passes through a polishing filter on its way to temporary storage under nitrogen before shipment.

The liquid used to *scrub* the vapors is previously condensed deodorizer distillate that is chilled, recycled, and drawn off as necessary to maintain a constant level in the scrubber. The condensate may entrap vapors of pesticides if they get this far in the refinery. Deodorizer distillate is rich in tocotrienols or tocopherols, some of which have vitamin E activity. During the time that consumption of vitamin E supplements in the United States was growing, and strong markets for natural antioxidants existed, deodorizer distillate was very much in demand and the domestic supply from refineries was committed by contracts with vitamin E producers. As much as 60% of the tocopherols in soybean oil could be extracted at the deodorizer, but in doing so, the refineries no longer are available to stabilize the shelf life of the oil or provide its full natural nutritional benefits. In recent years, tocopherols and tocotrienols from palm oil processing have eased supplies.

At this point in processing, the peroxide value in the oil should barely be detectable (<1 ppm), but will soon start increasing again. Thus, margarine and other profiled-temperature fats are blended before shipment. A rule of thumb in the deodorization department is: "Don't deodorize oil until it is sold and ready to be shipped."

After cooling to appropriate temperatures, processors may add additional oil-soluble ingredients, antioxidants, vitamins, colors, and others that customers might have difficulty dispersing in the oil/fat at their processing sites. Unless the fat needs to be texturized into a soft-plastic form by the addition of nitrogen and chilling to a shortening for specific handling requirements, it is shipped and kept at about 10°C above the melting point. Nitrogen purging of oil during pumping, and storage under a *nitrogen blanket,* are common if held for more than several days before use by the processor. Contact with copper- and iron-bearing materials and contamination with water should be avoided. Typically, one to two percent *trans* fats are produced during deodorization, with lesser quantities formed at lower temperatures. Ultra-high vacuum steam distillation, operating at microbars

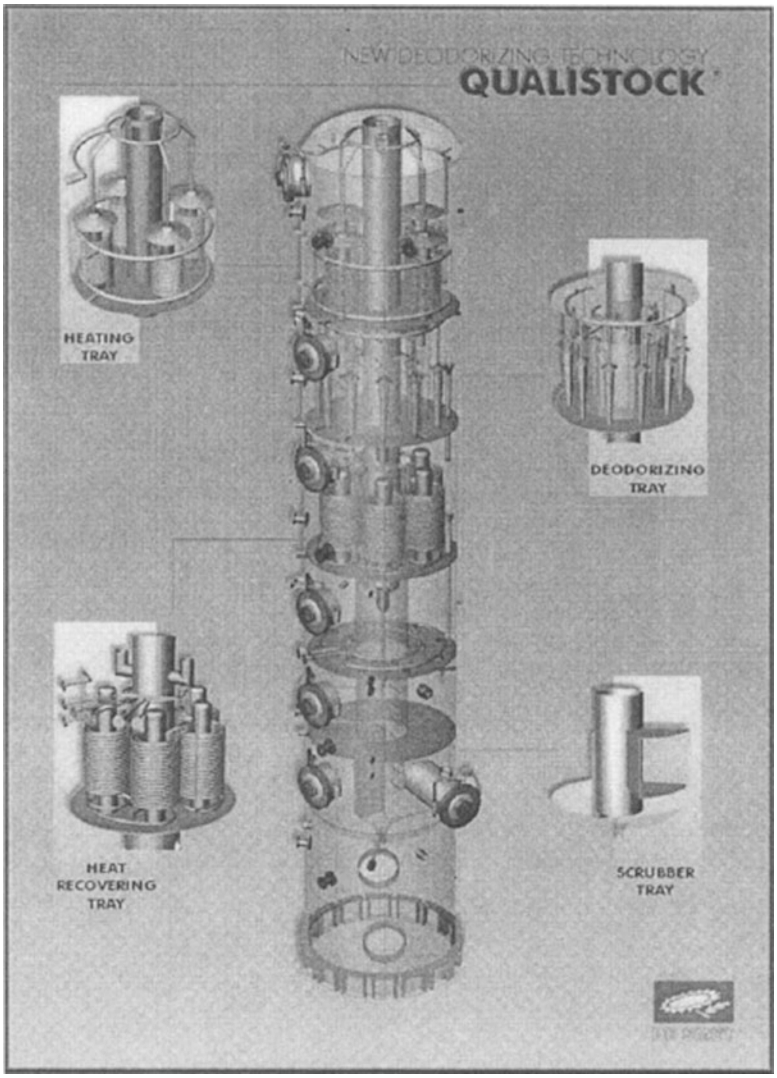

Fig 34.31 Cut-away drawing of DeSmet Qualistock® Continuous Deodorizer. (Courtesy of Desmet Ballestra Oils and Fats, Brussels, Belgium)

rather than millibars, has successfully deodorized oils and fats in laboratory and pilot plant scale and is used in the production of higher-priced products. However, fats and oils scientists have reported that the flavor of this oil is not as acceptable as from traditional deodorization/physical refining. Several steam distillation methods for the removal of cholesterol from animal fats were developed and patented after the fast foods industry switched from tallow to vegetable oils for frying French fries in the 1980s. Currently, the ability of tallow to regain this former market seems doubtful.

Notes on Major Row Crop Oilseeds

Soybean

Soybean (*Glycine max* L.) was domesticated in north China, probably during 1700–1100 BC in the Shang Dynasty or earlier [146]. Samples found their way to Europe during the 1700s, where it was grown as a curiosity in botanical gardens [147]. Documentation exists for soybean brought, grown, and made into soy sauce near Savannah, Georgia in 1765, by Samuel Bowen, an English seaman who had sailed to Canton, China earlier as an employee of the East India Company. Benjamin Franklin sent seed from London to a botanist in Philadelphia in 1770 [148]. A sample, from a salvaged Japanese junk, was brought from San Francisco to Alton, Illinois, in 1851, where it was grown and also distributed to botanists in other states.149 Additional samples were brought back by Commodore Matthew Perry's expedition to Japan in 1854, sent by missionaries in the Far East, and distributed in the United States before establishment of the Department of Agriculture in 1864 [149]. However, the plant mainly was grown for feeding cattle and as green manure to enrich soils.

The Treaty of Portsmouth (New Hampshire) to settle the 1904–1905 Russo–Japanese War gave Japan control of the Liaotung Peninsula in Manchuria. This area was leased previously from China by Russia during construction of the Trans-Siberian (Moscow to Vladivostok) Railroad for establishing all-weather naval and trading ports in Port Arthur (now Lüshun) and Dairen (Lütita, Talien, Dalian) [150]. The withdrawal of Japanese occupation troops from Manchuria resulted in a local surplus of the soybean crop, which had been expanded to feed the soldiers. Manchurian soybean was shipped to England in 1907 [151], and to Germany, other Northern European countries, and the US Pacific coast, by 1910 [152]. Dairen, Manchuria became the international soybean processing and export center for the early part of the 1900s. An English hydraulic press mill had been sold to China in 1868 [153], but Manchurian and Japanese soybean extraction continued mainly by crushing seed with stone edge runners and pressing with wedge presses, which produced press cake that could not survive shipment to Europe [152, 154, 155].

Europe wanted the soybean for oil and the meal for animal feed, but was dissatisfied with leaving 5–6% to six percent oil in the cake, characteristic of box presses and expellers (screw presses). England and Germany initiated work on batch solvent extraction processes, but World War I interrupted progress. The Bollman basket countercurrent extractor was patented in Germany in 1919, followed by the Hildebrandt U-tube extractor in 1934 [152].

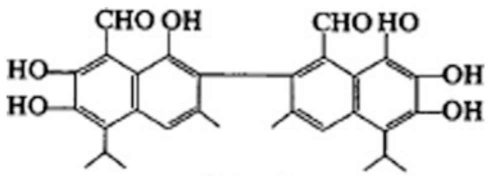
The first domestic crushing of soybean occurred in Seattle, Washington, in 1910, using seed imported from Manchuria [152]. Domestically produced soybean was crushed at cottonseed oil mills in the South and linseed (flaxseed) oil mills in the Midwest during the 1910–1920 era [152, 156]. The first commercially successful domestic soybean solvent continuous extraction plants were installed by Archer Daniels Midland Company (ADM) and the Glidden Company in Chicago in 1934, both using 100 tpd Hildebrandt U-tube extractors and commercial hexane as solvent. They also were equipped to produce phosphatides [153].

United States production of soybean, for domestic processing and exporting to Europe, grew slowly until acceleration by World War II, which devastated the German oilseed crushing industry [157]. This left the United States in the position of the world's largest soybean producer and processor. Soybean utilization increased during the reconstruction of Europe and Japan, by uses in famine abatement programs throughout the world, to meet growing world population food needs, and as feed to support world growth of the broiler industry which started about 1960. Eventually, land-rich countries in South America also became major soybean producers.

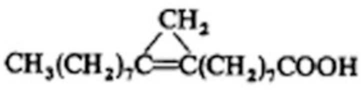
Cottonseed

Cotton (*Gossypium arboreum* and *G. herbaceum*) was grown in the Indus River Valley (modern Pakistan) as early as 3000 BC. "New World" cottons were grown in Peru (*G. hirsutum*) about 2500 BC, and Sea Island cottons (*G. barbadense*) in the Caribbean Islands. Most of the world's cotton today is *G. hirsutum*, with a fuzz-covered seed that requires removal of the fibers by *delinting* before dehulling and subsequent processing. Pima and Egyptian cottons (*G. Barbadense* type) have fuzz-free (*naked*) seed and can be processed directly. Cottonseed is among the first examples of a reclaimed byproduct in our industrial age. Invention of the cotton gin by Eli Whitney in 1793 led to increased domestic production of cotton and also to seed disposal problems. The state of Mississippi passed the first antipollution law in the nation in 1857, prohibiting throwing cottonseed into rivers and requiring its orderly disposal from gins located less than one-half mile from a town.

Cottonseed contains the polyphenolic yellow-red pigment gossypol, 1,1′,6,6′,7,7′-hexahydroxy-5,5′-diisopropyl-3,3′- dimethyl (2,2′-binapthalene)-8,8′-dicarboxaldehyde, in discrete bodies called *gossypol glands*. Processing challenges include removal of gossypol, or its 15 or more derivatives, from the oil to reduce color, and deactivate its toxic effects (through binding to the protein with moist heat) to enable feeding the meal to monogastric animals. Cottonseed oil also contains the cyclopropenoic acids, C18:CE malvalic acid (8,9-methylene-8-heptadecenoic acid) and C19:CE sterculic acid (9,10-methylene-9-octadecenoic acid), which form the pink color in the Halphen Test used to detect its adulteration of higher-priced olive oil [158]. Concerns about adulteration of olive oil appeared again when fractionated palm oil was introduced to Europe.

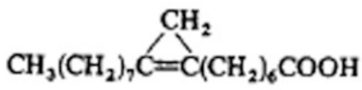


Gossypol



$$CH_3(CH_2)_7\overset{CH_2}{C{=}C}(CH_2)_7COOH$$

Sterculic acid



$$CH_3(CH_2)_7\overset{CH_2}{C{=}C}(CH_2)_6COOH$$

Malvalic acid

Cottonseed oil has long sold at a slight premium over soybean oil because of greater stability to oxidation and desirable flavor in fried snack foods such as potato chips. However, gossypol content and lower protein quality put the meal at a price disadvantage. Feeding whole cottonseed to dairy cattle, whose rumen microorganisms can detoxify limited amounts of gossypol, now utilizes over 70% of the supply and may portend eventual abandonment of oil extraction.

Rapeseed/Canola

Rapeseed/Canola belongs to the turnip rutabaga, cabbage, Brussels sprouts, and mustard family of crops that can be grown at low temperatures and moderate humidity. Three species have been grown as oilseeds: *Brassica napus*, known in Europe as rape, oil rape, Swede rape, and Argentine rape; *B. campestris*, known as rapeseed, oil turnip, turnip rape, and Polish rape; and *B. juncea*, known as leaf mustard, brown mustard, Oriental mustard, and Indian mustard. *B. campestris* was grown in India as early as 2000–1500 BC.

This crop is the classic example of an effective crop improvement program mobilized by a country in response to impending loss of international markets. When it was reported in the early 1960s that erucic acid (12-docosenoic, C22:1 *n*–9) in rapeseed oil could cause heart damage and other diseases, the Canadian government established a crash development program that led to the release of the first low-erucic acid rapeseed (LEAR) in 1969. Continuing efforts to develop varieties with even lower erucic acid content led to later release of double zero (low-erucic, low-glucosinolate) varieties, which were named canola in 1980. Because of reduced glucosinolate levels, considerably more of the meal could be used in animal feed than earlier. Canola oil, which contains less than 2% erucic acid compared with 20–40% in earlier rapeseeds, was granted GRAS status by the US FDA in 1985 [159].

However, the introduction of canola left unmet needs for erucic acid in industrial markets. High-erucic acid rapeseed then was imported from Northern Europe for extraction, followed by efforts to increase erucic acid contents in domestic industrial rapeseed as well as development of crambe (*Crambe abyssinica*) specifically for its erucic acid content. At the current state of development, equipment corrosion and poisoning of hydrogenation catalysts by sulfur in canola oil still are problems. Also, oil from the new canola varieties favors formation of β crystals, in contrast to β' formation in the earlier rapeseed varieties.

High *oleic acid canola* varieties were introduced recently to directly compete in applications formerly using olive oil.

Sunflower Seed

Sunflower (*Helianthus annus* var. *Marco-carpus*) is a New World crop, known to have been grown in Arizona–New Mexico in 3000 BC and in the Mississippi–Missouri Basin at least since 900 BC. A midsummer weed relative, with small multihead flowers, is common in the central United States. The crop was taken to Europe by early explorers and developed as a source of edible oil in Russia. The gray and white striped seed is known as *confectionery-type*. Its kernel is loose within the hull, and the seed usually is shelled for eating. No major antinutrition factors are known to exist in the raw seed. *Oil-type* varieties predominantly are black-hulled, with seeds about one third the size of confectionery types. The seed adheres tightly to the hull and provides a challenge in dehulling. It has been repeatedly shown that, although the setting of seed by sunflower plants is not as sensitive to day length as for soybean, the oleic acid content is inversely related to the temperature of seed maturation. Early users desiring polyunsaturated oil with high linoleic acid content specified northern-grown sunflower seed oil, whereas those desiring extended oil stability, as in the production of fried foods, have preferred oil from seeds matured during the summer in the southern states. Sunflower varieties with high-oleic acid content (85–92%) have been developed with the intention of using the oil as a feedstock in chemicals manufacturing processes [122]. Recently, the sunflower seed industry has developed mid-oleic acid oil, containing ~65% oleic acid. Also, high-oleic confectionery-type sunflower seed has been developed, enabling extension of the shelf life of roasted seed.

Peanut

Peanut, groundnut (*Arachis hypogae*), also is a New World crop and was grown in the Upper Plata River Basin of Bolivia in 2000 BC. It was taken to Europe by early explorers and was returned to the southeastern United States from Africa by slave traders. Broad cultivation did not occur domestically until the early 1920s, when the southeastern United States was looking for a crop substitute for cotton, which was severely ravaged by the boll weevil [160]. Most domestically grown peanut is consumed as food, with over one half of the crop produced used in making peanut butter. Peanut is very susceptible to *Aspergillus flavus* mold invasion in the soil, which produces carcinogenic aflatoxins. World production of peanut for oil has slowed because of limitations on feed uses of the meal. Direct food uses of peanut have increased in developing countries.

Some Miscellaneous Oils Processed at the Food Protein R&D Center, Texas A&M University

Pistachio Oil

Pistachio oil is extracted from the fruit of *Pistacia vera* by expeller or screw press. Compared to other nut oils, pistachio oil has a strong flavor. It tastes like the nut from which it is extracted. Pistachio oil is high in Vitamin E, containing 20–25 mg/100 g. It contains 12.8% saturated fats, 54.8% monounsaturated fats, 33.7% linoleic acid, and 0.7% omega-3 fatty acid. Pistachio oil is used as a table oil to add flavor to foods such as steamed vegetables. The fruit is a drupe, containing an elongated seed, which is the edible portion. The fruit has a hard, whitish exterior shell. The seed has a light green flesh, with a distinctive flavor. When the fruit ripens, the shell changes from green to a yellow or red and abruptly splits. This is known as dehiscence. Each pistachio tree averages around 40–50 kg of seeds, or around 60,000, every 2 years. The shell of the pistachio is naturally a beige color, but it is sometimes dyed red or green in commercial pistachios. Most pistachios are now picked by machine and the shells remain unstained, making dyeing unnecessary except to meet consumer expectations. The kernels are often eaten whole, either fresh or roasted and salted. Pistachios are also used in ice cream, pistachio butter, and confections. Recently, the FDA approved the first qualified health claim specific to nuts lowering the risk of heart disease.

Emu Fat/Oil

Emu is the largest bird native to Australia. The soft-feathered, brown, flightless birds reache up to 2 m (6.6 ft) in height. They have long thin necks and legs. Emus are farmed primarily for their meat, leather, and oil.

The Food Protein R&D Center at Texas A&M University has special expertise in emu fat processing to produce premium quality emu oil. There are presently no established special methods to process emu oil. However, current oil processing technology can be used. The entire refining process involves rendering the fat, cooking, fat separation, and fat drying. The crude oil is treated by caustic (caustic neutralization) for free fatty acid removal followed by bleaching and a deodorization. The general physical properties of emu oil are similar to those of a vegetable oil with intermediate content of saturated fatty acid. Emu oil is similar in oleic acid content to oils such as peanut or canola. With regard to saturated fatty acid, emu oil resembles cottonseed oil. The ultimate quality of the refined emu oil depends strongly on the starting material. For example, if the crude oil has blood tissues producing a high content of free fatty acids, even though the refining process will eliminate the acidity of the oil, the final product will contain a high concentration of mono- and diglycerides which easily degrades during storage. Emu meat is a low-fat meat (less than 1.5% fat), and with cholesterol at 80–90 mg/100 g, it is comparable to other lean meats. There is some evidence that the oil may have anti-inflammatory properties.

Mink Oil

Mink oil is produced from the thick fatty layer which lies just under the skin. This fat is removed from the pelt when the mink is skinned and is then rendered into mink oil. The crude oil is dark yellow in color. Crude mink oil is directly bleached and deodorized without being caustic neutralization. The bleached and deodorized oil is light yellow in color. Mink oil and its fatty acids are unique among animal-derived fats and oils. The total unsaturated fatty acids in mink oil account for more than 75% of the fatty acid content, but the oil, nevertheless, has a greater oxidative stability than other animal or vegetable oils. Mink oil is a source of palmitoleic acid, which possesses physical properties similar to human sebum. It is used in several medical and cosmetic products, and also for treating, conditioning, and preserving nearly all kinds of leather.

Ostrich Oil

The Ostrich (*Struthio camelus*) is a large flightless bird native to Africa. It is farmed around the world, particularly for its feathers, which are decorative and are used as feather dusters. Its skin is used for leather products and its meat is marketed commercially. The refining process for ostrich oil is similar to that for EMU oil. It starts with the cleaning of fat to eliminate blood, skin, dirt followed by fat separation (separate the solids by decantation), fat drying (heat under vacuum), refining (remove free fatty acid), bleaching (to eliminate color, peroxides, metals), and deodorization (to remove odor, peroxides, free fatty acids). Ostrich oil is high in omega-3, omega-6, and omega-9 EFAs. It contains around 20% saturated fatty acid followed by 35% monounsaturated and 39% polyunsaturated fatty acids. It is used in cosmetic and in the treatment of lesions, burns, contact dermatitis, dry skin, and many other ailments. Ostrich oil and EMU oil have very similar properties.

Trans Fats Nutritional Labeling

Trans fats have been created, often intentionally, during hydrogenation of TAG to obtain fat solids with specific properties for use in shortenings, spreads, confections, and other semisolid foods. Lesser amounts result during hydrogenation to reduce linolenic acid content and slow the oxidation of fats and their breakdown during frying. Small quantities (seldom more than 2.0%) are created during high-heat treatments in deodorization or physical refining. *Trans* fat formation is part of the oxidative sequence at ambient temperatures and is accelerated in frying. *Trans* fats in ruminant meat and dairy products, produced by biohydrogenation, are considered “natural” as described earlier. The US FDA has estimated the average domestic intake of *trans* fat at about 5.8 g, or 2.6% of calories per day for individuals 20 years of age or over. Consumption of saturated fat is estimated at four to five times more. Estimated sources of *trans* fat are: cakes, cookies, crackers, pies, bread, and the like ~40%; animal products ~21%; margarine and spreads ~7%; fried potatoes ~8%; potato chips, corn chips, popcorn ~5%; household shortening ~4%; salad dressing ~3%; and breakfast cereals and candy ~1% each [161].

In response to a petition by a consumer advocate group, the FDA published a proposal in the *Federal Register* [64] (221, 62745–62825, Nov 17, 1999) to include *trans* fat information in Nutrition Facts labels of packaged foods. (Listing of saturated fat and dietary cholesterol has been required since 1993.) The proposal initiated one of the most intensive dialogues ever in domestic food regulation between consumer advocates, public sector researchers, commodity producers, food processors, and government officials. The net effect was that separate listing of *trans* fat content was required on packaged food Nutrition Facts panels as of January 1, 2006. Also, dietary supplements, which contain 0.5 g or more *trans* or saturated fats per serving, must list their amounts in the Supplement Facts panels. The Nutrition Facts per serving format is:

	Percent daily value[a]
Total fat, 12 g	18
Saturated fat, 3 g	15
Trans fat, 1.5 g	—
Cholesterol, 30 mg	10

[a]Percent daily values are based on a 2000-cal diet

Daily value (DV) has not been established for *trans* fats; thus, calculation of a DV is not possible. Amounts of *trans* fat less than 0.5 g per serving are recognized as "*Trans* fat 0 g." Processors, who wanted more favorable nutrition facts labels on their packaged foods, reformulated their products. Those, choosing to claim "0 *trans,*" *typically* provided fat solids from interesterified fats, fully hydrogenated fats (because these do not contain *trans* bonds), or higher melting fractions of palm and other oils. Exclusion of conjugated structures from the FDA *trans* fats definition enables claiming products where all the fat is from ruminant sources (butter, cheese, cream, dips, ice cream, beef, and tallow) as containing "0 trans." Saturated fat content also must be shown on the label. *Trans* fats are unsaturated. Currently, some nutritionists and regulators are seeking means to inform restaurant, institutional, and fast foods customers about *trans* fats contents of specific products sold at these outlets.

The FDA's regulatory chemical definition for *trans fatty acids* is: "all unsaturated fatty acids that contain one or more isolated (i.e., nonconjugated) double bonds in a *trans* configuration." Under this wording, CLA would be excluded from the definition of *trans* fat, but *trans* vaccenic acid would be included. This definition was reconfirmed as of June 24, 2004 [162].

Copies of announcements, communications, and transcripts of open hearings during regulation making are available at the US-FDA Internet Web site. Readers may gain insight into regulator–nutritionist thinking on the *trans* issue from the transcript of the Nutrition Subcommittee Meeting on Total Fat and *Trans* Fat on April 27–28, 2004 [163].

During the review process, each responding interest group typically rationalized its position using generally accepted research findings. However, the diverse findings have yet to be integrated into a coherent system. FDA's communications have taught that consumption of saturated and *trans* fats causes undesired increases of total cholesterol in blood serum. They also has taught that *trans* fats cause undesired increase of LDL (LDL that carry cholesterol), which is termed "bad" cholesterol and is the rationale for listing *trans* fat in Nutrition Facts labels. However, it is generally accepted in the scientific community that not all saturated fats are equal, and likewise for *trans* fats. More specifically, stearic acid has been considered "neutral" in raising total cholesterol or LDL based on research initiated nearly a half-century ago and frequently reconfirmed. In response to concerns about defamation of palm oil as its world sales increased, that industry initiated extensive nutrition research, even involving noted United States scientists, on palm oil's dietary effects in the mid-1980s. Palm oil contains approximately 44% palmitic acid, 5% stearic acid, 39% oleic acid, and 10% linolenic acid. Repeatedly, diets containing palm oil (palm olein) raised neither total cholesterol nor LDL, and in some experiments decreased total cholesterol and increased "good" HDL (high density lipoprotein). In comparative experiments, *trans* fats fared negatively compared to palm oil, as also did palm kernel and coconut oils and lard. (In palm oil, 75% of the fatty acids in TAG position 2 are unsaturated.) It has been suggested that myristic acid (C 14) leads in increasing LDL, followed by lauric acid (C12). But, myristic and lauric acids, in limited amounts, also play essential nutrition roles. Current nutrition thought is shifting to dietary ratios of saturated and unsaturated fatty acids as more important in the diet than individual fatty acids. However, the world's major saturated fatty acid is palmitic, and together with stearic acid (which occurs in beef tallow consisting of approximately 25% palmitic acid, 19% stearic acid, 36% oleic acid, and 3% linolenic acid) accounts for the far majority of domestic dietary saturated fat intake. This leads to the question: If the majority of saturated fatty acids are essentially cholesterol neutral, why are they grouped with the LDL-raising saturated fatty acids in nutritional labeling?

With exception of the dairy and ruminant animal industries, which are recommending exemption of *trans*-vaccenic acid, no one is promoting increased consumption of *trans* fats. However, the dichotomy of procholesterolemic and cholesterol-neutral saturated fats has divided the nutrition community into two groups, each with well-respected members and spokespersons. Many scientists strongly recommended against combining saturated fat and *trans* fat into one number on the Food Nutrition Facts label in invited letters to the FDA. Others repeated that a better system for classifying "good" and "bad" nutrients is needed. Some nutritionists have suggested that earlier FDA Nutrition Facts labeling and the USDA Food Pyramid have: (1) been interpreted by the public as "all fats are bad;" (2) participated in causing current national obesity problems; and (3) led to development of "low carb" weight loss diets which include increased fat intake [163]. More discussions and new diets can be expected in the future.

Historically, the presence of CLA in vegetable oils was considered minimal, well below 1%, and little was known publicly about their actual occurrence in hydrogenated fats. In 2002, a group of Korean researchers published a pioneering study on effects of catalyst types and concentration, hydrogen pressure, and operating conditions on CLA formation in different oil species. Using selective catalysts, they obtained 23.2, 23.7, and 23.3% total CLA production in corn, cottonseed, and soybean oils (originally containing ~58, 51, and 51% linoleic acid, respectively). As much as 2.4% 9 *cis*-11 *trans*-18:2 and 1.7% 10 *trans*-12 *cis* 18:2 were obtained in mixtures from individual trials [164]. Biological activity of the CLA was shown later. Another publication from the same laboratory, incorporating the latest separation techniques developed in the United States CLA research program, and mass spectroscopy for CLA identification, reported separation and identification of 20 different CLA isomers in hydrogenated soybean oil [165]. These studies report that CLA production can be a result of hydrogenation conditions, and concentrations as much as eight times greater can be produced chemically than in ruminant sources. Thus, CLA are no longer unique to ruminant fats, and potentially can be made available in quantity. However, because of the unknown biological activity of other CLA isomers produced simultaneously, they should be carefully reviewed before broad authorization in the food supply.

New regulations can markedly change equipment requirements and practices of an industry. While regulators, lobbyists, and lawyers negotiated the new law, the fats and oils industry had to start preparing for new market requirements, and food formulators had to develop new products. Likely, the first consideration was selection of ingredients that make Nutrition Facts panels look attractive compared to competitor's products and also have functional properties necessary for making the products. But formulators are well experienced in matters such as ingredients listings. Research is continuing on ways to better control *trans* fat production during hydrogenation [166], but the industry has to formulate with currently available technologies. Reserving the use of hydrogenation for making fully hydrogenated hardstocks (~5 IV), the two most promising routes for obtaining fat solids are blending selected fractionated fat solids, hard stocks, and oils and interesterification of the above. However, as mentioned earlier, skepticism exists about increasing the number of saturated fatty acids in the TAG 2 position by randomization. Enzymatic interesterification at the 1,3 positions seems more appealing in theory.

Trans-free margarines and spreads were well established in Canada and European markets, before promotion in the United States. Many major domestic snack food fryers have adopted *clean ingredient listings* in which only potatoes or corn, vegetable oil, salt, and flavorings are listed (but no hydrogenated products or preservatives). Formulators of more complex foods have options of using emulsifiers, antioxidants, and an ever-increasing variety of hydrocolloids and gums.

Not all fat products have been reformulated for "0 *trans*" labels. Margarines must contain 80% fat, just like butter. Both have been largely replaced by spreads, or "lite" spreads, which contain lower amount of fat; a far majority of spreads claim "0 *trans*." Many home makers prefer to cook or bake with the higher fat content margarines, or (100% fat) shortenings, which often show positive *trans* fat content on their labels.

Edible Uses of Fats and Oils

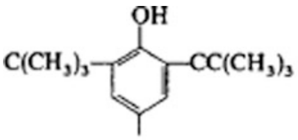
Antioxidants

Fats and fat-containing products may be stabilized against oxidation by the addition of antioxidants as adjuvants. These compounds are believed to act as hydrogen donors or as free radical acceptors that intercept and hold quantums of energy that otherwise might induce oxidation. The major food grade synthetic antioxidants used include: butylated hydroxyanisol (BHA), butylated hydroxytoluene (BHT), tertiary butylhydroquinine (TBHQ), propyl gallate (PG), and 2,4,5-trihydroxybutyrophenone (THBP). Generally, they are allowed in food products at 0.01% of total fat weight each, with a total of 0.02% if a combination is used.

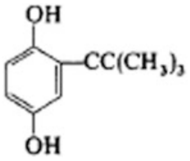
Synergists used in combination with antioxidants include citric acid, isopropyl acid, phosphoric acid, ascorbic acid, ascorbyl palmitate, iso-ascorbic acid, tartaric acid, and lecithin, most of which act as chelators of pro-oxidative metals.

Natural antioxidants include gum guaiac, tocopherols (including vitamin E), and oil of rosemary (containing rosmaridiphenol). antioxidant properties but are not counted in the maximum amounts of antioxidants permitted in the food. Types, mechanisms, and health effects of natural antioxidants are described in the references [168, 169].

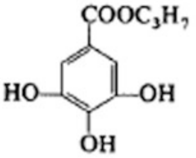
The cross-linking that occurs in drying oils also is an oxidation reaction. Polymerization of oils can occur rapidly in products such as fish meal that contain significant amounts of polyunsaturated triacylglycerols, even to the point of building up sufficient heat for a pile to spontaneously burst into flame. Thus, feed grade antioxidants, such as ethoxyquin, often are added before storage. Ethoxyquin also has been used for sparing the natural tocopherols for vitamin E activity in nutrition.



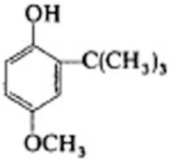
Butylated hydroxytoluene (BHT)



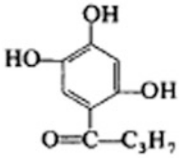
Tertiary butylhydroquinone (RBHQ)



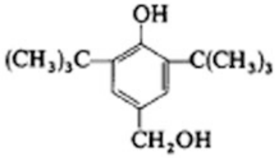
Propyl gallate (PG)



Butylated hydroxyanisol (BHA)



Trihydroxybutyrophenone (THBP)



Hydroxymethylditertiarybutylphenol

Because of cost, they usually are reserved for premium-priced foods. Many types of tocopherols and associated compounds exist, and understanding of the mode of action is continually improving. The forms that give the most antioxidant protection do not always show the greatest vitamin E nutrition activity [167].

Assemblers of grocery store or food service convenience foods have the same general limitations. However, they also have access to natural cereal ingredients and herbs, herb extracts such as oils of rosemary, sage, and other materials in formulation that possess.

Synthetic and natural antioxidants are known to be heat- and steam-distillable and preferably should be added to oil products after the maximum heat encountered in processing. It further is known that many natural phenolic compounds in cereal–oilseed products, as well as reaction products of Maillard (nonenzymatic amino acid-reducing sugar) browning and natural wood smoke, have antioxidant effects. Additional techniques for reducing oxidative activity include maintaining nitrogen blankets on oils stored in tanks and distributing oils in opaque containers or brown bottles to limit exposure to ultraviolet light, although this is not popular with many marketing departments who want to display clear, light-colored oils.

Nonionic Surfactants and Emulsifiers

Nonionic surfactants and emulsifiers, whose molecules have both aqueous (polar) and alkane (nonpolar) compatible sectors, also are common adjuvants. Their molecules have regions that are sufficiently similar to become part of either the water or oils phases, and other regions sufficiently dissimilar to repel that phase. For example, when added to a crystallizing fat, some nonionic surfactants may orient themselves to become part of the crystal, thus preventing further replication and limiting crystal size. Likewise, some will react with gelatinized starch in aqueous and bread systems and prevent its recrystallization (retrogradation). Furthermore, surfactants may orient around discrete droplets to stabilize water in oil (W/O) or oil in water (O/W) emulsions. When this occurs, the compatible end becomes associated with the discrete droplet, leaving the other end turned outward to associate with the compatible continuous phase [170].

The major groups of commercial emulsion stabilizers include: (1) glycerol esters, favoring W/O emulsions; (2) esters of mono-acylglycerols with hydroxycarboxylic acids (including lactic, succinic, malic, and tartaric); (3) sodium stearoyl-2-lactylate (SSL), favoring O/W emulsions; (4) fatty acid monoesters of ethylene glycol; (5) sorbitan fatty acid esters, known as SPANS favoring W/O, and TWEENS favoring O/W emulsions; (6) phosphorlipids; (7) water-soluble gums, including gum arabic, tragacanth, xanthin, agar, pectin carrageenan, and methyl- and carboxymethylcellulose; and (8) proteins [170, 171].

Glycerol has three exposed hydroxyl groups, resulting in a compound completely miscible in water at all concentrations. Fatty acids have both hydrophilic (water-attracting) and lipophilic (oil-attracting) ends. As they are esterified to glycerol, the molecular structure that originally was primarily water-soluble becomes increasingly oil-soluble. Finally, when all three positions are esterified to fatty acids, the molecule is nonpolar and soluble only in organic solvents.

Table 34.12 HLB (hydrophile–lipophile balance) numbers for some surfactants

Name	CAS number	HLB value
Oleic acid	112-80-1	1.0
Acetylated monoglycerides (film formers)	–	1.5
Sorbitan trioleate (SPAN 85[a])	26266-58-6	1.8
Glycerol dioleate	25637-84-7	1.8
Sorbitan tristearate (SPAN 65[a])	26658-19-5	2.1
Glycerol monooleate	25496-72-4	3.4
Glycerol monostearate	31566-31-1	3.8
Sorbitan monooleate (SPAN 80[a])	1333-68-2	4.3
Sorbitan monostearate (SPAN 60[a])	1338-41-6	4.7
Soy lecithin	8020–84–6	8.0
Sodium stearoyllactylate (anionic type)	18200-72-1	8.3
POE sorbitan monooleate (TWEEN 81[a])	9005-65-6	10.0
POE sorbitan monostearate (TWEEN 60[a])	9005-67-8	14.9
POE sorbitan monooleate (TWEEN 80[a])	9005-65-6	15.0
POE stearic acid (monoester) (TWEEN 20[a])	9004-99-3	16.9

[a] Atlas brand names

The hydrophilicity of nonionic surfactants can be characterized numerically as their hydrophile–lipophile balance (HLB). An HLB value of 3–6 indicates that the compound is a likely W/O emulsifier; 7–9, a wetting agent; 8–13, an O/W emulsifier; 13–15, a detergent; and 15–18, a solubilizer (of oil or other non-polar compounds) in water. The HLB values of some common compounds are presented in Table 34.12 [170]. An HLB value of 8.0 is shown in Table 34.12 for lecithin, but manufacturers are able to supply modified lecithins with values of 2–12.

Table Oils

The processing of RBWD table oils has been mentioned earlier. Depending on positioning in the marketplace, these products may also serve as light duty cooking/frying oils and may be brush hydrogenated and contain added natural or synthetic antioxidants and methyl silicones at 0.5–3.0 ppm to slow breakdown, initiation of foaming, and smoking during frying [172]. United States and Northern Europe markets consider light product color and bland flavor as indicators of oil quality. Olive oil aficionados often prefer the green color and its stronger taste as an indication of virgin or minimum processing. All oils revert to stronger flavors in time. Slight flavor reversion generally is acceptable in cottonseed oil, but not in soybean oil. Many years of research were required to reduce the problem in soybean oil, and the mechanism still may not be fully understood. Converting the industry to only stainless steel oil contact surfaces (specifically avoiding iron and copper), reducing residual phosphatides content to essentially "zero," early inactivation of phospholipases and associated enzymes when preparing seed for extraction, nitrogen blanketing and reduced storage temperatures of bulk oil, and the use of antioxidants are believed to have helped.

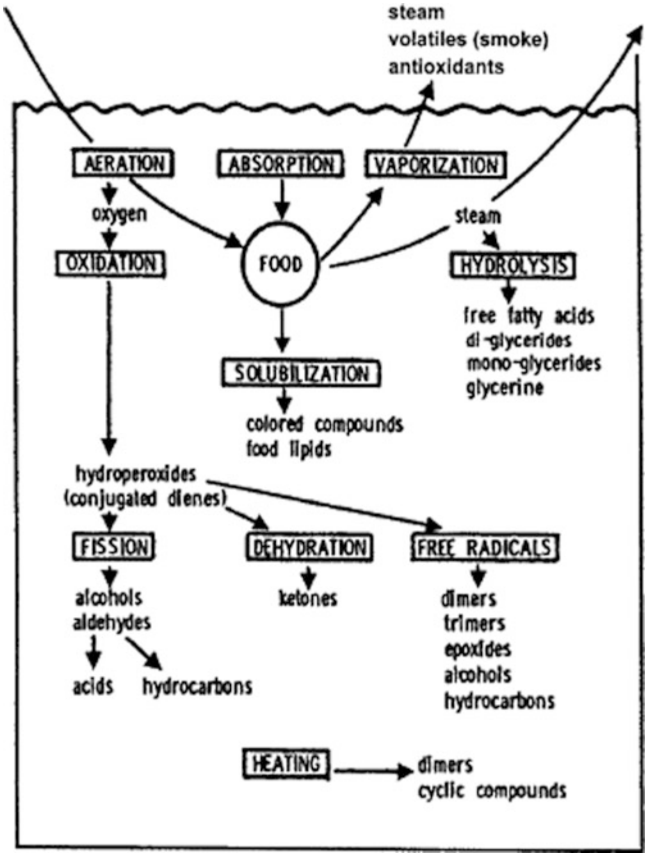


Fig. 34.32 Changes occurring during deep fat frying. (From Fritsch [173], With permission)

Frying Oils

Oil acts as a heat transfer medium during the frying process which rapidly heats, cooks, and sometimes puffs, dehydrates, or forms a crust around the product. The mechanics of deep fat frying are shown in Fig. 34.32 [173]. The entering material carries oxygen that temporarily aerates the hot oil, and water that forms steam, with both rapidly swept out because of low solubility of gases in the hot liquid. Besides enzymes, which are likely to be inactivated rapidly, raw materials also carry oxidation catalysts such as iron in the hemoglobin of fresh meats, chlorophyll, and color pigments. Alkali may accompany the material, especially in chemically leavened doughnut batter and alkali-treated corn snacks. In short, almost every concern mentioned thus far in seed preparation, extraction, and oil processing occurs during frying.

The high temperatures of frying, 177–204°C/350–400°F, are deleterious to oil quality. *Trans* fats are produced, and some of the degradation-prone anisidine value products remaining after refinery deodorization deteriorate. Oils start breaking down into simpler compounds, and also form cyclic compounds and polymers. This process continues while food shop fryers are left hot and inactive during afternoons between preparation of lunch and dinner meals. However, limited self-cleansing occurs in the system by steam distillation, as noted by reduction of carbonyl compounds in oils after inactive fryers are put into service again. An excellent review on frying has been edited by Perkins and Erickson [174].

Unlike in some countries, few United States households have dedicated frying pots containing oil in readiness for meal preparation. Most domestic deep frying is done by commercial operations such as: snack foods processors, producers of convenience fried foods such as Chinese egg rolls and frozen meals, and fast food vendors who prepare French fries, fried chicken, and other products.

Industrial fryers generally are of two types: (1) those who sell all the purchased oil with the product, and (2) those who must recondition and occasionally dispose of oil. Requirements for the selection and use of frying oils in these applications differ [175]. Industrial snack food fryers, designed to use all the oil, are equipped with clean-out systems and inline filters. In theory, they should be able to operate indefinitely, only adding make-up oil as needed. In *clean label,* operations, company policy dictates that no, or minimum, additives can be used. Typically, company personnel periodically inspect and monitor refinery operations of self-certified suppliers. Antioxidants or silicone defoamers are not permitted in these oils. Oils are received in bulk, typically at less than 0.05% FFA, < 1.0 PV, < 4 ppm phosphorous, and <0.75 ppm chlorophyll, and are kept in stainless steel tanks under nitrogen [175].

Stability against oxidation of soybean oil has consistently increased in frying trials as linolenic acid content decreases, whether by plant breeding, mixing with other oils, or by hydrogenation [176–178]. Less than 2% linolenic acid content has been a long-term industry goal, with the way by which linolenic acid is reduced (hydrogenation or breeding) appearing to have little effect on fried product stability [179]. Oils with PVs higher than 2.5 are not used in well-disciplined frying operations.

The freshness of fried snack foods is dependent on use of packaging impermeable to moisture and oxygen, including laminates of windowless aluminized films that block 99+ percent of the light to prevent photo-induced oxidation. Additionally, the pouches are nitrogen flushed before sealing, thus creating pillow packs that further protect the product against crushing. The snacks often are delivered by company delivery personnel, who place them on store shelves or racks. Products may have shelf lives of 6–8 weeks, but inventories are carefully managed to ensure rapid turnover and fresh products [175].

Normally, the warm surface oil serves as the binder (“tacking agent”) for adsorbing salt and dry flavorings to snack foods. The concept of reducing or entirely eliminating oil from snack foods appeared during the early 1990s. Rather than deep fat frying, snacks were dried at high temperatures in fluidized bed continuous dryers. A far smaller amount of oil was then sprayed onto the dried product for flavor. Where a “fat-free” snack food was desired, solutions of edible gums or specialty starches were sprayed onto the snack to serve as tacking agents, for water-soluble flavors; the product then required an additional drying step (to less than 1.5–2.0% moisture content to ensure crispiness) [175].

Industrial fryers, who cannot turn the oil over completely, have lengthened its life 3–10 times by using polydimethylsiloxane (methyl silicone), which is not allowed in some countries. Levels as low as 0.2–0.3 ppm have been found effective, with commercial usage of 0.5–5.0 ppm reported. Users are advised to minimize levels of usage to 1.0–3.0 ppm. Dispersion of polydimethylsiloxane in oil is difficult. The compound operates by suppressing foaming and polymerization and increasing smoke points of oils by up to 13.9°C/25°F. Antioxidants steam distill out of the oil during normal frying. Their initial inclusion essentially protects the oil only until the time of use, but some operators insist on periodically adding them to the fryer. For greater effectiveness, antioxidants in fresh oil are best sprayed onto the product after frying, or included in dry seasoning mixes [175]. Additional steps to prolong the use of frying oil include: inline filters, periodic cleaning of fryers to remove settled charred product, neutralization of fatty acids, and refreshing the oil by passing through adsorbent earth filters continuously, or at the end of the day. Numerous kits and advisory services are available.

Large commercial frying operations, and fast food franchises that prepare French fries and chicken, have provisions and personnel trained to care for frying oils. The greatest food safety concerns are about small restaurants which do occasional frying during midday and evening meals. Several countries have imposed standards on the quality of frying oil in use. For example, Germany requires that the smoke point be not lower than 170°C/338°F, and total polar compounds not exceed 24% [180]. Products fried in oils usually would be objectionable in taste to most Americans long before they reach the unusable specifications. Yet, with exceptions of reduced digestibility and depletion of vitamin E (which can be supplemented), laboratory animals directly fed thermally degraded fats have not done as poorly as anticipated from the history of the oil and known presence of mutagens. Obviously, gaps exist in our toxicology and nutrition knowledge. Many practical details are presented in a new book [181].

Specialty Oils

A variety of specialty oils exists. Pumpkin seed oil is popular in Central Europe. Sesame oil is used throughout the Middle East and the Orient; and roasted sesame oil is used in very small amounts to flavor Asiatic foods. Nut oils, grape seed oil, tomato seed oil, and herb-flavored oils are available.

The organic and "natural" foods markets demand nonchemically treated oils. These often are made by hard pressing the source and water degumming the oil, followed by bleaching with "natural" (nonchemically treated) earths and removing FFA by physical refining.

In 2004, ADM Kao LLC, a joint venture of Archer Daniels Midland Company (United States) and Kao Soap Company (Japan), launched a new type of cooking oil, Enova™ Brand in the United States market. Enova™ is a 1,3 diglyceride (diacylglycerol, DAG) intended for use in nutritional beverages/drinks, nutritional bars, salad dressings, and general cooking [182]. Enova™ oil was initially developed by the Kao Corporation and is the best-selling cooking oil in Japan under the "Econa® Healthy Cooking Oil" brand name. The manufacturer claims the US product is made from all natural soybean and canola oils, has the lowest saturated fat content of any cooking and salad oil, contains zero grams of *trans* fat, and is metabolized differently by the body: instead of being stored as fat, the majority of DAG is burned as energy.

In the early 1970s, Triple "F" Incorporated, a feed manufacturer in Des Moines, IA, developed a low-cost extruder for on-farm use, which inactivated trypsin inhibitor in whole soybean by heat produced by friction shearing. This made soybean directly usable by cattle, pigs, and poultry, without sending it to extraction plants and buying back soybean meal. However, the oil content of the product was too high for direct feeding, and purchase of defatted soybean meal often was necessary. In the mid-1980s, the INTSOY program at the University of Illinois developed a procedure for hard-pressing the sheared soybean, reducing fat content of the meal by about a half and producing saleable crude soybean oil. As domestic livestock operations increased in size, large farmers and cooperatives installed the InstaPro International Company ExPress® Extruder/Press System to process soybean, cottonseed, and occasionally other oilseeds for feed. Production of oil byproducts also increased. Research has shown many desirable properties in the crude hard-pressed ("expeller") soybean oil, including highly hydratable phosphatides content which are easily water degummed and a high resistance of the refined oil to oxidation. After physical refining, the oil shows unexpectedly good stability as frying oil, without hydrogenation or formation of *trans* fats while still retaining its linolenic acid (omega-3) content. After 35-h potato frying tests, soybean oil had a total polar compound level of 17.7% (degradation), whereas the "expeller" oil had 9.1%. Soybean oil with TBHQ antioxidant had 8.8% and hydrogenated soybean oil had 9.7%. Potatoes fried in the expeller oil had significantly higher flavor scores than those fried in the other oils [183]. Test results have been repeated in other laboratories [184]. The reason for the good performance is not yet known. Some believe the high heat (~130°C/266°F) generated in the process almost instantaneously inactivates most of the destructive enzymes (lipases, phospholipases, and especially lipoxygenases) at the time the seed is first sheared [185]. Others believe the benefits come from physical refining [186]. The industry is very excited about market potential for expeller-produced oil.

Margarines and Spreads

Margarine is one of the major temperature-profiled fat products. It was invented in France in 1869 intentionally as a butter substitute and was first produced in the United States in 1873. Originally, it was made from animal fat; coconut oil became the lead fat in margarine in 1917, partially hydrogenated cottonseed oil in 1934, and partially hydrogenated soybean oil in 1956. Various legal principles have been tested through margarine. Among the first was protectionism for butter and the dairy industry, with a requirement that a "Oleomargarine Sold Here" sign be posted on the door of every store offering it. (In retrospect, modern marketers might see this as the best free advertising possible.) In response to dairy industry claims of product inferiority, a law was passed in 1923 requiring that margarine be fortified to the same level of vitamin A as butter; vitamin D was added later. The principle that an intended direct substitute be at least as nutritious as the replacement had become part of the FDA's expectations for new products. Sales of colored margarine were approved on a state-bystate basis in the 1950s and 1960s, and United States per capita consumption of margarine surpassed butter in 1956.

The major enabling technical break-throughs were invention of the internal scraped surface heat exchanger (SSHE, "Votator") in 1937 for chilling the margarine oil mixture, and the lifting of emulsifier restrictions in 1992, which permitted development of a wide range of reduced-fat spreads. Margarine typically has had the same fat content as butter in most nations and is 80% in the United States. Spreads contain less than 80% fat and have become the most popular of the group. Some contain as little as 20% fat, the minimum amount being technical rather than legal.

SFI profiles of several margarine types, an all-purpose shortening, frying oil, and two shortenings are shown in Fig. 34.33 [128]. The SFI profile of butterfat varies with

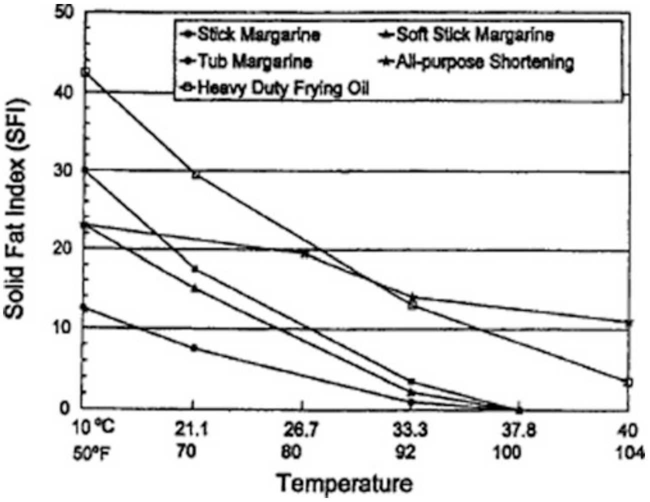

Fig. 34.33 Solid Fat Index (SFI) profiles for hard stick, soft stick and tub margarines, and for all-purpose shortening and heavy duty frying oil. (Data plotted from Erickson and [128])

Table 34.13 Crystal forming tendencies of hydrogenated oils, collected and updated from various sources

Beta prime (β′) type	*Beta* (β) type
Cottonseed	Soybean
Rapessed—HEAR[a]	Canola—LEAR[a]
Lard—modified[b]	Lard—nonmodified[b]
Palm	Palm kernel
Rice bran	Sunflower
Herring	Olive
Menhaden	Corn
Milk fat (butter fat)	Peanut
Tallow	Safflower Cocoa butter Coconut Sesame

[a] By elimination of erucic acid from traditional high erucic acid rapeseed, the C22 fatty acid family also was eliminated. The replacement canola (low-erucic-acid rapeseed) had one less variety of fatty acids and became a *β* crystallizer

[b] A reverse situation occurred in lard, which has few predominant TAG types. Rearrangement created additional types which led to *β*′ crystallization

the season and feed and typically is in the 40–50% solids range at 10°C/50°F. Soft stick margarine is softer than butter when taken from the refrigerator, and tub margarine is spreadable.

The basic sequence for making margarines/spreads includes:

- Formulation of an oil mixture from hydrogenated base stock or interesterified fats, hard stock, and oil that has the desired SFI or SFC profile.
- Ensuring that sufficient diversity occurs in the species and fractions to provide a variety of TAG that will form small *β*′ crystals.
- Compounding the margarine oil blend at the refinery; final deodorization; shipping the melted blend to the margarine plant; and storage under a nitrogen blanket.
- Preparing an oil-soluble additives mixture containing mono- or diglycerides and other emulsifiers, flavorings, oil-soluble vitamins, and yellow color at the margarine/spread plant.
- Preparing a water-soluble additives mixture containing water, salt, anti-microbial compounds, viscosity thickeners, and water-soluble flavorings. Formula amounts of thickeners and water-soluble flavorings increase as the fat content of a spread is reduced. The water should be microbiologically potable and deionized to remove calcium, magnesium, iron, and copper.
- Blending the heated oil-soluble additives mixture into the warm oil in a mixing tank. Slowly adding the warmed water-soluble additives mixture into the blend to produce a water-in-oil emulsion.
- Pasteurization; partial cooling.
- Chilling and working the emulsion in a series of (typically ammonia-chilled) internal scraped-surface heat exchangers (“A” units) and “picker bar” workers (“B” units), with resting tubes interspersed to ensure adequate time for establishment of the desired crystal structures.
- Filling.
- Holding under controlled temperature conditions for establishment of the desired crystals.
- Shipping.

Much of the physical chemistry for making temperature-profiled fats, including Figs. 34.1 and 34.2, has already been reviewed. Additional references are available [53, 187]. We cannot change the laws of thermodynamics, but can slow or hasten arrival at equilibrium. The margarine literature often shows a table similar to Table 34.13, but does not explain the practical implications. Basically, the beta prime (β′) tending oils contain a greater variety of fatty acids than the beta (β) tending. A greater diversity makes it more difficult for identical TAG to align and crystallize. It is easier to make whole cottonseed oil margarines/spreads than whole soybean oil counterparts because the former contains about 2.5 times more palmitic acid than soybean oil. For years it was common practice to include about 10% cottonseed hard stock in soybean margarines. A reduction in TAG diversity increased the problems of making margarine when erucic acid was eliminated from canola (rapeseed); but increasing diversity, as by rearrangement of lard and increased presence of *trans* fats, has assisted in making smooth-textured margarines. A similar lack of diversity is encountered in making palm oil margarines, and addition of C 18 hard-stocks and lengthening pin working and resting times have been employed. The newer high oleic acid oil varieties often present more difficulties in texture development than the traditional varieties in the same oil species. Crystals grow by aligning

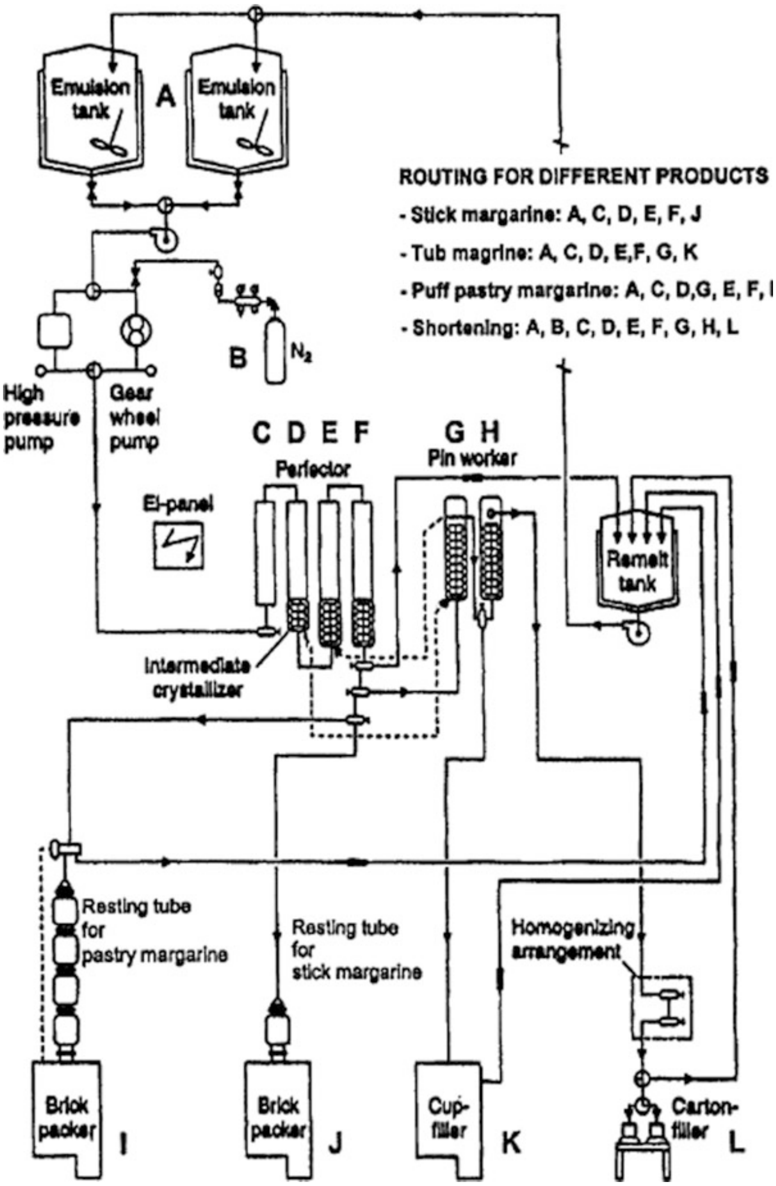

Fig. 34.34 Flexible Perfector Plant™ for making stick, tub, and pastry margarines, and shortening. (Courtesy of Gerstenberg Schröder, Brondby, Denmark)

identical molecules side by side. Emulsifiers, such as mono- or diglycerides, can align next to the crystal and be accepted as part of the lattice. But, not being identical, they foul the surface and stop crystal growth. Increasing the viscosity of lower oil content spreads makes it more difficult for similar TAG to align and crystallize, especially if temperature cycling occurs during storage.

Margarine, like butter, and spreads, is a water-in-oil emulsion. The water and all water-soluble ingredients are encapsulated in a continuous phase of oil. This has many practical advantages. Growth in individual droplets is limited by available nutrients, and bacteria cannot cross over to a second nearby food supply. If the product is salted at 1.5%, the water droplets will have a salt concentration of 7.5%, which is inhibitory to many bacteria. If the emulsion has been properly made and pasteurized, many droplets will be small and not contain bacteria cells. Lecithin is included in margarines/spreads at 0.1–0.5% as an antispattering agent used for frying; it is introduced with the oil-soluble additives initially added to the base oil.

The margarine/spread production flow sheet in Fig. 34.34 shows how these principles are applied. The figure represents a multipurpose plant, in which various products can be made. The legend in the upper right corner shows results of the sequences employed. The emulsions are prepared in tanks (A), although the provisions for pasteurization and cooling before processing are not shown. Consumer margarines must meet FDA Standards of Identity, which specify the permissible additives. Industrial buyers may arrange to have other FDA-approved ingredients added as a means to simplify their dispersion in manufactured products. The emulsion is pumped to an internal scraped-surface chiller and exits at

10–19°C/50–65°F as a soft glass (stiffening when held in the hand). Because this is not the type of final crystal desired, the chilled emulsion is then sent through a series of pin workers (tubes through which the margarine is pumped while a shaft with fingerlike pins mixes it), chillers, and resting stops to craft the desired crystal. The final temperatures for table margarines and margarine–butter blends are −18–−20°C/0–14°F, and −5°C to −1°C/12–23°F) for low-calorie spreads [188].

Figure 34.34 shows that tub margarine is pin-worked considerably more to keep it more liquid until filling. The solids content profile also is different from the stick margarine, and a smooth-textured product with minimum stiffening is desired.

Some bakery products ("puff pastries," phyllo) consist of flaky layers, made by rolling the dough thinly, covering it with shortening, folding, rerolling, and repeating the process many times. On baking, they puff up. The gluten layers must stay intact, and the shortening also must be flexible but not give off free oil during the machining. Puff pastries such as croissants, whose fat melt and clean-up in the mouth, can be made from butter, but must be prepared at low temperatures (10°C/50°F) in refrigerated rooms using chilled equipment. A very flat SFI curve (30.0–33.5 at 10°C; 28.0–30.0 at 21.1°C; 24.5–26.5 at 33.3°C; and 19 minimum at 40.0°C) is recommended for tallow–vegetable oil puff pastry margarines. They melt slightly above mouth temperature, but some people notice greasiness. Historically, puff pastry margarine was made using chilling rolls, but processes exist now for using scraped-surface heat exchangers, "B" units, and large resting tubes [188].

Shortenings

Typically, the function of fats in baking is to "shorten" or control development of wheat flour gluten and avoid or limit toughness in the product. In doing so, starch becomes the predominating matrix, and tenderizing complexes can be established between the fat and carbohydrates. A fat with a flatter solids temperature profile like the "All-purpose shortening" in Fig. 34.33 can accomplish its "shortening effect" during machining of the dough and baking even if it does not melt substantially during eating.

Numerous emulsifiers are available for dough (continuous gluten) and cake (sugar, corn sweetener, starch, and fat emulsion) systems. Emulsifiers act as conditioners in dough systems by: improving tolerances to variations in flour and other ingredients; increasing resistance to mixing and mechanical abuse; providing increased gas retention, shorter proof times, and increased product volume in yeast-leavened systems; improving uniformity of gas cell size, cell walls strength, and grain texture; improving slicing; and extending product freshness by delaying starch retrogradation and staling [171].

Cakes essentially are emulsified slurries before baking. Considerable use is made of sugar (with corn sweeteners increasingly used), starch in low-protein content flours, and fat. Emulsifiers have three functions in cake systems: to improve air incorporation; to disperse shortening into smaller particles to maximize the number of air cells; and to improve moisture retention. Complexes occur between fats, emulsifiers, and starches that result in smooth, tender, moist cakes. Emulsifiers include broad classes of lecithin and lecithin derivatives, mono- and difatty acid glycerol esters, hydroxycarbocylic acid and fatty acid esters, lactylated fatty acid esters, polyglycerol fatty acid esters, ethylene or propylene glycerol fatty acid esters, ethoxylated derivatives of monoglycerides, and Sorbitan™ fatty acid esters [171]. Many oil processors sell proprietary brands of shortenings containing emulsifiers, and large bakers can arrange to have emulsifiers added to their melted fat mixtures before shipping.

As shown in Fig. 34.34, nitrogen is injected into the first scraped-surface chiller, with the shortening oil mixture, to give an opaque white appearance and increase plasticity. Some bakers prefer to use semi-plastic shortenings in applications where oil may shorten the dough too rapidly, and for "creaming" sugar and shortening as in making cake frostings. Some small restaurants prefer semi-solid "shortenings" and have fryers able to accept standard 18.2-kg (40-lb) cubes. Care should be taken to avoid development of large air spaces when melting cubes over the (electric) heating rods to avoid burning the shortening.

Other Edible Applications

Cocoa butter (CB) has a challenging chemistry and has attracted many efforts to develop lower cost, acceptable alternatives. The following definitions provide a quick introduction to this field: (1) cocoa butter equivalents (CBEs) are compounded mostly from tropical oils other than palm. Because their melting and crystallization properties closely resemble CB, they are compatible as diluents at all levels of substitution; (2) cocoa butter replacers (CBRs) are made from nondairy oils (typically soybean, cottonseed, or palm) partially hydrogenated for maximum *trans*-C18 isomer formation to acquire a steep melting profile. They are best used for enrobing bakery products, but their melting profiles can be improved by chill fractionation; and (3) cocoa butter substitutes (CBSs) are made primarily from lauric-type fats (C8–C12 of palm kernel and coconut origin) and are hydrogenated under conditions that favor *trans* formation, but may contain a limited amount of hydrogenated C18 trigly-cerides. CBS limitations include: they must be used alone because of incompatibility with cocoa butter, they require the use of cocoa for "chocolate" flavor, and all ingredients with active lipase systems must be avoided to prevent the development of a soapy flavor [189].

The reader is referred to the volume by O'Brien [172] for other food applications of fats, including icings for sweet goods; spray-dried nondairy creamers; coffee whiteners; aerated whiteners with encapsulated air to produce a cappuccino effect when added to coffee; dried powders designed to be reconstituted, pasteurized, homogenized, and packaged for restaurant use as creamers; vending machine dry creamers; whipped topping shortenings, also used for making bakery cream pie fillings and cake toppings, aerosol toppings, powdered toppings, and frozen ready-to-use toppings; cheese analogue shortenings, frozen mellorine dessert shortenings, sour cream analogue, and dip base fats; and sweetened milk and sweetened condensed milk analogue fats.

Industrial Uses of Fats and Oils

Timeline

Industrial uses typically means nonfood-nonfeed applications, although feed uses are not consistently excluded. No one knows when man first used oils or fats for lighting, medical, and cosmetic applications, lubricants, or combined them with wood ashes to make soaps. The following sequence has been published for soybean oil [21].

- <AD 980—China: soybean oil likely used for illumination in lubricating fluids and coatings.
- AD 980—China: documented use of soybean oil boat caulking materials.
- 1908—Europe: soybean oils used in soaps; glycerin sought for making explosives for Panama Canal project and printer's inks; oil additionally used in rubber substitutes and linoleum flooring.
- 1910—United States: soybean oil classified as a drying oil; used as cheap replacement for linseed oil in paints.
- 1914–1918—United States: largest soybean oil industrial market is soaps, followed by paint, varnish, enamel, linoleum, oilcloth, asphalt, and other waterproofing materials.
- 1919—Blowing warm air through heated soybean oil found to increase viscosity by initiating oxidation and polymerization; blown oil improves properties of printing inks.
- 1926—Soybean oil used for plasticizing and increasing the elongation of rubber.
- 1930s—United States: Kienle and Hovey of General Electric developed soybean oil alkyd resins used in paints to improve drying, adherence, endurance, and color; Ford Motor Company used soybean oil and its derivatives in enamel paints for automobiles; DuPont's "four-hour enamel," based on soybean oil, is considered the most important factor in furthering soybean oil usage in paint. Japan also initiates programs.
  – Quality of soybean oil first reported suitable for food use and hydrogenation; replacement of cottonseed oil begins.
  – Strong chemurgic movement initiated; credited with nearly 200 industrial uses during its ten-year existence. Ford Motor Company uses significant amounts of soybean oil for enamel paint, glycerin for shock absorbers, in 1937 automobiles.
- 1945—Chemurgic programs decline after World War II.
- 1950s—D. Swern, USDA scientist, develops epoxy plasticizers from oils or monohydric fatty esters for use in plastics.
- Late 1970s—Converting oil triglycerides to methyl or ethyl fatty acid esters by transesterification ("alcoholysis") reduces injector fouling, carbon deposits, and degradation of lubricating oils in diesel engines, compared with direct use of vegetable oils or diesel fuel–vegetable oil mixtures.
- Early 1980s—American Newspaper Publishers Association develops first-generation soybean oil-based inks to replace uncertain mineral oil supplies.
- Mid-1980s—Degummed, alkali-refined cottonseed and soybean oils used in pesticide aerial spays.
- 1987—USDA Federal Grain Inspection Service allows the use of soybean and other edible oil sprays to reduce the risk of grain dust explosions in elevators. Use of one to two percent soybean oil in livestock feeds reduces dust in pig-rearing facilities, improves animal health, and gives five to ten percent increase in weight gains.

Chemurgy Revisited

Chemurgy is the use of replenishable farm crops as feedstocks for industrial processes. The concept became very popular with onset of the Great Depression in the early 1930s because it promised new uses for agricultural crops and development of a self-sustaining national economy. Famous advocates of the era included Henry Ford, industrialist, and George Washington Carver, crop scientist. The movement was heavily subsidized by the federal government, slowed as World War II approached, and ended in the prosperity of the postwar era. Currently, the United States again has agricultural surpluses, especially soybean oil. Naturally, the following question arises: Are business prospects for chemurgy products different now than in 1937, especially with the United States committed to an open global trade policy? New factors include: (1) Replenishable materials offer the promise of biodegradability, which is becoming increasingly popular with an environment-concerned public. (2) The global politics of petroleum carry many hidden costs, including threats of supply interruption, occasional price fixing, and potential involvement in wars to keep trade sources and routes open. (3) The petroleum companies are driven by economies of scale and have limited flexibility in responding to small, although reliable, markets.

(4) Biotechnology offers the promise of tailored crops, able to produce high levels of specific chemical feedstocks, previously unavailable. But (5) the portion of the public engaged in agriculture and agribusiness is the smallest ever, and federal subsidies may not be easily obtainable in the future.

Nevertheless, current chemurgy research and applications is the highest ever, and many products have been launched by small entrepreneurs to regain markets previously lost by vegetable oils to petroleum feed stocks (Table 34.14). Several factors seem obvious. (1) Supplies of fossil carbon sources (coal and petroleum) and minerals are limited and access to new sources is increasingly expensive. It seems almost certain that plastics and composites will become more important as structural and manufacturing materials, and people will have to increasingly replenish more of their carbon needs through agriculture. (2) The question of where replenishable resources will be grown and converted into industrial and consumer products is heavily political and yet to be answered as national policies compete with global companies. (3) the transition will not occur smoothly. Interests vested in the status quo are likely to first act to preserve current positions as long as possible, but will provide capital when change becomes inevitable.

Industrial Oils Utilization

Estimates of recent domestic edible and industrial oils and fats use are shown in Table 34.15, and industrial uses of soybean oil in Table 34.16.

Fatty acids chemistry and processes have been summarized by Johnson and Fritz [190] and oleochemicals manufacture and use by Gunstone and Hamilton [191]. Pathways for converting oils and fats into various oleochemicals are shown in Fig. 34.35 [21, 192].

Crude soybean oil has limited uses as sprays. Spray nozzles are in danger of clogging by phospholipids, which also leave repeatedly sprayed surfaces sticky. Generally, *once-refined oil* (degummed, alkali-neutralized, water-washed, and dried) is the minimum quality used for dust control and aerial spraying of pesticides. Anticorrosion and anti-polymerization agents are added in lubricants and also in hydraulic fluids. Current industrial applications include: inks, paints and coatings, biodiesel fuels and additives, lubricants, ion exchange resins, adhesives, foams, fatty alcohols, fatty amines, and associated processing [191, 193–196].

Table 34.14 Examples of soybean oil and lecithin industrial uses[a]

Soybean oil technical uses	Oleochemicals from oil	Soybean lecithin
Anti-corrosion agents	Methyl esters	*Wetting agents*
Anti-static agents	Soy diesel fuel	Dry powders
Candles	Solvents	Cosmetics
Caulking compounds		Plant pigments
Composite materials	Fatty acids	
Concrete release agents	Fatty alcohols	*Nutritional*
Core oils	Glycerin—industrial and explosive uses	Medical

Fatty Acid Methyl Esters, Biodiesel

Fatty acid methyl esters (FAME) are the gateway to many products. Use for glycerol, a byproduct of alcoholysis interesterification. Current FAME uses include: cleaning graffiti stains and sticky deposits, light lubricants, degreasing baths, inclusion in penetrating oils, asphalt and concrete

Table 34.15 Reported fats and oils uses in the United States, 2002 (million pounds)[a,b]

		Percent of reported	
Fat or off	Amount (million pounds)	Crop oil	Total edible oils
Edible uses

mold release agents, and adjuvants in various applications. FAME are called *methyl soyate* if made from soybean oil. Large investments in manufacturing facilities are being made in expectation of rapid growth of this industry.

Vegetable oil fuels have been prepared by various methods, including micro-emulsification, transesterification, and pyrolysis. Tests during the mid-1970s and early 1980s showed that diesel engines can initially run on vegetable oils or animal fats, or their mixtures with diesel fuel; but, despite various additives to the fuel and engine oil, problems eventually were encountered with fuel injection valve clogging, cylinder head carbon deposits, and engine oil fouling by fuel blow-by.

The fuel properties of some vegetable oils and soybean FAME are presented in Table 34.17. The heat of combustion of various vegetable oils is nearly 90% that of No. 2 diesel fuel, but engine viscosity is 10–20 times greater. Conversion of soybean oil to methyl soyate reduces fuel viscosity to approximately twice that of diesel fuel. Cetane numbers (CN) indicate the comparative ignition delay time of fuels in the combustion chamber: the shorter the ignition delay, the higher the CN [195]. A flow sheet of a process currently installed for making methyl or ethyl fatty acid esters is shown in Fig. 34.36.

Problems encountered in handling vegetable oil-based fuels include: higher viscosity and higher cloud and pour points, which may require supplemental heating of fuel tanks in cooler weather. Various techniques have been tried to reduce cold temperature viscosity of methyl soyate. Winterization lowered the crystallization temperature by 7.1°C [197]. Increasing the molecular diversity by the addition of isopropyl and 2-butyl (branched alcohol) esters lowered the crystallization temperature of soybean methyl esters by 7–11°C and 12–14°C, respectively [198]. But, molecular diversity effect is reported significantly diluted in 20:80 mixtures of methyl soyate and No. 2 diesel fuel [195].

Domestically, methyl esters are made from soybean oil, spent frying oils, and inedible animal fats. Palm oil is used in Southeast Asia, and rapeseed in Europe. Although appreciable in quantity, supplies of such materials actually are small compared with the amount of TAG that would be required if significant quantities of methyl esters were used in fuels. Governmental support of biodiesel development has included funding of research and demonstration projects, and reducing or eliminating state or federal taxes collected for its fuel use. In turn, this funds the amount of methyl esters that can be blended to make biodiesel competitive with nonblended fuels.

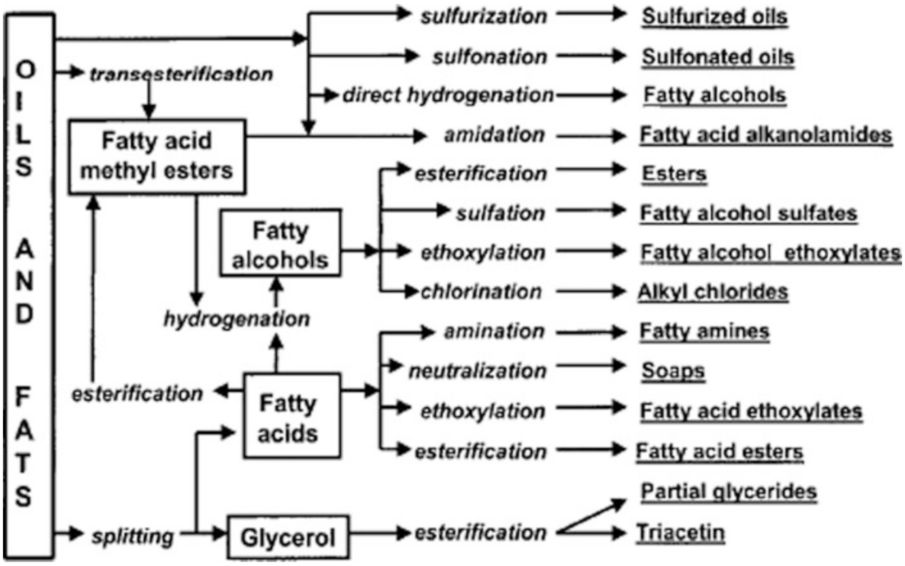

Fig. 34.35 Oleochemical derivatization pathways. (Modified from Zoebelein [192])

Table 34.17 Fuel properties of some vegetable oils and soybean esters[a]

Oil or ester	Viscosity (mm^2/s)	Cetane no.	Gross heat of combustion (kJ/kg)	Cloud point (°C)	Pour point (°C)
Oils[b]					
Castor	297.0	–	37,274	None	−31.7
Corn	34.9	37.6	39,500	−1.1	−40.0
Cottonseed	33.5	41.8	39,468	1.7	−15.0

[c] Viscosity determined at 40°C

The attraction of biodiesel is reduced discharge of undesirable combustion emission compounds into the air. Undoubtedly, effectiveness is related to the degree of petrochemicals replacement. Biodiesel is sold with a numerical designation of the oil/fat-ester content. B20 is a frequent blend, containing 80% petroleum diesel fuel and 20% FAME. A major farm equipment manufacturer has announced it will ship its new equipment with B2 in the fuel tanks. A salt mine has begun using B 100 as a means to improve air quality for its workers.

Progress on biodiesel development can be followed on the National Biodiesel Board (NBB), Jefferson City, MO, Web site (www.biodiesel.org), and the United Soybean Board (USB) St. Louis, MO, Web site (www.unitedsoybean.org) for soybean oil-based fuels; also *Render Magazine*, Camino, CA (www.rendermagazine.com) has kept that industry's members informed on worldwide developments on biodiesel development [199–205].

While a number of bio feedstocks are currently being studied, algae (an autotrophic organism, ranging from unicellular to multicellular forms) have emerged as one of the most promising sources of biodiesel feedstock. Algae have some important advantages over other oil producing crops. It can be grown in almost any enclosed space and it requires

very little support to grow such as sunlight, water, and carbon dioxide. However, maintaining a pure culture is a major challenge, including during the oil extraction process. Currently, efforts are being focused on these two areas by academicians and by the bio-industry. Algae contain anywhere between 2 and 60% of lipid oil by weight depending on type of strain. Microalgae have been investigated for the production of a number of different biofuels including biodiesel, bio-oil, bio-syngas, and bio-hydrogen.

The global market for biodiesel is changing rapidly, creating both uncertainty and opportunity. The first-generation biodiesel markets in the United States and Europe have reached impressive production levels, but remain constrained by feedstock availability (see Table 34.18). As a result, a surge in demand for alternative feedstock is driving new growth opportunities in this sector. Biodiesel from non-food feedstock is also gaining attention around the world. For example, jatropha plantations in India and China. In Brazil and Africa, there are significant programs underway dedicated to producing non-food crops such as jatropha and castor for biodiesel. Also, an increasing number of second-generation biodiesel projects are now emerging in anticipation of growing sustainability concerns by governments, and in response to market demands for improved process efficiencies and greater feedstock production yields. A great deal of research is under way on reducing the cost of feed-stocks such as algae, jatropha, castor, used vegetable oils, tallow. Given recent efforts in these areas, it is reasonable to expect significant advances at the industrial scale in the near future.

Other Industrial Applications

Essential oils, used in perfumes and cosmetics, are extracted in several ways by perfusion into fat, distillation, batch solvent extraction, and critical CO_2. The oldest method, used today only for extremely valuable essential oils, is *enf eurage–def eurage*. This consists of layering blossoms of plants to be extracted between lard-coated glass plates and allowing the essential oil to perfuse into the fat. The blossoms are renewed daily. At the end of the season the fat is scraped from the plates, melted, poured into containers, and sold as pomade or is batch-extracted with cold ethanol and sold as extraits. Another technique consists of macerating the material and extracting with hot fat. The most common extraction process for essential oils is steam distillation of a mash of the leaves or seeds to be extracted. Selective solvent batch extraction also is used.

New oilseed crops, currently studied as potential sources of specialty fatty acids, include *Crambe abyssinica* for erucic acid, *Limnanthes alba* for very long-chain fatty acids, *Dimorphotheca pluvialis* for dimor-phecolic acid, *Lesquerella fendleri* for lesquerolic acid, *Calendula officinalis* for calendic acid, and *Euphorbia lagascae* and various *Vernonia* species for vernolic acid.194 The lowest cost sources (inedible fats and oils and palm oil fractions) are most likely to be exhausted first as world trade in industrial applications grows. Cornstarch is becoming a major feedstock for plastics production. This may compete with potential oil uses, but also will increase production of corn oil.

Other current areas of soybean oil industrial applications research include plastics, coatings, lubricants, and hydraulic fluids. Potential applications are only limited by imagination, economics, and the business skills of the respective entrepreneur. The United Soybean Board maintains a Web site (www.unitedsoybean.org) of current soybean oil-based industrial products manufacturers, listed under the categories of adjuvants, alternative fuels and fuel additives, building and construction, cleaners, concrete, dust suppressants, engine oils, hydraulic fluids, ingredients, metal working fluids, printing, and miscellaneous. The categories list suppliers and as many as several hundred products each. In many cases, suppliers list their Web sites for interested persons to learn more about uses and specifications of their products.

Analytical Methods

Selected analytical methods, adopted by the American Oil Chemists' Society (AOCS) [22] for characterizing the composition, structure, physical properties, and stability of fats and oils, are summarized below. Prescribed equipment must be used and conditions followed. Some of these techniques are limited to specific oil species, but adaptations are available for other species. Procedures for sample drawing and preparation also are specified.

AOM for fat stability (Cd 12–57): determines the time (in hours) for a sample of fat or oil to attain a predetermined peroxide value (PV) under the conditions of the test. The method is used to estimate the comparative oxidative stability of fats and oils. The method has been placed in surplus, in favor of Cd 12b-92 (Oil Stability Index), but retains official status and is still used in domestic industry. *p*-anisidine value (AV) (*Cd 18–90*): determines the amount of aldehydes (principally 2-alkenals and 2,4-dienals) in animal and vegetable fats and oils. These are degradation products of peroxides, which are not removed by bleaching. Some fats and oils chemists propose increased use of this method in purchase specifications.

Bleaching Test for Soybean Oil (Cc 8e-s63): determines the color of a sample of soybean oil after treatment with a specified bleaching earth. Specific methods exist for other oil species.

Boemer Number, Foreign Fats in Lard (Cb 5–40): estimates the presence of tallows and similar fats, based on differences in melting points of foreign glycerides and fatty acids as compared with pure pork fat. *Cloud Point Test (Cc 6–25)*: determines the temperature at which a cloud first forms in cooling a sample of melted fat to the first stage of crystallization

Cold Test (Cc 11–53): measures the relative resistance of a sample to crystallize at an established temperature in terms of time. The 5.5-h test at 0°C is used as an index of stearin removal in the winterization of salad oils.

Color Measurement by Lovibond–Wesson (Cc 13b-45): determines the color of clear oil samples by comparison with glasses of known color characteristics.

Fatty Acid Composition by Gas Chromatography (Ce 1–62): *quantitatively* determines saturated and unsaturated fatty acids with 8–24 carbon atoms in animal fats, vegetable oils, marine oils, and fatty acids after conversion to their methyl ester forms.

Fatty Acid Composition by GLC (Ce Ic-89): measures the fatty acid composition and levels of *trans* unsaturation and *cis, cis* methylene-interrupted unsaturation of vegetable oils using capillary gas liquid chromatography.

Flash Point–Pensky–Martens Closed Cup for Fats and Oils (Cc 9b-55): determines the temperature at which an oil sample will flash when a test flame is applied. This technique sometimes is used to estimate levels of residual hexane and to ensure the safety of workers handling the oil. Some refineries use gas chromatography methods instead.

Free Fatty Acids in Crude and Refined Fats and Oils (*FFA*) *(Ca 5a-40)*: determines FFA, as oleic acid, by ethanolic sodium hydroxide titration.

Halphen Test for Detecting Cottonseed Oil (Cb 1–25): estimates the presence of cottonseed oil in vegetable or animal fats or oils as the result of a pink color formed between the reagent and cyclopropenoic fatty acids (sterculic and malvalic) normally present in cottonseed oil.

Hexane Residues in Fats and Oils (Ca 3b-87): determines, by gas chromatography, the "free" volatile hydrocarbons remaining in fats and oils after extraction with hydrocarbon solvents. The results are expressed in terms of hexane.

Insoluble Impurities in Fats and Oils (Ca 3a-46): determines dirt, meal, and foreign substances that are insoluble in kerosene and petroleum ether.

Iodine Value of Fats and Oils—Cyclohexane Method (IV) (Cd lb-87): measures the unsaturation of fats and oils in terms of centigrams of iodine absorbed per gram of sample. The method is applicable to all normal fats that do not contain conjugated double bonds. It often is used to estimate the degree of hydrogenation of oils.

Melting Point–Capillary Tube Method (Cc 1–25): determines the temperature at which a sample of fat in a closed capillary becomes completely clear and liquid; broadly applicable; popular for tropical fats.

Melting Point–Mettler Dropping Point (Cc 18–80): determines the temperature at which a sample becomes sufficiently fluid to flow in a specified apparatus; the major melting point determination method used by domestic industry.

Melting Point–Open Tube-Softening Point (Cc 3–25): determines the temperature at which a solidified fat, in an open capillary tube, softens sufficiently to slip and rise to the top of the heating bath. This method is applicable to fats such as coconut oil, stearin, hydrogenated fats, and hard tallows. The results sometimes are reported as the "melting slip point," but the method is different from the AOCS Slip Point (Cc 4–25).

Melting Point–Wiley Method (Cc-38): determines the temperature at which a sample disk of solidified fat assumes a spherical shape while suspended in a heating bath with an alcohol–water density gradient. A seldom-used method, primarily replaced by the Mettler Dropping Point.

Moisture-Distillation Method (Ca 2a-45): determines only moisture in triacylglycerols and emulsions by distillation with an immiscible solvent (toluene).

Moisture and Volatile Matter —Air Oven Method (M&V) (Ca 2c-25): determines the moisture and volatile matter by heating in a hot air oven. This method is applicable to animal and vegetable fats, but not to drying oils, coconut group fats, or oils with added monoacylglycerols.

Oil (Aa 4–38): determines oil content in a dried sample of oil-bearing material by extraction with petroleum ether. This method is specific for cottonseed, which first must be fumed with hydrochloric acid to prevent oil adsorption to the fiber. Additional methods exist for other oilseeds.

Oxygen Stability Index (OSI) (Cd 12b-92): measures the oxidation induction period of fat sample (essentially the time for a sample to exhaust its antioxidant properties) under conditions of the test.

Peroxide Value, Fats and Oils (PV) (Cd 8–53): determines all substances, in terms of milliequivalents of peroxide per 1000 g of sample that oxidize potassium iodide (KI). These substances generally are assumed to be peroxides or products of fat oxidation.

Phosphorus in Oils (Ca 13–55): estimates the phospholipid content of crude, degummed, and refined vegetable oils in terms of phosphorus. Refineries often use ICP spectrographs to analyze divalent cations rapidly in aspirated crude oil. The calcium and magnesium measured are mainly responsible for NHP and are determined directly. An AOCS method for analysis by ICP is being developed.

Refining Loss, Vegetable Oils, Crude (Ca 9a-52): determines the loss of free fatty acids and impurities when crude oils are refined under specified procedures.

Residual Lint (Aa 7–55): determines the lint content of cottonseed by fuming (digesting) with hydrochloric acid.

Saponification Value of Fats and Oils (Cd 3–25): determines the number of milligrams of (alcoholic) potassium hydroxide necessary to saponify a 1-g sample of a fat or oil.

Schaal Test (Schaal Oven Method): an accelerated test for determining the oxidative stability of a fat or a fat-containing food product. Results are reported as the time elapsed until a rancid odor is detected. This is not an AOCS method; see American Association of Cereal Chemists' Method Manual. Modifications, using OSI apparatus, have been reported.

Smoke, Flash, and Fire Point—Cleveland Open Cup Method (Cc 9a-48): determines the temperatures at which fats and oils smoke, flash, or burn. Smoke point determinations sometimes are used to follow degradation of frying oils with use.

Solid Fat Content of Fats and Oils by NMR (SFC) (Cd 16–81): estimates the percentage of solids in a semi-solid fat on the basis of the pulsed NMR signal of hydrogen in the liquid fraction. The method is used in the palm oil industry and widely throughout the world.

Solid Fat Index—Dilatometric Method (SFI) (Cd 10–57): estimates the percentage of solids in a semi-solid fat on the basis of changes in volume with temperature. This method utilizes glass dilatometers and is the primary method in the United States. *Totox Value:* an estimate of the degree of oxidation of a fat or oil, calculated as:

$$\text{Totox} = 2 \times (\text{PV}) + \text{AV}.$$

Triglycerides by GLC (Ce 5b-86): quantitatively determines triglycerides (triacylglycerols) in liquid vegetable oils in terms of molecular weight and degree of unsaturation as a function of their equivalent carbon number using high-pressure liquid chromatography.

Unsaponifiable Matter in Fats and Oils, Including Marine Oils (Ca bb-5, 3): determines substances dissolved in fats and oils that cannot be saponified (turned into sodium salts) by the usual caustic treatment, including higher aliphatic alcohols, sterols, pigments, and hydrocarbons. This method is not suitable for marine oils or feed grade fats.

Sugar and Other Sweeteners

35

Mary An Godshall

Introduction

Sugar and starch are among the most abundant plant products available, and large industries exist worldwide to extract and process them from agricultural sources. The world production of sugar (sucrose from cane and beet) in 2007/2008 was 170.4 million metric tons, raw value [1], with 20.7% being beet sugar and 79.3% cane sugar. The proportion of beet sugar to cane sugar has fallen steadily since about 1971, when it constituted 42.8% of total sugar production [2]. The decline in beet sugar proportion represents not so much a decline in beet production, which has remained in the range of 33–39 million metric tons, but rather a continued increase in cane sugar production from around 72 million metric tons in 1991 to 134 million metric tons in 2008. The total production of world sugar has risen dramatically since 1971/1972, when it was 71.7 million tons [3].

Although cane and beet are physically very different from one another, the factory processes for extracting and producing sugar are similar. Two major differences are the types of color produced during beet processing compared to cane processing, which allows direct processing of beets into white sugar; and the fact that cane factories are essentially self-sufficient in fuel because they can burn bagasse, the cane plant residue, whereas the beet factory does not produce a consumable by-product fuel.

Sugar is primarily used as a sweetener in the manufacture of food and in household use. When used for such purposes in industrialized nations, most of it is highly refined or purified, but considerable quantities are consumed in less industrialized areas of the world as a less refined sugar, called plantation white sugar or mill white sugar. In India, crude sugar products such as gur (also known as jaggery), khandsari, and cane juice are popular and represent as much as 29% of consumption [4]. Sugar is used to a limited extent in the production of other chemicals, such as sucrose esters, and in the form of by-product molasses, as a substrate for fermentation processes and to produce alcohol, both for consumption and power, usually mixed with gasoline.

Starch is widely used in the textile and paper industries, as well as for food. A major use of starch is its hydrolytic conversion to glucose and enzymatic conversion to fructose for use as a sweetener in the food industry. Technological developments and governmental price-support programs for the domestic (United States) cane and beet sugar industries begun in the mid-1970s greatly magnified the importance of starch as a source of nutritive sweeteners [5]. Starch-derived sweeteners compete directly and successfully with sugar in the United States, and increasingly in other countries.

The sugar industry has been characterized by steady, small incremental improvements in technology and production over the years, with subsequent improvements across the process, from field practices to new products [6, 7].

Sugar

History [8]

The ancestry of sugarcane and its use as a food have been traced to the island of New Guinea. An interesting legend by Hugill [9] associated sugarcane with the origin of the human race. Around 8000 BC, the plant started on its migration from New Guinea to many areas of southeastern Asia, Indonesia, the Philippines, Malay, Indochina, and eastern India, with humans probably acting as its main dispersal agent [10]. Sugarcane was first cultivated in Bengalese India as a field crop and the juice manufactured into various solid forms. A general knowledge of sugar was prevalent throughout India by 400 BC. By the tenth century AD, sugar cultivation and manufacturing had become important industries in Persia and Egypt. The early Islamic movement spread knowledge of the sugar industry throughout the Mediterranean area.

On the second voyage of Columbus to America, in 1493, sugarcane was introduced in Santo Domingo. It spread rapidly through the West Indies and Central America. Cortez brought cane to Mexico, and Pizarro introduced it in Peru. By 1600, the sugar industry was the largest industry in tropical America [11].

The modern sugar industry dates from the end of the eighteenth century, when steam replaced animal energy and made possible the development of larger and more efficient production units. The vacuum pan appeared in 1813, bag filters in 1824, multiple-effect evaporators in 1846, filter presses in 1850, centrifugals in 1867, dryers in 1878, and packaging machines in 1891 [12]. Cultivation of the sugar beet plant and the manufacture of sugar from the beet developed in the industrial nations of Europe during the eighteenth and nineteenth centuries. In 1747, the German chemist, Marggraf, established that sugar from beets was the same as sugar from cane. His pupil, Achard, in 1799, demonstrated that sugar can be commercially prepared from beets. During the Napoleonic wars, a short-lived beet sugar industry was established in France [13]. Today, beet is the major source of sugar in Europe.

Raw Sugar Production

Traditionally, raw sugar is produced at the cane mill and refined sugar is produced at a refinery, usually far removed from the source of the raw sugar, and close to areas of consumption. Figure 35.1 is a generalized flow diagram for the manufacture of raw cane sugar. In summary, the juice is extracted from the harvested cane stalks, the juice is purified (clarified), concentrated by vacuum evaporation, and crystallized. The several steps are described in the sections that follow.

Agriculture. The sugarcane is a large perennial tropical grass belonging to the genus *Saccharum*. Three basic species, *S. officinarum*, *S. robustum*, and *S. spontaneum*, make up the sugarcane complex, with a large number of varieties. Sugarcane is propagated commercially by cuttings, each cutting consisting of portions of the cane plant having two or more buds, or "eyes." The buds sprout into shoots from which several other shoots arise below the soil level to form a clump of stalks known as a "stool." From 12 to 20 months are required for the crop to mature from new plantings and about 12 months for ratoon crops (i.e., cane stalks arising from stools that have been previously harvested). Most of the field operations have been mechanized, but planting is still done by hand in some cane-producing areas. Fields are replanted after two to five or more ratoons (cuttings made from the original planting). As cane grows, its foliage is largely limited to the upper one-third of the plant, as the lower leaves die off from shading as the stalk grows taller. The cane stalk is round and jointed, and grows to more than 10 ft when mature (Fig. 35.2). It is covered with a hard rind that varies in color from light brown, green, yellowish green, purple, or striped, depending on the variety. There is usually a fine film of waxy material on the surface of the rind, heavier in some varieties than others. The stalk is divided into a series of internodes, from 3 to 10 in. in length, separated by nodes. The internodes contain the pithy

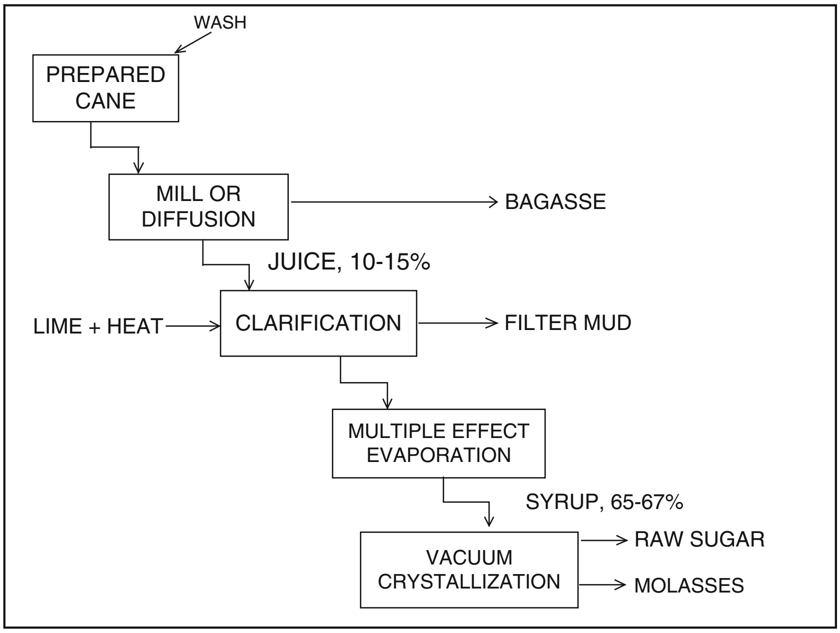

Fig. 35.1 Generalized flow diagram of steps in raw cane sugar manufacture (adapted from Clarke [104])

Fig. 35.2 Sugarcane in the field

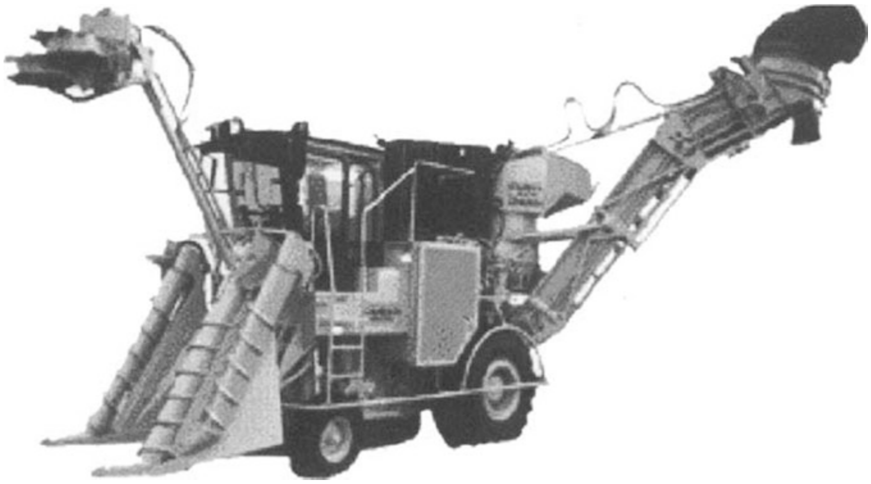

Fig. 35.3 Cameco single-row harvester

material from which most of the sucrose-containing cane juice is obtained. The nodes, somewhat woody in nature, contain one bud or "eye" on alternating sides, which sprout when planted.

Breeding programs throughout the world develop cane varieties that are suited to their particular climatic conditions, to give the highest yield, balanced with disease resistance and other desirable agronomic traits. In Louisiana, for example, cane varieties are bred for cold tolerance, among other traits, because of the short growing season and the possibility of freezing weather during the harvest. Varieties retain vigor for 10–15 years and then need to be replaced by new varieties. There is ongoing research in genetic manipulation of sugarcane for herbicide and disease resistance, but no commercial varieties exist to date.

Harvesting. Sugarcane is cut by hand with machete-type knives in a few producing areas. In hand-cutting, the tops and leaves are removed, and the cane is cut at ground level. In more industrialized areas, cane is harvested by machines. Two types of machine harvesting are in widespread use: whole-stalk harvesters, also known as soldier harvesters, and chopper harvesters, also known as combine harvesters, in which the cane is cut into smaller pieces, known as billets, about 8–12 in. in length. Combine harvesters exist as single-row (Fig. 35.3) and two-row

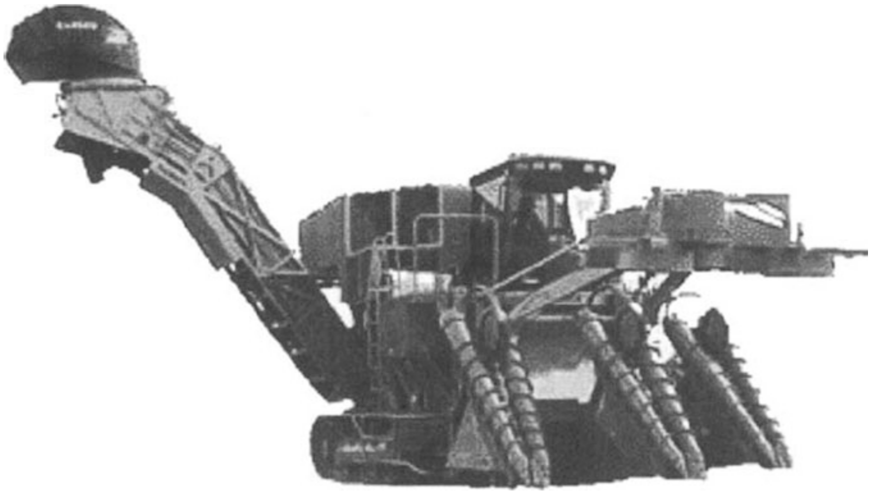

Fig. 35.4 Cameco two-row harvester

models (Fig. 35.4). The whole stalk cane may be transported immediately to the mill where it is dumped in large cane yards for future processing, or left in the field for future pick-up. Billeted cane should always be processed as soon as possible because of the faster deterioration rate of the juice quality caused by the shorter pieces. In many areas, cane is burned before harvesting to help remove leaves and trash. The practice of burning has become less environmentally and socially acceptable in recent years, and, in spite of many efforts by the industry to control adverse effects, the practice is in decline. The practice of harvesting unburned cane is called green cane harvesting, and it introduces a host of challenges to the processor because of the heavier load of impurities, such as color-producing molecules and polysaccharides, that are expressed into the juice [14, 15]. Cane may be transported to the mill by railcars, trucks, trailers, and carts.

A new development in harvest control for better quality of cane and beet has been the use of global positioning systems (GPS) based on satellite navigation facilities [16].

Preparation of cane for milling. Because of the presence of adhering soil, rocks, and field trash, mechanically harvested cane usually must be washed before milling. In some carefully controlled situations, when the weather has been dry, washing can be eliminated. Washing systems range from a simple spraying with warm water on the carrier or cane table to an elaborate system consisting of conveyors with water jets, stripping rolls, and baths for the removal of stones. In most mills, a biocide is added to prevent bacterial growth in the cane. Mill sanitation is important to control bacterial activity, which can result in direct sucrose loss as bacteria consume the sugar, and in the production of undesirable by-products, such as dextran, a polysaccharide that has deleterious effects in the production of sugar, or lactic acid. With the advent of billeted cane, more sucrose can be lost in the wash water due to the multitude of cut ends, resulting in some reduction in yield.

The cane is prepared for milling by mechanically knifing or shredding or a combination of the two to chop the cane into smaller pieces. It is important for the mill to pay attention to good cane preparation, in as much as this is one of the most important parameters affecting extraction of the juice [17]. The Unigator, developed in the late 1970s, combines the action of the chopper and the shredder into a single unit [18]. The advantages gained are a greater increase in juice extraction by the mills, an increase in the grinding rate, and, in some cases, a decrease in power consumption by the milling operation. The preparation index (PI) is a measure of how well the cane has been prepared for juice extraction, and represents the percentage of cane plant cells that are ruptured by the cane preparation equipment. It is measured as brix (percent of sucrose) in the ruptured cells as a proportion of the total brix in the cane.

A novel approach to the preparation of sugarcane for the extraction of sugar was demonstrated in a machine called a Tilby separator. Cane stalks, cut into 8–12-in. segments, are fed into the separator, split in half, and depithed by a depithing wheel, resulting in a clean, sucrose-containing pith and rejected rind segments (Fig. 35.5). This approach has not been adopted on any large scale, but is used in some tropical countries to produce edible cane juice and also has some uses for research purposes.

Juice extraction. The shredded cane passes through a series of three horizontal rollers (mills) arranged in a triangular pattern, with the top roll rotating counterclockwise and the bottom two rollers clockwise. A series of three-roller mills, numbering 3–7, is called a tandem. The pressure on the top roll is regulated by hydraulic rams and averages about 300 t. Below each mill is a juice pan into which expressed juice flows. The crusher and first mill extract 60–70% of the cane

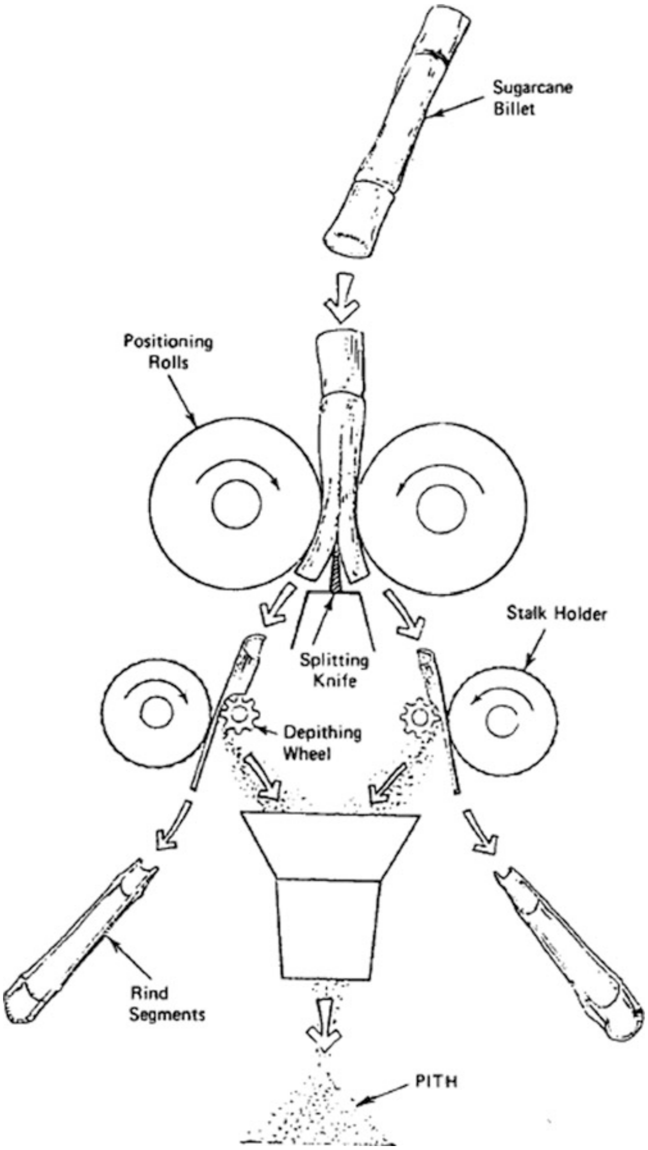

Fig. 35.5 Tilby separator process (Courtesy Ander-Cane, Inc., Naples, FL)

juice, and the remaining mills take out 22–25%. The fibrous cane residue remaining after juice is extracted is called bagasse. When the fiber content of the bagasse reaches about 50%, extraction by conventional milling approaches zero. Because the juice remaining with the fiber contains the same proportion of sucrose as the original cane juice, the yield of sugar would be substantially lowered if extraction were terminated at this point. Consequently, a process called "compound imbibition" is used to reduce the sucrose in the bagasse by repeated dilution and milling. In a five-mill tandem, water is added to the fourth mill, and the expressed juice from that mill is brought back to the second mill. The expressed juice from the third mill is recirculated to the first mill and the fifth mill to the third mill. In this way, the juice in the bagasse is always diluted ahead of each mill.

The amount of imbibition applied at each mill is approximately equal to the amount of water applied to the fourth mill or to the penultimate mill in a differently numbered tandem. The expressed juice is screened through perforated metal screens with 1-mm diameter openings. Additional screening may be provided by stationary or vibrating metal cloths.

The capacity of cane factories can vary from as little as 1,000 t of cane per day (tcd) up to 25,000 tcd. Factories operate only during the harvest, which may last for only 3 months or all year long, depending on the location.

Diffusion. Diffusion represents an alternative way to obtain juice from the cane. In diffusion, the cane is carefully shredded to disrupt the cells for maximum expression of juice. Diffusers have capacities ranging from 200 to 500 t of cane per hour (newer ones have capacities up to 875 t/h) and may be used alone or in conjunction with part of a milling tandem, the crusher and the first mill. Preparation of the cane for diffusion is essential for good extraction. In the diffuser, the shredded cane is countercurrently washed with imbibition water at an average temperature of 85°C. The high temperature helps to prevent microbial growth in the cane juice, but also increases the color of the juice. The last stage of a diffuser, the bagasse exit, receives water that gradually increases in sugar content as it proceeds to the final stage. Most of the sugar is extracted in the first four or five stages by simple displacement of sucrose from the ruptured cane cells. In later stages, diffusion appears to take place in unruptured cane cells. One or two mills are used to express water from the bagasse after discharge from the diffuser [19]. Chainless diffusers were introduced by Bosch Projects in 2006. The chainless diffuser eliminates the need for chains to move the cane, consisting instead of modules that move independently, actuated by hydraulic cylinders [20].

In comparing diffusers and milling, it is observed that sucrose extraction by a diffusion system averages 97–98%, whereas milling will produce 95–97% extraction. Diffusion provides a clearer juice (due to the filtering effect of the bagasse mat) with lower starch and gums but with about 25% higher color. Power requirements for diffusers are less than for mills and less filter cake is produced, as the mat of shredded cane in the diffuser acts as a primary filter, but more steam is needed to heat the juice [21, 22]. Cane diffusers have been installed in cane mills throughout the world and are manufactured by a number of companies. Many large cane mill installations have diffusers, the major exception being in the United States, where only one mill has a diffuser.

Biocides. Microbial inhibitors, or biocides, mentioned briefly above, are important for control in both beet and cane processing, as the juice contains sucrose and other nutrients in the right concentration for promoting microbial growth. The biocides in most common use around the world are dithiocarbamates, glutaraldehyde, and ammonium bisulfite. Combinations of these may act synergistically [23]. The use of natural products as antibacterials has received attention in recent years. Hop acids, rosin acids, and palm kernel fatty acids, especially myristic acid, have shown promise [24, 25]. They are recommended to be used in mixtures in rotation to prevent adaptation by microorganisms. These have the advantage that they are biodegradable and used in human food. Additionally, myristic acid is precipitated by lime during clarification [25].

Dextran. The major microbiological losses in sugar processing are caused by the common soil bacterium *Leuconostoc mesenerioides*, which uses sucrose as a food source, producing a long-chain polysaccharide, known as dextran, as a waste product. Dextran is composed of linear α-1,4-glucose with branches of α-1,6-glucose. In high enough concentration, dextran causes gummy solutions and difficulties in processing, along with sucrose loss. It also interferes with the polarimetric analysis of sucrose because, having a positive rotation, it is interpreted as sucrose, resulting in false high estimates of the sugar content in the cane or beet juice. Various methods exist for dextran measurement, all with some limitations.

Juice purification (*clarification*). The first stage of purifying the juice, designed to remove the maximum amount of impurities, is called clarification, or defection, and employs lime and heat. Clarification affects the juice filterability, evaporator scale composition, sucrose crystallization, and the quality of raw sugar produced [26]. The cane juice obtained from milling or diffusion is acidic (pH around 5.5–5.7), turbid, and dark brown in color. It contains 12–18% by weight sucrose (depending on the maturity of the cane), in addition to soluble and insoluble impurities, such as soil, protein, waxes, polysaccharides, starch, fine bagasse (bagacillo), organic and phenolic acids, soluble salts, and pigments. Cane juice also contains from 0.5 to 3% reducing sugars (glucose and fructose in approximately equal quantities). Lime serves the dual purpose of raising the pH and stabilizing the juice against hydrolysis of the sucrose in the acid juice and forming a precipitate to remove impurities. The heat helps to disinfect the juice of harmful bacteria and improves coagulation and precipitation of the impurities.

In simple lime defection, lime is added to the juice to raise the pH to 6.7–7.5 and to react with inorganic phosphate present in the cane juice to form a calcium phosphate floc, which entraps insoluble impurities from the cane juice, as it settles. The lime is added either in the form of milk of lime, lime-juice mixtures, or lime saccharate. Lime addition may be batchwise or continuous, and the addition of the lime may be to cold juice (35–40°C), to intermediate juice (72–76°C), or to hot juice (100°C) [26]. Polyacrylamide flocculants are added to aid in the coagulation of the precipitate.

In cold liming, milk of lime is added to the cold juice, and the limed juice is then pumped through heaters in which the juice is heated to 90–115°C. Many modifications to this process exist, especially with respect to the heating of the juice. Fractional liming with double heating involves liming the cold juice to pH 6.4, heating, liming to pH 7.6, and heating again before sending the juice to the clarifiers. Studies have shown the advantage of hot or intermediate liming over cold liming, resulting in less sucrose loss through inversion, less dextran formation, and better control of pH and turbidity with intermediate and hot liming [27, 28].

The combination of lime and heat forms a flocculent precipitate with various components in the juice, consisting mostly of insoluble lime salts, coagulated protein, and entrapped colloidal and suspended matter. The precipitate is removed by sedimentation or settling in continuous closed-tray clarifiers. The juice leaving the clarifier is a clear brown liquid. The flocculent precipitates that settle on the clarifier trays are called “muds.” They contain about 5% solid matter. Entrained sugar is recovered from the mud by means of rotary vacuum filters equipped with a perforated metallic screen cloth. The turbid filtrate is returned to the clarification system, and the press cake or filter mud is usually sent to the fields as fertilizer. Good clarification depends upon the formation of a stable flocculent precipitate that settles rapidly. Juices low in natural phosphates (less than 300 ppm P_2O_5 on juice solids) tend to be difficult to clarify and phosphate may need to be added. Very fine silty soil carried in from the field may also interfere with clarification. The main change in clarifiers over the last 20 years has been the development of the trayless SRI-type clarifier, which can handle much higher throughputs than the older-type clarifiers [29].

Syrup clarification. In some factories, a process known as syrup clarification is used to produce a higher-quality raw sugar and better yield. Evaporator syrup is treated with phosphoric acid, lime, and a polymer flocculent; insoluble impurities are floated to the surface of the syrup with aeration and removed by skimming. The clarified syrup goes to the vacuum pan for crystallization. Syrup clarification reduces the color and turbidity of the sugar produced, and can also be used in conjunction with sulfitation to produce an off-white, edible sugar [30].

Sulfitation. Sulfitation (alternate spelling, sulphitation) is the practice of adding sulfur dioxide (SO_2) to cane juice and syrup for the purpose of color control. In many parts of the world, sulfur dioxide is used to process cane juice into a semi-refined white sugar, known as plantation sugar or mill white sugar, used for domestic consumption (see the section "Direct Consumption Sugars"). Sulfitation is not generally used in the manufacture of raw sugar, which is produced for export to refineries, and is never used in the US cane sugar industry. Sulfur dioxide gas is produced by burning elemental sulfur. The gas is added to the cane juice during clarification, in the presence of lime, and many of the complex, little understood reactions that produce color in cane juice are inhibited by the presence of SO_2 gas. For example, enzymes responsible for the enzymatic browning reaction are inhibited, and reducing sugars (glucose and fructose) are blocked by sulfur addition at the aldehyde group and cannot react with amino acids to form browning polymers in the Maillard reaction.

Double sulfitation is practiced in many mills in India and China. In this process, a second dosage of sulfite and lime is added to the evaporator syrup at a solids content of 55–65% [31]. Double sulfitation provides a better quality white sugar.

There are many variations for the addition of SO_2 to juice, based on temperature, order of addition, and pH levels. These include liming first, sulfiting fist, simultaneous addition of lime and sulfite, and fractional procedures, as well as sulfiting cold or hot or stepwise heating of juice. If sulfitation is done first, because it lowers the pH of the juice, it is important to add the lime (about 0.20% on juice) in as short a time as possible to prevent sugar loss [31, 32]. The advantage of using SO_2 is a much lower color in the produced sugar. Disadvantages include increased scaling problems in the evaporators, high sulfite content in the final product, higher sugar loss due to lower pH, and secondary color formation (color return) on storage. Recently, the use of liquid SO_2 has been shown to have advantages over the gas, especially in a significant reduction in gas consumption (up to 69%) and a better quality of product [33]. There is a trend to decrease the use of SO_2 in the cane sugar industry in favor of alternative color control methods, such as polyaluminum coagulants and hydrogen peroxide.

Evaporation. The clarified juice (about 85% water) is pumped to evaporators where it is concentrated to a clear heavy syrup containing about 65% solids. Evaporation is carried out in multiple-effect evaporators in order to achieve maximum steam economy. Each effect is arranged in series and operated so that each succeeding one operates under a higher vacuum (lower pressure). This arrangement allows the juice to be drawn from one vessel to the next and permits it to boil at progressively lower temperatures. The concentrated juice (final evaporator syrup) is removed from the last effect by a pump. Triple, quadruple-, and quintuple-effect evaporators are used, with the quadruple-effect type plus a preevaporator being a common configuration. In a four-effect (quadruple) evaporator, 1 lb of steam evaporates 4 lb of water.

Several types of evaporators exist [34]. The older, more traditional, evaporators are the Roberts and the Kestner, both rising film, tubular evaporators. The Roberts, first introduced in the 1800s, is known as a short tube, natural circulation, vertical tube evaporator. The tubes, inside which the evaporation takes place, are in the range of 1.5–3 m in length. The Kestner evaporator consists of numerous long vertical tubes, 6–7.5 m long, inside a cylindrical shell. In both, the juice to be concentrated is fed to the bottom of the tubes and heated, causing the juice to boil and rise through the tubes. At the top, concentrated juice and vapor are separated in separators. The Kestner evaporator has a short residence time and a high heat transfer coefficient, but is more subject to scale deposits. The Roberts evaporator does not have a juice/vapor separator.

Newer types of evaporators are the falling film tubular evaporator and the plate evaporator, either rising film or falling film configuration. The falling film tubular evaporators have long tubes, like the Kestner, but the juice is fed at the top and flows down the tube wall as a thin film, resulting in higher heat transfer coefficients and reduced contact times. However, the tubes require feeding equal quantities of juice and must be kept wet at all times, as even a short time without adequate wetting can lead to severe fouling. Advances and innovations in evaporation are driven by the need for energy efficiency and to improve heat transfer coefficients. The goal in evaporation is to move the liquid through as quickly as possible at the highest temperature without causing degradation of the sucrose. The newest of the evaporators is the falling film plate evaporator (e.g., Balcke–Dür, Niro, Inc., GEA Ecoflex GmbH), the first one being installed in 1992. Recently, technology has become available that allows the retrofitting of existing Robert evaporators with falling film plate packs and some peripheral equipment, allowing the total steam demand of a cane sugar factory to be decreased by almost 30% on cane [35]. Plate evaporators are more common in the beet industry.

Evaporator scaling. A severe problem in cane sugar processing is the deposition of scale on the evaporator tubes or plates. Scale deposits consist of calcium and silicate salts, enmeshed in a matrix of organic material that can accumulate very rapidly, causing a severe drop-off in heat transfer and efficiency of evaporation [36, 37]. Cane mills are forced to clean their evaporators on the order of every 10–15 days, using mixtures of acid and alkali and mechanical cleaning. Various antiscalants are available, with some, though not a great deal, of efficacy. Evaporator scaling is a problem in cane sugar refining and beet sugar production as well, but not to the extent that it is in raw sugar production. Good control of clarification will help to minimize evaporator scale.

Crystallization. The final evaporator syrup is pumped to a vacuum pan, in which it is evaporated to supersaturation to cause sugar crystallization. The vacuum pan is a single-effect evaporator designed to handle viscous materials. It is a vertical cylinder with its bottom designed to allow easy removal of the crystallized mass. The heating elements used in vacuum pans either are short, large-diameter vertical tubes (calandria pans) or coil around the inner surface of the truncated cone of the pan (coil pans). A typical vacuum pan with a "catchall" or entrainment separator for separating syrup from vapors measures approximately 25 ft in height and 15 ft in diameter. The working capacity is about 1,000 ft^3 of massecuite (mixture of crystals and syrup or mother liquor). The shape of the pan and the positioning of the heating elements within the pan are important design factors in maintaining good circulation of the massecuite. For example, floating calandrias (calandria not attached to the shell of the pan), horizontal pans, and pans having mechanical circulators are used. The process of crystallization is called boiling or pan boiling in the industry.

The move toward continuous processing has resulted in the development of continuous vacuum pans, and low-grade continuous pan boiling is well established [38], and raw sugar boiling with continuous pans is increasing as well. The benefits of continuous pan boiling include control simplicity, improved product quality, low product losses, steam savings, steadier demand, and energy savings [39]. Most continuous pans are a variation of the original 1931 Werkspoor patent, of a horizontal cylindrical pan divided by 8–18 stationary partitions or compartments, each heated by steam. Continuous vacuum pans are used in both the cane and beet sugar industries.

It should be noted that batch pans are still required for the production of high-quality refined sugar. One version of the continuous vacuum pan is a horizontal cylinder with compartments in its lower part. The pan is provided with an additional evaporator called the concentrator, where the density of the syrup is raised to 78–80° Brix.[1]

Seed is added in the first compartment, and the resulting massecuite moves progressively through the compartments of the pan. Additional syrup is added to each compartment to control the fluidity of the massecuite. Approximately 20% of the syrup is introduced at the concentrator, and 80% of the syrup is fed to the various compartments through special feed headers.

The crystallization of sucrose in vacuum pans is called "sugar boiling" and each boiling is termed a "strike." Because a single crystallization does not recover all the sucrose from the syrup, mother liquor from a strike is recycled for recovery of additional sugar. There may be as few as two and as many as four strikes to recover the maximum amount of sugar. A three-boiling system is the most popular. The strikes are designated by letters. Thus, the first strike is the A boiling, and the products of the A massecuite after centrifugation are A sugar and A molasses. The boiling systems are based on "purity," the amount of sucrose remaining in solution, and usually are expressed as the ratio of the polarization value to the total solids as measured by a Brix refractometer. In a three-boiling system, the purity of the A massecuite is set between 80 and 85 by blending syrup with A molasses; the purity of the B massecuite is set between 70 and 75 by blending with syrup and A molasses; the purity of the C massecuite is set between 55 and 60 by blending with syrup and B molasses. Other variations are possible.

The A and B massecuites, after being discharged from a vacuum pan, are sent to centrifugals for separation. The A and B sugars are combined to become commercial raw sugar, the principal product of a cane sugar factory. The C massecuite is a low-purity, highly viscous material that is not immediately sent to the centrifugals because of the large amount of recoverable sucrose remaining in solution. Instead, it is placed in crystallizers, U-shaped horizontal containers equipped with coils attached to a hollow rotating shaft through which water circulates. The massecuite remains in the crystallizer from 1 to 4 days to allow additional crystallization to take place. Centrifugation of the C massecuite yields a final molasses (blackstrap molasses) and a C sugar that is used for seeding the A and B boilings.

Centrifugation. Massecuite from the vacuum pans is sent to centrifugal machines in which the crystals are separated from the mother liquor. A centrifugal consists of a cylindrical perforated basket lined with a screen of perforated sheet metal. The basket, enclosed in a metal casing, is mounted on a vertical shaft that rotates the basket, imparting centrifugal force to the massecuite. In a batch centrifugal, hot massecuite is fed into the basket through a short chute from the holding vessel. As the basket rotates, the massecuite forms a vertical layer on the screen lining. When the machine reaches operating speed (1,000–1,800 rpm), the syrup flows through the perforations lining the basket and is removed through an outlet at the bottom of the casing. The sugar on the lining is washed with a spray of water to decrease the amount of molasses adhering to the crystals. The basket continues to rotate until the sugar is fairly dry, at which time the machine is switched off and brakes applied. The sugar is discharged by an automatic plough.

In continuous centrifugals, the machines do not stop, but continue in motion while receiving fresh supplies of

---

[1] The Brix scale is a density scale for sugar (sucrose) solutions. The degrees Brix are numerically equal to the percentage of sucrose in solution (wt/wt). The term Brix solids refers to the solids in solution as determined by a refractometer.

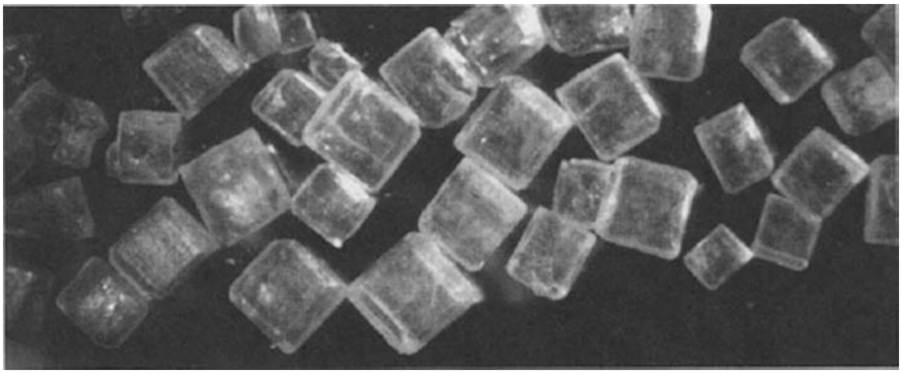

Fig. 35.6 Plantation sugar crystals, showing the ideal shape of sugar crystals

massecuites. The rate of feed must be carefully regulated to obtain the optimum separation of molasses from crystals, while at the same time not abrading or breaking too many crystals.

Raw sugar. The final product of the mill is raw sugar, about 98.0–98.5 purity, a bulk commodity shipped around the world to be refined by importing countries. All raw sugar produced in the United States is refined within the United States; none is shipped offshore. The quality of raw sugar is determined by its polarization (i.e., purity), color, moisture, ash, dextran, invert (i.e., glucose and fructose content), crystal uniformity, and proportion of color on the crystal surface. These parameters determine the commercial price of raw sugar.

Control. Factory control is based on temperature, pH, and polarization. Cane is tested by various means as it comes to the mill to determine its characteristics and to determine the amount to pay the farmer. Control of microbial infection, discussed above, is important. The starch content of juice from immature cane can be significant (e.g., in Louisiana and South Africa), and amylase enzyme may be added continuously to the clarified juice to reduce it. Starch will cause severe viscosity problems if not removed. If there is a problem with dextran, dextranase enzyme can be added, but it is expensive and not as effective as desired [40].

Molasses exhaustion. Molasses contains a significant amount of sucrose and its maximum exhaustibility (removal of sucrose) has always been a priority for the sugar industry. Well-exhausted cane molasses contains about 33–35% sucrose. Many factors contribute to poorly exhausted molasses, besides inefficiency of process, and these include the impurities present in the cane juice. Many of these impurities, such as polysaccharides, ash components, and organic acids are melassigenic (i.e., they increase the solubility of sucrose), making sucrose more difficult to crystallize, and therefore going preferentially into the molasses [41].

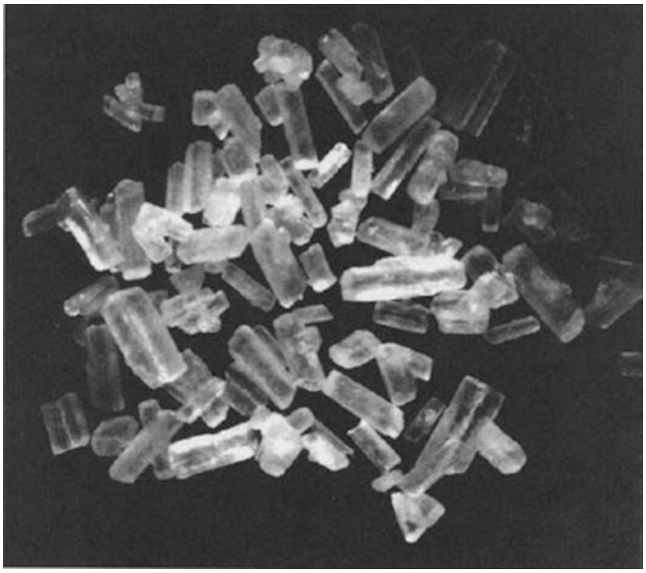

Fig. 35.7 Raw sugar crystals elongated in the presence of dextran and/or oligosaccharides

Crystal Quality

Sucrose forms anhydrous monoclinic crystals of the sphenoidic class [42]. In appearance, the ideal sugar crystal is a slightly asymmetrical square with 8–14 faces or planes (Fig. 35.6). Certain impurities in the mother liquor can affect the growth of the sugar crystal and change its morphology. Figure 35.7 shows the elongating effect that dextran and certain oligosaccharides have on the crystal shape. Sucrose also can form twinned crystals. Figure 35.8 shows refined sugar crystals.

Bagasse

Bagasse is the fibrous portion of the cane stalk that remains after extraction of the cane juice. When discharged from the milling train, bagasse contains about 50% by weight of water.

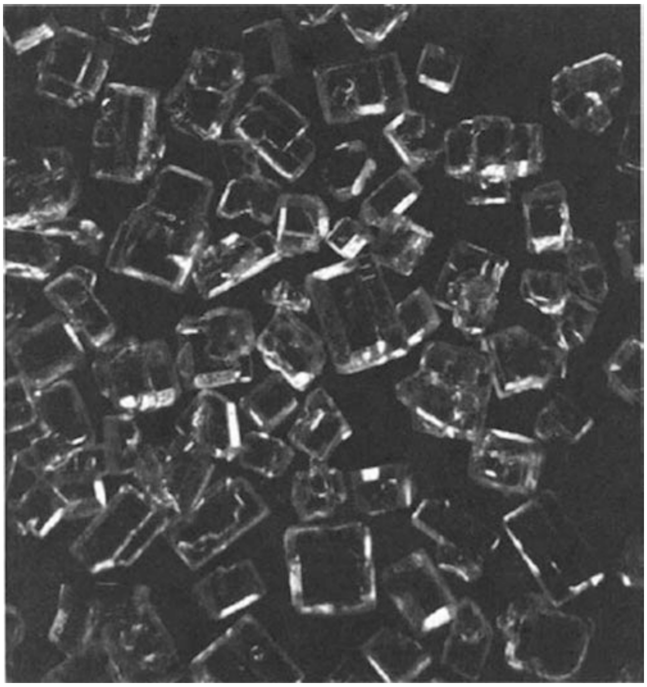

Fig. 35.8 Refined sugar crystals

The average fuel value of ash-free dry bagasse is 8,300 BTU/lb (gross calorific value 19,400 kJ/kg dry, ash free). It is a valuable by-product because it is used to fire the boilers in cane mills, making cane factories essentially energy-sufficient. Sometimes excess energy is produced which can be sold to the power companies. A sugar mill that processes one million tons of sugarcane per year produces in bagasse fuel the equivalent of about 420,000 barrels of imported crude oil, more than enough to operate the sugar mill and co-generate electricity [43]. Excess bagasse is used for paperboard and wallboard and as a chemical feedstock for conversion to furfural [44]. It is made into a number of paper products in China [45].

Direct Consumption Sugar

Many cane sugar mills in tropical countries produce white sugar by using combinations of sulfitation, syrup clarification, or carbonation. These edible sugars are known as mill white sugar or plantation white sugar. When compared to refined sugar, mill sugars are higher in color, ash, moisture, and reducing sugars. Because sulfur is used in production, the finished product may have sulfite in it.

Talodura. The Talodura process, used in syrup clarification, consists of using a combination of sulfite clarification followed by subsequent clarification of the evaporated liquor with lime and phosphoric acid to which a flocculant is added. It has led to improvements in the color of the mill white sugar, boiling house recovery, and chemical costs per ton of sugar [46].

Blanco Directo. Blanco Directo is a trademark of Tate & Lyle Process Technology. The process and similar processes (as described above) are used at sugarcane factories to produce a high-grade white sugar suitable for use in food and beverages. This product is economically competitive with imported refined sugars. Although the term “Blanco Directo” is the trade name for one particular process, it appears to be used somewhat generically for similar processes.

Carbonation. In this process the mixed juices from the mills are heated, clarified with lime, and evaporated to about 35° Brix. The syrup is relimed and treated with carbon dioxide, filtered, recarbonated, reheated, and refiltered. After carbonation, the syrup is given a double sulfur treatment and filtered. The resulting syrup is subjected to a three- or four-boiling system with the A and B sugars used as the white sugar product.

Edible Products from the Mill

Raw sugar is not considered an edible food in the United States, but in many other countries it is. There has been a growing trend to produce food-grade sugar at the cane mill (see discussion about plantation white sugar above). The growing societal interest in “unrefined” or “natural” products has led to a huge growth industry for products from sugar mills [47]. These include such products as demerara, Barbados, muscovado, and turbinado sugar, which are various grades of brown/raw sugar. Turbinado sugar is raw sugar that has been washed (centrifuged in the presence of steam) to remove some of the colored molasses coating on the surface of the crystal, resulting in a light golden sugar with large crystals and a mild cane taste.

Organic sugar. The largest area of growth for edible mill products is organic sugar. This sector is growing at 25–30% per year [48]. There are many regulations and restrictions in place for a mill to be certified to produce organic sugar; these deal with land preparation and the use of herbicides, fertilizers, and chemicals. The yields from organic production are decreased 30–60% from conventional sugar production, resulting in a product which is about four times more expensive than refined sugar. Brazil is the largest producer of organic sugar.

New Technology

In recent years, a number of new technologies have been explored for the production of raw sugar, refined sugar, and

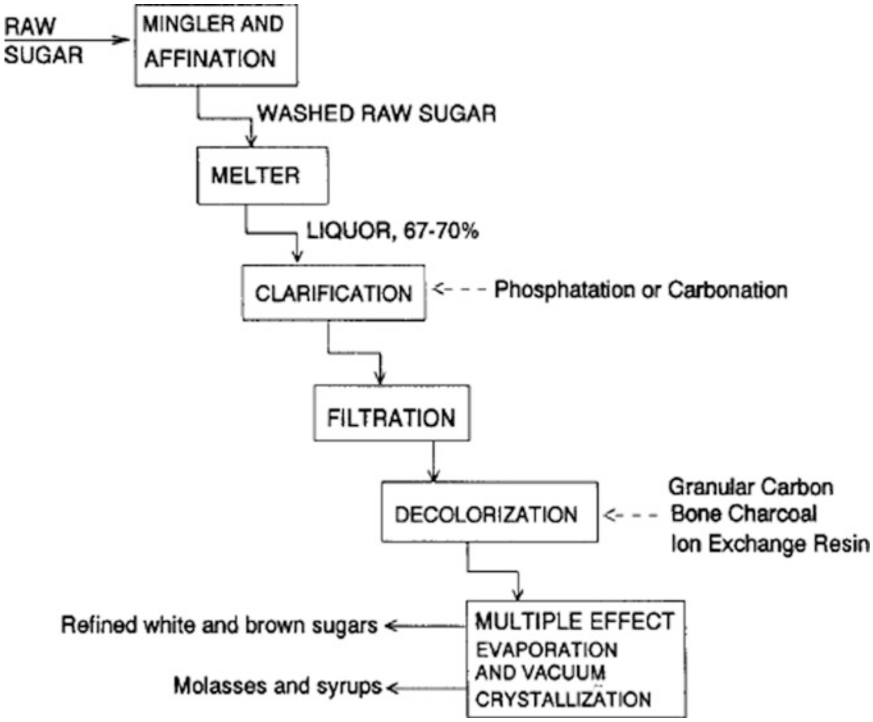

Fig. 35.9 General flow diagram of sugar refining (adapted from Clarke [104])

beet sugar, including ultra- and membrane filtration, ion-exchange, juice softening (the use of weakly cationic resin to remove calcium [49]), and chromatographic methods, which are, in the words of one author, "beginning to blur the demarcation of steps like clarification" [50]. These techniques are not limited to raw sugar production but are also being explored in the beet industry, although less so in cane refining. The goals in the use of these technologies are to reduce or eliminate the use of lime and/or sulfur, to produce a better quality sugar, or to produce refined sugar directly from cane juice at the mill.

Membrane filtration technology has not yet proven economically feasible in the industry, but continued research may eventually lead to viable commercial products [51, 52]. Carousel chromatographic systems, such as the continuous ion-exchange separation (ISEP) and continuous chromatographic separation (CSEP) systems, offer some promise in the sugar industry. They have been used successfully in other industries, and may be tailored to obtain a number of different fractions or products [53, 54].

Cane Sugar Refining

The raw sugar produced at the factory is light brown in color and contains about 98% sucrose. As described above, in most instances this product is not considered an edible food, but rather is a bulk commodity. The process of purifying raw sugar to make a white sugar is called refining, and the sugar produced is called refined sugar. Refining traditionally involves several unit stages, as shown in Fig. 35.9. Because of the increased quality of the raw sugar produced in some areas, not all the stages are used, and various combinations of processes are used at different refineries.

Affination and Melting

The first step in refining raw sugar is called affination (or washing), and consists of removing the film of molasses, which contains a large portion of the impurities in the sugar, from the surface of the raw sugar crystal. The raw sugar is mixed with saturated sugar syrup (72–75° Brix) at about 50°C in a U-shaped trough called a mingler. Saturated syrup is used to avoid dissolving the raw sugar. The mingler has a rotating agitator to maintain maximum contact between the sugar and the syrup. The mixture is centrifuged to separate the crystals from the syrup, and the crystals are then washed with a small spray of hot water or steam. The "washed" or "affined" sugar is "melted" or dissolved in water to a density of 55–60° Brix. Potable water, steam condensate, and "sweet waters" are used for dissolution. The liquor from the melter is screened to remove insoluble matter, such as sand, stones, wood, cane fibers, and lint. Screening is done by vibrating screens, cyclonic separators, or centrifugal screens.

Today, most refiners have eliminated the affination stage by buying very high-purity, low-color raw sugar, in effect, requiring the raw sugar mill to do the affination at the mill.

Purification

The melted liquor is then purified by any of several combinations that include clarification and decolorization. In clarification, the liquor is treated chemically to remove suspended matter, colloids, and other impurities that contribute to turbidity. Clarified liquor is optically clear, but is still highly colored. Decolorization procedures include treating the clarified liquor with various filtration media, such as bone char, granular activated carbon (GAC), or ion exchange resin, either alone or in some combination. It is necessary to clarify the liquor before the filtration medium because the particulate impurities will quickly "blind" or foul the filtration material and render it useless.

Clarification. All clarification treatments include the addition of lime. Lime increases the pH, stabilizing the sucrose against hydrolysis at high temperatures, and the calcium forms insoluble precipitates with many of the impurities in the raw liquor. Simple liming is rarely used in refining. The important clarification processes are phosphatation and carbonatation, which include combinations of lime with either phosphoric acid or carbon dioxide.

Phosphatation. In phosphatation, the screened liquor is heated to 60–70°C and mixed with phosphoric acid (0.005–0.025% P_2O_5 on solids). The mixture is immediately limed to pH 7.0–8.0, aerated with compressed air, and sent to a clarifier, a tank equipped with heating coils. The liquor enters the clarifier at one end and is heated to 88°C while flowing to the outlet at the opposite end. A flocculent precipitate of calcium phosphate forms, reacting with or entrapping colloids, organic acids, some coloring matter, and suspended particles. Air flotation is used to separate the precipitate from the liquor, causing it to rise to the top of the clarifier as a blanket of scum, which is skimmed off by moving paddles. (This process is sometimes known as phosflotation.) About 25–30% of the color is removed in this process.

Talofloc process (*color precipitation*). The addition of flocculants and surfactants has greatly improved the simple phosphatation process. The Talofloc process (developed by Tate & Lyle) consists of adding a cationic surfactant (Talofloc) to the raw melt liquor in concentrations ranging from 0.02 to 0.07% on solids. This is followed by the addition of lime and phosphoric acid and the incorporation of air. Just before the liquor enters the clarifying chamber, a polyacrylamide flocculant (Taloflote) is added that induces aggregation of the calcium phosphate precipitate, causing a faster and more complete separation of the impurities. As much as 60% of the color can be removed by this process. Other similar additives are commercially available.

Carbonatation. In carbonatation (sometimes also known as carbonation), the melter liquor, heated to about 60–80°C, is limed to about pH 10 (0.4–0.8% CaO on solids), gassed with carbon dioxide, heated to about 85°C, and regassed until the pH drops to between 7.7 and 8.5. Because of the two-stage gassing, carbonatation requires two clarifiers, a primary and a secondary. Washed flue gases are the source of carbon dioxide. The carbonated liquor resides in tanks called saturators for about 3 h to allow growth of the calcium carbonate. The calcium carbonate precipitate that forms entraps some colored matter, colloids, organic acids, and inorganic compounds. The precipitate, known as mud, is removed by filtration, such as Sweetland presses. Carbonatation alone achieves about 50% decolorization and, with the addition of polycationic additives, can achieve as much as 70% [55].

There are continuing discussions about the merits of one type of clarification over the other, phosphatation vs. carbonatation. In summary, the consensus appears to be that carbonatation reliably removes more color and colloidal material and is more flexible in handling different types of raw sugar, but is more expensive to operate, generates more waste, and may have slightly higher levels of sucrose loss to molasses than phosphatation. Environmental restrictions on disposal of phosphate-containing waste are a consideration for phosphatation refineries.

Filtration. The liquor from phosphatation and carbonatation contains small amounts of finely dispersed particulate matter that require filtration for removal. The filtration process is similar for both types of clarified liquor. A precoat of filter aid (diatomaceous earth or perlite) is first deposited on the filter surfaces of the press. Additional filter aid is added to phosphate-clarified liquors to improve press runs. Liquor at 70–85°C is fed to the press at a pressure of about 60 psig until the flow rate drops below a predetermined level, ending the filtration cycle. The calcium carbonate particles in carbonated liquor act as a fairly good filter aid medium, as long as the particles are developed to optimum size during carbonatation. Large quantities of sugar polysaccharides (starch, dextran, and others) in the melt liquor will restrict the growth of calcium carbonate, requiring the use of diatomaceous earth. A filter cycle may last from 2 to 12 h depending upon the quality of the feed liquor.

New developments. At least one refinery has, in recent years, been able to omit all chemical clarification by using only very high-purity, low-color raw sugar. Clarification is accomplished by a two-stage coarse filtration, followed by a finer filter-aid filtration. Again, this development is possible only because of the high quality of the incoming raw sugar.

Scums and muds. Both phosphatation and carbonatation produce scums or muds that have a moderate level of entrained sucrose, which must be recovered. Various schemes exist for removing the sugar, such as secondary clarification of phosphatation scums and sluicing of carbonation muds with dewatering on rotary vacuum filters.

Decolorization. Filtered clarified liquor is a clear brown liquid having a solids content between 55 and 65%, pH of 6.7–7.2, and temperature between 65 and 85°C. The next stage of refining involves removing this color to produce a clear, nearly colorless solution from which white sugar can be crystallized. During decolorization, the liquor is passed through one or a combination of decolorizing adsorbents, such as bone char, GAC, or ion-exchange resins. Bone char, consisting of the sintered long bones of cattle, is composed of calcium hydroxyapatite (80–85%) in a carbon matrix. It removes colorants, colloidal material, and a considerable amount of the ash components. GAC by itself only removes color; it is usually treated with magnesium oxide in order to buffer the sugar liquor and may remove a small amount of ash. Ion exchange resins absorb color and change the composition of the ash.

Bone char and granular carbon generally are used in cylindrical columns 20–25 ft high and about 10 ft in diameter. Liquor flow through bone char is about 1,500 gal/h over 30–60 h. Liquor flow through GAC is 3,000 gal/h for 20–30 days. After the decolorizing cycle is completed, the adsorbent is sweetened off (sugar removed) by displacing the liquor with water. After washing, the spent carbonaceous adsorbent (bone char or GAC) is transferred to regenerating equipment consisting of dryers, kilns, and coolers. Bone char is regenerated at 540°C in a controlled amount of air. GAC is revivified at 950°C in a limited oxygen and steam atmosphere. After regeneration, the adsorbent is returned to the system for a new decolorizing cycle.

Ion-exchange resins are used in columns 8–10 ft high and 6–10 ft in diameter, holding between 100 and 300 ft^3 of resin. Flow rates are rapid (3,000–4,500 gal/h), and the cycle is short (8–16 h). Regeneration is accomplished in the column with a 10–15% salt solution at 45–60°C. The chloride form of a strong anionic resin decolorizes the liquor. Resins can be either acrylic or styrenic in composition. Acrylic resins have a higher capacity for color removal, especially for high molecular weight color bodies, and good resistance to organic fouling. Styrenic resins, although having less capacity, can remove the remaining small molecular weight colorants. Because styrenic resins will foul more easily, acrylic resins are usually placed ahead of them to protect from fouling, and they are used mainly for "polishing" the fine liquor to remove the final traces of color. Both types of resins have ion exchange as the primary mechanism for color removal; styrene resins also exhibit an adsorption mechanism for color removal [56]. The sugar in the sweet water from washing the various adsorbent columns is recovered by returning it to the melter. In recent years ion exchange systems have made use of fractal technology to improve flow and prevent excess pressure drop.

Crystallization

Decolorized liquor is a pale yellow liquid (International Commission for Uniform Methods of Sugar Analysis [ICUMSA] color 200–300) with solids content of 55–65% (see section "Process Control and Instrumentation" for further information on ICUMSA). This liquor goes to multiple-effect evaporators to be concentrated to a solids content of about 72° Brix, and is then pumped to the "white pans" for crystallization. There are four stages in the crystallization process: (1) seeding or graining; (2) establishing the seed; (3) growth of crystals; and (4) concentration. Crystallization is governed by the degree of supersaturation, which is the state in which more solids are in a solution than can be dissolved by water at a given temperature. (The supersaturation coefficient is defined as the mass fraction of sucrose in water divided by the mass fraction of sucrose in water in a saturated solution at a given temperature.) There are three phases of supersaturation: [57]

1. The metastable phase—existing crystals grow in size, but no new ones form.
2. The intermediate phase—existing crystals continue to grow and new ones form.
3. The labile phase—crystals form spontaneously without the presence of others.

Sugar-boiling for proper crystallization is done in the metastable and intermediate phase; below the metastable zone, crystals dissolve and inefficiencies result; above the intermediate phase, uncontrolled "false grain" or extra, small, and agglomerated crystals form, resulting in poor-quality crystals. When the syrup is in the metastable phase, it is "seeded"; that is, a predetermined amount of very small crystals is added, which act as nuclei for crystal growth. A sufficient quantity of evaporated liquor is drawn into the pan to cover the heating elements, and water is evaporated from the syrup until its supersaturation coefficient approaches 1.25. At this point, the steam pressure is lowered, and seed crystals are added. The seed consists of finely pulverized sugar dispersed in isopropyl alcohol or sugar liquor. This method is called shock seeding because addition of the seed induces an immediate formation of crystal nuclei throughout the supersaturated syrup. The nuclei are grown to a predetermined size or grain. Once the grain is established, the crystals are grown to size by maintaining supersaturation between 1.25 and 1.40 through control of the steam pressure, vacuum, and the feed rate of the evaporated liquor. Adequate circulation during crystal growth is important.

When the volume of the massecuite reaches the maximum working capacity of the pan, the syrup feed is shut off, and evaporation is allowed to proceed until a thick massecuite is formed. When the massecuite concentration is considered “tight,” the steam and the vacuum are shut off, and the massecuite is dropped into a holding tank equipped with agitators, where it is kept in motion until discharged into the centrifuges.

The boiling system in a refinery is straightforward. The first strike is boiled from evaporator liquor; the second strike is boiled from the runoff syrup of the first strike, continuing on to three or four strikes. These strikes are blended to form the final white sugar product. The runoff of the last strike, which is quite high in color and ash, can be used in a variety of ways: as syrup for affination, as syrup for remelt, or as syrup for producing brown sugar, also called “soft” sugar in the industry.

Centrifuging. Refined sugar crystals are recovered from the mother liquor by centrifuging the massecuite in equipment similar to that used for affining raw sugar. However, at this point, the crystals are washed with a greater quantity of hot water. The washed crystals are discharged into a holding bin supplying a dryer.

Drying and conditioning. Sugar from the centrifugals contains 1–2% moisture and is too wet to be placed in storage or packaged. The wet sugar is fed to drying equipment called granulators, which are large rotating drums, 15–35 ft long and 6–7 ft in diameter, inclined slightly for gravity discharge. Screw conveyers, scrolls, vibratory “grasshoppers,” or linear belts are used to transport wet sugar from the centrifuge to the drier, where heated air is blown through the dryer, concurrent with the flow of the sugar. Sugar exiting the granulators has a moisture content of about 0.03%.

Remelt Sugar

The sugar contained in affination syrup must be recovered for economy, which is accomplished by crystallizing the sugar in a vacuum pan. The area of the refinery where various “low-grade boilings” take place is called the remelt house. The resulting sugar is “raw” in composition and is returned to the refinery at the affination station, hence it is “remelted.” The residual syrup from the remelt station is known as refiners’ blackstrap, from which no further sugar can be recovered. Various grades or streams of remelt are produced, depending on the refinery.

Packaging and Storing Refined Granulated Sugar

Sugar leaves the dryer at around 52–55°C and is allowed to cool to about 45°C. Sugar leaving the dryer still contains enough moisture to cause problems with caking on storage, and the proper bulk storage and conditioning of sugars in silos is a widely discussed topic [58, 59]. One of the most important considerations for refined sugar is its ability to store well, without caking or darkening in color.

Granulated sugar remains free flowing for a longer period of time if it is “conditioned,” as conditioning further reduces the moisture level, which is necessary to prevent caking. Conditioning takes place in large vertical silos, with up to three million pounds capacity. Conditioned dehumidified air is percolated into the sugar from the bottom of each silo. Residence times in silos vary, from about 24 to 72 h. Proper control of air flow, humidity of the air, and temperature are essential for good conditioning. Sugar leaves the silos with a moisture content of 0.025% or less. Following conditioning, the sugar is screened to meet the particle size requirements of customers. Screened sugar is then sent for packaging or for transport in bulk.

Sugar that is not immediately used is placed in storage silos for periods that can be as long as 2 months. Sugar storage is another area where problems with caking and solidification can occur due to moisture migration, and newer systems are beginning to appear where sugar in storage is treated with a slow stream of conditioned air.

Granulated sugar is packaged in 1, 5, 10, 25, 50, and 100 lb bags, 2,000 lb sacks, as well as cartons and heat seal packets. Other packaging configurations are possible.

Specialty Sugars

Refineries produce a number of specialty sugars and syrups designed to meet the needs of customers. These include sugars with various crystal sizes, powdered sugars, brown sugars, and liquid sugars [60].

Liquid sugars. Liquid sugars (sugar dissolved in water) are economically important because food manufacturers often prefer to use sugar in the form of syrup because of the ease of handling a liquid product. Liquid sugars are prepared by one of two methods: dissolving refined sugar in water; or further purification of in-process liquors by ion-exchange treatment to remove minerals, and further decolorization using bone char and pulverized or granular carbon. Liquid sugar can consist only of sucrose, as a mixture of sucrose and invert sugar, or as a blend with various glucose syrups from starch hydrolysis. Sucrose liquid sugars are usually distributed at a 67% sugar concentration, whereas invert sugar and mixtures of invert and sucrose are distributed at concentrations of 72–77% sugar. Partially inverted sugar syrups are commercially preferable because of the higher solids content and greater microbiological stability.

Partially inverted sugar syrups are made by one of three hydrolytic methods: acid hydrolysis with mineral acids (sulfuric or hydrochloric), hydrolysis by cation ion-exchange resin, or inversion by enzymes. Acid hydrolysis by mineral acids has the disadvantage that the resulting syrups have a high ash content because the solution is neutralized with sodium or potassium hydroxide. Enzymatic conversion has the disadvantage of being expensive and not very efficient at the high temperature and densities of the solutions being hydrolyzed. Cationic resin treatment offers the best alternative, resulting in nearly ash-free invert syrup. The most popular invert syrup is a 50% mixture of sucrose and invert [61].

Liquid brown syrups are also available, known as refiners syrups, and can be adjusted in color, flavor, ash level, and sucrose content according to the specifications of the customer.

Brown or soft sugars. Brown sugars range in color from light to dark brown. They have very small crystals and high moisture content, ranging from 0.5 to 3%. The combination of very small crystals and high moisture gives the sugars the "soft" appearance and texture. Brown/soft sugars also contain higher ash, invert sugar, and an array of compounds that contribute to the characteristic flavors [62]. They are made in two ways. The traditional method is to boil them from a low-purity process liquor to obtain the desired color, flavor, and composition. The newer and more common method is to "paint" or coat a lesser quality (third or fourth strike) refined sugar with refiner's syrup or molasses to produce a product with similar appearance and characteristics. A typical brown sugar composition is 85–90% sucrose, 2–5% invert, 2–4% moisture, and 1–3% ash.

Screened sugars. These are sugars that have been separated on various sieves to give a narrow defined range of particle size. Baker's special, known as caster sugar in England, has a fine grain size, about 75–150 μm, and is desirable because it mixes, blends, and dissolves evenly. Fruit sugar is another screened sugar with a slightly larger grain.

Pulverized sugars. A range of products are manufactured by milling granulated sugar to a desired size. Examples include powdered or confectioner's sugar, with particle sizes 45–75 μm, and characterized by the proportion of the sugar passing through certain sieve sizes. In the United States, these sugars usually are mixed with 3% corn starch to prevent caking. Elsewhere, tricalcium phosphate may be added for the same purpose.

Fondant sugar. Fondant sugar is a special form of pulverized sugar, which exists as a blend of sugar (in the 90–95% range) and another ingredient, such as maltodextrin, invert, glucose, or starch. It may be dry and free-flowing or a paste. It is also called icing sugar or glazing sugar. Dry fondants usually are agglomerated forms.

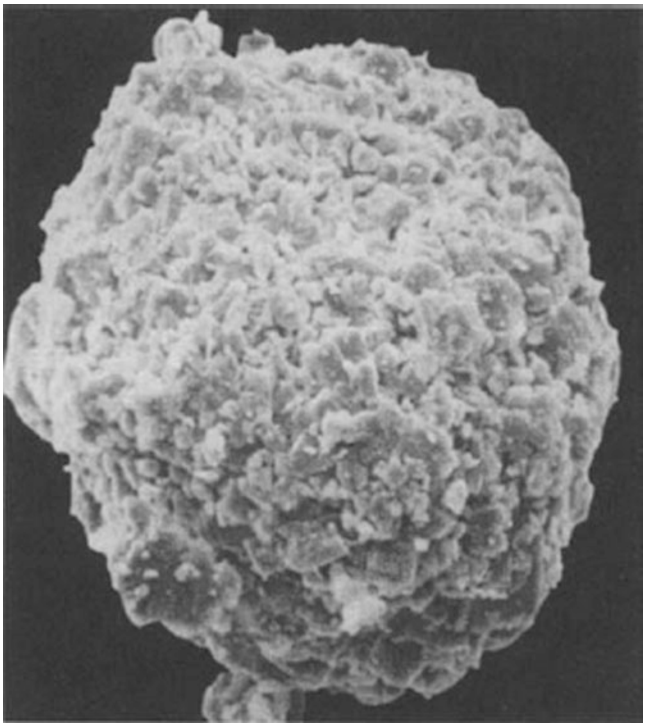

Fig. 35.10 Example of a co-crystallized sugar product. The ball represents many microsized sugar crystals agglomerated into a porous granule, which allows inclusion of a second ingredient throughout the structure

Agglomerated sugars. The agglomeration of sugar crystals helps to prevent caking, so products, such as soft sugars that are subject to caking, can be converted into a free-flowing dry product. Several companies manufacture "dry fondant" by agglomerating mixtures of invert sugar and very fine (less than 40 μm) sucrose particles. Particles below 40 μm cannot be distinguished by the tongue, so the product is perceived as a smooth paste.

Compound products. Compound products are made by manipulating the crystal size and shape and incorporating another ingredient in a process called co-crystallization. A very hot (120°C), supersaturated sucrose solution is allowed to cool with agitation in the presence of a second ingredient, resulting in a dry, free-flowing, agglomerated, porous granule, shown in Fig. 35.10 [63]. Typical products include granulated brown sugar, powdered brown sugar, molasses granules, honey granules, and some fondants. Flavors, such as apple or peanut butter, may be co-crystallized with sugar. The process is said to protect the flavors from loss of volatiles and from oxidation.

Beet Sugar

Like cane sugar processing, the main stages in the extraction and production of sugar from sugar beets have remained basically unchanged for the last 100 years, with cumulative improvements in sucrose yield and processing taking place over the years. Unlike cane sugar manufacture, white sugar is made directly from the sugarbeet. The process is a simple one, with many variations: beets are harvested, stored until needed, washed, sliced, and the sugar-laden juice extracted by diffusion. The juice is purified using lime and carbon dioxide, sometimes also sulfur dioxide, filtered, concentrated, and crystallized. The goal is to produce a good quality white sugar in the highest possible yield. Europe and the United States are the major beet sugar producing areas of the world. Sugar beets are grown in ten states, with Minnesota, North Dakota, Idaho, and Michigan the major producers [64].

Agriculture

The sugar beet, *Beta vulgaris*, is a temperate-zone root crop grown largely in the Northern hemisphere (Fig. 35.11). It is adapted to a wide range of climatic conditions, growing, for example, in the short cold summers of Finland and the hot dry climates of the Imperial Valley of California and southern Spain. Sugar beet agriculture began in earnest in Europe around 1830 and in the United States around 1880. Better-yielding beet varieties, mechanization of the harvest, and increasing efficiency in processing have helped the beet sugar industry grow to the extent that it competes in parts of the world with cane sugar.

The original sugar beet seed is of the multigerm type, which results in several plants germinating in one spot, necessitating laborious hand thinning. In 1950–1952, two Russian scientists, V.F. and Helen Savitsky, working in the United States, developed two lines of monogerm seeds. These seeds develop only one plant per seed, which reduced or eliminated the need to thin the young beet plants. Today all sugar beet cultivation uses monogerm hybrids.

Harvesting and Beet Handling

After the plants have reached maturity in late fall, they are harvested by machines that remove the top growth of leaves, lift the roots from the ground, and deliver them to a holding bin or a truck.

Storage. Because the harvesting season is shorter than the processing season, beets are stored in piles or "clamps" at the factory or at outlying points near transportation. Proper storage of sugar beets is very important to prevent deterioration of the beets. Frequently, storage piles are ventilated to lower the temperature of the beets, thus reducing sugar loss due to respiration during storage. Sucrose losses inevitably occur if the temperature fluctuates widely and if there are freeze–thaw cycles.

Fig. 35.11 A sugar beet (Courtesy of American Sugarbeet Growers Association)

In the Red River Valley area of Minnesota and North Dakota, storage sheds for sugar beets were constructed in the mid-1980s that measure 210 ft wide by 520 ft long and hold 50,000 t of beets. The temperature in these storage facilities is controlled at not much above freezing to minimize degradation of the sucrose content.

Washing. Beets are transferred from storage to the factory in water flumes. These flumes lead directly into a rock-catcher, which allows rocks to settle out, and then on into a trash-catcher and a rotary washer. A large amount of soil usually is entrained with the beet roots, and processes for recovering and returning the soil to the field are in use.

Slicing. The washed beets are sliced into thin V-shaped cossettes by means of specially shaped knives set in frames mounted around the periphery of a rotating drum. Good removal of rocks and trash is essential for a reasonable life for the knives.

Extraction of the Juice

Diffusion. The process of extracting the juice from the beet is called diffusion. The cossettes are weighed and transferred continuously into a diffuser where water passes countercurrent to the movement of the cossettes and where, by diffusion, sugar and some of the nonsugars of the beet are extracted. For optimum extraction of juice, the sucrose-containing plant cells need to be fully disrupted to allow the escape of the juice. This is done mechanically (5–15% of cells are disrupted by the slicers) and with heat. A balance between temperature and the time of heating is necessary: it should be high enough to maximally extract the juice, but not so high as to cause extraction of undesirable nonsugars, such as pectins, or to cause color formation and sugar degradation. The temperature of the juices during diffusion is around 70°C. Retention time is around 1 h. Antifoam agents are used to control foam in continuous diffusers, and bactericides are added for microbiological control. Continuous diffusers have largely replaced batch diffusers. Continuous diffusers come in a variety of forms and shapes, but all employ the same principle, namely the movement of juice countercurrent to the movement of the cossettes.

The RT-type diffuser is a large revolving drum with an internal helix that separates the drum into moving compartments. As the drum revolves, the cossettes travel by the action of the moving helix from one end of the drum to the other end, while the juice moves in the opposite direction. The BMA diffuser is a cylindrical tower with a conveyor mechanism attached to a central rotating shaft. Guide plates on the shaft direct the cossettes upward, while the juice exits through screens at the bottom.

Beet pulp. Beet pulp is the solid residual portion remaining after diffusion, and is a valuable by-product. Wet pulp, containing 85–90% moisture, is dewatered in horizontal double-screw presses, reducing the moisture content to about 75%. Pulp is further dried to about 8–10% moisture in pulp dryers, direct-fired horizontal rotating drums. Newer pulp-drying technology, utilizing a pressurized fluid bed, results in 40% more capacity and better energy efficiency [65]. Beet pulp is mainly used as a pelletized animal feed, either alone or mixed with molasses.

In the 1980s, several beet companies developed edible fiber from beet pulp to take advantage of interest in the health benefits of dietary fiber [66]. The fiber has a high water-holding capacity and other interesting properties, but the market has remained small and specialized, with uses as a fiber additive in both human and pet food.

Juice Purification

The diffusion juice (also called raw juice) is a turbid liquid ranging in color from lavender to nearly black, containing 15–18% sucrose and 1–3% nonsugars, including proteins, nitrogenous bases, amino acids, amides, inorganic material, and pectinaceous matter. It also contains 0.25% sodium and potassium. These impurities are removed by a series of purification processes using lime and carbon dioxide (carbonation), and sulfur dioxide (sulfitation). In recent years, there has been some use of ion exchange resins to produce high-quality refined granulated sugar.

Knowledge of the chemistry of the raw beet juice is important in controlling the phases of juice purification. The addition of increasing amounts of lime and carbon dioxide should precipitate pectinaceous materials and insoluble anions such as phosphate, sulfate, oxalate, and others, as calcium salts, cause alkaline degradation of invert sugar into lactic and other acids, and flocculation of colorants. Lime is also essential for promoting good filtration.

Classic juice purification consists of preliming, main liming, first carbonation, first sludge separation (clarification), second carbonation, second sludge separation, sulfitation, and filtration. Control of pH is very important throughout the process and depends on the quality of the beet juice, which is determined in the lab.

Preliming. A small amount of lime (0.12–0.3%) CaO is added to the juice, increasing the juice pH from about 6.2 to 10.8–11.4. The lime reacts with nonsugar impurities in the juice to make insoluble precipitates and soluble products. Calcium carbonate in the form of recycled first carbonation sludge is added to provide colloid adsorption and stabilization. Temperature may be cool (50°C) or hot (80°C) depending on the factory design. Insoluble precipitates are formed quickly. Retention time is 15–30 min.

Main liming. The addition of more lime (main liming) to an alkalinity of 0.8–1.5% CaO on juice results in a second set of reactions that produce soluble products. During these reactions, the small amount of invert sugar present in the raw juice is destroyed and amides are saponified. These reactions help to stabilize the juice. A great deal of color is formed during this stage, but this type of alkaline-derived colorant is fairly easy to remove in crystallization.

First and second carbonation. In this process, heated, limed juice is sent to a carbonator for gassing with carbon dioxide. The carbon dioxide reacts with the lime to form calcium carbonate, which helps to absorb the insoluble impurities, and some of the soluble impurities as well. The resulting mixture, containing insoluble lime salts, is pumped to subsiders (thickeners, clarifiers) to remove the insolubles by settling (sludge separation), and clarified juice is decanted. From the subsider, the partially clarified filtrate is recarbonated (second carbonation) to lower the pH further, and the residual lime is precipitated. The juice is then treated with about 150 ppm sulfur dioxide gas (sulfitation), which helps to inhibit further color-forming reactions in the juice, removes any remaining traces of calcium, and provides the final pH adjustment, to a pH of around 8–8.5. This treatment is followed by press filtration. The sludge from the subsiders is filtered on rotary-drum filters, and the sugar-containing filtrate is returned to the first carbonation step. The carbonation process can be either continuous or batch. In some factories the clarified juice is also sent to softeners (cation resins) to remove any remaining calcium.

Beet processing uses a large amount of lime (2–2.5% on beet) and efforts are being made to reduce the usage by effective control of temperature, pH, and other parameters [67], which can bring down usage to about 1.0–1.2% and inclusion of innovative processes, such as membrane filtration [68], which can further reduce lime usage to around 0.8% on beets. The recovery of lime by reburning is also being studied. The clarified juice is called “thin juice” and contains about 15% solids.

Evaporation and Standard Liquor

The thin juice discharged from the filter presses after clarification is evaporated to “thick juice” or evaporator syrup (50–65% solids) in multiple effect evaporators, containing five, six, or even seven effects. If decolorizing absorbents are used, they are usually added to the thick juice. Granular and powdered carbons have been used for this purpose. Thick juice that has been treated with powdered carbon usually must be double filtered to remove all the carbon.

Low raw sugars (sugars with purities below that of refined sugar) and white centrifugal wash water are added to the thick juice in the melters to make “standard liquor” from which white sugar is crystallized. Standard liquor is usually filtered with diatomaceous earth before going to the vacuum pan.

Extending the Processing Cycle: Thick Juice Storage

Depending on location, sugarbeet harvesting begins as early as August or as late as October. At least one American company has extended the season by allowing beets to freeze naturally so that they can be processed over the winter. Many other companies in the United States and Europe store excess thick juice over the winter, which can extend production time an additional 40–80 days. Proper storage conditions are critical to maintaining the integrity of the thick juice to prevent sugar loss or microbial contamination, including pH of 9.2, a high solids content of 67–69%, cooling to below 30°C, and addition of soda lye or hop β acid in the upper layer [69].

Crystallization, Centrifuging, and Drying

Crystallization practices in the US beet sugar factories are similar to those in a cane sugar refinery and result in a white granulated sugar comparable in quality to refined cane sugar. White sugar centrifuge stations as well as drying operations are comparable with those operations described earlier for cane sugar factories.

A major difference between cane and beet sugar refining is that beet refining is done in one stage, with refined sugar produced directly from the sugar beets, whereas refined cane sugar is produced first as a raw sugar and then refined. It is possible for beet sugar to be produced directly because the nature of the coloring material in beet sugar is fundamentally different from that of cane. A beet evaporator syrup with color over 3,000 ICUMSA color units produces a white sugar with an ICUMSA color of 25–40. However, for a cane white sugar of the same color to be produced, the color of the evaporator syrup must be only 200–300 color units. The nature of these differences appears to be associated with lower molecular weight colorants in beet, lower polysaccharide content in beet, and colorant mainly composed of alkaline degradation products of invert sugar [70].

Molasses Desugarization

Sugar Recovery from Beet Molasses

Molasses is the viscous, dark-colored material that remains when no more sugar can be economically extracted by crystallization. Beet molasses is generally high in sucrose, 60% dry basis, and represents considerable value. Sugar is routinely recovered from beet molasses by various ion exclusion chromatographic systems.

Historically, recovery of sucrose from molasses was accomplished by the Steffen process, in which sucrose is precipitated from dilute molasses at low temperature (9–14°C) as the tricalcium saccharate by adding finely ground burnt lime. The process uses an excess of lime (100–130% on molasses sugar) and does not work if there is more than 0.4% invert sugar, and other impurities, such as raffinose, which inhibit crystallization [71]. Molasses desugarization today is accomplished by various forms of ion exclusion. Chromatography is no longer done in batch form, which is inefficient, and commercial operations utilize any one of several procedures involving moving beds, simulated moving beds (SMBs), or coupled loops. These are discussed in detail in the literature [72, 73]. Up to 90% of the sucrose in the molasses can be recovered and other valuable products, such as betaine, can also be recovered. Most beet factories today desugarize molasses.

Desugarization is accomplished using cross-linked strong cationic resin in the potassium form. Sucrose is preferentially absorbed by the ion exchange resin and separates by lagging behind the majority of the nonsucrose components. Continuous processes are based on countercurrent technology. The SMB process avoids mechanical movement of resin, keeping the whole resin bed stationary while changing product inlets and outlets with an internal circular flow. Typically, molasses SMB systems have 8–20 resin compartments (or cells) in series. The countercurrent resin movement is simulated by changing the inlet and outlet ports forward in the direction of the liquid flow. In coupled loop technology, developed by Amalgamated Sugar in the 1990s, a cascade of several loops is provided instead of connecting several individual cells. This allows recovery of additional nonsucrose components, such as betaine, and provides a purer sucrose fraction. For proper operation of a molasses desugarization plant, the molasses must be low in calcium and magnesium ions (this is usually achieved by thin juice softening), free of suspended solids, and free of oxygen, which irreversibly damages the resin [74]. The sucrose fraction, called “extract,” goes to pan crystallization, is mixed with thick juice, and crystallized, or is further purified with activated carbon or ion exchange resin and sold as liquid sugar. The waste fraction, called the “raffinate,” is concentrated and sold as fodder molasses.

Desugarization of Cane Molasses

Desugarization of cane molasses is more difficult and less economical for several reasons: it has a lower content of sucrose (about 35%) and a higher content of invert sugar (about 10%); it is more viscous because of higher concentrations of polysaccharides; it has a lot more suspended material; and it has a higher salt and calcium concentration which has to be “softened” before it can be put on a resin. Therefore, cane molasses must be clarified to remove suspended matter and gums, and prior softening is necessary to extend the life of the resin. The resulting product fraction from cane molasses contains a mixture of sucrose and reducing sugars. There has been little adoption of this process in the cane sugar industry [75].

Process Control and Instrumentation

The sugar industry has always been in the forefront of chemical control. The most important areas of control include measurement of sugar content (done by polarization), pH control (because sugar is unstable at low or high pH, and more so when high temperatures prevail), color measurement, and control of vacuum pans (for good crystallization).

At the end of the nineteenth century, the ICUMSA was formed. This organization, which continues today, is dedicated to all aspects of sugar analysis, validation of methods, and promulgating official methods that are scientifically valid. A good early history of ICUMSA, covering the first session in 1897 up to 1936, can be found in Bates [76].

Raw sugar quality characteristics that are measured include polarization, color, grain size, moisture, invert, dextran, starch, and surface color (color that could be removed in affination). New techniques, such as gas chromatography, enzymes, high-pressure liquid chromatography (HPLC), and near infrared (NIR) analysis are in use for determining various parameters, particularly sucrose, glucose, and fructose. NIR is particularly promising because it is nondestructive and can theoretically measure a wide range of parameters, such as moisture in bagasse and polarization of juice. These methods are coming to the forefront because the older method of determining sugar content, polarization, has several drawbacks. Originally, lead acetate was used to clarify solutions for polarization measurement; with lead use restricted in most countries, aluminum and zinc salts have replaced it, but these are not as effective clarifiers. Polarization is also not a direct measurement of sucrose, so it can be inaccurate in low-purity materials, such as molasses.

Instrumentation is used extensively in sugar boiling to control the process of crystallization. Some of the principles used to provide control of vacuum pans for boiling a strike of sugar are listed below [57].

1. Boiling point rise (BPR): thermometers are used to measure the temperature of the massecuite and its vapors (the difference between these two temperatures is the observed BPR).
2. Electrical conductivity of the massecuite, based on the principle that conductivity is inversely proportional to the viscosity of the solution, which in turn has a similar relationship to the water content and thus the degree of supersaturation.
3. Fluidity of the massecuite: An ammeter is used to measure the current used by the motor of a mechanical circulator; changes in current indicate changes in the fluidity of the massecuite.
4. Soluble solids measured by a refractometer.
5. Radiofrequency.
6. Microwave density probe [77].

Cane and Beet Sugar Production

Sugar (cane and beet) is produced in 119 countries. Cane sugar is produced in tropical and subtropical areas, and beet sugar is produced in temperate zones. The United States is fourth among the world's sugar-producing countries and is the only country with significant sugarcane and sugar beet acreage [78]. Cane sugar production is approximately 79% of the world sugar production and beet sugar is 21%. The major producers of cane and beet sugar are shown in Table 35.1. The biggest change to occur in world sugar production is the ascension of Brazil as the major producer [79]. Brazil, India, and China alone account for 41.0% of world sugar production, but only Brazil is a major exporter.

Sugar Consumption and Usage

Per capita consumption of sugar varies widely from country to country and is often a measure of the affluence and level of industrial development of a country, except in Asia, where dietary customs do not include high sugar intake.

Table 35.2 shows the per capita consumption of selected areas [80]. Sugar usage patterns, particularly in developed countries, have not changed markedly over the years except in the United States, where high fructose corn syrup (HFCS) has replaced sugar in the manufacture of beverages (see Table 35.3). Nonfood uses of sucrose constitute a small portion of total use [81].

Derivatives of Sucrose: Sucrochemistry

Because of its high purity and wide availability, sucrose has been viewed as an attractive feedstock for organic chemical synthesis. Sucrochemistry has been pursued for many years, and many products have been produced [82–84]. However, the economics of production have not been good and the reactivity of sucrose is difficult to control. Among the derivatives of sucrose are ethers, fatty and other esters, acetals, and reduction products. Successful products from

sucrose include surfactants, surface coatings, food and feed additives, polymers, textile chemicals, pharmaceuticals, and pesticides. A promising development is the conversion of sugar-based feedstocks into conventional liquid fuels and chemicals using a patented catalytic aqueous phase reforming process [85]. Other sucrose-based products in successful commercial distribution include olestra, a liquid sucrose polyester fat substitute, sucrose acetate isobutyrate, and sucrose-based detergents [86]. Sucralose, a sucrose derivative containing three chlorine molecules, was developed in 1976 by Tate & Lyle, and received approval for food use in the United States in 1998. It is 600 times sweeter than sucrose, is noncaloric, and stable to high temperature and low pH.

Sweeteners Derived from Starch

Starch is hydrolyzed to produce a range of sweeteners, including syrups and crystalline products. The bulk of starch-derived sweeteners comes from corn (maize) starch. Other starchy products are also used to produce starch-derived sweeteners, and small specialty markets exist for syrups from rice, barley, wheat, tapioca, and cassava.

The United States is the largest producer of corn sweeteners and the largest market for high-fructose corn syrup. The major use of HFCS is in beverages and soft drinks, which account for 75–80% of usage. Important milestones in the development and growth of HFCS are shown below [87].

- Late 1950s—Discovery that glucose isomerase enzyme converts glucose into fructose
- 1967—First commercial US production
- 1972—Immobilization of glucose isomerase for continuous production of HFCS-42
- 1977—Commercial production of HFCS-55
- 1980—HFCS approved as 50% of the sweetener in Coca-Cola
- 1983—HFCS approved as 50% of the sweetener in Pepsi-Cola
- 1984—100% level of HFCS approved in Coca-Cola and Pepsi-Cola

The 1984 approval of 100% HFCS as a sweetener in soft drinks resulted in phenomenal growth in the HFCS industry. In 1985, HFCS production was 5.3 million short tons (dry weight) and in 2000, it was 9.3 million short tons, with 9.6 million forecast for 2002 [87, 88]. In 2001, consumption of sugar and HFCS was almost equal in the United States.

In Europe, where other starch sources, such as wheat and potato, are used, these are referred to as high fructose syrups (HFS) or high fructose starch-based syrups (HFSS).

The corn industry makes widespread use of enzymes for carbohydrate conversion. The advent of enzyme technology in the corn industry in the 1960s dramatically changed the starch industry and allowed the development of new products. Today, enzyme hydrolysis of starch has largely replaced acid hydrolysis, which is used as an adjunct in starch conversion. Enzymes used to make corn syrups and HFCS include the following.

- Alpha amylase—Converts starch into dextrin; used in the manufacture of glucose syrup.
- Glucoamylase—Converts dextrin into glucose; specific for amylose.
- Pullulanase—Converts the amylopectin fraction of starch into linear segments.
- Beta amylase—Releases maltose units from the nonreducing end of a polysaccharide.
- Glucose isomerase—Converts glucose into fructose; used to make HFCS.

Starch Conversion

Starch conversion refers to the process of converting starch into other products. It involves gelatinization, liquefaction, and saccharification. Liquefaction refers to the acid- or enzyme-catalyzed conversion of starch into maltodextrin. Starch, usually from wet milling of corn, is pumped in a slurry to the conversion plant, where it undergoes one or more hydrolytic processes to yield mixtures of various carbohydrates in the form of syrups. The kind and amount of the various carbohydrates obtained depend upon the type of hydrolysis system used (acid, acid–enzyme, or enzyme–enzyme), the extent to which the hydrolytic reaction is allowed to proceed, and the type of enzyme(s) used. The fact that most starches consist of two different kinds of polymers (amylose and amylopectin) also influences the nature of the products obtained.

The extent to which starch is converted into simpler carbohydrates is indicated by the dextrose equivalent (DE), a measure of the reducing sugar content calculated as dextrose and expressed as a percentage of the dry substances. Hydrolyzates having dextrose equivalents ranging from 5 to 100 are produced. Those having a low dextrose equivalent frequently are referred to as dextrins and are not sweet. They are produced by minimal acid hydrolysis or roasting. Starchhydrolyzate syrups commonly are produced as “low,” “intermediate,” “high,” or “very-high” conversion products, as more or less standard products, as shown in Table 35.4. HFCSs are classified according to the fructose content, as a percent of solids (i.e., 42%, 55%, 90%), rather than by DE. Table 35.5 shows the composition of various corn syrups. In addition to carbohydrates, the syrups contain some sodium chloride and traces of nitrogenous substances. Maltodextrin is a dried corn syrup having a DE below 20, whereas the dry dextrins with a DE above 20 are called corn syrup solids.

Acid Hydrolysis of Starch

As mentioned above, this process now serves mainly as an adjunct to enzymatic conversion of starch and is rarely used alone. A starch slurry containing 35–45% solids is acidified with hydrochloric acid to about pH 1.8–1.9. The suspension is pumped into an autoclave (converter) where live steam is gradually admitted to a pressure of 30–45 psi. The conversion time largely determines the DE of the hydrolyzate; for example, 8 min may produce 42 DE syrup, and 10 min may produce 55 DE [89]. Converted liquors are neutralized with sodium carbonate to a pH of 5–7, with coagulation of insoluble protein, fats, and colloidal matter. The scum is removed by centrifugation.

The dark-colored clarified liquor is pressure-filtered and concentrated to 60% solids in multiple-effect evaporators. The concentrated liquor is decolorized with granular carbon in columns 12 ft in diameter and 30 ft high in a countercurrent manner; that is, liquor flows upward in the columns, while a portion of the carbon is removed from the bottom periodically. Carbon is used at a rate of 2.5% of dry solid processed, and approximately 5% of carbon is lost during revivification [90]. In some cases, granular carbon has been replaced by synthetic polymeric adsorbents to decolorize the syrup. “Low ash” syrups usually are deionized with ion-exchange resins. The processed liquor is evaporated to a final solids content of 75–85% in a single-effect evaporator.

Acid–Enzyme Hydrolysis

Starch is first liquefied and hydrolyzed to specific dextrose equivalents with hydrochloric acid. After evaporation to 60% solids, a saccharifying enzyme (fungal α-amylase) is added to continue hydrolysis to the desired level. By choosing two or more types of enzymes (such as α-amylase, β-amylase, glucoamylase, pullulanase) and adjusting the initial acid hydrolysis, syrups with different ratios of dextrose, maltose, and higher saccharides can be obtained [91].

Table 35.4 Conversion groups for starch hydrolyzates

Conversion	DE
Low (Type I)	20–38
Intermediate (Type II)	38–58
High (Type III)	58–73
Very high (Type IV)	73 and above

Enzyme–Enzyme Hydrolysis

Enzyme–enzyme conversion employs heat and an enzyme for starch liquefaction in place of acid. This is the most common form of corn processing today. Subsequent hydrolysis is by enzymes, as above. The choice of hydrolytic system depends upon economics and the kind of endproduct desired. Enzymes are usually inactivated by heating the syrup to 75–80°C, with the exception of the heat-stable α-amylases that have come on the market in the last 10–15 years.

A starch slurry of 30–40% dry matter is gelatinized and liquefied in a single dose jet-cooking process. Heat-stable α-amylase enzyme is metered into the starch slurry after pH adjustment to 6.0–6.5, and the slurry pumped through a jet cooker. Steam is injected to raise the temperature to 105°C and held for about 5 min, which is sufficient to gelatinize the starch (break up the starch granules). The partially liquefied starch is then cooled to 95–100°C and the enzyme is reacted at this temperature for 1–2 h, until the required DE is obtained [91]. Following liquefaction, the starch undergoes saccharification (conversion to sugars) using glucoamylase and pullulanase enzyme, resulting in maltose syrups, glucose syrups, and mixed syrups, as described above. Two enzymes are required at this point because starch is made up of two types of glucose polymers—amylose, which is a linear polymer, and amylopectin, a branched polymer—and each requires a different enzyme to break it up. Glucoamylase hydrolyzes the linear chains of amylose, and pullulanase specifically attacks the amylopectin at the branching points. The proper combination and time of hydrolysis will result in the desired range of products, all the way to syrups with as much as 97% glucose content. The glucose syrup may also undergo isomerization with immobilized glucose isomerase to make fructose syrups.

Crystalline Dextrose

Highly purified, high-dextrose syrup is crystallized to produce crystalline dextrose. The high-purity liquor is pumped to insulated crystallizers fitted with slowly moving

Table 35.5 Carbohydrate composition of glucose syrups (saccharides as a percent of total carbohydrates) [106]

DE	Glucose	Maltose	Tri-[a]	Tetra-[a]	Penta-[a]	Hexa-[a]	Hepta-[a]	Higher

[a] Refers to the number of glucose units in the oligosaccharide: tri maltotriose; tetra maltotetraose; penta maltopentaose, etc.

agitators for crystallization of dextrose monohydrate. A heavy seed base (about 25%) from a previous batch is mingled with the syrup and cooled to about 38°C. The seeded liquor is held at this temperature for several days until about 60% has crystallized. The mixture then is centrifuged to separate the crystals from the mother liquor. The wet sugar is dried in rotary dryers or recrystallized into anhydrous dextrose. The monohydrate also may be converted to anhydrous dextrose by drying in hot air. A second crop of crystals is taken from the mother liquor, and the runoff syrup from this step is final molasses or “hydrol.”

Crystalline Fructose

The newest sweetener from the corn industry is crystalline fructose, which came on the market around 1987, and is now available in retail outlets as a sweetener as well as used in commercial products.

High Fructose Corn Syrup

HFCS is produced from very pure glucose syrup using glucose isomerase. Commercial glucose isomerase is produced from a variety of microorganisms: *Bacillus coagulans*, *Actinplanes missourensis*, and several *Streptomyces* species. Glucose isomerase is always used in immobilized form because it is an intracellular enzyme. Immobilization is generally done by cross-linking with glutaraldehyde after the cells have been disrupted by passing through a homogenizer. The isomerization reaction is carried out at 60°C at pH 7–8. Reaction time is limited to prevent degradation of the fructose. All isomerization reactions today are done in continuous mode, rather than batch mode. The operating lifetime of a column of immobilized enzyme can be as long as 200–360 days, depending on the robustness of the enzyme used [91].

The basic feature of the isomerization process is a series of reactors containing the immobilized enzyme fixed in a packed bed. The feed material is of the highest practical purity possible because enzymatic activity is closely related to the purity of the glucose syrup. Glucose syrup of about 94 DE is filtered, treated with activated carbon to remove residual color, and deionized with ion-exchange resin to lower the ash content, particularly the calcium ion, which interferes with the magnesium enzyme activator. The dissolved oxygen is reduced by flash evaporation, which also concentrates the feedstock to 40–45% glucose and raises the temperature to 60–65°C. At this point, prior to entering the reactors, magnesium ions are added as enzyme activators. The pH is adjusted to about 8. Isomerized liquor is removed from the process when the equivalent of 42% fructose on a dryo basis is reached. After isomerization, the pH of the syrup is lowered to 4–5, and it is purified by ion-exchange resin and activated carbon. This results in a 42% HFCS. For use in soft drinks, it is converted to 55% HFCS by passing through large chromatographic columns of zeolites or the calcium salts of cation-exchange resins, which absorb and separate the fructose from the other components. This produces a stream of about 90% fructose, which is then blended with 42% fructose syrup to produce the desired 55% fructose syrup product.

HFCS technology and products have spread to Canada, Japan, and several western European nations.

Molasses

Molasses, defined as the residual mother liquor from which little or no additional sugar can be recovered economically, is a by-product of the cane, beet, and dextrose industries. Each type of manufacturer has designated this liquid by-product with its own name. The molasses from both raw cane sugar production and cane sugar refining is commonly called blackstrap molasses. In the cane mill, it is also called final molasses, and in the refinery it is sometimes called refinery molasses. Molasses from beets is simply called beet molasses, and that from starch hydrolysis is known in the United States as hydrol. The composition of molasses varies depending on location, varieties harvested, and the efficiency of the operation. The amount of sugar remaining in molasses is a measure of its “exhaustion.” The amount of refinery molasses is usually small, because as much as possible is recycled and a lot of it goes into the manufacture of brown sugar. Some cane refineries have no molasses output at all. The general composition of each type of molasses is shown in Table 35.6.

Blackstrap molasses from the cane mill contains significant quantities of sucrose and reducing sugars, some of it produced during the processing of the cane juice, caused by hydrolysis of sucrose, and some of it from the native cane juice. Refinery blackstrap has fewer impurities because the raw sugar starting material has fewer impurities than the cane juice but more sucrose. Beet molasses contains primarily sucrose and little or no reducing sugar because of the lower content of reducing sugars in beet juice and because the highly alkaline processing conditions destroy most of the reducing sugars. Hydrol contains no sucrose. Higher saccharides result from incomplete hydrolysis of starch. Cane and beet molasses contain polysaccharides that come from the plant (starch and cell wall polysaccharides) as well as some oligosaccharides that either occur naturally or are formed during processing.

Table 35.6 Composition of molasses from various sources[a]

Constituent	Cane final molasses	Refinery blackstrap	Beet molasses	Hydrol
Sucrose	31–40	50–60	60–63	0
Reducing sugars	20–30	5–10	0.5–1.5	55.0
Higher saccharides[b]	1.5–4.0	0.5–1.0	1.0–2.0	1
Ash	10–14	5–10	8–10	7.2
Nitrogen	0.4	0.1–0.3	2.0	0.07

[a] Values are on a dry basis
[b] Includes polysaccharides

The main uses of molasses are for cattle feed, production of some fermentation products, such as citric acid, and ethanol production. The sucrose in beet molasses is recovered by chromatographic processes described earlier. Cane molasses can also serve as a fermentation substrate for rum and "power" or fuel ethanol and for the production of baker's yeast.

Brazil has been in the forefront of producing fuel ethanol from cane sugar. Brazil unveiled the world's first alcohol-powered car after the 1970s oil crisis, using its abundant supplies of sugarcane. In spite of some difficulties in the 1990s, this innovative program was very successful. Brazil is the major producer of alcohol from sugarcane, with a total production in 2009 of 5.67 billion gallons. The United States is the major producer of alcohol in the world, with a total production in 2009 of 10.6 billion gallons [92]. US bioethanol is made from corn. Profitability is enhanced by the fact that the sugarcane mills produce both sugar and ethanol and can decide at any time on the product mix that gives the best return.

Other Sweeteners

Several carbohydrate-based sweeteners exist on the market today. Although sucrose is the "gold standard" for sweeteners, other sweeteners gain commercial viability because they are less expensive (such as corn-based sweeteners), have fewer calories, or are better suited for diabetic diets. Unlike the synthetic sweeteners, most of the carbohydrate-based sweeteners are less sweet than sucrose, with the notable exception of sucralose, which is 600 times sweeter than sucrose and is nonnutritive. Fructose and xylitol are reported to be sweeter than sucrose. Table 35.7 shows the relative sweetness of the carbohydrate-based sweeteners [93, 94].

An important group of carbohydrate-based sweeteners are the polyols, also known as sugar alcohols. These are not considered sugars for labeling purposes, so foods containing them as sweeteners can be called "sugar free." The polyols are usually 15–30% sweeter than their corresponding sugar. Some of the polyols give a cooling sensation on the tongue. Several of the new carbohydrate sweeteners are described below.

Table 35.7 Relative sweetness (RS) of carbohydrate-based sweeteners

Sweetener	RS
Crystalline fructose	180
Fructose in solution (5–15 %)	115–125
High fructose corn syrup	100–130
Invert syrup	105
Sucrose	100
Tagatose	92
Xylitol (10 % solution)	85
Xylitol (10 % solution)	100
Xylitol (10 % in solution)	120
Glucose (2 % solution)	50
Glucose (8–10 % solution)	60–70
Glucose (50 % solution)	90–100
Erythritol	70
Sorbitol (hydrogenated glucose)	70
Maltitol (hydrogenated maltose)	68
Maltose	50
Trehalose	45–50
Mannitol	40
Lactitol (hydrogenated lactose)	30–40
Lactose (milk sugar)	15–30

Erythritol, 70% as sweet as sucrose, is a polyol (sugar alcohol), currently used as a bulk sweetener in reduced-calorie foods. It has only 0.2 cal/g (sucrose has 4 cal/g). It was given Generally Recognized As Safe (GRAS) status by the Food and Drug Administration (FDA) in 1997, which allows it to be used in foods in the United States [95]. Erythritol is produced by fermentation with the fungus *Moniliella pollinis* [96].

Tagatose, a monosaccharide similar to fructose, received GRAS status from the FDA in April 2001. This sugar, 92% as sweet as sucrose, with 1.5 cal/g, is produced from galactose obtained from whey, using immobilized enzymes [97]. It has similar bulking properties to sucrose.

Trehalose, a disaccharide sweetener, 45–50% as sweet as sucrose, was given GRAS status in 2000. It is naturally found in mushrooms, honey, lobster, shrimp, and foods made with yeast. It has been used in Japan for decades, and is commercially produced from starch by bacterial enzymes [98]. Besides its mild sweetening power, it maintains cell structure during freezing and dehydration of foods. It is a nonreducing sugar, so it does not participate in the Maillard reaction (will not brown) and helps to protect the color of processed foods [99].

Other naturally occurring sweeteners include palm sugars, maple sugar, honey, and agave syrups (composed of about 90% fructose).

Regulation and Trade in Sugar

Raw cane sugar, refined sugar, sugar syrups, specialty sugars, and sugar-containing products enter the United States under a variety of tariff-rate quotas (TRQs). Low within-quota tariff rates facilitate access to the US market. The minimum sizes of the TRQs and the corresponding duties reflect obligations made by the United States. When Congress ratified the NAFTA and WTO (Uruguay Round) treaties, these TRQs became part of the US Harmonized Tariff Schedule.

Most of the sugar produced in the world (about 70%) is used for local or domestic consumption. The remaining 30% is in excess of local demand and makes up the global trade in sugar. In recent years, the trend has been toward the export of more white sugar instead of raw sugar. The European Union (EU-25) exports around 5.5 million tons of white sugar, and Britain, France, and Finland continue to import raw cane sugar for refining. Brazil is currently the largest exporter of sugar, at 27.4 million tons in 2008/2009 [78, 79].

Trade in sugar throughout much of the world is controlled by agreements and special trading arrangements. The United States regulated sugar production, distribution, and importation by means of the Sugar Act of 1948 as amended (US Congress, Public Law 339), but the act was allowed to expire in 1974. From 1981 to the present, the United States has had a price support program, connected to farm legislation. In 1982, an import quota system went into effect to supplement the price support program. In 1988, Australia filed a complaint against the United States, charging that the import restriction on sugar violated the General Agreement on Tariffs and Trade (GATT) rules. When the United States was found to be in violation on some of these rules, it implemented a change from an absolute quota to a tariff rate quota. The United States also has a program called the General System of Preferences (GSP) that exempts countries (mostly in the Caribbean area) from any duty. The EU countries import raw sugar within a special agreement with ACP (Africa, Caribbean, and Pacific) countries.

Raw cane sugar prices are based on the price of sugar delivered to New York and is quoted on the New York Coffee, Sugar, and Cocoa Exchange as Sugar Number 14 Contract (domestic). There is no futures market for US refined sugar. The world refined sugar price is based on the Number 5 Contract on the London International Financial Futures and Options Exchange (LIFFE), which is based on the London daily spot market price for refined sugar in free-on-board ships in European ports [100]. Copies of the Number 11 (world sugar) and Number 14 contracts (domestic) for raw sugar can be found in issues of *F.O. Lichts World Sugar and Sweetener Yearbook* prior to 2002.

The USDA's Sugar-Containing Products Re-Export Program is designed to put US manufacturers of sugar-containing products on a level playing field in the world market. The Refined Sugar Re-Export Program is designed to facilitate the use of domestic refining capacity to export refined sugar into the world market. The program establishes a license against which a refiner can export domestically produced refined sugar and later import world raw sugar, import world raw sugar for refining and distribution into the domestic market, and later export refined sugar, or import raw sugar, refine it and export it into the world market. The program was implemented to mitigate the imposition of restrictive quotas, which reduced the quantity of raw sugar allowed to enter the US domestic market.

Environmental Concerns and Sustainability

The sugar industry, in common with all other sectors of the food and chemical processing industries, is charged with protecting the environment. This means that close attention must be paid to all gaseous and liquid effluents, with the aim of minimizing their production and ensuring that they meet all minimum standards before being discharged into the environment. The goal of the sugar industry is to be ecologically sustainable and economically viable and efficient [101]. It also must take into account community concerns, such as the question of whether to continue the preharvest burning of sugarcane in various areas. Another factor of community concern is the odor produced by beet factories, and odor abatement programs are in place. It is certain that present standards will not be relaxed and that they can be expected to become more restrictive as time goes on [102]. Lead usage in polarization analysis was discussed earlier; most sugar producers now use alternatives (aluminum salts) or newer methods of analysis such as high wavelength polarimetry, NIR, or HPLC.

Issues of Genetic Engineering

In the United States, herbicide-tolerant genetically engineered sugar beet was approved in 1998, and has been available to the market since 1999. However, farmers have been wary about planting it because soft drink, food, and other industrial users are concerned about the growing consumer doubts and the inability to export such foods to the European Union. As of this writing, no genetically engineered commercial cane exists, but research in various countries has developed modified varieties. Brazil developed the first transgenic canes in 1994 and continues an intense program, with at least three varieties developed for herbicide tolerance, cold tolerance, and flowering control. The introduction of GMO cane is not foreseen for at least 5 years in Brazil due to social factors and strong regulations [103]. Successful introduction of modified cane or beet sugar varieties will depend on public opinion rather than scientific factors. Modified corn has been grown in the United States for many years, and several of the enzymes used are from modified organisms. Because these have been in place for some years, there is more acceptance of the products.

Soap and Fatty Acids

Introduction

The origin of the word “soap” is traced to sacrificial Mount Sapo of ancient Roman legend. The mixture of fat and wood ashes that reacted to form soap was carried by rain to the banks of the Tiber River and was found as a clay deposit useful for cleaning clothes [1].

The boiling of fats with ashes was recorded as early as 2500 B.C. Commercial soap-making was a widespread art in the Middle Ages in Europe. The invention of the soda ash process by LeBlanc in 1791, and the discovery by Chevreul in 1811 that soap was composed of a mixture of fatty acids paved the way to modern soap-manufacturing processes [1, 2].

Chemistry

The modern definition of soap relates to cleansing agents derived from fats, oils, and other fatty derivatives: the soaps are alkali and ammonium salts of fatty acids containing 8 to 22 carbon atoms. These fatty acids are generally a mixture of saturated, unsaturated, and polyunsaturated moieties:

$$
\begin{gathered}

\mathrm{CH_3(CH_2)_6CH_2CH{=}CHCH_2(CH_2)_6COOM}\text{:}\\
\text{mono-unsaturated soap}\\
\mathrm{CH_3(CH_2)_3(CH_2CH{=}CH)_2CH_2(CH_2)_6COOM}\text{:}\\
\text{di-unsaturated soap}\\
\mathrm{CH_3(CH_2CH{=}CH)_3CH_2(CH_2)_6COOM}\text{:}\\
\text{poly-unsaturated soap}\\
[\mathrm{M = Na, K, (HOCH_2CH_2)_3NH^+}]
\end{gathered}
\tag{36.1}
$$

In general, two types of chemical reactions are utilized in the manufacture of soap: the saponification of triglycerides (fats and oils) and the neutralization of fatty acids (which themselves are produced from the triglycerides by a variety of methods, most notably splitting or hydrolysis of fats and oils with steam under high pressure). Sodium hydroxide (the predominant alkali employed in the manufacture of soaps), potassium hydroxide, sodium carbonate, and triethanolamine are the most commonly utilized alkaline moieties in these processes (Fig. 36.1) [3, 4].

In recent years, soap manufacture by an alternate route, the saponification of fatty methyl esters, has been under development, most notably in Japan (Lion Corporation) and Italy (Ballestra). The fatty methyl esters are obtained from the methanolysis of triglycerides; inorganic alkali, quaternary ammonium salts, and enzymes (lipase) have

been used as catalysts for methanolysis in commercially practiced processes (Fig. 36.2). The methyl ester process for soap manufacture is typically more capital and cost intensive vs. the more traditional fats/oils saponification and fatty acid neutralization (FAN) processes.

Manufacturing Technology

Several designs of commercial equipment, based on the two processes described in Fig. 36.1, are available for the manufacture of soap.

Neutral fat saponification	Fatty acid neutralization
Kettle processes	Mazzoni SSCT and Binacchi CHBS
Semi-boiled	Alfa Laval
Boiled	Sato
Modern processes	
Mazzoni SCNT-N, SCT	
Dial Saponiflex	
Binacchi CSWE, CSFA	
Alfa Laval Centipure Hitachi	

A critical review of these processes is beyond the scope of this chapter. However, the processes themselves are described in a subsequent section.

Raw Materials

The triglycerides (triesters of fatty acids with glycerin) are the basic raw materials for the manufacture of soap utilizing a variety of processes. These triglycerides, as a renewable resource, occur widely throughout the plant and animal kingdoms.

Soap products in the United States are produced almost exclusively from tallow (beef) fat and palm kernel oil or their fatty acid derivatives. The utilization of palm oils, and other all vegetable oil soaps, along with palm derivatives for soap manufacture is more commonly practiced in many other parts of the world, especially in Asia. More recent trends in lauric oil pricing have driven the purchase and use of palm kernel oil and palm kernel olein as cost-effective alternatives to the previously more commonly used coconut oil. The frequent substitution of coconut oil with palm kernel oil is done primarily for cost optimization of soap-manufacturing feedstocks. More recently, concerns have been escalating regarding the environmental impact of palm oil usage. Many manufacturers have active programs and have joined industry coalition groups working to ensure that the palm oil used in their products are grown and harvested in a sustainable manner. Among other triglycerides, cottonseed oil, rice-bran oil, castor oil, neem oil, sunflowerseed oil, fish oil, and olive oil have also been used as indigenous feedstocks in many developing nations. Palm stearin, the by-product of palm oil fractionation, is increasing in use as a substitute for tallow outside of tallow-producing markets. Depressed pricing in 2000 and continuing fears of Bovine Spongiform

Encephalopathy (BSE) or Mad Cow disease have driven this use trend in Europe. Fatty acid composition and analytical characterization data of some of the key fats and oils utilized for soap production are given in Table 36.1.

Most of the fats and oils utilized for soap manufacture require a combination of steps: degumming, deodorization, refining, and bleaching, which are further discussed in the section on fatty acids.

For both saponification and neutralization reactions, sodium hydroxide is the most commonly used base. In some special situations, such as the manufacture of transparent and translucent soaps, potassium hydroxide and triethanolamine are also employed.

Functional Properties of Soap

Almost as a rule, the solubility of soap in water increases with an increase in the size of the monovalent cation (base); however, an increase in the size of a divalent cation (Mg^{+2}, Ca^{+2}) results in a decrease in the solubility. An increase in the chain length of the fatty acid moiety of soap results in a decrease in the solubility of soap, whereas the presence of unsaturation results in an increase in its solubility. In general, an increase in the water solubility is accompanied by an increase in the softness and use-up properties of soap. Adequate solubility results in good performance in soft water, although in hard water, lather decreases due to the formation of insoluble Ca^{+2} and Mg^{+2} salts. Cleansing bars formulated with various levels of synthetic detergents (combars or syndets) provide improved performance in hard water conditions.

Consumer-acceptable lather requires the consideration of a variety of lathering attributes, such as the speed with which lather is generated, volume, quality (i.e., loose or creamy), and the stability of the lather. In general, the use of fatty acids of C_{10}-C_{12} chain length provides voluminous lacey foam and fatty acids of longer chain length, from C_{16} to C_{18}, contribute to a richer, creamier foam.

Thus, a combination of lauric oil (C_{10}–C_{12}) and tallow (C_{16}–C_{18}) fatty acids is most suitable from the viewpoint of providing a balance in lathering attributes to deliver consumer-acceptable lather. Commonly accepted ratios of these soap feedstocks are 80–90% tallow and 10–20% lauric oil for standard purpose bars, and 60–75% tallow and 25–40% lauric oil for the higher lathering bar-soap products. Cleansing bars formulated with free fatty acids (superfatting) improves the quickness of lather generation and provides open bubbly foam. Commonly accepted levels of superfatting range from 1 to 7% for various types of bar soaps. Various methods are employed to evaluate bar lather attributes [5].

Manufacturing Processes

The following describes neutral fat/oil saponification and FAN as is commonly available from the two main equipment manufacturers (Binacchi and Mazzoni). These processes revolve around a continuous stirred tank reactor (CSTR) type of soap making reactor and neutralizer, and subsequent intermediate cooling and separating stages to produce soap and lye of a desired composition. There are many alternate processes available in the world today which, while operating with the same general theories, branch out to various plug flow reactions, improved efficiency high solids based reactors, optimized equipment and operating

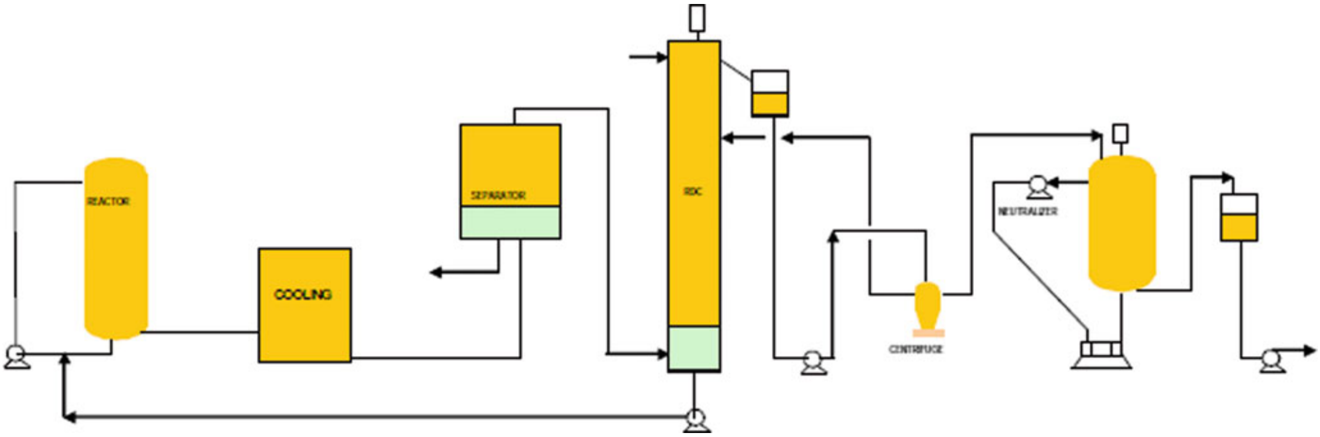

Fig. 36.3 Flow diagram of the general continuous saponification process with generic cooling area and standard neutralizer (Courtesy of Colgate Palmolive)

condition configurations, and combination processes which link the soap making and drying processes. This chapter provides the reader with knowledge of the more standard saponification process as it relates to the standard Binacchi and Mazzoni soap making designs.

Neutral Fat Saponification. In the saponification of triglycerides with an alkali, the two reactants are rather immiscible. Because saponification is a bimolecular nucleophilic substitution (SN2), the kinetic rate enhancement is achievable by both a high-shear mixing and an increase in the reaction temperature during the processing. Increasing the pressure of the reaction assures that vaporization does not occur at the high reaction temperatures and helps to accelerate conversion of the fatty feedstocks and of alkali to soap as well. The saponification reaction is self-catalyzed to some extent: the formation of soap product affects the emulsification of the two immiscible reactants, causing an acceleration of the reaction rate by providing increased surface area for the saponification reaction to occur.

The amount of alkali required to saponify a triglyceride blend is calculated by the following equations:

$$\begin{aligned}&\text{Triglyceride} + 3\text{NaOH} \rightarrow 3\text{ROONa} + \text{Glycerin}\\&\text{NaOH} = \text{weight oil} \times [\text{SV} \times 0.000713]\\&\quad \times 100/\text{NaOH}(\%)\ \text{in solution}\\&\ = \text{weight oil} \times \text{SV}\ (1\ \text{g}/1{,}000\ \text{mg})\\&\quad (\text{MW NaoH}/\text{MW KOH})(100\%/\%\text{NaOH})\end{aligned} \tag{36.2}$$

where SV = saponification value (mg KOH/g triglyceride) and MW = molecular weight. In general, the most commonly used soap feedstocks have these saponification values:

	(g NaOH/100 g triglyceride)
Beef tallow	14.09
Coconut oil	18.32
Palm kernel oil	17.81
Palm oil	14.19
Palm stearin	14.26

The use of these values simplifies the calculation of the stoichiometric alkali equivalent, for example:

$$\begin{aligned}&100\ \text{g beef tallow} \times 14.09\ \text{gNaOH}/100\ \text{g tallow}\\&\quad \times 1\ \text{g}\ 50\%\ \text{NaOH caustic}/0.5\ \text{g NaOH}\\&\quad = 28.2\ \text{g}\ 50\%\ \text{NaOH caustic required}\end{aligned}$$

The process for a typical triglyceride saponification plant is shown as a flow diagram in Fig. 36.3 [6]. In general continuous soap making processes have replaced the kettle process in most large scale soap making operations. The driving forces for this change include economies in utilities, simplification of manpower training, elimination of operator bias in process control, and more consistent, high quality soap base. In most locations, the continuous process of choice is the continuous saponification of fat/oil (neutral fat) with caustic soda. It must be understood however, that for a given level of finished soap color and odor quality, the "natural" color and odor quality of fats and oils to be continuously saponified must be better than the color and odor of materials for kettle saponification. Also, the saponification color must be lower. This is because in continuous saponification a significant portion of the oil and alkali soluble color components are not removed, representing roughly 5–10% of a typical fats/oils charge to saponification in the kettle process. This quantity of poorer quality soap is not reprocessed and returned as a cleaner base to the primary soap making system. In contrast, a small quantity (1–2%) of poorer quality soap is degraded from the kettle process as slurry soap thereby removing a greater amount of these color bodies as well as odor in the full boiled kettle process.

Also, smooth continuous saponification processing requires frequent standard analyses of all raw materials and, in addition, a number of simple analytical determinations of minor ingredients in raw materials.

Saponification Reactor

As the title of the process step implies, the purpose of the step is to saponify fat/oil. Fat/oil, caustic soda, aqueous salt solution (brine), water and Column Lye from a later process step, are metered into a pressurized reactor equipped with a recycle loop and a high-shear recycle pump. The point of injection of raw materials is at the pump suction, where they are immediately mixed with a large mass of recirculating reaction mass from the reactor, under conditions of elevated temperature and pressure, and high-shear mixing (from the pump). While the elevated pressure is important as it prevents vaporization, it is the elevated temperature and high shear mixing, combined with the effects of the recycling soap mass which cause the immediate homogenization and emulsification of the raw materials. This in turn results in the rapid saponification rate associated with the continuous soap making process.

Recycle takes place during the entire process. As long as the reactor and recycle loop are full, the metering of raw materials into the Reactor is continued as an equal weight of reaction mass is withdrawn and passed on to the next process step, Cooling.

The rate of addition (metering) of raw materials into the Reactor is governed by four requirements:

- That the fat/oil be almost completely saponified before it leaves the Reactor.
- That complete saponification takes place by the time the continuous process mass passes through the next process step, Cooling.
- That the Spent Lye by-product contains a minimum of alkali, and sufficient salt to keep the process mass in the Neat Soap/lye phase configuration, and to promote optimum separation of soap and Spent Lye during Separation.
- That the required soap production rate be met.

The design considerations of the saponification autoclave center around considerations for residence time, recycle rate, and mixing capability of the entire reactor design. Residence time and mixing efficiency determine the uniformity of the mixture exiting the reactor, as well as the required control efficiency and reaction time required to assure completeness of reaction and absorb various process deviations. The recycle ratio is studied to maximize the quantity of already reacted soap present during the saponification of the newly entering fats/oils and/or fatty acids as the reaction is autocatalytic, meaning that the more soap that is present, the faster the reaction can proceed.

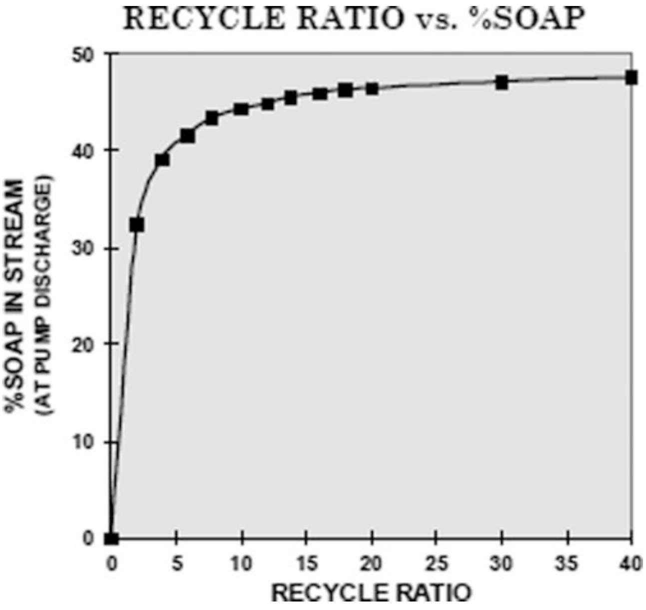

Fig. 36.4 Recycle ratio vs. per cent soap. This graph shows the change in the quantity of recycling soap in the reactor as compared to recycle ratio for a typical continuous saponification reactor (Courtesy of Colgate Palmolive)

A typical chart used to determine required recycle rate of a saponification reactor can be found in Fig. 36.4. This figure illustrates the dramatic effect of recycle ratio on emulsification, as measured in terms of % soap at the pump discharge of the recycle loop. Recycle ratios of about 13–25 have been found sufficient to achieve nearly complete saponification in the Reactor. Utilizing these design criteria, the small changes in process flow due to viscosity assure that the quantity of soap at the point of initial reaction can be held relatively constant.

Cooling

Because the temperature of the saponified soap/lye mixture is elevated, effective separation is made possible by passing this mass through a cooling stage and then to a static separator for separation of the unwashed soap from the spent lye solution.

The cooling process can be achieved in a number of ways depending on the desired process design. The most common in older plants is to pass the soap through a cooling vessel in which the soap is cooled utilizing water as the cooling medium. The most common form is the mixer type cooler where the soap is passed over a series of cooling coils while being constantly agitated. The water through these coils can be at various temperatures, and can have heat recovery so as to aid in reducing total energy required for process operation.

Improving on process optimization Mazzoni offers a flash cooler as its standard design which allows for process water to be flashed off from the saponification mixture. The theory

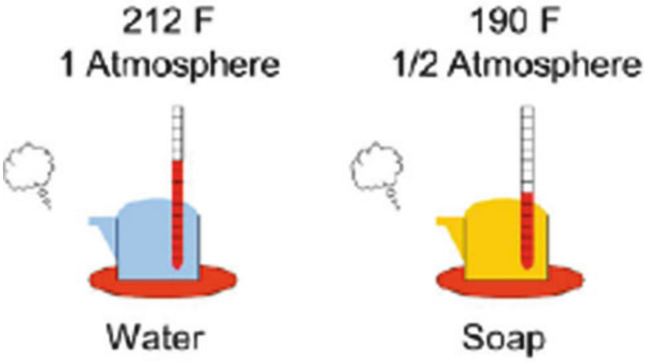

Fig. 36.5 Relative boiling point diagram showing boiling points for water at atmospheric pressure and soap at typical process pressure. The teapot provides reference to the constant temperature regardless of the amount of heat applied (Courtesy Colgate Palmolive)

behind the operation is like that of a pot boiling on the stove, where for a given pressure the soap will always boil at a constant temperature. At atmospheric pressure the pot of water on the stove will maintain 100°C regardless of how much water is in the pot, or how much heat is applied. At an absolute pressure near 0.5 atmospheres a flash cooler will maintain soap between 85 and 92°C with near constant temperature, an ideal condition for soap and lye separation. Exact pressures required will depend on solids and electrolyte content (Fig. 36.5).

The flashing of steam also increases the concentration of the components in the remaining soap and lye, including the glycerin. This allows the Mazzoni process mass balance to be altered so as to allow spent lye glycerin concentrations in excess of 40% glycerin where the solubility of soap in lye can often be lower, further increasing total process efficiency, reducing total required raw materials required per ton of soap produced as well as costs associated with subsequent glycerin recovery. The flashed steam can also be recovered to reduce water feed required, and can at the same time be used to preheat raw materials or other process streams to save on total energy requirements.

Another option to consider is a process design offered by Binacchi, which seeks to reduce total process capital by eliminating the cooler. This can be achieved by directly injecting cooled lye into the saponification mixture after it exits the saponification reactor. The lye can be sourced from the separator, which is the next process step. While making for a slightly bigger separator to accommodate the increased recycling lye flow, the reduction in capital can be quite attractive. The lye can be withdrawn from the separator and cooled, with a portion of the heat removed used for reheating a portion of the raw materials, further increasing process efficiency. Finally in eliminating the need for the cooling vessel Binacchi has eliminated the need for the cooler discharge pump and has reduced process footprint, further reducing capital and energy costs.

Soap Separator

No matter which cooling route is chosen, the process mass exiting the soap cooling process will require separation of the soap from the spent lye. This is accomplished in a soap separator.

The purpose of this process step is to provide sufficient residence time and sufficiently lowered process flow velocities to promote the gravity separation of the cooled process mass into an upper layer of crude Neat Soap and a lower layer of Spent Lye.

Static separation of the soap mass from the cooling process is accomplished in a simple insulated, cylindrical tank. However, because of the small density difference between Neat Soap and Spent Lye, approximately 0.97 vs. 1.05 g/cc, phase separation during this process step is far from complete; from 15 to 25% of the mass of the soap exiting the separation process is entrained spent lye. This entrainment is not a serious problem because in the next process step, Glycerin Extraction, entrained lye combines with lye passing down through the extraction column, and is recycled back to the saponification reactor as part of the Column Lye.

The Spent Lye that does separate from the soap mass must be clear, that is, free of visible soap, suspended or otherwise.

The soap mass, crudely separated from lye in the separation process is then fed to Glycerin Extraction. The clear separated Spent Lye is sent to glycerin recovery.

The soap separator is a vessel where the soap and lye mixture enter near the center of the vessel, with soap exiting from the top, and lye being withdrawn from the bottom. Spent lye discharge rates are then controlled so as to maintain a constant-level soap/lye interface, which provides for a constant, specified flow rate of soap from the top of the Separator to a holding tank at a specified temperature, and on to the Glycerin Extraction Column. Interface position is generally monitored using a sight glass with some processes also expanding to electronic level detection for improved process control.

The separator itself is most commonly an atmospheric tank with dimensions determined based on soap velocity and residence time for the soap and lye phases. In this design the soap and lye are fed to level control tanks to aid in maintaining a stable process, and in keeping discharge rates constant for both soap and lye. Alternatively the separator can be a pressurized device where the soap continues to separate as before, but the driving force for pushing the soap and lye is from a pump such as the Mazzoni cooler discharge pump, or the dosing pumps feeding the Binacchi reactor. In this case the pressure in the separator eliminates the need for the constant level tanks, the soap discharge pump, and in many cases the spent lye discharge pump as well.

Significant to the separation process in the temperature of the process mass to be separated, and the electrolyte composition. Lower temperatures generally increase separation efficiency, but usually required increased operating cost, and can in turn increase the viscosity of the process mass, making flow and pocketing of the lye within the soap an issue.

The electrolyte content (or content of salt and alkali) in the soap and lye is kept relatively high (as compared to the rest of the process) from the saponification stage up until separation. Electrolyte is defined in reference to a lye limit concentration (LLC), and the percentage above the LLC that the spent lye electrolyte is maintained. The Reactor Lye is usually tested to make sure the correct electrolyte content is maintained for good separation and flow, but will may analyze slightly higher than target because water flashes off analysis samples taken as the reactor is at elevated temperature.

From a practical viewpoint, the required total electrolyte levels of Spent Lye are functions of:

- The viscosity of the soap mass in the Reactor.
- The soap content of Spent Lye.
- The clarity of Spent Lye.

Changes in the tallow/lauric oil ratio affect the exact electrolyte requirement but all soaps generally have an elevated viscosity and poor separation with too high or too low an electrolyte, with an ideal intermediate electrolyte level which maintains the resulting wet soap in the Neat or Wax phase.

Also important is a general thought that Spent Lye should be as low as possible in caustic soda to minimize the quantity of acid required to neutralize the lye during glycerin recovery, while at the same time assuring near complete reaction. Salt concentrations therefore are the only electrolyte variable that can be adjusted to minimize the concentration of soap in the Spent Lye and to clarify it “to the appearance of fresh-brewed tea.” The color intensity of this lye (and its glycerin content) is a function of Lye Bulk (and of course raw material quality, especially fat/oil).

Soap Extraction

The purpose of this process step is to extract glycerin from the soap mass that is fed continuously from the separation process. The glycerin extracted is the glycerin from the soap which is also the glycerin that did not partition into the Spent Lye during the previous process steps.

Extraction is accomplished in a countercurrent extraction column in which the soap mass from separation and Fresh Lye is brought into intimate continuous countercurrent contact. The soap mass enters the bottom of the column while Fresh Lye enters the top. Droplets of lye trickle downward through a continuous phase of soap, become enriched in glycerin (more soluble in lye than in soap), and form a continuous lye phase at the bottom of the column. The lye from the bottom of the column, Column Lye, is then metered back to the saponification reactor so as to maintain both column interface level and reactor composition.

The soap mass that collects at the top of the column overflows into a constant level tank from which it is pumped to Centrifuging.

Also during Glycerin Extraction the lye-soluble color and odor bodies are extracted from the soap mass.

The column lye, as stated previously, is a mixture of the lye that has passed through the soap in the column, as well as the entrained spent lye which has entered the bottom of the column with the separated soap. The entrained lye has a density greater than the soap in the column, and also is contacted by the lye falling down the column, preventing the entrained spent lye from rising through the column.

Electrolyte composition for the extraction process is very important. The concentrations of salt, caustic soda, and glycerin in the Fresh Lye provide for:

- The final adjustment of the alkali and salt concentrations of the soap so as to meet desired soap electrolyte composition.
- The concentration of caustic soda required in the Column Lye (the lye exiting the bottom of the Glycerin Extraction Column and pumped back to Saponification in the Reactor).
- The glycerin extraction efficiency of the Fresh Lye in the Extraction Column (it must be noted also that the glycerin content of the Fresh Lye must be low enough so that the soap in equilibrium with the lye can satisfy its glycerin specification).
- Separation efficiency at the Centrifuge, where lye is separated from soap.

The concentrations of salt and caustic soda in this process step also must be such that the soap phase maintains its required phase configuration—Neat Soap.

With attention paid to all this detail, a multi-equilibrium, glycerin extraction equilibrium process is established within the Column between the two phases (soap and lye) as they pass through each other—the glycerin-laden crude soap from Static Separation passing up through the Column, and the Fresh Lye passing down.

The lye flowing down through the Column joins with the entrained Spent Lye from soap entering the bottom of the Column and exits as Column Lye. This lye flows back to Saponification. This resulting final Column Lye mixture is elevated in glycerin, and as the continuous saponification plant has a glycerin by-product stream, the glycerin rich Column Lye stream is sent to the reactor. Within the reactor the reaction of the fats/oils produces added glycerin further enriching the glycerin content of the lye. Also important to note is that column lye is also termed Half lye, where the caustic content is at an intermediate level between the Fresh and Spent Lye. The Column Lye or Half Lye is sent to the reactor to also utilize the remaining alkali in the lye to saponify a portion of the incoming oils.

The soap at the top of the column first passes through a small separation zone within the column to allow a portion of the lye to separate from the soap in a manner similar to the separation process, to minimize the quantity of lye sent to the next step, centrifugation. The soap, having passed through the separation zone at the top of the column, now stripped of most of its glycerin, flows from the top of the extraction column at specified temperature, composition, and rate to a constant level holding tank and on to Centrifugation. This lye and soap are at near-equilibrium with respect to salt, caustic soda, and glycerin.

While temperature of the separation process is governed by the previous soap cooling process, temperature within the column is controlled by two factors. The first is the incoming soap temperature and the second is by the temperature of the incoming Fresh Lye to the top of the extraction. The Fresh Lye controls not only the temperature of the soap at the top of the extraction column, but also the temperature of the soap at the next process, Centrifugation, where input soap temperature is a critical parameter in maintaining proper machine performance.

Flow rates to and from the Column are controlled to maintain a constant-level soap/lye interface near the bottom of the Column. This provides for a constant, specified overflow rate of soap from the top of the Column for optimum centrifuge performance, and a constant specified flow rate of Column Lye from the bottom of the extraction column to minimize required electrolyte adjustments at the Reactor, and to maintain a constant desired spent lye glycerin concentration.

Centrifugation

The purpose of this process step is to separate as much entrained Fresh Lye as possible from the soap mass exiting from the extraction column, thus producing Neat Soap ready for Neutralizing or direct consumption by the soap plant. This is accomplished via the elevated gravitational forces produced in a centrifugal separator.

The separated Centrifuge Lye exiting the centrifuge process is returned back to the extraction column where it enters near the top of the column. The centrifuged Neat Soap is sent for Neutralizing. Centrifugal separators remove entrained lye from the soap directly after extraction. This centrifuging step, accomplished from one or several centrifuge units operating in parallel, reduces moisture and electrolyte content from the soap that is required in downstream processing stages.

Pressures within the centrifugation system are manipulated to adjust for interface position within the machines as well as for downstream pressure so as to optimize separation efficiency.

Important factors in the centrifugation process include:

- A controlled electrolyte level in Fresh Lye flowing into the extraction column, and thus the electrolyte level of the extracted soap flowing from the extraction column into the Centrifuge.
- Constancy of temperature and feed rate of soap into the Centrifuge.
- Centrifuge operations within prescribed parameters to maintain a stable soap–lye interface utilizing correct and constant soap and lye discharge pressures.

Given equilibrium in centrifuge operations, constant-composition Centrifuge Lye flows from the Centrifuge and back to the Extraction Column, and high quality centrifuged soap flows out and on to Neutralization.

Neutralization

In the production of most toilet soap, residual-free alkali in Neat Soap from Centrifuging is adjusted downward continuously in a CSTR type neutralization reactor equipped with a recycle loop. This reactor is generally designed to operate at or below 1 bar pressure, and at 80–90°C, so as to produce soap at a temperature suitable for atmospheric operations or soap storage.

The neutralizing agents are various, all capable of reacting with the residual alkali, and are often combined with a preservative to also start the preservation of the neutralized soap as early as possible to minimize degradation of the newly formed soap. The degree of neutralization is determined by measuring pH in-line or alkalinity by direct titration of a representative sample. Ultimately the need is to determine the concentration of caustic soda and salt. Salt concentration is also determined to make sure that the fresh lye is providing for a soap/lye equilibrium satisfactory for properly satisfying specifications for salt in soap drying, and that potential changes in brine to not subtract from the separation efficiency of the centrifugation process.

This finished base soap, once confirmed as meeting desired composition is then dried (typically on vacuum spray-type dryers) to produce soap as pellets (70–82% total fatty matter), ready for processing into finished product on finishing lines.

Soap Drying. The soap mass obtained after the completion of saponification (neat soap) is most commonly dried nowadays on vacuum spray dryers (Fig. 36.6). The moisture content of soap is thus reduced from 30 to 35% in neat soap to 8–18% in soap pellets (soap flakes or chips are produced on APV-type dryers, after milling). A variety of vacuum spray-dryers, from single-stage to multistage designs, are available from several manufacturers. The operation of a single-stage

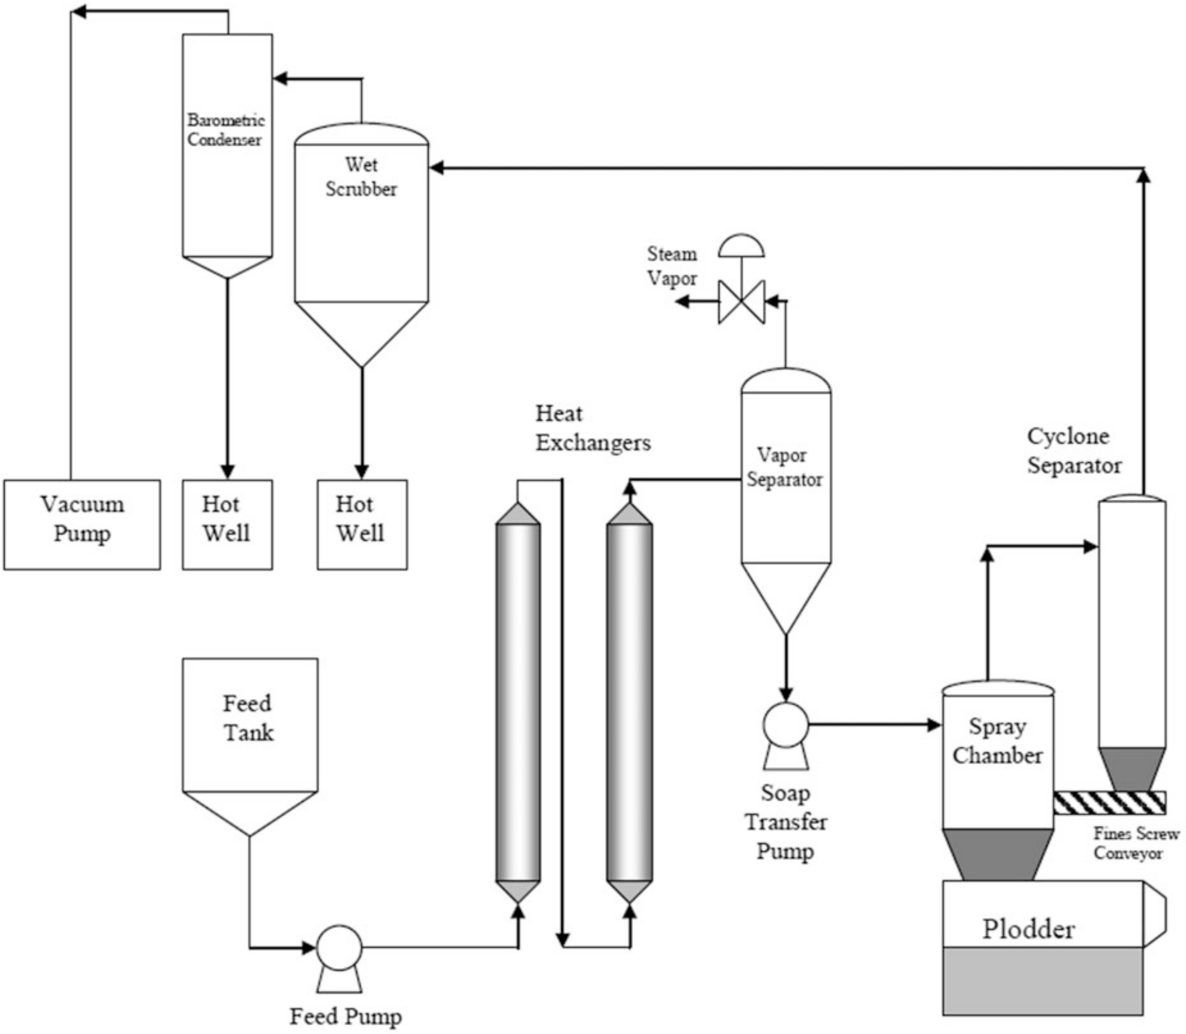

Fig. 36.6 Typical soap dryer configuration including vapor separator and wet scrubber (Courtesy Colgate Palmolive)

vacuum spray-dryer involves the pumping of neat soap at 80–90°C through a shell-and-tube heat exchanger where the soap is heated by high-pressure (6–10 bar) steam passing through the outside tube in a countercurrent manner. The soap is preheated to 135–155°C and sprayed onto the walls of a cylindrical vacuum chamber through either a stationary or revolving nozzle. The thin layer of dried and partially cooled soap deposited on the walls of the vacuum chamber is removed by rotating scrapers and falls to the bottom of the chamber onto a discharge plodder. This plodder extrudes the dried soap mass in the form of noodles or pellets.

The excess moisture from the incoming soap is either flashed off directly in the spray chamber of the dryer or first sent to a vapor liquid separator following the final soap heat exchanger. In the case of the vapor liquid separator the steam generated by the heating of the soap is removed under controlled pressure prior to the spray chamber so as to reduce the quantity of fines generated, the load on the barometric condenser, as well as to potentially create a valuable source of steam that can be used to drive the dryer booster, or provide heating to an intermediate process stream. In certain circumstances the steam can also be atmospherically vented to gain the fines reduction and barometric condenser benefits if the steam generated is not needed in the booster operation. With or without the vapor liquid separator the heated soap will be sent to the spray chamber, where it will be under 40–60 mmHg vacuum and the remaining moisture will be removed as vapor. This vapor will be passed through one or two cyclone separators to remove the majority of soap fines produced, and then potentially to a wet scrubber for added fines removal, and then on to the booster (if installed) and barometric condenser system. Proper control of moisture, temperature, vacuum, flow rate, vapor liquid separator level, and pressure if installed, spray chamber entry pressure and scraper function ensure the drying of acceptable quality soap pellets. Typically these soap pellets are conveyed pneumatically to storage bins/silos that act as surge for the soap finishing process. Soap storage silos are constructed of stainless steel and have angled bottoms that direct soap pellets toward centrally located single or twin discharge screw conveyers for efficient transfer to the finishing lines.

Fatty Acid Neutralization. The hallmark of soap making by the continuous FAN process is simplicity relative to the complexity of soap making by the continuous saponification of fat/oil. Consider for example the fundamental steps of the two processes:

- In FAN (the Direct Neutralization process variant) there are three process steps: raw material dosing, neutralizing with caustic soda, and post-addition of minor finished soap ingredients.
- In fat/oil saponification, there are seven process steps: raw material dosing, saponification with caustic soda, cooling, static phase separation, glycerin extraction, centrifuging, and neutralizing.

Four of the fat/oil saponification steps have to do with the requirement to separate large quantities of by-product glycerin from the process mass—cooling, static phase separation, glycerin extraction, and centrifuging.

The continuous neutralization process mass need not be cooled to separate phases; the process mass is a single phase, Neat Soap. The process mass need not be allowed to quiescently separate into two phases, Spent Lye and Neat Soap; again, it is a single phase, Neat Soap. Large quantities of glycerin need not be extracted from the process mass and the process mass does not need to be centrifuged.

A consequence of the process simplicity of FAN is its contribution to the relative economics of soap making through reduced initial required capital and floor space.

There are two FAN processes, namely:

- The so-called Direct Neutralization Process in which fatty acids are neutralized with sodium hydroxide (caustic soda).
- The Carbonate Neutralization Process in which fatty acids are first partially neutralized with sodium carbonate and then the neutralization process completed with sodium hydroxide (caustic soda).

The chemical reactions of the above-mentioned processes are:

- Direct Neutralization:

$$\mathrm{RCOOH} + \mathrm{NaOH} \rightarrow \mathrm{RCOONa} + \mathrm{H_2O} + \mathrm{heat}$$

- Carbonate Neutralization:

$$\mathrm{RCOOH} + \frac{1}{2}\mathrm{Na_2CO_3} \rightarrow 70 - 85\%\ \mathrm{RCOONa} + \mathrm{CO_2} + \mathrm{H_2O} + \mathrm{heat}$$

$$\mathrm{RCOOH} + \mathrm{NaOH} \rightarrow 30 - 15\%\ \mathrm{RCOONa} + \mathrm{H_2O} + \mathrm{heat}$$

where NaOH for reaction = weight of fatty acid × AV× 0.000713

with AV (acid value of fatty acid blend) = mg of KOH required to neutralize 1 g of fatty acid.

AV = acid value (mg KOH/g of fatty acid), and the remaining portion of the equation being derived as in (36.1).

The average molecular weight of a fatty acid blend is calculated from the following equation:

$$\begin{aligned}\text{MW fatty acid} &= 56.1 \times 1{,}000/\text{AV}\\ &= (\text{MW KOH/AV}) \times (1{,}000\ \text{mg/g})\\ &\quad \times (1\ \text{mole KOH}/1\ \text{mole fatty acid})\end{aligned} \tag{36.2}$$

A typical Mazzoni FAN soap plant is illustrated in Fig. 36.7 [6]. The principal raw materials for the Continuous Neutralization processes are fatty acids, alkali (caustic soda or soda ash/caustic soda), and brine (salt and water). These raw materials must be of rather high quality because:

- The soap mass is not "fitted" as in kettle saponification—to remove a quantity of lower quality soap from the in-process soap mass. There is no lye for "fitting."
- The soap mass is not in contact with lye as in both kettle saponification and continuous saponification—to remove water-soluble impurities from the in-process soap mass.

The impurities that go into the process in raw materials exit the process in the product, Neat Soap, ready for drying.

Direct Neutralization

In Direct Neutralization, caustic soda, brine, and any required additional water are premixed in-line and dosed into the high shear mixer simultaneously with fatty acid. This procedure produces heat (the heat of dilution of sodium hydroxide with water and the heat of neutralization of fatty acids with sodium hydroxide). Depending on raw material temperatures and required throughput rate, it may be necessary to preheat or precool one or more raw materials to maintain the process mass at 85–98°C during the entire short process. In both instances, only caustic soda/water mixtures should be directed through the heat exchanger. Brine should be added after heat exchanging to minimize heat exchanger corrosion (and required metallurgy) and fouling.

Neutralizing takes place in the high shear mixer and draft tube mixer shown in Fig. 36.7 With the positive displacement recycle pump, the equipment is a closed recycle loop neutralizer operating under sufficient agitation and recycle rate to ensure homogeneity in the process mass. Dosed raw

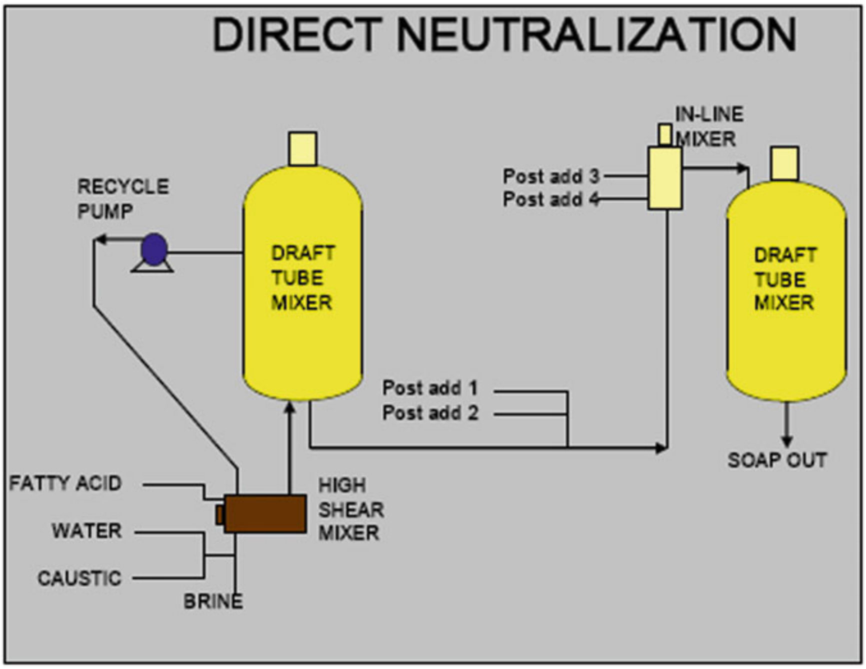

Fig. 36.7 Flow diagram of the general Direct Neutralization process with post-addition option and standard neutralizer (Courtesy of Colgate Palmolive)

materials enter the recycling process stream just prior to the shearing zone of the high shear mixer. Neutralization is essentially instantaneous.

Relative to the conditions for the previously described Continuous Saponification Reactor, operating conditions for Direct Neutralization are considerably less severe.

In summary, the paths of raw materials and process mass in the Neutralizer during this second process step are as follows:

- Raw materials are dosed into the recycling soap stream just prior to the shearing zone of the high shear mixer. Within the mixer the raw materials are almost instantaneously emulsified and the fatty acids and almost instantaneously neutralized by caustic soda.
- From the high shear mixer, the soap mass passes on to the draft tube mixer where neutralizing is brought to completion.
- From the draft tube mixer, the process mass moves on to a positive displacement pump for pumping back to the high shear mixer where it receives fresh raw material and is recycled through the several elements of the system—the high shear mixer, the draft tube mixer, and the positive displacement recycle pump.

A pH probe can be mounted in the recycle loop prior to raw material entry to monitor the alkalinity of the recycling soap mass. Alternatively, samples can be taken, usually just prior to raw material entry, and titrated with acid (i.e., phenolphthalein indicator). As necessary, adjustments are made in the quantity of either caustic soda or fatty acid being dosed into the system.

Neutralizing is brought to completion as the process mass passes through the neutralizing equipment in the above-described path. A typical Na_2O specification for process mass exiting the Neutralizer is 0.03–0.07%.

Carbonate Neutralization

The Carbonate Neutralization Process consists of five process steps—Raw Material Dosing (for Carbonate Neutralizing); Partial Neutralizing With Soda Ash; Carbon Dioxide Separation; Raw Material Dosing (for Caustic Soda Neutralizing); and Completion of Neutralizing With Caustic Soda; See Fig. 36.8 for a process flow diagram.

It might seem that, with five steps, the Carbonate Neutralization process could never be preferred over Direct Neutralization with only three steps. However, in some locations the availability, cost and/or purity of soda ash relative to caustic soda may make Carbonate Neutralization the preferred process. Appreciate however that operationally and with currently available equipment Carbonate Neutralization is relatively problematic. The viscosity of the process mass is the major issue. See later remarks on viscosity.

Soda ash alone cannot be used effectively in FAN processes for two reasons.

- First, after 70–85% of the fatty acid has been neutralized with soda ash, the viscosity of the process mass becomes so high that pumping the mass becomes difficult.
- Second, since fatty acids are weak acids and soda ash is a weak base, the neutralization reaction rate falls off dramatically as the process proceeds, making impractical a process based on soda ash alone.

Hence, the need for the fourth and fifth process steps of Carbonate Neutralization.

Raw material dosing equipment (proportioning pumps and mass flow meters) and dosing processes are similar to those for Continuous Saponification.

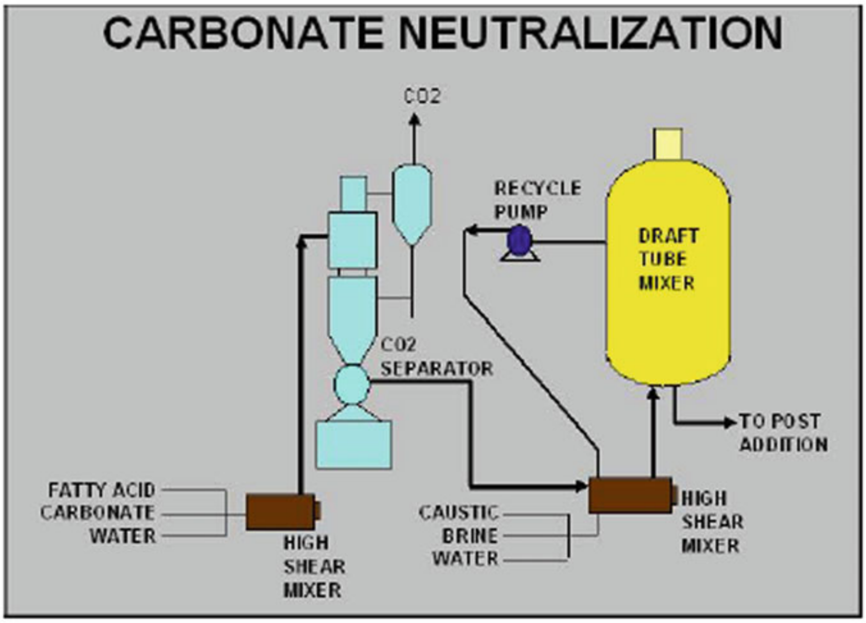

Fig. 36.8 Flow diagram of the general Carbonate Neutralization process with post-addition option and standard neutralizer (Courtesy of Colgate Palmolive)

Soda ash purchased in granular form is pre-dissolved in water to make a 20–22% solution. The aqueous solution of soda ash, fatty acid, and any extra required water are dosed into the high shear mixer at whatever temperature is required to maintain the neutralizer process mass at 85–98°C.

Partial Neutralizing with Soda Ash

As shown in Fig. 36.8 above, this partial neutralizing is accomplished in a high shear mixer, without recycle. The progress of the reaction is estimated by analysis of the process mass for unreacted fatty acid and by measuring pressure drop in the process mass transfer pipe between the high shear mixer and the CO_2 Separator. Alternatively, and crudely, it can be estimated by monitoring the pump speed required to transfer the process mass through the pipe at the required throughput rate.

The viscosity increase is very large, the result of the intimate dispersion of CO_2 into the process mass.

Viscosity can be reduced if necessary by diluting with water the soda ash solution being dosed into the Neutralizer or by reducing the targeted degree of Neutralization with soda ash. Both of these process modifications of course negatively affect production rate and efficiency.

As shown in Fig. 36.8, the continuous stream of process mass exiting the high shear mixer passes on to the CO_2 Separator.

Carbon Dioxide Separation

The Carbon Dioxide Separator is a tall, jacketed column equipped with a high-viscosity pump at the bottom. CO_2 is eliminated from the process mass and passes out of the top of the Column as the reduced-viscosity CO_2-free process mass moves downward in the Separator and is pumped from the bottom and onward to the second Neutralizer for completion of neutralizing with caustic soda. In some columns a screw impeller is mounted at the bottom of the Column to force process mass into the pump. As with process equipment for the other process steps, the Carbon Dioxide Separator is jacketed and insulated so as to maintain the process mass temperature within the range 85–98°C.

Raw Material Dosing, Caustic Soda Neutralizing

The raw materials are caustic soda in sufficient quantity to complete the neutralization of fatty acid and brine in sufficient quantity and concentration to bring the process mass into the desired Neat Soap phase configuration.

Completion of Neutralizing with Caustic Soda

At this point the process mass passes through a neutralizer identical to Direct Neutralization, and once combined with the correct raw materials in the desired flow ratios, the process mass consists of a single phase, Neat Soap.

Neutralization Soap Viscosity

The viscosity (flowability) of the soap through the neutralization process, be it direct neutralization or carbonate neutralization, is highly important as it provides insight as to composition and governs pressure drop through the process. Three factors affect viscosity—soap phase configuration, temperature, and electrolyte content. To elaborate:

- The process must always be Neat Soap as the target. None of the alternative phase configurations is satisfactory.

Slurry Soap is very low in soap content (and high in water). Middle Soap and Kettle Wax are too high in viscosity for satisfactory throughput rates.

- Process mass temperature must be suitable for required throughput rates. The lower the temperature the higher the viscosity and vice versa. The solidification temperature of the soap in process is about 70°C. However, at temperatures approaching the boiling point of water, steam forms and becomes dispersed in the soap mass, thus increasing viscosity.
- The process mass must contain a concentration of electrolyte within prescribed limits. Concentrations both above and below the limits increase viscosity.

Having kept the soap at the correct composition and temperature, a uniform quality soap product can be produced ready for drying or for use in other areas of the soap making system. The soap drying process can be accomplished by vacuum spray-dryers, as described earlier, to produce soap pellets ready for finishing into soap bars.

Soap Finishing. The starting point for soap finishing is usually the amalgamator, a horizontal mixer that coarsely blends soap pellets with minor ingredients such as color and fragrance. The soap mix from amalgamation is conveyed to subsequent processing stages like milling and refining to provide satisfactory homogenization and working of the soap before extrusion. A mixer/refiner process is also available for blending of soap pellets with minor ingredients on a more continuous basis. Sufficient working of the soap through fine-mesh screens in the refining stages provides uniformity and frictional heat necessary to produce acceptable-quality billets for pressing into bars. The finished product is extruded from the last plodder as a continuous slug. Vacuum is provided at the final extrusion chamber to evacuate entrained air. This step ensures the extrusion of a uniform slug that will not separate or exhibit surface bubbles/deformities. A multiblade chain cutter or uniblade cutter with blades separates the extruded slug into individual “billets” that are stamped with a press into soap bars of the desired size and shape.

The wrapping, cartoning, and end packaging machinery complete the bar finishing lines. The schematic diagrams of a variety of soap finishing configurations are illustrated in Fig. 36.6.

Soap Aesthetics. The soap finishing stage is also critical in defining the final appearance of the bar, an important factor in the consumer appeal of the product. Aside from the bar color, several options are available to the soap manufacturer in developing unique soap aesthetics. A widely used look, pioneered by Colgate-Palmolive and others, is bar striation. Here, a liquid mixture of contrasting color is injected into the soap pellets in the final finishing stages just prior to extrusion. By preventing the liquid mixture from fully blending into the soap, a randomized striping effect is created. A similar process with minor modifications can be used to achieve a marbleized look. Another example of multiphase look has recently been introduced by Unilever’s Lux in Latin America. Here relatively large, discrete particles of a second soap of slightly different color and composition are dispersed within the bar. Sometimes it is possible to incorporate soap performance enhancers such as skin conditioners into the aesthetic features of the bar. Other commercial examples of soap-aesthetics are exfoliating soaps where micron-sized particles of exfoliants such as polyethylene beads are added to the soap pellets in the plodder hopper. A bar with a shimmery of pearlescent effect can also be produced by dosing a low level of mica into the soap pellets generally in a mixing device such as an amalgamator.

Fatty Acids

The fatty acids are produced industrially from triglycerides. This process involves the steps shown in Fig. 36.9 [7, 8].

Refining involves the purification of triglyceride to remove impurities (phosphatides, polyethylene, chlorophyll, heavy metals, off-odors, color bodies) by a combination of acid/alkali washing, clay/activated silica bleaching, deodorization, and hydrogenation steps.

Splitting, or the hydrolysis of triglycerides, is usually performed with high-pressure steam, resulting in the formation of split crude fatty acids and glycerin. The production of fatty acids by more sophisticated “splitting” processes, such as hydrolysis of fatty methyl esters, ozonolysis of unsaturated fatty acids, and chemical oxidation is practiced in special situations.

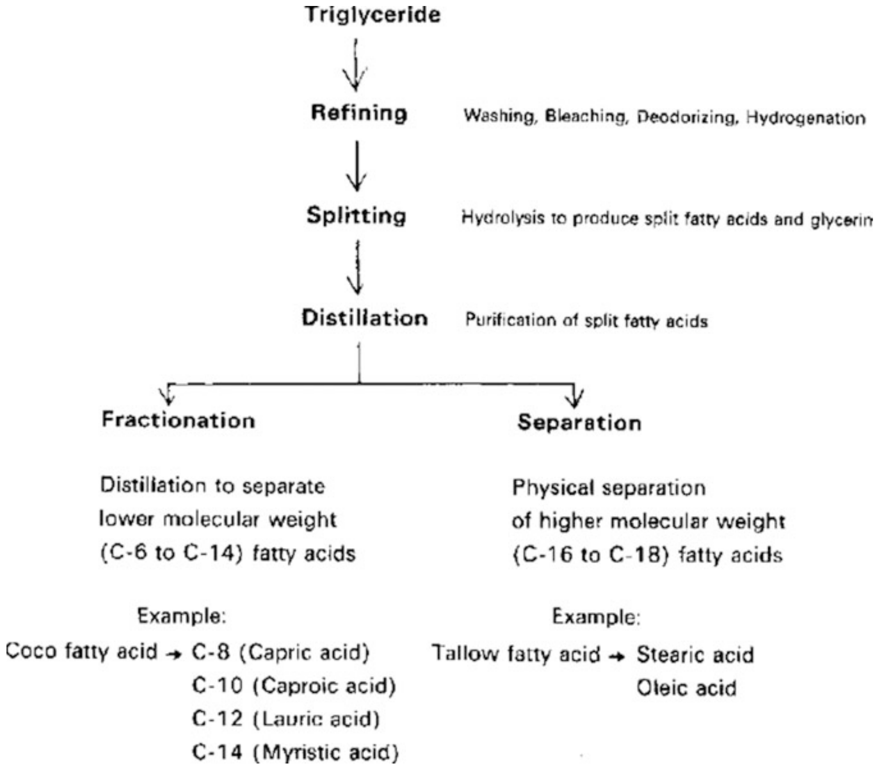
Distillation of split fatty acids results in the improvement of chemical, color, and odor quality of the finished product.

Fractionation and Physical Separation

Distilled fatty acid streams are separated to obtain individual components of those fatty acid streams in a higher state of chemical purity. Fractionation is performed to separate the more volatile lower molecular weight fatty acids (C_8-C_{14} chain length). Physical separation is practiced to obtain higher molecular weight, less volatile, or thermally unstable fatty acids (C_{16}-C_{18} chain length).

Hydrogenation is utilized to reduce the unsaturation and poly-unsaturation of fatty acids. Hydrogenated fatty acids can also be produced by the hydrogenation of triglycerides followed by splitting of the resulting fat/oil blend. The

Fig. 36.9



selective reduction of di- and poly-unsaturation is accomplished frequently by the use of nickel-based specialized catalysts in a process often called “touch” hydrogenation.

In the partial hydrogenation of the unsaturated moities the isomerization of the double bonds of mono-unsaturated components is a common occurrence; it results in the transformation of the *cis* to the corresponding *trans* stereoisomer. As the physical properties of these isomers may vary significantly, their impact on the properties of the final product should be evaluated rather carefully, for little information is available on this subject at present.

Fat Refining

A typical fat refining plant (Alfa-Laval process) for the acid washing of fats and oils is illustrated in Fig. 36.10 [9]. The triglyceride is degummed to remove phosphatides and other impurities such as mucilage, proteinaceous matter, and trace metals by acid washing with citric or phosphoric acids, and then is sent to a bleaching plant where it is dehydrated and treated with an activated clay for the removal of color bodies, heavy metals, chlorophyll, and polyethylene (Fig. 36.11) [6].

Because odor is a key quality attribute in bar soaps, a deodorization step is commonly used following earth bleaching to remove objectionable odor bodies from fats/oils. The base odor of the refined triglyceride affects the fragrance character of the finished bar and needs to be minimized for optimum fragrance delivery in product use. Deodorization is typically accomplished with 0.2–0.5% stripping steam at 1–3 mmHg and 200–250°C. The material of construction for refining processes should be stainless steel, 316L preferred, to avoid contamination with trace metals that are common to the use of mild steel.

Fat Splitting Processes

The direct reaction of triglycerides with alkali followed by acidification or the treatment of triglyceride with water (with or without an acid catalyst) results in the splitting of fats/oils into fatty acids and glycerin. The splitting, or hydrolysis of fats/oils with water, can also be performed by using various lipase enzymes as catalysts. The enzyme process is still in the developmental stages. The inter-esterification of triglycerides with methanol followed by acid or alkali cleavage of the resulting fatty methyl ester is used for the production of certain molecular weight (C_8-C_{10}) fatty acids; those methyl esters are generally the by-products of fatty alcohol production (Fig. 36.12).

The splitting of fats/oils can be done either in a batch (Twitchell process) or in a continuous (Colgate-Emery process) mode; the enzyme-based processes are still under development for commercial applications. A comparison of these processes follows [10, 11].

Process	Hydrolysis time (h)	Conversion (%)

(*continued*)

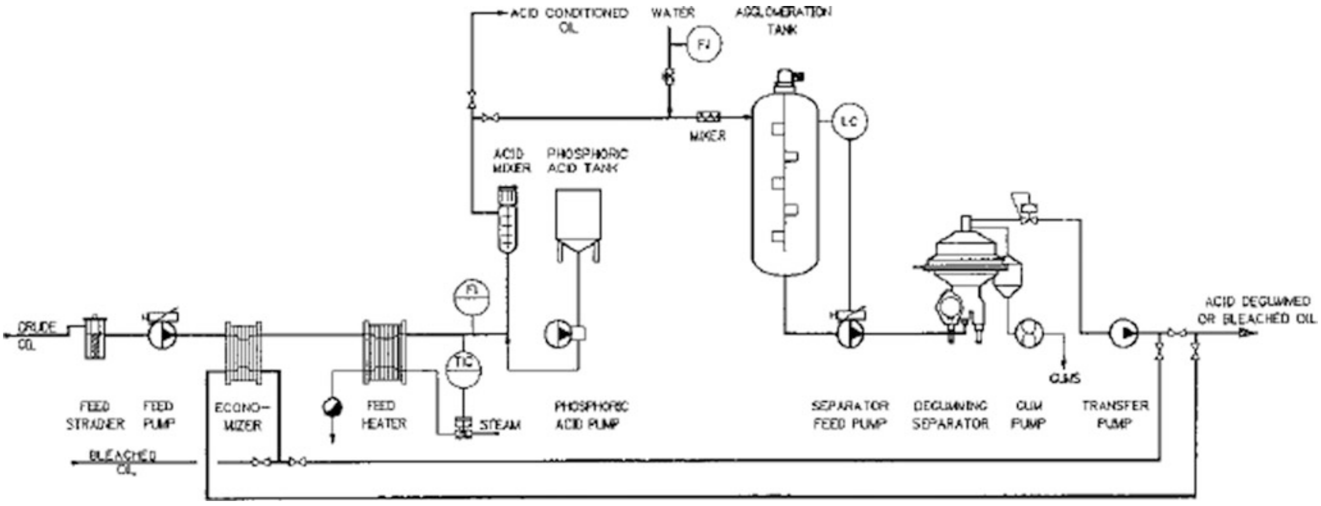


Fig. 36.10 Acid degumming plant for acid washing of fats and oils (*Courtesy Alfa-Laval, Tumba, Sweden*)

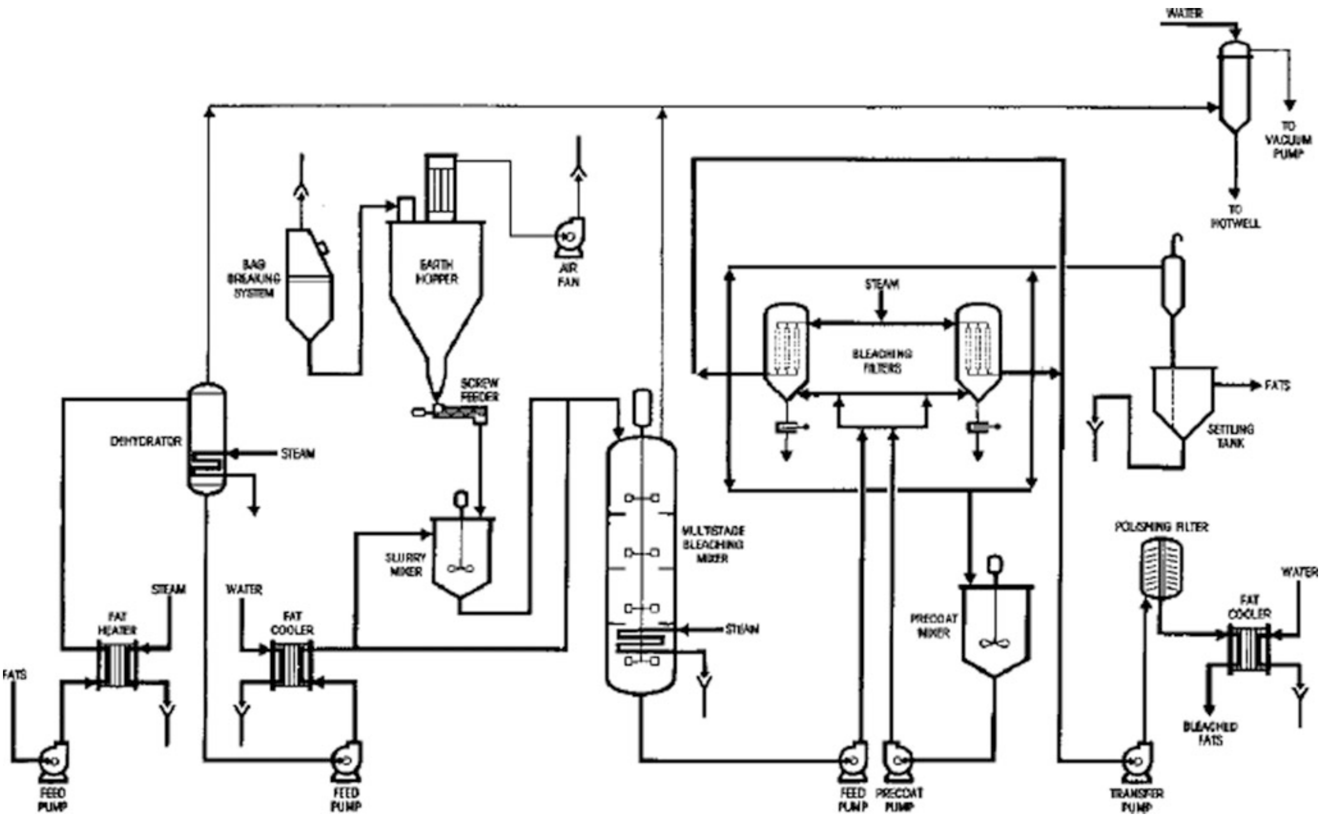

Fig. 36.11 Continuous fatty matter bleaching plant (*Courtesy G. Mazzoni S. p. A., Busto Arsizio, Italy*)

Process	Hydrolysis time (h)	Conversion (%)
Twitchell batch	8–24	95
Continuous	1–3	98–99
Enzyme	72	98

The manufacture of fatty acids from triglycerides via their reaction with alkali followed by acidification is not used commercially. However, the recovery of fatty acids from alkali refining of fats/oils (to produce acid soaps) and soap reboiling operations (the recovery of fatty acids from the acidification of soap waste streams) are practiced still in special situations, for example, in edible oils refining where soap-stock that is generated from chemical (alkali) refining

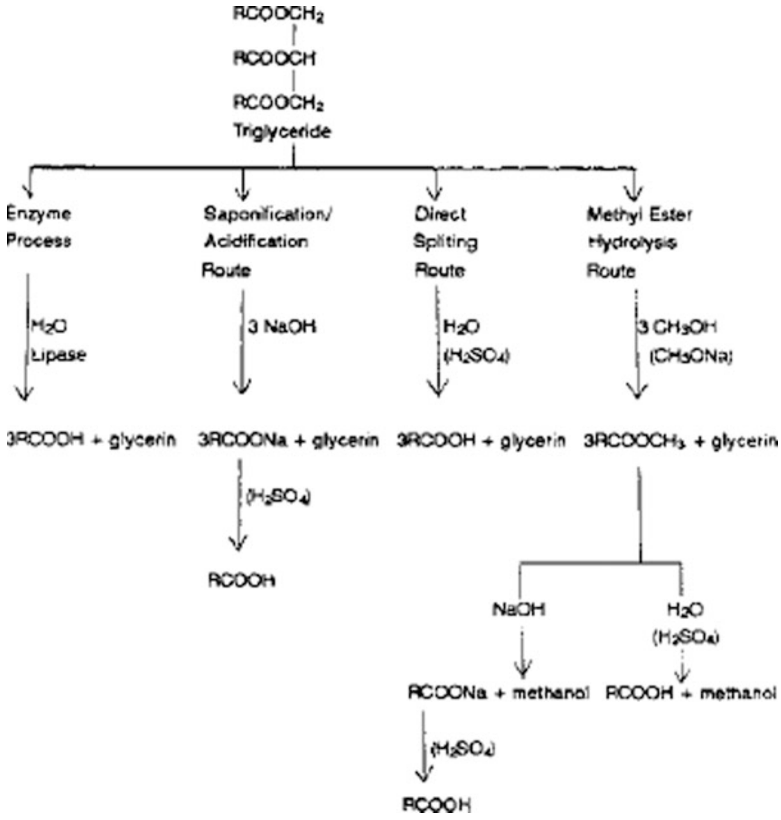

Fig. 36.12 Fat splitting processes

requires acidulation to produce acid oils with commercial value.

Industrially, the fatty acids are produced predominantly by the high-pressure, high-temperature splitting of triglycerides. Both batch and continuous processes are available, the continuous process being in greater worldwide use today.

Batch Process. The triglyceride is heated with water at 150–250°C and 10–25 bar pressure. The splitting is achieved in 6–10 h, depending on the nature of the triglyceride feed, for example, the higher the molecular weight of the triglyceride, the slower the splitting reaction. The reaction can be accelerated by increasing the temperature; under high pressure and at 225–260°C, no catalyst is required.

A typical commercial batch splitting plant (Lurgi) operates at 230°C/400 psig with over 96% split yields after two changes of water to remove the glycerin by-product. The sweetwater (glycerin/water mixture) is circulated continuously from the base to the top of the autoclave in this process [12].

A number of other batch fat splitting plants are also available.

Continuous Fat Splitting Process. Currently, continuous fat splitting is the most widely used process in the industry. In the single-stage splitting process, fat and water are fed countercurrently into a continuous flow column at up to 260°C/60 bar pressure conditions. The glycerin by-product generated in the splitting process is removed by water (sweetwater), thus accelerating the reaction equilibrium toward completion (Fig. 36.13) [12]. The high splitting temperature ensures

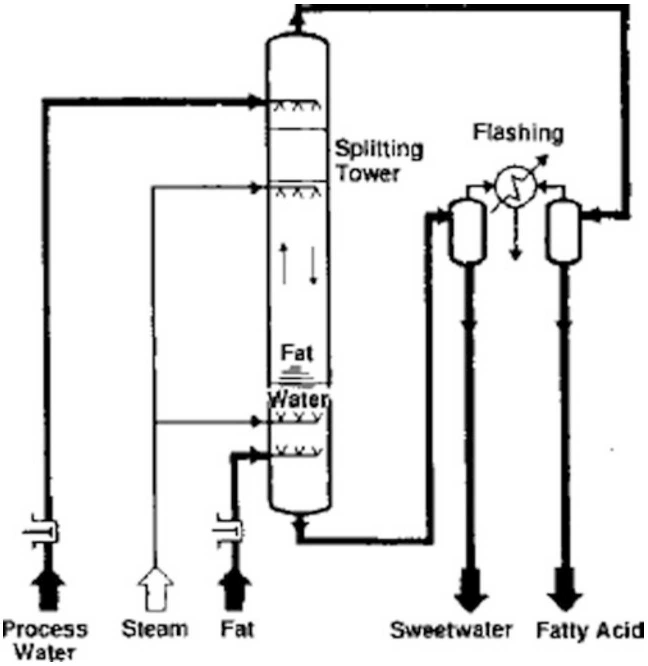

Fig. 36.13 Single-stage countercurrent fat splitting plant (*Courtesy Lurgi GmbH, Frankfurt am Main, Germany*)

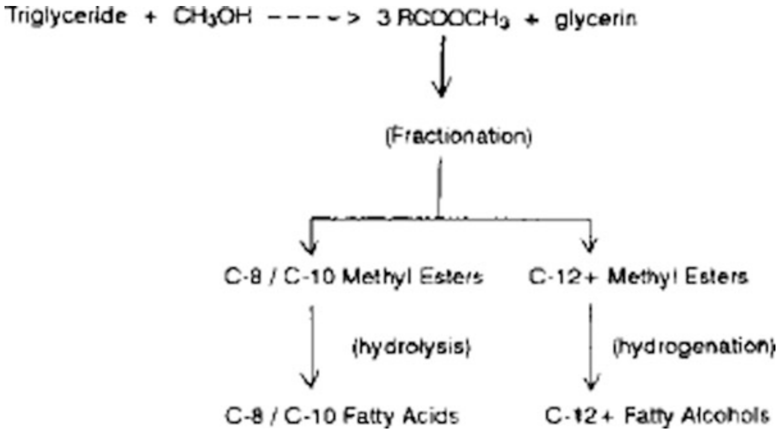

Fig. 36.14 Fatty acid production via methyl esters

adequate dissolution of the water phase in the fat to the extent that mechanical forces for contacting the two reactants are not required. The fat phase passes from bottom to top through the tower, with the void volume of the tower acting as a reaction chamber. The water phase travels downward through the mixture of fat and fatty acid, concentrating the glycerin by-product in the sweetwater phase. The top and bottom sections of the tower are also designed to effect the transfer of heat from the products to the incoming reactant streams. Split yields of up to 99% can be achieved by the use of prepurified fat/oil feedstocks.

In summary, the continuous high-pressure splitting of fats and oils involves:

1. The use of excess water to drive the reaction to completion and for the removal of glycerin from the reaction zone.
2. The use of a proper combination of temperature and pressure conditions to increase the solubility of water in the fat phase while maintaining the boundaries of the fat/water interface. These conditions also result in an increase in the rate of splitting.
3. The possible use of an acid catalyst to accelerate the reaction rate.

Saponification/Acidification Process. The recovery of fatty acids from soapstocks and soap reboil operations is of commercial value:

$$\underset{\text{(unrefined)}}{\text{Triglyceride}} \xrightarrow{\text{caustic refining}}$$

$$\text{Triglyceride} + \underset{\text{(soapstock)}}{\text{RCOONa}} \xrightarrow{(H_2SO_4)} \text{RCOOH}$$

$$\underset{\text{(impuresoap)}}{\text{RCOONa}} \xrightarrow{\text{reboiling}}$$

$$\underset{\text{(purifiedneatsoap)}}{\text{RCOONa}} \xrightarrow{(H_2SO_4)} \underset{\text{(purifiedfattyacid)}}{\text{RCOOH}}$$

The recovery of fatty acids from soapstocks by a continuous process has been described: soap-stocks obtained from degumming and alkali refining operations are subjected to a saponification step followed by controlled acidification for cost efficiency and pollution control [13, 14].

The saponification/acidification route is used for the manufacture of fatty acids that are sensitive to excessive heat. The splitting of castor oil with NaOH at 100–220°C followed by acidification has been used to produce castor fatty acids [15].

Enzymatic Processes. The enzyme hydrolysis of triglycerides is catalyzed by lipases:

$$\text{Triglyceride} + 3H_2O \xrightarrow{\text{enzyme}} 3\text{RCOOH} + \text{Glycerin}$$

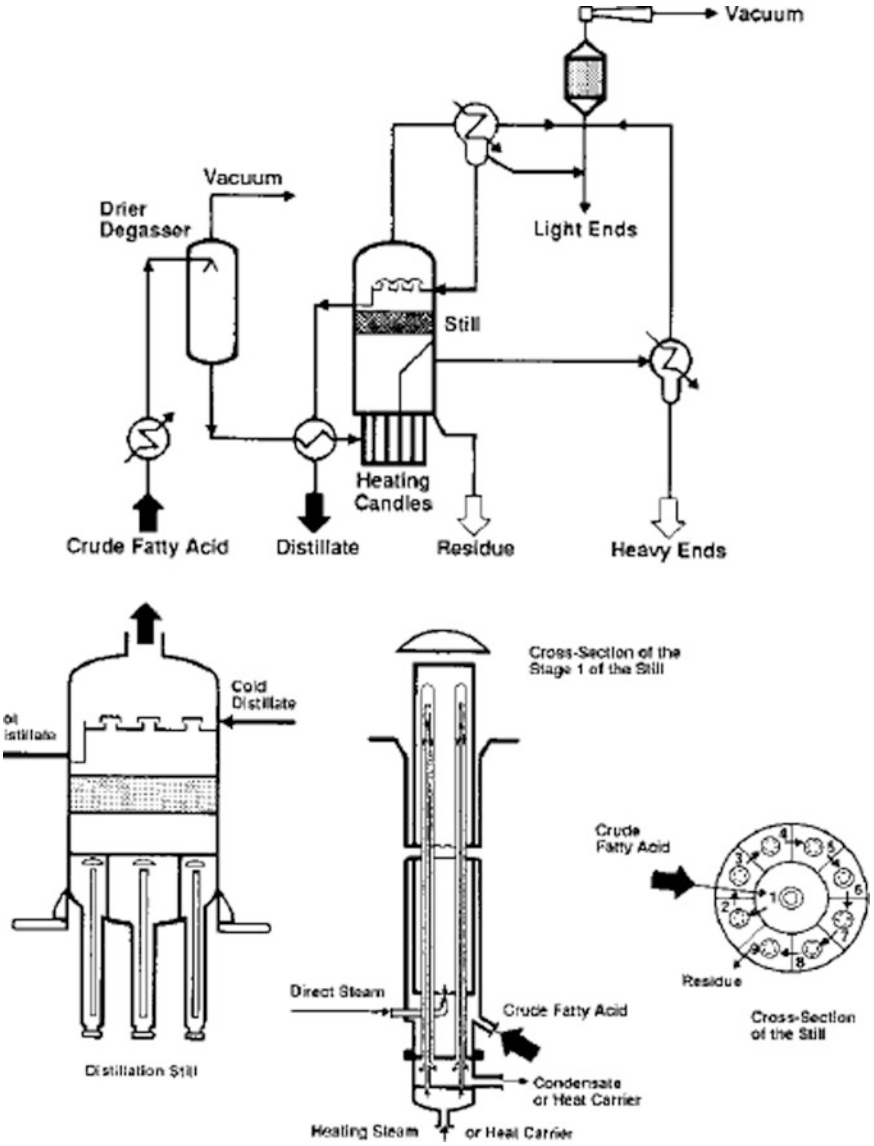
Enzyme-based splitting of triglycerides is under active development and offers the following advantages over modern steam hydrolysis plants.

- The hydrolysis occurs under mild conditions (35–37°C, ambient pressures).
- The color quality of the products is superior.
- The capital investment may be lower.
- The split yields are equivalent.

The selection of a suitable lipase for a commercially viable process is based on the following criteria.

- It should be nonspecific and nonselective as to the structure of the triglyceride.
- It should be stable at above ambient processing temperatures, typically 45–65°C.
- It should be economically viable. (This aspect has initiated a number of ongoing studies on the recycling and immobilization issues of lipase utilization for triglyceride hydrolysis.) [16, 17]

Fig. 36.15 Continuous fatty acid distillation plant (*Courtesy Lurgi GmbH, Frankfurt am Main, Germany*)



Methyl Ester-Based Processes. The fatty methyl esters are produced predominantly by the transesterification of fats and oils with methanol in the presence of an alkaline catalyst under very mild reaction conditions [18, 19]. They are used in the production of lauric-type (C_{12}) alcohols. The short-chain fatty methyl esters (C_8-C_{10}), produced as by-products via the fractional distillation of crude lauric-type (coconut, palm kernel) methyl esters, are converted to fatty acids via acidic or alkaline hydrolysis (Fig. 36.14). The hydrolysis of short-chain fatty methyl esters by stream splitting or Twitchell-type processes is not very efficient because of unfavorable equilibrium constants [20, 21].

Fatty Acid Distillation

The removal of contaminants (unreacted triglycerides, odor and color bodies, polymerized matter, and decomposition products) from split fatty acids is achieved by simple distillation [22, 23]. The products obtained from such straight distillations are called "whole cut" fatty acids (e.g., whole coconut fatty acid).

The separation of individual fatty acid components from whole fatty acid distillates is achieved by fractional distillation [24, 25]. However, fractional distillation cannot efficiently separate C_{16}-C_{18} saturated from the corresponding unsaturated

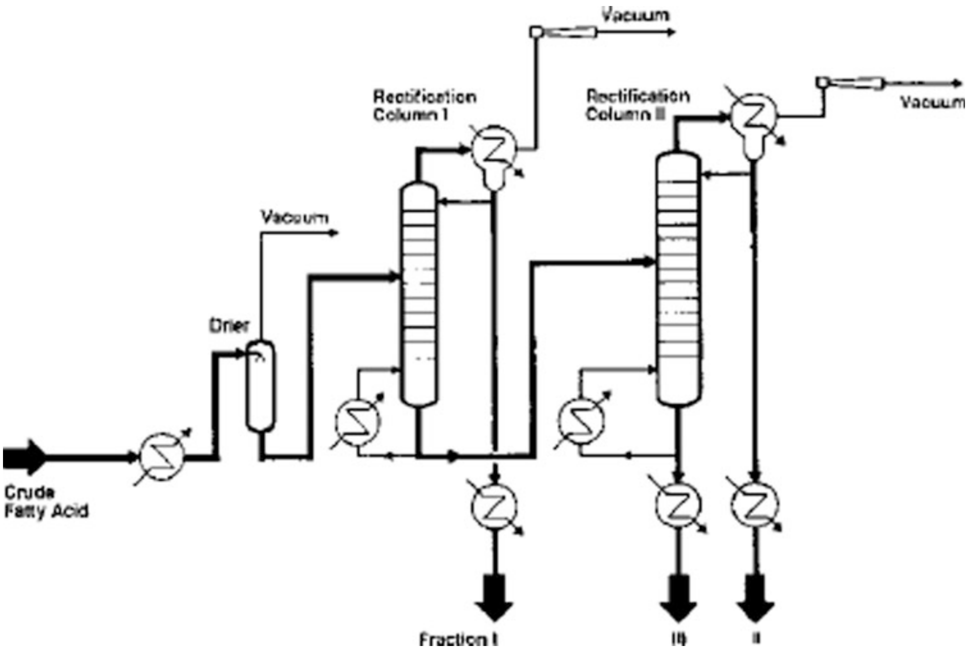


Fig. 36.16 Fatty acid fractionation (*Courtesy Lurgi GmbH, Frankfurt am Main, Germany*)

fatty acids. In such cases, the melting points vary considerably with the degree of unsaturation and this property is used for their separation via a number of industrial processes [26, 27].

Distillation. Straight distillation is used for the removal of low-boiling (top cuts) and high-boiling (pitch or bottoms) impurities from the crude split fatty acid stock. The distillation can be done either in a batch or a continuous manner. Generally batch distillation is employed for small-capacity manufacturing; continuous distillation is utilized for large-scale manufacturing and is highly automated (Fig. 36.15) [12].

The split fatty acid (deaerated and preheated) is sent to a distillation column (Fig. 36.15) where it is vaporized rapidly by flowing over heated trays under high vacuum (10 mbar) with the addition of live steam (for fatty acid circulation and reduction of the partial pressure). The high boilers are removed by two stages of entrapment: the high boilers and bottoms from the distillation column pass through additional heated trays and a reboiler section to vaporize residual fatty acids from the bottoms; the light end condenser traps the low boilers and the distilled product. The heavy "bottoms" distillate is collected at the bottom section of the still.

The distillation process is not used for the narrow-cut fractionation. However, by passing a second time through the distillation tower the main-cut distillates may be separated into a light and heavy fraction; the light end is collected at the top products section and the heavy end is collected at the bottom residue section of the still. The separation of light and heavy fractions in the first pass is possible for high lauric-type split fatty acids, for example, coconut and palm kernel fatty acids where the lower molecular weight C_6–C_{10} fraction is "topped" from the heavier C_{12}–C_{18} fraction.

The operation of a Lurgi fatty acid distillation system [12] proceeds as follows. The crude fatty acid is dried and degassed under vacuum. This dried and deaerated crude fatty acid is pumped into the distillation chamber (vacuum of 10–12 mbar) that is divided into 5–10 chambers by vertical plates. Each chamber is equipped with a heating element and a baffle. Live steam is passed into the system to effect recycling of the liquid between the heating elements and the baffles by the principle of an air-lift pump. The fatty acid is sprayed on the baffles as a fine mist to allow it to evaporate easily; non-vaporized liquid is recycled from the bottom. The fatty acid passes through each chamber, from which it is discharged continuously. The fatty acid vapor is condensed in the surface condensers. Typical yields from the fatty acid distillation process are:

Tops or head cut	1–5%
Refined product	85–91%
Residue	7–11%

Fractionation. The separation of individual components of a fatty acid mixture into high purity fractions (98% +) is achieved by fractional distillation. In a continuous fractionation still the fractionation column can be equipped with trays, in the "Thormann" system, or with the traditional packing to effect contact between the upward-moving vapors and the downward-flowing condensing liquid states.

A typical high-efficiency fractionation system (Fig. 36.16) consists of one continuous straight distillation and one, or preferably two fractionation columns [12, 22, 23]. This system is very efficient for the separation of low-boiling fatty acid components [6, 12], a C_{12} fraction of 99.5% purity from coconut fatty acid or a C_{22} fraction of 95% purity from rapeseed fatty acid is readily obtained.

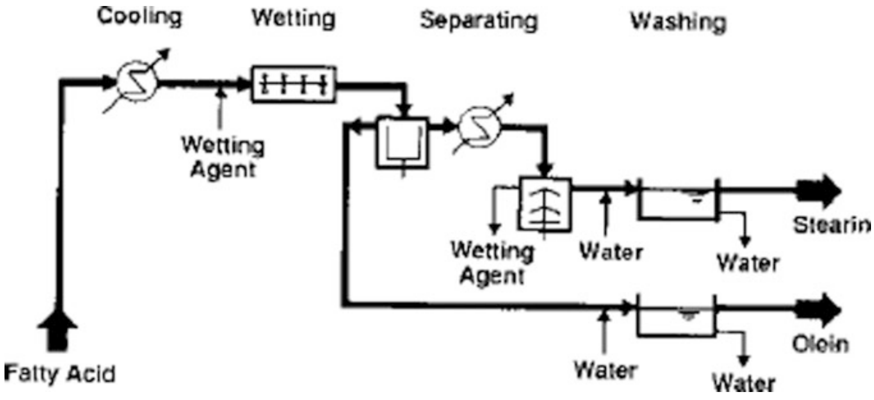

Fig. 36.17 Hydrophilization process for separation of olein and stearin (*Courtesy Lurgi GmbH, Frankfurt am Main, Germany*)

From an operational perspective, in rectification column 1 of Fig. 36.16, crude fatty acid is dried and vaporized with the addition of live steam under a vacuum of 8–40 mbar. A mixed fraction is withdrawn from the column top. The product from the bottom of column 1 is vaporized in rectification column 2 with live steam under a pressure of 6–8 mbar. The low-boiling fraction is collected in downstream scrubbers after the vapor has been condensed in surface condensers.

The separation scheme for coconut fatty acid is shown in Fig. 36.9. A variety of alternate fractionation schemes can readily be devised.

Fatty acid distillation has been done for over 100 years [22, 23]. However, most of the currently practiced art has originated in the past several years [24, 25]. The majority of the recent work falls in the following areas.

- Designs with gentle heating
- Improvements in the column design to reduce residence time
- Enhancements of system design to minimize pressure drops
- Demister designs for better air/effluent water pollution control

Special Separation Methods

The separation of long-chain saturated fatty acids (C_{16}–C_{18}) from the corresponding unsaturated fatty acids by distillation is not practical because of the proximity of their boiling points. However, both the melting points and the solubility (in organic solvents) of these two types of fatty acids are vastly different [28]. These properties are used to advantage for separating mixtures of saturated and unsaturated fatty acids into fractions that are rich in either saturated (stearin) or unsaturated (olein) components [26, 27].

$$\text{Tallow fatty acid} \xrightarrow{\text{separation}} \underset{(\text{Stearin})}{\text{Stearic acid}} + \underset{(\text{Olein})}{\text{Oleic acid}}$$

The following processes are used commercially for the separation of such fatty acids: mechanical pressing, solvent crystallization, and hydrophilization.

Mechanical Pressing. This method, also called panning or pressing, is the simplest and oldest method, and is still practiced in many developing countries. In this method, fatty acids are melted in shallow pans and then allowed to cool. The material transforms into a crystalline solid with a liquid phase trapped between the crystals of the solid phase. The liquid portion (olein) is pressed, or squeezed out by the application of mechanical force, separating it from the solid (stearin) component.

The pressing can be done by hydraulic presses in either a batch or a continuous mode. A multiple number of melting/crystallization/pressing cycles are utilized for obtaining fractions of increased purity:

$$\text{Tallow fatty acid} \xrightarrow{\text{first pass}}$$

$$\underset{(\text{stearicacid})}{\text{Single press}} \xrightarrow{\text{second pass}}$$

$$\underset{(\text{Stearicacid})}{\text{Double press}} \xrightarrow{\text{third pass}} \underset{(\text{Stearicacid})}{\text{Triple press}}$$

The unsaturation, as determined by the iodine value (IV), decreases from an IV of 10.0 for a single press to an IV of 1.0 for a triple press stearic acid grade.

Solvent Crystallization. Two processes, one utilizing acetone (Armor) and the other employing methanol (Emery), are well known. Using the latter, fatty acid is dissolved in 90% aqueous methanol in a 1:2 acid/solvent ratio by the application of heat. The resulting solution is then cooled to −15°C in a multi-tubular crystallization chamber equipped with scrapers for efficient heat transfer. The crystallized fatty acids are removed by filtration. The filter cake is melted and stripped

Table 36.2 US consumption of soap and synthetic detergent[a]

Year	Soap (MM lbs)	Synthetic detergent (MM lbs)	Total
1940	2,306	30	2,336
1950	2,882	1,443	4,325
1960	1,230	3,940	5,170
1970	1,050	5,650	6,700
1980	1,300	6,400	7,700
1990	1,625	9,000	10,625
1996	–	18,214[b]	0

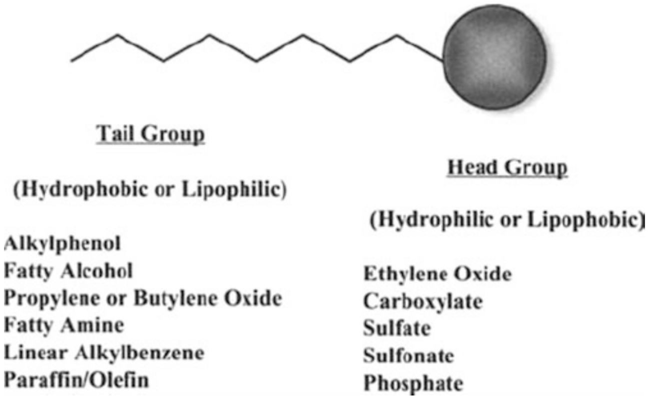

Fig. 36.18 Representation of surfactant amphipatic structure

of any residual solvent to yield the refined stearin fraction, and then the liquid stearin is converted to flakes or powder by a variety of processes, for example, chill roller, and the like. The mother liquor from the filtration is stripped to obtain the olein fraction. The separated stearin and olein fractions have a variety of commercial applications in both the chemical and food processing industries.

Hydrophilization Process. In this process, olein and stearin are separated by forming a suspension of the stearin moiety in water with the aid of a surfactant followed by filtration to remove the stearin (Fig. 36.17). The mixture of fatty acids is melted and then partially crystallized by cooling. The resulting slurry, which is a mixture of liquid olein and crystalline solid stearin, is mixed with water containing a wetting agent (sodium dodecylbenzene sulfonate, sodium lauryl sulfate). After mixing for a specified period, the slurry is centrifuged; the light fraction provides the liquid olein moiety, the middle fraction is a suspension of solid stearin in water and the lower fraction is a water/surfactant solution [12].

Synthetic Detergents

In the beginning there was soap, and soap was used for thousands of years to wash virtually everything. After the First World War, much of the European economy was destroyed. Edible fats and oils, the basic raw material for soap production, were in very short supply. Synthetic detergents were developed to replace soap but it was soon discovered that the new synthetic compounds were more surface active and provided better hard water tolerance and improved cleaning performance. The term "synthetic detergent" has been shortened to "syndets" to describe detergent compositions comprising surfactants, hard water control agents (builders), and other detergent additives. Since their introduction in the 1940s, synthetic detergents have continued to grow in both total volume and the percentage of detergent use as shown in Table 36.2.

Modern detergent products are complex mixtures of many different ingredients. Typical formulations consist of surfactants, builders, and other additives designed to maximize performance for the consumer while maintaining reasonable raw material and manufacturing costs. Typical detergent formulations contain multiple surfactant types to optimize performance and product stability [29, 30]. Performance additives such as bleaches, bleach activators, enzymes, enzyme stabilizers, antiredeposition polymers, fluorescent whitening agents, dye transfer inhibitors, and fabric softeners are commonly used to increase overall performance. Regardless of the product format or formulation type, surfactants play a critical role in the cleaning process.

Characteristic Features of Surfactants

Surfactants have a characteristic molecular structure consisting of one structural unit that has very little attraction for the solvent (lyophobic group) combined with a group that has a strong attraction for the solvent (lyophilic group). This duality is known as an amphipathic structure. When a surfactant is dissolved in a solvent, the presence of the lyophobic group distorts the solvent liquid structure, resulting in an unfavorable increase in the Gibbs free energy of the system. This acts to force the molecules out of solution in an attempt to decrease the free energy of the system. However, the presence of the lyophilic group prevents the surfactant from being completely expelled from the solvent. The opposing forces give the surfactant molecule their surface active properties. In aqueous solution, the lyophilic group is known as the hydrophile and the lyophobic group is called the hydrophobe.

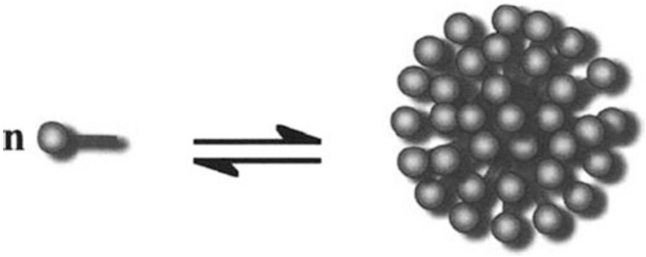

Fig. 36.19 Micelle formation in aqueous solution

Table 36.3 Typical HLB values for different applications

HLB range	Typical application
1–3	Reverse micelles
3–6	W/O emulsifier
7–10	Wetting agent
8–18	O/W emulsifier
11–15	Detergent
>15	Solubilizing agent

Surfactant molecules are typically depicted using a stick and ball representation as shown in Fig. 36.18. The stick portion represents the hydrophobic group or "tail" whereas the ball represents the hydrophilic "head group." Examples of common hydrophobes include alkylphenol, fatty alcohol, paraffin, olefins, and alkylbenzene. Examples of common hydrophiles include ethylene oxide (EO), sulfates, sulfonates, phosphates, and carboxylic acid groups. Depending on the charged nature of the head group, surfactants are classified as:

1. Anionic. The head group bears a negative charge. Examples: linear alkylbenzene sulfonate (LAS), AS, alkyl ether sulfonate (AES), PE, alpha olefin sulfonate (AOS), methyl ester sulfonate (MES)
2. Cationic. The head group bears a positive charge. Examples: cetyl trimethyl ammonium chloride (CTAB), cetyl pyridium chloride (CPC), hydroxyethyl quat (HEQ), benzalkonium chloride (BAC)
3. Zwitterionic. The head group has either a positive or negative charge depending on solution pH. Examples: betaines, amine oxides, amine propionates, amphoacetates
4. Nonionic. The head group bears no formal ionic charge. Examples: AE, alkyl phenol ethoxylate (APE), alkyl polyglycoside (APG), EO/PO Block Copolymers, ethoxylated methyl esters (MEEs)

Aside from their ability to adsorb at interfaces, the most important aspect of surfactants is their ability to form colloidal-sized aggregates in solution. In dilute solution, the surfactant is present as individual molecules. Increasing the concentration promotes the formation of surfactant aggregates or "micelles" as shown in Fig. 36.19. The concentration at which micelles start to form is referred to as the critical micelle concentration (CMC). Micelle formation is an important phenomenon because interfacial effects such as detergency and solubilization depend on the existence of micelles in solution. Over the years, the term "surface active agent" has been shortened to "surfactant."

Surfactant molecules can be tailored for use in either aqueous or nonaqueous systems, depending on their solubility characteristics. The most common way to describe surfactant solubility is the hydrophile–lipophile balance (HLB). In the HLB method, a number is assigned (0–40) related to the balance between the water-loving (hydrophile) and lipid-loving (lipophile) portions of the molecule. In some cases the HLB number is calculated from the structure of the molecule, in others it is based on experimental emulsification data. In general, there exists an optimum HLB for different applications as shown in Table 36.3. Matching the HLB of the surfactant to that of the application generally gives the best performance.

For example, alkylbenzene is slightly surface active in nonaqueous media but is insoluble in water. Addition of a single SO_3H group to the molecule imparts solubility and excellent surfactant characteristics in water but insolubility in petroleum solvents. If alkylbenzene is di- or trisulfonated, the compound becomes more and more water-soluble and loses much of its surface activity. In both cases, the hydrophile balance is exceeded with insufficient lipophilic influence to cause micelle formation. However, neutralization of the SO_3H group of a highly water-soluble alkylbenzene sulfonic acid with a long chain amine produces an effective nonaqueous surfactant. A similar effect of decreasing water solubility and increasing nonaqueous detergency can be achieved by increasing the alkylbenzene carbon chain length from C_{12} to C_{18} or higher.

Commercially available surfactants typically consist of a complex mixture of homologues. For instance, "lauryl sulfate" is a generic designation for a mixture of sulfates whose largest fraction is derived from the C_{12} alcohol but also contains higher and lower alkyl chain lengths. The homologue distribution depends upon the alcohol source and degree of fractionation. Alcohol ethoxylates are also complex mixtures of homologues. Not only is there a distribution of different alkyl chain lengths, but EO adds to the alcohol according to a normal distribution of adducts. Although it might seem that highly purified products would show a competitive advantage, mixtures are frequently more effective than pure compounds.

Raw Materials for Surfactant Production

Surfactants are produced by various chemical routes, using either natural or synthetic raw materials as shown in Fig. 36.20. Natural raw materials include fats and oils

Fig. 36.20 Raw materials for surfactant production

derived from vegetable and animal sources. Synthetic raw materials include coal, crude oil, and natural gas. Regardless of their origin, raw materials are chemically modified to produce a wide variety of surfactant intermediates. Because chemical processing is required to produce the surfactant intermediate, the distinction between natural and synthetic is a bit fuzzy. In general, raw material prices increase with the number of processing steps.

The current world production of fats and oils is around 65 MM metric tons of which 30% is from animal sources and 70% is of vegetable origin. Fats and oils are composed of long chain fatty acid esters of glycerin called triglycerides. Plant-derived oils are composed of fatty acids with an even number of carbon atoms from 8 to 22 and can be either saturated or unsaturated. Oils with a high content of C_{12} and C_{14} fatty acids are most commonly used by the detergent industry and are readily obtained from coconut and palm kernel. Other important oils include soya, rapeseed, and palm stearin, The most important animal fats are lard and tallow which are rich in C_{16} and C_{18} fatty acids. The carbon chain distributions of common fats and oils are shown in Table 36.4.

Common natural-based raw materials for surfactant production include fatty acids and methyl esters. After purification to remove phospholipids and sterols, fats and oils are treated with alkali to produce soap which is acidified with inorganic acids to give the corresponding fatty acid. To produce methyl esters, fatty acid can be reacted with methanol. Alternatively, the oil is treated with methanol using a base catalyst to give the corresponding methyl ester. Both processes generate one mole of glycerin for every three moles of fatty acid or methyl ester.

Common synthetic-based raw materials for surfactant production include ethylene, and propylene. Crude oil consists of a complex mixture of long chain hydrocarbons and aromatic molecules. Natural gas is a mixture of short chain hydrocarbons rich in methane, ethane, propane, and butane. The exact composition of both depends on its source and how it has been processed. Ethylene and propylene are produced by thermal or catalytic cracking of natural gas or aromatic rich petroleum streams.

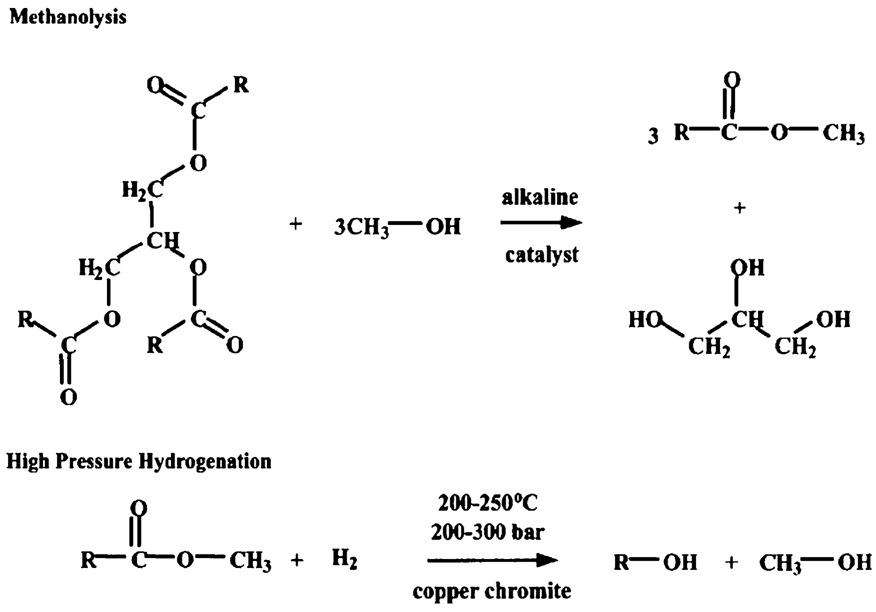

Fig. 36.21 Methyl ester process for production of natural fatty alcohols

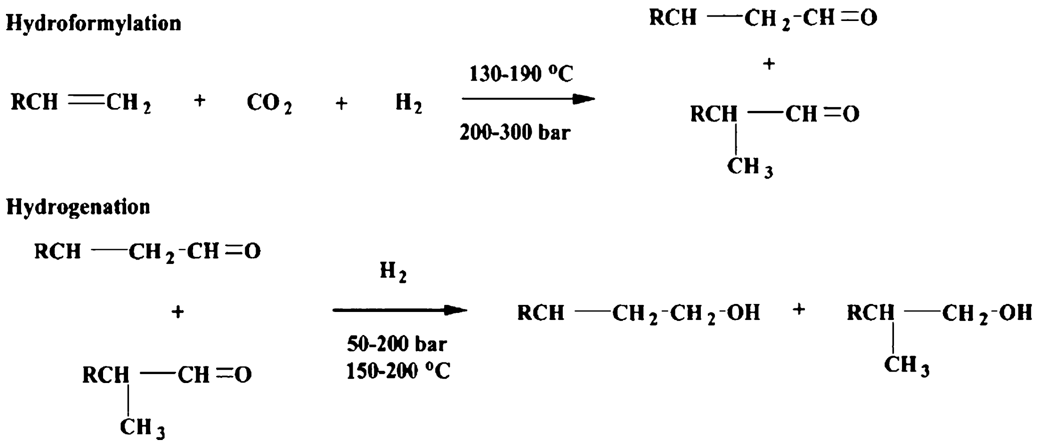

Fig. 36.22 Oxo-process for production of synthetic fatty alcohols

Intermediates for Surfactant Production

Fatty Alcohols. Surfactant raw materials and intermediates are used to produce a wide variety of different surfactant types. One of the major factors leading to the development of modern synthetic detergents was the industrial manufacture of fatty alcohols. This was first achieved in Germany in the 1930s using the sodium reduction process. Although this process was commonly used until the 1950s, it has been largely replaced by less costly processes. Today, there are three important technical processes for the manufacture of detergent grade fatty alcohols: high-pressure hydrogenation, the Ziegler process, and the oxo-synthesis [31].

The most important process for the manufacture of natural fatty alcohols is the high-pressure hydrogenation of fatty acids or their corresponding methylesters. Common raw materials for the production of detergent-range alcohols include coconut, palm kernel, palm stearin, soya, tallow, and lard. In the methyl ester process, the crude oil is reacted with an excess of methanol at 50–70°C to give three moles of methyl ester and one mole of glycerin as shown in Fig. 36.21. The reaction can be accelerated using sodium methoxide as a catalyst. The glycerol separates at the bottom of the reactor after an appropriate reaction time. The transesterification is complete when the methylester no longer contains glycerol.

The hydrogenation reaction is run at 200–350°C and hydrogen pressures of 250–300 bar using an appropriate catalyst. A variety of different metal oxide catalysts can be used; however, copper chromite is the most common. Under these relatively extreme reaction conditions, the ester group is reduced to the primary alcohol. Any unsaturation in the

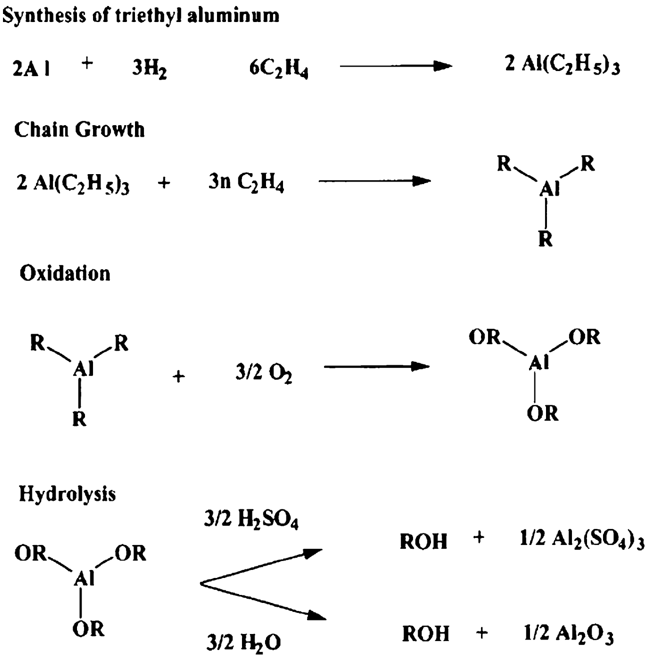

Fig. 36.23 Ziegler process for production of synthetic fatty alcohols

starting raw material is also destroyed under these conditions although it is possible to produce unsaturated fatty alcohols using various zinc catalysts. A number of different process designs have been developed including the fixed bed, the trickle bed, and the suspension process which differ primarily in the way in which the catalyst contacts the feedstock.

The oxo-process is based on petrochemical feedstocks. The oxo- or hydroformylation reaction was first discovered in Germany in the late 1930s, but was not used commercially until 1948, by what is now Exxon Chemical. The oxo-process uses α-olefins obtained from oligomerization of ethylene, which are reacted with carbon dioxide and hydrogen at 200–300 bar and 130–190°C, to give a mixture of linear and branched aldehydes as shown in Fig. 36.22. The resulting aldehydes are hydrogenated at 50–200 bar pressure and 150–200°C using copper, zinc, or nickel catalyst to give the primary alcohol. Oxo-alcohols contain both even and odd carbon numbers and are more highly branched than natural or Ziegler alcohols. Using a conventional cobalt catalyst, the amount of branching exceeds 50%.

The Ziegler process based on chemistry discovered in the 1950s produces linear primary alcohols with an even number of carbon atoms. The main reaction steps are shown in Fig. 36.23. Aluminum metal is reacted with hydrogen gas and ethylene to form triethyl aluminum which is then reacted with additional ethylene to form trialkyl aluminum using a one-step or two-step process. In practice, the one-step process yields more by-products and is seldom used. The distribution of chain lengths follows a Poisson distribution with only slight deviations due to competing side reactions. The aluminum alkyls are oxidized to the corresponding alkoxides using dry air and hydrolyzed using water or sulfuric acid to yield fatty alcohol. The Ziegler process produces alcohol similar to that obtained from natural sources.

Olefins. Olefin is a key surfactant intermediate produced by thermal or catalytic cracking of paraffin or alternatively from oligomerization of ethylene. Olefins suitable for surfactant production are primarily linear with either terminal (α-olefins) or internal (i-olefins) double bonds.

Thermal cracking is not very selective and produces a mixture of products including *n*-olefin, i-olefin, di-olefin, aromatics, and paraffin wax. The major challenge associated with the cracking process is separation of the desired olefins from the other by-products.

Since the mid-1960s, *n*-paraffins have been used as starting materials for the manufacture of *n*-olefins. Today, *n*-paraffins are obtained from the distillation of paraffin rich oils with the use of molecular sieves.

The PACOL® process (paraffin conversion to olefin) produces *n*-olefins by dehydrogenation of paraffin over a heterogeneous platinum catalyst. The Pacol process is more selective than thermal cracking and produces smaller amounts of by-products.

Oligomerization of ethylene can be performed in a number of different ways. Reaction of ethylene with triethyl aluminum using the Ziegler process produces normal olefins by a three-step process. The first step consists of reacting ethylene with triethyl aluminum to give long chain trialkyl aluminum. Transalkylation of the trialkyl aluminum with ethylene (Alfol process) or a long chain olefin (Ethyl process) produces a mixture of olefins and regenerates the triethyl aluminum. The third step consists of separating the olefin from the undesired by-products.

Another commercial process to produce *n*-olefins is based on the Shell Higher Olefins Process (SHOP). The oligomerization reaction is carried out on a nickel phosphine complex which is separated and recycled by means of a solvent. The reaction product consists of α-olefins and i-olefins of different carbon chain lengths.

Recently there has been renewed interest in the use of the Fisher–Tropsch process to produce olefins. The process is named after F. Fischer and H. Tropsch, the German coal researchers who discovered it in 1923. Detergent-range olefins are produced by treating white-hot coal with a blast of steam to produce syngas, a mixture of carbon monoxide and hydrogen. Syngas is reacted in the presence of an iron or cobalt catalyst to produce a mixture of products including methane, synthetic gasoline, olefins, and waxes.

Ethylene and Propylene Oxide. Ethylene oxide (EO) and propylene oxide (PO) are commonly used raw materials for surfactant production. Both are highly reactive compounds

[b]Including lignin, petroleum sulfonates, and tall oil derivatives

that will react with alcohols, amines, carboxylic, and water. EO and PO will also self-polymerize to form high-molecular-weight polymers.

Ethylene oxide has been produced commercially by two basic routes: the ethylene chlorohydrin and direct oxidation processes. The chlorohydrin process was first introduced during World War I in Germany by BASF. The process involves the reaction of ethylene with hypochlorous acid followed by dehydrochlorination of the resulting chlorohydrin with lime to produce EO and calcium chloride. This process has now been replaced by direct oxidation which utilizes the catalytic oxidation of ethylene with oxygen over a silver-based catalyst.

PO is produced by one of the two commercial processes: the chlorohydrin process or the hydroperoxide process. The chlorohydrin process involves reaction of propylene and chlorine in the presence of water to produce the two isomers of propylene chlorohydrin. This is followed by dehydrochlorination using caustic or lime to produce PO and salt. The hydroperoxide process involves oxidation of propylene to PO by an organic hydroperoxide.

Alkylbenzene. Alkylbenzene is an intermediate for the production of alkylbenzene sulfonate (ABS). Alkylbenzene consists of a mixture of phenyl substituted *n*-alkanes of 9–14 carbon atoms. Prior to 1965, alkylbenzene was synthesized from propylene tetramer, obtained by oligomerization of propylene. The resulting “hard” alkylate was a highly branched chain compound. However, the slow biodegradability of propylene tetramer-based materials soon became apparent and by 1965, most of the detergent industry had switched over to linear alkylbenzene. Extensive research has demonstrated biodegradation effectiveness in sewage treatment plants in excess of 95% [32–35].

Today, there are two main routes for producing linear alkylbenzene as shown in Fig. 36.24. The most prevalent route to alkylbenzene uses partial dehydrogenation of paraffins, followed by alkylation of benzene with a mixed olefin/paraffin feedstock using liquid hydrogen fluoride (HF), aluminum chloride ($AlCl_3$), or solid alkylation (DETAL) catalyst. A second older process, which has largely been discontinued, uses partial chlorination of paraffins, followed by alkylation of the chloroparaffin feedstock in the presence of an aluminum chloride catalyst. Distillation is used in all the processes to separate alkylation reaction products into the targeted detergent alkylate homologue distribution. A coproduct stream of high molecular weight linear alkylbenzene and dialkylbenzene is also produced for use in lubricant detergents and industrial applications.

Products with low 2-phenyl isomer content (13–22%) are produced by HF alkylation of internal olefins obtained from paraffin dehydrogenation. High 2-phenyl products (25–35%) are produced using $AlCl_3$ or solid alkylation catalyst (DETAL). Super high 2-phenyl (>80%) products have been reported in the literature using shape-selective catalysts, but are not commercially produced at this time. Generally, high 2-phenyl products are preferred for use in liquid detergents due to increased solubility. Low 2-phenyl products are typically used in powder detergents but can be used in liquid formulations with the appropriate choice of hydrotrope.

Alkylphenol. Alkylphenol is a common surfactant intermediate used to produce alkylphenol ethoxylates. Phenol reacts with an olefin thermally without a catalyst but with relatively poor yields. Catalysts for the reaction include sulfuric acid *p*-toluene sulfonic acid (PTSA), strong acid resins, and boron trifluoride (BF_3). Of these, strong acid resins and BF_3 are mostly widely used for the production of surfactant-grade alkylphenols. The most common alkylphenols are octylphenol, nonylphenol, and dodecylphenol. Mono nonylphenol (MNP) is by far the most common hydrophobe. It is produced by the alkylation of phenol with nonene under acid conditions. All commercially produced MNP is made with nonene based on propylene trimer. Because of the skeletal rearrangements that occur during propylene oligomerization, MNP is a complex mixture of branched isomers.

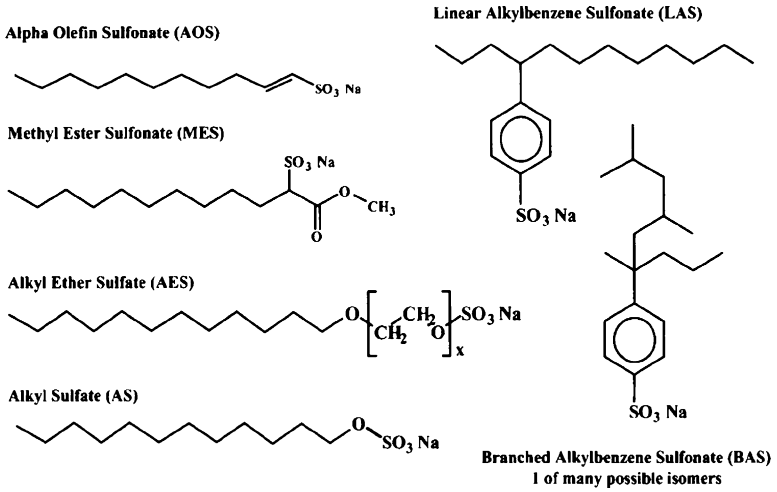

Fig. 36.25 Common anionic surfactants

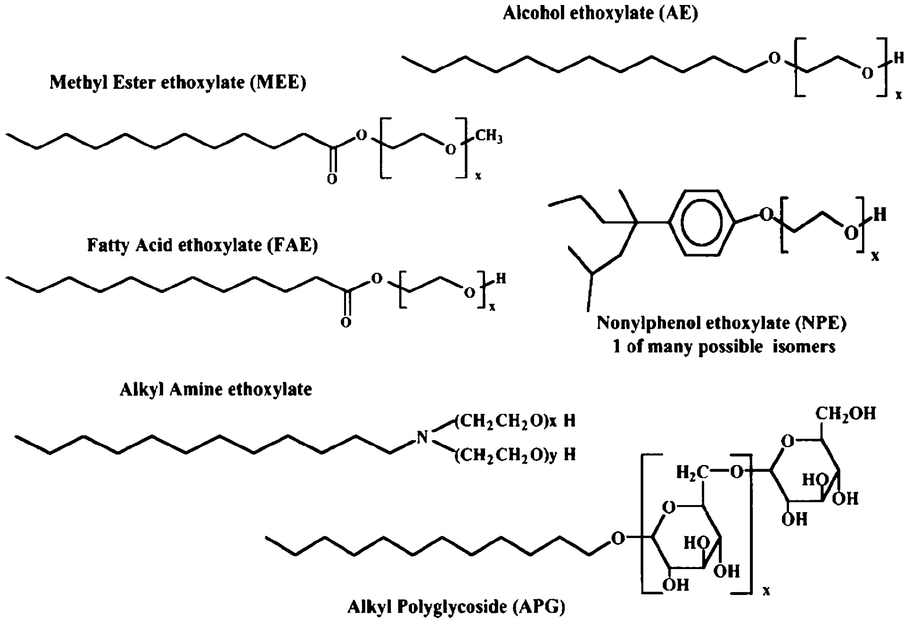

Fig. 36.26 Common nonionic surfactants

Fatty Amines. A variety of different fatty amines is used as intermediates for surfactant production. Primary amines are used to prepare alkoxylated amines. The primary amine is produced by reacting fatty acid with ammonia to form the nitrile followed by hydrogenation. Tertiary amines are used as an intermediate for producing betaine, amine oxide, and HEQ. The tertiary amine is produced by reacting olefin with HBr followed by substitution with dimethylamine.

World Surfactant Consumption

The worldwide consumption of surfactants in 2003 is shown in Table 36.5. In many parts of the world, soap is still the primary surfactant for textile washing and personal care. Synthetic detergents are widely used in the devolved regions of the world including North America, Western Europe, and Japan. Anionic surfactants dominate the world surfactant market. Common anionic surfactants include LAS, AS, and AES. The second largest class of surfactants is the nonionics of which AE and APE are most common. The use of APE is in decline because of concerns with biodegradability and endocrine disruption. Quats are commonly used in antibacterial formulations because of their ability to lyse the cell membrane of harmful bacteria and pathogens. Amphoterics are typically used in personal care products because they are relatively mild to the skin compared to typical anionics. The molecular structure of

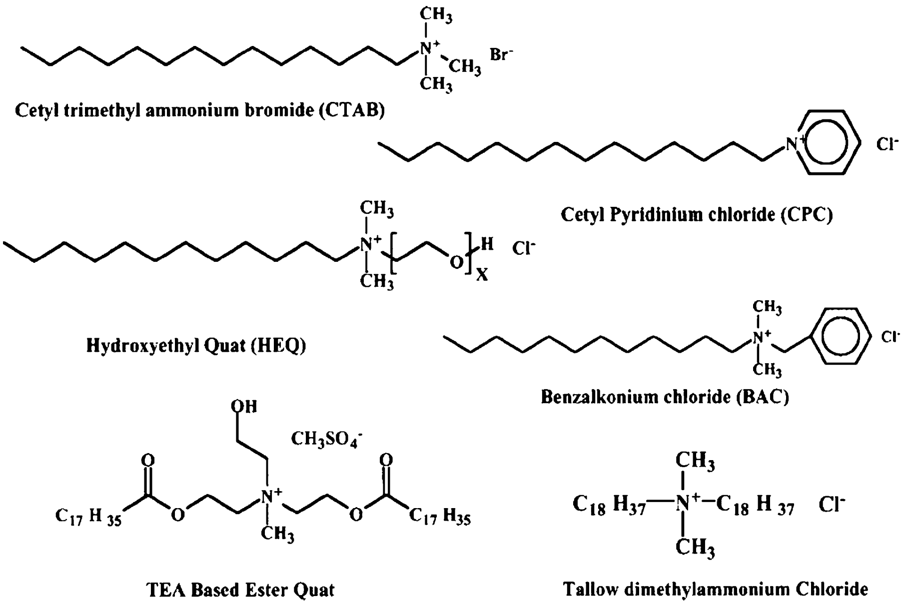

Fig. 36.27 Common cationic surfactants

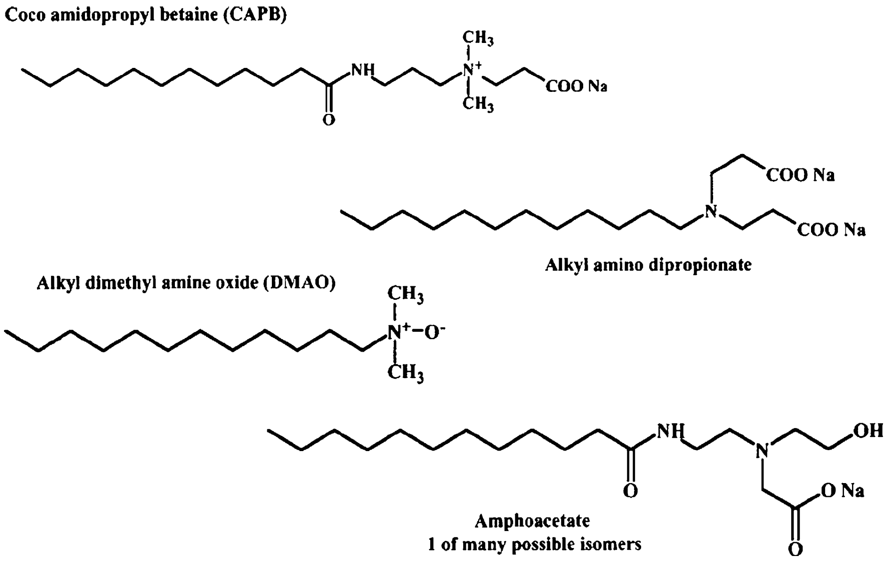

Fig. 36.28 Common amphoteric/zwitterionic surfactants

common surfactant types is shown in Figs. 36.25, 36.26, 36.27, and 36.28.

Anionic Surfactants

Alkylaryl Sulfonates. ABS has been the workhorse of the detergent industry for more than 40 years and accounts for approximately 50% of the total synthetic anionic surfactant volume. LAS has largely replaced branched alkylbenzene sulfonate (BAB) in most parts of the world due to its superior biodegradability. Products are typically sold as the free acid or neutralized with a strong base such as sodium hydroxide to give concentrated slurry, typically referred to as "paste." The major use of paste is in the production of spray-dried powder detergents. Paste can also be drum-dried to a powder or flake, or spray dried to light-density granules. Dried forms of LAS are used primarily for industrial and institutional cleaning applications.

To be useful as a surfactant, alkylbenzene must first be sulfonated. Oleum and sulfur trioxide (SO_3) are commonly used for sulfonation, with the latter growing in popularity in recent years. Oleum sufonation requires relatively inexpensive equipment and can be run as batch or continuous processes. However, the oleum process has major disadvantages in terms of cost compared to SO_3; the need for spent acid stream disposal and the potential corrosion problems due to sulfuric acid generation. The chemical reactions involved in oleum sulfonation are shown in Fig. 36.29. The oleum

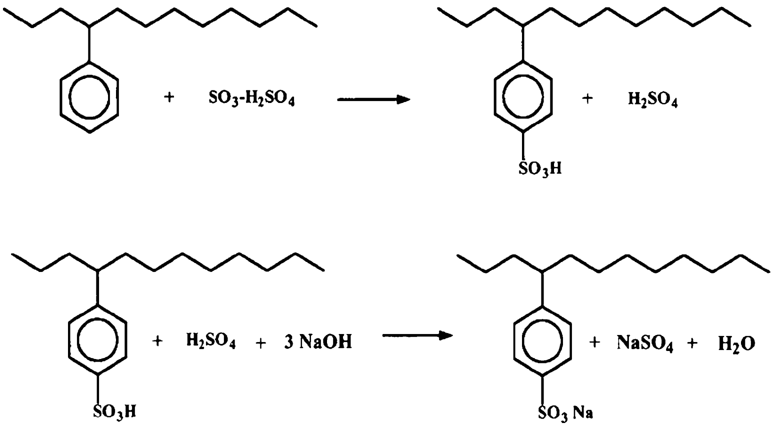

Fig. 36.29 Oleum sulfonation process

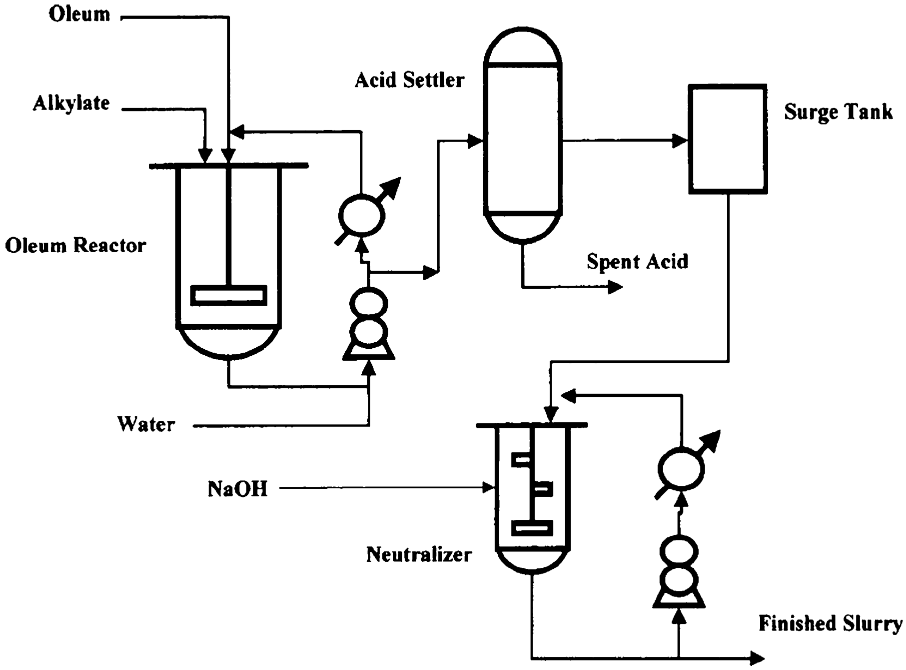

Fig. 36.30 Batch oleum sulfonation process

process typically yields around 90% ABS, 6–10% sulfuric acid, and 0.5–1% unsulfonated oils.

A typical batch oleum sufonation process is shown in Fig. 36.30. There are four basic unit operations prior to neutralization: sulfonation, digestion, dilution, and phase separation. In the sulfonation stage, alkylbenzene and oleum are mixed under an inert atmosphere. The sulfonation reaction is highly exothermic and heat removal is achieved by reactor jacketing and/or recirculating heat exchanger loops. Key variables in controlling the extent of reaction and product color are the temperature, acid strength, reaction time, and the ratio of oleum to alkylate. The product leaving the sulfonation zone is digested 15–30 min to allow for reaction completion. Following digestion, the mixture is diluted with water to quench the reaction. The reaction product is then fed to a separator to allow for gravity settling of the spent sulfuric acid layer from the lighter sulfonic acid. The separation time is dependent upon the separator vessel configuration, sulfonic acid viscosity, temperature, and the degree of aeration in the feed streams.

The gaseous air/SO_3 sulfonation process normally generates a product composed of 95–98% ABS, 1–2% sulfuric acid, and 1–2.5% unsulfonated oils. Although the initial capital costs are much higher than those for an oleum process, relative sulfonic acid yields and spent acid disposal costs are substantially lower. The chemical reactions involved in air/SO_3 sulfonation are shown in Fig. 36.31. The SO_3 sulfonation reaction differs from oleum in that the crude reaction product consists of a mixture of ABS and anhydride. At the end of the reaction, the anhydride is reacted with water to produce two moles of sulfonic acid.

A typical continuous air/SO_3 sulfonation process is shown schematically in Fig. 36.30. Sulfur trioxide is produced from vaporization of liquid SO_3 or generated on-site

Fig. 36.31 Sulfur trioxide sulfonation process

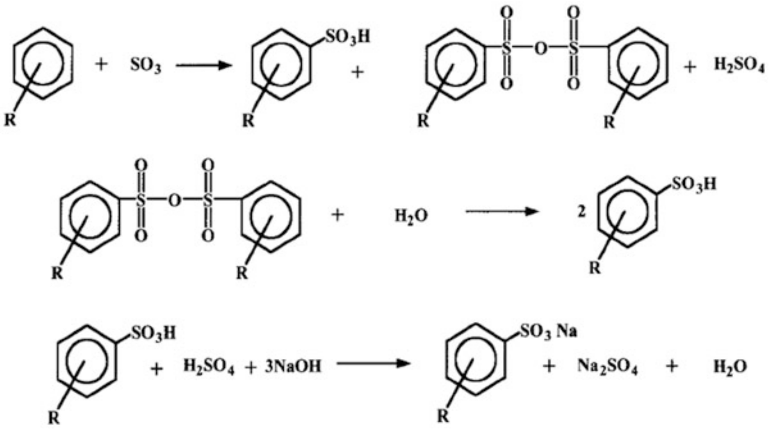

Fig. 36.32 Alkylbenzene sulfonation process

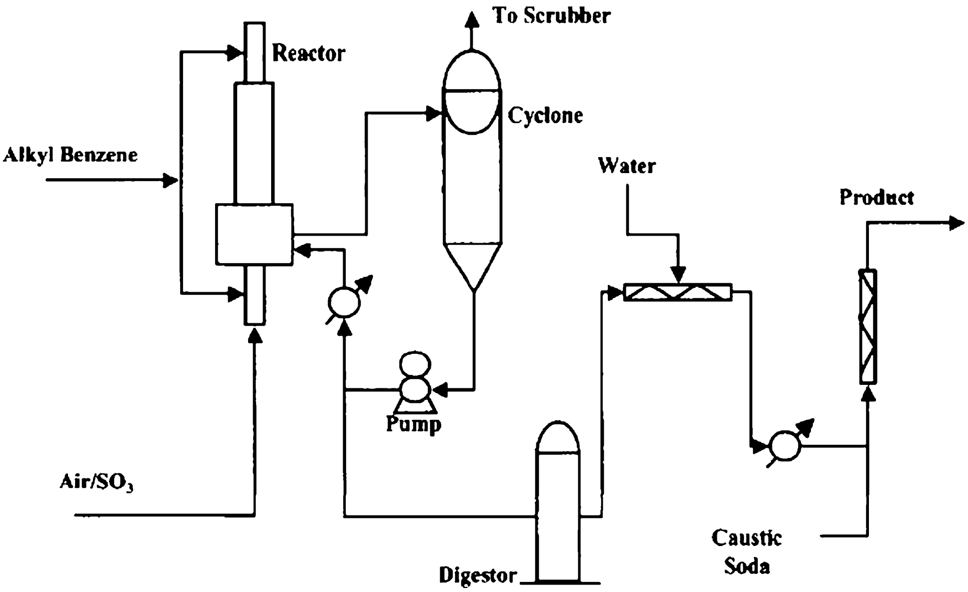

by burning sulfur and then catalytically converting SO_2 to SO_3 over a vanadium catalyst. Increased shipping regulations and sensitivity to storage of the highly hazardous liquid SO_3 has increased the trend toward on-site sulfur trioxide generation. The vaporized SO_3 is diluted to 4–8 weight percent in dry air prior to entering the sulfonation reactor. Air serves as both a diluent and heat sink for the highly exothermic sulfonation process. In the sulfonation reactor, the molar ratio of SO_3/alkylate is controlled between 1.03 and 1.0 to achieve optimum conversion to sulfonic acid without increased side reaction or color degradation.

The Chemithon [12, 13], Ballestra [15], and Mazzoni [36, 37] reactor designs each have unique falling film designs to provide intimate mixing of the alkylate and the air/SO_3 streams. The reactor temperature is controlled between 110 and 150 °F, depending on the desired production rates and product quality requirements. The digestion and hydrolysis temperatures are controlled between 110 and 125 °F. During hydrolysis, approximately 2 parts of water per 100 parts of reaction product are added to convert acid anhydrides to sulfonic acid. Both the oleum and SO_3 sulfonation processes are quite exothermic and almost instantaneous. In order to prevent decomposition and maintain optimum product color, an efficient reactor heat removal system is necessary (Fig. 36.32).

The Chemithon Corporation has patented a novel venture reactor [38, 39]. The organic to be sulfonated is injected into a stream of gas containing SO_3 at a venture. The reaction mixture is quenched and recycled downstream until sulfonation is complete. The reactor design can be used for highly viscous, high molecular weight specialty surfactants for industrial applications such as lubrication oil additives.

Cold sulfonation is also practiced using SO_2 as a solvent and refrigerant [40, 41]. The product color is extremely good due to the low reaction temperature and rapid removal of the reaction exotherm via SO_2 vaporization. Equipment consists of fairly simple glass-lined reactors equipped with gaseous SO_2 recovery. Purging of SO_2 from the reaction product and control of SO_2 recovery are key to achieving a high-quality

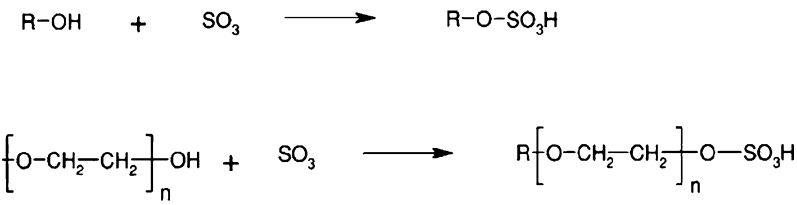

Fig. 36.33 Sulfation of alcohols and alcohol ethoxylates

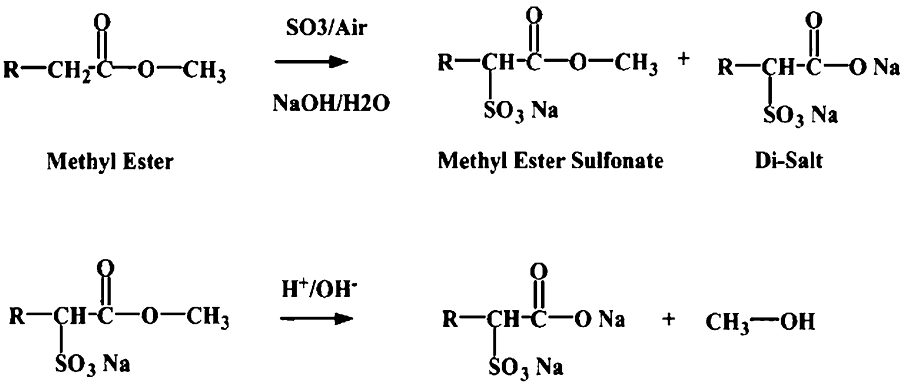

Under acid or alkaline conditions, MES will hydrolyze to di-salt

Fig. 36.34 Synthesis of methyl ester sulfonates

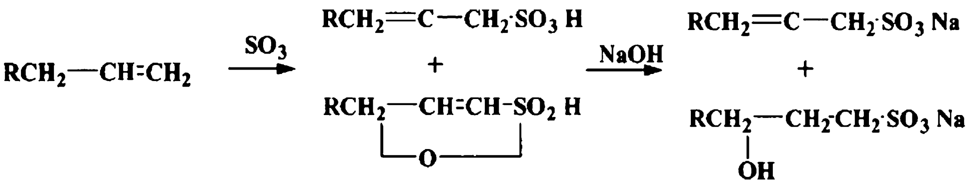

Fig. 36.35 Synthesis of α-olefin sulfonates

product. As in the case of air/SO_3 sulfonation, this process can be used to produce all detergent-grade surfactants including alkylbenzene, alcohol, and alcohol ethoxylates.

Neutralization of sulfonic acid is similar regardless of sulfonation process. ABS acid can be neutralized with an aqueous solution of NaOH, KOH, NH_4OH, or amines. Sodium salts are commonly used in spray-dried powders for household laundry detergents. Ammonium and amine salts are commonly used in light-duty liquid (LDL) detergents and in high foaming personal care products such as hair shampoos and body wash. ABS acid can also be processed to a dry powder form by in situ neutralization with a base salt, such as sodium carbonate. The neutralized sodium salt can be dry blended with other detergent additives to produce a free flowing powder detergent (Fig. 36.33).

Alkyl and Ether Sulfates. The second largest class of anionic surfactants is sulfated alcohols and ethoxylates. Falling film reactors are also used to sulfate these materials, however, cooling water and sulfation temperature are adjusted to lower values for these materials. The digestion and hydration steps are not required in sulfation and these systems are bypassed. The acids are neutralized immediately to minimize degradation and side reactions in storage. Typical SO_3 sulfation reactions for alcohols and alcohol ethoxylates are shown in Fig. 36.31.

Methyl Ester Sulfonates. MESs are an old product whose time may be coming. MES is produced by reacting detergent-range methyl esters with SO_3 to produce a mixture of α-sulfonated methyl ester and di-salt as shown in Fig. 36.34. The crude product is highly colored and must be bleached to produce acceptable products.

Alpha Olefin Sulfonates. The direct reaction of alpha-olefins with a strong sulfonating agent yields a mixture of alkane sulfonates, hydroxyllalkane sulfonates, and disulfonated products. These are known commercially as AOS. AOS manufacture is generally more complex than ABS because

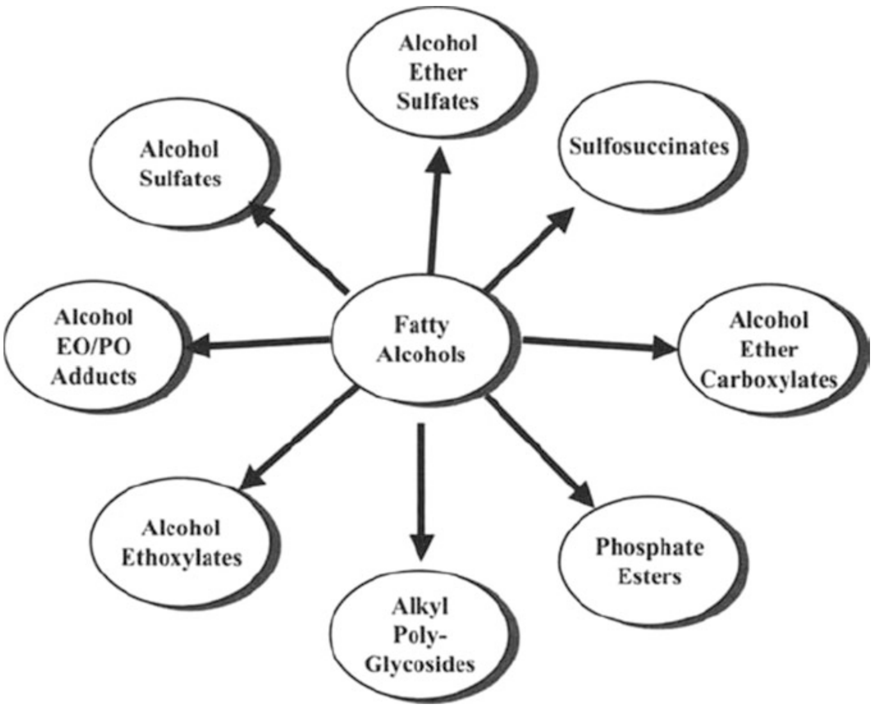

Fig. 36.36 Surfactants obtained from fatty alcohols

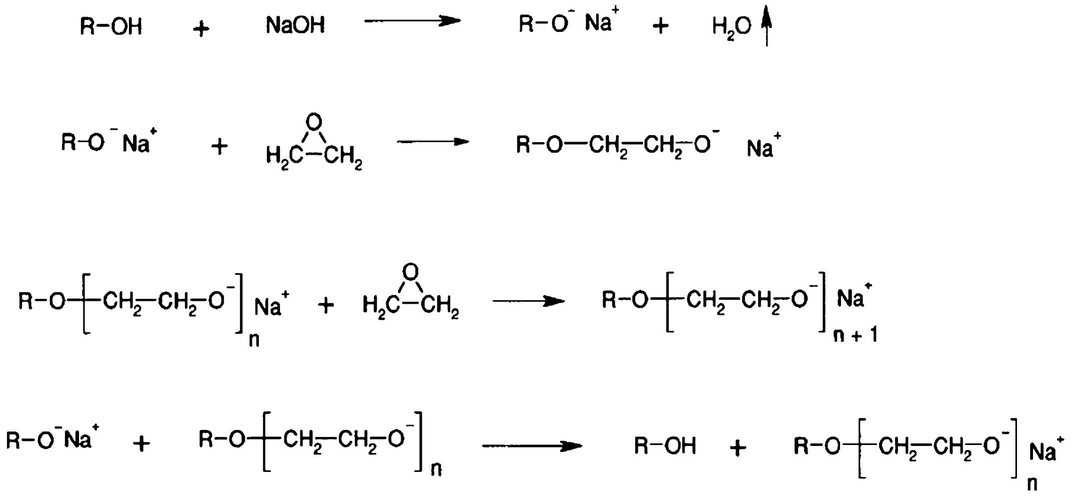

Fig. 36.37 Fatty alcohol ethoxylation chemistry

the initial reaction product is a mixture of sultones as shown in Fig. 36.35.

Nonionic Surfactants

Nonionic surfactants are increasingly popular active ingredients. The majority of nonionic surfactants are ethylene or propylene oxide derivatives of alkylphenols or fatty alcohols, although fatty acids, fatty amines, and alkanolamides are also used. In general, one ethylene oxide unit is required to solubilize each methylene unit in the hydrocarbon tails. By changing the ratio of ethylene oxide to fatty groups, the nature of the surfactant can be modified from oil-soluble to water-soluble products. This versatility makes applications possible in numerous areas, such as detergents, agricultural products, corrosion resistance, emulsion polymerization, textile applications, and de-inking to name a few.

Fatty alcohols are one of the most useful intermediates for the production of nonionic surfactants, some of which are listed in Fig. 36.36. A detailed discussion on all the

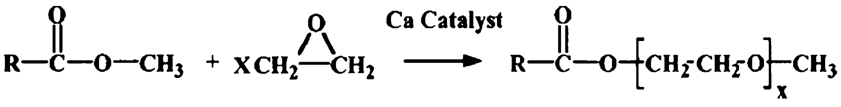

Fig. 36.38 Synthesis of methyl ester ethoxylates

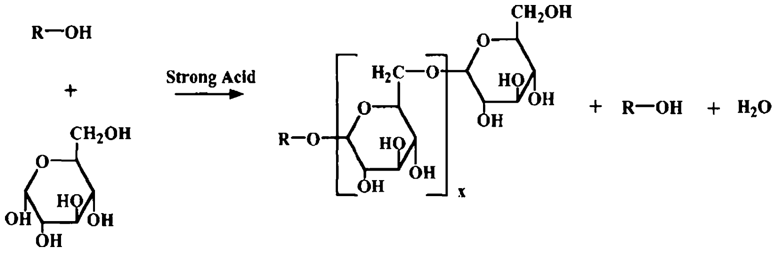

Fig. 36.39 Synthesis of alkyl polyglycosides

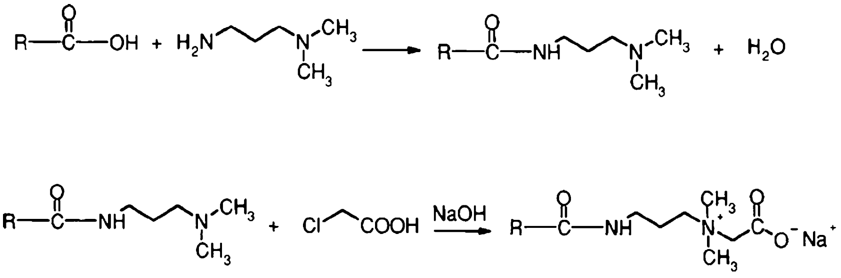

Fig. 36.40 Synthesis of coco amido propyl betaine

commercially available nonionic surfactants is beyond the scope of this work and only the major surfactant types are covered. A more complete discussion of different surfactant classes and their properties is available elsewhere [42].

Ethylene and propylene oxide are highly reactive species that will react with any molecule containing an active hydrogen. The alkoxylation reaction is best described as a two-step process. In the first step, the catalyst forms a charged complex with the initiator. In practice, the reaction is usually run using a base catalyst such as NaOH or KOH to avoid creating a large amount of polyethylene glycol (PEG) and other by-products. Alcohol and nonylphenol ethoxylates (NPE) are two of the most common types of nonionic surfactant. The reaction chemistry for the alcohol ethoxylate is shown in Fig. 36.37. The degree of ethoxylation follows a normal Poisson distribution.

To produce ethoxylated nonionics, the initiator and base catalyst are charged to a pressure reactor and purged with an inert gas to remove moisture. The reaction mixture is heated to 115–200°C and the oxide is added until the desired pressure is reached. The reaction is highly exothermic and heat removal rates control the rate of reaction. The reaction temperature and pressure are controlled until the desired quantity of oxide has been added. The batch is then cooled and the catalyst neutralized with a Lewis acid or removed by filtration.

Ethoxylated Methyl Esters. Even though methyl esters do not have active hydrogen, it is possible to insert EO into the ester group using calcium- or magnesium-based catalysts. The oligomer distribution is typically narrower than that obtained using a conventional base catalyst. The reaction is thought to take place by a complex series of transesterification reactions as shown in Fig. 36.38.

Alkyl Polyglycosides. A new type of nonionic surfactant has recently been developed that is not based on ethylene oxide. APG are prepared by reacting an excess of fatty alcohol with dextrose using a strong acid catalyst as shown in Fig. 36.39. The unreacted fatty alcohol is removed using a wiped film evaporator and the crude reaction product bleached to give light colored products. APG is readily biodegradable and nonirritating to human skin. APG is widely used in personal care and hard surface cleaning products but has not found wide acceptance in laundry detergents due to its poor cost/performance vs. other nonionics.

Amphoteric Surfactants

These surfactants contain both cationic and/or anionic groups on the same molecule. Amphoteric surfactants are relatively expensive due to the raw material and processing costs.

Typical applications include liquid dishwashing detergents, shampoos, body wash, and other personal care applications. In general, amphoteric surfactants detoxify and mitigate the irritation of anionic surfactants in the formulation. A typical reaction scheme for coco amido propyl betaine (CAPB) is shown in Fig. 36.40. Other examples of amphoteric surfactants include amine oxides, amphoacetates, and amino propionates. A detailed discussion of amphoteric surfactants and their properties is available elsewhere [43, 44].

Cationic Surfactants

Cationic surfactants tend to be specialty items that are tailored for diverse uses such as germicides, textile applications, corrosion inhibitors, and fabric softeners. Their primary growth has been in fabric softeners for home laundry detergents. Because cationics are antistatic agents, they perform well in removing static charges associated with synthetic fabrics.

Cationic surfactants have at least one hydrophobic group attached directly to a positively charged nitrogen atom. Cationic surfactants may be formed from nitriles, amines, amidoamines, or quaternary nitrogen bases. Significant literature reviews cover this subject in great detail [29, 30].

Detergent Additives

In addition to surfactants, modern detergent formulations contain many different additives to increase performance or assist in the detergent manufacture.

Detergent Builders. Builders are typically added to a detergent formulation to extend or improve the cleaning performance of a formulation across a wide range of use conditions. The combination of builders and surfactants exhibits a synergistic effect to boost total detergency and cleaning efficacy, as compared with an equal amount of either compound alone. The major properties and characteristics that are desirable for a compound to be considered a detergent builder include:

1. The ability to control water hardness and other metal ions
2. A contribution to final product alkalinity
3. Buffer capacity in the desired pH range
4. Deflocculation capability
5. Compatibility with other formulation ingredients and detergent additives
6. Consumer safety
7. Environmental acceptability
8. Processibility
9. Adequate cost/performance

In today's detergent products, a variety of builder materials is used singly or in combination with other builders to contribute unique properties for final product performance enhancement.

Phosphates. Tetrasodium pyrophosphate ($Na_4P_2O_7$, TSPP) became commercially available in the mid-1930s and soon gained acceptance as the preferred builder for soap-formulated products. The combination of TSPP and soda ash was more effective than either ingredient used separately. By the mid-1940s, sodium tripolyphosphate ($Na_5P_3O_{10}$, STPP) was commercially available and had supplanted TSPP as the preferred builder because of superior detergent processing, solubility, and hard-water sequestering properties. Sequestration is defined as the reaction of a cation with anion to form a soluble complex. The sequestration of Ca^{++} and Mg^{++} ions leads to softened water which results in better surfactant solubility and improved cleaning performance. STPP was the major builder ingredient in heavy-duty laundry detergents until the 1970s when phosphates were blamed for eutrophication of lakes and streams and thus have been almost completely removed from commercial laundry detergents. STPP is still widely used in automatic dishwashing detergents and in I&I cleaning applications.

Other possible builder salts include tetrapotassium pyrophosphate, sodium trimetaphosphate, trisodium and tripotassium phosphates, and sodium acid pyrophosphates. Significant literature reviews cover this subject in great detail [31, 45].

Silicates. Both sodium and potassium silicate solids or solutions have valued functionality including emulsification, buffering, deflocculation, and antiredeposition ability. Silicates also provide corrosion protection to metal parts in washing machines, as well as to the surfaces of china patterns and metal utensils in automatic dishwashers. Silicates are manufactured in liquid, crystalline, or powdered forms and with different degrees of alkalinity. The alkalinity of the silicate provides buffering capacity in the presence of acidic soils and enhances the sequestration ability of the builder system in the formulation. The silicate/alkali ratios of the silicates are selected by the formulator to meet specific product requirements. Silicate ratios of 1/1 are commonly used in dry blending applications with silicate ratios of 2/1 and higher commonly used in laundry and autodish applications.

Carbonates. In most areas of the United States, phosphates have been legislatively banned from use in home laundry detergents. Sodium carbonate, commonly called soda ash (Na_2CO_3), or a combination of soda ash and zeolite has replaced STPP as the builder in granular laundry products. Sodium carbonate softens water by precipitating hardness ions as insoluble carbonate salts. It is one of the most economical sources of alkalinity for detergents and provides some degree of soil dispersion and suspending action. Sodium carbonate is commonly used in powder laundry detergents, autodish powders, and hard surface cleaners.

Sodium Citrate. Sodium citrate ($Na_3C_6H_{25}O_7$) has builder characteristics due to its ability to sequester hard-water ions and deflocculate soils. Sodium citrate's principal use is in liquid detergents and personal care products.

Zeolites. Zeolites are an important alternative builder for powdered laundry detergents and structured surfactant systems. Zeolites are crystalline hydrated aluminosilicates of Group I and Group II elements. They are a complex mixture of sodium, potassium, calcium, and magnesium salts, and appear in natural and synthesized forms. Zeolite 4A ($Na_2{\cdot}Al_2O_3{\cdot}2SiO_2{\cdot}4.5H_2O$, commonly called Zeolite A) is the most widely used form of laundry detergents.

Zeolites are not water-soluble but they reduce calcium water hardness by ion exchange. The calcium ion passes through the zeolite pore openings and exchanges with the sodium ion. Magnesium ions are not significantly removed by zeolites because of the large atomic radium of the Mg^{++} ion. Zeolites are commonly used in combination with other builders such as sodium carbonate to control magnesium and other ions present in the wash water.

Sodium Nitrilotriacetate. One of the first compounds developed as a replacement for STPP was sodium nitrilotriacetate ($N(CH_2CO\ ONa)_3{\cdot}H_2O$—NTA), which has excellent sequestration and/or chelating properties. This product was quickly accepted by the detergent industry as an alternative builder. However, its use in detergents was suspended in the United States in 1970, when three major detergent manufacturers voluntarily agreed to discontinue its usage due to preliminary data suggesting that the compound could be teratogenic. Subsequent assessment by the EPA indicated that the risk to persons exposed to NTA from detergents is not significant. However, the EPA stated that NTA should not be used in products such as shampoos, hand-dishwashing detergents, foods, or other consumer products designed for direct dermal or oral exposure. Although NTA has not been used in the US household laundry products since the voluntary ban, it has been widely used as a detergent builder in Canada since 1970, and in the United States in I&I cleaning products. NTA is normally used in liquids as the primary builder or in combination with phosphates in spray-dried detergents.

Sodium Sulfate. Although considered a weak builder by some manufacturers, sodium sulfate (Na_2SO_4) contributes little to detergent performance. It is commercially available from natural sources and as a by-product from rayon processing. In dry mix and agglomerated type products, sodium sulfate is used to improve finished product flow characteristics. In spray-dried products, sodium sulfate acts as an inert filler and aids in density control.

Sodium Chloride. Sodium chloride (NaCl) is used by some detergent manufacturers, its main function being as an inert filler or diluent. In spray-drying operations, NaCl is used to control Crutcher slurry viscosity and the density of the spray-dried bead or granules. In liquid formulations, NaCl is used to control product viscosity through the salt effect. Although salt is used to some extent in autodish formulations, it is not recommended because of potential machine and dishware corrosion.

Antiredeposition Polymers. The surfactants employed in synthetic detergents are effective in removing soil and stains from the surface of the washed fabric. Under heavy soil loading, there is a tendency for these soils to redeposit on the fabric. Various charged polymers have been found to prevent soil redeposition. Sodium carboxymethylcellulose (NaCMC) is effective in reducing soil redeposition at a formulation level of 0.1–0.5%. The sodium salt of polyacrylic acid is also an effective antiredeposition polymer. Molecular weights of 5,000 g/mole give a good combination of performance-handling characteristics. Copolymer of styrene and maleic anhydride are also commonly used, although the optimum molecular weight is approximately 45,000. The polyacrylates are typically used at 0.5–1% in the formulation.

Optical Brighteners. Although the surfactant system in formulated detergents is effective at cleaning clothes, white fabrics tend to gray or lose their white appearance after multiple wash cycles. Optical brighteners are added to detergent formulations to visually improve the whiteness or brightness of the fabric.

All major liquid or powdered detergent products contain one or more fluorescent whitening agents [32]. Substantive to most fabrics, these materials absorb ultraviolet radiation and convert it to visible blue-white light that masks the natural yellowing or graying of the fabric. Most brightener systems are more effective on cotton than on synthetic fabrics. The usage range varies from 0.05 to 0.2% in the detergent formulation.

Hydrotropes. Hydrotropes are used primarily in liquid detergents to increase the solubility of sparingly soluble ingredients and improve storage stability. They are also used occasionally as viscosity modifiers in the slurry phase of manufacturing spray-dried detergent powders. Reduction of the detergent slurry viscosity improves its processing characteristics, reduces product bulk density, and insures

Table 36.6 Spray-dried detergent formulation

Ingredients	Phosphate built detergent wt%	Nonphosphate built detergent wt%
Sodium tripolyphosphate	20–35	0
Sodium carbonate	5–10	5–10
Zeolite A	0	0–20

Alcohol ethoxylate	0–15	0–20
NaAES	0–5	0–5
Sodium silicate	3–6	3–6
Sodium sulfate	10–30	10–30
NaCMC	0	0.1–1
Enzymes	0.1–1	0.1–1
Optical brightener	0.1–0.3	0.1–0.3
Bleach	0–5	0–5
Water	3–8	3–8

crisp, free-flowing granules. The most common hydrotropes are the ammonium, potassium, or sodium salts of toluene, xylene, or cumene sulfonates.

Enzymes. A number of different enzymes have been developed for use in detergent systems to remove common soils and stains. Protease enzymes are used to cleave the protein-based soils into smaller pieces more easily removed by the detergent system. Lipase enzymes are used to cleave lipid bonds resulting in fatty acid and glycerol. Lipase enzymes work better at elevated temperature and tend to become active in the drying operation. Noticeable removal of stains occurs after multiple wash cycles. Amylase enzymes tend to break carbohydrate bonds in sugar-based soils. Cellulase enzymes are designed to remove microfibulas in cotton fabric to help retain color intensity and appearance. Enzymes are available in liquid and powder form. Care must be taken when handling solid enzymes that the powder does not become airborne where it can be breathed in by production workers. Enzymes are used in both liquid and powder laundry detergents.

Pearlescent, *Opacifying*, *Thickening Agents*. These compounds are used in liquid detergent systems to produce a specific aesthetic effect. Pearlescent compounds, such as mica or ethylene glycol distearate (EGDS), are added to give a luxurious appearance to liquid formulations. Opacifying agents include water-soluble salts of styrene and maleic anhydride and are used to reduce translucence, modify the viscosity characteristics of liquids, and provide a creamlike texture to the product. Polymeric thickeners and clays are used to modify the rheological properties of liquids for various applications where cling to vertical surfaces is beneficial.

Anticaking Agents. The use of nonphosphate builders in laundry powders has changed the flow characteristics and caking tendencies. Products formulated with increased anionic surfactant levels and higher sodium carbonate content tend to exhibit compaction in storage. Anticaking agents have been added to the formulation to reduce this tendency, especially in warm humid climates. A wide variety of products is available, including sodium benzoate, tricalcium phosphate, colloidal aluminum oxide, silicon dioxide, magnesium silicate, calcium stearate, and microcrystalline cellulose.

Production of Synthetic Detergents

Modern detergent products come in a variety of different formats including liquids, powders, tablets, sachets, and wipes. Product format preferences change with different regions of the globe. Liquid laundry detergents account for 70% of the market in North America whereas powders are preferred in Europe and Japan. Tablets and sachets are a relatively new format which is very popular in the United Kingdom and other countries in the European Union. Recently, wipes have become popular especially for hard-surface cleaners. The following is a brief description of the common manufacturing processes.

Spray Drying. A major portion of powdered laundry detergents is spray-dried. In this process, the detergent raw materials are mixed with water to form a thick paste or slurry, atomized into spherical droplets, and dried to produce a free-flowing granular product. The art of spray drying was first patented in 1883, but was not practiced to any extent until the 1930s. With the advent of synthetic detergents in the 1940s, spray drying became the dominant method of detergent processing. The advantages of spray drying are numerous: the product density can be varied from 0.20 to 0.80 g/cm^3, the detergent granule solubility is significantly improved, very high production rates are easily achieved, and multiple formulations can be prepared using the same equipment. The major disadvantages of spray drying are the initial capital investment required and the energy-intensive nature of the process. A modern spray-drying operation consists of several unit operations: slurry preparation, atomizing, drying and conditioning of the product, post-additions, packaging, waste reclamation, and pollution control.

Spray-dried powders are formulated to give the best overall cleaning performance and flow characteristics at the lowest possible formulation costs. Typical spray-dried detergent formulations are shown in Table 36.6. Slurry preparation is considered to be the single most important factor in spray drying. Control of the raw material order of addition, slurry solids level, slurry temperature, viscosity,

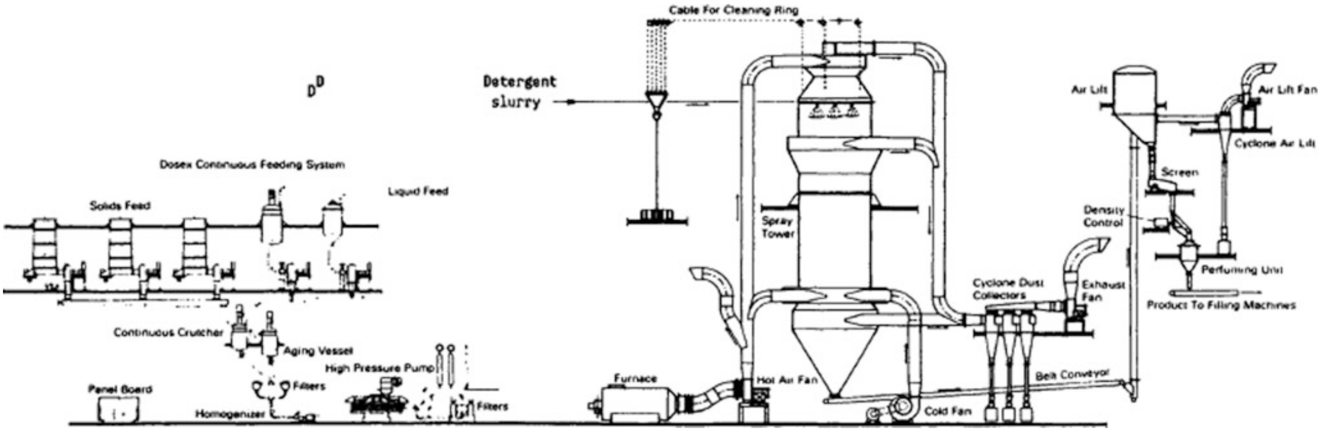

Fig. 36.41 Spray tower and slurry preparation

and aeration enable manufacturers to deliver the desired final product characteristics. The spray tower itself is simply a contained heat source that removes moisture at a uniform rate dependent upon the quality and the quantity of feed to the dryer. If feed variables are not controlled, variability in the density and moisture levels of the powder will vary. For example, if the slurry solids level is not constant (±2%), the evaporative load, production rate, particle sizing, and moisture levels of the spray-dried granules will vary. Compensating for nonuniform feed to the spray tower is difficult because of the interaction of control variables such as tower temperature, pump pressure, and gas velocity. Although some minor tower adjustments are possible, the major control for routine production is consistent and uniform preparation of the detergent slurry.

Slurries are prepared via batch, semi-continuous and continuous crutching units. Solids levels are normally kept as high as possible (64–72%) to reduce the heat requirements and maximize the tower throughput. After the detergent raw materials are mixed, the slurry is charged to a homogenizer and any large lumps or gritty particles are desized and screened to prevent plugging of the spray nozzle. The slurry is then charged to a booster pump, deaerated, and sent to a high pressure pump (300–1,200 psig) for atomization.

Most detergent slurries are atomized into spherical droplets via high pressure nozzles. The nozzles produce a hollow conical pattern with a spray angle of 45–90°. The slurry emerges from the nozzle as a film, which is sheared into droplets by the centrifugal force developed by specially grooved cores inserted into the nozzle before the discharge point. A series of spray nozzles (2–25) is placed near the top of the spray tower and angled so that one edge of the desired spray pattern is vertical to the spray tower side walls. Some spray towers use two or three rings of nozzles, depending upon the formulation and drying capacity of the unit. Production rates of detergent spray towers range from 5,000 to 80,000 lbs/h. In most cases, the rates are controlled by the slurry feed facilities, solids levels, and the drying capacity. A schematic of a typical spray drying facility is shown in Fig. 36.41. Spray towers vary in size from approximately 10 to 35 ft in diameter and range from 40 to 200 ft in height. The majority of detergent spray towers use countercurrent airflow patterns although some use a concurrent in design. In general, a countercurrent tower will produce a more high-density particle than the concurrent type. In countercurrent systems, the heated gas stream (250–270°C) is uniformly dispersed into the lower section of the tower through a series of plenum chambers or baffles equally spaced around the unit's periphery. The hot gases are cooled as they exhaust the top of the tower by the drying of atomized detergent droplets upon contact with the hot air stream. Because of the relatively low temperature (110–140°C) at this point in the tower, the particles do not expand to their full capacity as water evaporates. This lower expansion rate results in a bead with increased bulk density and thicker shell. If a similar formulation were dried in a concurrent spray tower, the higher temperature (250–270 °F) and increased drying rate would increase the evaporative rate and result in a thin-walled bead of lighter density.

In most spray towers, the air flow rate and the temperature are adjusted at the inlet ports to maintain balanced air/temperature patterns. When the atomized slurry is sprayed into the drying chamber, the air flow pattern is disturbed and becomes very turbulent. This effect can cause localized temperature gradients (hot or cold spots) and affect the particle drying characteristics. It is possible to have both over- and under-dried particles discharged at the same time from the tower because of poor adjustment of the air flow in the tower. Adjustment of the airflow patterns, as well as sending a balanced spray into the tower, can help counteract this situation. Increased impingement of the product on the tower walls is another negative effect of excessive turbulence and of excessive spray nozzle velocity. A ring of product may form approximately 10 to 20 ft below the

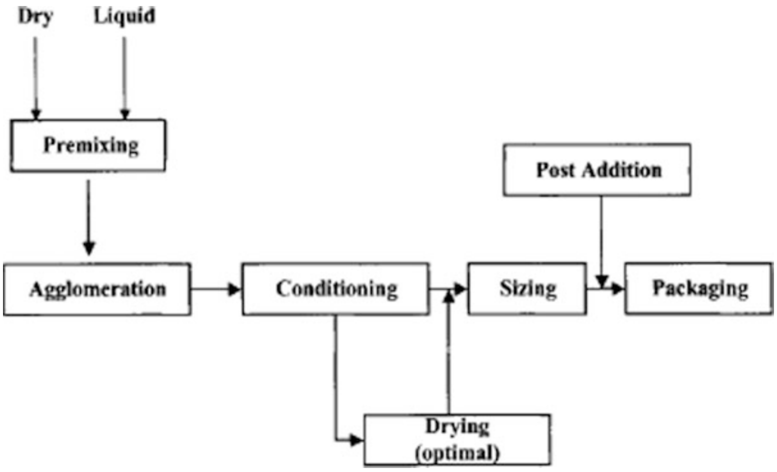

Fig. 36.42 Unit operations for batch agglomeration

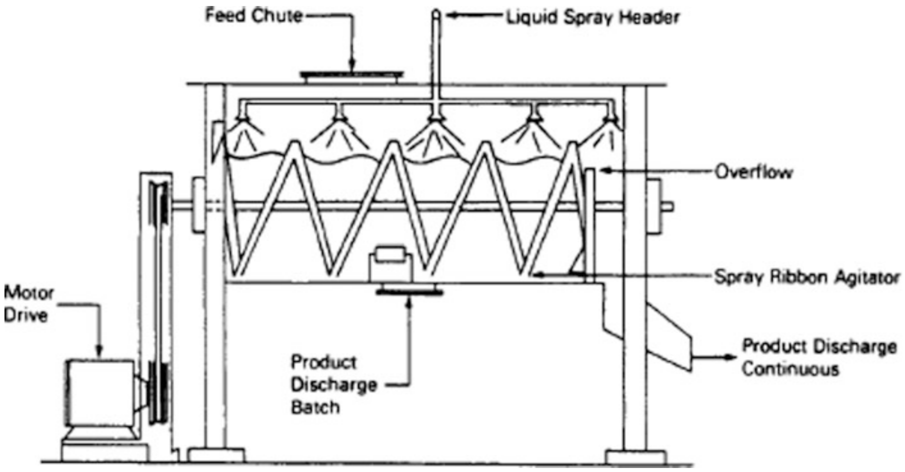

Fig. 36.43 Ribbon blender

spray nozzles and build in size until it cracks or scales off the walls. Ring removal methods, such as periodic cleaning using air or water lances, vibration, sonic shocks, or mechanical cleaning rings, sometimes are used to prevent a buildup that could result in blockage of the tower discharge.

After drying in the spray tower, the detergent granules are conveyed to storage silos prior to packaging. In some processes, product storage is preceded by fluid-bed conditioning. The product for the tower is very warm (75–120°C) and typically contains moisture levels of 1–3%. Conditioning is employed to prevent caking or product flow problems due to either the high temperature or excessive free moisture content. Following conditioning, perfume and other heat-sensitive ingredients (enzymes, surfactants, bleaches) may be added to the product. Post-addition is accomplished by metering the additives into the spray-dried base in a rotary drum or other mixing device. The post-additions normally comprise 2–15% of the total detergent formulation. An excellent review of spray drying and key patents is available. [32, 33]

Agglomeration

Agglomeration is a technique of binding a mixture of granular and/or dry powdered raw materials into an attractive granular form with enhanced aesthetic and flow characteristics. The majority of granular automatic-dishwashing compounds and some laundry powders are manufactured using the agglomeration process. The advantages of agglomeration are low capital costs relative to spray towers and reduced energy consumption. Agglomeration also yields a higher-density product, which results in reduced packaging costs. The major disadvantage of agglomeration is the limited surfactant loading due to raw

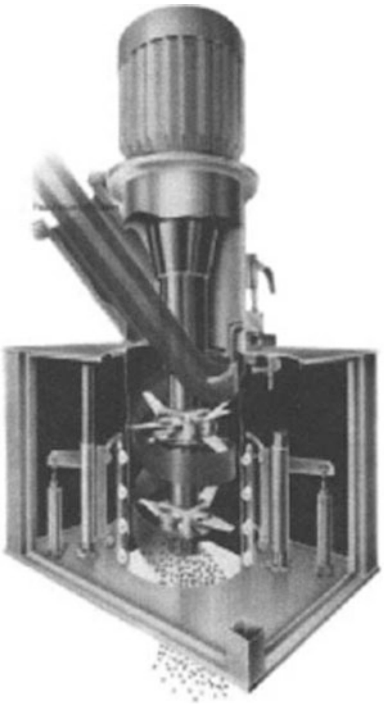

Fig. 36.44 Shugi Flex-o-Matic agglomerator

material absorption characteristics, particularly in laundry applications. As energy costs have assumed increasing importance, and higher-density products have gained in popularity, agglomerated or combinations of agglomerated and spray-dried powders have found wider use.

The typical process steps for formulating a laundry or autodish detergent usually are defined in the laboratory prior to continuous plant processing; however, they generally follow the scheme shown in Fig. 36.42. Frequently the dry raw materials are premixed and then metered into the agglomeration equipment. In the agglomerator, the surface of the dry raw materials is exposed to atomized sprays of surfactant or silicates to begin building the agglomerated particle. Following addition of liquids to the dry raw materials, the product has a wet or pasty texture and requires conditioning to remove excess water prior to storage or packaging. Conditioned agglomerates are screened to remove oversize particles and then blended with other additives (bleaches, enzymes, dyes, and perfumes) that would not be stable under agglomeration conditions.

Numerous equipment types can be used for agglomeration, including horizontal ribbon and vertical mixers, rotary drums, zig-zag mixers, and pan agglomerators. Horizontal ribbon mixers as shown in Fig. 36.43 are used primarily for dry mix formulating, where only limited agglomeration occurs. They comprise a U-shaped trough and a ribbon or paddle-type agitator. Liquids are sprayed onto the surface of the dry material and slowly dispersed into the mix. Mixer operations can be either batch or continuous.

Vertical mixers have become more commonly used due to low space requirements and high efficiency of operations. The vertical mixer shown in Fig. 36.44 utilizes high speed agitation to intimately mix and uniformly blend liquids and dry raw materials prior to discharge. The contact time is reduced to less than 5 s. The rotary drum units generally contain baffles that roll or lift the product for uniform dispersion or liquid feeds. Pan and zig-zag agglomerators generally are used for limited, specialty product manufacture.

The vertical and the rotary drum agglomeration equipment find most widespread use in the detergent industry because of improved agglomeration, increased liquid feed dispersion levels, and optimized product uniformity. In addition to agglomeration of detergent and autodish detergents, these units can be used for hydration of STPP, dry neutralization of sulfonic acids, post-addition of raw materials and fines to spray-dried products and particle encapsulation. An excellent review of detergent agglomeration is available [46, 47].

Liquid Detergent Processing

Liquid heavy-duty products account for approximately 60% of the 2001 US laundry detergent market [48]. The growth of heavy-duty liquids began in 1974, as the result of the phosphate ban in home laundry. Unbuilt liquids based on nonionic and anionic/nonionic surfactant combinations gradually increased in volume for various reasons including convenience, solubility, and improved performance vs. nonphosphate containing powdered detergents. In the mid-1980s the introduction of higher-performance liquids accelerated growth in this segment, with the market share essentially doubling from 1984 to 1990 [49].

Liquid products are approximately 50–60% water, with the remainder being a combination of surfactants, builders, foam regulators, enzymes and enzyme stabilizers, hydrotropes, antiredeposition polymers, optical brighteners, corrosion inhibitors, dye, and perfume. Two-in-one formulations also contain antistatic and fabric softening ingredients. Liquid systems require careful selection and blending of raw materials to achieve a stable product. Special attention is necessary for the following items.

- *Viscosity*. The product must be pourable and must retain the same viscosity characteristics from batch to batch. This variable can be controlled by proper solvent or hydrotrope selection.
- *Clear-cloud point*. The composition should have sufficient solubility to prevent hazing or separation of the product when subjected to storage in cool temperatures.

- *Freeze–thaw stability*. The formulation must be compounded to prevent phase separation or solidification at freezing temperatures.

Most LDL detergents are formulated using a combination of LAS and AES with various amphoteric foam stabilizers (CAPB, amine oxides, etc.). Heavy-duty liquid detergents often use a combination of actives such as LAS, AES, AE, and AOS. The manufacture of liquid products requires relatively basic equipment for mixing the various ingredients. The raw materials are added batchwise to a large mixing vessel or proportionated to in-line mixers before being fed to the filling lines. In 1986, liquid autodish detergents were introduced. These products were based on thixotropic slurries of STPP and soda ash. The rheology helped to solve issues with product dispensing rate and product physical stability. The slurries were generally viscous enough to prevent premature dispensing into the dishwasher prior to the wash cycle. The thixotropic nature of the product was achieved using natural clays of high molecular weight polymers. High-shear mixing equipment such as homogenizers is used to manufacture these products in batch or continuous stirred tank systems.

Detergent Trends

In the United States, liquid detergent sales continue to grow at the expense of powders. The trend is largely due to convenience as cost per load for liquids is significantly higher than for powders. In the United States, liquid products are clear and isotropic with vibrant colors. In Europe, liquid products have a lower market share and are typically based on structured surfactant systems with suspended STPP and/or zeolites. These systems tend to be opaque products and it remains to be seen if the US market will accept these products. The performance of liquid laundry detergent performance has been increased through the use of multiple enzyme and ancillary ingredients.

Recently, unit dose laundry tablets and liquid sachets have been introduced in the United States, which take customer convenience to the next step. Presently, the market share for these products is small and it also remains to be seen how these products will fare in the US market.

The machines used to wash clothes are also changing. The DOE has mandated energy efficiency standards on new washing machines. In order to meet these efficiency standards, most manufacturers are offering horizontal-axis washing machines similar to those that have been available in Europe for many years. The H-axis machines use less water and energy than conventional top-loader machines; however, they are currently more expensive than conventional washing machines. The new machines generate more mechanical actions, which in turn generates more foam. Detergent manufacturers now must formulate lower foam detergents for use in these machines.

The environmental movement, which began in Europe, is now beginning to appear in the United States. The use of NPE in household products is declining. To a large extent, NPEs have been replaced with alcohol ethoxylates. The use of environmentally acceptable surfactants continues to grow. Surfactants based on natural, regrowable raw materials are commercially available. APG based on sugar and fatty alcohol, MESs, and MEEs are examples of naturally derived surfactants. This trend can be expected to continue into the next decade.

Chemical Explosives

37

Don H. Cranney and Walter B. Sudweeks

Introduction

The average citizen in today's world gives little thought to the important role that commercial explosives play in their lives and how their use is linked to our standard of living and our way of life. Explosives provide the energy required to give us access to the vast resources of the earth for the advancement of civilization. In 2010, the Mineral Information Institute estimated that the average baby born in America will need the following quantities of minerals, metals, and fuels in their lifetime: copper—932 lb; salt—31,779 lb; clays—12,121 lb; zinc—544 lb; stone, sand, and gravel—1,100,000 lb; petroleum—72,499 gal; lead—777 lb; other minerals and metals—43,822 lb: natural gas—5.93 million ft^3; cement—41,181 lb; iron ore—14,530 lb; bauxite (aluminum)—4,040 lb; coal—542,968 lb; phosphate rock—15,152 lb; and gold—1.383 troy oz [1]. Availability of all of these materials, which total 2.9 million lb/individual, depends on the use of explosives.

Without explosives, the steel industry and our entire transportation system would not be possible. The generation of electricity has been largely dependent on coal, and coal mining today is still the largest consumer of industrial explosives. Rock quarrying for road building and cement production, excavations for skyscrapers, tunnels, roads, pipelines, and utilities are direct beneficiaries of the labor-saving use of explosives. Exploration for oil and gas involves the use of explosives in seismic studies to map underground strata to find structures that may have these resources present. Our food supply depends on the use of phosphate based fertilizers. Significantly, the industrialization cycle being experienced in several areas of the world, such as in China and other parts of Southeast Asia, is greatly ramping up the use of explosives worldwide to supply the needed materials for the massive building and infrastructure improvements.

Commercial Explosives Market

The use of commercial explosives in the United States over the last 10 years shows some cyclical behavior that basically follows the economic cycles. This is illustrated in Fig. 37.1, which indicates explosives usage by year as reported by the U.S. Geological Survey (USGS) [2] from 2000 to 2009. The data compiled in this figure show fairly level explosives sales for the years 2000 through 2004, hovering around 2.5 million metric tons/year. The years 2005 through 2008 show a distinct step up to volumes over three million metric tons consistent with the world wide commodities boom period and the booming U.S. economy during that period. This was followed by a sharp drop to below 2.5 million tons as the world wide recession of 2008/2009 sharply dropped explosives demand. Figure 37.1 also separates the volumes by industry use. The open-pit coal mining industry continues to be the largest user, as it has been for many years.

Table 37.1 shows the commercial explosive usage by the ten leading states for 2008 and 2009 [3]. These ten states represent 75% of the total explosive use in the U.S. In the year 2009 (the latest statics available at the time of this update), the four states consuming the most explosives (in decreasing order) were: Wyoming, West Virginia, Kentucky, and Indiana; all coal mining states. These states alone accounted for over 50% of the total U.S. market. The coal market continues a shift from the eastern states to the western states with lower BTU, but more importantly, lower sulfur coal. This trend is congruent with the shift to large open-pit mining operations, both in the west and in other regions, in order to increase production and competitiveness. The dramatic effect of the economic downturn was indicated

by the drop of Nevada from the 6th position in the leading explosives consumers in 2008 to the 20th position in 2009 (not shown in Table 37.1). This was due to the slump in gold mining, which at the time of this update is recovering strongly. Other metal and commodity mines are also in a positive upswing, while construction and quarry (aggregate) operations remain in a slump.

Chemistry of Combustion and Explosion

For a simple understanding of explosives, it is helpful to compare an explosive reaction with the more familiar combustion or burning reaction. Three components are needed to have a common fire: fuel, oxygen from the air, and a source of ignition. The process of combustion is basically an oxidation–reduction (redox) reaction between the fuel and oxygen. Once initiated, this reaction can become self-sustaining, producing large volumes of gases and heat. The heat given off further expands the gases and provides the stimulus for the reaction to continue by heating and igniting surrounding fuels.

The basic burning reaction is a relatively slow, diffusion-controlled process that occurs within the flames or near the surface of glowing embers. The size of the fire depends upon how much fuel is involved and on the rate of the combustion reaction. The rate of the combustion reaction depends on how finely divided the fuel is and how rapidly the oxygen reaches the flame, that is, the intimacy of contact between the fuel and the oxygen in the air. Burning rate is greatly increased when convection of the air, natural (wind) or man-made (fanning the flame), joins diffusion in supplying oxygen to the flame.

Another result of an intimate mixture of the fuel and air is the completeness or efficiency of the reaction. In a complete combustion all the fuel elements are oxidized to their highest oxidation state. Thus, burning of wood, being mainly cellulose and gasoline being generally a hydrocarbon (e.g., octane), produces primarily carbon dioxide and water vapor upon complete combustion. Once initiated, these burning reactions give off heat energy, which sustains the reactions. Heat is released because the oxidized products of the reaction are in a lower energy state (more stable) than the reactants. The maximum potential energy release can be calculated from the respective heats of formation of the products and reactants. Actual heats of combustion can be measured experimentally by causing the reaction to occur in a bomb calorimeter. The calculated energy values for the above reactions are 3,857 cal/g for cellulose and 10,704 cal/g for octane.

In the case of an inefficient burn, some less stable or higher-energy products are formed so that the resultant heat energy given off is lower than that for complete combustion. In the above examples, inefficient combustion could result from lack of accessible oxygen, producing carbon monoxide or even carbon particles instead of carbon dioxide. A smoky flame is evidence of unburned carbon particles and results from inefficient combustion where fuel particles are so large or so dense that oxygen cannot diffuse to the burning surface fast enough. If this inefficiency is great enough, insufficient heat is given off to keep the reaction going, and the fire will die out.

All chemical explosive reactions involve similar redox reactions; so the above principles of combustion can help illustrate, in a very basic way, the chemistry involved in explosions. As in a fire, three components (fuel, oxidizer, ignition source) are needed for an explosion. Figure 37.2 shows an explosion triangle, which is similar to a fire triangle. In general, the products of an explosion are gases and heat, although some solid oxidation products may be produced, depending upon the chemical explosive composition. As in normal combustion, the gases produced usually include carbon dioxide and water vapor plus other gases such as nitrogen, again depending upon the composition of the chemical explosive.

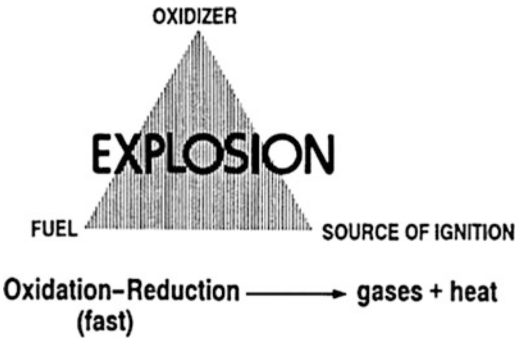

Fig. 37.2 An explosion triangle

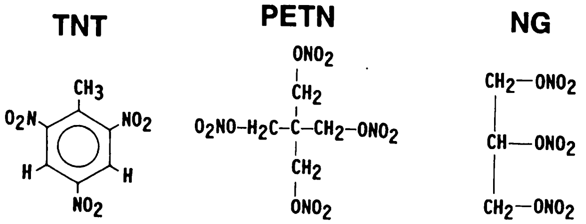

Fig. 37.3 Chemical structure of three molecular explosives

It should be noted that an explosion differs from ordinary combustion in two very significant ways. First, oxygen from the air is not a major reactant in the redox reactions of most explosives. The source of oxygen (or other reducible species) needed for reaction with the fuel—the oxidizer—may be part of the same molecule as the fuel or a separate intermixed material. Thus, an explosive may be thought of as merely an intimate mixture of oxidizer and fuel. This high degree of intimacy contributes to the second significant difference between an explosion and normal combustion—the speed with which the reaction occurs.

Explosives in which the oxidizer and fuel portions are part of the same molecule are called molecular explosives. Classical examples of molecular explosives are 2,4,6-trinitrotoluene (TNT), pentaerythritol tetranitrate (PETN), and nitroglycerin (NG) or, more precisely, glycerol trinitrate. The chemical structures of these explosives are shown in Fig. 37.3.

As can be seen in the structures, the oxidizer portions of the explosives are the nitro (–NO_2) groups in TNT and the nitrate (–ONO_2) groups in PETN and NG. The fuel portions of all three explosives are the carbon and hydrogen (C and H) atoms. Comparison of the ratios of carbon to oxygen in these explosives (i.e., approximately 1:1 for

TNT, approximately 1:2 for PETN, and 1:3 for NG) shows that TNT and PETN are deficient in oxygen; that is, there is insufficient oxygen present in the molecule to fully oxidize the carbon and hydrogen. Consequently, products such as carbon monoxide, solid carbon (soot), and hydrogen are produced, as well as carbon dioxide and water vapor. Prediction of the exact products of explosion is complex, especially for the oxygen-deficient explosives, because the amounts of CO_2, CO, H_2O, and H_2 will vary as will a host of trace products such as residual hydrocarbons, depending upon reaction conditions (explosive density, degree of confinement of the explosive, etc.) [4, 5]. The following equations show typical ideal reaction products along with calculated heats of reaction for these molecular explosives:

$$\begin{aligned}\text{TNT:}\quad & C_7H_5N_3O_6 \rightarrow 1.5CO_2 \\ & + 0.5CO + 2.5H_2O + 1.5N_2 + 5C + 1{,}290\,\text{cal/g}\end{aligned}$$

$$\begin{aligned}\text{PETN:}\quad & C_5H_8N_4O_{12} \rightarrow 4CO_2 \\ & + 4H_2O + 2N_2 + C + 1{,}510\,\text{cal/g}\end{aligned}$$

$$\begin{aligned}\text{NG:}\quad & C_3H_5N_3O_9 \rightarrow 3CO_2 \\ & + 2.5H_2O + 1.5N_2 + 0.25O_2 + 1{,}480\,\text{cal/g}\end{aligned}$$

Explosives in which the oxidizer and fuel portions come from different molecules are called composite explosives because they are a mixture of two or more chemicals. A classic industrial example is a mixture of solid ammonium nitrate (AN) and liquid fuel oil (FO). The common designation for this explosive is the acronym, ANFO. The oil used (typically #2 diesel fuel) is added in sufficient quantity to react with the available oxygen from the nitrate portion of AN. The redox reaction of ANFO is as follows:

$$\begin{aligned}& 3\underset{\text{AN}}{NH_4NO_3} + \underset{\text{FO}}{-CH_2-} \\ & \rightarrow CO_2 + 7H_2O + 3N_2 + 880\,\text{cal/g}\end{aligned}$$

"Oxygen balance" (O.B.) is the term applied to quantify either the excess oxygen in an explosive compound or mixture (beyond what is needed for complete combustion of the fuel elements) or oxygen deficiency (compared to the amount required for complete combustion). It is expressed as either a percentage or a decimal fraction of the molecular weight of the oxygen in excess (+) or deficiency (−) divided by the molecular weight of the explosive or the ingredient being considered. Individual components of an explosive mixture have O.B. values that may be summed for the mixture. Shown below are the O.B. calculations for AN and FO:

$$\underset{\substack{\text{AN}\\ \text{Mol. wt.=80}}}{NH_4NO_3} \rightarrow 2H_2O + N_2 + \underset{\substack{O_2\\ \text{Mol. wt.=32}}}{\tfrac{1}{2}O_2}$$

$$\text{O.B.} = \frac{(1/2)(32)}{80} = 0.20$$

$$\underset{\substack{\text{FO}\\ \text{Mol. wt.=}\sim 14n}}{-(CH_2)_n-} + \tfrac{3n}{2}O \rightarrow nCO_2 + nH_2O$$

$$\text{O.B.} = \frac{-(3n/2)(32)}{14n} = 3.43$$

From the O.B. values, one can readily determine the ratio of ingredients to give a zero O.B. mixture for optimum efficiency and energy. Thus, the weight ratio for ANFO is 94.5 parts of AN and 5.5 parts of FO ($94.5 \times 0.20 = 5.5 \times 3.43$). For the molecular explosives shown previously, the respective oxygen balances are: TNT, −0.74; PETN, −0.10; and NG, ±0.04. Thus, NG is nearly perfectly oxygen-balanced; PETN is only slightly negative; but TNT is very negative, meaning significantly deficient in oxygen. Therefore, combinations of TNT and AN have been employed to provide additional oxygen for the excess fuel, as, for example, in the Amatols developed by the British in World War I [6].

Modern commercial explosives react in a very rapid and characteristic manner referred to as a detonation. Detonation has been defined as a process in which a combustion-induced, supersonic shock wave propagates through a reactive mixture or compound. This high pressure shock wave compresses and interacts with the reactive material it contacts, resulting in very rapid heating of the material, initiation of chemical reaction, and liberation of energy. This energy, in turn, continues to drive the shock wave, thereby sustaining the detonation. Pressure in a detonation shock wave may reach millions of pounds per square inch. Once initiated, molecular explosives tend to reach a steady-state reaction with a characteristic detonation velocity. Composite or mixture explosives also have steady-state detonation velocities, but these velocities are more variable than those of molecular explosives and are influenced by such factors as diameter of the charge, temperature, density, and confinement.

Historical Development

The first known explosive material was black powder, a mixture of potassium nitrate (saltpeter), charcoal, and sulfur. As such it is a composite explosive whose properties are dependent upon how finely divided each of the ingredients is, and how intimately they are mixed. The exact origins of black powder are lost in antiquity. Publications referring to it seem about equally divided between those that attribute its origin to third- or fourth-century China [7, 8] and those that place it

closer to the thirteenth century, at about the time of Roger Bacon's written description in 1242 [9–13]. Nevertheless, its use did not become very popular until the invention of the gun by Berthol Schwartz in the early 1300s; and its first recorded use in mining did not occur for over 300 years after that. First used for blasting in 1627, the production and application of black powder played a critical role in the rapid expansion of the United States in the early nineteenth century as canals were dug and railroads built to span the continent.

For over 200 years black powder was the only blasting agent known, but the 1800s brought a number of rapid developments that led to its demise, replacing it with safer and more powerful explosives. Table 37.2 presents a chronological summary of some of the significant discoveries of the 1800s. Credit for the first preparation of NG is generally ascribed to Ascanio Sobrero in Italy in 1846.

Swedish inventors Emmanuel Nobel and his son Alfred took an interest in this powerful liquid explosive and produced it commercially in 1862. However, its transportation and its handling were very hazardous, and eventually Alfred Nobel discovered that NG absorbed into a granular type of material (kieselguhr) was still explosive, but was much safer to handle and use than the straight liquid. This new invention, called "dynamite," was difficult to ignite by the usual methods used for pure NG. Therefore, also in 1867, Alfred Nobel devised the fuse initiated blasting cap using mercury fulminate. With this development dynamite became the foundation of the commercial explosives industry.

For military and gun applications, black powder continued to be the only explosive of choice as a propellant or bursting charge until the inventions of the late 1800s, when smokeless powder, based on nitrocellulose, proved to be a cleaner, safer, and more effective propellant than black powder. The synthesis of picric acid (2,4,6-trinitrophenol) followed by TNT and PETN gave solid, powerful, molecular explosives of more uniform performance for use in bombs and artillery shells. The main explosives used in World War I were TNT, Tetryl (2,4,6-trinitrophenylmethylnitramine), and Hexyl (hexanitrodiphenylamine), and in World War II they were TNT, PETN, and RDX (1,3,5-trinitro-1,3,5-triazacyclohexane) [14].

In the industrial arena the production of black powder in the United States dropped precipitously after reaching a peak of 277 million lb in 1917 [15]. By the mid-1960s, it had ceased to be of commercial significance in the explosives industry, but during the same time period dynamite production rose from 300 to 600 million lb.

In 1947, a spectacular accident of catastrophic proportions ushered in the next revolution in explosives. Fertilizer-grade AN, in the form of prills (small spherical particles coated with paraffin to prevent caking), was being loaded into ships in Galveston Bay, TX. Along with other cargo, one of these ships, the partially loaded SS Grandcamp, contained 2,300 tons of this material. On the morning of April 16, soon after loading was resumed aboard the Grandcamp, a fire was discovered in one of the holds containing AN. Efforts to extinguish the fire were unsuccessful, and an hour later the bulk of the coated fertilizer detonated, killing 600 people and injuring 3,000 [16].

This tragedy, along with several other large-scale accidents involving AN explosions, finally led researchers to the conclusion that inexpensive, readily available, fertilizer-grade AN could be used as the basis for modern industrial explosives.

Soon after the advent of porous AN prills, introduced in the early 1950s, investigators realized that these prills could readily absorb just the right amount of FO to produce an oxygen-balanced mixture that was both an inexpensive and effective blasting agent, in addition to being safe and simple to manufacture. This technology was widely adopted and soon constituted 85% of the industrial explosives produced in the United States [17]. With ANFO's cost and safety characteristics, it became practical for surface miners to drill larger boreholes and to utilize bulk ANFO delivery systems. Nevertheless, ANFO had two significant limitations: AN is very water soluble, so wet boreholes readily deactivated the explosive; and ANFO's low density of 0.85 g/cc limited its bulk explosive strength. Cook [18] hit upon the idea of dissolving the AN in a small amount of hot water, mixing in fuels such as aluminum powder, sulfur, or charcoal, and adding a thickening agent to gel the mixture and hold the slurried ingredients in place. As this mixture cooled down, the AN salt crystals would precipitate, but the gel would preserve the close contact between the oxidizer and the fuels, resulting in a detonable explosive. Other oxidizers also could be added, and the density could be adjusted with chemical foaming agents to vary the bulk explosive strength of the product. With the addition of a cross-linking agent, the slurry could be converted to a semisolid material, generally called a water gel, having some water resistance. The latest significant development in industrial explosives actually was invented only a few years after slurries [19, 20]. Water-in-oil emulsion explosives involve essentially the same ingredients that slurry composite explosives do, but in a different physical form. Emulsion explosives are discussed fully under the section titled "Explosives Manufacturing and Use."

The main developments in military types of explosives since World War II have been trends toward the use of plastic bonded explosives (PBXs) and the development of insensitive high explosives. Driving these trends are desires for increased safety and improved economics in the process of replacing aging TNT-based munitions and bomb fills. PBXs involve the coating of fine particles of molecular explosives such as RDX and HMX (1,3,5,7-tetranitro-1,3,5,7-tetrazacyclooctane) with polymeric binders and then pressing the resultant powder under vacuum to give a solid mass with the desired density. The final form or shape usually is obtained by machining. Explosives such as triaminotrinitrobenzene (TATB), nitroguanidine [21], and hexanitrostilbene (HNS) [22] are of interest because of their high levels of shock insensitivity and thermal stability. The development of new, explosive compounds and compositions is an ongoing area of research [23, 24], including interest in composite explosives similar to those used by industry. Examples are EAK, a eutectic mixture of ethylenediamine dinitrate, AN, and potassium nitrate [25], and nonaqueous hardened or cast emulsion-based mixtures [26].

Classification of Explosives

The original classification of explosives separated them into two very general types: low and high, referring to the relative speeds of their chemical reactions and the relative pressures produced by these reactions. This classification still is used, but is of limited utility because the only low explosives of any significance are black powder and smokeless powder. All other commercial and military explosives are high explosives.

High explosives are classified further according to their sensitivity level or ease of initiation. Actually sensitivity is more of a continuum than a series of discrete levels, but it is convenient to speak of primary, secondary, and tertiary high explosives. Primary explosives are the most sensitive, being readily initiated by heat, friction, impact, or spark. They are used only in very small quantities and usually in an initiator as part of an explosive train involving less sensitive materials, such as in a blasting cap. They are very dangerous materials to handle and must be manufactured with the utmost care, generally involving only remotely controlled operations. Mercury fulminate, used in Nobel's first blasting cap, is in this category, as is the more commonly used lead azide. On the other end of the spectrum are the tertiary explosives that are so insensitive that they generally are not considered explosive.

By far the largest grouping is secondary explosives, which includes all of the major military and industrial explosives. They are much less easily brought to detonation than primary explosives and are less hazardous to manufacture. Beyond that, however, generalizations are difficult because their sensitivity to initiation covers a very wide range. Generally, the military products tend to be more sensitive and the industrial products less sensitive, but all are potentially hazardous and should be handled and stored as prescribed by law. Table 37.3 lists some of the more prominent explosives of each type, along with a few of their properties.

For industrial applications, secondary explosives are subdivided according to their initiation sensitivity into two classes: Class 1.1 and Class 1.5. Class 1.1 explosives are sensitive to initiation by a blasting cap and usually are used in relatively small-diameter applications of 1–3-in. boreholes. Class 1.5 (historically known as blasting agents) are high explosives that are not initiated by a Standard #8 electric blasting cap under test conditions defined by the U.S. Department of Transportation (DOT) and that pass other defined tests designed to show that the explosive is "so insensitive that there is very little probability of accidental initiation to explosion or of the transition from deflagration to detonation" [27]. Being less sensitive, blasting agents are generally used in medium- and large-diameter boreholes and in bulk applications. Dynamites are always Class 1.1, but other composite explosives made from mixtures of oxidizers and fuels can be made either Class 1.1 or 1.5, depending upon the formulation and the density. Density plays a significant role in the performance of most explosives, and this is especially true for commercial, composite explosives such as slurries and emulsions where the density may be adjusted by air incorporation, foaming agents or physical bulking agents, irrespective of the formulation. The Class 1.5 explosives (blasting agents) are of interest because regulations governing transportation, use, and storage are less stringent than for Class 1.1 explosives. (Propellants and fireworks are classified by the DOT as Class 1.2 or 1.3 explosives, and blasting caps and detonating cord as Class 1.4.)

Structural Characteristics of Explosives

The number of potentially explosive compounds is virtually unlimited. A listing by the U.S. Bureau of Alcohol, Tobacco and Firearms of explosive materials under federal regulation [28] numbered 225, and many of the items listed were broad, general categories. The ten-volume *Encyclopedia of Explosives and Related Items* compiled by the U.S. Army

Table 37.3 Some properties of common explosives

Common name	Symbol	Composition	Molecular weight	Density (g/cc)	Detonation velocity (km/s)	Detonation pressure (kbar)	Explosive energy (cal/g)
Primary explosives							
Mercury fulminate		$Hg(CNO)_2$	284.7	3.6	4.7	220	428
Lead azide		$Pb(N_3)_2$	291.3	4.0	5.1	250	366
Silver azide		AgN_3	149.9	5.1	6.8	–	452
Lead styphnate		$C_6H(NO_2)_3O_2Pb$	468.3	2.5	4.8	150	368
Mannitol hexanitrate (nitromannite)	MHN	$C_6H_8(ONO_2)_6$	452.2	1.7	8.3	300	1,420
Diazodinitrophenol	DDNP	$C_6H_2N_4O_5$	210.1	1.5	6.6	160	820
Tetrazene		$C_2H_8N_{10}O$	188.2	1.5	–	–	658
Secondary explosives							
Nitroglycerin	NG	$C_3H_5(ONO_2)_3$	227.1	1.6	7.6	253	1,480
Pentaerythritol tetranitrate	PETN	$C(CH_2ONO_2)_4$	316.2	1.6	7.9	300	1,510
Trinitrotoluene	TNT	$CH_3C_6H_2(NO_2)_3$	227.0	1.6	6.9	190	900
Ethyleneglycol dinitrate	EGDN	$C_2H_4(ONO_2)_2$	152.1	1.5	7.4		1,430
Cyclotrimethylenetrinitramine (hexogen or cyclonite)	RDX	$C_3H_6N_3(NO_2)_3$	222.1	1.6	8.0	347	1,320
Cyclotetramethylenetetranitramine (octogen)	HMX	$C_4H_8N_4(NO_2)_4$	296.2	1.9	9.1	393	1,350
Trinitrophenylmethylnitraminc (tetryl)		$(NO_2)_3C_6H_2N(CH_3)NO_2$	287.2	1.4	7.6	251	950
Nitroguanidine	NQ	$CH_4N_3NO_2$	104.1	1.6	7.6	256	721
Nitromethane	NM	CH_3NO_2	61.0	1.1	6.2	125	1,188
Nitrocellulose	NC	Variable	–	1.4	6.4	210	950
Triaminotrinitrobenzene	TATB	$C_6H_6N_3(NO_2)_3$	258.2	1.8	7.9	315	829
Diaminotrinitrobenzene	DATB	$C_6H_5N_2(NO_2)_3$	243.2	1.6	7.5	259	993
Ethylenediamine dinitratc	EDDN	$C_2H_{10}N_4O_6$	186.1	1.5	6.8	–	948
Ethylenedinitramine (haleite)	EDNA	$C_2H_6N_2(NO_2)_2$	150.1	1.5	7.6	266	1,080
Picric acid		$C_6H_3O(NO_2)_3$	229.1	1.7	7.4	265	1,000
Ammonium picrate (explosive D)		$C_6H_6NO(NO_2)_3$	246.1	1.6	6.9	–	800
Picramide		$C_6H_6N(NO_2)_3$	228.1	1.7	7.3	–	1,070
Hexanitrostilbene	HNS	$[C_6H_3C(NO_2)_3]_2$	450.2	1.7	7.1	200	1,005
TACOT-Z		$C_{12}H_4N_8O_8$	388.2	1.6	7.2	181	980
Azobishexanitrobiphenyl	ABH	$C_{24}H_6N_{14}O_{24}$	874.4	1.8	7.6	–	
Dinitrotoluene	DNT	$CH_3C_6H_3(NO_2)_2$	182.1	1.5	5.0	–	700
Composition B		49/50/1 TNT/PDX/wax	–	1.7	8.0	294	1,100
Pentolite		50/50 TNT/PETN	–	1.6	7.7	245	1,100
Amatol		50/50 TNT/AN	–	1.6	6.5	–	950
Dynamite		Variable NG and various oxidizers and fuels	–	0.8–1.6	1.8–7.6	30–160	675–1,090
Prilled AN-fuel oil	ANFO	94/6 AN/FO	–	0.8–0.9	1.5–4.0 (depends on diameter)	–	880
Slurries or water gels		Variable mixtures of oxidizers, fuels, and water	–	0.9–1.4	3.5–5.0	–	600–1,200
Emulsions		Variable solutions of oxidizers in water and fuels	–	0.9–1.4	4.5–6.0	–	700–1,100
Heavy ANFO		50–75 % AN with 50–25 % emulsion	–	1.1–1.3	4.0–4.5	4.0–4.5	755–815
Tertiary explosives							
Mononitrotoluene	MNT	$CH_3C_6H_4NO_2$	137.1	1.2			
Ammonium perchlorate	AP	NH_4ClO_4	117.5	1.9	3.4	187	488
Ammonium nitrate	AN	NH_4NO_3	80.1	1.4	3.2	–	346

Picatinny Arsenal over a 25-year period contains several thousand entries. New organic molecular explosives are still being synthesized; composite explosives, such as current commercial products that are mixtures of oxidizers and fuels, present an infinite number of possible combinations. The complexity of trying to comprehensively list the chemical structures of explosives is shown by a 1977 reference that listed 13 separate categories just for primary explosives [29]. However; the majority of the most important explosives can be grouped into a few classes sharing common structural features that are of value to researchers in understanding and predicting explosive properties.

The following seven categories [30, 31], updated to include the relatively recent fluoroderivatives [23], appear to be the most encompassing. Many explosives may contain more than one category, but not every compound that contains one of these chemical groups is necessarily an explosive.

–NO
–N–N–, –NN–, and –N≡N
–C≡N– and –C≡N
–C≡C–
–ClO
–N–X, where X = Cl, F, I
–O–O–

Category 1 is by far the largest. It includes nitro groups, both aliphatic and aromatic; nitrate esters; nitrate salts; nitramines; and nitrosamines. Nearly all of the explosives listed in Table 37.3 fall into this category. Prominent examples are: nitromethane, an aliphatic nitro compound; TNT, an aromatic nitro compound; NG and PETN, nitrate esters; EDDN and ammonium nitrate, nitrate salts; and RDX and HMX, nitramines. Category 2 represents the hydrazine, azo, diazo, and azide compounds, both organic and inorganic. Hydrazine, tetrazene, and lead azide are examples of this group. Category 3 is represented by the explosives mercury fulminate and cyanogen, respectively. Acetylene and metallic acetylide salts constitute category 4. Category 5 consists mainly of inorganic and organic ammonium salts of chloric and perchloric acid, but would also include various chlorine oxides. Category 6 is generalized to include most of the amine halogens, nitrogen triiodide being a classic example. Also, considerable synthetic work has focused on inserting the energetic difluoroamine groups into various organic molecules to form explosives that fall into this category. Category 7 includes organic peroxides and ozonides as well as hydrogen peroxide itself.

Commercial industrial explosives such as dynamites, slurries, and emulsions are included in these categories because their major components, nitrate esters and nitrate and perchlorate salts, are listed. However, mixtures of fuels and oxygen or other gases that may be explosive at certain ratios are not covered, including the liquid oxygen explosives that saw limited application earlier in the twentieth century.

Explosives Manufacturing and Use

Details of the synthesis and larger-scale production of a number of molecular explosives including dynamites are given in the four-volume series by Urbanski (*Chemistry and Technology of Explosives*, Pergamon Press, 1964–1984) and in various military books such as *Engineering Design Handbook: Explosive Series*. Formulations of commercial slurries and emulsions generally are considered proprietary and are described mainly in the patent literature. Some specific examples of prominent explosives with general preparation methods are given below.

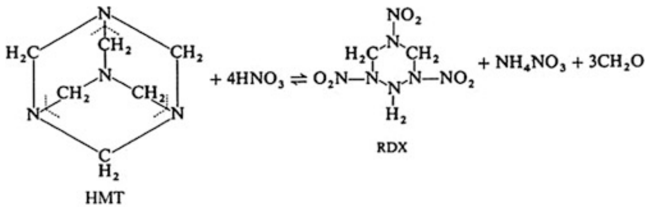
TNT

TNT is no longer manufactured in the United States for either commercial or military use. It is produced commercially in other countries and is imported into the United States for use in cast boosters to initiate industrial blasting agents. TNT use in military applications is still significant, but starting to decline as other higher technology munition and bomb fills come into use. Current TNT military needs are supplied from off-shore sources as well as through recycling from demilitarized weapons. A lot of the demilitarized TNT is also used commercially in the U.S. in cast boosters. In a relatively straightforward process, TNT is made by the direct tri-nitration of toluene with nitric acid. Most modern processes are set up for continuous production in a series of nitrators and separators with the nitrating acid flowing counter-currently. This procedure avoids having to isolate the intermediate mono- and dinitration products and may also employ continuous purification and crystallization, being carried out simultaneously with production.

Mixed nitric and sulfuric acids sometimes are used with the addition of SO_3 or oleum. The sulfuric acid or oleum helps drive the reaction to completion by removing the water produced by nitration and by dehydrating nitric acid to form the more reactive nitronium ion (NO_2^+). Because toluene is not very soluble in the acid, powerful agitation is required. The spent acid is removed in successive separation steps, and the sulfuric acid is reused after the addition of more nitric acid. The molten TNT product is purified with multiple water and sodium sulfate washes, which produce significant quantities of “yellow water” and “red water” waste streams, respectively, that must be properly handled to avoid environmental problems. The low melting point of TNT (80–82°C) is ideal for melt casting, and TNT usually is employed as a mixture with other higher-melting explosives such as PETN, RDX, HMX, and Tetryl. This feature and the excellent chemical stability of TNT have made it, historically, the most popular and widely used military explosive in the world.

RDX and HMX

Both RDX and HMX are cyclic nitramines made by nitrolysis of hexamethylene tetramine (HMT). Their good thermal stabilities, high melting points (7200°C), and high energy properties make these crystalline compounds popular as projectile and bomb fills and for use in cast boosters and flexible, sheet explosives. HMX has superior detonation properties and a higher melting point than RDX, but it is more difficult and more expensive to manufacture. Reaction 1 shows the formation of RDX by the action of nitric acid on HMT. Schematically, RDX formation can be pictured as nitration of the three "outside" nitrogen atoms of HMT (in more accurate, three-dimensional representations all four nitrogens are equivalent) with removal of the "inside" nitrogen and methylene (–CH_2–) groups. AN (NH_4NO_3) and formaldehyde (CH_2O) are produced as by-products, but can be used to form more RDX with the addition of acetic anhydride, as shown in Reaction 2. In actual practice these two reactions are run simultaneously, as shown in the combined reaction to produce approximately 2 mol of RDX for each mole of HMT.



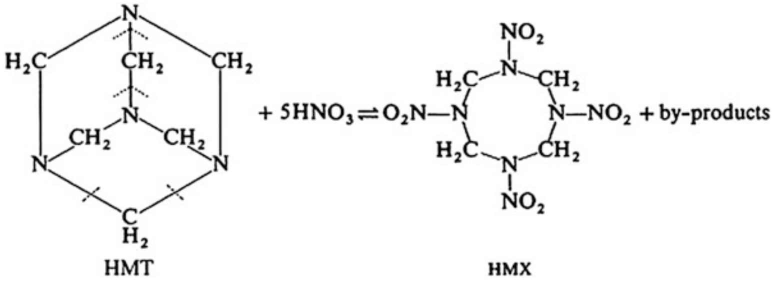
Reaction 2

$$\underset{\text{Formaldehyde}}{3CH_2O} + \underset{\text{AN}}{3NH_4NO_3} + \underset{\text{Acetic anhydride}}{6(CH_3CO)_2O}$$

$$\rightarrow \underset{\text{RDX}}{(CH_2 \cdot N \cdot NO_2)_3} + \underset{\text{Acetic acid}}{12CH_3COOH}$$

Combined Reaction

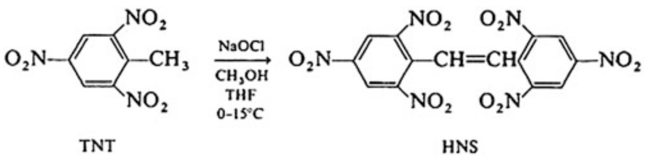
$$(CH_2)_6N_4 + 4HNO_3 + 2NH_4NO_3 + 6(CH_3CO)_2 \rightarrow 2(CH_2 \cdot N \cdot NO_2)_3 + 12CH_3COOH$$



HMX was discovered as an impurity produced in the RDX reaction. It is composed of an eight-membered ring rather than the six-membered ring of RDX. The latter is more readily formed than the eight-membered ring, but with adjustment of reaction conditions (lower temperature and different ingredient ratios), HMX formation can be favored. Schematically, its formation can be pictured by nitration of all four nitrogens in HMT and removal of two methylene groups as indicated in Reaction 3. To obtain pure HMX, the RDX "impurity" must be removed by alkaline hydrolysis or by differential solubility in acetone.

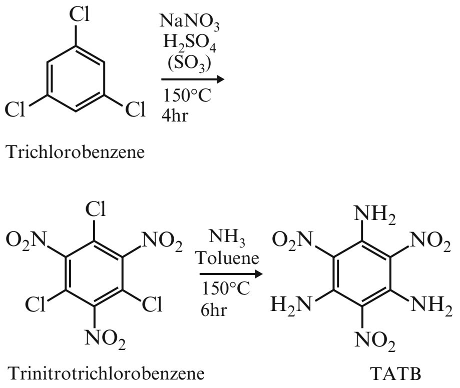
HNS (2,2,4,4,6,6-Hexanitrostilbene)

This explosive was prepared unequivocally for the first time in the early 1960s [32, 33]. It is of interest primarily for two reasons: (1) its high melting point (316°C) and excellent thermal stability, and (2) its unique crystal-habit-modifying effects on cast TNT. The former makes HNS useful in certain military and space applications as well as in hot, very deep wells, and the second property is used to improve TNT castings. It can be manufactured continuously by oxidative coupling of TNT as shown below. This relatively simple process from readily available TNT and household bleach (5% NaOCl solution) has been shown to involve a series of intermediate steps that give HNS in only low to moderate yields (30–45%) with many by-products. Although it also involves the use of expensive organic solvents that must be recovered, this synthesis is used commercially [34, 35].



TATB (1,3,5-Triamino-2,4,6-Trinitrobenzene)

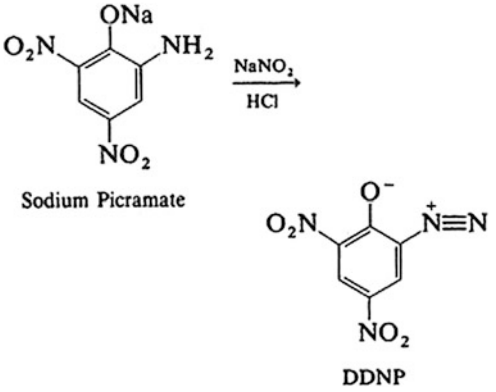
This highly symmetrical explosive molecule has even higher thermal stability than HNS (greater than 400°C) and has ongoing interest because of its extreme insensitivity [36–38]. Because accidental initiation is highly unlikely, TATB has been used in nuclear warheads and has been explored for use in plastic bonded systems for a number of military and space applications [21]. It is manufactured in large-scale batch processes that are little changed from its original synthesis over 100 years ago. The two-step process involves tri-nitration of trichlorobenzene followed by amination to displace the chlorine groups as shown below.



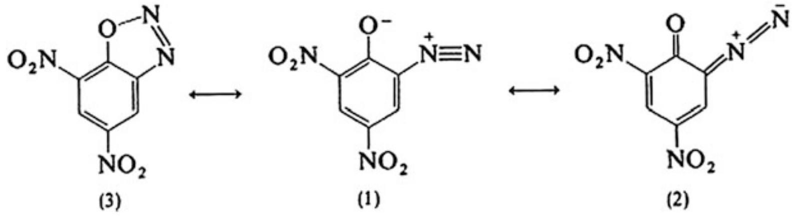
Both steps require high temperature and considerable reaction time but give 80–90% yields. The major problem areas are chloride impurities in the final product and the excessively fine particle size of the final product. Because TATB is highly insoluble in most solvents, it is difficult to purify the product or to change its particle size by recrystallization. Also the starting material is expensive and not very readily available. More recently, a similar synthetic procedure starting with 3,5-dichloranisole was reported [39].

DDNP

This yellow-to-brown crystalline material (melting point 188°C) is a primary explosive used as the initiator charge in electric blasting caps as an alternative to lead azide. It is less stable than lead azide but much more stable than lead styphnate and is a stronger explosive than either of them because it does not contain any metal atoms. 2-Diazo-4, 6-dinitrophenol (DDNP) is also characterized as not being subject to dead pressing (tested at pressures as high as 130,000 psi). It was the first diazo compound discovered (1858) and was commercially prepared in 1928. It is manufactured in a single-step, batch process by diazotizing a slurry of sodium picramate in water.

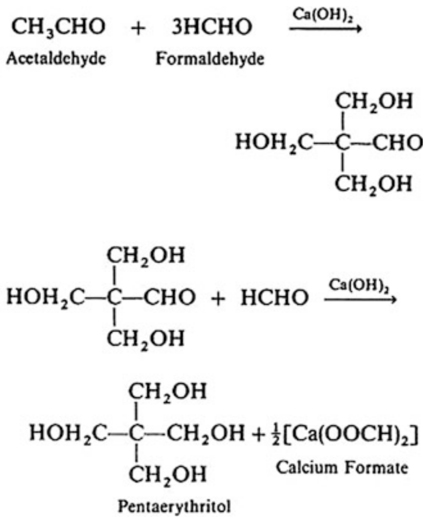


The structure shown in this reaction is convenient for visualization purposes, but DDNP actually exists in several tautomeric forms as shown below with form (2) apparently predominating. The sodium picramate starting material is itself explosive, but is commercially available as a chemical intermediate. It can be made by the reduction of picric acid with reducing agents such as sodium sulfide. The key to making useful DDNP is to control the rate of diazotization so that relatively large, rounded crystals are formed instead of needles or platelets that do not flow or pack well.



PETN

Although known as an explosive since 1894, PETN was used very little until after World War I when the ingredients to make the starting material became commercially available. The symmetrical, solid alcohol starting material, pentaerythritol, is made from acetaldehyde and formaldehyde, which react by aldol condensation under basic catalysis followed by a crossed Cannizzaro disproportionation to produce the alcohol and formate salt. Although the reaction takes place in a single mixture, it is shown below in two steps for clarity.



For PETN manufacture the pentaerythritol starting material can be readily purchased as a commodity chemical from commercial suppliers. The nitration is relatively simple, involving only nitric acid (96–98%) and the solid alcohol added slowly with mixing and cooling. PETN is not very soluble in nitric acid or water and is readily filtered directly from the acid or after dilution of the acid with water. Water washing and recrystallization from acetone–water mixtures give the desired particle size ranges and the desired purity. PETN can be made either batchwise or continuously for large-scale production.

Pure PETN is a white, crystalline solid with a melting point of 141.3°C. Because of its symmetry, it is said to have higher chemical stability than all other nitrate esters [40]. Relatively insensitive to friction or spark initiation, PETN is easily initiated by an explosive shock and has been described overall as one of the most sensitive, non-initiating, military explosives [41]. As with most explosives, the detonation velocity of PETN varies with the bulk density of the explosive. Most military applications of PETN have been converted to RDX because of its greater thermal stability. However, in industry PETN is widely used as a major component in cast boosters for initiating blasting agents, as the explosive core in detonating cord, and as the base load in detonators and blasting caps. For safety in handling, PETN is shipped in cloth bags immersed in water–alcohol mixtures and dried just before use.

NG (Nitroglycerin or Glyercol Trinitrate)

This nitrate ester is one of only a very few liquid molecular explosives that are manufactured commercially. It is a clear, oily liquid that freezes when pure at 13°C. As seen in the historical section, the first practical use of NG was in dynamites, where it is still used today more than 140 years later. It also is used as a component in multi-based propellants and as a medicine to treat certain coronary ailments. This latter usage is attributed to NG's ability to be rapidly absorbed by skin contact or inhalation into the blood, where it acts as a vasodilator. (At high exposure levels such as in dynamite manufacture and handling, this property is responsible for the infamous powder headache.) NG is undoubtedly the most sensitive explosive manufactured in relatively large quantities. Its sensitivity to initiation by shock, friction, and impact is very close to that of primary explosives, and extreme safety precautions are taken during manufacture. Pure glycerin is nitrated in very concentrated nitric and sulfuric acid mixtures (typically a 40/60 ratio), separated from excess acid, and washed with water, sodium carbonate solution, and water again until free from traces of acid or base. Pure NG is stable below 50°C, but storage is not recommended. It is transported over short distances only as an emulsion in water or dissolved in an organic solvent such as acetone. Traditionally, it has been made in large batch processes, but safety improvements have led to the use of several types of continuous nitrators that minimize the reaction times and quantities of explosives involved. Because of its sensitivity, NG is utilized only when desensitized with other liquids, combined with absorbent solids or compounded with nitrocellulose.

Packaged Explosives

Packaged explosives dominated the explosives market from the time dynamite was invented in 1867 until the middle of the twentieth century. At that time, other composite type packaged technologies began appearing, particularly in the 1960s and 1970s, concurrent with increasing market penetration of bulk explosives. During those years of rapid technology development, two packaged product types emerged, first water-gel explosives, followed in the 1970s and early 1980s by packaged emulsion explosives. All of these packaged product technologies remain active in parts of the world as of the date of this edition, but in the U.S., emulsions are pre-eminent followed by dynamites. Both are discussed below.

Dynamite

Dynamite is not a single molecular compound, but a mixture of explosive and non-explosive materials formulated in cylindrical paper or cardboard cartridges for a number of different blasting applications. Originally Nobel simply absorbed NG into kieselguhr, an inert diatomaceous material, but later he replaced that with active ingredients—mixtures of finely divided fuels (including absorbent combustibles) and oxidizers called dopes. Thus, energy is derived not only from the NG, but also from the reaction of oxidizers such as sodium nitrate with the combustibles.

The manufacture of dynamite involves mixing carefully weighed proportions of NG and various dopes to the desired consistency and then loading preformed paper shells through automatic equipment. Because dynamites represent the most sensitive commercial products produced today, stringent safety precautions such as the use of non-sparking and very-little-metal equipment, good housekeeping practices, limited personnel exposure, and barricaded separations between processing stations are necessary for manufacturing. Today, the "NG" used in dynamite is actually a mixture of EGDN (ethylene glycol dinitrate) and NG formed by nitrating mixtures of the two alcohols (ethylene glycol and glycerin), in which NG is usually the minor component. Table 37.4 lists the common general types of dynamites with their distinguishing features. The straight dynamites and gelatins largely have been replaced by the ammonia dynamites and ammonia gelatins for better economy and safety characteristics.

The use of NG-based dynamite continues to decline throughout the world. For example, by 1995 there was only one dynamite manufacturing plant left in North America, and in 2010 the dynamite production at this plant had dropped to about one-third the amount produced in 1990. The reasons for the declining use of dynamite are its unpopular properties of sensitivity to accidental initiation and the headache-causing fumes. However (despite its higher cost), for some difficult blasting applications it remains the product of choice due to its high density and high energy and sensitivity.

Packaged Emulsions

The first major non-dynamite package product technology was water gels. These were composite mixtures of hot, concentrated, dissolved oxidizer solution slurried with other ingredients including soluble and insoluble liquid fuels, particulate fuels, solid oxidizer salts, and thickeners consisting of natural and synthetic water soluble polymers. The thickened solution could be gelled by addition of cross-linking agents, typically inorganic salts of certain metals. The gelled structure gave significant, but not excellent water resistance.

Packaged water-in-oil emulsions are made from essentially the same oxidizer solutions as used for water-gel products, but are fueled with an organic external liquid hydrocarbon phase that provides much better water resistance. These products are basically formed with the same manufacturing equipment as the bulk emulsions (see next section). The fuel component usually contains waxes and other thickeners to give the emulsions a thick, putty-like consistency, and the oxidizer solution often contains both AN and a second oxidizer salt to produce optimum energy, physical stability, and improved after-blast fumes. After manufacture, the hot, thick emulsion is extruded into packaging material, normally a plastic film. The final product is then clipped together with metal clips forming firm, sausage-like chubs and is cooled which further thickens the product. Some packaged emulsions are also available in paper cartridges, designed to simulate dynamite packaging. To obtain reliable detonability in small diameters, the density of packaged emulsions must be maintained at a relatively low value, typically 1.10–1.20 g/cc. On the other hand, some dynamites are available with densities in excess of 1.40 g/cc. Figure 37.4 shows some commercial packaged emulsion cartridges in both plastic and paper wrappings.

Table 37.4 General types of dynamite

Straight dynamite	Granular texture with NG the major source of energy
Ammonia dynamite ("extra" dynamite)	AN replacing part of the NG and sodium nitrate of the straight dynamite
Straight gelatin dynamite	Small amount of nitrocellulose added to produce soft to tough rubbery gel
Ammonia gelatin dynamite ("extra" gelatin)	AN replacing part of the NG and sodium nitrate of the straight gelatin
Semigelatin dynamite	Combination of types 2 and 4 within-between properties
Permissible dynamite	Ammonia dynamite or gelatin with added flame retardant

Bulk Explosives

Ammonium Nitrate and ANFO

Ammonium nitrate (AN) continues to be the most widely used component of commercial explosives. It is used in nearly all of the packaged and bulk explosives on the market. Ammonia is the main raw material needed to manufacture AN. Some of the AN manufacturers make their own ammonia and some purchase it on the open market. It is obvious that the cost of manufacturing AN will depend on the price of ammonia and, even more basically, natural gas from which ammonia is made. Figure 37.5 shows the volatility of natural gas over the last decade. This volatility translates into volatility in the cost of explosives, although significant natural gas development in the U.S. over the past few years seems to be suppressing some of the price fluctuation.

There are many producers of AN in North America making both AN solution and explosive-grade AN prills. The AN solution is used in the manufacture of packaged and bulk emulsion and water-gel explosives, and explosive-grade AN prills are used to make ANFO, a composite explosive described in an earlier section. These low density AN prills are made by a specialized process, in which internal

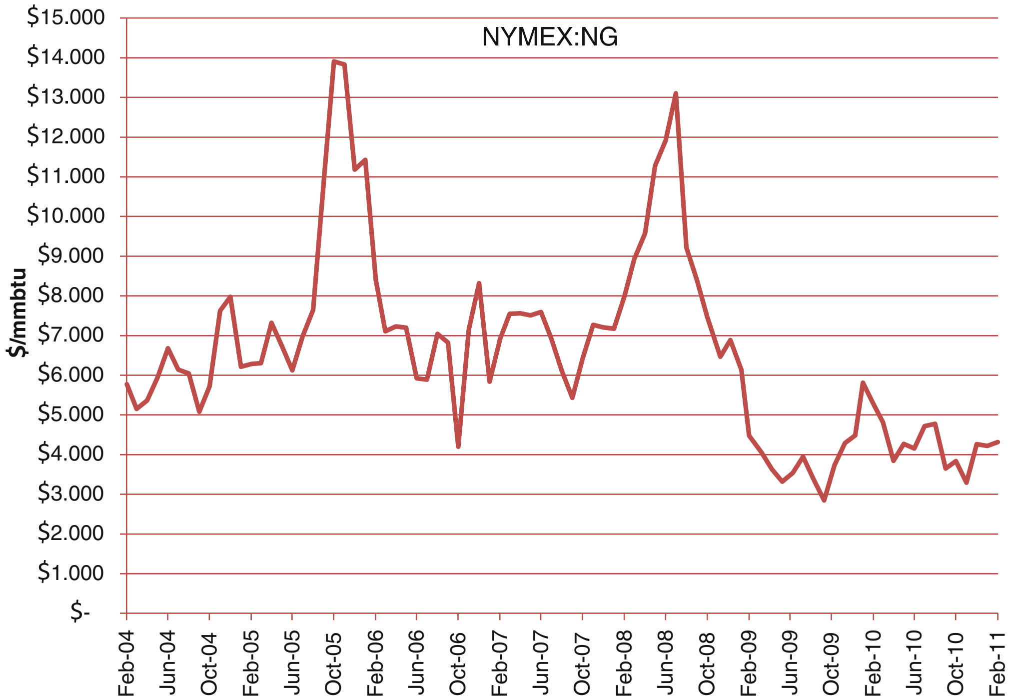

Fig. 37.5 Volatility of natural gas prices from 2004 to 2010. New York Mercantile Exchange, Natural Gas, Compiled Monthly

voids are created, making the prills porous and able to absorb the required 5.5–6% FO. ANFO remains the largest volume commercial explosive in use today around the world. Because of this, ANFO is commonly used as a reference when defining and comparing explosive properties. Some of these important explosive properties include density, detonation velocity, and energy release.

The crystal density of AN is about 1.72 g/cc, and the particle density of explosive-grade AN prills ranges from about 1.40 to 1.45 g/cc depending upon the manufacturing process. This difference in crystal and particle density reveals the volume of pores or voids created by the specialized prilling process. The porosity of AN prills is the property desired in the manufacture of ANFO, since this determines how much FO can be absorbed. This intimate mixture of AN with FO is critical to the efficient detonability of ANFO. The AN prill particle density and inherent void-space value also become important when predicting and calculating the densities of ANFO blends with water-gel and emulsion explosives.

The bulk density of ANFO ranges from about 0.80 to 0.87 g/cc. So, clearly about half of the ANFO is air or void space. Most commercial explosives require a certain amount of entrained void space in order to detonate optimally. These void spaces play a major role in the detonation reaction by creating reaction sites, "hot spots," under adiabatic compression and interaction with the shock wave in the detonation front [42]. The amount of void space in any given explosive and the resultant change in density have a significant impact on the detonation properties like detonation velocity, sensitivity, and even energy release.

Generally speaking, the detonation velocity of a composite explosive will increase with density until a failure point is reached. This failure point is commonly referred to as the critical density of that particular explosive in that particular diameter or other configuration. The density at that point is so high and the void space so low that the detonation cannot be sustained and failure occurs.

Other important parameters that affect the detonation velocity and performance of ANFO are charge diameter and confinement. The detonation velocity of commercial composite explosives such as ANFO will drop dramatically as the diameter of the charge nears the failure diameter. At a given density, the diameter below which a charge fails to propagate a detonation is called the critical diameter. As a charge diameter is increased from this point, the detonation velocity increases asymptotically to a maximum value for that particular explosive formulation. The detonation velocity of ANFO will also increase noticeably when the charge confinement is changed, such as from a PVC tube to a Schedule 40 steel pipe. A summary of test data on ANFO velocity vs. confinement and diameter is shown in Fig. 37.6. The temperature of composite explosives also affects sensitivity and critical properties.

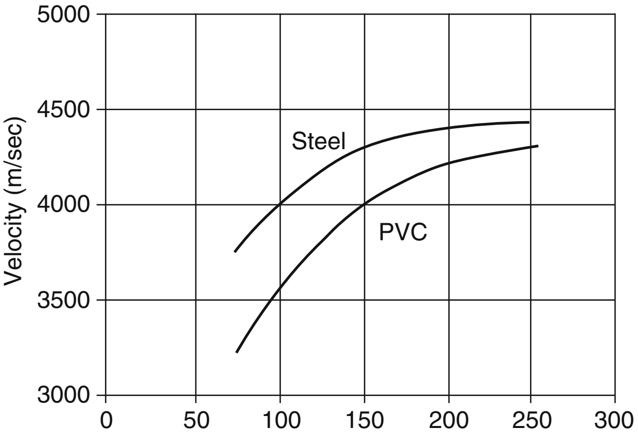

Fig. 37.6 Detonation velocity of ANFO vs. diameter and confinement

The basic chemical reaction of ANFO can be described with the following equation:

$$3NH_4NO_3 + CH_2 \rightarrow CO_2 + 7H_2O + 3N_2 + 880\,\mathrm{cal/g}$$

Using CH_2 to represent FO is generally accepted, but it really is an over-simplification, since it is a mixture of hydrocarbons. The heat energy release of 880 cal/g is the theoretical maximum value based upon the heats of formation of the reactants and products. Of course, all of the products of detonation are gases at the detonation temperature of about 2,700 °K.

The theoretical work energy that is released from an explosive reaction can be calculated using a variety of equations of state and computer programs [43]. Explosive energy can also be measured by a variety of techniques including underwater detonation of limited size charges with concurrent measurements of the shock and bubble energies [44]. Each explosive manufacturer has an energy measurement and equation of state that is used to calculate and report their product properties. This often leads to confusion and controversy when explosive consumers try to compare product lines when given only technical information sheets. Since theoretical calculations must of necessity be based on a number of assumptions, the most valid comparisons are done in the field with product testing and detailed evaluation of results.

Bulk Emulsions

During the past 50 years, the commercial use of bulk delivered explosives, including ANFO and other composite explosives, has continued to increase while the use of packaged explosives continued to fall on a percentage basis. Due to low cost and superior sensitivity compared to earlier water-resistant technologies such as water gels, bulk emulsions have been leading this trend over the last 25–30 years. Bulk products initially became very popular in large volume open-pit mining operations and this accelerated with the advent of bulk emulsion products and blends with ANFO. More recently, bulk emulsions have increasingly replaced packaged products in underground mining and particularly in quarry operations.

Emulsions are made by combining an oxidizer solution and a fuel solution using a high-shear mixing process. The oxidizer solution is normally 90–95% by weight of the emulsion. It contains AN, water, and sometimes a second oxidizer salt such as sodium or calcium nitrate. The solution must be kept quite hot, since the water is minimized for increased energy, and the crystallization temperature is typically 50–70°C. The fuel solution contains liquid organic fuels, such as FO and/or mineral oils, and one or more emulsifiers. An emulsifier is a surface active chemical that has both polar and nonpolar ends of the molecule. In the high-shear manufacturing process, the oxidizer solution is broken up into small droplets, each of which is coated with a layer of fuel solution. The droplets in this meta-stable, water-in-oil emulsion are basically held together with the emulsifier molecules, which migrate to the surface of the dispersed droplets and form a link between the hydrophobic external (continuous) oil phase and the hydrophilic phase within the droplets. In today's explosives industry, much of the research work is directed towards developing better and more-efficient, emulsifier molecules that will improve the storage life and handling characteristics of the bulk and packaged emulsions. The emulsifiers currently used in commercial explosives range from relatively simple fatty acid esters with molecular weights of 300–400 to the more complex polymeric emulsifiers having molecular weights in excess of 2,000.

Figure 37.7 shows a photomicrograph of an emulsion explosive at 400 power with the typical distribution of the fuel-coated oxidizer solution droplets (nominally 1–5 μm in diameter). Figure 37.8 shows a bulk emulsion exiting a loading hose and displaying the soft ice cream-like texture typical of bulk emulsions. The viscosities of bulk emulsions can range from nearly as thin as 90 weight oil to thicker than mayonnaise, depending upon the application requirements. Emulsion viscosity increases with product cooling, but most emulsions continue to remain stable at temperatures well below 0°C, dramatically below the crystallization temperature of the oxidizer solution. The oxidizer solution droplets in the emulsion are therefore held in a supersaturated state. Over time, the surface layers created by the emulsifier molecules can become less stable due to chemical degradation (oxidation) of the emulsifier or other spontaneous physical and chemical processes. Movement of the emulsion is also stressful to these systems, which in reality are thermodynamically unstable, tending towards crystallization and coalescence. Crystals can begin to form that break though the emulsifier layer and the emulsion begins to "break down" and further crystallize, thereby diminishing some of the desirable physical and detonation properties. For this reason emulsion compositions must be optimized for a particular application in terms of product stability and usable storage life.

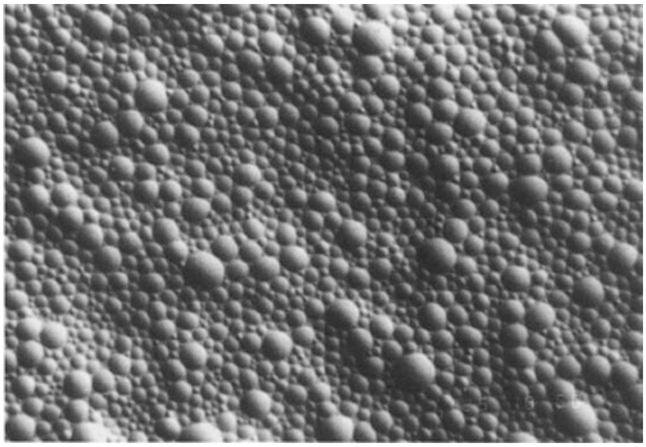

Fig. 37.7 Photomicrograph of a bulk emulsion

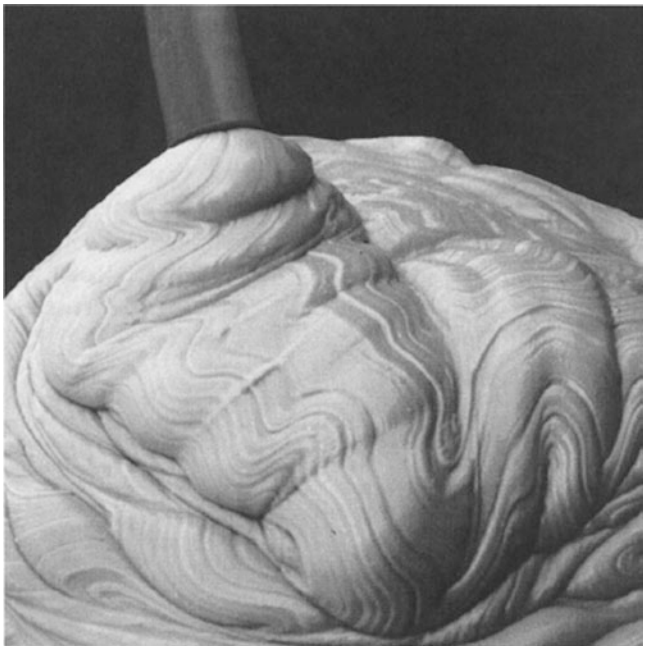

Fig. 37.8 Bulk emulsion exiting a loading hose

The intimate mixing of oxidizer and fuel in emulsions gives these explosives much higher detonation velocities when compared to ANFO. For example, in 150 mm diameter PVC, ANFO at a density of ~0.82 g/cc has a velocity of about 4,000 m/s, and a sensitized emulsion would have a velocity closer to 6,000 m/s at a density of 1.20–1.25 g/cc.

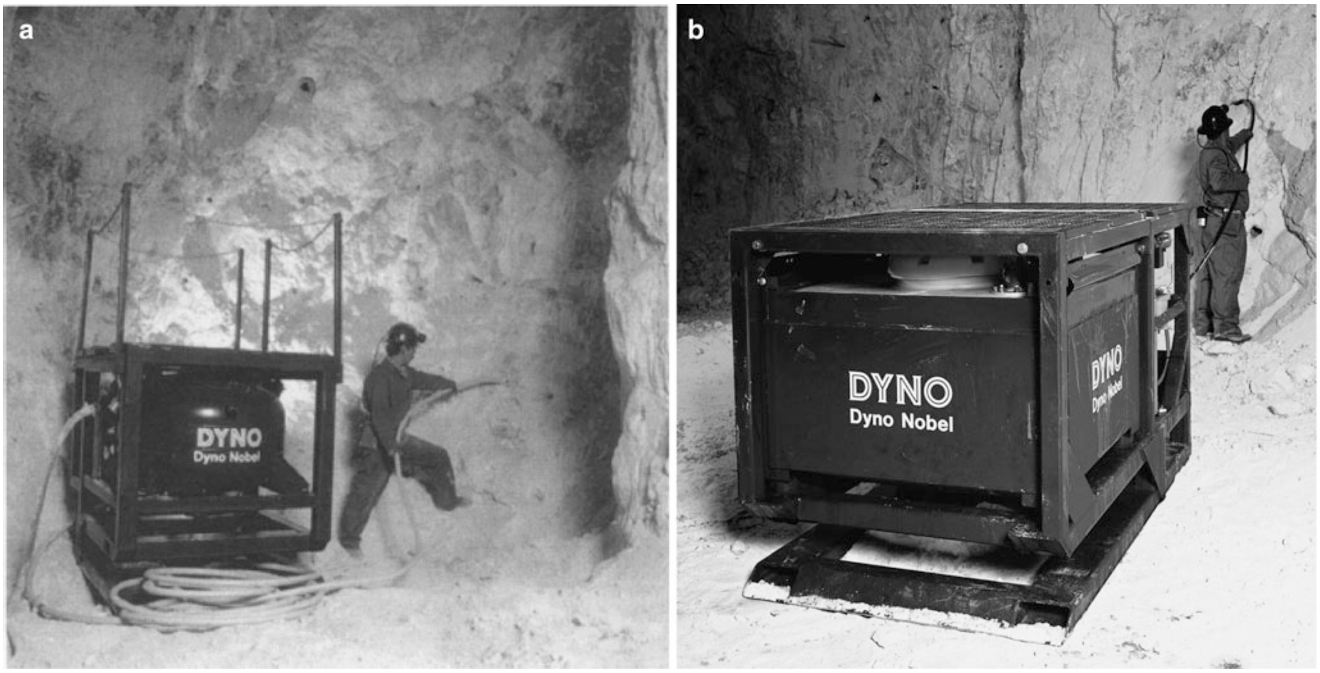

Fig. 37.9 (**a**) Underground pressure vessel loader. (**b**) Compressed-air, powered pumper for underground bulk emulsion (Courtesy Dyno Nobel)

Also, the layer of oil surrounding each oxidizer solution droplet protects the emulsion from extraneous water intrusion and subsequent deterioration of the explosive. Many studies have shown that when mining operations use emulsion explosives rather than ANFO, which has basically no water resistance, the amount of nitrate salts in mine ground water is reduced considerably. This can be a very important factor in today's environmentally conscious mining and explosives industry.

Bulk emulsions are generally non-detonable per se and are typically sensitized with some type of density control medium to become usable blasting agents. These voids interact with the shock wave, creating "hot spots," which are required to sustain the detonation front. The two most commonly used density control methods are hollow solid microspheres and gas bubbles created by an in situ chemical reaction. Both glass and plastic hollow microspheres are commercially available and used by explosives manufacturers. The in situ chemical gassing techniques require considerably more expertise and generally utilize proprietary technology. Emulsion blended with ANFO, with its internal and interstitial air voids, is also widely used as a less efficient but effective sensitizer in larger diameter boreholes.

Underground Bulk Emulsions

In the past decade the use of sensitized bulk emulsions has continued to increase in underground mining. In addition to the necessary small diameter sensitivity of emulsion based explosives in these applications, much of this trend has been due to the development of innovative loading equipment and techniques. One example of this is shown in Fig. 37.9a, which shows a small-volume pressure vessel that can be used for development and tunnel rounds utilizing horizontally drilled boreholes. The bulk emulsion blasting agent is pressurized inside the vessel and literally squeezed through the loading hose into the boreholes. A continuous column of explosives is assured by inserting the loading hose to the back of the hole and extracting it as the product is loaded. A more recently designed air-powered pumper unit for underground delivery of bulk emulsion is shown in Fig. 37.9b. This unit typically uses compressed air, available in most underground mines, to power a pump that delivers the bulk explosive. Much more complex underground loading units are available for loading bulk emulsion into boreholes drilled at any angle to the horizontal from straight up to straight down.

The emulsion explosives used in these specialized loading units were specifically designed for underground use nearly 30 years ago and remain essentially the same today. They are manufactured in central plants, either sensitized with microballoons to form as a 1.5 explosive or as a gassable matrix that can be transported and stored as a non-explosive, thence sensitized with gas bubbles at the point of use. They have been successfully used in underground mining operations around the world. The fuel and oxidizer contents are carefully balanced, and this, combined with the excellent water resistance and detonation efficiency,

Fig. 37.10 Bulk emulsion loading truck in a Florida quarry (Courtesy Dyno Nobel)

results in the near elimination of after-blast toxic fumes, such as CO, NO, and NO_2. The fume characteristics of this product have been shown to be considerably superior to either dynamite or ANFO. For example, a series of tests in an underground chamber in Sweden compared the after-blast fumes of this emulsion to ANFO. The CO was reduced from 11 to less than 6 L/kg of explosive, and the NO plus NO_2 was reduced from about 7 to less than 1 L/kg of explosive [45].

Surface Bulk Emulsions

Many open-pit quarries also use bulk emulsions for their blasting operations. As the size of the quarry increases, the size of the explosive loading trucks also must increase. Truck payloads can range from 5,000 to 30,000 lb of product. Figure 37.10 shows an emulsion pumper truck in a quarry in south Florida. These particular trucks, with a payload of about 20,000 lb, are specially designed for a site-mixed system, in which each truck is an emulsion manufacturing unit. Combining non-explosive raw materials directly on the truck maximizes safety and minimizes requirement for explosive storage. This particular bulk emulsion is manufactured at a rate between 300 and 500 lb/min and sensitized to the desired density with a chemical gassing system as it is loaded into the boreholes.

Figure 37.11 shows a Florida blast in progress. Note the ejection of cardboard tubes from some holes. These tubes must be used in most areas to keep the boreholes from collapsing in the layered, coral limestone formation.

Other surface, bulk delivery trucks use emulsions that are manufactured in central plants, then shipped to a surface depot, off-loaded into a bin or overhead silo, and loaded as needed into delivery trucks by pumping or gravity flow. The products can be shipped pre-sensitized with microballoons or as a non-sensitized, gassable matrix. The application of the product can be as a pumped straight emulsion or as a pumped or augured emulsion/ANFO blend.

Many of the large volume metal and coal mining operations around the world have both bulk emulsion and AN prills stored either on site or nearby so that any combination of these two products can be used. Figure 37.12 shows a typical explosive staging area in a large open-pit coal mine in Wyoming. The explosive truck in the foreground has compartments on board for emulsion, AN prills, and FO, so any combination of products ranging from straight emulsion to straight ANFO can be loaded. The truck has a capacity of about 50,000 lb and can deliver product to the boreholes at up to a ton per minute. Each borehole can contain as much as 5 tons of explosive, and some of the blast patterns can contain as much as ten million total pounds.

The emulsion/ANFO explosive blend selection to be used in any given mining application depends upon many factors. Typically, ANFO is the least expensive product, but it also has the lowest density and no water resistance. As emulsion is added to ANFO, it begins to coat the AN prills and fill the interstitial voids between the solid particles. This increases the density, detonation velocity, and water resistance compared to ANFO. The density increases nearly linearly with percent emulsion from about 0.85 g/cc with ANFO to about

Fig. 37.11 Florida quarry blast in progress (Courtesy Dyno Nobel)

1.32 g/cc with a 50/50 blend. This range of emulsion/ANFO blends is commonly referred to as Heavy ANFO. As the density increases, the amount of explosive that can be loaded into each borehole increases, and either drill patterns based on ANFO can be spread out or better blasting results can be obtained.

It is commonly accepted in the explosive and mining industry that at least 45–50% emulsion is required to protect the Heavy ANFO blend from borehole water intrusion. Pumped explosive blends with 60–80% emulsion can be used for even better water resistance when severe water conditions are encountered. These products can be pumped through a loading hose, which can be lowered to the bottom of the borehole and displace the water during loading. Trucks similar to that shown in Fig. 37.10 can be used for these products. Most Heavy ANFO products are more simply mixed through an auger and discharged into the top of boreholes by trucks similar to the one shown in Fig. 37.12. For Heavy ANFO products, especially those with less than ~45% emulsion, the holes should be either dry or dewatered using pumps.

The basic chemical composition of a typical all-AN oxidizer emulsion explosive would be: AN plus about 16% water plus about 5% fuels. The fuels may contain fuel oil, mineral oil, and emulsifiers; the majority of which can generally be described as CH_2 hydrocarbon chains. Therefore, a very simplified chemical reaction for a basic emulsion is similar to that for ANFO shown earlier.

By adding 16% water to the ANFO reaction described earlier, the theoretical heat energy release is reduced from 880 to 680 cal/g. The difference is the energy price paid for using water due to converting it to steam in the detonation reaction plus the energy loss in diluting the ANFO with a non-energy producing additive (water). The advantages and disadvantages of using ANFO or emulsions begin to become clear. ANFO is easily mixed and is probably the least expensive form of explosive energy, but it has no water resistance and has a relatively low loading density. Emulsions are considerably more complicated to formulate and manufacture, but they have excellent water resistance and more flexibility in terms of density, velocity, and higher bulk energy to match rock types and blasting applications.

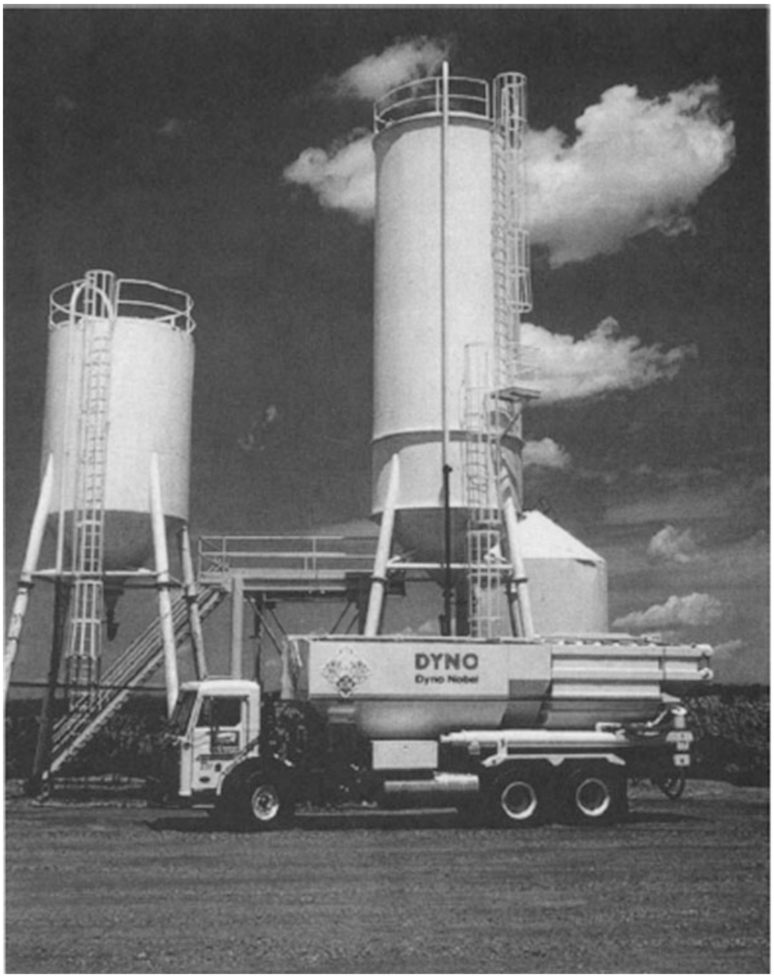

Fig. 37.12 Typical bulk explosives staging area in a large opt-pit mine

Initiation Systems

History of Initiation Systems

The first reliable initiation system for commercial explosives could probably be traced back to Alfred Nobel's invention of the blasting cap in 1864. These early caps had to be initiated with a strong shock, limiting their safety and convenience. In 1867, Nobel developed a cap that could be initiated with a fuse, a more convenient system that allowed an element of timing (length of the fuse) to the initiation of a blast, and hence, some increase in safety and predictability. This, combined with his invention of dynamite in 1866 [46], basically ushered in the modern era of blasting. The fuse cap and dynamite dominated the emerging blasting industry for several decades. In the century that followed, the initiation systems became more and more sophisticated and safe. The electric blasting cap which could be initiated by electrical current was developed around the turn of the century, adding further safety to blasting. Detonating cord, a flexible cord made of cloth or plastic with a core load of high explosives—usually PETN, was developed in Europe around the same time. Strings or circuits of detonating cord could be utilized to initiate several explosive charges with only one blasting cap. Electric caps were introduced in 1946 equipped with built-in, variable-delay elements (pyrotechnics that burn reproducibly) [46]. This allowed long rows of boreholes to be initiated in a sequential manner, optimizing blasting effectiveness as well as better controlling ground vibration and air blast damage to the surroundings. With caps having delays ranging from a few milliseconds to many hundreds and eventually thousands of milliseconds, the number of sequentially fired boreholes in a row depended only on the desired timing and the amperage capability of the electric blasting machine or other firing circuit. Sequential blasting machines were developed that could be used to control firing times between a number of rows of blastholes, greatly expanding the timing possibilities and size of blast patterns.

Fig. 37.13 Variety of commercial cast boosters (*Courtesy Dyno Nobel*)

Boosters

Prior to about 1950, most of the commercial explosives in the market were reliably detonable with just a blasting cap or detonating cord as the initiator. However, the use of non-cap-sensitive explosives (blasting agents) began emerging into the explosives market in the 1930s and 1940s. These products really took off with the advent of ANFO in the mid 1950s and water gels, invented by Melvin A. Cook in 1957 [47]. Emulsion based blasting agent products, which began significant commercialization in the mid 1970s, became the dominant non-ANFO product by the late 1980s and remains so to the present day. All of these blasting agents were adaptable to larger diameter packaged products and particularly to bulk loading.

These blasting agent explosive products were considerably less sensitive than dynamites and required larger "booster" charges for reliable detonation. At first, a high density and high velocity dynamite was used as the booster charge. Later, TNT-based cast boosters came into the market. Cast TNT by itself is not reliably detonable with a blasting cap or detonating cord, and so 40–60% PETN is normally added to the TNT melt and subsequent cast. The combination of TNT and PETN is called Pentolite. TNT has a melting point of about 80°C, which makes it an excellent base explosive for casting into forms. The military has used this concept for decades for filling bomb casings. Once the TNT has melted, other material can be added to give the final cast explosive composition the desired properties. Additives used for military purposes have included such as aluminum, ammonium nitrate, RDX, and also PETN, but Pentolite been dominant in commercial cast boosters. Cast boosters are available in a variety of sizes from about 10 to 800 g, as shown in Fig. 37.13, and continue to be predominant today in nearly all large mining operations and other blasting applications. Cap-sensitive composite explosives such as emulsion cartridges, dynamite, etc. are also used in less demanding situations. Coupled with the flexibility of blasting caps with variable delays to initiate the booster charge which then initiates the main charge, large patterns containing many thousands of pounds of explosive can be blasted.

Non-electric Initiation

In 1967, Per-Anders Persson of Nitro Nobel AB in Sweden invented a non-electric initiation system, designated Nonel®, that eventually revolutionized the explosives industry [46]. The Nonel system consists of an extruded hollow plastic tube (shock tube) that contains an internal coating of a mixture of powdered molecular explosive and aluminum. The plastic tube is inserted into and attached to a specially designed detonator or blasting cap. The Nonel tubing can be initiated by a number of starter devices, one of which uses a simple shotgun shell primer. The explosive/aluminum mixture explodes down the inside of the tube at about 2,000 m/s and will run at this velocity until all the interconnected tubing reacts, including initiating all the blasting caps. The tubing is about 3 mm outside diameter and 1 mm inside diameter, and the explosive core load is only about 18 mg/m, not even enough to rupture the tubing. The Nonel product is not susceptible to the hazard associated with electric blasting caps wherein premature initiation by extraneous electric sources can occur. Figure 37.14 is a photograph of both an electric blasting cap with the two electrical wires and a typical Nonel unit with the plastic tubing.

During the 1980s and 1990s, Nonel products continued to replace both electric blasting caps and detonating cord down lines around the world. It has long been known that detonating cord down lines disrupt and partially react with blasting agents causing some degree of energy and sensitivity loss. Also, the use of surface detonating cords to initiate blasts can lead to noise complaints. Using a range of long-lead delay caps down the borehole, a surface trunk-line of shock tubing, surface connectors to tie the tubing together, and surface delay elements that are available with this technology, huge and complex blasting patterns can be laid out and blasted with a multitude

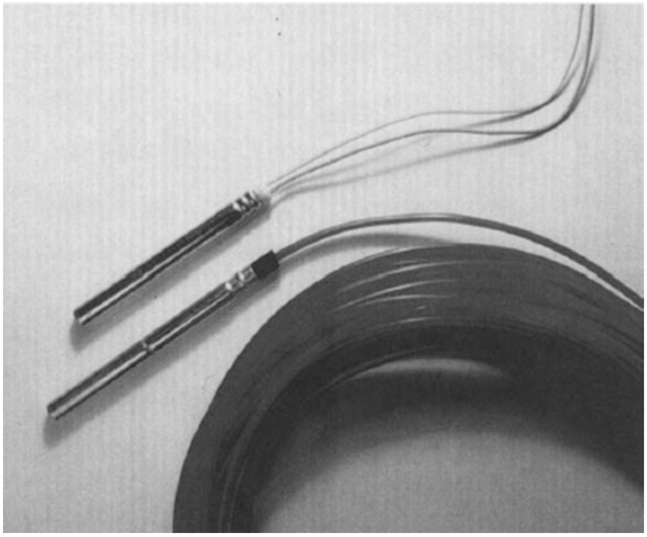

Fig. 37.14 An electric blasting cap showing electrical wires, typical Nonel unit with plastic tubing

of possibilities as to timing and sequence. As delay elements were perfected for the Nonel blasting caps, their application and use grew even further, especially in underground mining where a large percentage of blasting caps is used.

Electronic Detonators

The development of detonators with delay periods that were based on pyrotechnic elements (timing controlled by the burn rate and length of the element) had a dramatic effect on the explosives industry, enabling much of the size and complexity of modern blasting, as well as reducing off-site blast effects caused by ground vibration and air blast. When a blasting pattern is properly timed, the detonation of individual holes is such that damage from air blast and ground vibration is greatly reduced. This is a result of destructive wave interference, i.e., the ground vibration waves from detonation of each hole combine with each other and the air blast waves from the detonation of each hole combine with each other in such a way that the resulting wave patterns propagating from the blast have lower amplitudes and higher frequencies. This is key to controlling off-site structural damage. Over many years of development, the accuracy and repeatability of pyrotechnic delays was improved dramatically. However, delay times can still vary from detonator to detonator and from the target delay time by a few milliseconds to tens of milliseconds depending on the delay period of the detonator. There are also occasional fliers that occur well outside the normal scatter for a given delay detonator that can upset the blasting pattern. It was surmised that these variations could result in less than optimum blasts, considering not just air blast and ground vibration but also ground movement, fragmentation, ore dilution, fly-rock, etc.

In the late 1980s and early 1990s, several companies began developing and testing detonators wherein the delay timing was controlled with an integrated electronic circuit. These were initially very expensive and, by today's standards, were crude devices. However, they did demonstrate the promise of very accurate caps. As electronics technology improved into the 1990s, testing and field evaluation of such caps increased. However, cost and complexity in assembling the caps, the development of user friendly controllers to program and initiate them, and the unfamiliar equipment and technology on the blasting patterns slowed widespread implementation. It wasn't until mounting commercial experience began to demonstrate improved blasting results that the tide began to turn. This in turn resulted in accelerated improvements in manufacturing technology to make the caps less expensive, more reliable, improve ease of use, and increase expertise available to blasters in the field. By the 2000s, the technical case for electronic detonators had been well established. Despite the significant cost differences that remain between electric or non-electric detonators and electronic detonators, amounting to factors of perhaps five to ten times more costly per unit, there are dramatic increases in the use of electronic detonators in the blasting industry today. As of the date of this edition, they are still a minor part of the total global detonator market, but the market share is increasing. Several manufacturing companies with independent detonator technologies are involved and use is occurring in all segments of mining, construction, and other commercial blasting applications.

The construction of an electronic detonator has some features in common across all manufacturers. The timing and programmability features depend on an integrated circuit. One or more capacitors are included to store the electrical energy necessary to run the circuitry and to initiate the detonator via bridge or igniter elements. The detonator can be built to have a preset delay time or can be programmable as to delay period at the point of use. Electrical and electronic communication with the detonators is established via two or four lead wire connections, depending on the system chosen and the blast design, flexibility, control, and programmability features desired or needed by the blasters. The lead-wires are connected to the blasting machine which enables all of the features in the particular technology chosen, including programming (if needed), arming, and eventually initiating each line of detonators. The timing accuracy is on the order of only 1 to a few milliseconds depending on delay times, and variability is typically reduced by an order of magnitude compared to pyrotechnic detonators [48, 49]. Figure 37.15 shows the components of a four wire system

Fig. 37.15 Components of an electronic cap initiating system. *L–R*, logger, cap, base station (blasting machine), connectors (Courtesy Dyno Nobel)

and includes the cap, connectors, tagger (identifies and tags each detonator as it is placed in the borehole), and blasting machine (herein called the base station).

Electrochemical Energy Storage: Applications, Processes, and Trends

38

Gerardine G. Botte and Madhivanan Muthuvel

Introduction

Energy consumption in the world has increased significantly over the past 20 years. In 2008, worldwide energy consumption was reported as 142,270 TWh [1], in contrast to 54,282 TWh in 1973; [2] this represents an increase of 262%. The surge in demand could be attributed to the growth of population and industrialization over the years. In 2009, energy consumption was reported as 140,700 TWh, a slight decrease (1.1%) when compared to 2008 due to the world financial crisis [1], while in 2010 there was a rise in the consumption to 149,469 TWh, due to the recovery of the economy at that time [3]. Conversely, the total supply of energy in the world had caught up with the consumption as shown in Table 38.1 [2, 4]. Approximately 10–14% of the total energy supply in the world is delivered as electric energy. In addition, the amount of power supplied by renewables had increased over the years, from 37 TWh in 1973 to 612 TWh in 2008 (as shown in Table 38.1), which represents a growth of 94%. However, the total amount of energy available from renewables based on current technology could reach up to 834,280 TWh (distributed as: 53.2% solar, 20.0% wind, 16.7% geothermal, 8.4% biomass, and 1.7% hydropower); [5] that is, 5.7 times the world energy supply in 2008. Nevertheless, renewable sources of energy such as solar and wind are intermittent and only abundant in certain regions, which causes a limitation on the use and distribution of such sources of energy. An undersized world energy surplus (based on a total energy balance including supply, consumption, and losses) is usually reported annually; a comprehensive analysis is presented in the literature [2].

Given the increase in energy consumption as the world's population grows, the scarcity of traditional energy supplies (i.e., petroleum, oil, and gas), and the environmental impact caused by conventional power generation systems, it has become imperative to utilize unconventional energy sources and renewables, and to redesign traditional processes to make them more energy efficient. Within this context, energy storage and conversion play a significant role. Energy storage refers to devices, or physical media, that collect different types of energy to be used at a later time. Perhaps the use of devices to accumulate energy is the most popular way, as it brings to mind the term "batteries," which has become extremely important with the spiraling growth of modern electronic applications. Indeed, batteries are a way to store energy. Batteries are unique devices, as the energy that is stored is chemical, but delivered as electrical. That is, batteries play a dual role: they store chemical energy, which is then delivered or converted directly into electrical energy when needed (we will return to this definition later). The definition of energy storage also includes physical media, which can be easily related to fuels (e.g., gasoline, diesel, hydrogen). Fuels are ways to store chemical energy that needs to be conventionally converted into electrical energy quite differently than the way batteries do it. Traditional power generation involves heat engines (e.g., turbines). In this process, a fuel is combusted to release thermal energy, the thermal energy is then transformed into kinetic energy through a rotor (i.e., using a turbine), and finally the kinetic energy is transformed into electrical energy by an electrical generator. The efficiency of the conventional process to convert chemical energy into electrical energy is limited by the Carnot cycle and is much lower than the efficiency of batteries.

There are different ways to store energy: chemical, biological, electrochemical, electrical, mechanical, thermal, and fuel conversion storage [6]. This chapter focuses on electrochemical energy storage and conversion. Traditionally, batteries, flow batteries, and fuel cells are considered as electrochemical energy storage devices. However, the

authors believe that with the growth of renewable energy and intermittent energy sources, the concept of electrochemical energy storage can be extended to the electrochemical synthesis and production of fuels, chemicals, petrochemicals, etc. The vision of the approach is shown in Fig. 38.1 [7]. For example, the inspiration for the hydrogen economy is to use hydrogen as an energy carrier. The intention is to produce hydrogen through water electrolysis (electrochemical synthesis of hydrogen from water) by using electricity (electrical power) from intermittent (i.e., not available all the time) renewable power generation devices, such as solar panels and wind turbines. This way, hydrogen could be used to produce electricity when the intermittent source of electricity is not available, and to distribute the energy to remote sites. Conversely, the intention is to produce electricity by using hydrogen as the fuel in devices called fuel cells (we will return to this definition later). With this in mind, the vision of Fig. 38.1 is broader than the concept of the hydrogen economy. The final goal is to use intermittent and renewable sources of electricity (which represents 5.7 times the supply of energy in the world) to transform different feedstock into fuels, chemicals, petrochemicals, etc. That is, intermittent energy sources are used to store energy as products, commodities, or fuels via electrochemical synthesis.

Table 38.1 Energy and power supply in the world

Year	Energy (TWh)	Power (TWh)	Fraction of energy supplied as power (%)	Power from renewables[a] (TWh)	Fraction of power from renewables (%)
1973	71,117	6,116	9	37	0.6
1990	102,569	11,821	12	277	2.3

In this chapter, the authors outline the basic concepts and theories associated with electrochemical energy storage, describe applications and devices used for electrochemical energy storage, summarize different industrial electrochemical processes, and introduce novel electrochemical processes for the synthesis of fuels as depicted in Fig. 38.1.

Basic Concepts

There are some important terminologies and fundamental theories associated with electrochemistry and electrochemical engineering. Electrochemical engineering is the branch of engineering dealing with the technological application of electrochemical phenomena. Electrochemical engineering evolved from industrial electrochemistry, which was defined in the early years as [8, 9] "the application of electric current

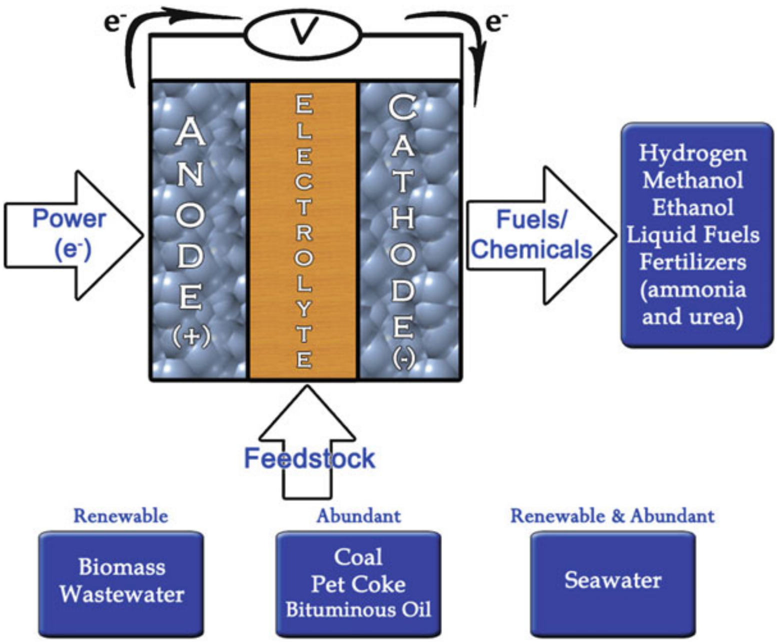

Fig. 38.1 Electrochemical synthesis of fuels, chemicals, and petrochemicals from different feedstocks [7]. Within the vision electrical power could be supplied from different sources, however, the concept creates the ideal platform to use renewal electrical energy from solar panels and wind turbines

to the chemical and metallurgical arts.” In this section, terminologies that are pertinent to the electrochemical energy storage devices are described.

The basis for a traditional electrochemical energy storage system (batteries, fuel cells, and flow batteries) and the extended electrochemical energy storage concept presented in Fig. 38.1, known as electrosynthesis, is the electrochemical cell. An electrochemical cell consists of a case, an anode, a cathode, an electrolyte, and current collectors (as shown in Fig. 38.1). Electrochemical cells allow the direct conversion of chemical energy into electrical energy (galvanic cells or spontaneous cells) or vice versa, the direct conversion of electrical energy into chemical energy (electrolytic or electrolysis cells). Traditional electrochemical energy storage devices, such as batteries, flow batteries, and fuel cells, are considered galvanic cells. The approach depicted in Fig. 38.1, electrosynthesis reactor, is defined as an electrolytic or electrolysis cell. Electrochemical cells can be electrically connected in series, in parallel, or other configurations according to the needs of particular processes or applications.

The basis for the direct conversion of chemical to electrical energy, or vice versa, is the electrochemical reaction. An electrochemical reaction is a heterogeneous chemical process involving the transfer of electrons to or from an electrode (generally a metal, carbon, or electrically conducting material). It is important to mention that electrochemical reactions take place only on the electrode surface; this distinguishes an electrochemical system from a traditional chemical reactor.

Within this context, other important definitions are presented in subsequent sections. Additional definitions, thermodynamics, transport mechanisms, and electrokinetic models can be found elsewhere [10–13].

Oxidation

The removal of electrons from an element or ion, even if the element is part of a compound, during a chemical reaction is known as an oxidation reaction. Corrosion of an iron sheet, also known as rusting, is an electrochemical process. The rusting of an iron sheet is a good example of an oxidation reaction, where the elemental iron is oxidized to ferric oxide (Fe_2O_3) by oxygen present in the electrolyte (38.1). The oxidation reaction for iron is shown in (38.2) where the elemental iron losses three electrons to form ferric (Fe^{3+}) ion. The rusting of iron will be accelerated in an acid electrolyte.

$$4Fe + 3O_2 \rightarrow 2Fe_2O_3 \tag{38.1}$$

$$Fe \rightarrow Fe^{3+} + 3e^- \tag{38.2}$$

Reduction

The reduction process is also related to transfer of electrons, where electrons are added to either the element or ion during the chemical reaction. For example, electroplating of copper metal on any electrically conducting surface is possible by the reduction of cupric (Cu^{2+}) ions found in the plating solution to elemental copper, by accepting two electrons provided by applied current supplied through the electrodes.

$$Cu^{2+} + 2e^- \rightarrow Cu \tag{38.3}$$

Anode

There are two established configurations for the electrochemical cells or systems: three-electrode and two-electrode systems. Generally, the two-electrode configuration is used in the commercial electrochemical devices, as shown in Fig. 38.1. In this two-electrode configuration, the electrochemical system consists of an anode, a cathode, and an electrolyte. The anode is the electrode where the oxidation reactions take place and it is connected to the positive terminal of the power supply unit. In order for the electrochemical oxidation reaction to take place on the anode, the anode has to be an electrically conducting material. Anode materials can be either insoluble or soluble substances depending on the electrochemical system. In the electroplating of precious metals, such as platinum, the anode material is made of platinum which is insoluble in the plating solution. On the other hand, for nickel electroplating, nickel sheet is used as the anode, which dissolves into the plating solution as nickel ions. The nickel ions eventually reduce as metallic nickel on the cathode electrode.

Cathode

On the other hand, the reduction reactions, such as (38.3), will take place at an electrode known as the cathode. The cathode electrode is connected to the negative terminal of the power supply unit. Similar to the anode material, the cathode material should also be electrically conducting so that the electrochemical reaction (reduction reaction) can take place. Generally, insoluble materials have been used as the cathode for the electrochemical systems. In the case of chrome plating on steel materials, the steel is the cathode electrode during the electroplating process.

The three-electrode system contains a working electrode, a counter electrode, and a reference electrode (will be discussed later). Either the working or the counter electrode could act as a cathode or an anode. The term working electrode is used to define the electrode that will be exposed

Table 38.2 Examples of different electrolytes used in electrochemical energy storage technologies and electrosynthesis

Electrolyte system	Supporting salt	Solvent	Conductivity (mS/cm)	Applications and details
1 M $LiPF_6$ in EC/DMC (50:50 wt. %)	$LiPF_6$	Organic solvents—EC and DMC	10.7 (at 25°C) [15]	Lithium ion batteries. No water should be present in the system. Nonaqueous electrolyte
H_2SO_4 (30 wt. %)	H_2SO_4	Water	730 [14]	Lead acid batteries and electroplating (low concentrations of H_2SO_4). Aqueous electrolyte
0.1 M KOH	KOH	Water	21.3 (at 25°C) [19]	Electrolytic systems and electrodeposition. Aqueous electrolyte
KOH (29.4 wt. %)	KOH	Water	540 [14]	Alkaline battery. Aqueous electrolyte
EC/PC/$LiClO_4$/PAN (38/33/8/21) (mol%) Solid polymer electrolyte	$LiClO_4$	EC, PC	1.7 (at 20°C) [16]	Lithium polymer battery. This is a solid polymer electrolyte
PC/$LiClO_4$/2p-MC-DBS/PEGPM (81.0/7.5/0.9/10.6) (wt. %)	$LiClO_4$	PC	4.6 (at 25°C) [16]	Lithium battery. Gel electrolyte in polymer matrix
$Na_3AlF_6/AlF_3/CaF_2/Al_2O_3$ (81/11/5/3) (wt. %)	Al_2O_3	Cryolite (Na_3AlF_6)	2,130 (at 950°C) [17]	Aluminum electrolysis. Molten electrolyte
$(Y_2O_3)_{0.08}(ZrO_2)_{0.92}$ Yttria-stabilized zirconia (YSZ)	Y_2O_3	ZrO_2	30 (at 800°C) [18]	Solid oxide fuel cells. This is a solid electrolyte, where yttria is doped in zirconia

to a detailed electrochemical analysis through the use of different polarization techniques [11]. The counter electrode is used to carry enough current that will not prevent or limit any of the processes taking place at the working electrode. The three-electrode cell configurations are typically used for detailed and fundamental understanding of electrochemical reactions [11]. However, they also find applications in sensors.

Electrolyte

In an electrochemical cell, the electrodes—anode and cathode—are immersed in a solution (liquid, gel, or solid); the solution is known as the electrolyte. The electrolyte provides the medium for the movement of the ions (mobility) between the anode and the cathode. The operation of an electrochemical cell functions as a closed electrical system. Externally, the current travels between the power supply unit and the electrodes through the electrically conducting wires (see Fig. 38.1). In the electrolyte (internally), the movement of ions between the anode and the cathode (current flows internally through the transport of the ions) will complete the electrical circuit for the electrochemical cell. That is the anode/electrolyte/cathode, and power supply complete the electric circuit.

The flow of the electrons through the external circuit is relatively fast due to the use of highly electrically conducting materials. The limitation in the flow of current in an electrochemical system is experienced usually through the internal media: anode/electrolyte/cathode due to the diffusion and migration of ions across the electrolyte. The electrolyte can be aqueous, nonaqueous, or molten salt solutions. The electrolyte can also be made of a solid mixture. A solution of sulfuric acid is one of the most commonly used aqueous electrolytes. A nonaqueous electrolyte is lithium perchlorate ($LiClO_4$) dissolved in propylene carbonate, which is used in the lithium batteries. For the production of metallic sodium, molten salt of sodium chloride is electrolyzed, where molten sodium chloride is the molten electrolyte. A good example for a solid electrolyte is yttria-stabilized zirconia (YSZ), which is a ceramic material used as solid oxide electrolyte in solid oxide fuel cells (SOFCs).

The electrochemical reactions taking place on the surface of the electrodes depend on the transport properties of the ions in the electrolyte medium. One of the important properties of the electrolyte is its ionic conductivity, which is affected by factors, such as temperature, supporting salt concentration, solvent, and pressure. Table 38.2 lists some of the different electrolytes used in the energy storage systems

Table 38.3 Classical separators, membranes, and diaphragms used in electrochemical energy storage technologies and electrosynthesis

Material	Type	Applications and details
Nafion (sulfonated tetrafluoroethylene-based fluoropolymer-copolymer)	Membrane	Chlor-alkali cell and proton exchange membrane fuel cell. Allows transport of cations, especially protons
Cellophane	Membrane	Nickel cadmium and silver oxide batteries. Provides gas barrier along with ion permeability
Polyethylene	Separator	Lead acid batteries. These separators with small pore size are used in heavy duty batteries and they provide longer life to the battery
Polypropylene	Separator	Lithium-based batteries. The separator is used in primary and secondary types of lithium batteries
Asbestos	Diaphragm	Chlor-alkali cell. This separator was used in the original design of chlor-alkali cell. The health problems associated with asbestos has restricted its application as separator
Teflon (polytetrafluoroethylene)	Diaphragm	Chlor-alkali cells and aqueous electrolysis. Chemically inert to acids, alkalis, and organic solvents

Sources: Linden [20]; Kuhn [83]

along with their conductivity. Usually aqueous electrolytes possess the highest ionic conductivity at room temperature. As shown in Table 38.2, the 30 wt. % sulfuric acid solution (aqueous electrolyte) used in the lead acid battery (LAB) has an ionic conductivity of 730 mS/cm [14]. The nonaqueous electrolyte used in commercial lithium ion (Li-ion) batteries consisting of 1 M $LiPF_6$ dissolved in the organic solvents of ethylene carbonate and dimethyl carbonate (50:50 wt. %) has an ionic conductivity of 10.7 mS/cm at 25°C [15]. Lithium batteries also use gel type electrolytes, such as PC/$LiClO_4$/2p-MC-DBS/PEGPM (81.0/7.5/0.9/10.6) (wt. %), where PC stands for propylene carbonate, 2p-MC-DBS means 1,3:2,4-di(*p*-methoxycarbonylbenzylidene) sorbitol, and PEGPM is poly(ethylene oxide) (PEO)—grafted poly (methacrylate). This gel electrolyte has an ionic conductivity of 4.6 mS/cm at 25°C [16]. The molten electrolyte used in the aluminum electrolysis process has alumina (Al_2O_3) mixed with CaF_2 and AlF_3 additives, which are dissolved in cryolite (Na_3AlF_6) solvent. The ionic conductivity for this molten electrolyte is 2,130 mS/cm at 950°C [17]. In SOFCs, zirconia (ZrO_2) doped with 8% of yttria (Y_2O_3), commonly known as yttria-stabilized zirconia, is used as the solid electrolyte. YSZ has an ionic conductivity of 30 mS/cm at 800°C [18]. The readers are requested to review the following literature for more details about transport processes in electrochemical systems and conductivity [10, 11].

Separator

In a divided electrochemical cell, an electrically insulated layer material is used to separate the electrode, electrolyte, and any products formed between the anode and the cathode side. This electrically insulated material is called the separator. The separators should be permeable to the ions present in the electrolyte to facilitate the completion of the electrical circuit. The different types of separators are membranes and diaphragms. The membranes have a smaller pore size which will result in selective permeability of ions across the compartments. On the other hand, diaphragms are those separators that have larger pore size and permits transfer of many ions at higher flow rate across the compartment without leading to intermixing of electrolytes. In general, the distinction between membrane and diaphragm is blurred as some separators can be engineered to have different porosity and selectivity for permeation. A list of various commonly used separators (membranes and diaphragms) is listed in Table 38.3.

Reference Electrode

In a three-electrode cell system, a third electrode other than the anode and cathode, the reference electrode, is used. Reference electrodes are standard electrodes, which are chemically and mechanically robust, and their potential is expected to remain unchanged under most electrolytic conditions. In electrochemistry, one cannot measure the potential of an electrode, but the potential difference between two electrodes is measureable. If one of the two electrodes is a standard or reference electrode, then the potential of the other electrode can be determined in terms of the reference electrode. So, every time a potential value is assigned to an electrode, it is always expressed with respect to a reference electrode.

The standard hydrogen electrode (SHE) is the primary reference electrode and its potential is assigned a zero value (see section on “Standard Potential”). For example, consider an electrolytic system where deposition of copper is carried out using an electrolyte containing copper sulfate and sulfuric acid. At the anode, a water molecule is oxidized to oxygen and protons, whereas metallic copper is deposited at the cathode electrode. The following half cell reactions (anode and cathode reaction) with their standard reduction potential illustrate the electrolytic cell.

Table 38.4 Standard reduction potential for some electrochemical reactions

Reaction	$E°$(V)
$Li^+ + e^- \rightleftharpoons Li$	−3.0401
$Na^+ + e^- \rightleftharpoons Na$	−2.71
$Al(OH)_3 + 3e^- \rightleftharpoons Al + 3OH^-$	−2.31
$Te + 2e^- \rightleftharpoons Te^{2-}$	−1.143
$Ni^{2+} + 2e^- \rightleftharpoons Ni$	−0.257
$Pb^{2+} + 2e^- \rightleftharpoons Pb$	−0.1262
$Fe^{3+} + 3e^- \rightleftharpoons Fe$	−0.037
$2H^+ + 2e^- \rightleftharpoons H_2$	0.0000
$NO_3{}^- + H_2O + 2e^- \rightleftharpoons NO_2{}^- + 2OH^-$	0.01
$Cu^{2+} + e^- \rightleftharpoons Cu^+$	0.153
$Cu^{2+} + 2e^- \rightleftharpoons Cu$	0.3419
$Ag^+ + e^- \rightleftharpoons Ag$	0.7996
$Pt^{2+} + 2e^- \rightleftharpoons Pt$	1.18
$Au^{3+} + 3e^- \rightleftharpoons Au$	1.498
$F_2 + 2e^- \rightleftharpoons 2F^-$	2.866

Source: Haynes [19]

Anode reaction:

$$H_2O \rightarrow \frac{1}{2}O_2 + 2H^+ + 2e^- \quad E^\circ = 1.23 \text{ V vs. SHE} \quad (38.4)$$

Cathode reaction:

$$Cu^{2+} + 2e^- \rightarrow Cu \quad E^\circ = 0.34 \text{ V vs. SHE} \quad (38.5)$$

The secondary reference electrodes have been frequently used in the electrochemical systems because they are easier to construct and maintain than the SHE. One of the commonly used reference electrodes is the saturated calomel electrode (SCE), which has a potential of 0.242 V vs. SHE. Another reference electrode used in the acidic electrolytes has been the silver-silver chloride electrode and its potential is 0.197 V vs. SHE.

Standard Potential

The standard potential ($E°$) is related to an electrochemical reaction on the electrode surface at standard condition of 25°C and 1 atmospheric pressure. The standard potential for the reduction or oxidation reaction of the chemical substance present in the electrochemical system is valuable information principally to determine the possible reactions taking place in the system. In general, the standard potential is represented as the reduction potential for that reaction vs. the SHE. Table 38.4 contains the standard reduction potential of commonly used reactions.

The formation of hydrogen from protons is zero volts as the reaction is measured with respect to an SHE. The standard reduction potential for lithium ion (Li^+) is −3.0401 V which is the least valued potential in Table 38.4. The most negative value of the standard reduction potential means that lithium (Li) is more likely to get oxidized into Li^+ ion. On the other hand, the reduction of the platinum ion (Pt^{2+}) to Pt (1.18 V) is more favorable than the Li^+ ion reduction.

Table 38.4 lists only a few reactions and its standard reduction potential, but a complete list for the standard reduction potential of various reactions can be found in the CRC Handbook for Chemistry and Physics [19]. The list of the standard reduction potential suggests thermodynamically which reaction would occur, or is feasible, in an electrochemical system. For example, a platinum electrode immersed in a solution containing 0.1 M Ni^{2+} in 1 M HCl will result in an open circuit potential greater than 0 V. Once the potential of the Pt electrode is shifted in the negative direction with respect to SHE, the reaction with most positive reduction potential will occur first. So, in this case the evolution of hydrogen (0 V vs. SHE) will occur even before the deposition of Ni on the Pt electrode (−0.257 V vs. SHE). On the other hand, by shifting the potential of the electrode in the positive direction, the reaction with least positive potential will occur first. If a gold electrode is immersed in a Cu^+ ion solution and the potential of the Au electrode was increased in the positive direction, then the oxidation of Cu^+ to Cu^{2+} (0.153 V vs. SHE) would take place before the gold electrode oxidizes (1.498 V vs. SHE). The table covering standard reduction potentials provides an opportunity to perform controlled and specific reactions on the electrode surface because each electrochemical reaction can be controlled by its potential.

Nernst Equation

The potential for an electrochemical reaction can be represented in terms of a thermodynamic quantity, the Gibbs free energy change. Equations (38.6) and (38.7) display the relationship between the Gibbs free energy change and the potential for the reaction at normal and standard conditions. Standard conditions are referred to temperature of 25°C and 1 atmospheric pressure with unit activity for the chemicals involved in the electrochemical reaction. The Gibbs free energy for the reaction taking place at conditions other than the standard condition is represented in (38.6).

$$\Delta G = -nFE \quad (38.6)$$

$$\Delta G^\circ = -nFE^\circ \quad (38.7)$$

where ΔG° and E° are the standard Gibbs free energy change and the standard reaction potential, respectively. On considering a simple electrochemical reaction at equilibrium as given in (38.8), an oxidized species (O) takes up n electrons to form the reduced species (R).

$$O + ne^- \rightleftharpoons R \tag{38.8}$$

From the basic thermodynamics, the Gibbs free energy for the above reaction can be written as

$$\Delta G = \Delta G^\circ + RT \ln \frac{a_R}{a_O} \tag{38.9}$$

where R is the molar gas constant (8.314 J mol^{-1} K^{-1}), T is the temperature (K), a_R and a_O are the activities for the reduced and oxidized species, respectively. On substituting the Gibbs free energy change from (38.6) and (38.7) to the (38.9), we obtain

$$E = E^\circ - \frac{RT}{nF} \ln \frac{a_R}{a_O} \tag{38.10}$$

The Nernst equation for an electrochemical reaction is represented by rearranging (38.10).

$$E = E^\circ + \frac{RT}{nF} \ln \frac{a_O}{a_R} \tag{38.11}$$

The potential of the reaction is dependent on the standard reduction potential (E°), and the activities of the oxidized and reduced species. The activity is a chemical thermodynamic term meaning effective concentration of the species in a mixture. The activity of the species is expressed as the product between the activity coefficient (γ) and the concentration of the species. Since, it is difficult to determine the activity of the species in an electrochemical reaction, the Nernst equation can be defined in terms of the species concentration (38.12).

$$E = E^{\circ'} + \frac{RT}{nF} \ln \frac{[O]}{[R]} \tag{38.12}$$

where the concentrations of oxidized and reduced species are $[O]$ and $[R]$, respectively, and $E^{\circ'}$ is the formal potential of the reaction. The formal potential is defined as the measured potential of the reaction when the ratio of the concentrations of oxidized and reduced species is unity. The following equation displays the relationship between the formal potential and the activity coefficient of the species.

$$E^{\circ'} = E^\circ + \frac{RT}{nF} \ln \frac{\gamma_O}{\gamma_R} \tag{38.13}$$

An electrode following the Nernst equation is referred to as the Nernstian system when the electrode potential changes because of the changes observed in the concentration of the species present in the electrochemical system. Alternatively, if the potential of an electrode does not follow the Nernst equation, then it is considered to be non-Nernstian system.

Cell Voltage

In a two electrode system, the potential difference between the anode and cathode electrodes is defined as the cell voltage. The term “potential,” which has been used extensively earlier, is only referred to as the potential difference observed between an electrode and a reference electrode. The cell voltage is denoted by V; it also uses the same thermodynamic relation with the change in the Gibbs free energy as shown in (38.6). The units for cell voltage are volts (V), which is also the unit for the electrode potential.

As described earlier, there are two types of electrochemical cells, namely electrolytic and galvanic cells. In a galvanic cell, such as silver oxide-zinc battery, a primary battery system, the cell voltage can be determined using the anode and cathode electrode potentials. The anode, cathode, and the overall reactions for the silver oxide-zinc battery are given below [20].

Anode reaction:

$$\begin{aligned} &\mathrm{Zn} + 2\mathrm{OH}^- \rightarrow \mathrm{Zn(OH)_2} + 2\mathrm{e}^- \\ &E^\circ = -1.249 \text{ V vs. SHE} \end{aligned} \tag{38.14}$$

Cathode reaction:

$$\begin{aligned} &\mathrm{Ag_2O} + \mathrm{H_2O} + 2\mathrm{e}^- \rightarrow 2\mathrm{Ag} + 2\mathrm{OH}^- \\ &E^\circ = 0.342 \text{ V vs. SHE} \end{aligned} \tag{38.15}$$

Overall reaction:

$$\begin{aligned} &\mathrm{Zn} + \mathrm{Ag_2O} + \mathrm{H_2O} \rightarrow \mathrm{Zn(OH)_2} + 2\mathrm{Ag} \\ &E = 1.591 \text{ V} \end{aligned} \tag{38.16}$$

At the anode electrode, the Zn is oxidized to zinc hydroxide in the presence of hydroxyl ions from the alkaline electrolyte and the silver oxide is reduced to silver at the cathode electrode. The overall reaction is the formation of zinc hydroxide and silver from zinc and silver oxide, which results in a generating cell voltage of 1.591 V. The voltage for the overall reaction was obtained by subtracting the standard potential of the anode reaction from the cathode reaction. This cell voltage is also known as the theoretical voltage for the battery [20]. The theoretical voltage of a battery represents the maximum cell voltage that can be attained by the battery. In practical applications, the theoretical voltage is very difficult to reach due to various factors, such as concentration, temperature, and transport of ions.

The influence of these factors leads to ohmic limitations, concentration limitations, surface limitations, and diffusion limitations during the operation of any galvanic system. For the silver oxide-zinc battery, even though it has the theoretical voltage of 1.591 V, the nominal voltage or voltage during practical application is only 1.5 V [20].

In the case of an electrolytic system, such as the electrolysis of water, the theoretical cell voltage required to split water into hydrogen and oxygen gases is 1.23 V. In the electrolytic system, the theoretical voltage is the minimum required voltage to initiate the electrochemical reaction and due to various factors the cell voltage has to be maintained more than the theoretical value in order to sustain the reaction. The key factors affecting the operation of electrolytic systems are the solution resistance, diffusion limitations faced by the ions at the electrode surface, occurrence of secondary or undesired reactions at the electrode surface, and even the resistance to the flow of electrons along the wire or electrical contact. Even though the theoretical voltage required for water electrolysis is 1.23 V, the commercial alkaline water electrolyzers operate between 1.7 and 1.9 V to compensate for the losses due to the above mentioned factors [21].

Faraday's Law

In an electrochemical reaction, electron transfer results in the formation of a new product or loss of a compound. The mass of the new product formed or the loss of the existing material is directly proportional to the number of electrons passed through the electrode. This is known as Faraday's law. The time rate of flow of electrons is known as current, and the number of electrons is referred to as charge (Q), and its units are coulombs (C).

$$m = \frac{Q \times M}{n \times F} \tag{38.17}$$

where m is the mass of the substance (g) formed or lost during the electrochemical reaction, M is the molar mass of the substance (g/mole), n is the number of electrons transferred per mole during the reaction, and F is the Faraday constant, which equals 96,485 C.

The mass of the material deposited or lost is directly related to the current passed through the electrochemical cell. If all the current supplied to the electrochemical cell is utilized for the expected reaction, then the Faraday efficiency is 100%. In most systems, however, part of the applied current results in undesired or secondary reactions and generates other products, which leads to lower than 100% in Faraday efficiency. The ratio of actual weight of the material formed to the theoretical weight based on that current is known as Faraday efficiency. In some places, Faraday efficiency is also referred as Faradaic efficiency, coulombic efficiency, or current efficiency. Faraday's law is a valuable concept along with current efficiency to estimate the total current required for scaling up an electrochemical process, as it would lead to the calculation of the number of cells, electrodes, and energy consumption needed for the process.

The use of Faraday's law can be demonstrated with an electrolytic system, aluminum production. The production of aluminum is an energy consuming process and it is performed by electrolysis of molten salt of alumina (Al_2O_3). In the aluminum industry, the modern aluminum reduction cell system is supplied with a total current of 300 kA and a cell voltage of 4.2 V is maintained for every day operation [22]. The molar mass for aluminum (M) is 26.98 g/mol and the number of electrons (n) involved during the reduction reaction is 3. The total charge, the product of current and time, supplied for a day to the electrochemical cell for aluminum reduction is Q.

$$\begin{aligned} Q &= \text{current} \times \text{time} = 300\ \text{kA} \times 24\ \text{h} \times 60\ \text{min} \times 60\ \text{s} \\ &= 25,920 \times 10^6 \text{coulombs} \end{aligned}$$

Substituting the values for charge (Q), molar mass (M), number of electrons (n), and Faraday's constant in (38.17), we obtain the theoretical amount of aluminum produced per day using 300 kA of current. The theoretical aluminum calculated was 2,416 kg/day. According to the aluminum industry literature, the industry produces 2,308 kg of aluminum per day using a current supply of 300 kA [22].

The Faraday efficiency for the production of aluminum using the electrolysis process can be calculated using the above values. The current or Faraday efficiency for the aluminum reduction process was 95.5%. Energy consumption for the electrolysis process is defined as the product of the total charge supplied and the voltage maintained in the cell. For the production of aluminum, the energy consumption was calculated to be 13.1 kWh for every gram of aluminum produced.

Battery Capacity

For battery systems, the total current which can be obtained from an electrochemical system in 1 h is termed as capacity. The units for capacity are ampere-hour (Ah). The theoretical capacity of a battery is dependent on the active material available as electrode with the internal resistance of the electrolyte not being taken into consideration. Using Faraday's law, the theoretical capacity for the electrode material is given as

$$C_e = 26.8 \frac{\mathrm{A-h}}{\mathrm{eq-g}} \frac{1}{M_e} \tag{38.18}$$

where the electrode material capacity is C_e (ampere-hour per gram) and M_e is the equivalent weight of the electrode material (grams per equivalent gram). The equivalent weight is represented by the molecular weight of the electrode material divided by the number of electrons transferred during the reaction [13].

For example, the silver oxide-zinc battery is composed of zinc as active material in the anode electrode and silver oxide is the active material in the cathode. The overall reaction for the battery is given in (38.16).

$$\begin{aligned} &\mathrm{Zn} + \mathrm{Ag_2O} + \mathrm{H_2O} \rightarrow \mathrm{Zn(OH)_2} + 2\mathrm{Ag} \\ &E = 1.591\ \mathrm{V} \end{aligned} \tag{38.16}$$

The equivalent weight for Zn (M_{Zn}) is 32.68 g/eq−g and the cathode active material, silver oxide, has an equivalent weight (M_{Ag_2O}) of 116 g/eq−g. Using (38.18), the theoretical capacity for anode electrode of the silver oxide-zinc battery can be calculated as $C_{Zn} = 820$ mAh/g and the cathode material has the theoretical capacity of $C_{Ag_2O} = 231$ mAh/g.

Once the theoretical capacity of the electrode material is calculated, then the total capacity of the electrode can be obtained from (38.19).

$$C_T = C_e W_e \tag{38.19}$$

where C_T is the total capacity for the electrode (ampere-hour) and W_e is the weight of the electrode material (grams). The total capacity of both the electrodes will be calculated using the above equations; the lowest capacity is taken as the theoretical capacity of the battery system. If the weight of active material for the silver oxide-zinc battery is assumed to be 5 g, then the total capacity for Zn is $C_T = 4{,}100$ mAh and for Ag_2O is $C_T = 1{,}155$ mAh. Since the theoretical capacity of the cathode material, silver oxide, is the limiting value, then the theoretical capacity for the silver oxide-zinc battery will be 231 mAh/g.

There is another equation used to determine the theoretical capacity of the battery system, which is based on the total quantity of electricity used in both the anode and cathode electrode [20].

$$C_T = \frac{1}{1/C_{e,\mathrm{negative}} + 1/C_{e,\mathrm{positive}}} \tag{38.20}$$

On using the equation for the silver oxide-zinc battery system, the theoretical capacity of this battery was found to be 180 mAh/g.

Energy Density

Energy density of a battery is determined by taking the product of the cell voltage and capacity of the battery. The unit for the energy density is represented by watt-hour per gram (Wh/g). Energy density is also an important property as the capacity for the battery. The theoretical energy density for a battery system is represented as: [20]

$$\begin{aligned} &\text{Theoretical energy density(Wh/g)} = \text{Theoretical voltage(V)} \\ &\quad \times \text{Theoretical capacity(Ah/g)} \end{aligned} \tag{38.21}$$

In the case of the silver oxide-zinc battery, the theoretical voltage is 1.591 V and the theoretical capacity determined in the previous subsection was 180 mAh/g. Using these values in the above equation, we obtain the theoretical energy density for the silver oxide-zinc battery as 0.286 Wh/g or 286 Wh/kg.

Electrokinetics

In the electrochemical systems, the rate at which reactions take place on the electrode surface depends on different properties such as electrode material, concentration of ions present in the electrolyte, mobility of the ions, and the concentration of ions at the electrode surface. At equilibrium, the ions in the electrolyte will cover the electrode surface based on their charge and form a layer known as double layer. The double layer is described as the combination of adsorbed ionic species and the layer of solvated ions over the surface of metal. Figure 38.2 shows the illustration of the metal/solution interface based on the geometric model. There are three established models, namely Helmholtz theory, Gouy-Chapman theory, and Stern theory, to elucidate the formation of the double layer over the metal surface.

The metal electrode immersed in an electrolyte is covered by absorbed ions due to the excess charge on the metal surface. An imaginary line running through the centers of the adsorbed ions form the inner Helmholtz layer or plane. The outer Helmholtz layer or plane is the locus of centers of the nearest solvated ions. Beyond the outer Helmholtz layer, there are nonspecifically adsorbed ions which form a diffuse layer. The double layer in the electrolyte solution is composed of the inner and outer Helmholtz layers, and the diffuse layer. The thickness and composition of double layer will determine the surface overpotential. For ionic concentrations more than 0.01 M, the double layer thickness is expected to be less than ~100 Å [11]. Surface overpotential (η_s) is expressed as the potential of the working electrode with respect to the reference electrode, which is placed just outside of the double layer. The term overpotential is defined as the difference between the measured potential and the equilibrium potential for that reaction.

Electrochemical reaction rates are defined in terms of the current density of the reactions, the concentration of ions in

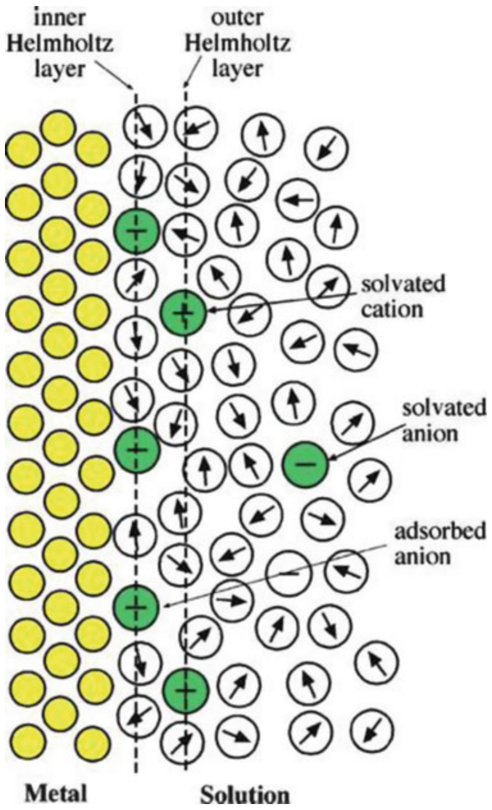

Fig. 38.2 Illustration of metal/solution interface to depict the presence of double layer [23]. The double layer is composed of adsorbed and solvated ions over the metal surface. The double layer has many layers; among those are the inner and outer Helmholtz layer

the electrolyte, and the overpotential. A classical way to relate these parameters is using the Butler-Volmer equation:

$$i = i_o \left[e^{((\alpha_a F/RT)\eta_s)} - e^{(-(\alpha_c F/RT)\eta_s)} \right] \tag{38.22}$$

where i_o is the exchange current (A), α_a and α_c are the transfer coefficients for the anodic and cathodic reactions, respectively, i is the current for the reaction (A), and η_s is the surface overpotential for the electrode.

For electrochemical reactions which are irreversible in nature, an approximation of the Butler-Volmer equation will lead to the Tafle equations (38.23) and (38.24). In the case where the anodic reactions are more applicable than cathodic reactions, then $a_a F\eta_s \gg RT$ and the Butler-Volmer equation is reduced to

$$i = i_o e^{((\alpha_a F/RT)\eta_s)} \tag{38.23}$$

Similarly, if the cathodic reactions are more applicable than the anodic reactions, then $a_c F\eta_s \gg RT$ and the Butler-Volmer equation is modified to

$$i = -i_o e^{(-(\alpha_c F/RT)\eta_s)} \tag{38.24}$$

Table 38.5 Various dielectric materials and their constants

Dielectric material	Dielectric constant (ε)
Air (dry, CO_2 free)	1.0005360
Aluminum oxide	9.34–11.54
Glass (Pyrex 7740)	5.0
Lead magnesium niobate	10,000
Lead titanate	~200
Mica (muscovite)	5.4
Polypropylene	2.3
Polystyrene	2.6
Potassium tantalate niobate (0°C)	34,000
Quartz (fused)	3.75
Tantalum pentoxide (α phase)	30–65
Teflon	2.1
Vacuum	1.000 (exact)
Water (liquid, 20°C)	80.1

Capacitor

An electronic device, which is capable of storing electric charge, is defined as a capacitor. Capacitors can be used in place of batteries to store electrical energy and can also discharge the electrical energy during a relatively short duration. This device has two electrically conducting electrodes, which are separated by a nonconducting material. The nonconducting material is known as a dielectric, which is made of an insulator material.

The capacitor is classified as polarized and non-polarized based on the characteristic of the dielectric material. The non-polarized capacitors have ceramics and polymers as the dielectric materials, whereas oxides of aluminum and tantalum are used in the polarized capacitors. Polarized capacitors are generally referred to as electrolytic capacitors, which are electrochemical devices [23]. Each dielectric material has a characteristic value known as dielectric constant. Vacuum is dielectric and it has been used in the old-fashioned capacitors. The dielectric constant for vacuum is assigned a value of unity. Technically, the dielectric constant of a material is the ratio of the relative permittivity of the material to store the electrical energy, when voltage is applied, with respect to the storage capability under vacuum. Various dielectric materials and their constants are listed in Table 38.5.

Capacitance is the measure of the capacitor's ability to store the electrical energy for a certain potential difference across the electrodes. When a voltage is applied between the electrodes, the positive charges are collected in one electrode and the negative charges will be generated on the other electrode.

$$C = \frac{Q}{V} \tag{38.25}$$

Table 38.6 Comparison of the characteristics of few primary batteries

Characteristics	Zinc chloride (zinc-carbon)	Alkaline manganese dioxide	Zinc-air
Anode	Zn	Zn	Zn
Cathode	MnO_2	MnO_2	O_2 (air)
Electrolyte	$ZnCl_2$ (aqueous solution)	KOH (aqueous solution)	KOH (aqueous solution)
Open-circuit voltage (V)	1.6	1.5–1.6	1.45
Nominal voltage (V)	1.5	1.5	1.5
End voltage (V)	0.9	0.9	0.9
Operating temperature (°C)	−10 to 50	−20 to 55	0–50
Energy density at 20°C: button size (Wh/kg)	–	38	340
Energy density at 20°C: cylindrical size (Wh/kg)	85	125	–
Power density	Low to moderate	Moderate	Low
Self-discharge rate at 20°C (% loss per year)	7	4	3 (if sealed)

Source: Linden [20]

The ratio of electric charge divided by the potential difference is referred to as the capacitance of the capacitor. The units for the capacitance are Farads (*F*). Applying a potential difference of 1 V across the electrode plates when 1 coulomb of charge is stored on the electrodes is referred to a capacitance of 1 farad for that capacitor. Capacitors for typical industrial use are manufactured in the range of μF to mF.

Electrochemical Energy Storage Technologies

Classical electrochemical energy storage technologies include batteries, flow batteries, and fuel cells. This section provides an overview of the different technologies; additional literature is recommended [13, 20, 24–32]. In addition, this section also includes a synopsis of super capacitors or electrochemical double layer capacitors (EDLCs), which could be considered advanced electrochemical energy storage systems.

Batteries

The most commonly known electrochemical energy storage device is a battery, as it finds applications in all kinds of instruments, devices, and emergency equipment. A battery's principal use is to provide immediate power or energy on demand. A battery is an electrochemical device where energy from a chemical reaction of the reactants is directly converted into electrical energy. There are two types of batteries: primary and secondary. In primary batteries, the chemical compounds as reactants are consumed to form electrical energy and products, but the products cannot be transformed back into reactants with the use of external electric power. On the other hand, secondary batteries can be recharged by producing the reactants from the products with the help of external electrical energy. Secondary batteries are also known as rechargeable batteries.

The batteries that come under the primary batteries are zinc chloride, alkaline (zinc-manganese dioxide), and zinc-air. Secondary batteries consist of LAB, nickel-cadmium (Ni-Cd), nickel metal hydride (Ni-MH), and lithium ion (Li-ion) battery. Other kinds of batteries, such as a flow battery, redox battery, and sodium nickel chloride battery, are the latest improvements in the area of batteries. In batteries, the convention is that the anode is considered to be the negative terminal and the cathode is considered to be the positive terminal. The electrochemical reactions of these batteries at both the positive and negative terminals, along with a brief description of their properties, are presented next.

Primary Batteries

The characteristics of the few primary batteries that are discussed in this section are listed in Table 38.6. The table provides information on the electrodes, electrolyte, cell voltage, operating temperature, energy and power density, self-discharge rate, advantages, and limitations for each battery.

Zinc-Chloride

This battery is one of the first kinds to be commercially sold, and it is an improved version of the zinc-carbon battery. A can, or the container of the battery that is made of Zn, will act as the negative terminal (anode) of the battery. A carbon rod is the positive terminal (cathode), which is covered by a manganese dioxide paste. Next to the manganese dioxide paste is a layer of zinc chloride electrolyte, which is separated by a paper separator. There are two types of separators used in the Zn-chloride batteries, gelled paste and a special paper coated with gelled paste or cereal. The electrochemical reactions for zinc chloride battery are given below:

Anode rection

$$Zn_{(s)} \rightarrow Zn^{2+}{}_{(aq)} + 2e^- \quad E^\circ = -0.76 \text{ V vs. SHE} \tag{38.26}$$

Cathode reaction

$$MnO_{2(s)} + H_2O_{(l)} + e^- \rightarrow MnO(OH)_{(s)} + OH^-{}_{(aq)} \\ E^\circ = 0.36 \text{ V vs. SHE} \tag{38.27}$$

Overall reaction

$$Zn_{(s)} + 2MnO_{2(s)} + ZnCl_{2(aq)} + 2H_2O_{(l)} \\ \rightarrow 2MnO(OH)_{(s)} + 2Zn(OH)Cl_{(aq)} \quad E = 1.1 \text{ V} \tag{38.28}$$

At the anode electrode, Zn is oxidized to Zn^{2+} ions and manganese dioxide is reduced to manganese oxyhydroxide (MnO(OH)) at the cathode electrode. The cell voltage for the overall reaction is 1.5 V.

The zinc chloride batteries are used in flashlights, penlight, photoflash, smoke detectors, and electronic applications. Commercially, these batteries are manufactured in cylindrical form in different sizes, such as AA, C, D, and F. Household flashlights use sizes C and D Zn-chloride batteries, whereas size AA is normally reserved for penlight, photoflash, and electronic applications [20].

One of the limitations of the Zn-chloride batteries is its high self-discharge rate which means that the Zn-chloride battery will lose its capacity even if it were left idle. Additionally, these batteries are known to have high gassing rates; that is, the Zn-chloride batteries produce more gas from the secondary reactions due to the presence of contamination in the Zn anode [20]. In general, the Zn-chloride battery is not able to keep up with the growing electronic industry because the Zn-chloride battery has lower power density due to the small size and the lack of rechargeable capabilities.

Alkaline Batteries

The electrode material used for the alkaline battery is similar to the Zn-chloride battery with the exception of the potassium hydroxide (KOH) electrolyte. The anode electrode for the alkaline battery is zinc powder, which is mixed with KOH to form a gel. The cathode electrode is manganese dioxide. The following equations illustrates the electrochemical reactions taking place in an alkaline battery: [33]
Anode reaction

$$Zn + 2OH^- \rightarrow Zn(OH)_2 + 2e^- \\ E^\circ = -1.25 \text{ V vs. SHE} \tag{38.29}$$

Cathode reaction

$$MnO_2 + H_2O + e^- \rightarrow MnOOH + OH^- \\ E^\circ = 0.36 \text{ V vs. SHE} \tag{38.30}$$

Overall reaction

$$Zn + 2MnO_2 + 2H_2O \rightarrow Zn(OH)_2 + MnOOH \\ E = 1.61 \text{ V} \tag{38.31}$$

The theoretical cell voltage for an alkaline battery is 1.61 V, but the optimum voltage will be closer to the zinc-based primary batteries (1.5 V). The purity of the electrode material and its activity determines the initial open-circuit voltage of the alkaline battery. These aspects lead to the lowering of the optimum open-circuit voltage of the alkaline battery to 1.5 V from the theoretical cell voltage (1.61 V).

Alkaline batteries have higher energy density and longer operation time in comparison with the inexpensive zinc-carbon and zinc chloride batteries. These batteries are popular for usage in various applications because of their relatively low cost, higher energy and power density, and good portability for providing power to portable electronic devices. Alkaline batteries are manufactured in both cylindrical and miniature sizes.

The alkaline batteries experience similar kinds of limitations as those of zinc chloride batteries. The corrosion of the Zn anode material is also prevalent in the alkaline battery, which essentially lowers the battery capacity and eventually degrades the life of the battery. Zinc in the environment of an alkaline electrolyte is active and it can reduce water into hydrogen gas. The presence of hydrogen gas will increase the internal pressure of the battery, and can cause leakage of the electrolyte and even possible explosion of the battery [34]. In addition, these alkaline batteries are the primary batteries which cannot be recharged to extend their life. In recent years, various research activities have been focused to convert the alkaline battery into a rechargeable battery by the addition of different active materials to the alkaline manganese dioxide cathode [35–38].

Zinc-Air

Zinc-air batteries are well known as the batteries used in hearing aid devices. A cross-sectional view of a Zn-air battery is displayed in Fig. 38.3. The voltage for this battery is produced from the oxidation of zinc in air. As the oxygen from the air is the active material on the cathode side, the cathode can (Fig. 38.3) has holes for the air to flow into the Zn-air battery. The anode electrode is made up of porous zinc powder which is mixed with KOH electrolyte. Air is dispersed on to the cathode electrode with the help of an air distribution membrane and air diffusion Teflon layer, as shown in Fig. 38.3. The current collector for the cathode is the carbon-pressed nickel-plated screen, which is separated from the anode material by a separator. The oxygen from the dispersed air is converted into hydroxide ions on the cathode electrode (38.33) and the hydroxide ion migrates to the

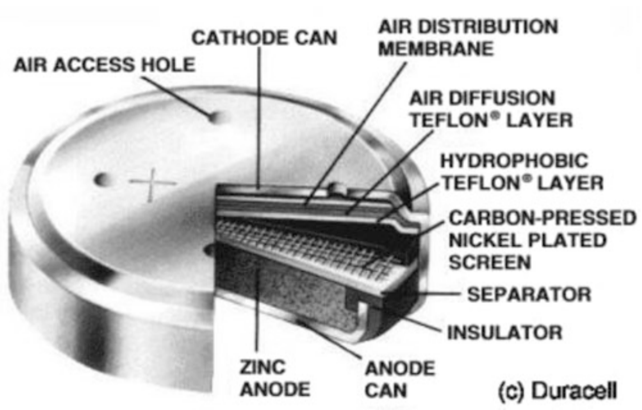

Fig. 38.3 Illustration of Zinc-air button cell [20]. The Zn-air battery has holes for air to pass through the cathode can. The oxygen present in the air is the active material for the cathode side and the Zn is the active material in the anode side. The spacing on the cathode side is smaller than any other battery

anode side to react with Zn. In this reaction, water or electrolyte is not consumed; only the Zn paste is consumed, which implies that replacement of the Zn paste could extend the operation of Zn-air batteries. A sectional view of zinc-air battery is displayed in Fig. 38.3.

The electrochemical reactions at the anode and the cathode electrodes of the Zn-air battery are listed below [33].
Anode reaction

$$\begin{array}{c} \mathrm{Zn} + 2\mathrm{OH}^- \rightarrow \mathrm{ZnO} + \mathrm{H_2O} + 2\mathrm{e}^- \\ E^\circ = -1.25\ \mathrm{V\ vs.\ SHE} \end{array} \tag{38.32}$$

Cathode reaction

$$\begin{array}{c} \mathrm{O_2} + 2\mathrm{H_2O} + 4\mathrm{e}^- \rightarrow 4\mathrm{OH}^- \\ E^\circ = 0.40\ \mathrm{V\ vs.\ SHE} \end{array} \tag{38.33}$$

Overall reaction

$$\mathrm{Zn} + \mathrm{O_2} \rightarrow 2\mathrm{ZnO} \quad E = 1.65\ \mathrm{V} \tag{38.34}$$

Theoretically, a zinc-air battery will produce 1.65 V, and it has the highest specific energy density (340 Wh/kg) of all of the primary batteries [20, 39]. The high specific energy density, flat discharge voltage, long shelf life, environmentally safe nature, and low cost of the Zn-air batteries make them attractive storage devices for many applications [20, 40]. Even though the initial application of Zn-air batteries was restricted to button cells for hearing aids, the recent developments on Zn-air batteries have found applications in cell phones, heavy equipments, and electric vehicles [41].

Zn-air batteries are limited by the amount of zinc present as active material in the anode electrode. The shelf life of the Zn-air battery will be affected by the self-discharge of the battery, meaning the corrosion of zinc will degrade the battery capacity. Other factors affecting the capacity or shelf life of a Zn-air battery are based on the gas transfer mechanism which takes place on the cathode side. The issues associated with gas transfer mechanism are direct oxidation, carbonation of electrolyte, and effect of water vapor transfer [20]. The process of the zinc anode's being directly oxidized by the oxygen that has passed into the cathode side after diffusing through the electrolyte is known as the direct oxidation mechanism. Carbonation of the electrolyte is observed when the alkaline electrolyte reacts with the carbon dioxide present in the atmosphere, and the electrolyte transforms into metal carbonate and bicarbonate. The degradation of the Zn-air battery is caused by the formation of carbonate crystals on the cathode structure which affects cathode performance. The presence of carbonate in the electrolyte will also increase the vapor pressure and enhance the loss of water vapor. Finally, any deregulation in the transfer of water vapor between the electrolyte and the environment will significantly affect the shelf life of the Zn-air battery.

Secondary Batteries

The secondary batteries that are described in this section are the LAB, nickel-cadmium, nickel metal hydride, and Li-ion batteries. The characteristics of the selected secondary batteries are provided in Table 38.7.

Lead Acid Battery

The LAB, which is based on electrochemical principles, was first invented in 1860 by Planté. Over the years, this battery has been thoroughly studied, researched, and developed. In the category of medium to large sized batteries, the LAB is the most commonly manufactured rechargeable battery. The negative electrode for this battery is a lead paste covered grid, and the positive electrode is the plate or grid which has lead dioxide. In secondary or rechargeable batteries, an electrode which behaves as an anode during the discharge process will act as cathode during the charging process because of the reduction reactions taking place at this electrode. The electrodes are therefore referred to as negative and positive terminals instead of as anode and cathode. The grid is made of a lead-antimony alloy and the electrolyte for the LAB is sulfuric acid. The discharging and charging reactions for both the terminals are given below: [42]
Negative terminal reactions

$$\begin{array}{l} \mathrm{Pb} + \mathrm{HSO_4}^- \xrightleftharpoons[\text{Charge}]{\text{Discharge}} \mathrm{PbSO_4} + \mathrm{H}^+ \\ +2\mathrm{e}^- \\ E^\circ = -0.358\ \mathrm{V\ vs.\ SHE} \end{array} \tag{38.35}$$

Table 38.7 Comparison of the characteristics of some secondary batteries

Characteristics	Lead acid (SLI design)	Nickel-cadmium (sealed design)	Nickel metal hydride	Lithium ion ($C/LiCoO_2$ system)
Anode	Pb	Cd	MH	C
Cathode	PbO_2	NiOOH	NiOOH	$LiCoO_2$
Electrolyte	H_2SO_4 (aqueous solution)	KOH (aqueous solution)	KOH (aqueous solution)	Organic solvent[a]
Open-circuit voltage (V)	2.1	1.29	1.4	4.2
Nominal voltage (V)	2.0	1.2	1.2	4.0
Operating voltage (V)	2.0–1.8	1.25–1.00	1.25–1.10	4.0–2.5
End voltage (V)	1.75	1.0	1.0	2.5
Operating temperature (°C)	−40 to 55	−40 to 45	−20 to 50	−20 to 55
Energy density at 20°C (Wh/kg)	35	30–35	50	90
Power density	High	Moderate to high	Moderate to high	Moderate
Self-discharge rate at 20°C (% loss per month)	2–3[b]	15–20	20	5–10
Cycle life	200–700	300–700	300–600	500–1,000

[b] Maintenance-free design

Positive terminal reactions

$$PbO_2 + HSO_4^{-} + 3H^{-} + 2e^{-} \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} PbSO_4 + 2H_2O$$

$$E^\circ = 1.69\ \text{V vs. SHE} \tag{38.36}$$

Overall reactions

$$Pb + PbO_2 + 2H_2SO_4 \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} 2PbSO_4 + 2H_2O$$

$$E = 2.048\ \text{V} \tag{38.37}$$

During the discharge process, the electrolyte (sulfuric acid) reacts with lead and lead dioxide to form lead sulfate and water. The cell voltage observed for an LAB is slightly more than 2V, and its specific energy density ranges between 25 and 35 Wh/kg [25]. The density of the sulfuric acid solution is often measured to estimate the status of charge for the battery. A fully charged LAB should possess 1.27–1.30 relative density for the electrolyte.

Since the LAB is a rechargeable battery, the external electricity is used to convert $PbSO_4$ to PbO_2 and Pb at the positive and negative terminals, respectively. This charging process also results, however, in secondary reactions, such as the evolution of oxygen at the positive terminal and the liberation of hydrogen gas at the negative terminal. These secondary reactions are the main cause for the loss of water in the electrolyte. As a result, the lead acid batteries have to be periodically replenished with water.

Research studies indicate that the presence of antimony on the lead grid electrodes was the cause for the secondary reaction which includes water electrolysis and that resulted in loss of water from the electrolyte. In order to avoid periodic replenishment of water and to retain a low maintenance LAB, the chemical composition of the electrode was changed to lead-calcium or lead-calcium-tin alloy instead of lead-antimony. The amount of water lost from the electrolyte in the low maintenance LAB is less than that lost in traditional lead acid batteries. Recent advances in lead acid batteries have focused on developing completely sealed systems. The new LAB is called a valve-regulated lead acid (VRLA) battery. In a VRLA battery, the oxygen gas generated at the positive terminal is transported internally to the negative terminal, where the oxygen is reduced with protons to form water. This process is known as the oxygen cycle [25]. The advantage of the VRLA battery is that no maintenance is required, and no gases (H_2 and O_2) escape from the battery system.

The lead acid batteries have been mainly used for automotive applications. Those batteries which are used for automotive purposes are referred to as an SLI (starting, lighting, and ignition) system. The SLI system of lead acid batteries finds application in automotive vehicles, golf carts, tractors, and lawn mowers. Additionally, the LABs are used in industrial trucks and electric vehicles for traction or motive power. The VRLA battery has been used for stationary applications, such as emergency and standby power systems, telecommunications, uninterrupted power supply (UPS), railroad signaling, and energy storage systems. The advancement in the LAB research has lead to portable systems which are sealed and maintenance-free systems. The portable lead acid batteries are mainly used in small appliances and devices, portable tools, and electronic equipments [20].

The generation of hydrogen and oxygen gas during the operation of the LAB limits its shelf life and capacity. These gases are released at levels which can lead to explosions, as in the case of SLI type lead acid batteries. Even in the sealed lead acid batteries, certain amounts of hydrogen gas are released during its operation; therefore, care must be taken while planning for charging and location of the battery for safety reasons. The lead acid batteries fail mostly due to the corrosion of the positive and negative grids or terminal. Lead and lead oxide, the active materials in negative and positive terminals, respectively, will react with sulfuric acid even if the battery is in idle condition. Therefore, grid corrosion is a major problem for the failure of lead acid batteries [20].

Nickel-Cadmium

The nickel-cadmium (Ni-Cd) battery is one of the rechargeable alkaline batteries because it uses KOH as its electrolyte. Ni-Cd battery was invented in the early twentieth century by the Swedish scientist Waldemar Jüngner. Almost at the same time, Thomas Edison in the USA invented another kind of nickel-based battery known as the nickel-iron battery, which also had similar electrochemical properties to those of the Ni-Cd battery [42, 43].

The negative terminal of an Ni-Cd battery has cadmium as the active material, whereas nickel oxyhydroxide (NiOOH) is the active material in the positive terminal. During the discharge process, cadmium, in the negative terminal, is oxidized by the hydroxide ion present in the electrolyte to form cadmium hydroxide. Nickel oxyhydroxide, in the positive terminal, is converted into nickel hydroxide. During the charging process, cadmium hydroxide is reduced to metallic cadmium at the negative terminal, and Ni^{2+} in the nickel hydroxide is converted into the Ni^{3+} species as nickel oxyhydroxide at the positive terminal [44, 45].

Negative terminal reactions

$$\mathrm{Cd} + 2\mathrm{OH}^- \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} \mathrm{Cd(OH)_2} + 2\mathrm{e}^- \qquad E^\circ = -0.80\ \mathrm{V\ vs.\ SHE} \tag{38.38}$$

Positive terminal reactions

$$2\mathrm{NiOOH} + 2\mathrm{H_2O} + 2\mathrm{e}^- \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} 2\mathrm{Ni(OH)_2} + 2\mathrm{OH}^- \qquad E^\circ = 0.49\ \mathrm{V\ vs.\ SHE} \tag{38.39}$$

Overall reactions

$$2\,\mathrm{NiOOH} + \mathrm{Cd} + 2\mathrm{H_2O} \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} 2\mathrm{Ni(OH)_2} + \mathrm{Cd(OH)_2} \qquad E = 1.29\ \mathrm{V} \tag{38.40}$$

Thermodynamically, the cell voltage for the Ni-Cd battery is 1.30 V. However, in practice, the voltage output is 1.20 V. Over the years, the specific energy density for Ni-Cd has improved from 30 to 40 Wh/kg to 60 Wh/kg [42]. Overcharging of the Ni-Cd battery will produce oxygen gas on the positive terminal (38.41). Since the positive terminal always gets fully charged before the negative terminal charges, generation of oxygen gas is a frequent occurrence at the positive terminal. Oxygen formed at the positive terminal will be transferred to the negative terminal with the help of oxygen permeable separator, for recombination with Cd to form cadmium hydroxide (38.42) [45]. Finally, the cadmium hydroxide will be converted into metallic cadmium during the overcharging process (38.43) [29]. These reactions are similar to the oxygen cycle found in the low maintenance and VRLA batteries.

$$4\mathrm{OH}^- \rightarrow 2\mathrm{H_2O} + \mathrm{O_2} + 4\mathrm{e}^- \tag{38.41}$$

$$\mathrm{Cd} + \frac{1}{2}\mathrm{O_2} + \mathrm{H_2O} \xrightarrow{\text{Gas Recombination}} \mathrm{Cd(OH)_2} \tag{38.42}$$

$$\mathrm{Cd(OH)_2} + 2\mathrm{e}^- \xrightarrow{\text{Charge}} \mathrm{Cd} + 2\mathrm{OH}^- \tag{38.43}$$

Sealed Ni-Cd battery was developed to avoid gassing (oxygen) from the positive terminal. Until nickel-metal hydride batteries came along in 1991, the Ni-Cd batteries were the main choice as the power supply for all cordless or portable electronic equipment [44]. The longer cycle life of the Ni-Cd battery has resulted in its extensive use in the spacecraft applications, such as satellites in low earth orbit (LEO) and geo-synchronous earth orbit (GEO) [45].

The limitations of using the Ni-Cd batteries have been associated with the generation of gases on the electrodes during the charge–discharge process. The operation of the Ni-Cd batteries is affected by the generation of hydrogen gas on the positive terminal due to over discharging. Even in a sealed Ni-Cd battery, the evolved hydrogen gas is consumed at a low rate, which leads to a buildup of internal pressure and eventually bursting of the Ni-Cd battery [45]. At the same time, during the charging process of a sealed Ni-Cd battery, the water formed at the positive terminal will dilute the electrolyte concentration on the pores of the active material, thereby causing a drop in electrode voltage or overvoltage. While operating the Ni-Cd battery in a low temperature environment with high rate of charging and discharging, the formation of water at the pores of the positive terminal will lead to the dilution of the electrolyte and freezing. However, on the negative terminal the electrolyte concentration will increase resulting in precipitations on the pores [45]. In addition to these issues, the Ni-Cd battery has the inherent problem of using a carcinogenic material, cadmium, which is also a pollutant that will harm the environment.

Nickel Metal Hydride

The Ni-MH battery is similar to the nickel-cadmium battery in most aspects, except for the active material in the negative terminal. The active material in the negative terminal is hydrogen, which is stored in the form of metal hydride. The hydrogen atoms are stored in metal alloys and these alloys are of two kinds, AB_5-type and AB_2-type. The AB_5-type alloy is made up of nickel and rare earth metals, whereas the AB_2-type alloy is a mixture of nickel, titanium, vanadium, and zirconium [45]. Typically, the negative terminal electrode is made of either $LaNi_5$ (AB_5-type) or $TiNi_2$ (AB_2-type) alloy and the AB_5-type alloys have better corrosion resistance than the AB_2-type [25]. In recent commercial development of the Ni-MH battery, the alloy composition for the negative electrode has been $MmNi_{3.2}Co_{1.0}Mn_{0.6}\,Al_{0.11}Mo_{0.9}$ (AB_5-type) or $Ti_{0.51}Zr_{0.49}V_{0.70}Ni_{1.18}Cr_{0.12}$ (AB_2-type), where Mm is misch-metal, which is composed of 25 wt. % La, 50 wt. % Ce, 7 wt. % Pr, and 18 wt. % Nd [45].

NiOOH is the active material for the positive terminal and the aqueous KOH is the electrolyte. The reactions at the terminals are listed below: [33]

Negative terminal reactions

$$MH + OH^- \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} M + H_2O + e^- \qquad E^\circ = -0.83\ \text{V vs. SHE} \tag{38.44}$$

Positive terminal reactions

$$NiOOH + H_2O + e^- \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} Ni(OH)_2 + OH^- \qquad E^\circ = 0.49\ \text{V vs. SHE} \tag{38.45}$$

Overall reactions

$$NiOOH + MH \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} Ni(OH)_2 + M \qquad E = 1.32\ \text{V} \tag{38.46}$$

The Ni-MH battery has been replacing the Ni-Cd battery in various types of electronic equipment because the specific energy density of the Ni-MH battery is 60–80 Wh/kg, which is higher than that of the Ni-Cd battery. The cell voltage of the Ni-MH battery is similar to that of the Ni-Cd battery, ranging between 1.2 and 1.3 V.

One of the advantages of using the Ni-MH battery over the Ni-Cd battery is the absence of a toxic pollutant (cadmium) in the battery system. The evolution of hydrogen and oxygen gases, even in the sealed Ni-MH battery during overcharging and discharging conditions, has been effectively eliminated by the design of the battery [45]. During the overcharging step, oxygen gas is produced at the positive terminal; the oxygen gas then migrates to the negative terminal, where it reacts with metal hydride electrode to form water (38.47), (38.48), and (38.49):

$$4OH^- \rightarrow O_2 + 2H_2O + 4e^- \tag{38.47}$$

$$M + H_2O + e^- \rightarrow MH + OH^- \tag{38.48}$$

$$4MH + O_2 \rightarrow 4M + 2H_2O \tag{38.49}$$

Similarly, during the deep discharging process, hydrogen gas is evolved from the positive terminal (38.50). The hydrogen gas migrates to the negative terminal, where it is oxidized into water in the presence of the metal hydride electrode (38.51).

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \tag{38.50}$$

$$H_2 + 2OH^- \rightarrow 2H_2O + 2e^- \tag{38.51}$$

The Ni-MH batteries do not show any memory effect caused by recrystallization on the electrodes. Moreover, the Ni-MH batteries have higher energy density in terms of weight and volume in comparison with the Ni-Cd batteries, which has resulted in the replacement of the Ni-Cd batteries by the high energy density Ni-MH batteries. In addition to the application of the Ni-MH batteries for all of the electronic devices, the prismatic cells with 250 Ah capacity are manufactured for electric vehicle applications. The Ni-MH batteries are capable of operating only in the temperature range of −20 to +45°C; beyond 45°C, the charging efficiency of the battery has been observed to decline [45].

The swelling of the electrode material from absorption of hydrogen gas and the leaching of the metal ions present in the electrode into the electrolyte are some of the issues related to Ni-MH batteries. The hydrogen storage materials have the problem of severe volume expansion with more intake of hydrogen gas. This excessive absorption of hydrogen gas can occur from the charging—discharging process, and the absorption of hydrogen gas can lead to cracking and

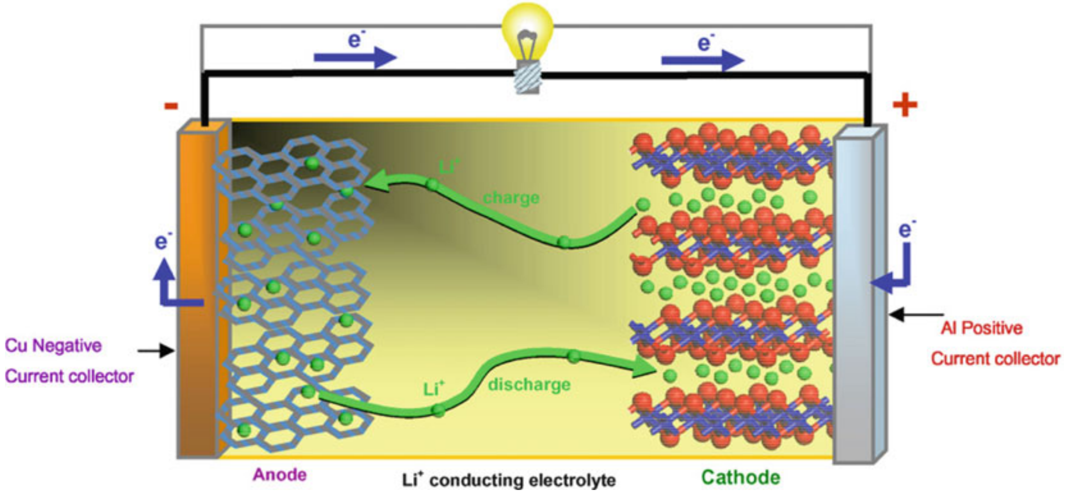

Fig. 38.4 Illustration of discharge and charge processes of Li-ion battery [46]. Copper is the negative current collector and it has graphite on the surface. Aluminum is the positive terminal with $LiCoO_2$ compound on the surface. The intercalation of Li-ions during charging and discharging is shown in this figure

pulverization of alloy present in the electrode [45]. The leaching of the metal ions from the metal alloy electrodes, due to the presence of organic impurities in the electrolyte, will lead to self-discharge of the battery and eventual decay of the battery capacity. The separators used in the Ni-MH battery can also decompose and disperse the organic impurities in the electrolyte, which is another problem related to Ni-MH batteries.

Lithium Ion Battery

Lithium is the lightest element among all the materials used in batteries. The standard reduction potential for Li is −3.04 V vs. SHE, which makes it a suitable component for batteries. Lithium batteries, commonly used in cameras, have an average cell voltage of 3.5 V. Lately, however, another kind of lithium battery, the lithium ion battery (LIB), has demonstrated higher cell voltages in the range of 4 V and a specific energy density of 100–150 Wh/kg, which translates into a longer cycle life than any other commercial battery [27]. So, the LIB finds application in mobile phones, laptops, portable music players, and even as a power supply unit for electric vehicles [43].

The electrochemistry for the LIB is not substantially different from other batteries. Graphite is the active material in the negative terminal and the positive terminal is made of lithium metal oxide compounds, such as $LiCoO_2$ and $LiNiO_2$. The element lithium is highly reactive and can catch fire, or even explode, when it comes in contact with water. So, the electrolyte used in the LIB is a nonaqueous solution, such as a combination of lithium salt ($LiPF_6$) with organic solvents, namely ethylene carbonate-dimethyl carbonate (EC-DMC). The electrochemical reactions for the LIB with $LiCoO_2$ as the active material in the positive terminal are listed below: [33]

Negative terminal reactions

$$\begin{aligned} &Li_xC \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} C + xLi^+ + xe^- \\ &E^\circ = -2.90\,\text{V vs. SHE} \end{aligned} \tag{38.52}$$

Positive terminal reactions

$$\begin{aligned} &Li_{1-x}CoO_2 + xLi^+ + xe^- \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} LiCoO_2 \\ &E^\circ = 1.20\,\text{V vs. SHE} \end{aligned} \tag{38.53}$$

Overall reactions

$$\begin{aligned} &Li_xC + Li_{1-x}CoO_2 \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} C + LiCoO_2 \\ &E = 4.10\text{ V} \end{aligned} \tag{38.54}$$

During the charging process, the Li-ions present inside the structures of the $LiCoO_2$ compound are removed or withdrawn, and transported via the mixed organic electrolyte into the graphite structure of the negative terminal. This process is reversed during the battery discharge by removing Li-ions from the graphite structure, and it is intercalated into the $LiCoO_2$ structure. The phenomena of Li-ion transported back and forth between anode and cathode material has led to the naming of the Li-ion battery as a “rocking-chair” cell [42]. The current collector used for the anode or the negative terminal (graphite) is copper, and aluminum is the current collector on the cathode or the positive terminal side (Fig. 38.4).

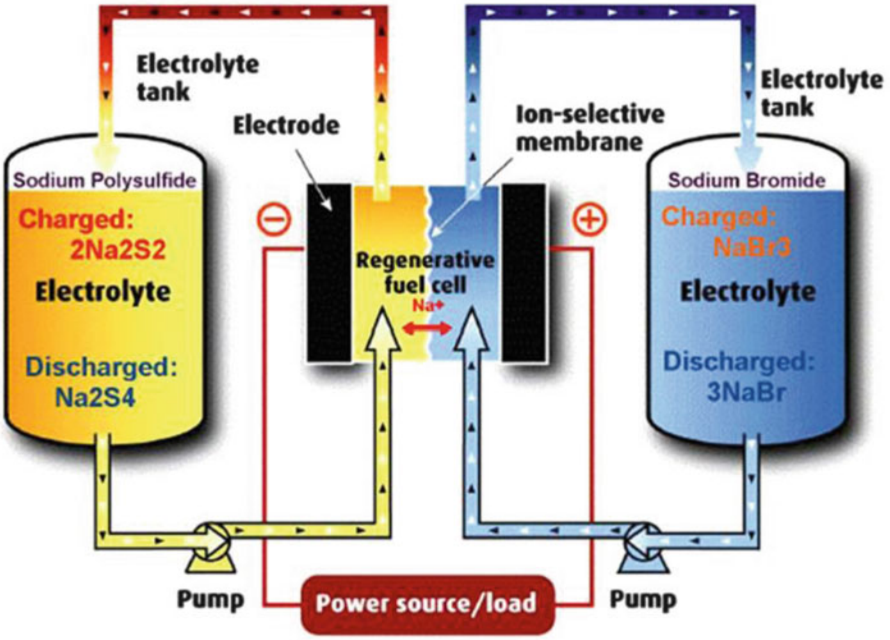

Fig. 38.5 Schematic diagram of polysulfide bromide battery (flow battery) [24]. The flow battery shown in this figure has reservoirs containing charged and discharged species of the compounds for each terminal. Sodium polysulfide solution is circulated on the negative side and sodium bromide is circulated through the positive side of the flow battery

Many researchers are working to improve and develop better Li-ion batteries for various applications. Electrolytes used in the first generation of Li-ion batteries have been liquid organic solvents, but the use of polymer and ceramic electrolytes has simplified the battery design resulting in improved safety and durability [46, 47]. Polymer electrolytes being studied are PEO, a solid polymer electrolyte, and poly(vinylidene fluoride) (PVdF) with hexafluoropropylene (HFP), a polymer gel electrolyte. In the case of ceramic electrolytes, $Li_{1+x}Al_xGe_{2-x}(PO_4)_3$, or LAGP, is considered to have relatively high conductivities [47]. In the same manner, different electrode materials for the LIB are being investigated as well. Anode materials that have caught the researcher's attention are carbon nanotubes (CNTs) with alloys, such as Sn_2Sb and SnNi, and Li alloys, such as LiAl, Li_3Sb, Li_2Si_5, and Li_2Sn_5 [46, 48]. In the case of cathode materials for the Li-ion batteries, $LiMn_2O_4$, vanadium oxides (V_2O_5), olivines ($LiFePO_4$), and layered lithium metal oxides—$LiMO_2$ ($M = Mn$, Ni, Co) have been actively considered [46, 48].

Flow Batteries

Other than the primary and secondary batteries, there are new types of batteries, which constitute the emerging technologies in the field of battery, also being investigated. The research activity surrounding these new types of batteries are focused mainly to improve the energy density of the battery system and also to develop advanced energy storage device capabilities. Among the new kinds of batteries, redox flow and high temperature batteries have demonstrated promising future.

The redox flow batteries are suited as energy storage units for the distributed power supply installations. The outlook for using the redox flow batteries is in stand-alone power applications and distributed energy installations for electric utility service. The salient features of the redox flow batteries are its modular design, ease in transportability, low cost compared to other power generation systems, long life, and high reliability [26]. A few examples of the redox flow battery systems are polysulfide-bromide, zinc-bromine, and vanadium-bromide redox flow cells [24, 49]. Recent advances and further reading on the flow batteries can be found in the literature [50–59].

The design and structure of a redox flow battery, as shown in Fig. 38.5, resemble a fuel cell rather than the traditional rechargeable battery. The functioning of the redox flow battery, however, is different from that of a fuel cell. A simple diagram of the polysulfide bromide flow battery is shown in Fig. 38.5. The positive and negative compartment of the redox flow cell is separated by an ion-selective membrane which provides the ionic conductivity required for the electrochemical reactions at the electrodes. The electroactive species for the positive and negative sides are dissolved in their respective electrolyte solutions. The electrolyte tank for the negative side of the polysulfide bromide battery has both disodium disulfide (Na_2S_2) and disodium tetrasulfide (Na_2S_4), which are the charged and discharged compounds, respectively. Similarly on the positive side, the electrolyte has sodium tribromide ($NaBr_3$) as the charged species and sodium bromide (NaBr) as the discharged species. The presence of charged and discharged species in an electrolyte is not used in the fuel cell system. These electrolyte solutions are circulated into their respective negative or positive side of the flow cell so that the electroactive species will be reduced or oxidized, and produce the electric voltage. The energy of the redox flow battery system depends on the volume of the electrolyte tank, so the energy component of this battery is determined independently from the battery power, which is based on the flow cell.

The electrochemical reactions for the $ZnBr_2$ system are listed below, where bromine gas combined with organic reagent forms polybromide compound in the positive electrode. The thermodynamic cell voltage for the $ZnBr_2$ system is 1.83 V, but only 1.3 V is typically observed during its operation [43].

Negative terminal reactions

$$\mathrm{Zn} \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} \mathrm{Zn}^{2+} + 2e^- \qquad E^\circ = -0.763\ \mathrm{V\ vs.\ SHE} \tag{38.55}$$

Positive terminal reactions

$$\mathrm{Br_2} + 2e^- \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} \mathrm{Br}^- \qquad E^\circ = 1.065\ \mathrm{V\ vs.\ SHE} \tag{38.56}$$

Another flow battery is based on the vanadium-bromide redox system. Normally, the specific energy density for the vanadium-bromide redox flow battery, for an ion concentration of 2 mol/L, is 25–35 Wh/kg. When the ion concentration of the redox species is increased to 3–4 mol/L, the specific energy density of the flow battery also increases to 60 Wh/kg. The negative electrode of this redox flow battery is the VBr_2/VBr_3 redox couple and the $Cl^-/ClBr_2^-$ redox couple is present at the positive electrode [26]. The reactions for the vanadium-bromine redox flow battery are as follows:

Negative terminal reactions

$$\mathrm{VBr_2} + \mathrm{Br}^- \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} \mathrm{VBr_3} + e^- \tag{38.57}$$

Positive terminal reactions

$$\mathrm{ClBr_2}^- + 2e^- \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} 2\mathrm{Br}^- + \mathrm{Cl}^- \tag{38.58}$$

High Temperature Batteries

New types of batteries, such as sodium (Na) beta batteries (NBBs), utilize high temperatures for their effective functioning. These NBBs have beta alumina as their solid electrolyte, in order to handle high temperatures. One of the beta batteries is the sodium-nickel chloride battery, also known as ZEBRA (ZEolite Battery Research Africa), so named because it was first developed in South Africa. The active material in the anode, or the negative terminal, for the ZEBRA battery is molten Na. The active material at the positive terminal is nickel chloride. The primary electrolyte used to separate anode and cathode is β″-alumina. In addition to $\beta''\text{-}Al_2O_3$, the battery also has a secondary electrolyte in the form of molten sodium aluminum chloride ($NaAlCl_4$), which provides good mobility for sodium ions. The sodium-nickel chloride battery is operated between 175 and 400°C. The electrochemical reactions at the electrodes are as follows: [49]

Anode, or negative, terminal reactions

$$2\mathrm{Na} \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} 2\mathrm{Na}^+ + 2e^- \qquad E^\circ = -2.71\ \mathrm{V\ vs.\ SHE} \tag{38.59}$$

Cathode, or positive, terminal reactions

$$\mathrm{NiCl_2} + 2\mathrm{Na}^+ + 2e^- \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} \mathrm{Ni} + 2\mathrm{NaCl} \tag{38.60}$$

Overall reactions

$$2\mathrm{Na} + \mathrm{NiCl_2} \underset{\text{Charge}}{\overset{\text{Discharge}}{\rightleftharpoons}} 2\mathrm{NaCl} + \mathrm{Ni} \qquad E = 2.58\ \mathrm{V\ at\ 300^\circ C} \tag{38.61}$$

Figure 38.6 displays a schematic diagram of the sodium-nickel chloride battery. In this battery, liquid sodium is enclosed in a metal shim and held in an anode end plate. The anode or the negative terminal side is separated from the cathode or the positive terminal side by copper wool. The copper wool separator comes in contact with the solid electrolyte (β″-alumina). In the cathode, which is the positive terminal side, the current collector is an Ni mesh which is surrounded by the active material for the cathode—$NaAlCl_4$. The α-alumina ring is the secondary electrolyte of the sodium-nickel chloride battery.

The sodium beta battery technology based on the beta alumina solid electrolyte has recently attracted interest for applications such as renewable energy storage, as well as

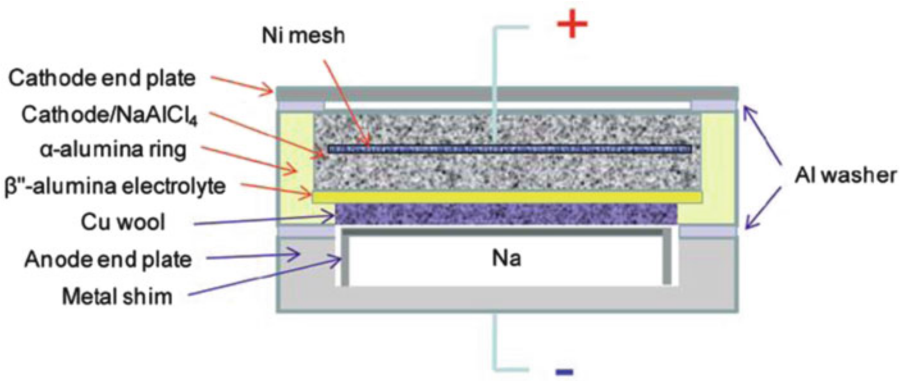

Fig. 38.6 Schematic diagram of a Sodium-nickel chloride battery [140]. Cross-section view of the high temperature battery system, where solid electrolyte is β″-alumina, anode is molten sodium, and molten $NaAlCl_4$ is the cathode material

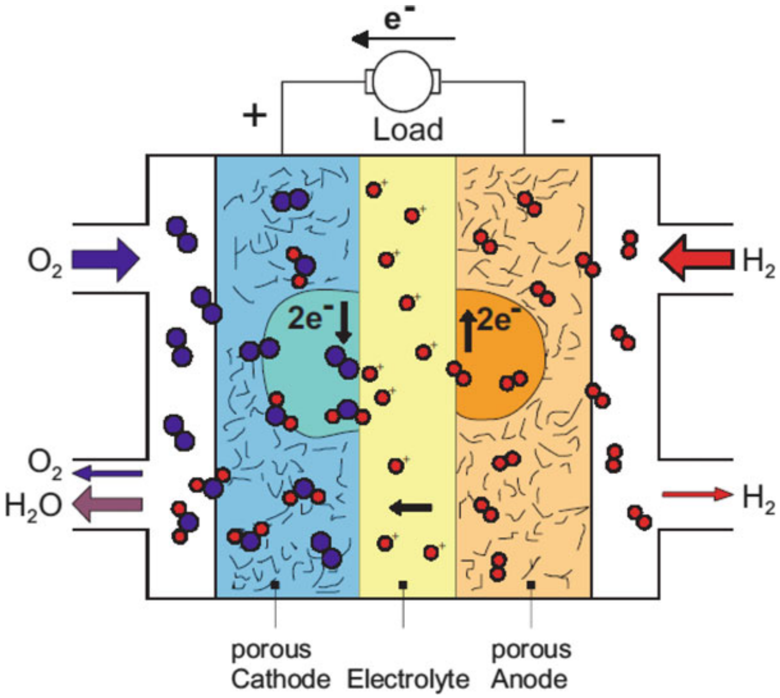

Fig. 38.7 Schematic drawing of a proton exchange membrane fuel cell (PEMFC) [31]. The electrolyte is capable of conducting or exchanging protons between anode and cathode. On the anode side H_2 is oxidized to protons on Pt surface over the porous anode. In the cathode side, the proton combines with O_2 to form water which is removed along with unreacted O_2

electric vehicles, because of its high energy density, high round-trip efficiency, and capacity to store energy for long durations [49].

Fuel Cells

In 1839, Sir William Grove invented an electrical energy conversion system known as fuel cells. The fuel cell is an electrochemical device which can directly convert chemical energy bound up in a chemical compound into electrical energy. Figure 38.7 is the schematic diagram of a proton exchange membrane fuel cell (PEMFC). Similar to the battery system, the fuel cell has anode and cathode compartments. The electrolyte used in the PEMFC is solid polymer electrolyte, Nafion (sulfonated tetrafluoroethylene-based fluoropolymer-copolymer). Hydrogen gas (the fuel) is supplied to the anode side of the fuel cell, and the cathode side needs oxygen or the oxygen present in the air for the electrochemical reaction. The reactants supplied to the fuel cell are in gaseous form. Both the anode and cathode side have a porous electrode with platinum (Pt) as the catalyst for the electrochemical reactions. On the anode side, hydrogen gas is oxidized to become a proton, which travels through the solid electrolyte to the cathode side. On the cathode side, the proton, along with electrons from an external circuit, reacts with oxygen to form water and produce an electric current.

According to Fig. 38.7, the hydrogen gas is fed to the anode side of the PEMFC and the platinum catalyst on the porous anode oxidizes a hydrogen molecule into a proton and two electrons (38.62). The electrons travel through the external circuit and the protons are transported through the proton exchange membrane (PEM), or the electrolyte, to the cathode side. On the cathode side, the protons combine

Table 38.8 Characteristics of the different types of fuel cells

Characteristics	AFC: alkaline fuel cell	PEMFC: proton exchange membrane fuel cell	DMFC: direct methanol fuel cell	PAFC: phosphoric acid fuel cell	MCFC: molten carbonate fuel cell	SOFC: solid oxide fuel cell
Electrolyte	Potassium hydroxide (8–12 N)	Proton exchange membrane	Proton exchange membrane	Phosphoric acid (85–100 %)	Molten carbonate (Li, K, Na)	Solid oxide (ZrO_2–Y_2O_3)
Operating temperature	50–250°C	50–90°C	50–90°C (≤130°C)	180–200°C	650°C	750–1,050°C
Charge carrier	OH^-	H^+	H^+	H^+	CO_3^{2-}	O^{2-}
Electrocatalyst	Pt, Ni/NiO_x	Pt	Pt	Pt	Ni/$LiNiO_x$	Ni/Perovskites
Fuel	H_2	H_2 (pure or reformed)	CH_3OH	H_2 (reformed)	H_2 and CO (reformed), CH_4	H_2 and CO (reformed), CH_4
Poisons	CO, CO_2	CO > 10 ppm	Adsorbed intermediates	CO > 1 % H_2S > 50 ppm	H_2S > 0.5 ppm	H_2S > 1 ppm
Applications	Transportation, space, military, energy storage systems			Combine heat and power for decentralized stationary power systems	Combined heat and power for stationary decentralized systems and for transportation (trains, boats, etc.)	
Realized power	Small plants 5–150 kW Modular	Small plants 5–250 kW Modular	Small plants 5 kW	Small—medium plants 50 kW–11 MW	Small power plants 100 kW–2 MW	Small power plants 100–250 kW

with the electrons and the oxygen gas on the porous cathode in the presence of Pt catalyst to form water (38.63) and produce an electric current. The oxygen gas stream is supplied to the cathode side and the water produced from the electrochemical reaction is carried away by the exiting oxygen stream. The electrochemical reactions at the anode and the cathode electrodes of the PEMFC are listed below.

Anode reaction

$$H_2 \rightarrow 2H^+ + 2e^- \quad E^\circ = 0 \text{ V vs. SHE} \tag{38.62}$$

Cathode reaction

$$\frac{1}{2}O_2 + 2H^+ + 2e^- \rightarrow H_2O \quad E^\circ = 1.23 \text{ V vs. SHE} \tag{38.63}$$

Overall reaction

$$\frac{1}{2}O_2 + H_2 \rightarrow H_2O \quad E = 1.23 \text{ V} \tag{38.64}$$

Fuel cells are capable of generating power as long as the fuel (hydrogen) and the oxidant (oxygen) are supplied to the system. On the other hand, even a rechargeable battery is limited in generating power; as all secondary batteries have a definite number of rechargeable cycles, known as cycle life, a rechargeable battery can be recharged (see Table 38.7). In the case of the redox flow battery, the charged and discharged species of the electrochemical reaction are stored in the electrolyte. There are two different electrolytes, one for the anode and one for the cathode. Conversely, the fuel cell has a single electrolyte with the ability to conduct ions between the anode and the cathode. The fuel cell is not designed to be recharged like in the secondary batteries to extend the battery life. A list of different types of fuel cell and its characteristics has been complied in the following Table 38.8.

Notice that traditionally the names for the fuel cells were based on the type of the electrolyte used in that system, except for the Direct Methanol Fuel Cell (DMFC). The DMFC is a PEMFC which uses methanol as its fuel. The most significant problems with adopting fuel cell technologies have to do with: hydrogen storage, transportation, and production. Alternative solutions for these problems will be discussed later in the chapter (see section on “Trends: Novel Electrosynthesis Processes”).

Alkaline Fuel Cell

The alkaline fuel cell (AFC) has the highest electrical efficiency (>60%) among all the types of fuel cells. In the USA, the National Aeronautics and Space Administration (NASA) has used the AFC power plant in the Apollo missions and Space Shuttle program due to its higher efficiency and proven reliability. Initially, nickel-based catalysts were used in the AFCs before switching to a Pt electrocatalyst.

However, one of the advantages of the AFC is that it can employ other metals as the catalyst, such as Pt-Co alloy for oxygen reduction reactions [60]. At the beginning, the AFCs used in the Apollo missions were operated at 200–230°C, whereas now the AFCs are normally operated less than 100°C. The electrochemical reactions at the anode and the cathode electrodes of the AFC are given below:
Anode reaction

$$H_2 + 2OH^- \rightarrow 2H_2O + 2e^- \quad E^\circ = -0.83 \text{ V vs. SHE} \tag{38.65}$$

Cathode reaction

$$\frac{1}{2}O_2 + 2H_2O + 2e^- \rightarrow 2OH^- \quad E^\circ = 0.40 \text{ V vs. SHE} \tag{38.66}$$

The alkaline electrolyte provides better ionic conductivity than acid electrolytes for the fuel cell [32]. Additionally, the fuel cells with alkaline electrolyte, such as KOH used in the AFC, has displayed better kinetics for the oxygen reduction reaction compared to the acid electrolytes [31]. In space applications, the KOH electrolyte for the AFCs is stabilized in an asbestos matrix, which has provided limited life for the fuel cell. In 1970, researchers found that circulating the KOH electrolyte increased the life of the AFC. Carbon dioxide (CO_2) found in the atmosphere and the alkaline electrolyte have been found to be detrimental to the operation of the AFC. CO_2 will react with the hydroxyl ion (OH^-) to form carbonate, which would precipitate on the electrode and the electrolyte, thereby decreasing the performance of the AFC (38.67). In this manner, electrolyte circulation will help in removing the CO_2 gas and reduce the build-up of carbonate in the electrolyte, which extends the life of the AFC. Additionally, a CO_2 scrubber can be used for the hydrogen and air streams in order to reduce the amount of CO_2 in the fuel cell.

$$CO_2 + 2OH^- \rightarrow (CO_3)^{2-} + H_2O \tag{38.67}$$

The AFCs have used in Apollo space craft and other shuttle programs by NASA. Both the USA and Russia have extensively used the AFCs in their space flights [32]. In addition to the space industry, the highly efficient fuel cell (AFC) also found application in the transportation sector. In 1970s, Kordesch built the first fuel cell car using the AFC. In one of the projects, the London cabs were fitted with AFCs modules to provide up to 10 kW power. The cab also had a battery to start and operate the car for the first 10 min before the fuel cell could generate enough power to control the vehicle [31]. Energy storage was the other application of the AFCs. Around the world various organizations, such as Allis-Chalmers, Siemens, Union Carbide, Exxon/Asthom, Fuji, Varta, IFP, CGE, and ELENCO, have installed and tested 1–10 kW capacity of AFC systems [32].

Proton Exchange Membrane Fuel Cell

The PEMFC was formerly known as solid polymer electrolyte membrane fuel cell. These fuel cells use polymer electrolyte as a membrane, which is capable of transporting protons between the anode and the cathode side. The membrane used in these fuel cells is Nafion, which is a perfluorocarbon sulfonic acid membrane. The Nafion membrane is highly acidic in nature with good conductivity for protons in the presence of water. Since Nafion structure is similar to Teflon, it is highly stable in oxidizing and reducing environments [31, 32]. Water management is very important for the efficient functioning of the PEMFC. The gas (hydrogen and oxygen, or air) streams are hydrated before being supplied to the fuel cell, so that ionic conduction of proton across the Nafion membrane can be maintained.

The operating temperature for the PEMFC is in the range of 50–90°C. Pt is the catalyst used in both the anode and cathode electrodes. The electrodes are made of porous gas diffusion electrodes (GDE) so that the gases can have better contact with the Pt catalyst. The electrodes for the PEMFC are prepared in a delicate manner in order to obtain the least resistance between anode, electrolyte, and cathode. This method to combine Pt, catalyst support, binders, and the Nafion membrane is known as membrane electrode assembly (MEA). Dispersion of Pt on carbon support enhances the oxygen reduction reaction on the cathode electrode. If air was used in the cathode side of the fuel cell, then the lower partial pressure of oxygen in the air will decrease the performance of the fuel cell.

In the anode electrode, Pt is the best catalyst for oxidizing pure hydrogen gas. However, the presence of carbon monoxide (CO) in the hydrogen stream will have damaging effect on the electrode and also the PEMFC. Carbon monoxide (CO) will adhere to Pt and block the active sites from the desired electrochemical reaction, evidencing the fact that CO is the major poison for the PEMFC. Cleaning the hydrogen stream off of the CO is one of the ways to avoid CO contamination for the PEMFC. Research on developing CO tolerant catalysts, such as Pt-Ru, is also being investigated [61–65].

Even though the PEMFCs are famously known for its application in cars or for transportation, it has also been used in the Gemini spacecraft. The PEMFC provided a power of 1 kW to the spacecraft [31]. Some of the well-known companies involved in the production of PEMFCs are Ballard Power Systems, Inc. in Canada; IFC, Energy Partners, General Motors, Plug Power, and H-Power is United States; Toyota, Honda, Mazda, and Fuji in Japan;

Daimler Chrysler in association with Ballard Power Systems, Inc. in Germany; and DeNora in Italy [32]. The PEMFCs are used in the modern electric vehicles to avoid the usage of gasoline in the cars. The hybrid electric vehicles are powered by batteries and fuel cells are used to sustain the power demand. Presently, most of the big car companies are involved in the development of fuel cell-based cars. For sometime fleets of PEMFC-powered buses have been operated and tested by Chicago Transit Authority and BC (British Columbia) Transit, for public transportation, with the help from Daimler Chrysler/Ballard [32].

In the area of low level power generation, the PEMFC systems are increasingly finding a good fit. Especially in the portable power applications, the PEMFCs with 35–250 W power have found use in video cameras, electric wheelchairs, laptops, intelligent transportation systems, and military communications [32]. On the other hand, the PEMFC systems are also crossing into the stationary applications. Interestingly, Plug Power has installed a 7 kW residential power system based on the PEMFCs to provide a single home in upstate New York with electricity, heat, and hot water [31].

Direct Methanol Fuel Cell

The PEM technology has been used in another kind of fuel cell known as the DMFC. The DMFC operates in the same temperature range as the PEMFC, and it also transports protons across the membrane to produce water and generate electric current. There are several advantages of the DMFC over the PEMFC. One of them is that methanol can be more efficiently stored than hydrogen. Therefore, operating directly with methanol minimizes a significant problem for fuel cell technology: hydrogen storage. Additionally, the use of 1 M methanol directly in the fuel cell helps the water and thermal management of the fuel cell with the PEM. The PEM requires water for the conductivity of protons. However, at the operating temperature, the membrane dries up and the presence of liquid methanol helps in hydrating the PEM. The electrochemical reactions on the anode and cathode electrode of the DMFC are listed below:

Anode reaction

$$\mathrm{CH_3OH + H_2O \rightarrow CO_2 + 6H^+ + 6e^-} \tag{38.68}$$

Cathode reaction

$$\frac{3}{2}\mathrm{O_2 + 6H^+ + 6e^- \rightarrow 3H_2O} \quad E^\circ = 1.23\ \mathrm{V\ vs.\ SHE} \tag{38.69}$$

At the anode electrode, the methanol is oxidized to CO_2, protons, and electrons. The electrons are transported through the external circuit and the protons are migrated through the membrane to the cathode side. At the cathode electrode, oxygen reacts with the protons and the electrons to form water. Pt is not an efficient catalyst for the electrochemical oxidation of methanol, so other metals, as alloys of Pt, are investigated as possible candidates for the anode electrode of the DMFC. The most commonly used catalyst for the methanol oxidation at the anode electrode is Pt-Ru. In the cathode electrode, similar to the PEMFC, Pt is the best catalyst for the oxygen reduction reaction.

One of the issues with the DMFC system is methanol crossover, where methanol migrates through the membrane from the anode to the cathode side of the fuel cell. The membranes used in the DMFC systems were mainly developed for the PEMFC, which was designed to transport protons along with water molecules. Methanol has similar properties to the water which results in easy diffusion as well as electroosmotic drag of the methanol molecules across the PEM. The oxidation reaction of methanol at the Pt catalyst surface interferes with the oxygen reduction reaction and degrades the performance of the DMFC. Membrane development to prevent methanol crossover is the key area of research for the DMFC systems. At the same time, investigation has also been focused on a methanol resistant catalyst for the cathode electrodes. This is a different approach to solve the presence of methanol on the cathode side of the DMFC. In this approach, the methanol crossover across the membrane is not prevented but methanol tolerant catalysts are used to avoid methanol oxidation at the cathode [66–69].

The DMFCs are typically PEMFCs, which uses easily transportable liquid methanol as fuel. Similar to PEMFCs, the DMFCs have the strong potential to be used for the portable power systems. The use of methanol in these fuel cells, which has low noise and thermal signature, shows the possibility in military and defense applications for the DMFC systems. Presently, the potential applications for the DMFCs are focused on the portable power systems and military, and later it could be extended to stationary power generation.

Phosphoric Acid Fuel Cell

One of the most commercialized fuel cells is the phosphoric acid fuel cell (PAFC). The PAFC systems are used as stationary power plants. They have been installed worldwide in the range of 5–10 MW capacity. Phosphoric acid is an excellent acid electrolyte for the fuel cell system and the PAFC electrolyte, phosphoric acid, is stabilized in an SiC matrix. The hydrogen gas obtained from steam reforming or other reformation process can be handled efficiently by the phosphoric acid electrolyte [32]. The PAFCs operating temperature is around 200°C, which is suitable for the electrolyte to provide good ionic conductivity.

The phosphoric acid electrolyte is inert and stable in a reducing and oxidizing environment. The electrolyte also has low volatility in the operating temperature. Among other advantages, the PAFC system has a relatively simple design construction, and it is also a thermally, chemically, and electrochemically stable system [31]. The high temperature operation of the PAFC has resulted in tolerances of up to 1% CO and 40 ppm H_2S. The electrochemical reactions in the anode and cathode electrodes are same as the ones observed in the PEMFCs (38.62) and (38.63). The electrocatalyst used on the anode electrode of the PAFC is Pt, whereas Pt-Co and Pt-Cr-Co supported on carbon has been studied as catalysts for the oxygen reduction reaction on the cathode electrode [32]. The expensive manufacturing cost for the PAFC systems is the main drawback from being widespread installations. The cost of the power from the PAFC power plant is still more than $4,000/kW.

The PAFC systems are mainly applied for stationary power generation. Since the PAFC systems operate at 200°C, the heat energy from the PAFC systems is recovered by integrating it with combined heat and power (CHP) plant. The major company involved in the manufacturing of the PAFC power plants is United Technologies Corporation (UTC). UTC along with its subsidiaries has installed more than 75 MW of PAFC power plants over 19 countries. UTC has manufactured and installed at least 250 PAFC units of each 200 kW power capacity. Presently, one of the UTC's subdivision, UTC Power, Inc., is marketing 400 kW units under the name of PureCell400. A 250 kW PAFC power plant has been used to power the police station at the New York City's Central Park [70]. Toshiba has installed a factory of PAFCs at Hamakawasaki works in Japan [32]. A major power plant of 11 MW capacity was commissioned by UTC along with Toshiba to provide power for Ichihara in Tokyo [31]. Military application of the PAFC systems is being investigated by the US Army Engineering Research and Development Center, Construction Engineering Research Laboratory (ERDC/CERL) with 30 units of 200 kW PAFCs [71].

Molten Carbonate Fuel Cell

The molten carbonate fuel cell (MCFC) is one of the high temperature fuel cells. The operating temperature for the MCFC has been in the range of 600–700°C. The advantages of the MCFC systems are: the use of non-noble metal catalyst for oxygen reduction reactions at the cathode electrode due to a relatively high operating temperature; carbon dioxide is supplied as fuel and not as a poison; the waste heat generated during MCFC operation can be recovered to increase the overall efficiency of the MCFC system; and the MCFCs are capable of combining fuel reforming of natural gas in order to produce hydrogen gas for fuel cell operation [32].

The electrochemical reactions taking place on the anode and cathode electrodes are listed below:

Anode reaction

$$H_2 + {CO_3}^{2-} \rightarrow H_2O + CO_2 + 2e^- \tag{38.70}$$

Cathode reaction

$$\frac{1}{2}O_2 + CO_2 + 2e^- \rightarrow {CO_3}^{2-} \tag{38.71}$$

At the cathode, oxygen reacts with carbon dioxide in order to form the carbonate ion, which is the charge carrier across the electrolyte to the anode side. The carbonate ion reacts with hydrogen on the anode to form water, carbon dioxide, and electric current. Carbon dioxide is recycled back into the cathode stream.

The high operating temperature of the MCFC helps in the use of a non-noble metal catalyst, such as NiO, on the cathode electrode for oxygen reduction reaction. Alternate cathode electrodes investigated are lithium oxide based, such as $LiFeO_2$, Li_2MnO_3, and $LiCoO_2$. A double-layered catalyst like $NiO/LiCoO_2$ has also been used in the MCFC systems to improve the stability of the oxygen reduction reaction [72]. At the anode, Ni is used as the electrode and Ni-Al or Ni-Cr has also been used as the anode to prevent Ni creeping into the molten carbonate electrolyte.

Molten carbonate stabilized in an alumina-based matrix is the electrolyte for the MCFC. The molten carbonate is obtained from the $LiCO_3/K_2CO_3$ (Li/K) mixture supported on the alumina. The sodium carbonate (Li/Na) in the above mixture (Li/K) has increased the alkalinity of the electrolyte and decreased the Ni dendrite formation in the electrolyte. The issues associated with the MCFC technology include the migration of Ni from anode into the electrolyte, corrosion of the NiO at the cathode, and electrolyte migration [32].

Stationary power generation is the area of focus for the MCFC technology. Among various demonstrations of this technology, the stand out and best outcome has been a 2 MW MCFC power plant at Santa Clara, California, USA. In 1996, the 2 MW MCFC power plant was built, commissioned, and tested by the Energy Research Corporation (ERC). It used natural gas as its fuel. This demonstration plant reached a maximum electrical power of 1.93 MW with 2 ppm NO_x, undetectable level of SO_x, and operated within the noise limits. In Bielefeld, Germany, a 250 kW power plant was tested by MTU Friedrichshafen, an affiliate of the Daimler Chrysler group. This power plant operated at 50% efficiency using natural gas, and it also provided heat and hot water to the university at Bielefeld. In 1997, the MC Power Corporation demonstrated a 250 kW power plant in Miramar (San Diego, USA) [31, 32].

Solid Oxide Fuel Cell

The other high temperature fuel cell is the SOFC, which utilizes solid electrolyte made of ceramic material for the electrochemical generation of power. The SOFC operates in the range of 750–1,050°C, which is higher than the MCFC. The high operating temperature of the fuel cell helps in tolerating carbon monoxide, carbon dioxide, and, possibly, reform hydrocarbon fuels. The electrochemical reactions observed on the anode and cathode electrode of the SOFC are listed below:

Anode reaction

$$H_2 + O^{2-} \rightarrow H_2O + 2e^- \tag{38.72}$$

Cathode reaction

$$\frac{1}{2}O_2 + 2e^- \rightarrow O^{2-} \tag{38.73}$$

At the cathode electrode, the oxygen molecule from the air is oxidized to an oxide (O^{2-}) ion, which is transported through the solid oxide electrolyte to the anode side. The oxide ions combine with the hydrogen molecule on the anode electrode to form water and generate electric current. The solid oxide electrolyte commonly used in the SOFC system is made of 85–90% zirconia (ZrO_2) and 10–15% yttria (Y_2O_3), which is referred to as YSZ. The defect in the perovskite (ZrO_2-Y_2O_3) structure as well as the high operating temperature of the SOFC helps in the movement of the oxide ion in the solid YSZ electrolyte. The solid form of the electrolyte results in only two phases (solid–gas) being available (instead of the solid–liquid–gas phases in other types of fuel cells) for the reactions. The two phase situation eliminates the problems, such as water management, flooding of the catalyst, and slow kinetics, due to mass transport of the reactant and products in the liquid phase.

The cathode materials employed for the SOFC are lanthanide-based perovskites, especially lanthanum strontium manganate ($LaSrMnO_3$—LSM). The lanthanide-based perovskites have displayed higher ionic conductivity for the oxide ion and good catalytic activity for the oxygen reduction reaction. Two phase cathode materials are investigated for the SOFC, where a layer of YSZ will be added along with LSM to form the two phase cathode. For many years, the material used as the anode for the SOFC has been Ni-YSZ. The Ni cermet is more stable than the pure Ni as the anode material for the SOFC.

The stack or planar design of the SOFC system has been well studied and documented. The most advanced design of the SOFC system has been a tubular design developed by Siemens-Westinghouse. The thermal stability of the SOFC was improved by the tubular configuration due to the presence of self-sealing structures. Incorporation of good sealing material for the SOFC system has been one of the many challenges faced by the SOFC technology. Additionally, the development of an efficient solid electrolyte, anode, and cathode material for the SOFC has always been emphasized.

Similar to the MCFC systems, application for the SOFC technology is in the stationary power generation or distributed power systems. Siemens-Westinghouse is pioneer in the field of SOFC technology. A 25 kW SOFC unit was installed by Siemens-Westinghouse and tested using natural gas at the University of California's National Fuel Cell Research Center situated in Irvine, California [32]. In 1998, Siemens-Westinghouse collaborated with NUON and ELSAM to develop a 100 kW power production plant in Westvoort, Netherlands. This power plant was able to produce 54 kW of heat from the system at normal operation conditions (400 V). This SOFC power plant has been providing electric current to the grid and hot water to the local heating system [31]. Siemens-Westinghouse has also investigated combining the SOFC systems with gas turbine to increase the overall electrical efficiency. In 1999, Siemens-Westinghouse built a 250 kW prototype of the SOFC gas turbine hybrid power plant. This hybrid power plant was tested by Edison Technology Systems at National Fuel Cell Research Center in Irvine, California [32].

Fuel Processing

The gas streams required for the fuel cells are hydrogen and oxygen, as oxygen can be obtained from air. Most of the fuel cells are supplied with hydrogen and air streams. As mentioned previously, hydrogen production, storage, and transportation represents a significant problem for fuel cell technology. Therefore, the production of hydrogen gas for the fuel cells has been an important field of research and development. Presently, approximately 95% of hydrogen produced in the world comes from reforming of fossil fuels (gasoline, natural gas, and oil) and the rest are from other methods [73, 74].

Reforming fossil fuels for hydrogen production has been achieved by steam reforming, partial oxidation, and coal gasification [75–80]. Hydrocarbons are used in the reforming processes to produce hydrogen, especially methane (CH_4) and methanol (CH_3OH). In the steam reforming method any hydrocarbon (C_nH_m) is capable of being reformed to produce hydrogen and carbon dioxide. The carbon dioxide produced is further converted into hydrogen using a water gas shift reaction. In the partial oxidation method, methane is the main raw material to be reformed into hydrogen gas. As the name suggests, the coal gasification process combusts coal, carbon material, and biomass in order to produce gaseous products. This gas product is composed of carbon dioxide, carbon monoxide, hydrogen, nitrogen, methane, and hydrogen sulfide. In all of the reforming methodologies, purification of hydrogen gas is necessary to meet the requirements of the fuel cells. Purification process is an additional, and energy consuming, step for hydrogen production. So, certain fuel cells, such as DMFC, MCFC, and SOFC, can use methanol as the fuel as well as tolerate some percentage of carbon monoxide and carbon dioxide along with a hydrogen stream.

One of the alternate methods used for the production of hydrogen is electrolysis, which has been primarily focused on water electrolysis. The electrolysis of water or other alternate hydrogen sources, such as ammonia, urea, and coal, are discussed in detail in the later section, "Trends: Novel Electrosynthesis Processes." As described in Fig. 38.1, the synthesis of chemicals using electrochemical methods, where the chemicals synthesized has the capability to produce energy or power. These chemicals store energy in their chemical bonds, so the electrochemical synthesis of the hydrogen gas can also contribute towards electrochemical energy storage systems.

Supercapacitors

After batteries, supercapacitors are considered the next most important device in the area of electrochemical storage. Supercapacitors are also known as ultracapacitors, EDLC, or electric double-layer capacitors. The EDLC has electrodes similar to the conventional electrostatic capacitor, but the capacitance for the EDLC is measured due to the presence of a liquid electrolyte (Fig. 38.8). The electrostatic capacitor is the conventional form of the capacitor where the electrodes are separated by non-polarized materials, such as vacuum or air or mica. A supercapacitor is composed of two electrodes and an electrolyte, such as a battery, but the electrode/electrolyte interface is a capacitor, which is the equivalent of a complete cell with two capacitors in series [29].

Ultracapacitors fall in-between electrostatic capacitors and batteries as they have higher power density (10 kW/kg) than batteries, and also more specific energy density than conventional capacitors. On the contrary, supercapacitors have less energy density (about 5 Wh/kg) when compared to 30–40 Wh/kg from a typical LAB [81]. Figure 38.9 displays a plot of specific power density vs. specific energy density for some energy storage devices.

Ultracapacitors have a longer cycle life than any kind of battery and they can also be more quickly charged than most of the batteries. Supercapacitors are generally divided into three different types based on the charge storage process. The types are double layer capacitors, redox-based electrochemical capacitors, and hybrid capacitors. Carbon derived from charcoal, such as activated carbon, is used as the active material in the electrode for supercapacitors. The electrolyte used for double layer capacitors is either sulfuric acid or organic liquid. The capacitance for double layer capacitors in organic electrolytes has reached 100–120 F/g, but it can be 150–300 F/g in aqueous electrolytes, with the exception that a lower cell voltage has to be maintained to avoid water decomposition [81].

Redox-based electrochemical capacitors are the devices in which fast and reversible redox reactions takes place on the surface of the active material. The active materials used in these capacitors are metal oxides, such as RuO_2, Fe_3O_4, MnO_2, and conducting polymers. Most commonly, RuO_2 has been investigated because it has three distinct oxidation states within 1.2 V. The redox reaction for the RuO_2 active material is fast and reversible, where RuO_2 reacts with protons by electro-adsorption of protons on its surface (38.74). RuO_2-based electrochemical capacitors have displayed a capacitance of more than 600 F/g.

$$RuO_2 + xH^+ + xe^- \rightleftharpoons RuO_{2-x}(OH)_x \tag{38.74}$$

A hybrid capacitor is the most recent electrochemical capacitor which combines a capacitor-like electrode with a battery-like electrode in order to obtain both high power and energy density systems. This concept of hybrid capacitors is based on Li-ion capacitors. In 1999, Amatucci's group developed a hybrid capacitor with nanostructured lithium titanate ($Li_4Ti_5O_{12}$) anode and activated carbon cathode, which was able to deliver a specific energy density of at least 10 Wh/kg at 2.8 V [82]. Recently, this material, $Li_4Ti_5O_{12}$, has been investigated by combining the material with carbon nanofibers in order to produce nanohybrid capacitors [28].

Applications of supercapacitors have been mainly in the consumer electronics area, but more research is currently focused on combining supercapacitors with battery packs in order to provide stable and on-demand power supplies for electric vehicles.

Industrial Electrosynthesis Processes

As discussed previously, under the vision described in Fig. 38.1, electrochemical synthesis can be viewed as a way to store energy, as renewable and/or intermittent electrical power could be used to store energy as chemicals, products, commodities, fuels, etc. Industrial electrosynthesis had been used in different large-scale processes, including: chlorine and sodium hydroxide production, aluminum production, metal winning and refining, hydrogen and oxygen production, and specialized synthesis of organics. This section describes some of these processes. Further reading can be found in the literature [8, 12, 21, 83–95].

Chlor-Alkali Process

One of the largest electrochemical operations in the world is the chlor-alkali process or technology. The industry based on the chlor-alkali technology has been around for more than

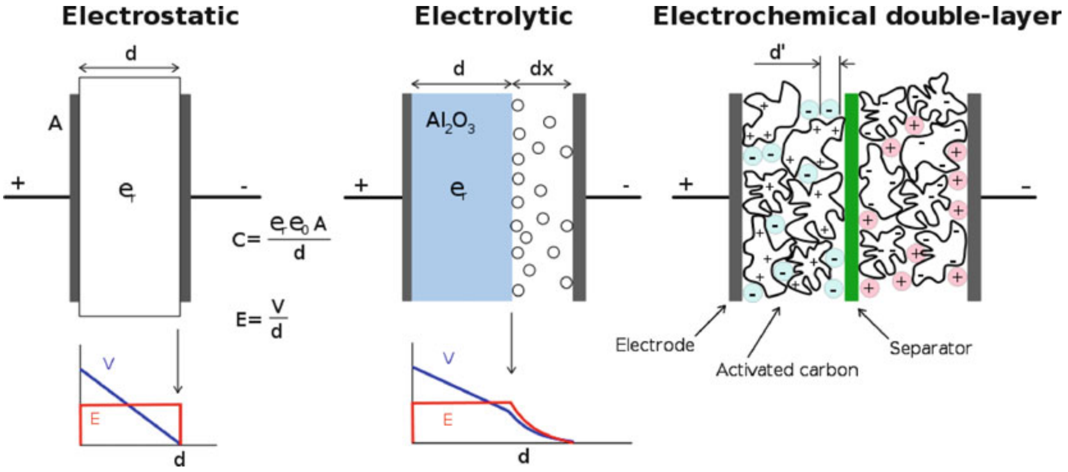

Fig. 38.8 Comparison of three kinds of capacitors [141]. The three types of capacitors are electrostatic, electrolytic, and electrochemical double-layer. The material in-between the positive and negative terminal determines the type of capacitor

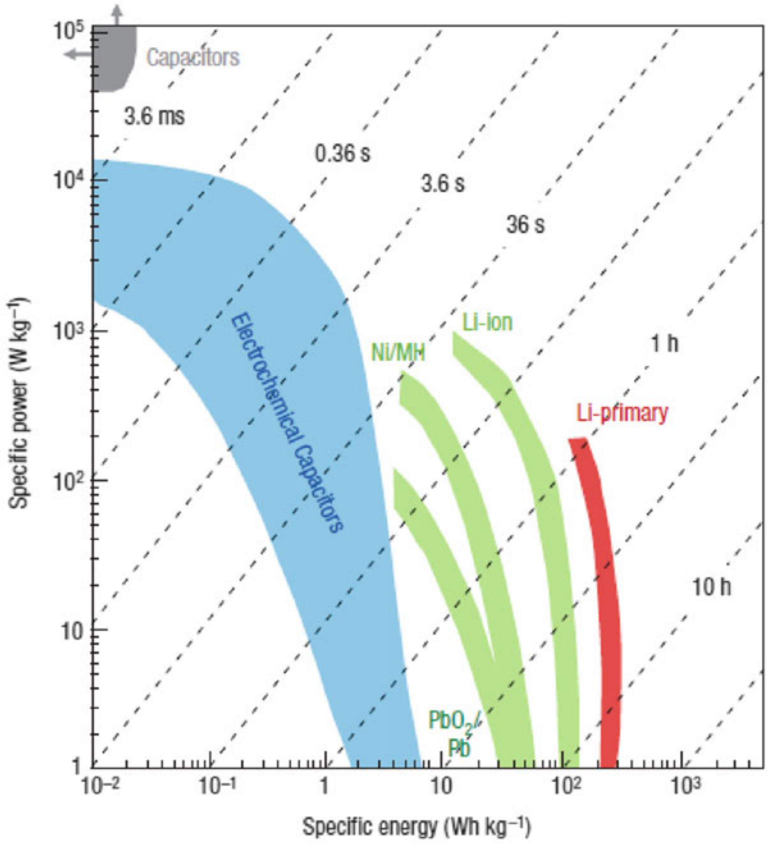

Fig. 38.9 Specific power vs. specific energy (Ragone plot) for energy storage devices [81]. Batteries have high specific energy density but low specific power density. Conversely, the traditional capacitors have very high power density and very low energy density. Electrochemical capacitors have the potential to possess optimum level power and energy density. *Legends*—*PbO_2/Pb* lead acid batteries; *Ni/MH* nickel metal hydride batteries; *Li-ion* lithium ion batteries; *Li-primary* lithium-based primary batteries

100 years. The chlor-alkali process produces chlorine and sodium hydroxide (caustic soda) from the electrolysis of sodium chloride or brine solution. A detailed description of the chlor-alkali technology with its accompanying history, advancements in different electrochemical cells used in the process (including their design), and engineering principles needed to establish chlor-alkali processing plants is available for further reading in the literature [12, 83, 84].

Among the electrochemical methods for producing chemicals, chlor-alkali technology consumes the second largest amount of electricity or electrical energy [86]. Chlorine and caustic soda are critically important chemicals in the world, and they are used in the production of various other chemicals and products which are used in everyday life. Production of more than 95% of chlorine and 99.5% of caustic soda are from the electrochemical method. Chlorine production capacity in the world was 22 million tons in 1970 and it increased to 53 million tons in 2002 [84]. The production of chlorine and caustic soda using this process is another example of the vision described in Fig. 38.1, storing electrical energy in the form of valuable chemicals. The chlorine is used in the manufacture of the polymer polyvinylchloride (PVC), and in the preparation of organic solvents (e.g., methylene chloride, chloroform, carbon tetrachloride), organic compounds (e.g., chlorobenzenes, alkyl chlorides), and inorganic compounds (e.g., hypochlorites of sodium, calcium). The bleaching property of the chlorine is used in the paper and pulp industry, and employed as an oxidizing agent in water treatment operations [12, 84]. The use of sodium hydroxide or caustic soda has been in the paper and pulp industry, soap and detergents manufacturing, and textile industry, as well as in the aluminum extraction process [12, 84].

The electrolysis of sodium chloride solution results in the formation of chlorine and hydrogen gases, and of sodium hydroxide. In 1800, Cruikshank discovered the electrolysis of brine in order to produce chlorine, but it took a relatively long time to scale up this process to manufacturing scale [84]. Development of the chlor-alkali process is attributed to the improvement of the electrolysis cell and its operation. There are three different types of cells used in the chlor-alkali technology, namely the diaphragm cell, the mercury cell, and the membrane cell. In 1855, the diaphragm cell process (Griesheim Cell) was introduced. At the same time, development of the mercury cell process led to the industrialization of the Castner-Kellner cell, which took place in 1892. Finally, in the early 1970s, the membrane cell process was developed as the modification to the diaphragm cell [85]. The current efficiency for the chlor-alkali process has been in the range of 85–98% depending on the type of the cell, operation of the electrolyzer, and purity of the brine solution. The electrical energy demand for performing electrolysis under different types of chlor-alkali technologies are 3,100–3,400 kWh/ton of Cl_2 for the mercury cell process, 2,300–2,900 kWh/ton of Cl_2 for the diaphragm cell process, and 2,100–2,900 kWh/ton of Cl_2 for the membrane cell process [85]. The schematic diagram of the three different cell processes of the chlor-alkali technology is displayed in Fig. 38.10. Brief descriptions of these three different cell designs are presented next.

Mercury Cell

The mercury cell is an undivided cell, as shown in Fig. 38.10, where the base of the container is made of steel in order to provide the electrical contact for the cathode. The cathode for the mercury cell process is liquid mercury (Hg), which is kept flowing during electrolysis. The anode electrode for the mercury cell process is a coated expanded titanium dimensionally stable anode (DSA). The anodes are left in a suspending manner on the top of the container or electrolyzer such that they are parallel to the pool of the Hg cathode. The electrolyte for the mercury cell is a brine (NaCl) solution. The saturated brine solution (25% NaCl), at a temperature of 60°C, is supplied to the top of the electrolyzer. With the electrolysis, the concentration of the brine solution is reduced in the mercury cell. The depleted brine solution (17% NaCl) is removed from the container just above the top of the mercury electrode. The electrochemical reactions taking place at the electrodes in the mercury cell are given below: [12]

Anode reaction

$$2\mathrm{Cl}^- \rightarrow \mathrm{Cl}_2 + 2\mathrm{e}^- \quad E^\circ = 1.31\ \mathrm{V\ vs.\ SHE} \tag{38.75}$$

Cathode reaction

$$\mathrm{Na}^+ + \mathrm{Hg} + \mathrm{e}^- \rightarrow \mathrm{NaHg} \quad E^\circ = -1.85\ \mathrm{V\ vs.\ SHE} \tag{38.76}$$

At the anode, the chloride ions are oxidized to a chlorine gas, which at first saturates the electrolyte solution before escaping the mercury cell. The Na^+ ions present in the electrolyte migrates to the Hg cathode where they are reduced to form an amalgam. The overall voltage for the reactions at the electrodes is 3.16 V but typical operation of the mercury cell requires 4.50 V due to the resistance from electrical contacts. This amalgam containing liquid Hg, from the mercury cell, is taken into a container known as a decomposer or denuder. In the decomposer, the mercury is recovered from the Na(Hg) amalgam and sent back to the electrolyzer in order to use it as cathode. The Na(Hg) amalgam, in the decomposer, trickled along with water over the graphite particles containing transition metals (e.g., Fe and Ni) to obtain sodium hydroxide and mercury (38.77) [86].

$$2\mathrm{NaHg} + 2\mathrm{H_2O} \rightarrow 2\mathrm{NaOH} + \mathrm{H_2} + 2\mathrm{Hg} \tag{38.77}$$

One of the issues with the mercury cell electrolyzer is the health and environmental damages associated with mercury. The mercury cell was widely used in many countries for the production of chlorine and caustic soda during the early days of the chlor-alkali industry. In 1984, 45% of the chlor-alkali plants in the world employed mercury cell processes and its

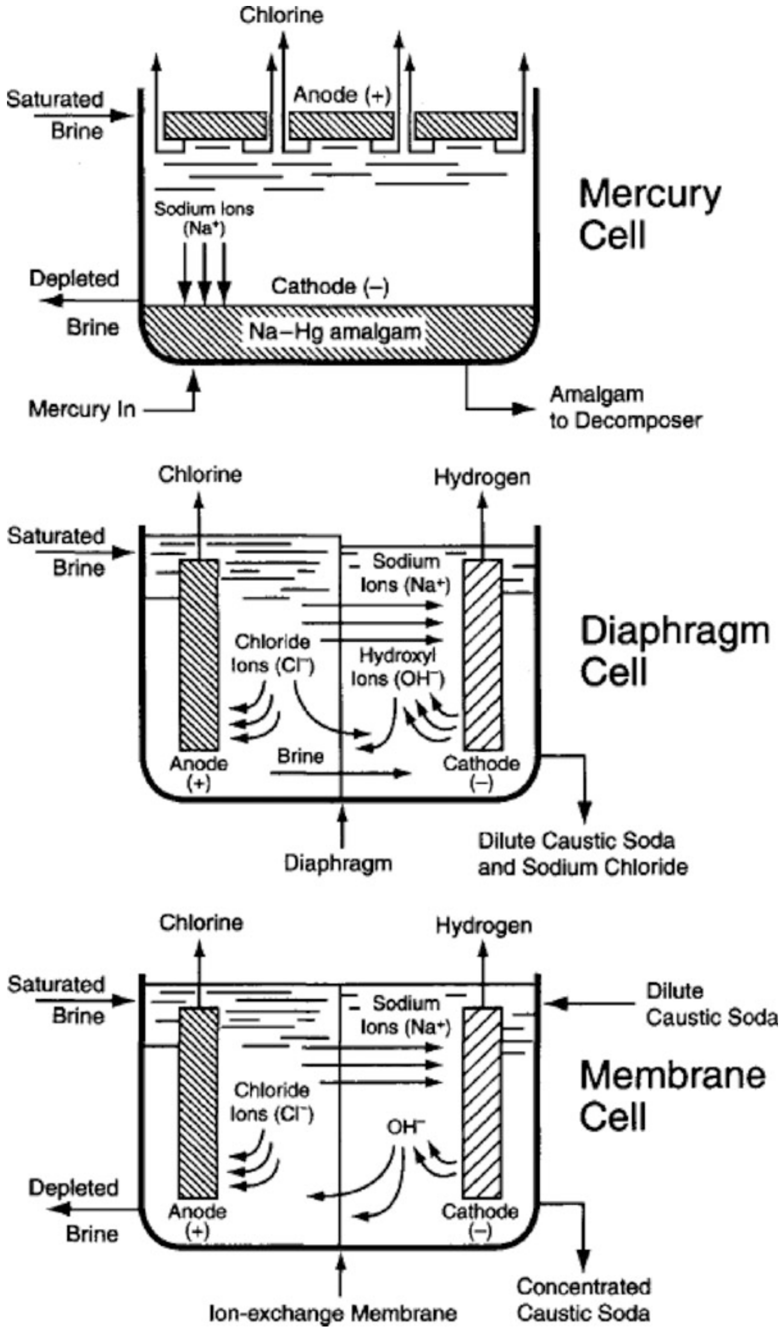

Fig. 38.10 Schematic diagram of the three different cells used in the chlor-alkali technology [84]. The mercury, diaphragm, and membrane cells are depicted with the flow of brine solution, flow of ions across the cells, and production of chlorine, hydrogen, and sodium hydroxide

percentage declined to only 18% in 2001 due to the health and environmental concerns of using mercury [84]. In fact, presently there are no functioning mercury cell type chlor-alkali plants in Japan and many countries are planning to gradually phase out the mercury cell process.

Diaphragm Cell

This process uses a divided cell, where a diaphragm is used to separate the anode side from the cathode side. Asbestos as diaphragm was used in the earlier days before the knowledge of the detrimental health effects of asbestos was known. Now, non-asbestos-based diaphragm are used in the construction of the diaphragm cells and plans are being taken to convert all the diaphragms to non-asbestos material.

Saturated brine solution is fed to the anode compartment of the diaphragm cell, where the chloride ions are oxidized to a chlorine gas as shown in the (38.75). The brine solution flows from the anode to cathode side through the diaphragm. The anodes used in the diaphragm cell process have either ruthenium-based or platinum/iridium-based coated titanium electrode (DSA) [86]. During the electrolysis, the temperature of the electrolyte is maintained between ~95 and 100°C.

On the cathode side, hydrogen gas is generated from the reduction of water (38.78) even using a nickel electrode. The Na^+ ion from the anode compartment migrates through the diaphragm into the cathode side to combine with hydroxyl ion from water reduction reaction to form sodium hydroxide (38.79).

Cathode reaction

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \quad E^\circ = -0.84 \text{ V vs. SHE} \tag{38.78}$$

$$2Na^+ + 2OH^- \rightarrow 2NaOH \tag{38.79}$$

Overall reaction

$$2NaCl + 2H_2O \rightarrow 2NaOH + Cl_2 + H_2 \quad E = 2.15 \text{ V} \tag{38.80}$$

The voltage for the electrolysis of brine to produce caustic soda, chlorine, and hydrogen is 2.15 V. However, the normal operational cell voltage for this process is in the range of 3.2–3.8 V, so as to overcome the resistance encountered during the electrolysis [12]. In this process, the cathode electrolyte solution with concentration of 12% NaOH and 15% NaCl is taken for further processing to separate the caustic soda from brine solution for commercial application [86]. The purpose of the diaphragm in this cell is to allow the passage of Na^+ ions from the anode to cathode side but also to avoid the mixing of caustic soda with chlorine. Still there are two parasitic reactions possible on the anode electrode, namely the formation of oxygen along with chlorine (38.81) and oxidation of hypochlorite to chlorate (38.82) [86].

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^- \quad E^\circ = 1.23 \text{ V vs. SHE} \tag{38.81}$$

$$6ClO^- + 3H_2O \rightarrow 2ClO_3{}^- + 4Cl^- + 6H^+ + \frac{3}{2}O_2 + 6e^- \tag{38.82}$$

Membrane Cell

The operation of the membrane cell electrolyzer is similar to the diaphragm cell process except for the ion exchange membrane being used in place of a diaphragm. The ion exchange membrane used in the electrolyzer is commercially known as Nafion, which is sulfonated tetrafluoroethylene-based fluoropolymer-copolymer. The electrochemical reactions at the anode and cathode electrodes for the membrane cell process are same as in the diaphragm cell process. The brine solution used as electrolyte for this process should have less than 0.1 ppm Ca^{2+} and Mg^{2+} ions to avoid precipitation of salt over the electrodes and the ion exchange membrane [86]. The saturated brine solution is added to the anode compartment and only the Na^+ ions along with water molecules are migrated across the Nafion membrane to the cathode side. The depleted brine solution is removed from the anode compartment. On the cathode side of the membrane cell, solution containing dilute concentration of caustic soda is added to increase the concentration of caustic soda in the product stream.

High purity of caustic soda, up to 50% NaOH, can be produced in the cathode compartment using this membrane cell process as the chloride ions are not migrated to the cathode side. However, in practice, 32–35% NaOH is normally produced on the cathode compartment from this process. Another interesting feature of this process is the distance between the anode and cathode electrode can be reduced to almost zero because of the use of ion exchange membrane. This option of sandwiching the electrodes with Nafion membrane has resulted in operating cell voltage of ~2.7 V compared to 3.2–3.8 V for diaphragm cell process. This means the membrane cell process will consume less energy than diaphragm cell process [12].

A new approach is being investigated in the membrane cell process for reducing the energy consumption of the electrolysis and also to avoid the production of hydrogen gas at the cathode. In the chlor-alkali industry, importance is given towards the production of caustic soda and chlorine from the electrolysis of brine (NaCl), but not as much importance as is given for hydrogen generation. So, the evolution of hydrogen gas at the cathode electrode is considered an undesired reaction. The approach is to use oxygen-depolarized cathode (ODC) electrode to avoid hydrogen formation at cathode by reduction of oxygen in the presence of water to form hydroxyl ions (38.83). The ODC is made of GDE which is normally used in the fuel cells [85].

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^- \quad E^\circ = 0.40 \text{ V vs. SHE} \tag{38.83}$$

Now combining the above cathode reaction with the oxidation of chloride ion to chlorine at the anode (38.75) and formation of NaOH with Na^+ ions (38.79), we obtain the overall reaction for the electrolysis of brine using ODC electrode as

$$2NaCl + \frac{1}{2}O_2 + H_2O \rightarrow 2NaOH + Cl_2 \quad E = 0.91 \text{ V} \tag{38.84}$$

From the (38.84), the voltage for the overall reaction is only 0.91 V compared to 2.15 V for the traditional membrane cell process. The use of ODC electrode has resulted in

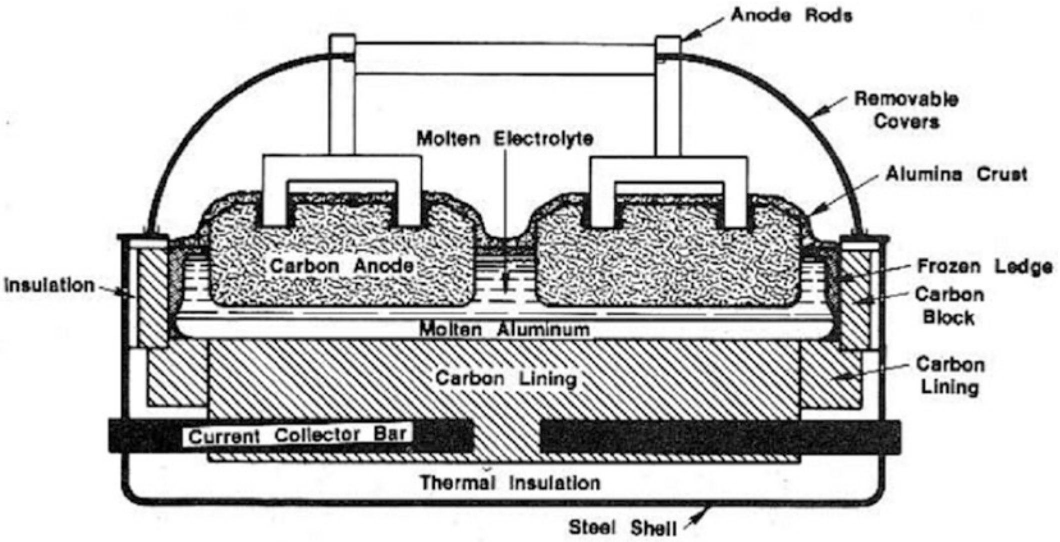

Fig. 38.11 Cross-sectional view of the electrolytic cell to produce aluminum [87]. Prebaked anodes are used in this type of electrolytic cell. Molten aluminum is produced from the Hall-Heroult process

the operation cell voltage of a mere 1.23 V for the new membrane cell process, which translates to almost 30% less electric energy consumption than the traditional approach of membrane cell where hydrogen gas is produced [85]. A detailed description on the development of the ODC electrodes with different catalyst and design of the electrolyzer can be found in the literature [85].

Aluminum Production

Aluminum is the third most abundant element in the Earth's crust. Since aluminum can easily react with oxygen, it does not exist in metallic form in the Earth's crust but in the form of ores, such as bauxite. The valuable properties of aluminum are its being soft, durable, lightweight, electrically conducting, nonmagnetic, stiffness equivalent to steel, and corrosion resistant. These favorable characteristics have resulted in various uses for aluminum. Aluminum has found application in the areas of transportation, packaging (e.g., beverage cans), construction, electronics, and electrical wires.

Electrochemical method of producing aluminum was not effective until 1886, when Charles Martin Hall from Ohio, USA, and Paul L. T. Heroult from Paris, France, independently invented the electrolytic way of extracting aluminum from its molten salt. The Hall-Heroult process, which is widely used throughout the world, for aluminum production has been a very reliable and efficient method for the past 125 years. Over these years, the process has undergone technological improvements mostly in the anode material [22]. This process involves electrolysis of alumina (Al_2O_3), which is dissolved in molten cryolite-based electrolyte. Alumina for the Hall-Heroult process was obtained from the aluminum ore, bauxite, using the Bayer process. In the Bayer process, the bauxite ore, which has almost 50% Al_2O_3, was digested in sodium hydroxide (NaOH) solution under pressure resulting in the formation of sodium aluminate and the impurities were left behind as red mud (38.85).

$$Al_2O_3 \cdot 3H_2O + 2NaOH \xrightleftharpoons{\text{extraction}} 2NaAlO_2 + 4H_2O \tag{38.85}$$

The aluminate solution was seeded with hydrated alumina crystals to re-precipitate alumina, which can easily be washed. In the final step, the hydrated alumina was calcined at 1,200°C to remove water vapor and obtain more than 99% pure alumina [12, 83].

In the Hall-Heroult process, the electrolytic cell is called as pot and a cross-sectional view of the electrolytic cell is shown in Fig. 38.11.

In this process, the anode electrode, mainly made of carbon, is consumed during the electrolysis of alumina. The electrolytic cells are differentiated by the kind of anode electrodes used. There are two kinds of anodes in the Hall-Heroult process, prebaked and self-baking, or Søderberg anodes. Both kinds of anodes are made of petroleum coke and coal tar, where the prebaked anodes are baked in brick lined pits before using in the electrolytic cells. However, the Søderberg anodes are allowed to bake in the cell using the heat from the electrolysis of alumina. In Fig. 38.11, the electrolytic cell has a steel shell container which is lined with carbon to act as the cathode for the electrolysis.

The electrolyte has alumina, from the Bayer process, mixed with molten cryolite (Na_3AlF_6) solution. Calcium fluoride is also included as an additive. The ratio of the sodium fluoride to aluminum fluoride is maintained at 1.5 in the molten electrolyte. The temperature of the electrolytic cell was maintained in the range of 920–980°C in order to keep the electrolyte in molten condition. Even though the Hall-Heroult process is 125 years old, the explanation for the electrode reaction mechanism has not been clearly documented due to the complex nature of the electrolyte and the possibility of having various species in the electrolyte. The readers are advised to check this literature to understand the complex nature of the ions present in the electrolyte and their reactions [87]. A simplistic explanation would be that the alumina dissociates into aluminum ion and oxide ion in the molten electrolyte. At the cathode, the aluminum ion is reduced to liquid aluminum metal at the operating temperature and collected on top of the cathode electrode. At the anode electrode, oxide ion is oxidized to oxygen gas, which reacts with the carbon anode to form carbon dioxide. So, the overall reaction would be alumina reacts with carbon to form metallic aluminum and carbon dioxide [12].

Anode reaction

$$C + 2O^{2-} \rightarrow CO_2 + 4e^- \tag{38.86}$$

Cathode reaction

$$Al^{3+} + 3e^- \rightarrow Al \tag{38.87}$$

Overall reaction

$$2Al_2O_3 + 3C \rightarrow 4Al + 3CO_2 \tag{38.88}$$

The cell voltage for the overall reaction is 1.18 V, but due to the electrolyte resistance and other voltage drops, the operating voltage required for aluminum production ranges from 4.0 to 4.5 V [12]. In 1914, on average 59 kg of Al was produced per day from a plant operating at 10 kA and 8 V with 73.3% as current efficiency. Over the years, the production capacity of the Hall-Heroult process has improved to 2,308 kg of Al per day, in 2000, at 300 kA and 4.2 V operating condition with a current efficiency of 95.6%. Still, among the electrolytic processes, the production of aluminum is the highest energy consuming process, which translates into high demand for electricity by this technology. During this period, the energy requirement has become better, from 32.53 kWh in 1914 to 13.10 kWh for every kilogram of Al produced in 2000 [22].

Electrowinning and Refining Process

The process of extracting metals from its ores using the electrochemical method is known as electrowinning. The electrowinning method is the last step in the entire extraction process of a metal from its ore. The ores of a metal are generally in the form of metal sulfides or oxides or mixture of both. For simplicity, let us consider the sulfide form of the metal as the ore to be used in the extraction process. The sulfide ore will be converted into oxide form by roasting the metal ore in the air [12].

$$2MS + 3O_2 \rightarrow 2MO + 2SO_2 \tag{38.89}$$

The oxide salt of the metal is leached or dissolved in acid solution especially with sulfuric acid to form acid solution containing metal ions [83].

$$MO_x + 2xH^+ \rightarrow M^{2x+} + xH_2O \tag{38.90}$$

In fact, the acid solution contains different metal ions from the ore along with the desired metal ion, so the solution is purified and subsequently concentrated with the desired metal ions. The electrowinning process is basically the electrolysis of the acid solution, where the metal ions are reduced into metal on the cathode electrode (38.91) and the oxygen gas is evolved at the anode (38.92).

$$M^{2x+} + 2xe^- \rightarrow M \tag{38.91}$$

$$xH_2O \rightarrow \frac{1}{2}xO_2 + 2xH^+ + 2xe^- \tag{38.92}$$

Along with the oxygen gas, the protons or acid is formed at the anode electrode, which will be recirculated for leaching the metal oxide ores. The overall reaction of the electrowining process is the deposition of the metal and the release of oxygen gas (38.93). There is no loss of water or the acid in this electrowinning process.

$$MO_x \rightarrow M + \frac{1}{2}xO_2 \tag{38.93}$$

The few elements that can be electrowon under aqueous conditions are copper (Cu), silver (Ag), nickel (Ni), cobalt (Co), chromium (Cr), and zinc (Zn). However, the highly reactive elements, such as lithium (Li), sodium (Na), magnesium (Mg), and aluminum (Al), needs molten electrolyte to extract them using the electrowinning process. Electrolysis of alumina to produce aluminum is also considered as the electrowinning process for aluminum metal, and a detailed description of this process was provided in the above section, “Aluminum Production.” The electrochemistry of extracting the above listed elements can be found in the literature [12, 83]. In addition to extracting the metal from its ores, the electrowinning process is used to recover the metals from industrial wastewater in order to eliminate or reduce the metal contamination in the wastewater.

The electrolytic process to refine or increase the purity of the metal is defined as electrorefining, and this method is employed in the metallurgy industry. The impure metal is taken as anode of the electrolytic cell and the electrolyte is the solution of that metal salt. During the electrolysis process, the desired metal is oxidized into metal ion at the anode (38.94), which dissolves into the electrolyte. At the same time, the pure metal is deposited over the cathode by reducing the metal ion from the electrolyte (38.95). The anode and cathode reactions ((38.94) and (38.95), respectively) are reversible reactions, which should result in a net zero cell voltage.

$$\mathrm{M} \rightarrow \mathrm{M}^{n+} + ne^{-} \tag{38.94}$$

$$\mathrm{M}^{n+} + ne^{-} \rightarrow \mathrm{M} \tag{38.95}$$

But in practical applications, the electrolytic cells used for the electrorefining processes require certain cell voltage. The cell voltage was necessary to overcome the solution resistance, voltage drops at the electrical contacts for the anode and cathode, and the overpotentials for both reactions (anodic and cathodic) to take place at a reasonable rate. At the anode electrode, metals nobler than M will be oxidized and retained in the electrode as residue, which is commonly known as the anode slime. But those metals which are less noble than M, after undergoing oxidation will be dissolved into the electrolyte as contaminants. These contaminants present in the electrolyte are not reduced onto the cathode before the reduction of metal M, and the undesired metal can build up during the electrorefining process thereby increasing the impurity.

In the electrorefining process, the use of aqueous electrolyte has been applied for elements, such as copper, nickel, cobalt, lead, silver, gold, and tin. The refining process for the copper metal is extensively used in the production of high purity copper metal for electronics applications. Similarly in the jewelry industry, the electrorefining process is used to remove or extract the noble metal (e.g., gold) from the anode slime or contaminated solutions. Electrorefining of aluminum is performed using the molten electrolyte, which is mainly applied for the recycling of waste aluminum scrap metal. More detailed information on the electrorefining process can be obtained in the literature [12, 83].

Hydrogen and Oxygen Production

Manufacturing of gases like hydrogen and oxygen is also accomplished using electrochemical methods. Hydrogen gas is formed as a by-product during the electrolysis of a brine solution in the chlor-alkali process. Depending on the type of the chlor-alkali cell, the hydrogen gas is purified for commercial applications. However, the water electrolysis process is entirely committed for the production of both hydrogen and oxygen gases with highest purity. A detailed description on the science and the electrochemical reactions associated with the electrolysis of water is explained in the following section, "Electro-Synthesis of Hydrogen."

In 1800, Nicholson and Carlisle discovered the splitting of water into hydrogen and oxygen [21, 83]. The development and commercialization of water electrolyzers for the industrial scale began in the 1920s and 1930s [90]. During that time several 100 MW electrolyzers were built around the world for ammonia fertilizers and petroleum refining [21, 90]. Among the notable installations of the water electrolyzers was at the Aswan High Dam site in the late 1980s with 144 electrolyzers, which was rated at 162 MW and a capacity to produce 32,400 m^3/h of hydrogen gas [21]. The cell designs used for the electrolyzer were monopolar electrodes in tank electrolyzers and bipolar electrodes in a filter press cells. High pressure electrolyzers were also tested and commercially produced. One of the industrial water electrolyzers manufactured by DeNora Impianti Electtrochimici S.p.A. is shown in Fig. 38.12.

The details of other commercially available water electrolyzers with their operation parameters are listed in Table 38.9 [21].

Organic Electrosynthesis

The synthesis of organic compounds was traditionally favored through chemical routes. From the beginning of the last century, however, the use of electrochemical reactions to synthesize organic compounds has been practiced for various reasons. The advantages on using the electrochemical synthesis method include: (1) product selectivity and purity is higher than for chemical synthesis, (2) less reaction steps are needed than for the chemical method, (3) inexpensive starting materials are used, (4) least polluting chemicals or by-products are formed, (5) less hazardous routes are involved, and (6) less energy is consumed [93, 96].

The electrosynthesis processes for organic compounds also have disadvantages or limitations in terms of selecting the electrode material and the electrolyte composition, because generally aqueous electrolytes are used in electrochemical synthesis, but solubility of organic compounds in aqueous solutions has to be sorted out. Some of the shortcomings of the electrochemical processes to synthesize organic compounds have been the discovery of an alternate catalytic route (sorbitol and propylene oxide), an alternate chemical route was discovered to avoid the electrochemical intermediate product (pinacol), the formation of a pollutant product (tetraalkyl lead), and the product had lost its market or the market never existed [93].

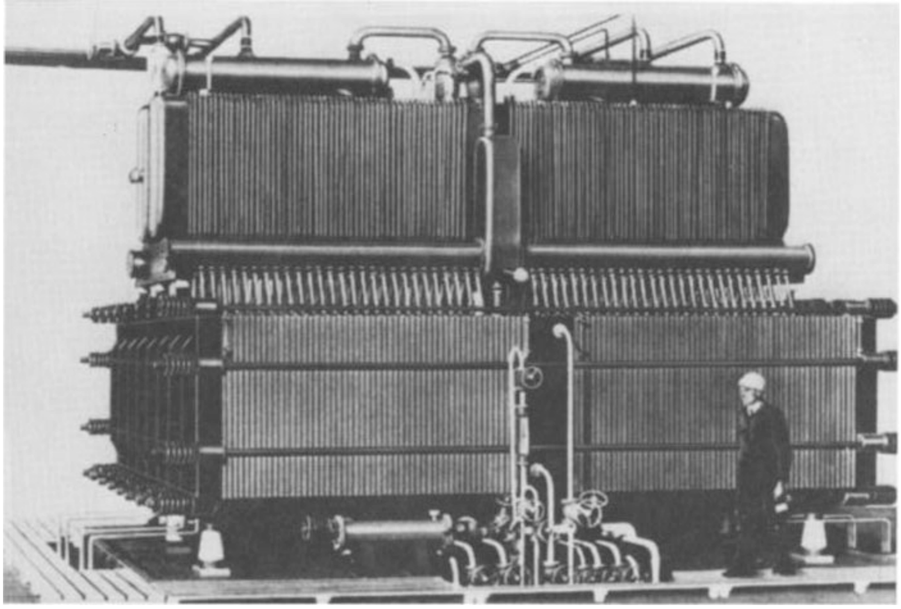

Fig. 38.12 Bipolar electrolyzer manufactured by DeNora Impianti Electtrochimici S.p.A. This unit has 54 cells, operated with a current of 2.5 kA, power consumption was approximately 4.6 kWh N/m^3 and the total capacity of the electrolyzer was 250 kW [90]

One of the well-known organic compounds electrochemically synthesized is adiponitrile. The chemical adiponitrile is an intermediate in the production of Nylon 66. In 1959, Manuel Baizer at Monsanto discovered the process to produce adiponitrile by the electrochemical method of hydrodimerization of acrylonitrile at the cathode. This method was later known as the Monsanto process. "More details and progress on the Monsanto process can be gathered from the literature [12]. In the Monsanto process, oxygen gas is evolved at the anode, while at the cathode acrylonitrile is electrohydrodimerized to adiponitrile, as shown below: [93]

$$2CH_2 = CHCN + 2H^+ + 2e^- \rightarrow NC(CH_2)_4CN \quad (38.96)$$

The Monsanto plant at Decatur, Alabama, USA, is capable of producing 200 million kg of adiponitrile per year. The cathode used for this process is cadmium and the anode is a steel electrode, which are both assembled in a bipolar way in an undivided cell. The electrolyte comprises acrylonitrile, a quaternary salt (hexamethylene(bisethyltributyl)ammonium phosphate), phosphate buffer, and the anode anticorrosive additives, borax, and EDTA. A current density of 2 kA/m^2 is maintained at 55°C operating temperature and the process has a power consumption of 2.4 kWh/kg of adiponitrile produced [93, 96]. Table 38.10 provides a list of various organic compounds manufactured in the world using the electrosynthesis approach; some of these processes are commercialized, others in the pilot stage, and some of them are decommissioned.

Table 38.10 List of some organic compounds produced using industrial electrosynthesis

Product	Starting material	Company	Operating status
Acetoin	Butanone	BASF	C
1-Acetoxynaphthalene	Naphthalene	BASF	P
Acetylenedicarboxylic acid	1,4-Butynediol	BASF	C
Adipoin dimethyl acetal	Cyclohexanone	BASF	C
Adiponitrile	Acrylonitrile	Monsanto (Solutia), BASF, Asahi Chemical	C
2-Aminobenzyl alcohol	Anthranilic acid	BASF	P
4-Aminomethylpyridine	4-Cyanopyridine	Reilly Tar	C
Anthraquinone	Anthracene	L. B. Holliday, ECRC	C
Anthraquinone	Naphthalene, butadiene	Hydro Quebec	P
Arabinose	Gluconate	Electrosynthesis Co.	P
Azobenzene	Nitrobenzene	Johnson Matthey Company	C

Trends: Novel Electrosynthesis Processes

The latest processes involved in the electrosynthesis of chemicals which have potential for power generation, and water and air remediation are discussed in this section. The new interest in utilizing solar energy to manufacture chemicals capable of being used as fuels has caught the attention of many researchers. Additionally, the electrochemical approach to synthesize hydrogen from various chemicals (water, ammonia, urea, and coal) is also described in this section. The main focus of the electrolysis of ammonia and urea has been to remediate the ammonia and urea rich wastewater. The hydrogen gas produced during the ammonia and urea electrolysis process is considered as high value by product. The advantage of coal electrolysis is to reuse the coal waste for the production of hydrogen, and also to generate other chemicals which have potential to be classified as liquid fuels.

Solar Fuels

In recent years, a new area of research has been devoted towards producing liquid fuels, which can be used for

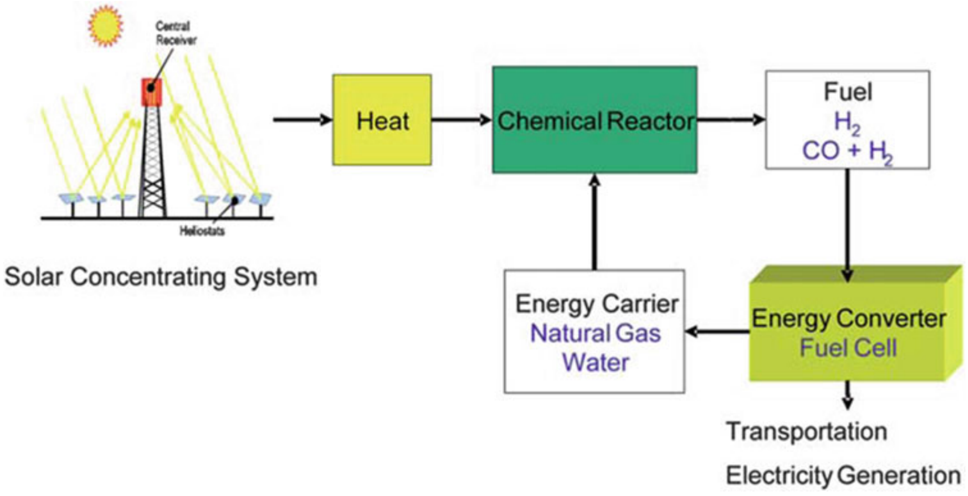

Fig. 38.13 Schematic diagram for the concept of solar fuel production [142]. The heat from the concentrated solar power plant is used in the chemical reactor to produce fuels, such as H_2 and syn gas ($CO + H_2$). The fuels produced from the chemical reactor will be utilized in fuel cells for power generation or transportation applications. Alternatively, the hydrogen can be combined with CO and CO_2 to form hydrocarbons, such as methane

generating energy or power from solar energy. These fuels are referred to as "solar fuels," because the energy needed to produce them comes from the sun. Solar fuels can be used as raw materials for manufacturing different kinds of chemical products as well as generating power. In this way, solar fuels can be considered energy carriers.

The methodology adapted to produce solar fuels was to utilize solar energy thorough solar cells in order to split water into oxygen and hydrogen. The hydrogen gas produced from water electrolysis is combined with carbon dioxide and/or carbon monoxide found in industrial effluents to produce hydrocarbons, which are referred to as "solar fuels." This method not only uses renewable energy sources to produce chemicals that have properties as fuel, but it also converts pollutants present in industrial effluents into useful products.

The solar energy is collected in large power plants, known as concentrating solar power plants (CSP). These systems are being built around the world in regions of relatively high solar radiation. A schematic diagram illustrating the idea of using solar energy obtained from the concentrated solar power plant for the production of solar fuels is shown in Fig. 38.13. The concept involves solar thermochemical cycles to produce hydrogen from solar steam forming of natural gas and methane cracking.

The splitting of water using solar energy is also achieved by photoelectrochemical (PEC) and photocatalytic methods [97]. In the photocatalytic method, the catalyst material is dispersed in pure water where it uses the solar energy to split water, and produce hydrogen and oxygen together in the solution. However, in the PEC method, the photoactive material is on the electrode and the process of splitting water is performed in an electrolytic cell with the ability to separate hydrogen and oxygen gases. In the PEC method of water splitting, titanium dioxide (TiO_2) is used as the active material on the electrodes [98, 99]. Other materials, including semiconductors, have been investigated as a photoelectrode for the conversion of solar energy to hydrogen gas.

An inexpensive and stable oxide photoanode material has been WO_3. This material is used along with dye sensitized solar cells (DSC) to capture solar photons, because the WO_3 is incapable of separately harvesting the solar photons. The efficiency to convert the solar energy to produce hydrogen gas is known as solar to hydrogen efficiency. The WO_3 photoanode has a maximum solar to hydrogen efficiency of only 8% [100]. A promising photoanode material, which is inexpensive, stable, and capable of harvesting solar photons, is iron (III) oxide (Fe_2O_3), especially α –Fe_2O_3 (hematite) [97]. The iron (III) oxide has the capacity to achieve 16.8% efficiency towards the solar to hydrogen conversion [100]. The Solar Fuel Center for Chemical Innovation (CCI Solar) at the California Institute for Technology has been working in the area of solar fuels for many years. They have developed an electrochemical fuel cell with nanorods as photoelectrodes, which can oxidize and reduce water to produce oxygen and hydrogen, sandwiched by a proton conducting membrane [101]. CCI Solar has been undertaking leading research in the area of solar fuels and more information on their solar fuels research can be obtained from their website [102].

Electro-Synthesis of Hydrogen

During the production of solar fuels, hydrogen gas is used as the main raw material to produce hydrocarbons. Hydrogen gas has, however, been used as a fuel for many years to generate electric power, in various types of fuel cells (see section on "Fuel Cells"). Hydrogen gas is also referred to as an energy carrier. So, the production of hydrogen gas by electrochemical methods and its storage should be considered as one of the methods for electrochemical energy storage. Traditionally, electrolysis is used to split a chemical compound into its elemental forms and water electrolysis has been utilized to produce hydrogen gas. In addition, other starting materials, such as ammonia, urea, and coal particles, are also available to produce hydrogen via electrolysis.

Water Electrolysis

The electrochemistry of water electrolysis is discussed in this subsection (For more details on industrial scale electrolyzers, see section on "Hydrogen and Oxygen Production"). The splitting of a water molecule into hydrogen and oxygen gases with the help of electric current is known as water electrolysis. Initially, nickel electrodes were used as the cathode and anode material for the electrolysis of water because of its low cost. Recent research indicates the use of nickel-based alloys, steel, and nickel-coated or noble metal-coated steel as effective electrode materials [21]. KOH solution is used as the electrolyte for water electrolysis, and is also responsible for the name "alkaline water electrolysis."

The anode and cathode reactions for the electrochemical splitting of water to produce hydrogen and oxygen are given below:

Anode reaction

$$4OH^- \rightarrow O_2 + 2H_2O + 4e^- \quad E^\circ = 0.40\ \text{V vs. SHE} \tag{38.97}$$

Cathode reaction

$$4H_2O + 4e^- \rightarrow 2H_2 + 4OH^- \quad E^\circ = -0.83\ \text{V vs. SHE} \tag{38.98}$$

Overall reaction

$$2H_2O \rightarrow O_2 + 2H_2 \quad E = 1.23\ \text{V} \tag{38.99}$$

The theoretical voltage required to dissociate water into hydrogen and oxygen gases is 1.23 V, whereas the thermoneutral voltage is 1.48 V. Commercially available water electrolyzers operate between 1.6 and 2.0 V. The anode and cathode sides of the electrolyzer are separated by a membrane that allows the ions to pass through but keep the gases separate. Therefore, the hydrogen gas produced using this method does not require further purification as it is almost 100% pure.

The hydrogen gas produced from water electrolysis can be supplied to a fuel cell to generate electric power and water. The reactions taking place inside the fuel cell are opposite to the ones observed in the water electrolyzer. So, combining the water electrolyzer with the fuel cell will result in a net energy or power loss because more energy is required to split water in the electrolyzer. Additionally, deionized water is necessary for the optimum functioning of the water electrolyzer [103].

Ammonia Electrolysis

Water is not the only source of hydrogen. There are other chemicals which have a higher atomic weight of hydrogen present, such as ammonia and urea. Ammonia is a colorless gas with a pungent smell. Ammonia is produced by the Haber-Bosch process, in which molecular nitrogen is reacted with hydrogen at high temperature and pressure in the presence of a catalyst to produce ammonia. Ammonia has, however, been found in the emitted gases associated with the fertilizer industry, livestock management, coke manufacturing industry, refrigeration methods, and combustion of fossil fuels [104]. In 2009, the United States was the fourth largest producer of ammonia in the world, as it produced 7,704 thousand metric tons of ammonia [105]. In 2002, the US Department of Energy suggested that 65% of the emitted ammonia comes from fertilizer, livestock, and domestic sources, which accounts for nearly 3.25 million tons of ammonia in the atmosphere [106]. Additionally, ammonia is a pollutant as it can have an impact on vegetation and other organisms [107, 108].

The wastewater from some industries as well as residential community is rich in ammonia. Dissociation of ammonia present in the emitted gases as well as wastewater will help in cleaning up the environment along with the production of hydrogen gas. This rationale motivated the researchers at the Center for Electrochemical Engineering Research (CEER) at Ohio University to study ammonia electrolysis [109]. In 2005, Gerardine Botte, director of the CEER, proposed this new technology for the production of hydrogen gas from the electrolysis of ammonia and since then, there have been a consistent development in this technology [110–118]. During ammonia electrolysis, water present in the cathode electrolyte, a 5 M KOH solution, is reduced to hydrogen gas. On the anode side, 1 M ammonia dissolved in the KOH solution is oxidized to nitrogen gas:

Anode reaction

$$\begin{gathered} 2NH_3 + 6OH^- \rightarrow N_2 + 6H_2O + 6e^- \\ E^\circ = -0.77\ \text{V vs. SHE} \end{gathered} \tag{38.100}$$

Cathode reaction

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \quad E^\circ = -0.829\ \text{V vs. SHE} \tag{38.101}$$

Overall reaction

$$2NH_3 \rightarrow N_2 + 3H_2 \quad E = 0.059\ \text{V} \tag{38.102}$$

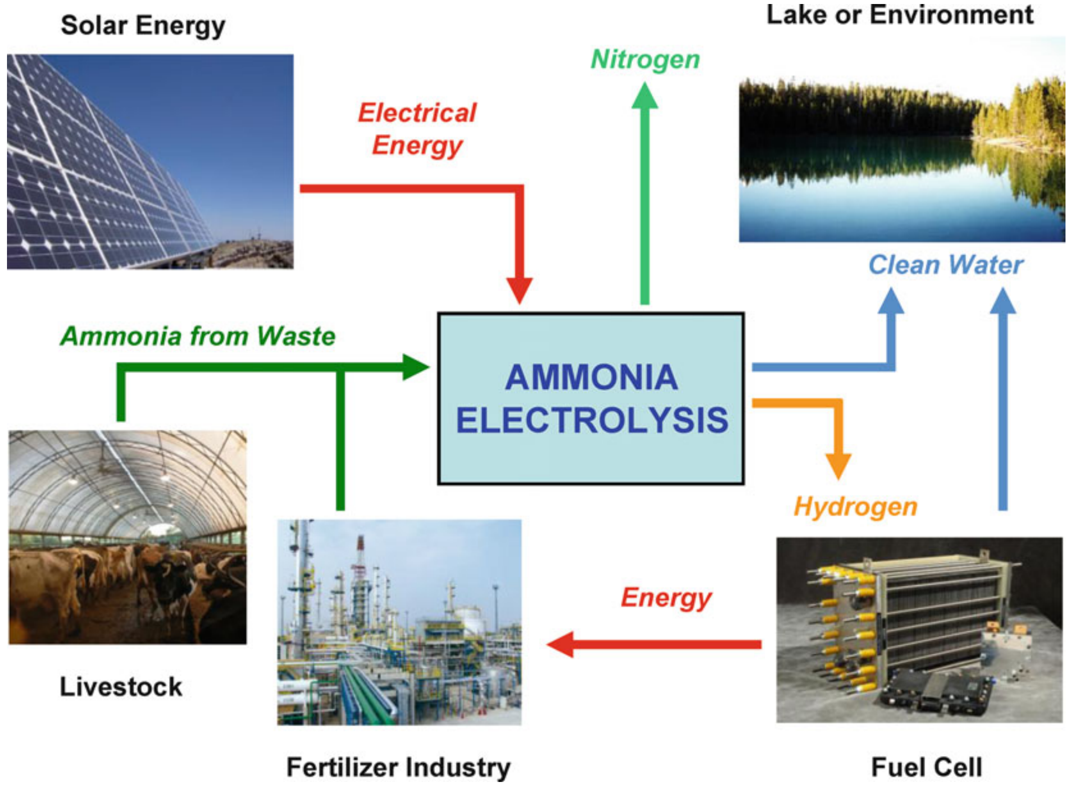

Fig. 38.14 Scheme of ammonia electrolysis along with renewable energy (e.g., solar energy) to remediate ammonia rich wastewater into hydrogen and clean water [143]. The idea of the scheme is to remediate the wastewater using electrolysis to produce hydrogen gas, which could generate additional energy, and also clean water for eventual use in other applications

The electrolysis of ammonia requires a theoretical cell voltage of 0.059 V, which is miniscule in comparison with that of water electrolysis (1.23 V). If solar energy ($0.21/kWh) is used to provide the electric current needed for ammonia electrolysis, then the cost for 1 kg of hydrogen produced from ammonia electrolysis will be $0.90 based on $175/ton of ammonia. In contrast, water electrolysis using electricity from solar energy would produce hydrogen gas at a cost of $7.10/kg. So, the production of hydrogen gas from ammonia electrolysis is less energy consumptive, as well as cheaper, than water electrolysis.

One of the goals of the CEER is to develop a scenario in which an ammonia electrolyzer can be used to clean ammonia rich wastewater in order to produce clean water and hydrogen gas for power generation (Fig. 38.14). In Fig. 38.14, the ammonia rich wastewater from industry, livestock, and residential communities are electrolyzed using the electricity from solar energy or any available energy to produce clean water, which can then be returned to bodies of water, and to produce pure hydrogen gas along with nonpolluting nitrogen gas. The industry or residential community can use the energy obtained from the hydrogen gas from fuel cells thereby reducing the demand for oil and natural gas. In addition to hydrogen production, the electrolysis of ammonia rich wastewater eliminates a pollutant from wastewater and produces clean water, which could be used for various activities. The technology represents a groundbreaking solution for the denitrification of water in wastewater treatment plants.

Urea Electrolysis

Urea is an important chemical for the mankind as it is used in the production of fertilizer. At the same time, urea is found in wastewater, such as agricultural runoff, as well as in human and animal urine. Even industrial wastewater, especially the wastewater from the fertilizer industry, has relatively high concentrations of urea. The chemical structure of urea (NH_2–CO–NH_2) has two amine groups attached by a carbonyl group. The presence of the amine group in urea was beneficial for CEER researchers in order to extend the ammonia electrolysis principle to the electrochemical oxidation of urea [119, 120]. Cleaning the urea rich wastewater is important for the disposal of the wastewater in bodies of water. Using the electrochemical approach to remove urea from wastewater has an added advantage of producing high value chemicals, such as hydrogen.

The anode and cathode reactions for urea electrolysis are given below, where 0.33 M urea along with 5 M KOH forms the anode side electrolyte solution and 5 M KOH forms the cathode electrolyte.

Anode reaction

$$CO(NH_2)_2 + 6OH^- \rightarrow N_2 + 5H_2O + CO_2 + 6e^- \quad E^\circ = -0.46 \text{ V vs. SHE} \tag{38.103}$$

Cathode reaction

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \quad E^\circ = -0.83 \text{ V vs. SHE} \tag{38.104}$$

Overall reaction

$$CO(NH_2)_2 + H_2O \rightarrow N_2 + 3H_2 + CO_2 \quad E = 0.37 \text{ V} \tag{38.105}$$

The electrocatalyst used in the anode electrode for the urea oxidation is nickel, which is oxidized to nickel hydroxide ($Ni(OH)_2$) in the alkaline solution, which can be KOH. The theoretical cell voltage for urea electrolysis is 0.37 V, which is 70% less energy consuming than water electrolysis [121]. The urea rich wastewater can be remediated using this electrolysis method, thereby producing hydrogen gas, an energy carrier and environmentally harmless nitrogen gas. CEER researchers are working towards developing an electrolyzer which can directly oxidize urine into hydrogen and nitrogen gas. The urea electrolyzer can be used in place of the ammonia electrolyzer in the scheme displayed in Fig. 38.14 in order to demonstrate the possibility of cleaning urea rich wastewater into clean water and producing valuable product as hydrogen gas [119–125].

Coal Electrolysis

In the world today, hydrogen gas is typically being produced from fossil fuels, including coal, using the gasification technique. An alternate method to utilize coal for hydrogen production is coal electrolysis, which was proposed by Coughlin and Farooque in the late 1970s, but their research was discontinued due to low oxidation currents [126–130]. Recently, Botte and her collaborators at CEER revitalized and significantly improved the electrolysis of coal for the production of hydrogen [131–139].

The production of hydrogen gas using the electrolysis technique described until now has been based on the use of an alkaline electrolyte. However, coal electrolysis uses sulfuric acid as its electrolyte; it therefore can be considered an acid electrolysis system. Electrolysis of coal is an excellent alternative method to the coal gasification technique mainly because of the high energy required under the gasification process (800°C) along with the required purification steps in order to obtain highly pure hydrogen gas. On the other hand, coal electrolysis uses 4 M sulfuric acid circulating in the cathode side, which is separated from the anode side by a membrane. The anode side electrolyte is composed of coal particles mixed with 4 M sulfuric acid as coal slurry. The electrochemical reactions at the anode and cathode electrodes take place at intermediate temperatures (40–108°C):

Anode reaction

$$C + 2H_2O \rightarrow CO_2 + 4H^+ + 4e^- \quad E^\circ = -0.21 \text{ V vs. SHE} \tag{38.106}$$

Cathode reaction

$$4H^+ + 4e^- \rightarrow 2H_2 \quad E^\circ = 0 \text{ V vs. SHE} \tag{38.107}$$

Overall reaction

$$C + 2H_2O \rightarrow 2H_2 + CO_2 \quad E = 0.21 \text{ V} \tag{38.108}$$

The theoretical cell voltage for the overall reaction from coal electrolysis is 0.21 V, which is less than the 1.23 V value associated with water electrolysis. The electrochemical cell used at CEER is known as a continuous electrolytic cell (CEC). Electrolytes for both the anode and cathode side are constantly circulated in order to oxidize a high percentage of the coal particles. The research at CEER has found that the addition of Fe(II)/Fe(III) redox couple to the coal slurry solution increases the rate for the electrochemical oxidation of coal [134, 136, 139]. The CEC used for coal electrolysis has a membrane separating the anode side from the cathode, which has resulted in almost 100% pure hydrogen gas from the cathode compartment. This approach eliminates the need for gas purification equipments.

Once the coal particles have been used in the electrolysis process, the electrolyzed coal is subjected to extraction of liquid chemicals. These liquid chemicals are expected to have high amounts of various hydrocarbons with properties of fuels so as to be termed as liquid fuels. The electrolysis of coal helps in the production of hydrogen gas, a high value chemical, and the solid waste from the electrolysis is further processed to obtain liquid fuels [133].

Summary

The concept of storing energy is as important as generation of the energy itself. Even though there are various methods of storing energy, the most promising methods will be based on electrochemical storage systems. Electrochemical energy storage devices are not limited to batteries, flow batteries, fuel cells, and supercapacitors. The advancement in rechargeable batteries, such as lithium-based batteries, has improved their usage as electrochemical energy storage devices for varying applications. There are new types of batteries being developed, namely high temperature and flow batteries, which has the potential to be used for large-scale power generation or storage units. Similarly, there are promising developments in the field of fuel cells and supercapacitors to improve the capacity to generate power and store energy, respectively, from these systems.

The idea of storing energy can be extended to the synthesis of the chemicals as well, in which the chemicals are generally used for producing power or energy. In this manner, during the synthesis of the chemicals the energy is stored in the chemical bonds of the compounds formed. On that basis, the electrochemical synthesis of the chemical compounds has been around for more than a century. Synthesis of chemical compounds using electrochemical processes provides precise control over the reaction, which results in higher yield and purity.

In the beginning, the manufacturing of chemicals using electrochemical methods was highly energy consuming and less efficient. These challenges meant that industrial electrosynthesis could hardly be considered a process for energy storage. In the earlier days, the focus of the industry and even the accompanying research was to improve the yield and purity of the chemical compounds produced. Over the years, there has been development and advancement in every aspect of the electrochemical and electrochemical engineering field as well as the other areas of science and technology. With the passage of time, improvements from all of the related fields have been incorporated at different levels (including nanotechnology) of the industrial scale electrosynthesis technology mainly to lower energy requirement and also to increase the yield of the products.

In the modern era, energy requirement for the synthesis processes along with the health and environmental impact of the synthesis routes have equal or even more importance than yield of the product as in earlier times. Consequently, more time and money are spent in the research and development process to improve the synthesis technique using the knowledge, including information obtained from other fields of science, which has resulted in a true multidisciplinary research. This research has focused on understanding the reaction mechanism using available analytical methods even under *in-situ* conditions, developing advance materials through nanotechnology and nanoscience, and systematic use of experimental studies at the laboratory, bench scale, and pilot level, along with theoretical investigations using computational and multiscale modeling methods. This approach to using multidisciplinary research and the involvement of new technologies reflect an encouraging and promising future for electrochemical energy storage systems.

  - spray drying, 1466
  - typical formulation, 1466
- Diaminodiphenyl sulfone, curing epoxy adhesives, 556
- Diammonium phosphate, 974–976, 1015, 1096
- 2-Diazo-4,6-dinitrophenol (DDNP), 1479, 1482
- Dichlorobenzene, 358
- 2,4-Dichlorotriazines (2, 4-D), 238, 650
- Diethanolamine, 893, 920, 1050
- Diglyceride salad and cooking oils, 1370, 1387, 1393
- Dihydrofolate reductase (DHFR), 1229, 1233
- Diisocyanate dimers, in urethane adhesives, 560
- Diisocyanates, 35, 43, 319, 451, 560–562, 596, 608–610, 635, 636, 910, 1088
- Dimensionally stable anodes, 467, 1096
- Dimethyl sulfide, 1074, 1086
- Dimethyl sulfoxide (DMSO), 15, 1059, 1086, 1213, 1235, 1281, 1291
- Dioxin, 9, 30
- Dipole interaction, adhesion, 549
- Diuron, 238, 648
- DNA, 13, 92, 286, 394, 407, 408, 410, 502, 528, 532, 652, 1131, 1133, 1135, 1136, 1142, 1145, 1153, 1178, 1179, 1183, 1185, 1187, 1190, 1193, 1196, 1197, 1205, 1223, 1234, 1235, 1243, 1245, 1259, 1264, 1324, 1325
- Docosahexaenoic acid, 1176, 1335
- Dust explosions, 75, 76, 1128
- Dyeing, 327, 426, 436, 445, 447, 449, 450, 455, 468, 469, 473–475, 477, 478, 480, 481, 483, 486, 487, 494, 496–499, 520, 1017
  - pigment, 499
- Dyeing textile fibers
  - dye-bath preparation, 496–497
  - fiber preparation, 496
  - finishing, 497
  - methods/batch, 497–498
- Dye manufacture
  - anthraquinone
    - acid, 529–530
    - basic, 530
    - disperse, 526–529
    - reactive, 530–533
  - azo
    - disazo, 519–521
    - monoazo, 518–519
    - polyazo, 521–523
  - fluorescent brighteners, 540–543

Dye manufacture (*cont.*)
  nitro, 515
  phthalocyanine, 540
  sulfur, 538–540
  triphenylmethane, 523–524
  vat
    anthraquinoid, 533–537
    indigoid, 537–538
  xanthenes, 524–525
Dyes, classification
  acid, 479–481
  azoic, 481–482
  basic, 482–483
  direct, 483–487
  disperse, 487–491
  reactive, 491
  sulfur, 491–494
  vat, 494–496
Dyes, liquid crystal, 499
Dyes, non-textile uses
  biomedical, 502–503
  hair, 503–504
  ink-jet, 499–500
  laser, 502
  organic photoconductors and infrared absorbent toners, 500–502
  photographic, 504–505
  production and sales, 543–545
  synthetic, history of, 474
Dyestuff industry, 474–476
Dynamic vulcanization, 595, 632, 638
Dynamite, 9, 912, 1477–1480, 1483, 1484, 1489, 1491, 1492

E
Effectiveness factor (catalysts), 204, 1206
Elastomeric fibers, 451–452
Elastomers
  high temperature, 595, 619, 638, 639
  olefin, 632
  silicone, 634–635
  thermoplastic, 582, 583, 586, 594–596, 613, 621, 622, 632, 636, 639
Electrochemistry
  electrolyte, 1500–1501
  Faraday's law, 1504
  Nernst equation, 1502–1503
  oxidation, 1499
  reduction, 1499

Electrolysis
  ammonia electrolysis, 1533–1534
  coal electrolysis, 1535
  urea electrolysis, 520–521
  water electrolysis, 87, 1498, 1504, 1510, 1522, 1529, 1532–1535
Electrolyzer, 277, 1030, 1031, 1046, 1504, 1524, 1526, 1527, 1529, 1530, 1533–1535
Elemental analyses, 231, 239, 245–246, 1098, 1296
Emergency planning, 90, 92, 97, 98, 108, 123–125
Emergency preparedness programs
  checklist, 109, 110, 114, 117, 118, 120–123
  community involvement, 121–122
  elements, 107, 111, 120, 123
  emergency response plan, 107, 109, 113, 114, 117
  hazard identification/mitigation, 110, 112–113
  laws and regulations, 124–125
  managing, 107–128
  need for, 108
  personnel training, 113–114, 120
  preventing and predicting, 107–110
  release detection, 112–113
Endocellulase measurement, 1279
Endoenzymes, 1280
Endoglucanases, 1102, 1261, 1273, 1276–1279
Endoxylanases, 1275, 1280–1282
Energy
  crops, 1169–1170, 1254, 1292, 1304
  density, 1105, 1168, 1292, 1296, 1505, 1507–1515, 1522, 1523
  storage, 291, 1170, 1200, 1342, 1497–1536
  use, 159, 164, 182, 192, 193, 291, 838, 913, 1251, 1254, 1257
Environmental effects, 70, 294, 296, 1046
Environmental Fate and Risk Assessment Tool (EFRAT), 181–183
Environmental fate of chemicals
  heuristics for predicting, 176
  transformation in the environment
    abiotic processes, 172–174
    biotic processes, 170–172
  translocation, 166–170
Environmental impact assessment
  combined tiers assessment, 182–186
  EFRAT, 181–183
  HYSYS process simulator, 181–182
  maleic anhydride example, 179, 182, 184
  methyl methacrylate synthesis, 180, 181
  Tier I-Tier III, 176–182
Environmental risk assessment, 156, 176
Environmental risk minimization, 156, 182
Enzymatic degradation, 1273, 1275, 1330
Enzymatic hydrolysis, 1099, 1102, 1170, 1198, 1201, 1213, 1252, 1259, 1273–1275, 1279, 1280
Enzyme databases, 1187, 1274
Enzyme-linked immunosorbant assay, 1234
Enzymes
  accessory, 1280
  binding, 1186, 1188, 1189, 1207, 1214
  debranching, 1197, 1199, 1274, 1275, 1280, 1281, 1283, 1284
  depolymerizing, 1281, 1282, 1284
  immobilized
    glucose isomerase, 1200, 1206, 1425
    kinetics of, 1188–1189, 1206
    penicillin acylase, 1207
    production, 1206, 1207, 1217, 1223
  industrial, 1143, 1145, 1183–1225, 1250
  polysaccharide hydrolysis, 1283, 1288
  recovery process, 1136, 1142, 1143, 1145, 1210, 1220
Epichlorohydrin, 313, 314, 361, 362, 551–554, 558, 599, 919
  in epoxy resin manufacture, 551–554, 919
Epoxide, adhesive, 551, 557
Epoxy resins
  in acrylic adhesives, 548, 566
  commercial, 551–554
  cycloaliphatic, 553
  reactive diluents, 552–554, 558
    monofunctional, 552, 554, 558
    polyfunctional, 552, 553, 557
  specialty, 554
  transesterification, 557, 564
Escherichia coli, 13, 273, 276, 278, 1103, 1133, 1134, 1160, 1164, 1167–1171, 1173, 1174, 1190, 1196, 1202, 1216, 1218, 1220, 1230–1232, 1243, 1259, 1260

Esterases, 1189, 1201–1202, 1205, 1220, 1280, 1281, 1283, 1284
Ethane, products from, 7, 718, 807, 812, 814, 815, 820, 823, 1051
Ethanol
  cellulose hydrolysis, 1259
  feedstock
    carbohydrate content, 1268, 1271, 1272
    composition, 1269–1272, 1294, 1297, 1298
    effect on ethanol price, 1271, 1272
    proximate and ultimate analyses, 1292

  textured yarns, 443–445
Polyethylene
  chlorinated, 636
  high-density, 7, 44, 101, 452, 579, 585
  linear low-density, 3, 586
  low-density, 229, 455, 578, 585
  production, (Cr catalyst), 101, 377
  production, (Ziegler catalyst), 328, 329
  ultra-high molecular weight, 456, 585, 593
  ultra low density, 586

  very low density, 586
Polyethylene glycol, wood stabilization, 1091
Polyethyleneimine (PEI), 1206–1207, 1234
Polyethylene rubbers, 636–638
Polyethylenes, 2, 3, 6, 7, 11, 31, 35, 41, 43, 44, 101–103, 137, 141, 201, 228–229, 312, 313, 322, 330, 448, 452, 453, 455–457, 465, 468, 566, 571, 573, 574, 576, 578, 579, 585, 586, 590, 593, 601, 611, 612, 623, 632, 636–638, 659, 889, 902, 1084, 1091, 1443, 1444, 1501
Polyethylene terephthalate (PET), 11, 35, 131, 136, 193, 320, 377, 441, 442, 445, 446, 470, 585, 589, 592, 593, 603, 611, 1124
Polyisobutylenes, 23, 575
Polyisoprene using free radical catalyst, 626
Polymer chains
  branching, 578, 585, 586, 619, 621, 627
  cross linking, 560, 566, 620, 622, 634, 636
  crystallinity, 442, 476, 576, 586, 623
  curatives to crosslink, 555, 557, 623
Polymerization
  addition, 577
  anionic, 578
  bulk, 580
  cationic, 577, 578
  chain growth, 554, 555, 557
  chain-reaction, 577
  coordination, 579
  emulsion, 581, 613, 1461
  free radical, 565, 577–579, 586, 601, 638
  metallocene catalysts, 579, 580, 638
  photo initiated, 566, 1122
  solution, 458, 565, 580–581, 588
  step growth, 551, 554, 555, 559, 567, 577
  step-reaction, 576–577
  suspension, 581, 611, 613, 638
  synthetic rubber, 581, 620, 630, 632, 1166, 1168
  Ziegler-Natta catalysts, 575, 579, 638
Polymerization catalysts
  alkyllithium, 627, 629
  free radical, 579
  neodymium, 630
  Ziegler-Natta, 229, 455, 575, 579, 580, 626, 630, 632, 638
Polymers
  amorphous, 574, 575, 584, 608
  atactic, 452, 453, 575, 579, 586, 630, 638
  chain structure, 447, 456, 573–575, 630
  chain termination, 564
  chemical structure, 574, 576
  cold-drawing, 439, 584, 585
  creep, 445, 457, 461, 547, 583, 587, 590, 596, 597, 600–602, 639
  cross-linking, 450, 464, 560, 566, 577, 589, 596, 599–602, 610, 611, 616, 620, 622, 624, 625, 634–639, 1092, 1121, 1123–1126, 1206, 1207, 1214, 1251, 1273, 1338, 1384, 1484
  crystallinity, 440, 442, 461, 476, 576, 578, 582, 585, 586, 592, 593, 600, 623, 1058
  crystallization kinetics, 576, 623
  fatigue, 288, 468, 558, 584, 585
  glass transition temperature, 445, 565, 574–576, 582–584, 611, 619, 622–623, 631, 633, 635, 638
  hydrogen-bonding, 439, 549, 555, 574, 576, 588, 600, 623, 1058, 1064
  isotactic, 453, 579, 586
  melting point, 438, 442, 457, 461, 576, 600, 625
  molecular flexibility/rigidity, 600
  molecular weight, 445, 454, 548–550, 554, 565, 635, 1455
  orientation, 439, 442, 445, 446, 456, 457, 468, 550, 562, 587, 600, 604, 1064, 1123, 1279
  polarity, 574, 575, 588, 593, 600, 602, 608
  SEBS, 595, 637
  semicrystalline, 574, 576, 595, 632
  sequence distribution, 621
  stress relaxation, 583, 584, 639
  stress-strain behavior, 584
  structure-polymers, syndiotactic, 469, 573, 579, 600, 602, 619–622, 629, 1262
  yield point, 584
Polypropylene
  diethyl aluminum fluoride, 229
  production, 229
  Ziegler-Natta catalyst, 539, 638
Polypropylene fibers
  atactic, 452, 453, 575, 579, 586, 638
  isotactic, 452, 579, 586, 638
  production, 4, 452
  syndiotactic, 452, 453, 574, 575, 579
  synthesis, 453
Polysaccharides, 470, 1058, 1073, 1086, 1097, 1099–1103, 1107, 1108, 1112, 1142, 1148, 1183, 1201, 1218, 1250–1251, 1273–1275, 1280–1284, 1288, 1406, 1408, 1411, 1414, 1420, 1421, 1423, 1425, 1426
  hydrolysis, 1283, 1288
Polystyrene
  expanded, 588
  high-impact, 588, 589, 631, 637
  styrene/acrylonitrile copolymers, 588–589, 593, 629, 631
Polytetrafluoroethylene (PTFE)
  expanded polymer (ePTFE), 462, 470, 471
  fiber manufacture, 461
  polymer manufacture, 460–461
  properties, 461–462
Polyurethane, 33–34, 41–43, 241, 320, 330, 452, 466, 478, 548, 560, 562, 563, 567, 571, 595, 596, 601, 608–610, 613, 614, 617, 635–637, 910, 931, 1047, 1091, 1107, 1121, 1163, 1355
  flexible foam, 596, 610, 611
  markets, 596
  reaction injection molding (RIM), 596, 597, 601, 608–610, 636, 931
  rigid foam, 596, 610
  rubber, 635, 636
Polyvinyl chloride
  elastomer, 43
  flexible, 587, 600, 601, 611
  plastisol/organosol, 587
  rigid, 587, 600, 601
  thermal stabilizers, 600
Population growth, world, projections, 421, 838, 961, 965, 1329, 1347, 1348
Potassium, minerals for fertilizer, 380, 765, 844, 939, 959, 964, 969, 978–981, 985, 987, 1019, 1156, 1299
Potassium nitrate fertilizer, 910, 979, 980, 984, 1476, 1478
Potassium phosphates, fertilizer, 980
Potassium salts, fertilizer, extraction and processing, 441, 893, 964, 978–980, 1022, 1177
Potassium sulfate fertilizer, 979–980, 984, 986, 992
Pressure swing adsorption (PSA), 227–228, 326, 875, 885, 886, 889–892, 1039, 1040, 1042, 1043, 1045, 1050
Prill, 911–913, 1477, 1485, 1486, 1489
Primary alcohols, 370, 374, 1331, 1454, 1455
