Foreword

Since the time I was a freshman in college, in 1935, I depended greatly on a fantastic source of chemical information, Riegel's *Handbook of Industrial Chemistry*. Later this invaluable source became Kent and Riegel's *Handbook of Industrial Chemistry and Biotechnology*. I am so privileged to have this opportunity to write a Foreword for the 12th edition of this work.

I have used it regularly throughout all of my professional life as a Professor of Chemical Engineering for 54 years and author of 94 technical books. This book is not meant to be an encyclopedia, and it is not. Rather, the *Handbook of Industrial Chemistry and Biotechnology* is a rich source of industry-wide information and insights. Designed and edited by Dr. Jim Kent, the 12th edition of this widely respected and frequently consulted reference work provides a wealth of information and guidance on industrial chemistry and biotechnology. Industries covered span the spectrum from salt and soda ash to advanced dyes chemistry, the nuclear industry, the wonders of biotechnology, and, most recently, electrochemical energy storage devices.

Dr. Emil Riegel started the handbook in the 1930s, and Dr Kent assumed responsibility beginning with the sixth edition in 1965. Over a period of roughly 50 years and seven editions, under his expert and enthusiastic guidance, it has grown from a handful of chapters, covering mostly the heavy chemicals which characterized that era of the chemical industry, to reflect the ever-changing nature of the industrial scene as well as the needs of scientists and engineers who work in the chemical industry. The present edition draws upon the expertise of 70 contributors, virtually all of whom are embedded in the industries they cover, and who wholeheartedly and even passionately share their intimate knowledge and insights.

Several editions ago, reflecting his early industry experience with Dow and Monsanto, Jim decided to introduce new chapters he chooses to call chemical industry infrastructure. Thus, the Handbook contains chapters on Chemical Process Safety, Emergency Preparedness, and the statistical concepts which underlie process design and control, and quality control. Also, reflecting the increasingly important area of energy, the Handbook includes several nicely integrated chapters on energy producing materials with the broad view of their usefulness in serving as raw material for a variety of industrial processes. Chapters on Fertilizers and Agricultural Chemicals provide crucial information needed to feed the growing population of the world. Adding a chapter on Sustainability in recent editions was timely and inspired.

Some years ago, I understand, a reviewer observed that he had referred to the handbook for information on a particular topic, and left it some hours later, having been captured by several of the interesting and informative chapters on topics in which he had no professional interest. The editor has retained that flavor through succeeding editions, and the contributing authors have uniformly presented their information in well-organized and very interesting chapters.

I have on a great number of occasions over the years consulted successive editions of the Handbook on a variety of topics and never left without having found exactly what I was looking for. The Handbook deserves a place in the library of every chemistry and chemical engineering department, as well as on the desk or in the library of everyone who has a responsibility in promoting, managing, regulating, or writing about any portion of the chemical industry. I have always considered it the most helpful book in my personal library.

John J. McKetta, Jr. Ph.D.

Department of Chemical Engineering
The University of Texas, Austin, Texas, USA

Preface

The central aim of this book is to present an up-to-date account of the science, engineering, and industrial practices which underlie major areas of the chemical process industry. It contains 38 chapters covering various areas of that industry. It should be noted that the products and processes associated with a particular area are discussed within the context of the corresponding chapter, rather than in the isolated manner characteristic of an encyclopedia.

This edition of the *Handbook of Industrial Chemistry and Biotechnology*, the twelfth, includes the topics included in the eleventh (2007), all of which have been carefully reviewed, updated, and revised as necessary. Indeed, some of the chapters have been completely rewritten by new authors. This edition also includes two entirely new chapters, *Industrial Applications of Nanostructured Materials* and *Electrochemical Energy Storage*. The Handbook follows the essential arrangement of earlier versions, i.e., several chapters devoted to general or “infrastructure” topics, with most of the book being given over to the various areas of the chemical process industry. This includes a wealth of very useful infrastructure material and greatly enhanced process industry content. In keeping with past practice, the chapters are written by individuals with demonstrated expertise and real world experience in their respective fields. All told, the work may in many respects be regarded as a sourcebook for practice in the chemical process industries.

The infrastructure or contextual material mentioned above is contained in three chapters which lie in the area often referred to as “green chemistry.” The first of these, titled *Green Engineering: Integration of Green Chemistry, Pollution Prevention and Risk Based Considerations*, provides an excellent guide for applying the methods of green chemistry and engineering to process and product development activities, whether for new products and processes, or for upgrading older ones. Written by a team of experts in the field, the chapter can be of considerable help to all practicing chemists and chemical engineers, as well as to students studying in either discipline. Another new chapter, *Industrial Catalysis; A Practical*

Guide, is a valuable adjunct to the "Green" chapter, since catalysis is an important aid in the practice of green chemistry. The third chapter in what might be termed the "green" group is entitled *Environmental Chemical Determinations*.

There is an important distinction to be made here. *Green chemistry*, or *sustainable chemistry*, is defined by that chapter's authors as "the use of chemistry to reduce pollution at the source, through the design of chemical products and processes that reduce or eliminate the use or generation of unwanted or hazardous substances." *Green engineering* is defined as "the design, commercialization, and use of processes and products that are feasible and economical, yet at the same time minimize (1) generation of pollution at the source, and (2) risk to human health and the environment." Risk assessment methods used in pollution prevention can help quantify the degree of impact of individual chemicals, and thus are a valuable tool for intelligent design of products and processes.

Biotechnology first appeared in the Handbook several editions back as a chapter titled *Industrial Fermentation*. In later editions that chapter has evolved into four, reflecting the rapidly increasing importance of biotechnology. To paraphrase the authors of one chapter, integrating gene discovery, functional genomics, molecular evolution and design, metabolic pathway engineering, and production processes including formulation of delivery systems, the chapter will help readers learn how to design and produce biotechnology products. Persons interested in the biotechnology area will be pleased by the breadth of coverage found in this handbook. Finally, the chapter entitled *Biomass Conversion*, introduced in the previous edition, addresses an area of great interest in connection with world energy needs. Written by a team whose primary work lies in that area, it provides comprehensive coverage of the subject, from biomass structure and composition to thermochemical and biological routes for conversion to energy and a host of chemicals and products including liquid transportation fuels. This chapter defines the opportunity for using sustainable sources of biomass as feedstock for new refineries that will produce fermentable sugars and chemical intermediates, from which several forms of fuels can be made.

As mentioned earlier, the core of the Handbook comprises 30 chapters which are devoted to various areas of the chemical process industry. This information, together with the supporting infrastructure material described above, viz., process safety, emergency preparedness, statistical methods, green engineering and chemistry, provides in toto many sophisticated and useful tools to aid in the design of new products and processes and for the evaluation of older ones. The handbook should also prove useful to individuals who possess a background in chemistry or chemical engineering and work in related areas such as regulatory agencies and environmental organizations. Among other benefits, it will help ensure that the work of such individuals reflects knowledge of relevant contemporary science and engineering and industry practices. Reflecting realities in the world energy situation, the Handbook, as in past editions, includes a chapter devoted to the nuclear industry.

Individuals who have responsibilities in the chemical process industries are usually engaged, consciously or otherwise, in continually reviewing their operations to ensure that they are safe, efficient, and in compliance with current environmental regulations. They are also, or should be, anticipating future needs. It is hoped that the information contained herein will provide the wherewithal by which chemists, chemical engineers, and others who have an interest in the process industries, for whatever reason, can ensure that they have touched every base, dotted every *i*, and crossed every *t* in their quest to make the processes and products for which they are responsible as environmentally sound, safe, and efficient as possible.

Because of the scope of the book and the large number of products and processes it covers, some redundancy is inevitable. For example, more than one chapter includes discussions of gasification and hydrogen production. However, there are significant differences in emphasis in the various discussions. Thus, rather than distract readers by referring them to information in locations outside that of their primary interest, such topics have been left intact in the context in which they are discussed.

As in all the earlier versions of this work for which I have been privileged to serve as designer and editor, I am happy to acknowledge again the unselfish and enthusiastic manner in which the contributing authors have shared their knowledge and insights so that many others may learn and still others may benefit. The picture of a bit of knowledge, like a pebble tossed into a quiet pond, its ripples spreading ever more widely, is, I think, apt. And if knowledge is power, the authors who have contributed their expertise to this work are pleased to have had this opportunity to empower others. All have been unstinting in their efforts to make their contributions as complete and informative as possible, within the boundaries of the space available, and I am indeed humbled and honored to have had a part in bringing it about. Needless to say, errors of omission and shortcomings in organization are mine.

Finally, grateful acknowledgement is made to the publishing houses and technical/scientific organizations for permission to reproduce copyrighted illustrations, tables, and other materials, and to the many industrial concerns which contributed drawings, photographs, and text material. I wish also to express my thanks to the Springer editor, Dr. Kenneth Howell, for his many helpful suggestions and support along the way. And finally, I wish to recognize with thanks the hard work and patience of my well-organized and capable daughter-in-law, Pamela Kent, for her unstinting efforts in helping to prepare the final manuscript.

Recent History of the Chemical Industry 1973 to the Millennium: The New Facts of World Chemicals Since 1973

1

Fred Aftalion

Overcapacities and the Search for Remedies

The first oil shock that occurred at the end of 1973 with the Yom Kippur war served to pinpoint the crisis which world chemicals were already undergoing.

The chemical industry's soaring development after the war was due to the extraordinary burst of innovations occurring between 1935 and 1955 and coinciding with sectors served by chemicals. Production units multiplied in Europe as well as in the United States and Japan.

Two other factors contributed to this rapid growth. The use of oil as a substitute for coal provided the chemical industry with abundant, cheap raw material that was easy to transport. With interest rates lagging behind the rate of monetary erosion over a number of years, industry leaders were tempted to carry out investments that they would not have made had currencies remained stable and interest rates higher. The fear of these leaders that competition would get the better of them if they slowed down their investments, the race for market shares advocated by a number of consultant firms like the *Boston Consulting Group,* the belief—quite widespread among world chemicals leaders—that they had to keep building new units to keep up with forecast needs, all had a share in building up production overcapacities which were already becoming apparent before 1973 in certain sectors of heavy chemicals (petrochemicals, synthetic fibers, thermoplastics, and fertilizers).

The establishment of an OPEC cartel that led to a rise in the price of a barrel of crude oil from $3 to $12, then the 1979 Iranian Revolution which made it soar to $40, and finally the publication of the gloomy forecasts of the Club of Rome experts which mistakenly saw oil shortages ahead when, in fact, these had been artificially engineered by the Cartel members—all these facts upset chemical leaders in industrialized countries. And yet some of them still continued to invest in new plants during the stock-building lulls that occurred in 1974 and 1979 through consumers' speculating on new price rises.

This only made the necessary adjustments much harder when they had to be carried out at the beginning of the 1980s. Companies were to suffer greatly from an error of judgment, building new plants at great expense at the same time that economic growth rates tumbled from over 10% to a mere 2–3%. Caught between the increasing cost of their hydrocarbon raw materials and the ever-lower prices they had to use to sell their products in markets where offer exceeded demand, leading chemical companies in industrialized countries were forced to go through agonizing reappraisals.

This led them to act in a number of different directions. First and foremost, they had to lower their operating costs by cutting down on excess personnel and taking the measures needed to increase the productivity of each company. At the same time, they had to reduce, in a concerted way if possible, the overcapacities affecting the hardest-hit sectors. Finally, it seemed advisable to redirect production into areas that were less sensitive to economic change. This meant increasing the share of specialties in relation to commodities in overall turnover.

A new generation of leaders was called upon to carry out the socially painful and politically delicate job of rationalizing and restructuring the chemical industry through layoffs and plant closures. These same leaders were also given the more exalting, but just as difficult, task of defining the redeployment strategy that needed to be followed and of determining on a case-by-case basis the sectors that should be abandoned and those that, on the contrary, had to be invested in force.

By 1973, it was obvious that the chemical industry had reached a degree of maturity to the extent that all the companies involved in that area in industrialized countries were long established and that no discovery likely to affect

---

F. Aftalion (✉)

DOI 10.1007/978-1-4614-4259-2_1,

its development had been made over the last two decades. While new areas of research like composite materials and biotechnologies had emerged, no immediate fallout was expected for a number of years. Thus failing any rapid internal growth brought about by major scientific breakthrough, the strategy of leaders anxious to refocus or diversify their portfolio of activities very often consisted of a kind of monopoly game, as a range of production was shifted from one enterprise to another without anything new being created.

The Restructuring of Sectors in Distress

Priority action was required in petrochemicals, in the large thermoplastics, in fertilizers, and in synthetic fibers where the most serious investment mistakes had been made. The hardest cases were those of *petrochemicals* and *thermoplastics*. For one thing, a steam cracker cannot technically operate under 60% of its capacity. For another, the products that emerge are linked to one another in almost invariable proportions. Finally, a polymerization unit cannot have its pace slowed down without this affecting the upstream monomer unit to the same extent.

In addition to such rigidities, there was the need to reduce not only the quantities produced but also the number of production units. The problem then arose of sharing the sacrifices among the different producers within an economic area.

The problem was most easily solved in Japan because of the discipline which MITI managed to establish within the country's petrochemical industry. Making the most of a new law that allowed competing producers to act in concert, a cartel was set up with the object of cutting down ethylene production. Four groups of petrochemical producers were formed within which the necessary arbitrations took place. This led Sumitomo to close its Niihama units, Mitsubishi a number of its Mizushima plants, and Showa Denko two of its Ohita installations.

At the same time, producers reached agreements on cutting down competing PVC and polyolefin sales networks, while MITI authorized the import of naphtha through an organization consisting of Japan's petrochemical producers. Its price served as a marker for naphtha produced in Japan.

In Europe, of course, it was difficult to show such disregard for market laws. The views of the European Economic Community Commission in Brussels had to be taken into account, and they upheld the principle of free competition as set down in article 85 of the Rome Treaty. Moreover, in Western Europe there were a number of petrochemical industries that operated according to the rules of private capitalism while there were others, as in France, Italy, Austria, Norway, and Finland, that were state controlled and more concerned about retaining market share than ensuring profitability.

Despite such obstacles, unilateral decisions were taken and bilateral arrangements carried out among firms, leading to some measure of production rationalization. Between 1980 and 1984, 25 ethylene and 8 polyethylene units were scrapped in Western Europe while ethylene oxide capacities were reduced by 10%.

The 1983 agreement between ENI and Montedison put some order in Italy's chemical industry, as ENI took over the PVC and polyethylene operations of Montedison. Previously in France, Rhône-Poulenc had sold its petrochemicals division and its thermoplastics to the Elf Aquitaine group. At the same time, steam crackers were being shut down in Feyzin and Lavera, and a vinyl chloride unit in Jarrie. The association between BP Chimie and Atochem in polypropylene and the exchange of Atochem's Chocques unit for ICI's Rozenburg polyethylene unit were other instances of rationalization.

The Brussels Commission also gave its approval to three large-scale operations: the ICI and BP Chemicals exchange of polyethylene/PVC, the vertical integration of vinyl chloride involving AKZO and Shell Chemicals, and the recent Enichem and ICI association, which produced European Vinyls Corporation and was intended to lead to major capacity cuts in PVC.

In West Germany, rationalization measures were less spectacular because the heads of Germany's leading chemical companies had not waited for the crisis to delineate their respective fields of operation and to establish close links with international oil companies, either through long-term supply contracts or through parity associations.

A number of American companies became involved in restructuring. Union Carbide sold its Antwerp site to BP Chemicals; Monsanto, its Seal Sands acrylonitrile unit to BASF; Esso, its Stenungsund steam cracker to Statoil; while Hercules joined up with Montedison to set up the Himont company, which accounted for 20% of the world polypropylene market.

In the *United States* the petrochemical industry set its house in order along purely capitalistic lines. Each company involved acted alone for fear of infringing antitrust legislation and the main concern was to restore profitability. Unlike Du Pont, which acquired Conoco, other chemical companies tried to get rid of their petrochemicals. Hercules sold its DMT units to Petrofina, and subsequently its 40% stake in Himont to Montedison, while Monsanto was shedding its Texas City petrochemical site.

Major divestments took place, particularly in the major thermoplastics, which were taken over by individual entrepreneurs who bought up the units the chemical giants wished to get rid of. As Hoechst, Union Carbide, Du Pont, Monsanto, ICI, and USS Chemicals withdrew from a number of the major oil-based intermediates as well as from polystyrene, polyethylene, and PVC, a number of large, hitherto unknown companies emerged: Huntsman Chemical, El Paso Products, Aristech, Vista Chemical, Sterling Chemicals, and Cain Chemical.

At the same time, oil companies were integrating downstream petrochemicals and polymers. Such was the case of Occidental Petroleum, which through its chemical subsidiary Hooker (later Oxychem) bought up Tenneco and Diamond Shamrock's PVC in 1986, becoming the largest American producer in this area. Likewise, BP Chemicals fully acquired its subsidiary Sohio. The long-standing petrochemical divisions of the large oil groups returned to profits in 1986 after some painful tidying up but no agonizing reappraisal, helped along by falling oil prices and dollar rates.

Most of them had cut down on operating costs and diversified to the point at which they were able to face up to the economic ups and downs without too much apprehension. Productivity improvements and a better utilization of existing capacities because of higher demand put Exxon, Mobil, and Texaco on the way to prosperity in petrochemicals in 1986.

Standard Oil of California added the petrochemicals of Gulf Oil, purchased in 1984, to its subsidiary Chevron Chemical. Other United States petrochemical producers took advantage of special circumstances. Amoco was served by a strong terephthalic (TPA) base and its good performance in polypropylene; Arco, by its Lyondell subsidiary in Channelview, Texas, and by its development of the Oxirane process through which propylene oxide could be produced by direct oxidation with styrene as a coproduct. The process also led to MTBE (methyl tertiary-butyl ether), the antiknock agent used as a substitute for tetraethyl lead.

Even Phillips Petroleum, badly affected by Boone Pickens' takeover attempt, managed to make substantial profits from its petrochemicals because of drastic restructuring. New prospects were also opening up for the United States chemicals industry as needs grew for butene and hexene comonomers used to produce linear low-density polyethylene (LLDPE), also as consumption of higher olefins to prepare detergent alcohols increased and as demand for MTBE used as a gasoline additive soared.

The problem of overcapacities in *chemical fibers* in each economic region was both easier to overcome because of the small number of producers and more complicated because of outside factors. In *Europe,* producers suffered heavy losses from 1973 onward. For one thing, the Europeans were not particularly suited to manufacture chemical fibers at satisfactory cost, a fact that was proved by growing imports from Southeast Asia. For another, the capacity increases decided upon did not tally with any comparable increase in demand in the foreseeable future.

In view of such imbalance, one might have thought that a number of producers would withdraw from the market. But this did not happen because some of them had to heed government instructions to maintain employment. Also textiles accounted for only a share of the business of the companies involved and could be kept up through the profits generated in other areas. From 1978 to 1985 two agreements were implemented with the blessing of the European Economic Community Commission. The first aimed for a linear reduction of existing capacities; the second and more important one allowed each producer to specialize in those areas where it held the best cards, giving up what amounted to marginal productions.

Thus Courtaulds withdrew from polyester and from Nylon to concentrate on its acrylics and cellulose fibers; ICI focused on Nylon and Bayer on acrylics; Rhône-Poulenc withdrew from acrylics but revamped its Nylon and polyester units well integrated in upstream intermediates; Montedison decided in favor of polyester and acrylics; AKZO focused on polyesters and on aramide fibers while keeping up its profitable rayon sector. Such efforts, which aimed to reduce European chemical fiber capacities by 900,000 tons and to increase productivity through specialization, undoubtedly corrected the situation.

Nonetheless, European producers are still faced with two kinds of competition: first imports of synthetic fibers from Turkey, Taiwan, South Korea, and Mexico, against which it is hopeless to expect that the multi-fibers agreements—which contravene GATT rules—will constitute a permanent obstacle; and second, imports of natural fibers such as cotton, for which prices have fallen spectacularly in recent times.

The Japanese solution to chemical fiber overcapacities naturally involved MITI which pushed through a 17% cut in existing polyester, Nylon filament, and acrylic fiber capacities between 1978 and 1982. These were linear cuts, however, and did not restrict the range of synthetic fibers developed by each producer, contrary to the specializations that marked the second stage of Europe's approach.

The United States was faced with an additional problem because its market remained wide open to textile imports from developing countries. These imports constituted an indirect threat to American producers of chemical fibers. Their first reaction was to reduce their bases in Europe. Du Pont closed its acrylic units in Holland in 1978 and in Northern Ireland in 1980; the following year it ceased production of polyester thread in its Uentrop unit in Germany. Monsanto did likewise in 1979, shutting down its Nylon units in Luxembourg and Scotland and selling its acrylic fiber installations in Germany and Ireland to Montedison.

In the United States itself, capacity cuts were not so substantial and the 1983 upturn boosted utilization of remaining units to 80% of their capacities. Major American producers such as Du Pont, Celanese, and Monsanto returned to satisfactory profit margins. Other companies for which fibers were not an essential sector withdrew from this area. Chevron Chemical, for instance, shut down its Puerto Rico Nylon and polypropylene fiber units between 1980 and 1982 as well as the polypropylene fiber unit in Maryland.

The fertilizer market was in no better shape than the petrochemicals and chemical fibers markets, for world producers had largely allowed supply to exceed demand.

The situation in this area was further complicated by the unequal distribution worldwide of the raw materials required to produce fertilizers and the special attention which governments bestowed on agriculture. Such attention had led to a surfeit of production units and their increasing control by governments, either directly through taking a stake in the companies concerned, or indirectly through establishing ceiling prices for home sales or export subsidies. The emergence of new producers in Eastern countries and in developing areas increased the share of state-controlled companies in world production from 30 to 64% for ammonia, from 40 to 65% for potash, and from 10 to 46% for phosphoric acid between 1967 and 1986.

In Western Europe, nitrate fertilizer producers had deemed it expedient to set up a cartel arrangement for exporters called Nitrex. But the collapse of demand in countries outside its area had prevented it from functioning properly, sparking a fight for market shares even within the community.

As a country like Morocco switched from its long-established role as phosphate exporter to downstream ammonium phosphate and superphosphate integration, traditional fertilizer producers were forced to reappraise their strategy and take severe rationalization measures.

Japan which had none of the required raw materials and, accordingly, had high production costs, began, as early as the 1970s, gradually to cut down capacities along the lines jointly agreed upon by the authorities and the five main Japanese producers of nitrate and phosphate fertilizers.

In *Europe,* the pressure of events disrupted the whole market as the number of producers was drastically reduced. Because of market proximity, production both from Eastern Europe of nitrates and from Africa of superphosphates were becoming dangerously competitive. Supply conditions for natural gas varied according to each country's policies. France, for instance, agreed to pay extra for Algeria's gas, while Holland's Groningen gas, which Dutch ammonia producers were getting at a very favorable price, was linked to the price of petroleum products. On the other hand, a number of Scandinavian state-controlled companies like Norsk Hydro and Kemira were pushing ahead with ambitious fertilizer programs, taking advantage of their interests in North Sea oil or of the conditions under which they were being supplied with oil and gas from the Soviet Union.

Between mergers and acquisitions, the structure of the fertilizer industry in Western Europe was spectacularly pared down. A few giants emerged to dominate the market. In France, there was CdF Chimie, later to be known as ORKEM, which had just taken a 70% stake in Air Liquide's subsidiary La Grande Paroisse, and Cofaz, which was taken over by Norsk Hydro; in Western Germany, there was BASF and Ruhr Stickstoff; in Britain, ICI and Norsk Hydro, which bought up Fisons; in Italy, ANIC and Montedison's subsidiary Fertimont; in Holland, DSM's UKF and Norsk Hydro NSM; in Finland, Kemira, which took over both Britain's Lindsay and its Kesteven facilities.

But the scene has not yet become sufficiently clear, since the competing companies do not all enjoy, within the community, the same raw materials supply conditions, and Europe is still open to imports from other countries that do not apply the rules of market economy.

In the *United States,* the situation was in many ways different. With its large sulfur, natural gas, phosphate, and even potash resources, America's fertilizer industry rested on a sound base. It was an exporter of minerals and fertilizers, and did not have to worry to the same extent as Europe's industry about competing imports from Socialist countries. But reserves of sulfur extracted by the Frasch process have been depleted in Louisiana and Texas, and President Ronald Reagan's "payment in kind" (PIK) farm-acreage cuts reduced the fertilizer requirement of American farmers. These farmers are also much in debt and are having trouble selling their products on saturated markets.

Consequently, very little money has been sunk into extracting phosphate rock in Florida or in increasing nitrogen fertilizer capacities, for a new ammonia and urea unit can cost as much as $250–500 million to build in the US, depending on the state of the existing infrastructure.

With such dim market prospects, it is understandable that W.R. Grace has decided to shut down its Trinidad ammonia unit, or that a company as large as International Mineral Chemicals has tried to diversify through purchase of Mallinckrodt and has put half its fertilizer assets up for sale.

The Nationalization of France's Chemical Industry

When a left-wing government came to power in 1981, France's chemical industry was in dire straits judging from the losses of the major groups: CdF Chimie was losing 1,200 million francs; Péchiney Ugine Kuhlmann 800 million francs; Rhône-Poulenc 330 million francs; Chloé Chimie 370 million francs; Atochimie 130 million francs; and EMC 100 million francs. Admittedly world chemicals were in poor shape. But while French leaders were posting losses amounting to 7–10% of their turnover, Hoechst and BASF were still making consolidated profits that year of 426 million DM and 1,290 million DM, respectively, even though they had noticeably slumped.

There were many reasons, some of them old, for the difficulties of France's chemical industry as illustrated by losses of 7 billion francs in 7 years—4 billion francs in 1981 alone. Caught between increasingly heavy charges and price controls on the home market, France's chemical entrepreneurs never managed after the war to achieve sufficiently profitable margins. They ran up high debts to make up for their lack of funds, building up ever heavier financial costs.

A further disadvantage of France's chemical industry was its scattered production sites, originally due to the need during the two World Wars to keep plants far from the battlefields. For both social and political reasons, it was inconceivable in France to have a site like BASF's Ludwigshafen where 52,000 people are concentrated on six square kilometers with three thermal power plants and countless production sites. The first concentrations which President Georges Pompidou sought to carry out had not changed things much, neither had they cut down increased operating costs. Indeed, the leaders of merged companies had not cared at the time to close sites down and reduce personnel, two moves that might have improved the performance of the new groups.

Although the state spent considerable sums for chemical research, particularly through CNRS and the universities, the fallout for industry was scarce because of the persistent lack of communication between industry and those doing research.

The research and development sectors of the companies themselves made few breakthroughs, so that the chemical industry had to rely for a large part on foreign technologies, a fact that left little room for maneuver.

In addition to the difficulties inherent in their environment, France's companies also suffered the effects of bad management decisions in specific areas. Rhône-Poulenc had been badly prepared for the chemical fibers slump and had sunk too much money in heavy chemicals. These did not fit in with the group's original calling, as its leaders demonstrated when they withdrew, at the height of the crisis, from petrochemicals and the base thermoplastics, concentrating on specialties. The purchase of GESA from PUK in 1978, of Sopag the following year from the Gardinier brothers, and the sale of Lautier were hardly fortunate decisions for a group that could draw no advantage from getting further into fertilizers and that could have diversified to good purpose on perfumes through Lautier.

PCUK had never managed to strengthen Francolor's international base to good purpose and had finally sold it to ICI. Also, it wasted a lot of money in belatedly trying to develop a PVC chain. In 1981, PCUK was negotiating with Occidental Petroleum the sale of its chemical division, which had long since ceased to be of interest to the group's leaders.

At no time since it was set up was CdF Chimie master of its destiny, subject as it was to political pressures rather than economic rationality. Constantly in the red despite a number of worthwhile activities, it received the final blow when the untoward decision was taken in 1978 to build, on borrowed money, a one-billion-franc petrochemical site in Dunkirk in the framework of Société Copenor set up in joint venture with the Emirate of Qatar.

Elf Aquitaine had established under Sanofi a small conglomerate with profit-making subsidiaries involved in pharmaceuticals and perfumes. But Atochem, set up on a joint basis by Total and Elf, was a loss-making concern, as was Chloé Chimie, a cast-off of Rhône-Poulenc, which retained only 19.50% of its capital, while Elf and Total each acquired a 40.25% stake in the new chemical entity.

EMC was more a mining than a chemical company. It focused on potash, having restricted its diversification to the purchase of the animal food company Sanders and to a subsidiary in Tessenderlo, Belgium.

It was in this environment that the nationalization measures decided upon by the new Socialist government took place. The state took control of 40% in value of production of commodity chemicals and 70% of petrochemicals in France, an event that had no precedent in the free world's industrial countries.

Société L'Air Liquide, which figured as one of the companies to be nationalized on the initial Socialist list, escaped this fate, no doubt because the disadvantages of taking over this star multinational had been pointed out to the President of the Republic by one of his brothers, who was adviser to the group. On the other hand, Roussel-Uclaf, which had never needed state funds, found the government partly in control of its capital in addition to the main shareholder Hoechst.

Short of the extreme solutions advocated by some socialists in favor of a single French chemical entity, the nationalized part was cut up along the lines announced by the Ministry of Industry on November 8, 1982. The restructuring signaled the death of PCUK as an industrial enterprise. Its various sectors were shared out among the other state-controlled groups. Most favored was Rhône-Poulenc, which received the agrochemicals and pharmaceuticals sectors with Sedagri and Pharmuka as well as the Wattrelos and La Madeleine sites in the north of France, together with a plant in Rieme, Belgium. At the same time, its fluorine division was boosted. The lion's share went to Elf Aquitaine with what amounted to two-thirds of PCUK's turnover, including, in particular, the halogen and peroxide products.

Complex negotiations with Total (Compagnie Française des Pétroles) ended with the group's withdrawing from Atochimie and Chloé Chimie, after which Elf Aquitaine set up its Atochem subsidiary to encompass all its chemical activities. After a long and brilliant independent career, Rousselot was split between Atochem and Sanofi.

Already sorely tried, CdF Chimie came out the worst from the restructuring. It inherited the Oxo alcohols and organic acids of the Harnes unit and had to call upon Esso Chimie to ensure their survival; it also got an ABS unit that was too small, which it exchanged with Borg Warner for a 30% share in their European subsidiary company—the Villers Saint-Paul site, which could become profitable only with the help of the industries to be set up there; the polyester resins division of the Chauny unit, and the downstream activities of the Stratinor subsidiary, both open to stiff competition. Among the lot there were some profitable sectors, however, such as Norsolor's acrylics, well integrated on the Carling site, and Société Lorilleux, a small ink multinational of PCUK's. But CdF Chimie was left to manage the difficult fertilizer sector swollen by Rhône-Poulenc's and EMC's divestments (GESA and APC), as well as a petrochemical branch set off balance by the unfinished Dunkirk site. As for EMC, all it got from PCUK was the historic site of Loos, which nevertheless served to boost its chlorine and potash divisions.

This enormous restructuring job, no doubt, did produce chemical groups with sounder bases and a more promising future. But the financial cost to the country was considerable, for not only were the shareholders refunded with public money to compensate for nationalization, but the companies that were now state controlled had to be bailed out: their losses in 1982 were even higher than those registered the previous year. Just as high was the social cost. Manpower cuts which the former company leaders had been loath to carry out had become not only absolutely necessary but also easier to implement by a leftwing administration.

Restructuring in Italy and Spain

As was to be expected, the path to overcapacities aided by state subsidies had brought *Italy's chemical industry* to the edge of the precipice. In 1981, SIR and Liquichima, on the brink of bankruptcy, had been taken over by ENI, the state-controlled oil group whose own chemical subsidiary ANIC was also losing considerable sums of money. Montedison had been able to show balanced books only once in 10 years, in 1979. Its debts had soared to $2 billion in 1984.

The rather belated restructuring measures consisted, in their first stage, in the sale of the state's 17% share in Montedison to private interests. Then Italy's petrochemicals and plastics companies were shared out between Montedison and ENI's chemical subsidiary Enichem.

These two groups then set out to concentrate their efforts on polyesters and acrylics in the fibers area. At the same time, Montedison gave up control of SNIA Viscosa, specializing in polyamides, to Bombrini-Parodi-Delfino (BPD). The restructuring, carried out together with manpower cuts and unit shutdowns, made it possible for Montedison in 1985 and Enichem in 1986 to post operating profits after long years in the red. Enichem received a further boost from association with ICI in PVC and with BP and Hoechst in polyethylene, for it had emerged from the restructuring in a less favorable position than Montedison because it was still saddled with commodity chemicals.

Montedison, now 45% owned by the Ferruzzi sugar group, reinforced its strategic sectors by purchasing Allied-Signal's fluorine polymers through its stake in Ausimont, by fully acquiring the Farmitalia and Carlo Erba pharmaceutical subsidiaries, and by buying from Hercules its 50% share in Himont, the joint subsidiary set up in 1983 in polypropylene.

The two Italian giants were still very much in debt, a fact that could lead to further divestments. But their leaders could nevertheless contemplate the future with some equanimity. Their heavy chemical sectors were finally merged under Enimont in 1988.

The *Spanish chemical industry* was also faced with considerable difficulties. Short of innovations, it had developed through foreign technologies and had lived a sheltered life behind customs barriers and import licenses not conducive to cost cuts. Neither Spain's petrochemicals industry, which was in the hands of the Enpetrol state group and the private company CEPSA, nor the main national companies Explosivos de Rio Tinto (ERT) and Cros, were in a position to face without transition the pressure of competition felt when Spain joined the Common Market. This was particularly true of ERT, which had missed bankruptcy by a hair, and Cros, which had remained in the red for a long time. Neither would be able to avoid severe restructuring.

Their total merger project failed through lack of financial means, and it was Kuwait in the end which, through the Kuwait Investment Office, took a 47% share in ERT and 24% in Cros in 1987 and promised to provide the necessary cash for the two groups to form a joint fertilizer subsidiary.

Arab Countries Gain a Foothold

As soon as OPEC was set up, Middle Eastern countries had sought to find ways to invest their oil revenues in downstream industries. *Kuwait*'s approach was, preferably, to acquire shares in existing companies. It thus bought up Gulf Oil's interests in Europe, took a share in Germany's Hoechst, and injected considerable capital into ERT and Cros in Spain.

Qatar had chosen to associate with CdF Chimie to set up a petrochemical base in the Emirate and to build the Dunkirk site through Copenor.

Saudi Arabia's policy has been to develop a national petrochemical industry that would sell its products worldwide. More than Qatar and Kuwait, it had abundant supplies of ethane and methane extracted from gases that were being flared. The ethane separation capacities of its refineries alone accounted for a potential of 3.5 million tons a year of ethylene.

Sabic, the body in charge of the project, had cleverly involved itself with major international groups such as Mobil, Exxon, Shell, and Mitsubishi. Production would then be easier to place in Europe, North America, and Southeast Asia without wounding national feelings. The first giant methanol unit came on stream in 1983, while the other Saudi productions located in Al Jubail and Yanbu have gradually begun supplying low- and high-density polyethylene, ethylene glycol, ethanol, dichloroethane, vinyl chloride (monomer and PVC), and styrene as the relevant units came on stream.

Since 1970, Saudi Arabian Fertilizer has been producing urea and melamine in Dammam, in association with Sabic; the two companies have scheduled construction of a 1,500-tons-a-day ammonia unit in Al Jubail.

Because of the obviously low cost of the principal local methane and ethane raw materials, and because the fixed costs of the installations are high with regard to variable costs, European petrochemical producers were afraid that Saudi Arabia with its low home consumption would flood outside markets with its ethylene derivatives and methanol at cut prices. So far, however, Saudi exports have not shaken up the market because they have been carefully channeled through the distribution networks of Sabic's international partners.

Taking a different course than Algeria with its liquefied natural gas, the Gulf States have thus upgraded their natural resources and already account for 10, 5, and 4% of world production of methanol, ethylene, and polyethylene, respectively.

The American Chemical Industry Caught off Balance

The difficulties resulting from world overcapacities were enhanced in the United States by the behavior of financial circles and the reaction to this behavior of the US chemical industry leaders. America's chemical giants had reached their advanced stage of development because of the long patience of their shareholders and the acumen of their leaders based on 30 years of product and process innovation. Just like their German and Swiss counterparts, the US chemical industry leaders had upheld the notion of long-term interest over the more immediate concern of the various types of shareholders.

The shock waves sent out by the two oil crises, which had not spared the United States, the growing influence of financial analysts on the behavior of shares quoted on the Stock Exchange, and the arrival at the head of the large industrial groups of graduates from glamorous business schools trained more in finance than in technology gave the scene a new twist. Shareholders were more interested in the instant profits they could draw from breaking up a group than with the added value that could be patiently built up through its development.

Drawn along by their own convictions or under pressure from bankers and "raiders," US chemical leaders were constantly redeploying their activities. The *leveraged buy-out* (LBO) system had already been applied by the leaders of FMC's American Viscose division when they sought to buy, with the help of the banking world in the early 1970s, the Avtex rayon and polyester producer, which thereby became a successful company. Despite the risk to buyers in borrowing from financial organizations as much as 90% of the amounts needed for the purchase, the system was eagerly seized upon by individuals wishing to set up their own business and taking advantage of the disenchanted mood of potential sellers. This is how *Huntsman* became the world's leading producer of styrene and polystyrene after buying up the relevant sectors from companies like Shell and Hoechst, which wanted to pull out of them.

Likewise, it is because Du Pont, having spent $7.4 billion to acquire Conoco, sought to reduce its debts by selling part of Conoco's chemicals and also because Monsanto, ICI, and PPG were withdrawing from petrochemicals, that firms like *Sterling Chemicals, Vista Chemical,* and *Cain Chemical* have emerged since 1984. Cain Chemicals was itself to be taken over by Oxychem (Occidental Petroleum) in 1988. Various acquisitions made at the right moment turned Vista within 3 years into one of the leading PVC and detergent alcohol producers in the United States. Through purchases made in its behalf by Sterling Chemicals, Cain Chemicals became a major petrochemical company with assets worth $1 billion in 1987, including ethylene, ethylene oxide, glycol, and polyethylene units, all strategically located in the Gulf of Mexico area. A further newcomer on the American scene was *Aristech,* which emerged through the takeover by its management of the heavy chemicals division of USX (US Steel).

All these companies were acquired under very favorable conditions, as more often than not they were sold by the large groups at 25% of their replacement value. Contrary to assumed notions, individual entrepreneurs were thus able to acquire installations which until then only the most powerful groups could afford to run. These groups gave up whole sections of their traditional chemicals to redeploy in specialties for which they had no particular disposition and, at times, in areas even further removed from their original areas of competence. Thus *Diamond Shamrock* gave up its chemicals to Occidental Petroleum at the worst possible time, to devote itself exclusively to the energy sector, which in fact failed to live up to expectations.

One of the most powerful of America's chemical companies, *Allied Chemical,* became a high-technology conglomerate under the leadership of Edward L. Hennessy, Jr., who was formerly with United Technology. After acquiring Bendix and Signal, it took on the name of *Allied-Signal* and is now focusing on electronics and space, having entrusted a large part of its chemicals to the portfolio subsidiary Henley, which will sell them to the highest bidder. As for *Monsanto,* it shed a number of fibers, plastics, and petrochemical units both in Europe and in the United States and decided to hinge its further development on biotechnologies, a new area for the group. It bought up in particular the aspartame producer *Searle* for $2.6 billion.

At the same time as these changes were being wrought by the protagonist themselves, other major changes were taking place under outside pressure. Wily businessmen acting as "raiders," with the help of financial concerns that issued high-risk and high-interest "junk bonds" to finance a large share of the targeted acquisitions, set their sights on large companies quoted on the Stock Exchange: they acted in the belief that the company's parts would be worth more sold separately than as a whole.

The raiders' takeover bids had instant attraction for shareholders, and their criticism of the way the firms they were after were being managed was often not without truth. But it stood to reason that once the raiders had bought the company, they would break it up to reduce financial charges and to refund the money borrowed for the raid. The more interesting assets were often the first to be sold off, for they found ready buyers. To counter the raiders, the managers of the targeted firms were likely to raise the ante. But this only aggravated the financial problem, and the group's dismantling was unavoidable.

The instant advantage which both shareholders and raiders drew from these operations was obvious. But their consequence was, sooner or later, to destabilize the enterprises concerned, when these did not disappear altogether. The most spectacular case was *Union Carbide,* coveted in 1985 by the real estate developer S. Hayman, who had already taken over GAF Corporation.

To fight off the raid, Union Carbide had to borrow $3 billion. To reduce such an unbearable debt, the group's management was forced to sell its best sectors (batteries, consumer products, engineering plastics, agrochemicals) and even its headquarters in Danbury, Connecticut. This was how one of the best chemical concerns in the United States, with sales amounting to $10 billion, was left with only three areas of business after divesting to the tune of $5.3 billion. Even these areas—industrial gases, petrochemicals and plastics, and graphite electrodes—were faced with stiff competition. And with debts that still remain three times as high as the industry's average, Union Carbide is in no position to invest in the short term in anything likely to push it back to its former major rank in chemicals.

Other US companies involved in chemicals were also the victims of raiders in 1985. To fight off C. Icahn, *UniRoyal* was taken over by its management and was forced to sell off its chemicals to Avery, which in turn placed them on the block, before accepting a LBO by the management. *Phillips Petroleum* had to buy back its shares from C. Icahn and B. Pickens and was forced to sell $2 billion worth of assets to refund part of its debt. And what about *Gulf Oil,* which sold itself to Standard Oil of California to escape the clutches of Boone Pickens, or *Stauffer Chemical,* which changed hands three times within a single year from Chesebrough-Pond to Unilever and finally to ICI, when it was broken up among ICI, AKZO, and Rhône-Poulenc?

Attracted to the US market, European investors had also joined the raiders' ranks. This is how the Britain-based Hanson Trust managed to acquire *SCM*. This was a company that had just completed its restructuring; but after Sylvachem was sold off by the new owners, it retained only chemical production of titanium dioxide.

Anglo-French tycoon J. Goldsmith, unable to take control of Goodyear, nevertheless made substantial profits from his raid on the company. Goodyear was left with the sole alternative of withdrawing from all the sectors except chemicals in which it had diversified outside of tires.

In a number of cases, transactions led to an agreement between the heads of companies that had stock options and were eager to make a profit, and the potential buyers. This was how *Celanese,* an able and well-diversified company that had the means to retain its independence and competitiveness with regard to any major company, was acquired by Hoechst following a transaction that was satisfactory both to the German buyer and to the shareholders of the American group, at least for the time being.

The fear that their company might be the target of an "unfriendly" takeover bid induced the boards of directors of some of the well-managed chemical companies to guard against such attacks either through deceptively appealing offers—"poison pills"—or through purchase of their own shares. This was certainly not the best for industrial firms to make use of their funds.

Coping with Safety and Environmental Problems

Handling chemicals has never been without danger, if only because of the unstable and harmful nature of a number of substances when they are placed in certain conditions of temperature, pressure, or concentration.

Chemists have always been haunted by the risks of explosion. The explosion which occurred on September 3, 1864, in the Heleneborg laboratory near Stockholm, where Alfred Nobel was handling nitroglycerin, caused the death of five persons, including Emile Nobel, his younger brother. The ammonia synthesis unit set up by BASF within the Oppau plant was totally destroyed in 1921 by an explosion causing the death of over 600 people. In 1946, the French cargo ship *Le Grand Camp,* carrying 2,500 tons of ammonia nitrate, exploded in Texas City, killing 512 people. Other disasters, such as that of Flixborough in England, which took place through rupture of a Nypro caprolactam pipe within the plant in 1974, or again the one caused in a holiday camp in Los Alfaques in Spain when a tank wagon carrying propylene exploded in 1978, are reminders of the explosive nature of certain chemical products and of the need to handle them strictly according to the prescribed security rules.

A number of chemicals, fortunately a limited number, become dangerous either when they are used wrongly, or when they are accidentally set free. *Thalidomide,* put on the market in 1957 by the German company Chemie Gruenenthal, was indeed a powerful sedative. But it took 3 years to perceive that when prescribed to pregnant women, it dramatically crippled the newborn children. The synthetic intermediate for insecticides, *methyl isocyanate,* which Union Carbide has used for years without incident in its West Virginia Institute plant, caused over 2,000 deaths when it escaped in 1984 from a storage tank in Union Carbide's Bhopal plant in India.

Other products act insidiously, so that it is harder to establish their effects on human and animal health and more generally on the environment. Indeed, progress in understanding the safe dosage of minute quantities of impurities has enabled governments to fix with greater care the maximum allowed content of *vinyl chloride monomer, formaldehyde,* and *benzene* beyond which these products could become dangerous for workers to handle.

Lessons have been drawn from accidents caused by faulty handling of certain substances. Through the work carried on by Alfred Nobel, we know how to stabilize nitroglycerin in the form of dynamite, and since 1946 methods have been devised to avoid the spontaneous explosion of ammonium nitrate. Ammonia units with capacities of 1,500 tons a day have been operating for decades without incident.

Because of the painful thalidomide episode, long and costly tests are now carried out to study the possible secondary effects of pharmaceutically active substances. A great number of drugs that today save many lives would not have been available had they needed to go through the long periods of tests that are now required by legislation.

Likewise, in industrial countries, increasingly stringent regulations limit noxious vapor discharge from chemical plants, which are required to treat their effluents effectively. The transport of dangerous substances is also closely monitored by the authorities. Such precautions stem not only from the publicity which the media now gives to any catastrophe worldwide, but also from the public's instinctive distrust of chemistry, which it still regards as a mysterious science.

But just as an air crash does not mean the end of commercial aviation, neither does the damage caused by improper use of certain substances mean the end of the chemical industry. The image of chemicals is tarnished, however. Citizens who deliberately risk their own death, when they are not actually killing others, because of speeding on the roads or because they are addicted to alcohol, tobacco, or drugs, are less and less inclined, for all that, to accept accidental security breaches when these are not caused by themselves.

Politicians in our parliamentary democracies who wish to please public opinion feel the urge to take into account demands that are more emotional than scientific, and advocate restrictions even when these go against the best interests of the citizens. The *Three Mile Island* nuclear power plant accident in the United States which resulted in no fatalities, the more recent *Chernobyl* explosion which, as of 1988 had directly caused two deaths, have, with no good reason, prevented any resumption of the US nuclear program and have aroused fears in European countries in people least likely to give way to mass hysteria.

The *Seveso* leak, which occurred in Italy on July 10, 1976, in the trichlorophenol unit belonging to Hoffmann-La Roche's subsidiary Givaudan, did have an impact on the immediate environment and a number of people were temporarily affected by the dioxin vapors. But the accident caused no lasting harm. It was the publicity which the media gave to it that forced Hoffmann-La Roche to close down the unit, turning Seveso into a dead city.

The litigation over residues left in the ground by Occidental Petroleum's affiliate Hooker, in *Love Canal,* in the state of New York, led to the evacuation of all the area's residents, beginning in 1978. But no clear explanation has yet been given of the ailments some of the inhabitants have been complaining about.

The lack of universally accepted scientific explanations for certain phenomena has often meant that the precautionary measures taken by one country do not necessarily apply in another. Where sweeteners are concerned, for instance, some governments have banned *saccharin* and other governments allow its use. The same is true of *cyclamates* and *aspartame.*

DDT was banned as an insecticide as early as 1974 by most industrial nations. But it is still widely used in many developing countries. The risks of *eutrophication* are perceived differently by governments, so that legislation applying to products for the production of detergents, like *alkylbenzene sulfonate*, *tripolyphosphate*, or *nitriloacetic acid* (NTA), differs from country to country.

The agreement which a number of nations reached in 1987 to ban the use of *chlorofluorocarbons* in aerosols is so far the only instance of harmonized legislation, even though no one has so far managed to prove scientifically that the chlorofluorocarbons (CFCs) really destroy the atmosphere's ozone layer.

Thus while it is understandable that authorities must be careful to soothe the fears of a public that is insufficiently informed of the dangers that threaten it, it must also be aware of the economic and social costs of refusing to accept the risks inherent in any human activity, and also conscious of the uncertainties surrounding the rules and regulations taken to satisfy its demands.

Some companies are turning the necessity of cleaning up the environment into new opportunities to improve their profitability. Thus Du Pont has found a useful application as a building material for the calcium sulfate that was piling up as a by-product in one of its Texas plants.

Scientific and Technological Breakthroughs

Short of fundamental discoveries over the past 15 years, the chemical industry has gone forward by systematically developing its store of knowledge in processes and products.

Process Improvement

Higher crude oil prices had revived studies in the use of coal as a chemical feedstock. But while the Fischer–Tropsch synthesis was still used in South Africa by Sasol, the only other industrial gasification unit was the one Eastman Kodak brought on stream in Kingsport, Tennessee, in 1983, to produce *coal-based acetic anhydride.* The coal came from the Appalachian Mountains and was cheap enough relative to oil prices at the time to warrant such an installation, and the plant is now to be expanded.

Together with these studies on synthetic gas, some progress has been achieved in the use of a group of aluminosilicates, the *zeolites*, as selective catalysts to boost certain reactions. Half the world production of *p*-xylene and a quarter of the production of ethylbenzene, an intermediate required to prepare styrene, are carried out using the zeolite-based ZSM-5 catalysts developed by Mobil Oil, which played a pioneer role in this area.

Applications of the olefin *metathesis* reversible chemical reaction, discovered by Phillips Petroleum in the 1960s, were also developed in the subsequent years. By this reaction, Arco produces propylene from ethylene and butene-2; Hercules prepares its plastic, Metton, from dicyclopentadiene; and Shell synthesizes its C_{12}-C_{14} SHOP (Shell Higher Olefin Process) alcohols used for detergents.

The application of *electrochemistry in organic synthesis* had already served to bring on stream in the United States in 1965 Monsanto's first industrial adiponitrile process from acrylonitrile. This was followed in 1977 by a similar installation in Seal Sands, England, which was later bought up by BASF.

The former *Reppe chemistry,* still practiced in Germany by BASF and in the United States by GAF, also led to new developments as demand for certain intermediates such as the 1,4-butane-diol increased. This diol, now also obtained from maleic anhydride, is used to produce PBT polyesters through reaction with TPA acid and leads to other major derivates (tetrahydrofuran, butyrolactone, *N*-vinylpyrrolidone).

New synthetic processes for the preparation of established products were also industrially developed: in Japan the manufacture of methyl methacrylate from C_4 olefins, by Sumitomo and Nippon Shokubai; in France, the simultaneous production of hydroquinone and pyrocatechin through hydrogen peroxide oxidation of phenol by Rhône-Poulenc; in the United States the production of propylene oxide through direct oxidation of propylene operating jointly with styrene production, developed by Ralph Landau and used in the Oxirane subsidiary with Arco, which the latter fully took over in 1980; in Germany and Switzerland, the synthesis of vitamin A from terpenes, used by BASF and Hoffmann-La Roche.

Processes apparently well established were still further improved, such as the *electrolysis of sodium chloride,* dating back to the last century: diaphragm and then membrane cells were substituted for mercury cells, which were a possible source of pollution.

Important progress was also made in *chemical engineering,* such as use of rotary compressors in ammonia synthesis or ICI's fermentation reactors in Billingham to produce the Pruteen protein from methanol reactors, having no mobile parts.

Product Development

Although research was not as fruitful after 1960, new materials put on the market in the 1970s were the outcome of research in high polymers essentially conducted within industry.

It was through such research that ICI's PEEK (polyether ether ketone), one of the first high-performance aromatic polymers, was put on sale, as well as Du Pont's aramide fibers Nomex and Kevlar, more resistant than steel in like volume.

To the range of engineering plastics were added polyethylene and polybutylene terephthalates (PET and PBT), as well as General Electric's poly ethers, the PPO (polyphenylene oxide) produced through polymerization of 2,6-xylenol and the Noryl plastic produced by blending PPO with polystyrene. Other special polymers, derived like the polycarbonates from bisphenol A, were added to this range: polyarylates, polysulfones, polyetherimides.

A major step forward was taken in the area of base thermoplastics with the application of Union Carbide's Unipol process. Variations of this were subsequently offered by other LDPE producers such as Dow and CdF Chimie (now ORKEM).

Under a process that consisted in copolymerizing in the existing high-pressure installation ethylene with 5–10% of an *α-olejin* (butene-1, hexene-1), a stronger linear LLDPE was produced with a higher melting point than LDPE. Thinner films could thus be produced that were just as strong but required less material.

The new polymers opened up an unexpected market for producers of C_4, C_6, and C_8 α-olefins like Shell, Ethyl, and Chevron. Their higher linear α-olefins were also used either for polyalphaolefins (PAO) intended for synthetic lubricants or to prepare detergent alcohols.

While no great new plastic has emerged over the last 15 years, researchers in major chemical companies did their utmost to improve both the features and the performance of known polymers.

As we have just seen, they improved LLDPE by adding comonomers in the carbon chain. But also through additives they managed to render polymers more resistant to fire, to oxidation, and to alteration through ultraviolet rays.

This slowly gave rise to a new industry that consisted in supplying polymer producers and plastic processors, not only pigments and charges, but also antioxidants, light stabilizers, and fireproofing agents. Added in small doses to the polymer, they added to its value by extending its life span. Such an activity, in which the Swiss firm Ciba-Geigy plays a noteworthy role, was boosted by the spectacular development of polypropylene, a particularly sensitive polymer that has to be stabilized with appropriate additives.

Another way of improving the performance of polymers consisted in blending them either with other polymers or with inert materials such as glass fibers, carbon fibers, or various mineral fillers. Thus were produced a series of *alloys and composite* materials. Glass fiber-reinforced polyester has long been in common use. But the possibility of introducing carbon fiber obtained through pyrolysis of polyacrylonitrile (PAN) fibers already developed in aeronautics, opened up fresh prospects, particularly in the area of sports articles. The need, in turn, to link organic polymers and mineral fillers led to coupling agents such as the silanes which Union Carbide and Dynamit Nobel have put on the market.

This is how, little by little, spurred on by the demands of the processing industries which are also under pressure from major clients like the automobile industry, a number of companies have brought a large number of improvements to plastics. While not very spectacular, these improvements have appreciably added value to existing materials.

More generally, the requirements of many downstream industrial sectors have hastened the development of derivatives that otherwise might have remained laboratory curiosities. Discoveries of new molecules have been particularly inspired by the needs of plant protection. This was because agriculture, before it became a crisis sector, offered worldwide markets for crop protection agents, and also because product approval was easier to obtain, and therefore less costly, than in the case of pharmaceuticals. The success of glyphosate, which Monsanto put on the market in 1971 under the trade name Round Up, has made it the world's leading selective herbicide, for it can be used throughout the year and becomes harmless when absorbed into the ground. A new range of synthetic pyrethroids, developed in the United Kingdom by Elliott of the National Research and Development Corporation (NRDC), a government agency, was marketed from 1972 onward under the trademarks of Permethrin, Cypermethrin, and Decis. These wide-spectrum insecticides owe their success to the fact that they are exceptionally active in small doses and are not toxic to humans. With increasingly strict legislation and stiff competition among pesticide producers at a time of slumping agricultural markets, the golden days could well be over for crop protection products, so that the years ahead are likely to be more favorable for restructuring than for new discoveries.

Over the last 15 years, the *pharmaceutical sector* also made great demands on the ingenuity of chemists. But from the time of the thalidomide drama, the testing times required by health authorities have increased, to the point that since 1980 10–12 years are needed instead of the three to four previously required to bring a drug on the market from the time of its discovery. Research and development costs, accordingly, have grown fourfold over the last 10 years, dangerously reducing the number of new specialties provided for patients each year. Because of such delays, a patent protecting a new substance may be left with but a few years of validity when final approval is granted to the laboratory that made the discovery.

Such difficulties have apparently not affected the zeal of researchers. Nor have they diminished the sums devoted each year to research and development, which on the contrary have been constantly on the increase. This is because any major discovery may have worldwide portent. And in most developed countries there is a system of refunding to patients the cost of ethical drugs, so that a new active principle may provide the laboratory that has exclusive rights over it with a considerable source of profits even if such refunds are coupled with tight price controls.

And while it is also true that 30 pharmaceutical companies alone account for 60% of worldwide ethical drug sales, the sums of money invested in research do not always get their full return. Thus it is that a small company like Janssen's laboratory, Janssen Pharmaceuticals, in Belgium, which was acquired in 1979 by Johnson and Johnson and which has among its discoveries diphenoxylate (1963) and loperamide (1975), has proved more innovative over the last 15 years than the Rhône-Poulenc group, which has produced no major new molecule during the same time, although it devotes far more money to its research.

Indeed, success depends at least as much on chance, the ability of researchers, and the strategy of management in that area as on the sums expended. Valium and Librium, which have been providing Hoffmann-La Roche with its largest profits since the end of the 1960s, were the outcome of Leo Sternbach's acumen. Instead of merely modifying the meprobamate molecule as management had requested, he began studying the sedative properties of benzodiazepines used as dyestuff intermediates and on which he had worked for 20 years previously at Cracow University.

One of the most prolific inventors of the 1960s was most certainly Sir James Black, a Nobel laureate in 1988. While working for ICI, he discovered the first β-blocking agent Propranolol in the early 1960s. He also discovered Cimetidine, sold under the trade name of Tagamet as an antiulcer agent by SmithKline & French from 1974 onward, and which has become the world's largest selling specialty. After working successively for ICI, SmithKline & French, and for Wellcome in Britain, Sir James now has his own business, and he is convinced that small competent teams are, by nature, more innovative than the large armies of researchers which many of the big companies have set up.

Likewise, the successful ventures of Merck Sharp & Dohme cannot be dissociated from the work of its president, Roy Vagelos. This biochemist, a latecomer to research, supervised the whole process of work to bring Mevacor, the new cholesterol miracle drug, onto the market. It has just been approved by the US Food and Drug Administration. Mevacor was but the crowning touch to Merck's scientific tradition with its long series of discoveries: α-methyldopa against hypertension, indomethacin and sulindac to fight arthritis, and cefoxitine, an antibiotic.

At a time when pharmaceutical research is becoming increasingly costly and the likelihood of a great discovery remains hazardous, success will come to laboratories which not only sink large sums of money into research but also rely on teams where competence does not necessarily rhyme with size, and whose management has reached a sufficient level of scientific maturity.

The Craze for Biotechnology

The catalytic action of living organisms, or rather of the proteins they contain, had received the beginnings of an explanation with the experiments of Payen and Persoz on malt amylase separation in 1833 and with JJ Berzelius's catalyst theory in 1835. In 1897 Eduard Büchner demonstrated that a yeast extract could turn sucrose into ethyl alcohol. Fermentation took place without the presence of living organisms through enzymes. In this case zymase was the catalyst.

Ethyl alcohol, already known to alchemists, was used by industry towards the middle of the last century when continuous distillation in columns was devised by Ireland's Aeneas Coffey in 1830 and when it became exempt from excise duties on alcohol if methanol was added to it.

After alcohol, *lactic acid* was the second product obtained industrially from sugar fermentation, starting in 1880. The levo-isomer is still made this way to the tune of 20,000 tons a year.

In 1890, the Japanese chemist Jokichi Takamine had introduced a fermentation process in the United States by which an enzyme blend was produced. This takadiastase catalyzed starch and protein hydrolysis. Some years later in 1913, Boidin and Effront discovered the *Bacillus subtilis* that produced an *α-amylase* stable under heat. This enzyme was used to desize cloth and later in the sugar fermentation process.

During World War I, Chaim Weizmann had succeeded in producing for the British Admiralty acetone and butanol on a large scale through anaerobic fermentation of starch. The Germans were then producing as much as 1,000 tons a month of glycerin from sugar. These war productions proved no longer competitive in peacetime. But *citric acid,* which Pfizer began producing in 1923 from sucrose, is still biochemically made today from *Aspergillus niger,* which Currie advocated in 1917.

The discovery of *penicillin* and its industrial development during World War II have led the pharmaceuticals industry increasingly to resort to *biosynthesis* for the preparation of its active principles. Through rigorous selection of the microorganisms extracted from the soil or from various molds, the cost of an antibiotic like penicillin has been brought down to $30 per kilogram, compared with $25,000 per gram initially—an impossible target if the exclusively synthetic process had been used. Moreover, it became possible to extend the range of antibiotics that could be used. The antianemia *vitamin* B_{12} and most of the amino acids were prepared in the same way through culture of microorganisms in selected environments containing precursors.

In the case of *steroids,* biosynthesis permitted reactions that could not be achieved through direct synthesis. In 1952, this was how Upjohn researchers in the United States managed to introduce on carbon atom 11 of the steroid nucleus, a hydroxyl group –OH, using the *Rhizopus arrhizus* fungus, making the switch from the pregnancy hormone progesterone to cortisone and its derivatives.

Microorganisms are also capable of separating optical isomers. In the case of sodium glutamate, where it is necessary to start from levo-glutamic acid to obtain the desired flavor, and where synthesis produces only a racemic blend, it was a particular yeast called *Micrococcus glutamicus* that led to the required isomer through carbohydrate fermentation.

Considering that sodium glutamate, like other amino acids, is contained in soy sauce, which is a traditional Japanese food, it is not surprising that Japan should have become interested very early in this type of fermentation. Firms like Ajinomoto and Kyowa Hakko dominate the world market for amino acids and particularly for *glutamic acid* and *L-lysine*. It is also through enzymes that the resolution of *DL-methionine* into its optical isomers is achieved since its laboratory synthesis yields the racemic form.

Heat-stable amylases are frequently used in both the United States and Japan to produce *syrups with a high fructose content* from corn starch.

Single-cell proteins such as ICI's Pruteen were produced through culturing microorganisms on a bed of organic material.

Interest in biosynthesis grew still further with the discovery in 1953 of the structure of DNA, then in the 1960s of the genetic code of proteins. It then became possible to clone microbe or plant cells, through *genetic engineering,* by recombination of fragments of genetic material from different species. Thus, towards the end of the 1970s, the biotechnology firm Genentech succeeded in isolating the human insulin gene and to insert it into the DNA of the *Escherichia coli* bacteria: through reproduction, these bacteria produced the *first human insulin,* which Eli Lilly and Company has been marketing since 1982.

The *human growth hormone* (HGH), which can only be extracted in minute quantities from the pituitary glands, can now be isolated in larger quantities through genetic engineering.

Monoclonal antibodies (mabs), which replicate the antibodies in the organism with the added advantage of being "immortal," were discovered in 1975 by scientists working at the Cambridge Medical Research Council in the United Kingdom. They serve more particularly as reactive agents for medical diagnostic purposes.

Through *plant genetics,* it has also been possible to render plants resistant to chemical agents (Calgene, Monsanto) as well as to improve crop yields (Pfizer) with new seeds.

With the prospects which *biogenetics* was opening up for medicine and agriculture, a number of private laboratories sprang up in the United States between 1971 and 1978—*Genentech, Cetus, Genetic Institute, Biogen, Amgen*, and *Agrigenetics* to mention but the principal ones. These laboratories managed to finance their work with the help of venture capital, research contracts with the major chemical firms like Du Pont, Monsanto, Eastman Kodak, W.R. Grace, or shares purchased on the stock exchange.

Vast sums of money have been spent over the last 10 years but with small tangible results, prompting the definition of biogenetics as a business likely to bring in a small fortune as long as a large one is invested! Thus far the only commercial fallout of biogenetic research involved human insulin (Eli Lilly), the human growth hormone (Genentech, KabiVitrum), the hepatitis B vaccine (Merck, Smith, Klein-RIT), interferon (Boehringer, Ingelheim), the amylase enzyme (Novo), a number of veterinary vaccines (AKZO Pharma), and monoclonal antibodies for diagnostic reactive agents. Hopes raised by interferon and interleukin-2 as cancer cures have not materialized, but the tissue plasmogen activator (TPA) as a blood clot dissolver in heart attacks was approved by the US Food and Drug Administration (USFDA).

Plant genetic research is encountering opposition from the US Department of Agriculture and the Environmental Protection Agency. Pressured by environmentalists, the US administration is loath to approve developments which could affect the environment in unknown ways. In addition to these administrative obstacles, there is uncertainty over patent rights, for there are no legal precedents. Finally, the biocompanies recently set up will need to associate with large pharmaceutical groups to develop and market the products born of their research.

Generally speaking, although *biotechnology* has acquired credibility in many areas, its development is being slowed by scientific, economic, and administrative obstacles. First and foremost, proteins are complex substances that cannot be handled as easily as the simple molecules involved in traditional organic syntheses.

It is true that Japan's Ajinomoto and Kyowa Hakko, in particular, have become masters of the art of producing amino acids. Likewise, enzymes have remained the specialty of Novo (now Novo Nordisk) in Denmark, Gist Brocades in Holland, and Bayer's subsidiary Miles in the United States, which together account for 60% of the world needs in the area.

Even when they are technologically sound, however, bioproducts may turn out to be economically uncompetitive. The profitability of L-lysine from 1 year to the next, for instance, depends on soy market prices. In the same way, the single cell proteins which BP produced in 1963 in Lavera from a petroleum base, using a process developed by France's Champagnat, never managed to compete with soy cakes for animal food. ICI has also just been forced to close down its 50,000-ton Pruteen unit in Billingham.

At current crude oil prices, the production of ethanol from biomass is not profitable, either. Whether produced from beets, sugar cane, or corn, it can become competitive only if it is subsidized. And these subsidies would only be forthcoming for political reasons: to please their farmer voters, the French, Brazilian, and United States governments would adopt such a policy to absorb excess agricultural products. From cereals, corn in particular, starch is produced and hydrolyzed to form glucose which ferments to ethanol.

Powerful groups like American Corn Products and France's *Roquette Frères* produce starchy matters in this way. The former is also the leading producer of *isoglucose* (a blend of glucose and fructose) in the United States, while the latter is the largest producer of *sorbitol.* Starch can, therefore, compete directly with saccharose both for foodstuffs and for industrial uses as a fermentation or enzyme-reaction base.

This gives rise to a permanent conflict in Europe between the starch manufacturers on the one hand and the sugar and beet refiners on the other, a conflict that the EEC Commission with its *Common Agricultural Policy* of quotas and subsidies has been unable to settle. The only point of agreement between the two parties is the price which they demand for their production from downstream community industries, a price that is far higher than world rates.

Spurred on by the Italian sugar group Ferruzzi-Eridiana, Montedison's and now Enimont's main shareholder and an associate of France's Béghin-Say sugar group, there is a campaign under way to introduce ethanol into gasoline. Farmers, of course, support the move because incorporating 7% of ethanol in gasoline would mean for a country like France the use of two million tons of sugar or four million tons of cereals. But ethanol happens to be in competition with methanol and the new MTBE antiknock agent as a gasoline additive. More important, a tax rebate would be needed at current gasoline prices to induce the oil industry to incorporate ethanol in prime rate gasoline. So the "farm" lobby can receive satisfaction only at the expense of the taxpayer, whether American, Brazilian, or European.

The rules that have always governed the use of ethanol, government policy favoring one agricultural raw material over another, the new constraints that limit the marketing of genetically engineered products—all these factors serve to remind those interested in the development of biotechnology how narrow is their room for maneuvering.

The Fine Chemicals Approach

In their search for products that could provide better margins than those achieved from commodity chemicals, the industry had hit upon *fine chemicals.* These typically involved derivatives from organic synthesis obtained in multipurpose units and sold in relatively small quantities at high prices.

The German and Swiss *dye manufacturers* (Hoechst, BASF and Bayer, as well as Ciba-Geigy and Sandoz) were in the most favorable position to develop such advanced chemicals. They had a long tradition behind them of multiple-stage syntheses involving intermediate derivatives that could also serve to prepare pharmaceutically active principles or pesticides. Starting from a number of major raw materials and working according to the chemical-tree concept, these producers can work down the line to well-defined molecules which they use in their own downstream production or sell as synthetic intermediates to outside clients.

In Europe, the giant ICI group, which had retained a strong position in dyes, also became involved in this kind of chemicals.

France, with PCUK having closed down in 1980 its Société des Matières Colorantes in Mulhouse and then having sold Société Francolor to ICI, had restricted its ambitions in this area. It retained only a few products of Rhône-Poulenc and of its 51% subsidiary *Société Anonyme pour l'Industrie Chimique* (SAIC), located in Saint-Fons and in Mulhouse-Dornach, respectively.

As was to be expected, the US chemical leaders, Du Pont, Allied Chemical, American Cyanamid, GAF, and Tenneco Chemicals, had all withdrawn between 1976 and 1979 from the dyes sector. Only three medium-sized companies were still active in this area: *Crompton & Knowles, American Color,* and *Atlantic Chemical.*

Yet at the end of World War II, America's dye production had been the leading one worldwide. For over 30 years it had enjoyed high customs tariffs protection through the American Selling Price clause. But dyes were produced by giant companies used to large-scale continuous productions. Their engineers were not trained to run month-long syntheses campaigns involving many stages. Moreover, American marketing executives were little attracted to the German methods for "motivating" their clients. There was also the fact that during the 1960s, the US dye manufacturers had come to rely on imported intermediates. With rising prices and the textile slump, they found themselves caught between rising purchase costs and falling selling prices. Finally, unlike their European counterparts, the US manufacturers had never given international scope to their dye business. It remained restricted to the home market.

For all these reasons and also because they were not tied down like the Germans by any prestigious tradition, they unhesitatingly gave up dyes, losing at the same time the know-how needed to succeed in fine chemicals.

With more modest means, other firms were more successful. They either developed their own "chemical tree" or put to good use the know-how acquired through development of certain processes.

Ethyl became a bromine and derivatives specialist and an expert in orthoalkylation (orthoalkyl phenols and anilines). Its acquisition of Dow's bromine activities has given Ethyl a leading role in this field. *DSM* developed its fine chemicals from the benzoic acid produced during manufacture of synthetic phenol by toluene oxidation. *Atochem* took advantage of the sulfur resources of its parent company Elf Aquitaine to build up successfully a thioorganic chemicals industry (thioglycol, mercaptans, DMSO). Its position will be further strengthened by the takeover of Pennwalt. *PPG* in the United States and *Société Nationale des Poudres et Explosifs (SNPE)* in France are producing a wide range of phosgene-based derivatives to be used in the most varied manner (carbonates, chloroformates). More than any other company, *Lonza* has extended its range of fine chemicals (diketenes, HCN derivatives, pyrazoles, pyrimidines). *Reilly Tar* has become a world leader in pyridine and derivatives. *Dottikon* in Switzerland and *Kema Nobel* in Sweden have put to use their nitration experience to extend their range of nitrated intermediates. Among others, *Rhône-Poulenc* and *Montedison* are involved in organic fluorine derivatives while *Hüls*' fine chemicals division has specialized in alkylation, hydrochlorination, and catalytic hydrogenation.

Thus a number of firms with special know-how in a family of products or in processes that were not among the biggest have succeeded in taking a more than honorable place as suppliers of fine chemical derivatives alongside the organic synthesis specialists originating from the dye business.

The Attraction of Specialty Chemicals

Besides fine chemicals sold according to specifications but accounting for only a small part of the sales of major companies, *specialty chemicals* held attractions for companies wishing to diversify. These chemicals involved substances or mixtures whose composition mattered less than the function for which they were intended: the test of success lay in performance. Thus old family businesses or more recent companies born of a leader's entrepreneurial spirit had been successful in performance products, whether these were paints, inks, or glues; or in specialties, cosmetics, detergent, or electronics industries.

Indeed, not much capital is needed to manufacture specialty chemicals compared with what is required for commodity chemicals. The development of new products is both quicker and less costly than it would be to find new processes for large-volume products or to bring to the market an original active principle for an ethical drug.

This largely explains why specialty chemicals managed to remain until the early 1970s products for medium-sized private companies. In the long run, however, the internationalization of trade, the size of advertising budgets for consumer products, and the necessary adaptation to new technologies requiring highly qualified personnel all called for funds that were not always available to family businesses. Many small owners were forced to sell out, and their need coincided with the attraction they held for large chemical groups trying to diversify away from heavy chemicals. They hoped to find in specialty chemicals the profit margins which their traditional branch of chemicals no longer supplied.

Barring a few exceptions such as *Gulf Oil* or *Diamond Shamrock,* which withdrew from downstream chemicals, all the major companies, both in Europe and in the United States, decided to make specialty chemicals a priority in their development strategy. In truth, some of them had not waited for the energy crisis for them to take a firm foothold in the specialty market.

In the United States, *Du Pont* and *PPG* had a long-established reputation in industrial and consumer paints. *W. R. Grace* since buying Dewey & Almy, and *Rohm & Haas* because of its age-old tradition in acrylics, drew substantial profits from their specialties. This was also true of *American Cyanamid* (additives for plastics, cosmetics) and of *Monsanto* (products for rubber, special polymers). Since its withdrawal from the tire business, *BF Goodrich,* aside from its PVC lines, is concentrating now on specialties.

In Europe, ICI had already acquired a large paints sector (Duco, Dulux). The three major German leaders—*Bayer, BASF,* and *Hoechst*—had not yet made great inroads into the specialties market, but the Swiss *Ciba-Geigy* could be said to be particularly well established in certain areas like additives for polymers, in which it was a world leader. *Rhône-Poulenc* had assembled some of its activities within a "chemical specialties" division. But on the whole, they could be said to be offshoots of fine chemicals rather than actual specialties, with the exception of the performance products brought out by subsidiaries such as Orogil, SFOS, Soprosoie, and Vulnax. Orogil is now fully owned by Chevron, however, and Vulnax has been acquired by AKZO. Failing to develop through internal growth, *AKZO* had very early developed its specialties by buying up companies involved in peroxides, paints, oleochemicals, and now rubber additives.

To increase their specialty sectors as fast as possible, the leaders of large companies found it more expedient to do so through acquisitions. The prices paid for the most interesting purchases can be considered high because, very often, they amounted to 15–20 times the profits. But the financial sacrifices made by the buyers seemed worthwhile, for they gained a foothold in the market without the long preliminary work that would otherwise have been needed.

There were, of course, many companies that were sufficiently important or prosperous to escape being bought up. Even then their independence was often at stake. Thus *Nestlé* took a share in the cosmetics group *l'Oréal*; and in the United States, the raider Perelman managed to buy *Revlon.*

Considering that the grass always looks greener on the other side of the fence, for many leaders of the chemical giants diversification into new areas might seem more attractive than mere concentration in well-known sectors; and it was in this sense that specialty chemicals seemed a good proposition. In 1983, *Olin* began to get involved in electronic chemicals by buying up 64% of *Philip Hunt Chemicals* and took a firm foothold in the sector through successive acquisitions. Other groups became interested in enhanced oil recovery and exploration, for the future of oil seemed assured at the time. In both cases, however, the electronics and oil exploration slowdown did not confirm established forecasts. The investments made in these areas have yet to prove their profitability.

Moreover, many firms were unable to contribute anything except capital to the development of sectors far removed from their traditional areas of business. They became discouraged and ended by selling out, not without suffering heavy losses. *Hercules* was seen to back out of its water treatment sector and *Rhône-Poulenc* from its very recently acquired media business.

Even when the businesses acquired are not too different, trouble can arise through disagreement between the new owners and the former boss of the purchased firm over how to manage it. The former tries to impose his own personnel and procedures, while the latter, used to making his own decisions, is unable to fit into a large unwieldy concern. As a large part of the worth of an acquisition in specialty chemicals lies in the competence of the personnel involved, some purchasers have understood that it is to their benefit to leave the day-to-day running of the business to those who have already shown their worth and to centralize only those activities related to the financing of new investments. This was how *Witco* proceeded in the United States, most likely because the father of the current president had founded and built up the business to the point of making it one of America's leading specialty concerns.

ICI followed the same policy when it bought *Beatrice Chemicals* for $750 million in 1985. But in this case, it was important to delegate power, because Beatrice Chemicals consisted of ten distinct companies established in 18 countries and involved in different businesses (composite materials, vinyl resins for paints, leather auxiliaries). Keeping in mind that cultural differences may produce problems that are not always easy to solve, the strong involvement of the big chemical groups in the specialties area over the past years had drastically changed the structures of the sector.

The Paint Industry

Few industries have been as affected by the restructurings of the past 10 years as the paint industry. The extension of markets worldwide owing to the multiplication abroad of client factories of this industry, the technological revolutions brought about by the introduction of electrophoresis, of water-based lacquers, and of powder coatings had the twin effect of pushing the chemical leaders to expand worldwide in this area and to lead those paint companies that were still independent to sell out for want of the funds needed to develop their research base. *ICI*, which was strongly established only in Britain and in the Commonwealth, became the world's leading paint producer with 750 million liters after buying *Valentine* in France and, especially, the *Glidden* division of the US-based SCM for $580 million in 1986.

PPG has been pushed back to second world position with 450 million liters. But with its 100% stake in France's *Corona* and its controlling share in Italy's IVI and in Germany's Wülfing, the US-based PPG has maintained a comfortable technological lead in the application of cataphoresis in automobile bodies, accounting for 60% of the world market in this specialty.

Through its costly $1 billion purchase of America's *Inmont, BASF* has become the world's third-ranking paint producer, leaving behind its German Rival *Hoechst,* which was too busy bailing out its British subsidiary Berger Paints to get a foothold in the US market.

AKZO, which holds an honorable place among the leaders, has not been able to penetrate the United States market, either. Most of its recent acquisitions (Blundell, Permoglaze, Sandtex, Levis) were European.

Other companies with comparable 250-million-liter paint capacities are Japan's *Nippon Paint* and *Kansai Paint,* as well as America's *Du Pont.* These three firms, however, have restricted their ambitions to filling the needs of their home markets. With a broader international base, Courtaulds' subsidiary, *International Paints,* ranks among the top ten, although it is mainly involved in the very special sector of marine paints.

Ranking fifth in the world with its 300-million-liter capacity, *Sherwin Williams* is the only large paint company that has retained its independence. It remains focused on the United States, essentially in the decoration market.

Although France is the world's third largest market for paints after the United States and Germany, none of its national manufacturers has thought of striking out beyond its frontiers. Indeed, most of the French companies involved in the sector, with the exception of *Blancomme* and *IPA*, have been taken over by foreign groups when they were not merged within state-controlled entities. *Astral Celluco* was one of the first to sell out to AKZO, *Corona* was taken over by PPG, *Celomer* by International Paints, *Bichon* and *Lefranc Bourgeois* by Sweden's Becker, *Valentine, Julien, Galliacolor* by ICI, *Ripolin Georget Freitag* became part of the *CdF Chimie* group as did *Duco* which has just been sold to *Casco Nobel,* while *La Seigneurie* was taken over by *Elf Aquitaine*.

In 1988 CdF Chimie, later known as ORKEM, took over full ownership of AVI, a profitable company specializing in decorative paints. Another subsidiary of ORKEM was *Lorilleux,* an ink manufacturer merged in early 1988 with *Coates Brothers* to become the third largest group in its field after Dainippon Ink Company (DIC) of Japan and Germany's BASF.

It must be pointed out that all the international groups involved in paints and inks on a worldwide basis produce, in addition, most of the resins and binding agents needed for their formulations. Only the solvents and pigments are likely to be partly brought in from outside sources. The restructuring of the paint industry has, accordingly, been to the advantage of the new groups. On the one hand, it reduced the number of producers and extended the range of products these producers were putting on the market, and on the other, it supplied a captive market for their resins which, until then they had mainly sold to outside customers.

Surface-Active Agents

Used for their good performance, more often than not in formulations, surface-active agents can be classified as specialties even though the quantities consumed in certain cases might connect them with commodities. The structure of the major part of the detergents industry has remained rather stable over the last few years despite some frontier adjustments. The *washing powder* sector, where advertising costs are considerable, is dominated by a small number of substantial soapmakers who came into business as far back as the nineteenth century: the American companies *Procter & Gamble* and *Colgate,* the Anglo-Dutch group *Unilever,* and Germany's *Henkel*. They are all, in various degrees, involved in the major world markets.

Then there are the Japanese companies *Kao Soap* and *Lion Oil,* which remain confined to their own home territory and to a few Southeast Asian countries. Behind these giants, a number of firms catering to their home markets stand out, such as *Purex* in the United States or *Benckiser* in Germany.

As in paints, France is curiously absent from the area. Since Germany's Henkel recently took over the detergents division of the *Lesieur-Cotelle* group and its trademarks Mir, La Croix, and Persavon, after buying up the Savon de Marseille soap flakes of *Union Générale de Savonnerie* (UGS), the French market is now 94% supplied by the big international soapmakers. The few remaining national firms such as *Chimiotechnic* merely sell their products through the supermarkets.

While the sector now seems to be structurally stabilized, washing powder components are fast changing to take into account the new rules and technologies laid down both by governments and consumers. For the companies which supply the soapmakers, these new rules and regulations are having major consequences throughout the world. Just as the requirement of biodegradability had doomed the use of *branched-chain alkylbenzenes* in industrialized countries in the 1960s and caused the shutdown of a large number of dodecylbenzene sulfonate units, so the new rules established by some governments against *tripolyphosphates* in Europe and elsewhere to ward off eutrophication are likely to wipe out the several-hundred-thousand-ton markets of producers like Rhône-Poulenc, Benckiser, Knapsack, or Montedison.

Replacing TPP by new formulations based on *polyacrylic acid* and *maleic anhydride* would, on the other hand, greatly boost companies like Atochem and BASF, which are very much involved in acrylic chemicals. Likewise the use in Europe of washing machines at temperatures that do not exceed 50–60 ºC, like the ones now used in the United States, should have immediate consequences for the formulation of washing powders. *Perborates,* used extensively in Europe as bleaching agents ever since Henkel invented Persil in 1907, are not very efficient at such low temperatures. Activators such as ethylenediamine tetraacetic acid (EDTA), produced by Warwick in England, are needed to hasten decomposition. *Enzymes* which had been very popular in the 1960s in the United States and Europe, then had disappeared in 1971 because they were considered harmful to the skin, have been reintroduced in washing powder formulations because they do help remove certain stains.

The use of *liquid detergents* is more widespread in the United States, where they account for 20% of the market, than in Europe, where their share does not yet exceed 8% on an average. This has consequences on the consumption of nonionic derivatives.

Different habits as well as different regulations have therefore led to frequent changes in the chemicals supplied to soapmakers. Few industries have changed as much as the detergent industry since the end of World War II as it shifted from soap to synthetic detergents, from branched alkyl benzenes to linear alkyl benzenes, from anionic to nonionic. TPP and enzyme regulations were changed; preference was given at times to perborates, at others to chlorine-based products such as bleaching agents.

To develop surface-active agents for industrial use did not require the same financing as was needed for washing powder consumer products. Therefore, producers of all sizes could become involved. Some of these producers were chemical giants who had gone into the business because they had the available raw materials or the right markets. Indeed, surface-active agents use a number of major raw materials to which suppliers attempt to add downstream value.

In Europe, for historical reasons, large chemical groups have become involved in this area. Thus the dye manufacturers had very early added to the range of products sold to the textile and leather industries, wetting agents, softeners, and dye auxiliaries. *BASF*—a pioneer in synthetic auxiliaries with its Nekal, patented in 1917—*Hoechst, Bayer,* and *ICI* were in fact interested at the same time in the markets which surface-active agents opened for their ethylene oxide, higher alcohols, sulfonating agents productions, and in the fact that they help provide better services for their traditional textile clients.

Hüls, the subsidiary of the German holding company VEBA, had no dye tradition. But it nevertheless acquired the Dutch surface-active unit Servo to ensure captive use for at least part of its ethylene oxide and alkyl benzene production. *BP* followed a similar line when it took over the Belgian company Tensia, selling back some of its product lines to ICI. Already involved in surface-active products through its Lissapol for many years, *ICI* has expanded in this sector by buying *Atlas Powder* and its special range of Tweens and Spans. *Shell*'s interest in surface agents went back to the development of its Teepol. It completed its range with ethoxylates, the "neodols" which used both its higher alcohols and its ethylene oxide. *Montedison* was also involved in surface-active agents through its stake in *Mira Lanza*.

In France, however, there was no vertical integration between the great national chemical industry and the surfactant sector. Producers of the latter had to find the necessary feedstock—whether ethylene oxide, alkylphenols, fatty acids, or higher alcohols—from rival companies, while for instance a medium-sized company like Berol Chemie in Sweden, recently acquired by Nobel Industries, had its own source of ethylene oxide, amines, and nonylphenol in Stenungsund to feed its surfactants division.

In the *United States,* vertical integration was not as thorough as in Europe. Although ethylene oxide producers like *Union Carbide, Dow,* or *Texaco* also had their range of ethoxylates, it was mostly specialized firms that produced the surface agents for industrial uses. The same was true in Japan, although a number of producers such as *Nippon Oil & Fats* for fatty acids, *Kao Corporation* and *Lion Corporation* for fatty alcohols and amines had direct access to their main raw materials.

Thus in addition to the large chemical and petrochemicals companies that had chosen downstream integration, there were a number of important surfactant producers that, in varying degrees, were integrated upstream. The most striking example of this, besides the three Japanese companies just mentioned, is Germany's *Henkel.* Its natural fatty alcohol production exceeds 170,000 tons capacity, and besides fatty acids, it produces its own range of carboxymethylcellulose-based thickeners. Recently Henkel even associated in this area with Hercules within a company called *Aqualon*, now fully owned by Hercules, and acquired from Quantum Chemicals in the United States their fatty acids subsidiary *Emery Industries.*

A number of surfactant specialists have also chosen the market approach. Because they are not tied down by their own produced raw materials, they can use those that are the most suitable for the type of surfactant they wish to offer their clients.

An independent producer like the US-based *Stepan* is in a position to provide a complete range of anionic, cationic, and nonionic agents because it has flexible units in four areas of the United States as well as one in southeastern France in Voreppe.

Witco is in the same position, but its own policy has been to develop through acquisitions rather than through internal growth, buying Humko Chemical and Onyx Chemical.

Right from the start *GAF* acquired, from IG Farben, experience in surfactants still of use today. This activity sector, however, was sold to Rhône-Poulenc in 1989.

With a market lacking the uniformity of the United States market, the European producers serve in greater numbers clients with standards and habits varying from country to country. The Tenneco group's *Albright & Wilson* has had to cover France, Italy, and Spain with its *Marchon* subsidiaries. Germany's *Hoechst, Henkel,* and *Schering*, which bought up *Rewo,* also have a number of subsidiaries abroad that produce their surfactants. Hüls's subsidiary *Servo* has only the single production unit in Delden, Holland. But because of the high concentration of its products, Servo manages to carry out three quarters of its sales abroad.

While the range of products offered by these companies is very wide, some of them, nevertheless, focus on specific sectors. Thus the cationic technology acquired in the United States from Armour by *AKZO* and from Ashland by *Schering* has given both these companies a dominant position in the market of textile softeners both in Europe and in the United States.

Companies like *Rhône-Poulenc, Berol,* and Witco are, for their part, interested in the pesticide formulation market. Fatty amines are in the hands of such European firms as *AKZO*, *Kenobel* (Nobel Industries), and *CECA* (Atochem).

Other European companies, such as *ICI* through Atlas and Tensia, *Th. Goldschmidt*, *Rewo*, and *Servo*, have particularly targeted the lucrative area of beauty care. In the United States, *Miranol* has been very successful with the amphoterics (imidazolines, betaines) for baby shampoos, an activity acquired by Rhône-Poulenc in 1989.

America's *Du Pont* and *3M* and Japan's *Sanyo* pay particular attention to the development of fluorine-based surfactants. *Air Products* with its acetylene derivatives Surfynol and *W. R. Grace* with its sarcosinates (Hampshire Chemicals) have also focused on well-defined segments of the business. With world demand exceeding two million tons, the market of surfactants for industry is of a nature to attract a large number of operators, raw material suppliers, processors of these raw materials into anionic, nonionic, and cationic derivatives, or downstream industries that use surfactants in various formulations.

Flavors, Fragrances, and Beauty Products

The sector of flavorings, perfumes, and beauty products has also had its share of restructuring and technological changes over the past 10 years.

Although many of the raw materials needed in this area still come in the form of essential oils from natural sources like jasmine from Grasse, roses from Bulgaria, ylang-ylang from Madagascar, oak moss from Yugoslavia, an increasingly significant role is now being played by semisynthetic or fully synthetic products.

Thus *terpenes* (α-pinene, β-pinene) can be produced from natural turpentine, as is traditionally done by rosin producers such as *Hercules, Glidden,* or *Union Camp* in the United States, or on a smaller scale in France by *Société des Dérivés Résiniques et Terpéniques, DRT*. BASF and Hoffmann-La Roche, however, have demonstrated that starting from acetylene or isobutylene, terpene chemicals can be synthetically reproduced. Both companies are able to produce both their vitamins and perfume bases in this way.

Likewise, *vanillin* is now largely produced synthetically. The world leader in this area is *Rhône-Poulenc*, which has a unit in Saint-Fons to which was added a unit bought from Monsanto in 1986 on the West Coast of the United States. In the latter plant, vanillin is still extracted from paper pulp liquor. *Menthol* from plantations in Brazil and China is also produced by synthesis since *Haarmann & Reimer*, bought by Bayer in 1954, managed to carry out industrially the resolution of racemic menthol, thus isolating the levo-isomer. *Anethole*, synthesized by Hercules from pine oil, is two to three times cheaper than when it is extracted from star anise.

Instead of identically reproducing natural products, chemists have also succeeded in making cheaper substitutes with similar features. Thus nitrated musks and later macrocyclic musks have become substitutes for more rare natural musk. Major chemical companies became interested in the firms that specialized in perfume chemicals. But their involvement in this area was not always successful, for their business views did not necessarily apply to this new activity.

While Bayer's association with Haarmann & Reimer proved successful, it took Hercules several years, from 1973 on, to understand properly how its *Polak Frutal Works* (PFW) had to be managed. Today it is autonomous and prosperous. In contrast, Rhône-Poulenc ended by selling *Lautier* to *Florasynth* in 1981.

When *Tenneco* bought Albright & Wilson in England, it did not see the point of keeping its *Bush Boake Allen* (BBA) aroma chemicals division. BBA, itself the outcome of a merger of several family businesses, was finally sold to the US-based Sylvachem in 1982. Sylvachem[1] already owned *George Lueders*, an essential oils concern Monsanto sold failing proper management. It would seem, therefore, that among the major chemical companies, only Bayer, Hercules and, more recently, BASF, which bought *Fritzsche Dodge & Alcott* in the United States in 1980, have achieved their downstream breakthrough in the flavor and perfume sector.

On the other hand, the pharmaceuticals group Hoffmann-La Roche, which purchased *Givaudan* in 1963, then *Roure Bertrand Dupont* a little later, has managed to rank third in the world in this difficult area. But the leader is undoubtedly *International Fragrances & Flavors* (IFF), an American company that accounts for 10% of the world market. Set up in 1929 by a Dutch immigrant, A. L. van Ameringen, IFF acquired its current form in 1958 and, pushed along by the creative invention of its perfumers and the quality of its compositions, has never ceased growing.

Close on the heels of IFF is the *Unilever* group, which developed in the field through acquisitions. After consolidating in 1983 its three perfume and flavor subsidiaries—PPL, Food Industries, and Bertrand Frères—to form *PPF International*, the group acquired a foothold in the U.S. market in 1984 with *Norda.* Three years later it merged PPF with Holland's *Naarden*, which was on the decline. Called *Quest International* (Unilever) the new company accounts for over 7% of the world market in its area.

Amongst the world leaders, the only privately owned company, the Swiss-based *Firmenich*, ranks fourth. It has retained its independence both because it was held together by the heirs of the founding family and because it produces quality products based on strong research. A number of smaller companies that do not belong to any multinationals are highly competitive. They include Japan's *Takasago*, which began in 1920, America's *Florasynth*, which took over *Lautier*, and Britain's *Pauls Flavours & Fragrances*, which has just established a hold in the United States market by purchasing *Felton International.*

France, which had in its favor the age-old reputation of Grasse and the world image of its perfumes linked to its haute-couture prestige, is nevertheless absent from the fray

---

[1] Sylvachem belongs to the Union Camp group.

of large suppliers in this area, even though it has some Grasse-based companies like *Mane* and *Robertet* and despite the efforts made by the Elf Aquitaine group which has assembled, around Sanofi, firms like *Méro et Boyveau, Tombarel,* and *Chiris.*

Flavors account for a substantial share of the sales of these firms: 30% for IFF, 40% for Givaudan, 50% for Unilever, and 100% for Sanofi-Méro. They are increasingly being used in foodstuffs since the fashion of fruity yogurts and instant desserts began between 1965 and 1970. The internationalization of food habits and the growing industrialization of the food sector have contributed to the development of demand for flavors and to the gradual substitution of natural substances by synthetic products that are less costly to produce and more active in small doses. Just as the perfume industry composes fragrances for its clients, subtle blends of flavors are now devised for the large food companies. Demanding customers, together with stringent regulations and sophisticated technologies, all combine to build up research costs. This explains the restructuring that has taken place in the sector as family businesses have been taken over by powerful international chemical, pharmaceutical, or food-industry groups, leaving only a few independents willing and able to make the necessary research efforts.

Although it still clings to a long tradition, the *world of perfumes* has also changed both in its structures and in its technologies. The highest volume consumption derives from products of the soapmakers. *Procter & Gamble* prepares its own compositions, but its competitors mostly rely on the laboratories of their suppliers for fragrance preparation.

With a few rare exceptions, such as *Guerlain, Chanel*, and *Patou*, the great names as well as the small perfumemakers do likewise. One of the world's largest-selling perfumes, "Anais-Anais" by *Cacharel* (l'Oréal), is prepared by Firmenich, while *Roure-Bertrand-Dupont* has signed two other recent successful perfumes, *Dior*'s "Poison" and *Saint-Laurent*'s "Opium." Launched in 1921, *Chanel No. 5* was the first perfume to carry a synthetic aldehyde note and is still one of the ten world best-sellers. But the market has now moved to floral and oriental fragrances. Perfumes for men with stronger notes have developed spectacularly and now account for 25% of alcoholic perfumery. In addition, the aerosol format has boosted sales of toilet waters and deodorants.

The most varied distribution systems have been developed, ranging from door-to-door sales, which *Avon* started, to sales by mail, a specialty of *Yves Rocher*'s, to sales in large department stores, to sales in selected areas such as perfume shops and pharmacies. Few "nonessentials" have become so indispensable. If they cannot be dispensed with, it is through the efforts of the industry, which relies upstream on the suppliers of both contents and containers, who adapted to all requirements, and downstream on efficient marketing networks. It can also devote to advertising the money that it need not spend on research conducted on the industry's behalf by the chemists.

Although it originated in France, the perfume industry is now mostly in the hands of foreign firms. While *Parfums Dior* and *Givenchy* (belonging to the Moët-Hennessy-Louis Vuitton group), as well as *Guerlain, Lanvin*, *Nina Ricci*, and *Patou* are still under French control, *Cardin Parfums* belongs to American Cyanamid, *Orlane* to Norton Simon, *Chanel* to the Swiss Pamerco group. *Rochas* was owned by Hoechst, which has now sold it, and *Parfums Saint Laurent* is now controlled by Italy's Carlo de Benedetti, who bought it from the US-based Squibb. As for the L'Oréal group, which had taken over the *Lancôme*, *Jacques Fath*, *Guy Laroche*, *Ted Lapidus*, *Cacharel*, and *Courrèges* perfume brands, it has been within the Nestlé orbit since 1973, although it was arranged that until 1993 it would be managed by those representing the interests of the founding family. Not surprisingly, the same great names recur in the area of *beauty products*, including, besides perfumes, *hair care products* and *cosmetics.* Each firm, indeed, wishes to complete its range by acquiring complementary businesses.

The cosmetics industry was born in the United States with the three great "ladies," *Elizabeth Arden, Harriet Hubbard-Ayer*, and *Helena Rubinstein.* In their wake are now *Estée Lauder,* the giant *Avon, Max Factor,* and *Revlon,* founded by Charles Revson. A number of these firms did not survive their founders. Elizabeth Arden was first bought by Eli Lilly and now belongs to the United States *Fabergé* groups; Helena Rubinstein has disappeared after being taken over by *Colgate Palmolive*; following 10 years of poor management and uncontrolled diversification, particularly in pharmaceuticals, Revlon has been grabbed by Pantry Pride, a chain store group belonging to the raider Perelman; Max Factor now belongs to the *Norton Simon* group.

While all this was taking place on the American scene, two groups, one Japan's *Shiseido*, and the other France's *L'Oréal*, were climbing to the rank of leading world producers, raised there by dint of good management and competent research and marketing skills. Although Shiseido was unsuccessful in its bid in the United States to take over the famous *Giorgio* of Beverly Hills, which was acquired by Avon, and the skin care company *Charles of the Ritz*, which Yves Saint-Laurent had sold back to Revlon, it nevertheless ranks second in the world after *L'Oréal* and has very strong positions throughout Asia.

L'Oréal's founder, Eugene Schueller, graduated as a chemist from Institut de Chimie de Paris. He resigned from his job at the Sorbonne to produce a "harmless" hair dye called l'Auréole. The trade name l'Oréal was adopted the following year. A skillful businessman and a true pioneer of ad campaigns, Schueller bought the Monsavon soap factory in 1928 and, before the war, brought on the market the

O'Cap hair lotion, then Ambre Solaire. When he died in 1957, his successors managed to develop the business both through internal growth and an efficient research base and through a series of acquisitions.

In 1961, Monsavon was sold to Procter & Gamble, and L'Oréal purchased the *Cadoricin* firm, which extended its range of hair products, to which were added *Garnier* and *Roja*. Then Lancôme was purchased, introducing high-class products. This was followed by the purchase of other perfumemakers. Tempted by the pharmaceuticals market, the company bought *Synthélabo* in 1973, consisting of four medium-sized laboratories. It is still too early to say whether the money sunk into the sector since then will bring in returns as large as those of the perfumes and skincare business. Mixing the two has not always been successful.

In the United States the marriages between Pfizer and Coty, Colgate and the US Vitamin, Eli Lilly and Elizabeth Arden, Squibb and Charles of the Ritz, Avon and Mallinckrodt, Revlon and Armour Pharmaceuticals all ended in divorce. There was, of course, Bristol-Myers' successful venture with Clairol, and American Cyanamid with its Shulton subsidiary. But these exceptions only confirm the general rule of failure.

In France, while Sanofi can draw satisfaction from its association with Yves Rocher, which enjoys great management freedom, the sector comprising Roger & Gallet, Stendhal, and Charles Jourdan has not yet lived up to the parent company's expectations. Only the British seem to have succeeded in combining such different businesses, possibly because from the start the skincare activities were intimately associated with pharmaceuticals within large groups like Beecham, Glaxo, and BDH.

The Chemistry of Additives

Used in small doses to improve the products in which they are incorporated, additives are to be regarded as specialties with well-stated functions even if, in many cases, they are well-defined chemical entities sold according to specifications. Because of this ambivalence, chemical companies have approached the sector of additives sometimes through the markets they serve, sometimes through the chemicals from which they derive, even at times from both ends.

Additives for Plastics

Additives for plastics have experienced the double approach. The opening up of the markets leading to uniform production of plastics gave worldwide scope to some additive producers. Tasks were shared since polymer producers did not consider it useful to prepare the additives they needed, while additive producers were, as far as possible, careful to avoid competing with their clients in the area of base thermoplastics.

It is true that a major polyolefin producer like *Hoechst* sells its own range of antioxidants and its subsidiary *Riedel de Haen* produces ultraviolet ray absorbers. Likewise, the world ABS leader *Borg Warner*, now acquired by General Electric, has been marketing, since it took over *Weston*, a series of organic phosphites for the stabilization of high polymers. In Japan, *Sumitomo Chemical* is a supplier of large-volume plastics as well as of a rather complete range of stabilizers.

These are exceptions, however. The world's largest additives producer for plastics, *Ciba-Geigy*, remains, for its part, at the sole service of its downstream customers and tries not to appear as a competitor. This is also the position of other additive suppliers like *American Cyanamid, Ferro, Witco, UniRoyal Chemical* in the United States, *AKZO, SFOS (Rhône-Poulenc) in Europe, Adeka Argus,* and *Dai-ichi Kogyo Seiyaku* (DKS) in Japan.

Ciba-Geigy owes its leading position to a number of factors: long perseverance in the specialty, an efficient research base through which the universally used *Irganox* antioxidants were developed, application services adapted to all the polymers requiring stabilization, worldwide production units established within large consumption areas (Europe, America, and Japan). Even where Ciba-Geigy did not invent a product but took a license on it as with *HALS* (hindered-amine light stabilizers), licensed from Japan's *Sankyo*, it developed it to the point of acquiring world supremacy in the area. Ciba-Geigy's success in this activity is all the more remarkable as it has no upstream integration on raw materials used in the synthesis of phenol antioxidants, of phosphites, of thioesters, of substituted benzophenones, of benzotriazoles, or of HALS. But this apparent weakness is fully compensated by the dominant position Ciba-Geigy has acquired in the different types of additives for plastics in its range, either through internal growth by its research, or through license acquisitions (Sankyo), or through purchase of relevant companies (Chimosa in Italy), or again through complementary activities (range of Goodrich's Goodrite antioxidants).

The other producers of plastics additives trail far behind Ciba-Geigy in variety of range or in market coverage. *UniRoyal Chemical* produces antioxidants and blowing agents and has production units in the United States, Latin America, Italy, and Taiwan, but its recent restructuring has cut short its development. *American Cyanamid* which pioneered a number of additives (substituted benzophenones, 2246) sold its European business to Ciba-Geigy in 1982 and now operates only in the American market. *AKZO*'s range is restricted to antistatic agents, PVC stabilizers, and peroxide catalysts, which it acquired through *Armak, Interstab*, and *Noury van der Lande*. *Borg Warner* is mainly focused on phosphites, which it produces solely in the United States; Elf Aquitaine's subsidiary *M & T* is focused on organotins; *Witco*, through its purchase of *Argus Chemical* and *Humko Products*, is involved in heat stabilizers, antistatic agents, and lubricants. *Ferro*, which also produces master batches, has developed specialties such as fireproofing agents and stabilizers for PVC and has recently joined forces with Italy's Enichem to produce and market new lines of polymer additives in the United States.

Other companies came to additives through the chemical tree, such as *Société Française d'Organo-Synthèse* (SFOS), a subsidiary of Rhône-Poulenc, which by isobutylating phenols produces a whole range of phenolic antioxidants as well as special phosphites, or *Ethyl*, which approached the Irganox family of antioxidants and bromine fireproofing agents through its orthoalkylation technology and its access to bromine. Similarly, because the US-based *Olin* was an important hydrazine manufacturer, it became interested in blowing agents like azodicarbonamide and bought up National Polychemicals, which also provided it with a range of phosphites. The blowing agent line has since been sold to UniRoyal Chemicals.

But the interest which major firms like ICI, Bayer, or even Hoechst still have in the sector is restricted by the small number of additives they supply to plastic producers. Under the circumstances, it is more than likely that Ciba-Geigy's lead in the variety of products offered, in research, in customer service, or in geographic coverage will be hard for competitors to catch up with. Indeed, their narrow approach to the market would hardly warrant the heavy investment to fulfill any high ambitions they might have in the area.

But favored by their access to certain raw materials or by their specialization in a very specific range, such competitors can, at least, be assured of a degree of prosperity inasmuch as the standards required for optimum use of plastics are closely related to incorporation in the high polymer of effective additives at a reasonable cost.

Rubber Additives

The specialists in *rubber additives* are distinctly different from the specialists in additives for plastics, even though the same products are sometimes used in both industries: blowing agents (azodicarboamide), phenol antioxidants (BHT, 2246), phosphites (tris-nonylphenyl phosphite). In the first place, additives for elastomers, unlike those which might come into contact with foodstuffs, do not require official approval, which makes it easier to put them on the market. In the second place, most of them are well-known products sold to specifications by a number of producers. The development of new products protected by patents is rarer than in the case of additives for plastics. In fact, while consumption of plastics has been constantly increasing, stagnant demand for both natural and synthetic rubber has not warranted any significant recent research efforts by suppliers of this industry.

If one considers that the automobile sector accounts for 75% of rubber consumption in developed countries, it stands to reason that the longlife radial frame and smaller diameter tires of modern vehicles should require smaller amounts of rubber for the same number of cars produced; in the United States alone, rubber consumption has fallen from 3.2 million tons in 1977 to a little over 2.6 million tons in 1989. This implies a consumption of some 150,000 tons of organic additives.

Faced with such a situation, producers of additives for rubber have either restructured or else rationalized production. In rarer cases, others have offered new products with higher added value than the conventional additives. In the United States, *American Cyanamid* in 1982 halted production in Bound Brook, New Jersey, of its accelerators; *Goodyear* terminated its substituted *p*-phenylenediamine production in Houston in 1984. In 1985, *Allied-Signal* took over *UOP*'s antiozonant unit, while in 1986 *UniRoyal Chemical* became part of *Avery, Inc*., before becoming the object of a leveraged management buyout in 1989. In Europe, Rhône-Poulenc and ICI merged their rubber divisions within a subsidiary called *Vulnax* and then finally sold it to AKZO in 1987. Atochem, meanwhile, was taking a minority stake in *Manufacture Landaise de Produits Chimiques*, henceforward leaving France and Britain with no significant producer with international clout.

In this changed environment, three major additives manufacturers emerged: *Monsanto* with its plants in the United States, Canada, Britain, and Belgium; *Bayer*, which owns two sites in Europe and produces antiozonants in Pittsburgh through Mobay; and *UniRoyal Chemical*, which has production units in Naugatuck, Connecticut, and Geismar, Louisiana, as well as in Canada, Brazil, and Italy.

UniRoyal Chemical was separated in 1966 from the US Rubber, which had provided it with a captive market. But two other tire manufacturers had retained their traditional activities in additives. They were *Goodrich*, which produced only in the United States, and *Goodyear*, which also operates in Europe in its antioxidant units in Le Havre, France. Both these giants sell part of their production through a rubber blend specialist, R.T. Vanderbilt. Goodrich, however, has recently withdrawn from the tire business in order to concentrate on its chemical activities, so that only Goodyear enjoys today the advantage of a captive outlet for the rubber chemicals it produces.

Although Monsanto can rely on only two of its own raw materials, tertbutylamine and *p*-nitrochlorobenzene, for its range of additives, it is regarded as an efficient producer and a pioneer in antiozonants based on *p*-phenylenediamine and prevulcanization inhibitors. It has one of the most complete ranges of additives for rubber and the most modern units to manufacture them.

Because of its long experience in organic synthesis intermediates, *Bayer* is possibly better integrated upstream than Monsanto. Its range of products is just as large, but its production units are essentially restricted to Leverkusen and Antwerp. With the exception of *AKZO, which, through its purchase of Vulnax,* seems to want to improve its range of additives and its geographic coverage, no other major European chemical group has gone beyond a small range of special products.

Like their competitors in Europe and in America, the Japanese producers have focused their attention on accelerators (vulcanization activators and agents) and on antiaging agents (antiozonants, stabilizers). Their automobile exports provide a market for tires that their counterparts in other countries cannot claim to the same extent.

Japan's additives production, however, is too scattered among a large number of producers to be truly profitable. With the exception of two principal companies in the area, *Sumitomo Chemicals* and *Mitsubishi-Monsanto*, firms like *Ouchi, Shinko, Kawaguchi*, and *Seiko Chemical*, which were the first to get into the business in 1930, do not have the required size to be competitive on international markets.

Additives for Lubricants

Additives for lubricants are also greatly dependent on the automobile industry, which alone uses some 60% of the lubricants produced worldwide, whether lube oils for engines (gasoline and diesel oil) or for gear boxes. Since the oil-price rise in 1973, lube oil consumption has been affected by a number of factors: smaller vehicles and therefore smaller engines, falling automobile production, larger intervals between oil changes, implying a higher additives dosage to extend oil efficiency. To these various changes should be added increasing use of diesel fuel in Europe because of favorable taxation. The generalized use of multigrade oils and the introduction of unleaded gasoline, and consequently of catalytic exhaust pipes, should lead to enhanced engine oils. In the circumstances, world consumption of additives for lubricants is likely to remain at around two million tons a year over the next few years, with higher additive doses compensated by extended lube oil efficiency and smaller casing size.

With the exception of *Lubrizol*, the world leader in this area, and *Ethyl,* which came to lube oil additives by buying Edwin Cooper off Burmah Oil in 1968, the main suppliers with extensive ranges of additives are the international oil companies *Exxon*, *Chevron*, *Amoco*, and *Shell*. The business was a natural extension of their lube oil production, which serves as a captive market.

All these oil companies market their additives as a package, the efficiency of which has been extensively tested. Most of the ingredients in the package are produced by the companies themselves: *detergents* (sulfonates, phenates, naphthenates), *dispersants* (succinimides, polybutene, succinates), *antiwear agents* (zinc dithiophosphates, chlorinated paraffins, sulfur, and phosphate hydrocarbons), *anticorrosion agents* (substituted amines, succinic acid derivatives, nitrites). On the other hand, the antioxidants are often supplied separately, as are pour-point depressants (polymethacrylates, PMA) and additives to improve the viscosity index of multigrade oils (PMA, olefin copolymers).

Originally called Graphite Oil Products, *Lubrizol* was founded in 1928 near Cleveland with a capital of $25,000 by six associates. Their close ties with the Case Institute of Technology gave the concern a strong technical orientation. In this manner, *Lubrizol* played a pioneer role in developing lube oil additives and is still today a world leader in its area, with 14 plants installed worldwide, including four in the United States, and testing sites in Wickliffe (Ohio), Hazlewood (Britain), and Atsugi (Japan). In its attempts at diversification, the company recently became interested in biotechnology with the purchase of *Agrigenetics* in 1985 and of a stake in *Genentech*. But it is too early to state whether this choice will bring the same long-term satisfactions as the company's traditional business.

Exxon came to chemical additives for lubricants by producing its Paraflow range of freezing-point depressants as early as 1930 in Bayonne, New Jersey. Through the agreements signed in 1937 with IG Farben, Standard Oil of New Jersey (later to become Esso and then Exxon) acquired the thickeners and additives based on polyisobutylene that improve the oil viscosity index. In the 1960s, Exxon further enlarged its range of lubricant additives and in 1979 set up the Paramins special division, which marketed a series of olefin copolymers (OCP) based on the chemistry of the group's ethylene-propylene elastomers. The object was to compete with the PMA in improving multigrade oils (VI improvers). Based in Houston, Texas, and involved in all world markets, Paramins has become Lubrizol's most dangerous rival.

Chevron approached the oil additives market in the 1930s by supplying metal naphthenates to its parent company Standard Oil of California. Some of these additives were marketed under the trademark Oronite from 1948 onwards. Chevron kept its main research center in Richmond, California, even when, in the 1950s, it spread to international markets through subsidiaries set up with local partners: *Orobis* with BP and *Orogil* with Progil in Europe, *Karonite* in Japan, *AMSA* in Mexico. In 1986, BP bought Chevron's 50% share in Orobis, and more recently Rhône-Poulenc sold to Chevron its 50% share in Orogil.

The interest shown by *Ethyl Corporation* in Edwin Cooper stems from its desire to diversify into the oil sector as unleaded gasoline begins to threaten the future of tetraethyl lead. But in a business in which it is a newcomer, Ethyl still has much to learn before attaining the efficiency and international coverage of its three main rivals. The same is true of *Amoco* and of *Texaco Chemicals*, although they are endowed with a significant captive market through their parent companies, Standard Oil of Indiana and the group made up of Texaco, Caltex, and Getty Oil, respectively.

For its part, the *Royal Dutch Shell* group came to additives after the Second World War in the United States with a range of alkaline sulfonates. Subsequently it enlarged its range with new additives (detergents, dispersants, VI improvers) and fuller geographic coverage through production centers located in Berre, France; in Stanlow, England; and in Marietta, Ohio, and in Martinez, California, in the United States. More recently, a common subsidiary with Lubrizol was set up in Brazil.

Besides these large companies, which offer a range of additives as extensive as possible, if only to recoup research expenses and the high cost of tests required to obtain approval of the "packages," there are a number of chemical companies that have also established a foothold in the market of lube oil specialties. Their reason for doing so was that they had acquired know-how in the chemical sector leading to the products marketed.

Rohm & Haas in Philadelphia developed additives to lower the freezing points of oils and to improve their viscosity index through work carried out as early as 1934 by the chemist Herman Bruson on the properties of PMA produced from higher methacrylates. Other companies, such as *Röhm* in Darmstadt and Melle-Bezons (whose Persan unit in France was bought from Rhône-Poulenc by *Société Française d'Organo-Synthèse* (SFOS) in 1978), also supplied PMA for such applications. Through the chemistry of phenol isobutylation, *Ethyl* and *SFOS* took a foothold in the phenol antioxidant market of oil companies, while *Ciba-Geigy* is developing a significant program in this area. But the need to be thoroughly acquainted with the lube oil business and to be well introduced in the world oil circles narrows the scope of chemical firms that have only a small range of additives to offer and precludes their taking a significant place in such a specialized market.

Food Additives

Because their nature, their uses, and their origins are extremely varied, *food additives* are supplied by a large number of different firms. In what is a fragmented industry, some producers stand out more because of the major place they occupy on the market than because of their range of additives.

In the United States, there are only two producers of *citric acid* (Pfizer and Bayer's subsidiary, Miles) and of *vitamin C* (Pfizer and Hoffmann-La Roche) and a single producer of *saccharin* (PMC, which bought Maumee from Sherwin Williams), *sorbates* (Monsanto), and *carrageenates* (FMC since it acquired Marine Colloids).

Because of the very strict rules that in industrialized nations govern additives used in human food, it has become very expensive to introduce new products. In some countries even some of the older derivatives that used to be considered nontoxic have been questioned. This is the case with saccharin, discovered by Ira Remsen in 1879 and used without drawbacks since then. Because of such limitations, few new producers have ventured into the area over the past few years except through purchase of existing companies that already had approved additives. The giants in the business are generally satisfied with being dominant in certain market sectors through their special technologies (fermentation, extraction, synthesis). The problems of excessively high sugar consumption, however, have induced a number of researchers to look for low-calorie substitutes for sucrose other than saccharin. Accordingly, new *synthetic sweeteners* have been discovered: *cyclamate* (sodium cyclohexyl-sulfamate), synthesized in 1937 and put on the market by Abbott in 1950; *aspartame*, isolated in 1965, produced by reaction of aspartic acid with phenylalanine methyl ester, and developed by Searle, which was subsequently purchased by Monsanto; and Hoechst's *acesulfame K*. Despite lack of coordination in this area among the different national legislatures, these synthetic sweeteners, with their low calorie content and a sweetening power that is 50–200 times as great as that of sugar, should sooner or later take root on international markets.

The use of *gelling* and *thickening* agents in foodstuffs goes back to earliest times. In the last few years, progress has been made in the extraction and purification of plant-based hydrocolloids used for the purpose. In addition, the polysaccharide *xanthane*, produced through fermentation, has been developed over the past 20 years to take its place among the water-soluble gums supplied to the food industry. At the same time, a semisynthetic gum, *carboxymethyl cellulose* (CMC), used in a number of industrial applications, was allowed in its purified form, in human foodstuffs.

The US-based *Hercules*, which started by producing precisely this CMC of which it is the world's leading producer, has gradually extended its range of products by purchasing companies. It is now involved in *pectin*, extracted in Denmark and in the United States from lemon peel; *guar*, prepared in Italy from a bush that grows in India and Pakistan; *carob* developed in Spain; and *carrageenates* extracted from algae growing along the Atlantic and Pacific coastlines. With the exception of pectin, these various gums recently became the business of *Aqualon*, a common subsidiary of Hercules and *Henkel*, its German partner, already involved in the guar and CMC market. In 1989 Hercules became the sole owner of Aqualon.

Hercules never did succeed in developing *Xanthane* through its association with the British company Tate & Lyle in 1979. This gum has remained a specialty of *Rhône-Poulenc* which produces it in Melle, France, and of *Kelco*, a San Diego, California, subsidiary of Merck that also owns *Alginates Industries*.

Other groups have likewise specialized in particular sectors. The Stein Hall subsidiary of Celanese, taken over by the British-based *RTZ Chemicals*, now part of Rhône-Poulenc, has focused on guar, while *Marine Colloids*, a subsidiary of FMC, and *Satia*, of the Sanofi Elf Bio Industries group, specialized in carrageenates. There are a great number of industrial applications for gum, and thus gum producers are usually drawn to the food industry because of their know-how in gum. It is seldom that they have chosen to manufacture thickeners because of their experience in foodstuffs.

The same is true of *antioxidants* like *BHT* (butylhydroxytoluene). Although it is used in purified form in human and animal food, its more common use is as a stabilizer for polymers and lubricants. Only *BHA* (butylhydroxyanisole), α-*tocopherol* (vitamin E), *TBHQ* (tertiary-butylhydroquinone), and *propylgallate*, which are marketed by *Eastman Kodak*, can be considered as purely food antioxidants for the two reasons that they are not toxic and that they are high priced. In fact, Eastman Kodak is the only chemical leader to produce an extended range of food additives: mono- and diglycerides and vitamins.

Producers of *acidulants* came to food applications through chemistry or biochemistry. *Malic acid* is produced by Denka, now owned by Mobay, in the United States and by Croda in England. Like *fumaric acid*, it is a derivative of maleic anhydride production. The major acidulant is *citric acid*, which is also used as a stabilizer. It is a fermentation product that is produced by a few traditional specialists—in Europe by La Citrique Belge, which was bought by Hoffmann-La Roche; in Britain by Sturges, taken over by RTZ Chemicals and now owned by Rhône-Poulenc; and in the United States by Pfizer and Miles.

Phosphoric acid, used in fizzy drinks, is produced in its food quality only by a small number of firms such as FMC and Stauffer, an activity taken over by Rhône-Poulenc in the United States, and by Prayon in Belgium.

Food conservation generally requires the use of chemical additives, although the problem can be solved at times through temperature control (pasteurization or sterilization through heating, freezing, or control of water content [dehydration]). Chemical additives act by working on the metabolism of the microorganisms responsible for food deterioration. More often than not they involve organic acids and their salts, *propionic acid, potassium sorbate, sodium and calcium propionates*, and *sodium benzoate*, traditionally used to preserve cheese, jam, cakes, and fatty materials.

Here again a few large companies such as Monsanto for sorbates and Pfizer for propionates have acquired a leading place on the markets. On the whole, the food additives sector is less open to restructuring and rationalization because it is made up of enterprises that are fundamentally different in size, technologies and in objectives pursued.

Photochemicals

Since the early 1980s, the major photographic companies have made efforts to bring changes to their basic technologies, which had long remained unchanged. The US-based *Eastman Kodak* became interested in reprography, setting up its own range of photocopying machines. It also became involved in electronics and video to counter competition from new Japanese equipment (such as Sony's Mavica filmless cine-camera). The other photographic giants like Bayer's subsidiary *Agfa-Gevaert* and *Fuji Photo Film* have also invested heavily in new areas, the former in magnetic tape and reprography and the latter in photo disks. *Polaroid*, whose founder Edwin Land remained to the day of his retirement an advocate of specialization, is also starting to put a range of videocassettes on the market. These changes, however, are essentially intended for the amateur and mainly concern camera manufacturers. Overall, the sensitive surfaces market should receive no shakeup from these new ventures, for there is still a high demand in a number of areas where photography remains irreplaceable (press and publishing, scientific research, industrial applications, radiographic control devices). The industry's structure reflects this stability. It is not likely to be upset in the immediate future because of the power acquired by the few large multinationals, which vie with one another on international markets and give any newcomer little chance of success.

Unable to compete with Kodak on the American market, *GAF* withdrew from the film industry in 1982. Previously, the first European merger had taken place between Belgium's Gevaert and Germany's AGFA, producing Agfa-Gevaert. Its early years were hard ones, and it is now fully owned by Bayer. Italy's *Ferrania* was taken over by America's *3M*, while Ciba-Geigy was bringing together Britain's *Ilford*, France's *Lumière,* and Switzerland's *Telko* within the Ilford group based in Britain.

Following these restructurings, which, in many cases, took place some time ago, the photographic film industry is now dominated by three giants: *Eastman Kodak*, with units in Rochester, New York, in the United States, in Châlons, France, and in Hemel Hempstead, England; *Agfa-Gevaert*, which produces its photochemicals in Antwerp, Belgium, and Vaihingen, West Germany; and *Fuji Photo Film*, which produces in Japan and has recently set up a film unit in Holland. *Ilford* and *Polaroid*, which went through difficult periods of readaptation; *3M*, which is involved in other areas besides photography; and *Konishiroku* (*Konika*) in Japan, which bought Fotomat in the United States, cannot be regarded as dangerous rivals to the Big Three.

The three major companies follow different policies in matters of raw materials. Fuji Photo film, which has no links with the chemical industry, buys 80% of its supplies outside, while Eastman Kodak and Agfa-Gevaert supply half their needs through their own production. They all produce their most "sensitive" organic derivatives, which are kept secret since they form the basis of emulsion quality.

Although polyester film, introduced by Du Pont under the trade name Mylar in the 1960s, has been added to the traditional supports like paper and cellulose acetate, the principle of photographic film preparation has remained unchanged since "daguerreotype" was developed. The sensitive surface always contains a silver halide crystal emulsion with a *gelatin* binder. Despite all the efforts to replace them, silver salts remain the basis of these emulsions, and film manufacturers still require gelatin, which they consume at the rate of 20,000 tons a year. The suppliers are few, and they are carefully selected. The world leader in this area is *Rousselot*, now a subsidiary of Sanofi Elf Aquitaine, with four units in Europe and one in the United States.

Reducing agents such as *hydroquinone, metol* (*p*-methylaminophenol), and *p-phenylenediamine* are generally purchased from outside producers. Eastman Kodak produces its own hydroquinone, however. The other producers get their supplies from Rhône-Poulenc or from Japanese firms like Sumitomo Chemicals or Mitsui Petrochemicals.

Color photography, now fully perfected, requires a *developer* like *N,N′*-diethylphenylenediamine which reacts with silver salts. The oxidized derivative obtained reacts with a coupling agent made up of groups (–CH=) or ($–CH_2–$) to produce the desired color.

Formulations for sensitive surface emulsions also include *accelerators* (alkaline carbonates, borax), *stabilizers* (sodium bromide, benzotriazoles), *conservation agents* (sodium sulfite), *hardeners*, which improve gelatin behavior (chloromucic acid, substituted 2,4-dichlorotriazines).

The great variety of products used by film manufacturers, their stringent quality standards, and their secretiveness, which prevents them from subcontracting their most advanced formulations, are all factors that keep photochemical producers apart from the rest of the chemical industry and keep newcomers out of their sector.

The Alliance of Chemicals and Electronics

Chemical products used today in electronics seem, at first glance, to be a very ordinary kind. They are different from those generally offered, however, by reason of the extraordinary degree of purity which their producers must achieve in order to satisfy the stringent requirements of the electronics industry. The maximum dose of impurities tolerated in monocrystalline silicon amounts to one part in 10^{13}.

Polycrystalline silicon, produced from silane (SiH_4) or trichlorosilane ($SiHCl_3$) forms the upstream part of the *semiconductor sector*. Monocrystalline silicon is extracted from polycrystalline silicon and sliced into wafers 25 μm thick and 8–10 cm in diameter.

Hoechst's subsidiary Wacker is the world's leading polycrystalline silicon producer, with a capacity exceeding 2,000 tons. The overcapacities that began affecting the electronics industry in the early 1980s forced Monsanto, one of the largest wafer producers, to slow down its silicon production units in 1984. It has since sold this business to Germany's Hüls. Rhône-Poulenc, which had ambitions in the area but lacked the right technology, has withdrawn from the business.

There are enough suppliers of this type of silicon, including, for instance, Dow-Corning, Dynamit Nobel, Shin-Etsu, Tokuyama Soda, Motorola, and Texas Instruments. A possible substitute for the silicon used to produce wafers is *gallium arsenide*, in which Rhône-Poulenc, ICI, and Shinetsu are already involved.

This situation shows how closely suppliers of electronic chemicals need to monitor the very rapid developments taking place in the area; otherwise, their productions run the risk of becoming obsolete before the full payoff.

Photosensitive products are also used for the production of wafers. These *photoresists* polymerize through X-ray treatment. They are called positive or negative according to whether or not they are soluble in solvents when exposed to light. The miniaturization of printed circuits tends to give a boost to positive resins. Germany's Hoechst has pioneered in such photosensitive resins. They are also supplied by Eastman Kodak, Olin Hunt, Ciba-Geigy, E. Merck, and Tokyo Ohka Kogyo.

A great number of chemical firms have set up special divisions to manufacture products for the electronics industry, essentially through acquisitions. For example, *Du Pont* bought *Berg Electronics* in 1972, and a little later *Olin* purchased *Philip A. Hunt*. Some companies, such as Du Pont, Olin, and Ciba-Geigy, have chosen an "integrated systems" approach in this area by providing as wide a range as possible of products and services for the electronics industry. Others have elected to remain strictly within the special areas in which they excel through long experience or proper chemical integration. Thus it was the work carried out before the war with AEG that led *BASF* to make its range of magnetic tapes and gave it the supremacy in chromates which it shares with Du Pont. *Hoechst* came to silicon through Wacker and to gases through Messer Griesheim, and now provides, besides high-purity special gases, a range of photosensitive polymers. Rhône-Poulenc became involved in printed circuits through its polyimide resins and Ciba-Geigy through its epoxy resins.

Most of the companies already producing diethylene glycol terephthalate polymers have launched into the applications of polyester film to video and data processing, Hoechst through its Kalle subsidiary, ICI, Rhône-Poulenc, Du Pont, Japan's Toray, Teijin, and Toyobo, the latter in association with Rhône-Poulenc in Nippon Magphane.

Although Rhône-Poulenc has given up direct upstream development after fruitless association with Dysan in magnetic supports and Siltec in silicon, it still believes it can use its know-how in rare earths to develop their electronics applications. Today, Rhône-Poulenc is the indisputable leader in rare earths, accounting for 40% of the world market. At its units in La Rochelle, France, and Freeport, Texas, it is capable of extracting from lanthanide sands the 14 elements they contain. Over the last few years, *samarium*, for instance, has become essential for microelectronics to the same degree that *europium* and *yttrium oxides* already are for color television.

Whether they approach electronics directly, or through chemicals, or both, chemical companies involved in this business can hope to reap the fruits of their efforts in this area, providing, however, that the sector is spared the technological and economic jolts it has suffered over the past 10 years.

Catalysts

Ever since England's Humphry Davy observed in the early 1800s that water was formed when hydrogen and oxygen react in the presence of a red-hot platinum wire, the phenomenon which Berzelius was to call catalysis has intrigued chemists. The uses of catalysts in industry were first consciously demonstrated by Peregrine Phillips in 1832 when he used platinum to oxidize sulfur dioxide (SO_2) to form sulfur trioxide (SO_3) and by Frédéric Kuhlmann in 1837, when he produced nitric acid from ammonia.

Early in the twentieth century, Germany's Wilhelm Ostwald, France's Paul Sabatier, and America's Irving Langmuir had advanced a step in interpreting the phenomenon of catalysis by showing that it was characterized by an acceleration of the rate of reactions and that it was conditioned by the state of the catalyst's surface. From then on, chemical technology made striking progress through use of catalysts. Between 1905 and 1920, and more particularly in Germany, there was a spurt of new industrial-scale processes, for example, Fischer–Tropsch synthesis and BASF's use of vanadium oxide to produce sulfuric acid.

It is no exaggeration to say that without catalysts Germany would have been in no condition to pursue its war effort until November 1918. Likewise, if Houdry had not developed in the early days of World War II its "catalytic cracking" process, the United States would have found it very hard to provide its bombers with light fuel. It was also through catalytic reforming that the United States managed to obtain from petroleum the toluene needed to produce TNT between 1941 and 1945.

Since then, catalysts have played an essential role, particularly in the production of ethylene oxide from ethylene (Shell, Scientific Design), in the synthesis of hydrogen cyanide and acrylonitrile through ammoxidation (oxidation in the presence of ammonia), of formaldehyde (from oxidation of methanol), and, of course, in the polymerization reactions to produce plastics, elastomers, and synthetic fibers. It is not surprising, under the circumstances, that a catalyst industry should have developed after World War II through internal growth or through acquisitions. The very diversity of catalysts and of their uses has necessarily led to a fragmented sector.

Some oil companies became involved in the production of catalysts because they needed them in their own refineries. *Mobil* has developed the ZSM 5 catalyst based on zeolite following studies which began as early as 1936 on catalytic cracking; *Shell* has used its own technology to develop the sales of its catalysts for hydrogenation cracking. Other companies became involved in catalysts because of their precious metals business. *Johnson Matthey, Engelhard*, and *Degussa* applied their know-how in platinum metals to industrial catalysts. Chemical firms, for their part, approached the area in different ways. *ICI* made the most of its acquired know-how, particularly in methanol and ammonia, by associating with *Nalco* to form *Katalco*, a catalyst supplier; *American Cyanamid* has set up a subsidiary in Holland with Ketjen; *Rhône-Poulenc* has formed *Procatalyse* in joint venture with Institut Français du Pétrole.

In other cases, the involvement in catalysts has been through acquisitions. *W. R. Grace* bought *Davison Chemical* in 1953, and in 1984 Union Carbide purchased *Katalistics International*, BV. One of the three leading United States companies in cracking catalysts, together with Engelhard and Davison, is *Harshaw-Filtrol*, which is the result of the merger of subsidiaries of Gulf Oil and Kaiser Aluminum & Chemical that have specialized in the area.

The developers of new processes have found it at times more expedient to set up their own separate entities to supply the catalysts they were advocating. Allied-Signal's subsidiary *UOP* did so for its platforming; *Houdry* for its catalytic cracking; *Ralph Landau* for the silver catalyst used for direct ethylene oxidation, which was marketed by *Halcon SD* and subsequently taken over by Denka, then by Bayer; and

Phillips Chemical for its polyolefin catalysts, sold through its subsidiary, Catalyst Resources.

Through inert supports, a number of firms have succeeded in creating a niche in catalysts—for instance, *Crosfield*, a subsidiary of Unilever in England and a silica producer; or the German *Süدchemie* group, which specializes in hydrogenation and polymerization catalysts; or again *Condea*, which produces in West Germany alumina of high purity. The sector also includes a few firms which are only involved in a very special sector. Denmark's *Haldor Topsoe* makes catalysts for the synthesis of ammonia and methanol; *Lithium Company of America*, an FMC subsidiary, produces lithium, while *Du Pont* makes boron derivatives.

Linked to the oil industry, to petrochemicals, and to the large commodity chemicals, the catalyst industry can hardly escape the economic ups and downs affecting these three large sectors. Its clients are understandably both demanding and prudent, for the catalytic system is basic to the good running of production units. This explains why it is an area of business that is so difficult to penetrate and run profitably. Its structure should therefore remain rather stable even with the development of catalytic exhaust systems. Introduction in the United States and in Europe of unleaded gasoline and the use of bimetallic systems for catalytic reforming should open up new markets for platinum and rhodium.

Retrospect and Prospect

The economic slump that started in 1973 when OPEC pushed up crude oil prices challenged what were until then regarded as indisputable truths.

First came the realization that just as no tree can climb as high as the sky, so *no growth can be guaranteed to be continuous*. Suddenly investments made at a time of high inflation and low interest rates turned out to be disastrous as demand slowed down simultaneously with monetary erosion.

The scale effect, which until then was assumed to be cost-saving, showed its weaknesses as the giant steam crackers proved more expensive to run at low capacity than smaller units already written off and working at full capacity.

The notion that production costs could be improved by grabbing a greater share of the market turned out to be fatal as the gain in sales was wiped out by severe price erosion.

Likewise the assumption that the fruits of research would be proportional to the funds devoted to the sector was totally invalidated, for never had the world's chemical industry spent so much money in research and development to so little avail. At the same time, the venture capital poured into biotechnology companies has yet to bring in the returns expected. The managers of chemical plants, wary of world petrochemical and heavy chemical overcapacities, believed they would find in a switch to specialties at least partial compensation for the losses incurred through traditional productions. Although they were not all disappointed in their hopes, some of them found that results obtained fell short of expectations, for until then specialties had been the special field of firms that had acquired experience in what were specific and as yet uncrowded sectors.

Manufactured by too many producers, some specialties were becoming commonplace. For a manufacturer, there are only two kinds of products, those that make money and those that do not. The profits that can be made on a sale are closely related to the number of producers on the market and to the day-to-day relationship between supply and demand. Whether a product is deemed a "commodity" or a "specialty," it is all the more profitable for its being offered by a smaller number of producers for a demand that remains unchanged. In this context, there are some pharmaceutically active materials protected by patents and some secret formulations that are genuine profit centers for their producers. Likewise, should a base product become scarce on the market because of an accident on a petrochemical site or because of sudden high demand, prices soar and the fortunate producer can turn out the product to maximum capacity and profit.

Over the last few years, the high cost of installations and of the money needed to finance them was not conducive to the building of new plants on any large scale in industrialized countries. But as demand trends have been moving upwards lately, *petrochemicals* have at long last *returned to profitability*.

The specialties rush of chemical leaders is, on the contrary, more likely than not to produce a surfeit of products, at least insofar as some specialties are concerned. These will shed their "added value" and consequently lose their attraction for the too numerous industry leaders that had decided to follow that path.

Other disappointments are likely to come from the organizational and managerial differences between a purchaser and the specialties firm acquired. The many divestments that have often followed upon hasty acquisitions show how difficult it is to force on an entrepreneurial company the management methods of a large multinational.

One of the paradoxes of the last few years has precisely been that specialties suitable for medium-sized firms capable of being flexible in their approach to daily matters should have fallen into the hands of chemical giants with necessarily heavier structures, while in the United States, for instance, through the "LBO" procedure, a few strong-minded individuals have succeeded in taking over large petrochemical and thermoplastic production units considered until then as the rightful field of the industry's greats.

It is not certain whether the errors of the past will be repeated in the future. The thirst for power could indeed lead some company heads to overinvest, especially if they have public funds at their disposal. They would then recreate the overcapacities that have been so harmful to fertilizer, petrochemicals, synthetic fibers, and plastic producers over the last few years. It is also likely that specialties will continue to attract industry leaders anxious to develop fresh prospects.

Let us hope that all the decision makers will bear in mind that capital funds, whether provided involuntarily by the taxpayer or willingly by the shareholder, are a rare resource that must be judiciously allocated and that success in all things comes from mastery acquired through long patience. In this respect, Germany's chemical industry, which has shown continuity from the time it was established in the last century to the present under the guidance of professionals, is a tried and tested model, showing profits even in the most adverse circumstances.

Drawing inspiration from this example for long years, the United States chemical industry, under the pressure of financial analysts and raiders, has in recent years undergone many upheavals. While they provided new opportunities for the fortunate few, they changed the environment and made people forget that to operate efficiently any industry must set its sights on the long term.

For reasons that were more political than financial, France's and Italy's chemical industries have also undergone too frequent changes over the past 20 years—in their structures, their strategies, and their management teams—to have had a chance of getting through the economic slump unscathed. It is only very recently that they have returned to profits by recovering a measure of stability.

Worldwide, in 1987–1989 the industry, whether in specialties or in basic chemicals, has certainly had its most prosperous years ever. The chemical industry, on the whole, does not, however, enjoy a very favorable image in the eyes of the public. The harmful spillovers caused by untoward accidents are given wider publicity by the media than the benefits the industry provides. In consequence, administrations that were anxious to soothe the more or less justified fears of their citizens have brought out a spate of regulations often more restraining and therefore more costly than is really necessary.

Since one cannot work simultaneously toward a thing and its opposite, no great spate of discoveries useful to humanity should be expected at a time when everything is being done to make it difficult to bring new products onto the market. For a long time the chemical industry was left free to apply its own safety standards and could devote most of its time to the development of new products. In the last few years, it has had to submit to increasingly costly and prolific rules and regulations that require its attention and delay the development of innovations that could save human lives or at least improve our living conditions. Some balance will have to be found between safety requirements and the wider interest of the public.

As in all history, the story of chemicals recalls past events and makes an attempt to explain them. But it can neither create them nor prevent them from recurring. While such history, therefore, teaches us the essential facts that have taken place within two richly endowed centuries, it does not tell us which major facts will form the threads of the next years. It is this unknown factor which makes up the spice of our professional life. We can at least hope that if we conform to reason, to ethics, and to scientific and economic laws for all that is within our scope, each of us will have served this wonderful science that is chemistry to the best of our capacities and in the interests of the greatest number of people.

The Period of the 1990s

The Chemical Industry under Pressure from Public Opinion and Regulatory Authorities

Prior to the mid-1980s the chemical industry experienced some upheavals of which the thalidomide tragedy of the early 1960s and the Bhopal catastrophe in 1984 are two major examples. However, the lessons learned from such sad events led to a spectacular improvement during the 1990s in the safety record of the industry in the Western world.

At the same time much progress has been made in the abatement of pollution in the air and the treatment of effluents from chemical operations in North America, Western Europe, and Japan. Between 1978 and 1988 the content of SO_2 in the atmosphere was reduced by 30% in the United States. Similarly, constant improvements in the way chemicals are manufactured have reduced the amount of by-products resulting from chemical operations and, therefore, of the quantities of effluents to be treated.

Paradoxically, as these improvements were brought about, the chemical industry in the Western world has become the preferred target of environmentalists, and through the influence of the media, its image has been deteriorating in the eyes of the public at large. The time is indeed long gone when a firm like Du Pont could print as a motto on its letter-head "better things for better living through chemistry."

Public opinion was just one area in which the chemical industry of the developed nations suffered setbacks. The industry had to face a more tangible threat in the form of increased pressure from regulatory authorities. For the United States alone, Edgar Woolard, then chairman of Du

Pont, cited a figure of $585 billion for the financial burden incurred by industry in 1993 as a result of federal regulations, and he predicted the figure to reach $660 billion in 2000 ("In Praise of Regulation Reform," *Chemistry & Industry*, 5 June 1995). At the same time the Environmental Protection Agency itself projected that by the end of the 1990s the United States would spend $160 billion per year on pollution control. In 1996 Ben Lieberman, an environmental research associate with the Competitive Enterprise Institute, estimated that in the United States the cost of the phase-out of CFCs in accordance with the 1987 Montreal Protocol on Substances That Deplete the Ozone Layer could reach $100 billion over the next 10 years. Indeed chemical manufacturers had to develop eco-friendly substitutes such as hydrochlorofluorocarbon (HCFC) and hydrofluorocarbon (HFC), which are more costly to make, and hundreds of millions of pieces of air-conditioning and refrigeration equipment using CFCs had to be discarded.

In fact the chemical industry has been affected in many different ways by the flurry of regulatory edicts in the 1990s. For example, the banning of CFCs, together with new restrictions on the use of chlorinated solvents, has forced chemical producers to steer their product mix of chlorinated hydrocarbons away from precursors of these two categories of chemicals. Similar disruptions in the "chemical tree" of derivatives have been caused by the phasing out of tetraethyl lead as an antiknocking additive for gasoline and by its replacement with methyl tertiary butyl ether, whose fate is now held in balance by the authorities in California.

The fear of dioxins, which was born from an accident occurring on July 10, 1976 at the unit in Seveso, Italy, of Givaudan, a subsidiary of the Swiss Hoffmann-Laroche, has also changed the way many chemical operations are conducted. That accident, although it caused no human fatalities, damaged the environment by releasing in the atmosphere some 500 g of a very noxious chlorinated impurity of the family of the dioxins. In order to avoid a release of even the most minute quantities of this particular dioxin again, hexachlorophene, a very useful germicide is no longer manufactured. In addition, pulp and paper mills in North America have been asked to drastically curtail the use of chlorine and chlorates for bleaching the pulp, and industrial and municipal waste incinerators are being submitted to stricter air-pollution controls, which make it necessary to install high-efficiency scrubbers.

The more stringent regulations enacted by Western governments have led, in turn, to a delocalization of chemical activities to places where such rules are less strictly enforced. Nations like India and China have thus become world leaders in the production of some fine chemical intermediates and dyestuffs. Similarly in Mexico many maquiladoras owe their success, in part, to this process of delocalization.

International trade in chemicals has been affected in many other ways by the vagaries of national legislations. For instance, meat treated with hormones is considered safe as food for Americans but not for the citizens of the European Union. Bovine somatropin (BST), a hormone that increases milk production in cows, has long been cleared by the US Food and Drug Administration, yet it is banned by health authorities in Brussels. Products derived from biotechnology have been particularly prone to these inconsistencies. Hoechst spent 7 years and 80 million DM to obtain permission to operate its artificial insulin unit in Frankfurt. Meanwhile one of Eli Lilly's plants located in Strasbourg, France, was regularly exporting an identical product to Germany.

While the use of genetically modified organisms in pharmaceuticals has finally been accepted because of their beneficial effects on human health, environmentalists, particularly in Western Europe, strongly object to the application of such organisms to agriculture. Transgenic crops, which offer increased resistance to herbicides and reduce the need for synthetic insecticides, have received the blessing of public authorities in the United States, Canada, and Argentina and have been planted with enthusiasm by farmers in these countries over the last 10 years. Even though no harmful effect resulting from their use has ever been detected during that period, Greenpeace and other environmental organizations, with public backing, were able to convince European officials that the planting of transgenic crops should be severely restricted until more is known about how they react with the environment. The European Union's sudden conversion to the "precautionary principle" will have important consequences. International trade of transgenic food and feed based on genetically modified corn or soy will be submitted to stricter regulations. Further development of disease- and pest-resistant seeds may take more time to benefit the farmers and, in turn, the final consumers. As these restrictions are being implemented, chemical companies specializing in life sciences will have to consider a drastic restructuring of their portfolio of products.

The Status of Science and Technology

At the end of the 1990s the chemical industry in its main activities had reached a stage of maturation with respect to innovation. Several factors can help explain this situation. First, the pace at which new discoveries were made between the 1930s and the 1960s was not sustainable for the same reason that new elements of the periodic table were not easily found once most of them had already been described. Second, the part of the turnover that chemical firms were able to devote to their research and development budgets became smaller as more of the available funds were used to cover increasing environmental expenditures. Third, the management of companies whose shares were quoted on the stock market had to pay closer attention to the wishes of stockholders and financial analysts, who were often more interested in short-term accomplishments than in ambitious R&D programs, which are necessarily lengthy, costly, and risky.

However, while no major breakthrough was made during the last 10 years of the century in their traditional fields of endeavor, chemical corporations continued to improve the performance of their products by devising new methods for their manufacture. A case in point is supplied by the development of the metallocene catalysts. First described by Walter Kaminsky of the University of Hamburg in the 1980s and pioneered in the field of polyolefins by Exxon and Dow, these organometallic initiators are still more expensive than the conventional Ziegler-type catalysts. They have nevertheless already gained wide acceptance in the field of polymer production because they make possible, owing to their special configuration, the production of a second generation of polyethylene and polypropylene plastics with improved characteristics. The substitution of butane for benzene in the production of maleic anhydride, which began in the 1980s, has at the same time lowered the cost of manufacture of this intermediate and done away with benzene as an objectionable raw material. In the period covered in this chapter, only biotechnology has offered the chemical industry new opportunities for spectacular developments in applications related to both pharmaceuticals and agrochemicals.

In the 1980s, as has been discussed (see p. 342), only a few bioengineered products were developed: human insulin and HGH, both by Genentech, came on the scene, followed by the antithrombotic tissue plasminogen activator (Genentech, 1987) and the red corpuscle producer erythropoietin (Amgen, 1989). About the same time (1985) Abbott introduced a diagnostic test that could detect the AIDS virus in human blood collected for transfusions. By the early 1990s, however, through alliances with pharmaceutical laboratories, all these bioengineered products were already in commercial use with annual sales passing $100 million, and one third of the research projects of the major pharmaceutical companies were based on biotechnology. It is significant that Genentech, the biotechnology company that Roche now controls with ownership of 59% of its shares, has diversified its product range to include oncologic drugs for the treatment of lymphoma and breast cancer as well as cardiovascular products.

The technologies that have thus transformed drug discovery have also been applied to agriculture in such a way that new transgenic plant varieties were produced with characteristics that could not be easily obtained through cross-pollination. Monsanto, which had relied until the end of the 1980s on agrochemicals obtained synthetically, started selling seeds, which yielded transgenic crops engineered in such a way that they either offered outstanding resistance to herbicides or generated insecticides in the form of *Bacillus thuringiensis* toxins. By 1999, 33% of America's corn and 55% of its cotton crop as well as 99% of Argentina's soybeans came from such genetically modified varieties. Contrary to what happened to the pharmaceutical applications, the use of biotechnology in agriculture has been opposed by such pressure groups as Greenpeace and by public-sector agricultural institutions, so it may take some time before genetically modified crops are universally accepted.

In the 1990s the pharmaceutical industry proved to be innovative not only through the use of biotechnology but also through the discovery of new drugs by other methods. It applied the technique of chiral chemistry to isolate from a racemic blend the optically active molecule that is the one desired as a drug. Combinatorial chemistry was another tool the industry began to use: in one stroke thousands of small molecules could be made for screening as drugs rather than having to synthesize the molecules one at a time. It made use of improved drug-delivery systems that could bring new life to older products or maximize the number of potential drug formulations likely to accelerate the path from preclinical trials to final approval.

It even met with luck through serendipity in the field of "lifestyle drugs." Sildenafil, for example, which is being offered by Pfizer under the brand name Viagra as a treatment for male impotence, was initially developed as an antianginal drug before its property of improving male sexual performance was detected. Upjohn first marketed minoxidil (Rogaine) as an antihypertensive before it came to be recommended as a hair growth stimulant for the treatment of male baldness.

The New Landscape

The 1990s were characterized by two main trends in the world economy. First was a move toward globalization made possible by the further development of free trade between nations; this led to a more competitive environment and made it necessary for corporations to streamline their operations and increase their productivity. Second was an expansion of stock markets, with more attention being paid to the financial performance of companies by the pension funds holding their shares and more generally by the various stakeholders.

In order to cope with the changing conditions, the management of many chemical companies of the Western world concluded that they had to operate along new lines. They gave priority to the concept of being the leaders in a few selected fields, and in order to obtain quick results, they came to favor external growth by acquisition at the expense of internal growth by innovation. This in turn led to a flurry of mergers, joint ventures, and divestitures that radically modified the landscape of the industry. Some companies already involved in pharmaceuticals and agrochemicals decided to concentrate on their life science activities exclusively. Oil companies that had previously diversified into fine chemicals and specialties left these fields and limited their ambitions to being strong in petrochemicals. Conversely, various chemical groups well established in basic chemicals tried to divest product lines considered to be too cyclical in favor of specialties. Meanwhile some individual entrepreneurs and financial buyers became interested in the very commodities that chemical giants were divesting.

At the same time these various acquisitions and divestitures were taking place, a minority of more traditional companies decided to retain the various areas in which they had been operating; they decided to try to grow internally by promoting products related to their "chemical tree" or, less often, by developing new molecules through their own research. As a result of these different attitudes, while the products made by the chemical industry remained generally the same over the decade, the ownership of the plants in which these products were made changed hands rapidly, and some well-known names in the industry disappeared, with new ones springing up in their place.

The Trials and Tribulations of the Pharmaceutical Industry

For historical reasons the activities of the pharmaceutical industry in the Western world had been operated either by "stand-alone" pharmaceutical laboratories or by divisions or subsidiaries of diversified chemical groups. To the first category belonged such well-known firms as American Home Products, Bristol-Myers Squibb, Eli Lilly, Merck, Abbott, Upjohn, and Pfizer in the United States; Burroughs-Wellcome, Glaxo, and Beecham in the United Kingdom; Roussel-Uclaf and Servier in France; E. Merck, Schering, and Boehringer, Ingelheim in Germany; and Hoffmann-La Roche (now Roche) in Switzerland. The second category included the life science operations of American Cyanamid, Hoechst, Bayer, Rhône-Poulenc, Elf Aquitaine, ICI, Ciba-Geigy, and Sandoz. However, independently of their origin, all companies involved in pharmaceuticals had to face similar challenges in the period considered in this chapter:

- A growing population of older people with more ailments to be treated;
- Higher R&D expenditures requiring returns between $300 million and $600 million for each approved active pharmaceutical ingredient;
- Patents due to expire for blockbuster drugs, which would invite competition from producers of generic drugs; and
- Higher marketing costs at a time when Social Security institutions and health maintenance organizations insisted on lower selling prices for the drugs being offered.

As if this were not enough, the pharmaceutical industry was also confronted, as were other industries, with the new concepts of globalization and "shareholder value."

In order to increase their geographical coverage, most firms on both sides of the Atlantic resorted to mergers and acquisitions. Thus, beginning in the late 1980s, Squibb merged with Bristol-Myers, SmithKline & French merged with Beecham, Rhône-Poulenc acquired Rorer, and Bayer took over Miles and Cutter Labs. Other transfers of ownership followed in 1994 and 1995: Roche bought Syntex, the Swedish Pharmacia merged with Upjohn, Hoechst acquired Marion Merrell from Dow and completed its control of Roussel-Uclaf to become HMR, and Glaxo and Burroughs-Wellcome formed a single entity. This was also the time when the pharmaceutical, crop protection, and nutrition operations of Ciba-Geigy and Sandoz were combined into a new company called Novartis (1995) and when similar operations belonging until then to American Cyanamid went to American Home Products (1996).

As the process of globalization proceeded, many diversified chemical groups started to pay more attention to the lucrative market of pharmaceuticals at the expense of their traditional chemical lines and to get interested in the promising field of biotechnology. Already in 1985 Monsanto had bought Searle before entering the field of genetically modified seeds. Du Pont also got involved on a limited scale in pharmaceuticals through a joint venture with Merck and moved into seeds. ICI, after the threat of a takeover by the British conglomerate Hanson Trust, split its life science and specialty chemicals operations from the rest of its portfolio by giving birth to Zeneca (1993).

Eastman Kodak decided in 1994 to part with Sterling Drug: the ethical drug division went to Sanofi (Elf Aquitaine), and over-the-counter drugs went to SmithKline Beecham. Dow also divested its pharmaceutical business by selling Marion Merrell to Hoechst, which later was to announce its intention to become a life science company (1997). After some hesitation Rhône-Poulenc followed the same path as Hoechst, and in 1999, having proceeded with the separation of their chemical activities from their core life science business, both firms put together, under the aegis of a new company to be called Aventis, their pharmaceutical divisions and subsidiaries as well as the former crop protection operations of Rhône-Poulenc and of AgrEvo, jointly owned until then by Hoechst and Schering.

These various moves, made under the pressure of financial analysts and with the purpose of enlarging the pipeline of active pharmaceutical ingredients close to approval, caused drastic changes in the structure of the chemical industry. Some of these changes were also a result of the outsourcing by pharmaceutical laboratories of most of their upstream chemical production, which gave a strong impetus to companies specializing in organic synthesis.

Within the pharmaceutical industry itself, the wish of each company's management to see its firm reach what is considered a "critical size" remained a constant feature as the century came to an end and the new millennium began. It led to new national and transnational mergers. In France, Sanofi (Elf Aquitaine) merged with Synthélabo (L'Oréal) and Laboratoires Pièrre Fabre with BioMérieux. Elsewhere the Swedish Astra and the British Zeneca combined their operations; Pharmacia-Upjohn took control of Monsanto; and two giant firms, Glaxo Wellcome and SmithKline Beecham, announced their intention to combine their activities, which would lead to a group with a turnover of $25 billion, exceeded only by Pfizer after its acquisition of Warner Lambert.

However, serious problems remain after such mergers take place. Short-term savings do not necessarily produce long-term growth. Furthermore, the executives and their subordinates of the merged companies may not get along with each other, the best researchers sometimes leave, and most of the time size is not the corollary of creativity. For all these reasons some "contrarians" in the industry have decided to pursue a different course at least for the time being.

Roche, with its capital still controlled by the founder's family, has opted for internal growth. Although still a market leader in vitamins, the company is concentrating on its own research for pharmaceuticals. It is developing simultaneously a line of diagnostics after acquiring Boehringer, Mannheim and has gained access to biotechnology through its controlling interest in Genentech. In order to finance these activities, Roche has at the same time announced the spin-off of its flavors and fragrances business known as Givaudan. Among other contrarians, mention should also be made of Bayer, which with a pharmaceutical operation amounting to more than $5 billion in sales, has until now run the business under its existing structure. Other chemical giants like Solvay with Solvay Pharma, BASF with Knoll, and Akzo Nobel with Organon are following a similar strategy. It is possible, however, that because of the relatively small size of their pharmaceutical businesses they may decide to do otherwise in the future.

Stand-alone pharmaceutical laboratories have also in many cases preferred internal growth to mergers and acquisitions and have prospered by doing so. Such is the case particularly in the United States with Johnson & Johnson, Eli Lilly, Schering Plough, and Merck and Company. In addition biotechnology companies, which have developed products until now commercialized by well-established laboratories, are reaching a size (as with firms like Amgen, Chiron, Genentech, and Genzyme in the United States) that will allow them to consider acquiring their own pharmaceutical companies in the not-too-distant future.

This survey of the Western world should not make us forget that Japan also has a thriving pharmaceutical industry. Three firms in particular—Takeda, Sankyo, and Yamanouchi Pharmaceutical Company—are of international repute. Takeda, the largest, is also the oldest, having been founded by the Takeda family in 1781. It has a joint venture with Abbott in the United States. Out of 25 blockbuster drugs currently available in the United States, six were discovered in Japan. But Japan remains weak in biotechnological developments, which are the source of much Western drug innovation.

The Reshuffling of Chemical Assets

Many large groups, once deprived of their life sciences activities, were left with sizable chemical activities that had to be dealt with. One widely used solution was the creation of new chemical entities through various spin-offs. Thus, between 1993 and 1999, Kodak gave birth to Eastman Chemical Company, American Cyanamid to Cytec Industries, Ciba-Geigy to Ciba Specialty Chemicals, Sandoz to Clariant, Monsanto to Solutia, and Rhône-Poulenc to Rhodia. Some more complex cases had to be solved differently. Hoechst, for example, proceeded in successive steps: in 1994 it set up a 50-50 joint venture with Bayer, called Dystar, for the purpose of managing their respective dyestuffs businesses. In 1997 it transferred its specialty chemicals operations to Clariant in return for a 45% stake in the enlarged company; finally, in 1999, it passed its industrial chemicals assets on to Celanese—the US corporation it had acquired 12 years earlier—and passed Herberts, its coatings company, on to Du Pont.

ICI also was faced with difficult problems after the creation of Zeneca, as it had an impressive range of commodity chemicals to dispose of and wanted to acquire activities that would be more lucrative and less cyclical than the ones it was left with. In 1997, having changed its top management, ICI was able to acquire from Unilever, which wanted to focus on consumer products, three profitable businesses: National Starch (adhesives), Quest International (fragrances), and Unichema (oleochemicals), now called Uniqema. While taking advantage of this opportunity to re-enter the specialty chemicals markets, ICI began to divest its bulk chemicals and polymer operations: polyester fibers and films went to Du Pont; fertilizers and ammonia to Terra Industries; explosives to AECI and Orica; autopaints to PPG Industries; polyurethane, aromatics, and titanium dioxide (TiO_2) to

Fig. 1.1 Sir James Whyte Black, one of the recipients of the 1988 Nobel Prize in physiology or medicine. While at ICI, his pioneering work in analytical pharmacology led to the discovery of β-adrenoceptor and histamine type 2 antagonists. Courtesy Nobel Foundation

Huntsman; and acrylics, fluorochemicals, Crossfield silicas, and chloralkali units to a privately held financial company called Ineos. At the end of 2000, with this ambitious program of divestitures completed, ICI had become an efficient specialties and paints company, and the three letters *I*, *C*, and *I*, which originally stood for Imperial Chemical Industries, are the only reminder of its past glory. Other groups did not even retain their former names (for example, American Cyanamid, Sandoz, Hoechst, and Rhône-Poulenc) and therefore will soon survive only as entities in the memory of old-timers. Many other changes were to occur as the reshaping of the chemical industry continued (Fig. 1.1).

The Impossible Marriage of Pharmaceuticals with Agrochemicals

Placing all life science activities under one roof appeared to be a logical decision, and it at first had the blessings of financial analysts. However, it proved unwise. Indeed, no sooner had Novartis, AstraZeneca, Pharmacia-Upjohn-Monsanto, and Aventis been created than their managements were made aware of some important facts:

- There was very little synergy between the pharmaceutical and the crop protection parts of the business.
- The margins generated in the human health sector were far higher than the ones obtained in selling products to farmers.
- Pesticide sales are cyclical because they depend on the weather and on commodity prices.
- The backlash begun in Europe against genetically modified foods has decreased—at least temporarily—the expectations for high-tech seeds.

As a result all the above-mentioned companies have decided to divest their agrochemical operations through either mergers, spin-offs, or straight sales, and new entities devoted entirely to crop protection are being born: Syngenta from the merging of the agrochemical divisions of Novartis and AstraZeneca; Aventis CropScience, the merger of the crop protection activities of Rhône-Poulenc and of Hoechst Schering, formerly known as AgrEvo, once the problem raised by the participation of Schering in AgrEvo had been solved; and Monsanto, to be left essentially as a separate unit by Pharmacia-Upjohn shortly after having been acquired by them.

While these divestitures are taking place, large chemical groups less spoiled by the high margins of the pharmaceutical industry are reinforcing their position in agrochemicals. Such seems to be the case with BASF, which in March 2000 acquired the pesticides line of American Cyanamid from American Home Products, and of Bayer, which has added strength to its range of fungicide products by buying the Flint product line of Novartis. Other groups like Du Pont that are very active in seeds and Dow Chemical, which purchased Eli Lilly’s remaining share in DowElanco in 1997, have also kept faith in the future of agrochemicals, a market worth $30 billion worldwide. Even smaller firms can find the agrochemical business particularly rewarding, provided they focus on “niche” products as FMC and Uniroyal Chemical (now part of Crompton Corporation) have done. In any case the trend seems to be for life science companies to focus on pharmaceuticals and for large chemical groups with relatively small operations in human health to negotiate a withdrawal and concentrate on agricultural chemicals, an activity closer to their traditional practice. The announcements at the end of 2000 that Knoll, part of BASF, will be sold to Abbott and that Bayer and Du Pont are considering a separation of their pharmaceuticals from the rest of their businesses provide further proof for this line of thinking.

The Fate of the Dyestuffs Sector

Still in 1992 there were six major producers of dyestuffs in Europe—BASF, Bayer, Hoechst, Ciba-Geigy, Sandoz, and ICI—and an American manufacturer of smaller size, Crompton & Knowles. However, the pressure of small competitors in India and China has since led to major changes in the industry. Indeed, with their low overhead, favorable labor costs, and lack of consideration for environmental issues, these Far East firms began to offer intermediates for dyestuffs, then finished dyes, at very attractive prices. The established producers of the Western world reacted initially by using these cheaper intermediates in their own production, but they soon realized that more drastic moves were necessary. In the case of ICI the textile dyes were transferred to Zeneca Specialties, which in turn made toll-manufacturing arrangements with BASF before being taken over by venture capitalists (Cinven and Invest Corp) in 1999 to form Avecia. As has already been mentioned, Hoechst and Bayer combined their textile dyes in a 50–50 joint venture called Dystar (1994), which BASF later joined. The dyestuffs lines of Ciba-Geigy and Sandoz went, respectively, to Ciba Specialty Chemicals and Clariant after the creation of Novartis in 1995. Crompton & Knowles sold its textile dye business in 2000 to a British manufacturer, Yorkshire Chemicals, now called Yorkshire Group.

These various changes of ownership were accompanied by plant closures and the transfer of production to such places as Brazil and the Asia-Pacific area, which offered cheaper labor costs and less severe regulatory constraints. Smaller producers of textile dyes in Europe also lowered their ambitions, with Holliday Chemical Holdings, now part of Yule Catto, closing their historical site of Huddersfield in the United Kingdom and Yorkshire Chemicals discontinuing production at its unit in Tertre, Belgium. Conversely, large firms like Ciba Specialty Chemicals and Clariant, while delocalizing their commodity dyes to more propitious regions, were able to link their dye expertise with their pigment technologies and to develop more sophisticated products for use in such applications as plastics, paints, and inks.

Consolidation in the Field of Specialty Chemicals

In their pursuit of “shareholder value” chemical companies have generally favored developing specialty chemicals over manufacturing large-volume commodities, which are considered to be less profitable and too cyclical. However, for historical reasons, the balance between these two categories of products varied from one group to another. This was particularly evident in the case of the newly born companies that resulted from the split of life science operations. Thus Ciba Specialty Chemicals was from the beginning a company focused on specialties and performance chemicals. It became even more focused with the acquisition in 1998 of Allied Colloids, a British company specializing in flocculants, and with the sale of its epoxy resins, a line of polymers in which it had been a pioneer, to Morgan Grenfell Private Equity. Clariant, with the product ranges inherited from Sandoz and more recently from Hoechst, belonged in the same league. It further enhanced its position by acquiring the former British Tar Products (now BTP) with its fine chemicals arm Archimica, a leading manufacturer of active molecules for the pharmaceutical industry, and PCR, a high-tech product specialist. The new ICI under the guidance of Brendan O’Neill had been re-created into a leading specialty chemicals corporation.

Other newly born companies were not so lucky, and their image remained blurred in the eyes of financial analysts because their product mix still included a significant proportion of commodities. Eastman Chemical Company, for example, still relied heavily on polyethylene terephthalate plastics and cellulose acetate in the field of polymers and on the acetyl chain and oxoalcohols as far as high-volume chemicals were concerned. Its management, by acquiring Peboc in the United Kingdom from Solvay Duphar as well as two other fine chemicals units in the United States, had made plans to enter the sector of organic synthesis for pharmaceuticals, only to give it up a few years later. Instead, Eastman Chemical Company decided to increase its presence in the resin market after it acquired Lawter International, an ink resin manufacturer; in 2000, Eastman also acquired the rosin esters and hydrocarbon resin lines of Hercules.

Rhodia, because of earlier mergers, is also regarded as a conglomerate rather than a purely specialty chemical firm. Having placed its toluene diisocyanate unit outside its perimeter of activity and sold its chloralkali business to a US investor, La Roche, it still retains such commodity chemicals as phenol, phosphoric acid, and sodium tripolyphosphate (STPP) and maintains a presence in such unrelated fields as rare earths, styrene butadiene rubber latex, and cellulose acetate tow. Its core businesses are also very diversified; they include nylon fibers, polyamide engineering plastics, biopolymers (guar and xanthan gum), diphenols and derivatives, silica, silicones, and surfactants. In the future Rhodia intends to develop its activities in organic synthesis for pharmaceuticals, and it has recently acquired ChiRex, a US company that complements the units it already operates in the United Kingdom and in France (ICMD, Industrie Chimique Mulhouse Dornach). Rhodia recently made a successful bid for the old British firm Albright & Wilson, which gives it a leading position in the field of phosphoric derivatives, while the surfactant line will be resold to Huntsman.

Solutia, a firm created through a spin-off by Monsanto in 1997, also looks more like a conglomerate than like a specialty chemicals company because it retains large operations in nylon and acrylic fibers as well as in upstream commodities. It has entered its phosphorus chemicals operation into a joint venture with FMC called Astaris. Another joint venture, this time with Akzo Nobel, runs its former rubber chemical business under the name of Flexsys. Solutia has acquired, from Akzo Nobel, CPFilms and has purchased from Deutsche Morgan Grenfell the line of Vianova resins that belonged initially to Hoechst. The prospects for the lucrative polyvinylbutyral film for safety glass (Saflex) look particularly promising.

Another newly born corporation, Cytec Industries, having sold its acrylic fibers to Sterling Chemicals, looks more entrenched in the field of specialties than either Rhodia or Solutia. As a spin-off of American Cyanamid, Cytec has gained a leading position in the production of acrylamide derived from acrylonitrile and is a major producer of flocculants destined for water treatment. Recently, however, it sold its line of paper chemicals to Bayer. Among the new entities that appeared after the restructuring of the life sciences operations of several large groups, the former specialty chemical business of ICI, renamed Zeneca Specialties and then Avecia after it was acquired by Cinven and Investcorp, should be mentioned.

Aside from the above-mentioned changes from outside causes, consolidating this sector of the chemical industry has also been to a great extent the work of long-established firms already well positioned in the field of specialties and performance chemicals. In the United States, for instance, Rohm & Haas through its acquisition of Morton International in mid-1999 has greatly enhanced its status as a leading producer of chemical specialties—a status it had earned through its past presence in such lines as plastics additives, biocides, agrochemicals, and electronic chemicals. With the purchase in 1999 of Lea Ronal and of the photo-resist business of Mitsubishi, Rohm & Haas has further increased its presence in the electronic materials market, and its decision to divest the salt production activities of Morton International can only strengthen its position as a supplier of specialty chemicals.

Another American firm, Great Lakes Chemical Company—whose most profitable product, tetraethyl lead, made by its subsidiary Octel was being threatened by regulatory authorities—has also decided to concentrate its efforts on specialties and performance chemicals. Great Lakes, after deciding to focus on plastics additives, acquired successively Société Française d'Organo-Synthèse (SFOS), a Rhône-Poulenc subsidiary; LOWI, an independent German firm; and the antioxidant and ultraviolet absorber lines of Enichem in Italy. Finally, in 1998, Great Lakes demerged Octel and became a company in which over 80% of its sales was devoted to specialties. Ethyl, Great Lakes' main competitor in bromine chemistry, took a different path. In 1994 it set up two autonomous companies: Albermarle Chemical Company, which took over the polymer and fine chemicals businesses, and Ethyl, which was to specialize in petroleum additives.

Olin, one of the few conglomerates left on the American scene, clarified its structure in 1999 by regrouping under a new company called Arch Chemicals all its fine chemicals operations, while retaining the metal, ammunition, and chloralkali operations under the existing organization. A year later Arch Chemicals took over the British company Hickson International, which was involved in wood-treating chemicals, coatings, and fine chemicals. The trend toward further consolidation has led FMC to plan the separation of its chemical divisions, which represent almost 50% of its turnover from its machinery and engineering operations.

Other large groups, however, have chosen to maintain their specialties in their traditional structure. General Electric, for example, generates over $6 billion worth of plastics and chemical sales, including sales of acrylonitrile butadiene styrene resins and plastics additives acquired from Weston Chemical (a former Borg Warner subsidiary) and now managed by GE Plastics. Similarly Riedel de Haen, the fine chemicals German company taken over from Hoechst by Allied-Signal is run as part of that conglomerate whose turnover of specialty chemicals exceeds $1 billion. Several other American firms belong to the category of companies with at least $1 billion worth of sales in specialties and performance chemicals, including W.R. Grace, Lubrizol, Crompton, Hercules, and B.F. Goodrich. The fate of these companies is worth considering.

W.R. Grace has shrunk considerably from its earlier days as a conglomerate under Peter Grace, and it has to be considered as a specialty chemicals company from now on. Lubrizol is still a lube additives specialist with some growing activity outside its core business. But Crompton is the outcome of two mergers that have greatly expanded the portfolio of products it now manages.

In 1996 Crompton & Knowles, then a manufacturer of dyestuffs and polymer-processing equipment, took over Uniroyal Chemical, a company resulting from a leveraged management buyout after the tire business, which had gone to Michelin, was split off. Three years later Crompton & Knowles and Witco were merged through an exchange of shares, Witco having become vulnerable as a result of unsuccessful restructuring. The new entity, now called Crompton, no longer includes the oleo-chemicals of Witco, which went to Th. Goldschmidt (SKW Trostberg), or the textile dyes of Crompton & Knowles, sold to Yorkshire Chemicals. With a turnover of around $3.3 billion it is nevertheless a well-diversified specialty chemicals company, with leading positions in ethylene propylene rubber, plastics additives, and rubber chemicals as well as crop protection products and silanes.

At the same time that Crompton appeared as a strong contender with its wide range of specialties, two well-known American firms were approaching the end of their existence as specialty chemicals manufacturers. B.F. Goodrich, originally a tire maker, had diversified successfully into chemicals. However, at the end of 2000, it had become a major aerospace industry supplier with only $1.2 billion worth of specialty chemicals sales left. This business unit has now been sold to an investor group led by AEA Investors Inc., a closely held business, and B.F. Goodrich has divested the last of its former operations. The other firm,

Fig. 1.2 Crompton's silane unit, Termoli, Italy. Courtesy Crompton Corporation

Hercules, was originally a prominent and innovative producer of chemicals and polymers with leading positions in several niche markets. When Thomas Gossage, from Monsanto, took over as chairman in 1991, Hercules had already sold its dimethylterephthalate (DMT) business and the 50% share it owned in Himont, a polypropylene joint venture with Montedison. From 1991 to 1996 the company went through a restructuring that combined the sale of various parts of its portfolio of activities (aerospace, flavors and fragrances, polypropylene packaging films, electronics, printing materials, and so forth) with an ambitious share repurchase program. This program raised the market value of Hercules stock to a peak of $65 per share in 1995, a year before the chairman retired (Fig. 1.2).

By that time, however, the company was left with only a few businesses, which although quite profitable, offered little growth potential. To give the company a boost, the new chairman considered entering the field of water treatment. In 1997 Hercules made an offer for Allied Colloids, but it was outbid by Ciba Specialty Chemicals. A year later, however, Hercules, by paying a high premium, was able to acquire BetzDearborn, a water-treatment specialist formed when Betz Laboratories bought the Dearborn units of W. R. Grace. The deal boosted Hercules' revenues from $1.9 billion to $3.5 billion, but it also increased its debt substantially at a time when competition in the water treatment market had become much more acute owing to the consolidation of the two entities Calgon and Nalco Chemical Company under the aegis of the French group Suez Lyonnaise des Eaux. The management of Hercules, hoping to improve the company's debt ratio, decided to part with other assets: their food gum operation is now a joint venture with Lehman Brothers Merchant Banking partners as majority shareholders; the resins operation, for which they held a leading position, has been sold to Eastman Chemical; and FiberVisions, the world's largest producer of thermally bonded polypropylene fibers, is for sale. As was to be expected, the valuation of Hercules stock has been severely downgraded, reaching a low of $14 per share. This decline has in turn attracted the attention of the well-known raider Samuel Heyman, the chairman of International Specialty Products, which is the new name for the former GAF Corporation. With Thomas Gossage now back in the driver's seat, Hercules may not have any other choice but to be sold and disappear as a going concern after a long and often brilliant existence that began in 1912.

This story is typical of what happens to an otherwise healthy company when it is managed for too long under the pressure of short-term financial considerations. The fate of Laporte Chemicals, a British company founded in 1888 by the chemist Bernard Laporte to produce hydrogen peroxide (H_2O_2) for use as a bleach, was not any better than that of Hercules. Yet by 1995 Laporte had grown into a uniquely large specialty chemicals corporation with a turnover of £1 billion. It had quit the phthalic anhydride and TiO_2 sectors in the 1980s and in 1992 dissolved its joint venture with

Solvay, Interox making H_2O_2. Having made several acquisitions in the fields of organic peroxides, adhesives, and process chemicals, Laporte was operating through 16 strategic business units. Between 1995 and 1998, however, the management of the company started to divest some businesses that were underperforming, the remaining portfolio being focused on fine organics, peroxide initiators, construction chemicals, electronic materials, pigments, and additives. This reshuffling of activities culminated in 1999 with the acquisition of Inspec, a British firm that resulted from the leveraged management buyout 7 years before of several chemical operations and in particular of parts of British Petroleum's specialty chemicals and of Shell's fine chemicals divisions. No sooner had this last acquisition been completed than the new management in charge of Laporte, with a view to reducing the outstanding debt, decided to part with those units that were not directly involved with fine organics and performance chemicals. As a result the units that represented half of the total turnover were sold at the beginning of 2000 to Kohlberg Kravis Roberts & Co., a private equity investor. Finally, having reached a perfect size for being taken over, Laporte, or rather what was left of it, was acquired a few months later by Degussa AG and disappeared from the British scene as an independent chemical corporation after 112 years of operation.

Degussa AG is the new name of a German group that is slated to become one of the largest fine chemicals and specialty chemicals corporations in the world. But to achieve this status, further restructuring is needed. Indeed Degussa itself, which celebrated its 125th anniversary in 1998, was by then a member of VEBA AG, a large German energy concern that owned 100% of Chemische Werke Hüls. The next step was for Degussa and Hüls to be merged through an exchange of shares that gave VEBA a stake of 62.4% in the new company. Meanwhile, another energy company, VIAG AG, established in Bavaria, had taken full control of SKW Trostberg, to whom it was supplying power. In 1997 VIAG gained a controlling interest in a family business, Th. Goldschmidt, which it merged with SKW Trostberg 2 years later. VIAG thus owned 63.7% of the merged entity. Then VEBA and VIAG announced their intention of combining their chemical assets and gave birth at the end of 2000 to what is now called Degussa AG with initial sales of 14 billion Euros per year. In order to streamline its operations into a true specialty chemicals group, Degussa AG will need to dispose of several commodity activities (e.g., phenol, fertilizers, salt and metallic chemicals, dimethyl terephthalate, C-based alcohols, and plasticizers) and to sell its pharmaceutical subsidiary Asta Medica as well as its automotive catalyst sector. It will then be left with leading positions worldwide in such diversified fields as amino acids, carbon black, precipitated silicas, organosilanes, specialty polymers, flavors (Mero & Boyveau) oleochemicals (Th. Goldschmidt), and hydrogen peroxide.

As the consolidation of the specialty chemicals industry continued, it affected many firms in which the founder's family still held substantial portions of the capital, even though some of them kept on thriving. One example was Union Chimique Belge, whose management had been wise enough in the late 1980s to focus on three profitable lines: the pharmaceutical sector, with a blockbuster antiallergic drug called Zyrtec; the chemical sector, with ultraviolet curing and powder-coating technologies; and the film sector, with a leading position worldwide in oriented polypropylene and cellophane films. The German company Wacker, in which Hoechst had been a partner from the start, also managed to retain its independence, although it was still active in some commodity-type products (acetic acid, vinyl monomers and polymers, and silicon carbide), it chose to emphasize lines that showed greater profitability, such as silicones, hyper pure silicon for semiconductors, and specialty and fine chemicals. In France the well-run starch and derivatives producer Roquette Frères, after a short flirtation with Rhône-Poulenc, was able to recover its autonomy.

Other firms were less fortunate; they lost their independence because the founder's successors either could not agree on a management plan or had to sell their shares to pay inheritance taxes. Thus, Compagnie Française des Produits Industriels, which belonged to the Hess family, was sold in 1996 to Fernz Nufarm, a firm from New Zealand specializing in agrochemicals. As has been discussed, Th. Goldschmidt of Germany was taken over by VIAG. Another German firm, Raschig, which was founded in Ludwigshafen in 1891 and which had remained under the control of its family owners since then, was integrated in the mid-1990s into the PMC Group of Philip Kamins, a California-based entrepreneur with interests in plastics and specialty chemicals. Even a powerful company like the venerable Henkel had to reconsider its position. In 1999 it set apart under the name of Cognis its specialty chemicals activities, including production of an important range of oleochemicals. Henkel, still controlled by the heirs of Fritz Henkel, has made clear its intention to leave this field in order to better compete in the consumer products area with such large groups as Unilever and Procter & Gamble.

The specialty chemicals industry is estimated to have an annual turnover of $200 billion worldwide, with production scattered among a great variety of suppliers. Consolidation of that industry was to be expected owing to the pressure of shareholders and to management eager to rationalize their portfolio of products. Some corporations like Ciba Specialty Chemicals, Clariant, ICI, Rohm & Haas, Crompton, and Great Lakes have succeeded in being considered as specialty chemicals companies in their own right. Others, such as Rhodia and Degussa AG, still have a product mix that is much too diversified to reach that status. They will have to restructure their portfolio further if they want to improve their share value. Still others, because their management was led by short-term objectives or made unwise divestitures and acquisitions, have been penalized by the stock markets and will no longer survive as independent entities: Laporte and Hercules are among these sad cases. Aside from bowing to financial considerations, the consolidation of the industry also had at its root the necessity of reducing the number of participants once their customers became less numerous and acquired a worldwide presence. For instance, with only three major tire manufacturers left—Michelin, Goodyear, and Bridgestone—the number of the main rubber chemicals manufacturers also had to shrink: Solutia and Akzo Nobel merged into Flexsys, facing Uniroyal Chemical (Crompton) and Bayer as their major competitors.

The Case of Fine Chemicals

Fine chemicals, sold in relatively small volumes and at rather high prices, are obtained through various organic chemical reactions. Their production does not require heavy investments as they are made in multipurpose units equipped with glass-lined and stainless-steel reactors. For this reason this sector of the chemical industry has attracted skilled entrepreneurs who know how to surround themselves with teams of good chemists capable of conducting multistep syntheses leading to the formation of complex molecules used by pharmaceutical laboratories and agrochemical firms. Over the years, however, these customers of the fine chemicals industry realized that they should make their active ingredients themselves and so created their own chemical departments to carry out at least the final steps of the synthesis of the products they had developed.

During the 1990s a drastic change took place in that many pharmaceutical companies saw their R&D and marketing expenditures rise considerably, so they decided to outsource the synthesis of their proprietary drugs. At the same time many patents protecting well-known ethical drugs expired, and the same drugs came to be offered on the market as generics by competitors. As a result the chemical subsidiaries of major laboratories were offered for sale, and the toll-manufacturing activities of well-established fine chemicals firms increased spectacularly.

Thus, in 1997, Glaxo Wellcome handed over its Greenville site in the United States to Catalytica and its Annan plant in Scotland to ChiRex in exchange for supply contracts running for a 5-year period. Similar deals were made when in 1997 Warner Lambert sold Sipsy Chimie Fine, the chemical operation of its French subsidiary Laboratoire Jouveinal, to PPG Industries and a year later when the British firm BTP bought the French firm Hexachimie from Bristol-Myers Squibb. Prior to its merger with Sandoz, Ciba-Geigy had, for its part, divested its French subsidiary La Quinoléine, which was acquired by Organo-Synthése. Sanofi sold its operation in Spain, Moehs SA, to PMC.

While these divestitures were taking place, traditional fine chemicals manufacturers were able to enjoy new contracts for the synthesis of active ingredients from companies involved in crop protection products and pharmaceuticals. Many European companies were the beneficiaries of the new trend. In Switzerland the leader was Lonza, which became independent in 1999 when its mother company, Alu Suisse, merged with the Canadian aluminum manufacturer Alcan. Other Swiss firms—such as Siegfried AG, EMS-Dottikon, Cilag, and Orgamol, Röhner, now part of Dynamit Nobel—took advantage of these developments. Clariant entered the field on a big scale in 2000 with its acquisition of BTP.

In France as well, some companies that had been traditionally involved in fine chemicals through their specific expertise engaged in similar activities. The state-owned Société Nationale des Poudres et Explosifs decided to make use of its skills in phosgene and nitration chemistry by buying Isochem from the Wirth family and making inroads in the field of polypeptides. Rhodia, which had inherited ICMD from its former links with Rhône-Poulenc, acquired ChiRex at the end of 2000. Another firm, Produits Chimiques Auxilliaires de Synthèse (PCAS), which belonged to Dynaction, a medium-sized French conglomerate, also expanded by taking over Pharmacie Centrale de France's chemical subsidiary and a plant in Limay belonging to the German Schwartz Pharma.

In Holland, under the leadership of Simon de Brée, DSM chose to diversify into fine chemicals first by acquiring the Austrian Chemie Linz from ÖMW, then in 1999 by taking over Gist-Brocades, a Dutch supplier to the pharmaceutical industry. Finally, with the purchase of Catalytica's pharmaceutical subsidiary in 2000, DSM has become a leader in this field and now generates a turnover of $1.3 billion.

Conversely, the United Kingdom has seen many of its fine chemicals companies disappear from the map: Hickson International is now a part of Arch Chemicals, Courtaulds Chemicals has been taken over by Akzo Nobel, and the fine organics and performance chemical lines of Laporte were recently acquired by Degussa AG. Peboc got sold by Duphar to Eastman Chemical Company, which now wants to dispose of it. A similar trend has occurred in Germany where Riedel de Haen was acquired in 1995 by Allied Signal, Raschig by PMC, and Boehringer Mannheim by Roche.

Italy, long the source of expertise in multistep synthesis built up over the years by individual entrepreneurs, did not fare any better. Francis in Milan, after having been owned by Laporte, is now controlled by Degussa AG; Profarmaco was acquired by Nobel Chemical, which in turn is owned by

Cambrex; OPOS went successively to Hoechst Marion Roussel and then to Holliday Chemical Holdings, itself a part of Yule Catto.

The United States was not as strongly endowed with fine chemicals expertise as were many European countries since the skills of the organic chemist were less cultivated in America than those of the chemical engineer and only a few American companies have been successful in this field in the past. But mention should be made here of Cambrex, a company that began with the acquisition of the former Baker Castor Oil Company and of Nepera Chemicals, a manufacturer of pyridine and derivatives. In 1993 Cambrex decided to become a global supplier of products to the life sciences industry. It made two major moves to accomplish this: in 1994 it acquired from Akzo Nobel the Nobel pharmaceutical chemistry business, with its lucrative subsidiary in Italy, Profarmaco, a producer of generics; and in 1997 it purchased BioWhittaker, a supplier of human cells and cell cultures, which gave Cambrex a promising future in the field of bioscience. Thus the sector of fine chemicals has been the scene of many divestitures and acquisitions, and since its consolidation is far from complete, it still offers opportunities to those firms that either enjoy some lucrative niche markets or that reach a size that allows them to compete successfully with the established leaders.

The Further Concentration of the Industrial Gas Business

At the end of the 1990s there were four major producers of industrial gases in the world: L'Air Liquide, British Oxygen Company, Praxair, and Air Products. In addition to these leaders the German firms Messer Griesheim, the Swedish AGA, and the Japanese Nippon Sanso played an important role in their respective markets. If we consider that Praxair was the former Linde Division of Union Carbide Corporation, these companies were well-established firms, the youngest among them, Air Products, having celebrated its fiftieth anniversary in 1990. Since it is not economical to transport liquefied gases long distances, all of these producers operated on a worldwide basis, with plants scattered throughout the five continents.

British Oxygen had invested more heavily than its competitors in the former Commonwealth and in the Asia-Pacific area, while AGA had invested more heavily in the Nordic countries and in Latin America. Air Products was the only company with a sizable part of its total turnover devoted to commodity and specialty chemicals, which represented over 30% of its yearly sales of $5 billion. L'Air Liquide, although initially involved in chemicals, had sold its fertilizer subsidiary, Société de la Grande Paroisse, to Elf Atochem and its pharmaceutical arm, Lipha, to E. Merck, in Darmstadt, Germany. Although the competition for industrial gases was fierce between these companies, new applications were developed in the fields of electronics, semiconductors, health, oil refining, and food processing, and all the firms with standardized plants and similar technologies were enjoying a thriving business.

At the end of 1999, however, British Oxygen, which was overinvested in Southeast Asia, approached Praxair with an offer to merge the two groups. Dating back to 1992, Praxair was a spin-off of Union Carbide, made necessary when in 1985 in order to fight a takeover bid from Sam Heyman, the majority owner of GAF, Union Carbide decided to buy back its shares and as a result considerably increased its outstanding debt. The proposed merger of Praxair and British Oxygen would have had a considerable impact on the industrial gas market. Feeling threatened, Air Liquide and Air Products made the unusual move of a joint bid for British Oxygen, but antitrust considerations led the parties to give up their plan after a long period of negotiation.

Meanwhile less ambitious schemes have materialized. Indeed, in 2000, Linde took over AGA and Messer Griesheim, which was owned initially by Hoechst, now part of Aventis (66.6%), and the Messer family (33.3%) cut a deal whereby two financial associates, Allianz and Goldman Sachs, will buy from Aventis the shares formerly held by Hoechst. The new landscape offered by these various moves may still change somewhat as the companies just merged will for financial or antitrust reasons have to dispose of assets that should be of great interest to the majors.

The Changing Ties Between the Oil and Chemical Industries

Beginning with the World War II effort, oil companies in the United States became involved in petrochemicals and polymers and contributed to major innovations in those fields. The process of downstream integration was then seen by them as a way to upgrade their feedstocks and to develop new activities. Over the years oil majors like Exxon and Shell, either through a frenzy of acquisitions or through internal growth, became important producers not only of petrochemicals, synthetic rubbers, resins, and plastics but also of specialties and even fine chemicals. In the 1990s low crude-oil prices and increased competition on a worldwide scale led the management of the oil companies to reconsider their position, with the idea of restricting their chemical operations to base commodities produced at the site of their main refineries. In order to achieve this goal, a vast program of divestitures was begun either through straight sales or spin-offs or through joint ventures run at arm's length from the companies' owners.

Thus in 1994 Texaco sold its chemical operations to Huntsman. ARCO Chemical Company, after floating its Texas-based petrochemical activity under the name of Lyondell in 1989, sold to that new entity 9 years later the remaining operations of ARCO Chemical. The joint-venture route was used by Shell when in 1989 it bought the stake Montedison held in Montell, their polypropylene subsidiary, before merging it with the polyolefin operation of BASF, now called Basell. Similarly, Occidental Petroleum, which with Oxychem still holds strong positions in chloralkali products and specialties inherited from the former Hooker Chemical, is trying to unload some of its petrochemical operations. To this end it has become a shareholder of Equistar Chemicals, now the largest US producer of ethylene, which is as a result a joint venture between Lyondell (41%), Millennium (29.5%), and Oxychem (29.5%). Millennium Chemicals was itself born in 1996 from a demerger of Quantum Chemicals, formerly owned by Hanson Trust, and like Oxychem it wishes to find a buyer for its shares in Equistar.

The consolidation of the oil industry, which started at the end of 1998 with the merger of BP-Amoco and was followed in 1999 by BP-Amoco's acquisition of ARCO and then by the still larger Exxon-Mobil merger, can only further dilute the part of petrochemicals in the product mix of these new entities. The announced takeover of Texaco by Chevron will have the same effect. The chemicals of Chevron and Phillips Petroleum have already been combined under a new entity, Chevron Phillips Chemical Company. Oil companies everywhere have followed a similar trend.

Thus in 1999 the Spanish Repsol, by acquiring YPF in Argentina, and the Norwegian Norsk Hydro, by taking over Saga Petroleum in Norway, have both contributed to a decrease in the share of chemical sales in their consolidated turnover. Norsk Hydro, still strong in fertilizers, no longer considers its ethylene, vinylchloride, PVC, and chlorine operations as core businesses. ENI in Italy is also prepared to part with some of Enichem's activities: it disposed of its acrylic fibers and sold at the end of 2000 the polyurethane business of Enichem to Dow Chemical while trying to take over Union Carbide's share of Polimeri Europa, following Dow's acquisition of Union Carbide and the resulting antitrust rulings. Similarly, the Nesté Chemicals subsidiary of the Finnish Nesté Oil has been divested and acquired by a Nordic investment firm, Industri Kapital, which merged it with Dyno, a recent acquisition specializing in explosives and fine chemicals.

The only important exception to this policy of unloading chemical activities not strictly related to the immediate downstream production of refinery operations appears to be the French oil company TOTAL. Historically, TOTAL, the former Compagnie Française des Pétroles, had only a limited presence in petrochemicals and polymers through aromatics produced at the Gonfreville refinery and minority participations in alkylbenzene, polyolefins, and butyl rubber joint ventures in France. The situation changed in 1990 when ORKEM, a company born from the restructuring of the state-owned French chemical industry, was split and its assets transferred to TOTAL for the specialties and to Elf Aquitaine's chemical arm Atochem for the petrochemicals and polymers. Through a deal completed in June 1999, TOTAL made a public exchange offer for Petrofina of Belgium. This was followed a few months later by the merger of the newly created TotalFina with Elf Aquitaine. That way a new group, TotalFinaElf, was born, with an impressive chemical arm, AtoFina, having global sales of $16 billion a year.

Ranking as the fifth largest chemical company in the world, after BASF, Bayer, Du Pont, and Dow, once its merger with Union Carbide is completed, AtoFina is a very diversified producer. Its product mix includes fertilizers and a variety of agrochemicals, four of the major thermoplastics (polyethylene, polypropylene, polystyrene, and PVC), acrylics and polymethyl-methacrylates, a chloralkali chain, oxygenates (H_2O_2 and organic peroxides), hydrazine and derivatives, and fluorinated products. While commodity petrochemicals and plastics represent less than 20% of its business, AtoFina has inherited from TOTAL a lucrative portfolio of specialties in such varied fields as resins (Cray Valley), adhesives (Bostik), radiation curing coatings (Sartomer), paints (Kalon), and rubber articles (Hutchinson). Originating from various restructuring steps and acquisitions over the last 10 years, AtoFina, because of its size and diversity, does not resemble any of the chemical operations of the major oil companies.

Its future within TotalFinaElf will depend on whether the management of the group feels that its chemical activities should be closer to the cracker or can be run as a full-fledged chemical operation. In any case some streamlining cannot be avoided. In fact, prior to the merger, TOTAL had already sold its Ink Division (Coates Lorilleux) to Sun Chemical, a subsidiary of the Japanese Dainippon Ink & Chemicals. More recently a department specializing in metal treatment has gone to Henkel, whereas unsuccessful attempts have been made to dispose of the agrochemicals of ElfAtochem. At this stage anyway and for historical reasons the approach of TotalFinaElf can be considered unconventional when we compare it with that of the oil companies. With improving crude oil prices and better capacity utilization in their refinery units, the oil companies are concentrating their major reinvestments on what they consider to be their core business and limiting their production of chemicals to the base commodities derived from the olefins of the steam cracker or other feedstocks.

The Role of Entrepreneurs and Private Equity Funds

The various mergers and divestitures described in this chapter have provided opportunities for entrepreneurs and venture capitalists to make acquisitions in fields that were no longer of interest to major chemical firms. Already in the 1980s a similar situation had given birth to new chemical entities launched by such daring entrepreneurs as Gordon Cain and Jon Huntsman. Cain Chemical, the result of a highly leveraged management buyout, was for a while a large petrochemical concern before being taken over in 1988 by Oxychem.

Huntsman Chemical, however, has proved longer lasting. Its first steps in the chemical business started with the acquisition of the polystyrene activities of Shell, followed 3 years later by those of Hoechst. By 1999, through external growth, Huntsman Chemical ranked as the largest privately held chemical company. That year its revenues reached $8 billion as a result of the acquisition of ICI's polyurethane, titanium dioxide (TiO_2), aromatics, and petrochemical operations by Huntsman ICI Holdings (70% Huntsman Chemicals and 30% ICI). ICI's Wilton, Teesside cracker has in particular given Huntsman a strong position in olefins.

With the cash obtained from the sale of its styrene business to the Canadian NOVA Chemicals, Huntsman could afford to proceed with more acquisitions, and in 2000 it took over the surfactants operations of Albright & Wilson, a British firm that is now part of Rhodia.

Another American entrepreneur, D. George Harris, who had managed the SCM chemical conglomerate before it was acquired and dismantled by Hanson Trust, had also shown an interest in basic commodities being divested by the majors. During the 1990s Harris was able to set up operations in such fields as soda ash, phosphate, and boron, both in the United States and in Europe. In 1998, facing a difficult period, Harris managed to sell these operations to IMC Global, an American firm active in agribusiness.

Recently, new opportunities were offered to private equity institutions and to ambitious managers who can use the funds that venture capitalists provide to revamp companies in need of restructuring and make substantial money when selling them a few years later. In Europe the PVC field has offered such an opportunity because it suffers from intense competition and is submitted to the pressure of such environmentalists as Greenpeace. As a result several PVC producers have been anxious to sell their assets or at least to participate in the restructuring of the sector. They have found buyers among the private equity institutions. With a consortium of financiers, including Advent International and Candover, George Harris acquired in December 2000 Vestolit, the vinyl business of Degussa-Hüls. For its part Advent has also bought Vinnolit and Ventron from Wacker and Celanese, respectively. European Vinyls Corporation (EVC), the troubled joint venture formed by Enichem and ICI, may well be the next to go to private capital for the consolidation to be further advanced.

The fibers sector is another area in which European producers are suffering because of the presence in Asia of strong competitors, a situation still aggravated for these producers by the gradual elimination of the protective textile quotas set up under the Multi Fiber Agreement. Here again the situation is attracting the attention of financial investors as well as that of private textile firms in countries enjoying the advantage of low labor costs. As an example CVC Capital Partners, in January 2000, purchased a 64% stake in Acordis, the new entity resulting from the takeover of Courtauld's fiber business by Akzo Nobel and its subsequent float on the stock market. Du Pont, in its effort to unload part of its activities in polyester fibers, set up between 1999 and 2000 joint ventures with two foreign firms: Alpek, a subsidiary owned entirely by the Mexican firm ALFA, the largest private petrochemical concern in Latin America, and Haci Ömer Sabanci Holding, an important financial and industrial conglomerate in Turkey.

The increasing role played by private equity capital can be explained by the important sums of money they can collect from pension funds and other institutions. It may seem strange that they should direct investments toward chemical operations that are being spun off by the big players. However, some of the assets being divested are offered at attractive prices, and the managers who are put in charge as well as their backers can hope to restore rapidly some profitability to the operations through a thorough program of cost cutting and restructuring. In any event these investors are generally inclined to take a short-term view of the business, and with the exception of entrepreneurs like Huntsman a quick profit is their main objective.

The Everlasting Presence of Contrarians

In the past 10 years many chemical companies have changed their product mix and even their names and have taken entirely new directions in order to cope with a new environment and in the hope of pleasing financial analysts. During that same period, however, some large chemical corporations, while prepared to streamline their operations and take advantage of new opportunities, have maintained their faith in the traditional activities that had been the key to their success. These contrarians have taken a long-term view of the business they are in, in the hope that their approach will in the end meet with the approval of the stock market because internal growth, which takes time to deliver, is an essential part of any industrial undertaking.

The German chemical giant BASF ranks among the top contrarians. Its management still believes in the *verbund* concept of linking products from the raw material down to the most elaborate derivatives. It is a concept particularly suited to a large site like Ludwigshafen where vertical integration can be easily practiced, with products flowing from one unit to another. BASF has also maintained its connection to oil as a raw material, which started in 1952 through Rheinische Olefin Werke in Wesseling, BASF's joint venture with Shell, and was amplified in 1969 when the Wintershall refinery was acquired. The fact that BASF remains diversified in various lines of organic and inorganic chemicals does not prevent it from restructuring its traditional operations when the need arises. Joint ventures were thus entered into at the end of the 1990s, in polyolefins with Shell (Basell), in PVC with Solvay (Solvin), and in dyestuffs with Bayer and Hoechst (Dystar). BASF finally decided to part with its pharmaceutical subsidiary Knoll, sold at the end of 2000 to Abbott, and it is negotiating with Kali und Salz its withdrawal from some fertilizer operations. With a turnover around $30 billion per year in group sales, BASF retains a leading position in the world chemical industry.

Dow Chemical has followed a similar path. Over the last 5 years it has reinforced its position in Europe in basic chemicals and commodity polymers by the acquisition and reconstruction of the Buna Sow Leuna Olefinverbund complex in eastern Germany, which has been fully owned by Dow since June 2000. At the same time the olefin crackers in Terneuzen, Holland, have been greatly expanded, while methylene diisocyanate (MDI) capacities for use in polyurethanes are being increased in Stade, Germany, and in Estarreja, Portugal. Above all, Dow has seen at the beginning of 2000 its acquisition of Union Carbide approved by both the Federal Trade Commission in Washington and the European Commission in Brussels. This merger, leading to yearly sales of $28.4 billion, puts the new Dow Chemical in the same league with BASF and Du Pont. The approval of the merger implies that Dow sell its ethylene amine business, which will go to Huntsman Chemical, and its ethanol amine operations, which will be acquired by Ineos, a financial institution. It also commits the new entity to part with the 50% stake Union Carbide held in Polimeri Europa, a joint venture with Enichem to manufacture polyethylene. At the same time Dow will further strengthen its position in polyurethanes by acquiring the polyurethane line of Enichem, which includes TDI, MDI, and polyols.

Like BASF, Dow is a firm believer in vertical integration. It has always tried to connect its thermoplastic and elastomer productions to upstream steam crackers while making its chloralkali operations less dependent on PVC than other producers by developing various lines of chlorine derivatives on site. Even before BASF, Dow left the field of pharmaceuticals with the sale of Marion Merrell to Hoechst and has increased its stake in crop protection chemicals through the acquisition of Eli Lilly's interests in DowElanco. The announced takeover of Rohm & Haas fungicide and insecticide lines will further enhance Dow's presence in this sector.

Among the contrarians, Bayer has had for historical reasons a different approach to the problem of remaining a well-rounded producer of chemicals. It has always been a leader in such specialty chemicals as plastics and rubber additives and supplies master batches through its subsidiary Rhein Chemie. Its polymers are mainly centered on synthetic elastomers and specialty plastics like polyurethanes and polycarbonates that Bayer itself develops. These are not subjected to the cutthroat competition that commodity thermoplastics are. Bayer has remained involved in aroma chemicals with a well-known subsidiary, Haarmann & Reimer. In pharmaceuticals the company occupies an honorable rank, although in the future its management may want to separate that branch from the rest of its activities in preparation for further alliances. Like BASF, Bayer considers its agrochemical line as a core business. However, unlike BASF, it is less interested in integrating upstream production to oil raw materials and has therefore decided to sell to its partner BP-Amoco its 50% stake in their EC Erdölchemie joint venture. When necessary, Bayer is also prepared to divest noncore activities as it did in mid-1999, with 70% of Agfa-Gevaert or with its Dralon fiber operation sold to the Fraver Group in Italy. Taking these divestitures into account, Bayer's yearly turnover should approach that of the new Dow Chemical—Union Carbide merger.

Another chemical giant, Du Pont, while still broadly based, has been less inclined than its above-mentioned rivals to remain focused on its traditional lines of activity and has changed its course of action several times over the last 10 years. In 1981 Du Pont purchased Conoco in order to protect itself from oil shocks; 20 years later its management was no longer interested in maintaining that business, which was then spun off. Du Pont also seemed eager at one time to enter the pharmaceutical sector and had made an alliance with Merck in that field. In 2000 Du Pont tried to acquire the former Romainville research center of Roussel-Uclaf in France, which belonged by then to Aventis. After failing in that attempt, Du Pont became somewhat disenchanted with its pharmaceutical business, which had yearly sales of only $1.6 billion out of a total turnover of $27 billion; it is predicted that they will eventually give up that business. Du Pont remains determined, however, to become a leader in seeds after its acquisition in 1999 of Pioneer Hi-Bred. In spite of some temporary setbacks in Europe for genetically modified organisms, this branch of life science should provide the company with a bright future. Like other Western synthetic fiber manufacturers, Du Pont has been trying to unload some of its assets in that area, which has suffered from the impact of

Asian producers. And as discussed earlier, it has to that effect made joint ventures in polyesters with such private groups as ALFA in Mexico and Haci Ömer Sebanci in Turkey.

Akzo Nobel, with yearly sales about half as large as those of the four majors, belongs nevertheless to the league of contrarians in that it occupies leading positions in many traditional lines of the chemical industry. Under a 5-year plan initiated in the second half of the 1990s, the company, which resulted then from the merger of the Swedish Nobel Industries with the Dutch AKZO, undertook an ambitious restructuring program. The merger had given Akzo Nobel the number-one position worldwide in coatings and a valuable stake in surfactants and in pulp and paper chemicals. From the former AKZO the company had inherited a lucrative pharmaceutical line with the Organon prescription drugs and with Diosynth, a producer of raw materials for pharmaceuticals, which was reinforced by the Buckhaven unit of Courtaulds in the United Kingdom. The animal health care business Intervet International is also profitable. The restructuring of the group involved the creation of joint ventures for rubber chemicals with Monsanto (Flexsys) and for PVC with Shell (Rovin), acquired in late 1999 by the Japanese Shin-Etsu. The soda-ash operation was sold early in 1998 to Brunner, Mond. The problems of the fibers division were treated first by a merger with the British Courtaulds, followed by a spin-off of the fibers operations of the joint entities, sold in 2000 as Acordis to its new owners, which included—aside from a minority stake held by the management—the financial institution CVC Capital Partners and Akzo Nobel itself.

Another contrarian, DSM in the Netherlands, had been a state-owned company before it became privatized, a process that began in 1989 and was completed in 1996. From its past it had inherited positions in fertilizers, industrial chemicals, and such intermediates as melamine and caprolactam as well as polyolefins, with access to basic olefins through its own crackers in Geleen, Netherlands. In 1997 DSM acquired the polyethylene and polypropylene operations of Hüls (VEBA) with the Gelsenkirchen site. The company had also diversified into elastomers, having purchased in the United States the Copolymer Rubber and Chemical Corporation, which contributed to DSM's expansion into the fields of ethylene propylene, styrene butadiene, and nitrile rubbers. DSM is also a supplier of industrial resins and engineering plastics products. It had made inroads in the fields of fine chemicals in 1985 when it bought Andeno, a producer of synthetic intermediates for the pharmaceutical industry. By the end of the 1990s this initial acquisition had been followed by that of Chemie Linz; of Gist Brocades, a biotechnology firm; and in 2000 of Catalytica, thus giving DSM a yearly turnover of $1.3 billion in life science operations out of a total yearly turnover of around $7 billion. The surge in such activities will probably force DSM to slow down its heavy investments in olefins and petrochemicals, giving the company a better balance between commodities, performance, materials, and fine chemicals.

The last contrarian worth mentioning, with a turnover at the level of that of DSM, is Solvay, a company that dates back to 1863 and is still involved in most of its traditional lines. It is organized around four main sectors—chemicals, plastics, processing, and pharmaceuticals—with no intention of spinning off any of them. Solvay remains a leader in such commodities as soda ash, chloralkali chemicals, and oxygenates (H_2O_2 and peroxides). For its lines of polymers, it set up joint ventures with BASF (PVC) and Petrofina (high-density polyethylene) in order to improve its access to raw materials and acquire new technologies. Solvay also has considerable experience in plastics processing, an activity that represents more than one third of its total sales. In the health sector the group—after selling its crop protection line to Uniroyal Chemical (now Crompton) and the U.K. fine chemicals producer, Peboc, to Eastman Chemical—has decided to concentrate all its efforts on Solvay Pharma, its pharmaceutical unit that already accounts for 22% of its earnings and specializes in such areas as gastroenterology, psychiatry, and gynecology.

It takes courage these days on the part of the management of the contrarians to go on thinking of the chemical activities in which they operate as made up of several parts to be kept under one roof. Indeed many investors have come to feel, as do financial analysts, that a split-up of the activities of large and diversified chemical groups would unlock more value in the shares they hold. This makes the temptation to dismantle existing organizations sometimes hard to resist.

The Case of Japan

In the 10 years discussed in this chapter, the economy of Japan languished, and the Japanese chemical industry, the third largest in the world, could not avoid the consequences of that situation. It also suffered from several factors specific to Japan. First, the largest chemical companies belonged to the "Keiretsu" system, which had replaced the "Zaibatsus" of pre-World War II, and featured a complex network of cross-shareholdings dominated by banks. Second, these companies remained under the influence of the Ministry of International Trade and Industry (MITI), which proved to be a hindrance when the time came to restructure the chemical sector in the early 1990s. Third, internationally, with the exception of such firms as Dainippon Ink & Chemicals and Shin-Etsu, Japanese chemical groups had not developed a strong presence outside Asia and depended heavily on indirect exports through their domestic customers or on licensing for their activities overseas. Fourth, Japanese society, used to lifetime employment, was not prepared for the social upheavals inherent in any serious restructuring. For all these reasons the changes required from the chemical industry by the new conditions of world trade have been slow in coming and were only partially accomplished by the end of the 1990s.

As an example, the necessary merger of Mitsui Petrochemicals and Mitsui Toatsu Chemicals became effective only in 1997 and was long delayed because of the reluctance of each senior management group of these two members of the Mitsui group to merge. Similarly difficult to achieve has been the consolidation of Mitsubishi Chemicals and Mitsubishi Petrochemical, which finally took place in October 1999 and led to the birth of the eighth largest chemical producer in the world, with a yearly turnover equivalent to $15.7 billion in fiscal year 1999–2000. The proposed merger of Sumitomo Chemical with Mitsui Chemicals should create an even larger group when it is implemented.

These three majors of the Japanese chemical industry can be considered as contrarians in their own right since they maintain a strong presence in all facets of their industry. Contrary to their American or European counterparts, they are not submitted to the pressure of investors eager to obtain the best value for their shares. While this could be an advantage in that it allows the management to undertake long-term projects, it may lead to some complacency at a time when cost cutting and restructuring are the necessary requirements for companies to survive in a fiercely competitive environment.

The Chemical Industry at the Beginning of the Third Millennium

The general trends described at the end of the previous chapter have been amply confirmed over the last 10 years. Regulatory burdens have multiplied, especially environmental ones, causing higher costs to the industry and yielding either no benefits or negative consequences. Globalization has proceeded at a faster pace, and as products have matured and technologies have become more readily available, competition between chemical firms has been fiercer on the international scene. The expansion of stock markets, with the increased interest paid to profitability by financial analysts, pension funds, managers, and individual investors in the Western world, has given prominence to the concept of “share value.” The management of chemical companies on both sides of the Atlantic could not remain indifferent to these trends and reacted in several ways to the heavier pressure they implied. In an effort to meet regulatory expenditures and at the same time remain competitive while pleasing their shareholders, Western chemical groups had to resort to severe cost-cutting measures.

Except in such fields as biotechnology R&D budgets were made smaller, and as a result organic growth was somewhat sacrificed, with fewer innovative products coming to the market. Preference was given instead to growth by acquisition, which offered companies an immediate way of achieving a better rank and a higher turnover in some selected activities, if not always better profits. More generally, short-term considerations took precedence over long-term ones, and chemical groups went into a frenzy of asset transfers through mergers, acquisitions, divestitures, and joint ventures. Since 1994 the total value of merger and acquisition deals across the chemical industry in the United States and in Europe has reached a figure of $200 billion, and there is no end in sight to this restructuring fever, greatly facilitated by the ample availability of funds. These moves provided an opportunity for new players to enter the game.

Individual entrepreneurs not accountable to outside shareholders tried their luck by acquiring at rebate prices businesses that larger companies did not want to keep anymore. Private equity institutions bought pieces of business that were for sale with the hope of combining and rationalizing them before returning them to the market 3–5 years later through an initial public offering. Financial services groups played their role either by financing some of the deals or by acting as brokers between the parties. While profitable to some individuals or banking institutions, these transfers of assets did not always meet the expectations of those who had engineered them or for that matter of the new shareholders.

Indeed the creation of pure play companies focusing on selected fields in which they come to command leading positions cannot achieve the required results if the remaining competitors keep fighting each other in order to maintain or even to improve their market share in such a way that the benefits of the consolidation are lost through the erosion of selling prices. When the number of suppliers is reduced, there is often a corresponding reduction in the number of customers, and the pressure on prices remains unabated. Furthermore, when acquisitions are purchased at too dear a price, they affect the purchaser’s balance sheet by denting the bottom line and lowering the operating profit. Aside from these facts that can be assessed quantitatively, there is the less visible aspect of mergers and acquisitions, which has to do with the “morale” of the employees involved in the deals.

Sometimes at all levels valuable people do not like the new “environment” in which they would have to operate, so they decide to leave, offering their talents to competition and thereby weakening the newly born organization. Some chemical groups acting as contrarians have opted for a more stable course in the way they shape their future. Although they are prepared to take advantage of opportunities in order to enlarge or streamline their activities, they keep their diversified operations under one roof, making use of existing synergies and managing their assets with a medium- to long-term objective. It is to be hoped that these contrarians can remain successful because the chemical industry is too vital to our well-being to be submitted entirely to the whims of short-term financial considerations.

Safety Considerations in the Chemical Process Industries

2

John F. Murphy

Introduction

Why Process Safety Is Important

There is an ongoing emphasis on chemical process safety as a result of highly publicized accidents such as the recent BP Deep Water Horizon well blow out in the Gulf of Mexico that resulted in a fire and explosion that killed 11 people and a massive leak of oil that caused catastrophic damage to the environment and economy of the Gulf Coast. Public awareness of these accidents has provided a driving force for industry to improve its safety record. There has also been an increasing amount of government regulation.

The chemical industry is one of the safest industries, but its safety record in the eyes of the public has suffered. Perhaps this is because sometimes when there is an accident in a chemical plant it is spectacular and receives a great deal of attention. The public often associates the chemical industry with environmental and safety problems, which results in a negative image of the industry.

So why is process safety important? It is important because good process safety performance, the lack of major process safety incidents, allows a company the freedom to manage its business without the interference of government regulators, litigation, and adverse public opinion. By avoiding injuries to people, major property loss, and business interruption loss, process safety results in the creation of positive business value for a company. The actions that are required to manage process safety well are the same actions required to manage business well.

Occupational Safety Versus Process Safety

It is important to differentiate between occupational safety which involves accident prevention through work systems which are aimed at minimizing the risk of injury to workers and process safety which involves the prevention and mitigation of fires, explosions, and accidental chemical releases that can have far reaching impacts. Occupational safety focuses on the prevention of worker injuries and occupational illness, primarily relating to trips, slips, falls, cuts, burns, etc. These injuries result from the failures in the control of traditional work procedures. Process safety focuses on the prevention of leaks, spills, process upsets, toxic releases, and equipment failures which may or may not injure or result in fatalities to workers or others at or near the site. This chapter deals primarily with process safety.

Process Safety Technology Issues

The Internet provides considerable information on incidents, good industry practice, and design guidelines. The best practices in industry are briefly discussed in this chapter. Details are readily available from resources listed in the references section at the end of the chapter. Hazards from combustion and runaway reactions play a leading role in many chemical process accidents. Knowledge of these reactions is essential for the control of process hazards. Much of the damage and loss of life in chemical accidents are caused by a loss of containment that results in a sudden release of hazardous material at high pressures, which may or may not result in fire; so it is important to understand how loss of containment and sudden pressure releases can occur. Loss of containment can be due, for example, to ruptured high pressure tanks, runaway reactions, flammable vapor clouds, or pressure developed from external fire. Fires can cause severe damage to people and property from thermal radiation. Chemical releases from fires and pressure releases can form toxic clouds that can be dangerous to

people over large areas. Static electricity often is a hidden cause of accidents. It is very important to understand the reactive nature of the chemicals involved in a chemical facility.

Process Safety Management Issues

Chemical process safety involves both the technical and the management aspects of the chemical industry, and this chapter addresses both. It is not enough to be aware of how to predict the effect of process hazards and how to design systems to reduce the risks of these hazards. It also is important to consider how chemical process safety can be managed. Technical and management people at all levels in an organization have process safety management responsibility, and can contribute to the overall management of safer chemical processing plants.

Loss of containment due to mechanical failure or misoperation is a major cause of chemical process accidents. The publication *One Hundred Largest Losses: A Thirty Year Review of Property Damage Losses in the Hydrocarbon-Chemical Industry* [1] cites loss of containment as the leading cause of property loss in the chemical process industries.

It has become clear that process safety can be and must be managed as any other part of the business. A process safety management system is focused on preparedness for the prevention and mitigation of catastrophic releases of chemicals or energy from a process associated with a facility. It also includes the response to and restoration from these events. The term process safety management was first recognized on a broad scale in the late 1980 after Bhopal (see case histories). It formed the basis for many of the American Institute of Chemical Engineers' Center for Chemical Process Safety's guideline books and eventually led to US regulations (OSHA PSM) in 1992.

Barrier Analysis and Layers of Protection [2]

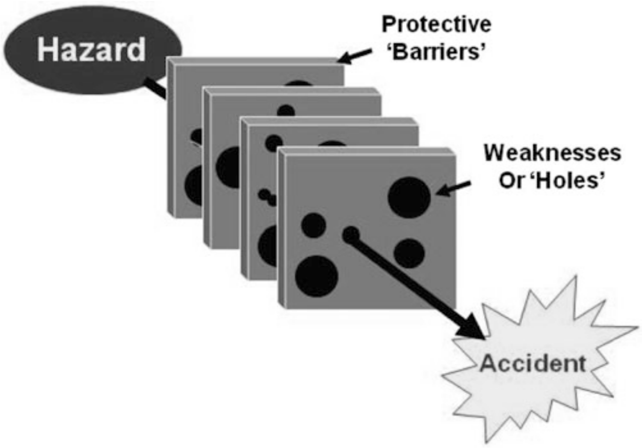

Fig. 2.1 Barrier analysis

There are certain concepts that people and companies have found useful in preventing and minimizing process safety incidents. The US Department of Energy has published a comprehensive and useful report on barrier analysis methodology (Document EH-33, Office of Operating Analysis and Feedback, 1996). The first concept is that of the use of barriers (see Fig. 2.1). Each of these cards represents pieces of Swiss cheese such that when the holes line up an incident will result. The objective of process safety management is to remove and/or minimize the sizes of the holes so that the hazard cannot propagate and become an incident. These barriers include systems for prevention, mitigation, and recovery. Examples of prevention barriers include control systems, procedures, alarms, and maintenance. Examples of mitigation barriers include dikes and containment, facility siting, gas detectors, and fire protection systems. Examples of recovery barriers include medical capability, mutual aid, spare part systems, and insurance.

Another way of looking at barriers is the use of an onion skin model shown in Fig. 2.2. The layers of protection include the tanks, vessels, and piping systems; the basic process controls; and various safety systems both preventive and mitigative. This is sometimes also called defense in depth. All of these barriers or layers of projection must be effectively managed.

Process safety is part of every facet of design and operation of a chemical processing facility during its lifetime as illustrated in Fig. 2.3. The risk of chemical processing must be managed at an acceptable level by the application of inherently safer design strategies, risk reduction measures, and risk-based process safety management, all of which will be discussed further in this chapter.

Anatomy of an Incident [3]

The Anatomy of an Incident Model

One definition of process safety is the sustained absence of process incidents at a facility. The anatomy of an incident is a useful model that explains how process incidents occur. The model will be used to logically introduce the technical elements of process safety. Figure 2.4 illustrates the model. To understand the model, several definitions are necessary:

- An incident is an unplanned event or sequence of events that either resulted in or had the potential to result in adverse impacts.

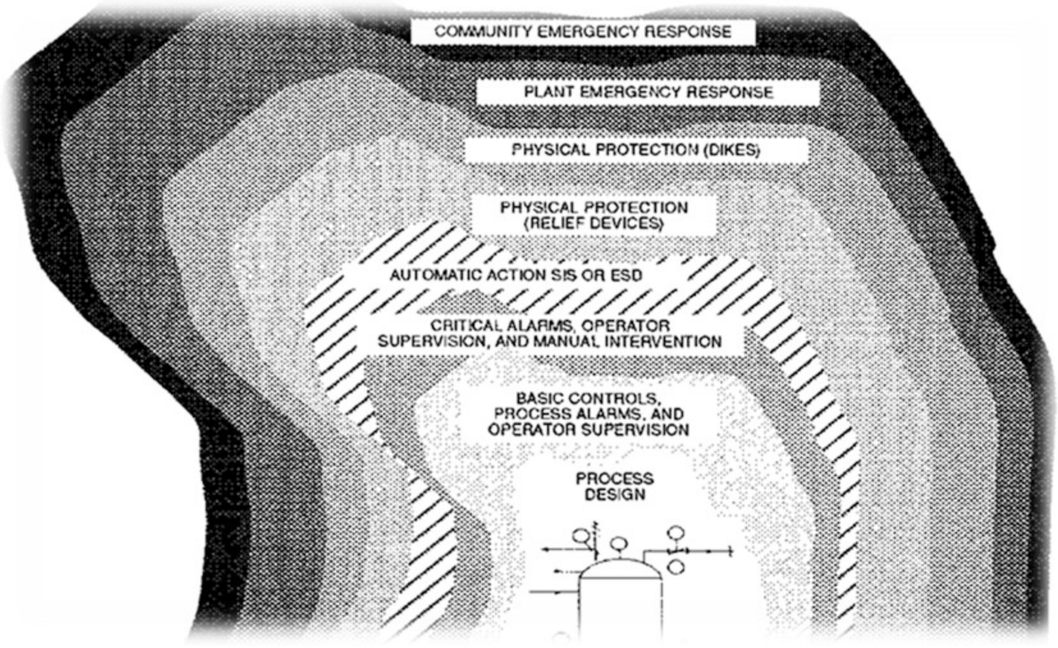

Fig. 2.2 Layers of protection (Copyright 1993 Center for Chemical Process Safety (CCPS) of the American Institute of Chemical Engineers (AIChE), www.aiche.org/ccps,and used with permission)

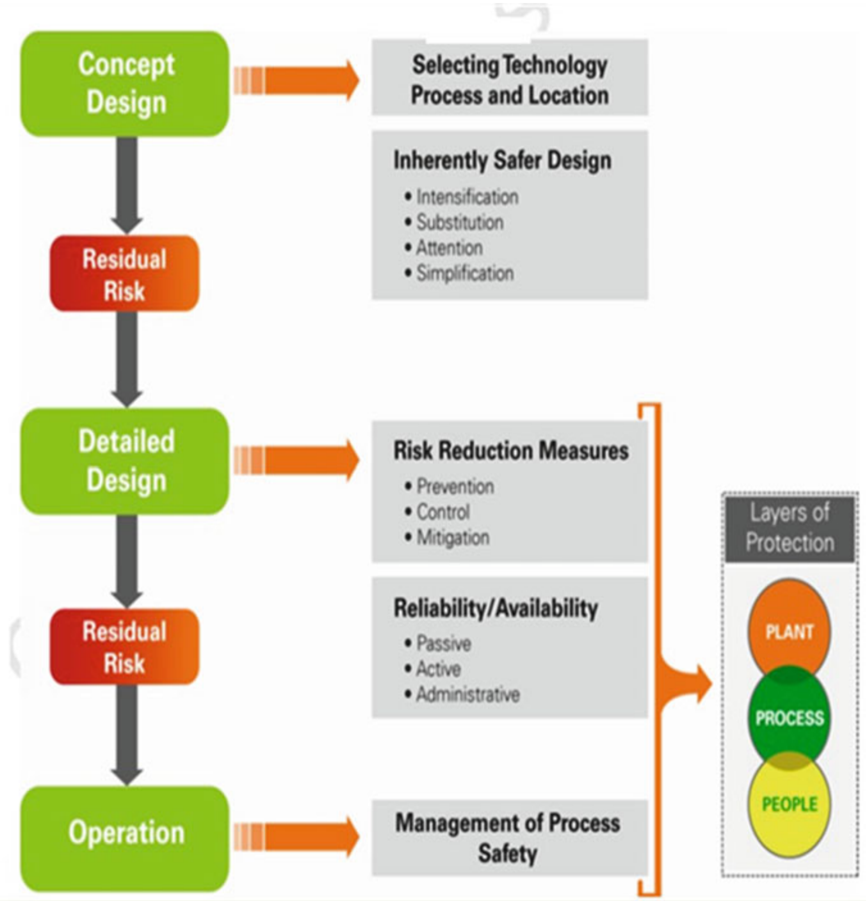

Fig. 2.3 Process safety key principles (Copyright 2010 Center for Chemical Process Safety (CCPS) of the American Institute of Chemical Engineers (AIChE), www.aiche.org/ccps, and used with permission)

Fig. 2.4 Anatomy of an incident (Copyright 2008 Center for Chemical Process Safety (CCPS) of the American Institute of Chemical Engineers (AIChE), www.aiche.org/ccps, and used with permission)

- *Loss events* will result if a deviation continues uncorrected and the process is not shut down. Loss events are generally *irreversible process material/energy releases* but may also be related to production or equipment failures.
- A process hazard is the presence of a stored or connected material or energy with inherent characteristics having the potential for causing loss or harm.

Without safeguards, a cause (such as a process upset) will result in a deviation (such as an increase in pressure rupturing a tank) that will result in the process hazard (such as a flammable liquid in storage) becoming a loss event (e.g., a leak of a flammable liquid that ignites becoming a pool fire) with subsequent impacts (such as injuries and economic and/or environmental damage). However, in a well-designed and operated chemical processing facility there are numerous prevention safeguards to prevent the loss event from happening and mitigation safe guards to minimize the impacts if there is a loss event.

Loss of Containment [2]

The major thrust of process safety is to prevent and mitigate accidental or unintentional loss of containment of hazardous materials. Chemical plants are designed to avoid this consequence but loss of containment has resulted in all the process safety incidents that have occurred and those that are likely to occur in plants in the future. Good process safety design prevents and/or mitigates all forms of loss of containment. Unexpected releases of hazardous materials can occur as a result of:

- Mechanical failure of the pressure envelope (the pressure/temperature limit of a vessel or pipe).
- Process upset causing overpressure, high temperature or volume increase.
- Human error resulting in the direct release of material to environment.

In some cases the leaks are small to begin with and slowly increase such as a small flange leak which continues to open over time. Other sources, such as a major vessel failure, have maximum leak rates initially and as the pressure of the source diminish the leak rate decreases. The type of release can change as well. A line rupture can result in a jet release which could eventually degrade to a slower continuous liquid release.

Common loss of containment events include:

- Opening a maintenance connection during operation
- Piping failure from corrosion
- Overfilling vessel or knockout drum
- Mechanical failure of a process vessel due to thermal or mechanical shock
- Overpressure due to process upset
- Failure to shut valve after transfer operation
- Hot work within berm ignites vapors from tank
- Leaking roof seams
- Leaking floating roof seal
- Non-uniform mixing of contents—temperature anomaly
- Internal explosion due to violent chemical reaction
- Rupture of furnace tube
- Rupture of tube in heat exchanger
- Failure of an internal baffle due to corrosion
- Vacuum due to various causes
- Excess flow into vent system
- Mechanical impact

Containment and Control [2]

The first layer of protection is to control the process so that it remains within its normal operating conditions. During the operational mode or normal operation, the objective is to maintain normal operation and to keep hazards contained and controlled. Layers of protection that help to attain this objective include the:

- Basic process control system
- Maintenance procedures

- Inspections, tests, maintenance
- Operating procedures
  - Training people in procedures
  - Conducting a procedure or operating a process correctly and consistently
  - Keeping a process within established limits
- Guards, barriers against external forces
- Management of change

The design of the instrumentation is extremely important. The control system addresses process deviations as they occur and has either built in control systems or operator actions to bring the process back into control. Process control systems maintain normal operation with manual operator controls relying on operator procedures and process alarms or automated process control systems utilizing basic process control systems, distributed control systems, and programmable logic controllers.

Initiating Cause or Event [2]

If an initiating cause develops then the control system is the first layer of defense to help bring the process back into control. Some possible initiating events include:

- Equipment malfunctions
  - Pumps, compressors, agitators, valves, instruments, sensors, control systems
  - Spurious trips, vents, reliefs
- Loss of utilities
  - Electricity, nitrogen, water, refrigeration, air, heat transfer fluids, steam, ventilation
- Human errors
  - Operations
  - Maintenance
- External agencies and events
  - Vehicle impact, extreme weather conditions, earthquake, knock-on effects, vandalism/sabotage

The safeguards and alarms built into the basic process control system and/or operator actions will attempt to bring it back under control. Many protective features are built into basic process control systems. However, these are not truly independent safety systems. If control is lost because of some instrument failure, that same instrument will normally not be able to function as a safety device. In a basic process control system there is usually no independence between control and protection because they are all controlled by the same control function.

Prevention of Loss of Containment Events [2]

Preventive safeguards come into play once an initiating cause results in an abnormal situation that cannot be controlled by the basic control system when a process deviation has occurred. Bringing the process into a safe condition requires the application of preventive safeguards. Preventive safeguards normally attempt to shut the process down when other safeguards have been unsuccessful in bringing the process back under control.

Safety Instrumented Systems [2, 4]

Typically Safety Instrumented Systems or SIS are the normal means employed to shut the process down. Although an operator may be in charge of initiating shutdown manually, the operator sometimes faces conflicts of interest in deciding whether to let the process operate or shut it down and he may not always be able to reliably assess the data available in a short time. The SIS will try to act such that any loss of containment is averted (Of course the reason the SIS may be shutting the process down is because it was already caused by a loss of containment event!). This includes any loss of containment through relief systems if possible. If the SIS works, then the system will have to go through another startup sequence before it operates again.

There are specific standards that regulate the use of SIS. Testing capability is designed from the beginning. If the SIS can only be tested during shutdowns, there may be a long wait. A safety instrumented system:

- Achieves (or maintains) a safe state of the process
- Is designed and managed per
  - ANSI/ISA 84.00.01-2004
  - *Guidelines for Safe and Reliable Instrumented Protective Systems*, CCPS
  - Other applicable practices
- Requires rigorous management system with respect to inspection, testing, and maintenance to justify risk reduction claim
- Requires that all components of the “system” must be included in the certification of the system (not just the final element) and maintained and tested to justify the risk reduction claim

The key feature of an SIS is that it is totally independent of control. It should have its own independent sensor(s) and final element(s). Because of the additional complexity the plant may endure more spurious trips. Voting systems are sometimes employed to improve reliability while still maintaining the safety levels required.

Redundant Instrumentation and Control Systems [5]

Computer-controlled chemical plants have become the rule rather than the exception. As a result, it is possible to measure more variables and get more process information than ever, and chemical plants can be made safer than ever before. However, it must be kept in mind that instruments and control components *will* fail. It is not a question of *if* they will fail, but *when* they will fail, and what the consequences will be. Therefore, the question of redundancy must be thoroughly considered. *The system must be designed so that when failure occurs, the plant is still safe*.

Redundant measurement means obtaining the same process information with two like measurements or two measurements using different principles. Redundant measurements can be *calculated* or *inferred* measurements. Two like measurements would be two pressure transmitters, two temperature measurements, two level measurements, and so on. An example of inferred measurement would be using a pressure measurement and vapor pressure tables to check an actual temperature measurement.

A continuous analog signal that is continuously monitored by a digital computer is generally preferable to a single point or single switch, such as a high level switch or high pressure switch. A continuous analog measurement can give valuable information about what the value is *now* and can be used to compute values or compare with other measurements. Analog measurements may make it possible to predict future values from known trends. Analog inputs may be visual, and one can see what the set point is and what the actual value is. The software security system should determine who changes set points, and should not be easy to defeat.

A single point (digital) signal only determines whether switch contacts are open or not. It can indicate that something has happened, but not that it is going to happen. It cannot provide information to anticipate a problem that may be building up or a history about why the problem happened. Single point signals are easy to defeat. Some single point measurements are necessary, such as fire eyes, backup high level switches, and so on.

As a rule, it is best to avoid:

- Both pressure transmitters on the same tap
- Both temperature measuring devices in the same well
- Both level transmitters on the same tap or equalizing line
- Any two measurements installed so that the same problem can cause a loss of both measurements

It is a good idea to use devices that use different principles to measure the same variable, if possible.

An alarm should sound if any time redundant inputs disagree. In many cases the operating personnel will have to decide what to do. In some cases the computer control system will have to decide by itself what to do if redundant inputs disagree.

The more hazardous the process, the more it is necessary to use multiple sensors for flow, temperature, pressure, and other variables.

Since it must be assumed that all measuring devices will fail, they should fail to an alarm state. If a device fails to a nonalarm condition, there can be serious problems. If a device fails to an alarm condition, but there is really not an alarm condition, it is also serious, but generally not as serious as if it fails to a nonalarm condition, which can provide a false sense of security.

Usually it is assumed that two devices measuring the same thing will not fail independently at the same time. If this is not acceptable, more than two devices may be used. If this is assumed, one can consider the effects of different levels of redundancy:

Number of Inputs Consequence

One failure provides no information on whether there is an alarm condition or not.

Two failures of one device show that there is a disagreement, but without more information, it cannot be determined whether there is an alarm condition or not. More information is needed; the operator could "vote" if there is time.

Three failures of one device leave two that work; there should be no ambiguity on whether there is an alarm condition or not.

Pressure Relief Systems

If the process cannot be shut down in time, then a relief system may be called into action. Although this is also a "loss of containment," the fluid is discharged to a specific safe location. Sometimes defining a "safe" location is difficult.

The design of relief systems involves, in general, the following steps:

1. Generate scenario. What could reasonably happen that could cause high pressures? This could be fire, runaway reactions, phase changes, generation of gases or vapors, leaks from high pressure sources, and so on.
2. Calculate the duty requirements—the pounds per hour of material that has to be vented, and its physical condition (temperature, pressure, ratio of vapor to liquid, physical properties). This is a rather involved calculational procedure.
3. Calculate the relief area required based on the duty, inlet and outlet piping, and downstream equipment. This is also a rather involved calculational procedure.
4. Choose the relief device to be specified from vendor information.

A group of chemical companies joined together in 1976 to investigate emergency relief systems. This later resulted in the formation of The Design Institute for Emergency Relief Systems (DIERS), a consortium of 29 companies under the auspices of the AIChE. DIERS was funded with $1.6 million to test existing methods for emergency relief system design and to "fill in the gaps" in technology in this area, especially in the design of emergency relief systems to handle runaway reactions [6]. DIERS completed contract work and disbanded in 1984.

Huff was the first to publish details of a comprehensive two-phase flow computational method for sizing emergency relief devices, which, with refinements, has been in use for over a decade [7–10]. The most significant theoretical and experimental finding of the DIERS program was the ease with which two-phase vapor–liquid flow can occur during an emergency relief situation. *The occurrence of two-phase flow during runaway reaction relief almost always requires a larger relief system than does single-phase flow vapor venting*. The required area for two-phase flow venting can be from two to much more than two times larger to provide adequate relief than if vapor-only venting occurs [7]. Failure to recognize this can result in drastically undersized relief systems that will not provide the intended protection.

Two-phase vapor–liquid flow of the type that can affect relief system design occurs as a result of vaporization and gas generation during a runaway reaction or in many liquid systems subjected to fire (especially tanks that are nearly full). Boiling can take place throughout the entire volume of liquid, not just at the surface. Trapped bubbles, retarded by viscosity and the nature of the fluid, reduce the effective density of the fluid and cause the liquid surface to be raised. When it reaches the height of the relief device, two-phase flow results. Fauske and Leung [11] described test equipment that can be used to help determine the design of pressure relief systems for runaway reactions that often result in two- or three-phase flow.

Blow Down Systems/Flare Systems/Incinerators [2]

Relief devices most often discharge into collection/treatment systems called blow down systems. These collection/knockout systems are usually pressure vessels. Treatment systems, usually scrubbers and/or flares/incinerators, are located downstream of the collection/knockout vessels. More blow down systems are being designed to collect relief valve discharges especially two-phase discharges. Collection systems can at times be pretty sophisticated. Retrofit of these systems can be very difficult in placing them within existing process equipment. Some design considerations related to relief systems include:

- Relief capacity based on simultaneous release of several PSVs from a single contingency.
- System approach used to determine limiting scenario.
- Blocked in circuit, fire, or loss of cooling. Which one is quicker acting?
- May not take credit for instrumentation or human intervention.
- System capacity must consider backpressure at all points of entry.
- PSV’s have full capacity at 10% overpressure.
- Step configuration for variable loads.
- Flare systems and incinerators [2].

A flare system is used to collect and burn excess flammable vapors and safely disperse the byproducts to atmosphere. A blow down (piping manifold) system is used to collect surplus vapors from a process. Most releases occur under emergency or upset (unplanned) conditions and are directed from the outlet of one or more relief valves. Entrained liquid is removed from the vapors (knock out drum) and the vapors are burned in a central stack. The flare stack is usually elevated to reduce thermal radiation effects on the ground and equipment and also to disperse smoke.

An incinerator is a waste treatment device that involves the combustion of organic materials in the solid or gaseous state. It is usually a direct fired piece of equipment where feedstock undergoes combustion. Processes may or may not recover the heat released from combustion.

Mitigation of Loss of Containment Events [2]

Mitigative safeguards limit the extent of the loss event. Mitigative safeguards include both physical as well as administrative components. As the incident progresses, mitigation is successful or unsuccessful. Mitigative safeguards include:

- Isolation of piping systems and equipment
- Detectors and alarms
- Flame arrestors/suppression systems
- Explosion containment rooms
- Fire protection
- Water or steam curtains
- Emergency response

Design for Emergency Isolation of Piping Systems [2]

Design of piping systems with its associated equipment must include provision for safe and rapid isolation of the contents of the system should the need arise. This can be accomplished by strategic placement of emergency block valves (EBVs). EBVs are typically located at

- Loading/unloading lines in hazardous service
- Furnace crack gas outlet lines
- Inlet and outlet of compressors
- Inlet and outlet of reactors
- Inlet of pumps from vessels with 10,000 lb of flammable material
- Major lines entering a system of vessels containing more than 10,000 lb of flammable materials which operate together
- Battery limits for pipelines containing hazardous materials

Through proper design, it would be possible to provide for isolation of an individual item or section, or to effectively shut down an entire operation. The location of block valves must include consideration of potential hazards to operating personnel. Therefore, manually operated devices must be easily and safely accessible and easy to operate. Remotely or automatically operated block valves, usually recommended in situations where operating personnel would be exposed to hazardous conditions, should be placed in locations where, insofar as possible, they will not be subject to conditions which might impair their operation. If there is a possibility that they might be exposed to fire in the case of an emergency, block valves should be fireproof or fire resistant to the extent necessary to ensure dependable operation under such conditions. It should be apparent that proper use of block valves has the potential to greatly reduce loss of containment with its resultant explosions and fires because they.

- Provide isolation between different hazards within a system
- Quickly interrupt flow through a system or prevent gross movement of hazardous material into an exposed location
- Block in specific pieces of hardware that may be involved in an incident
- Cause an orderly shutdown of equipment

Categories of EBVs include:

  - Manually actuated valve at the equipment to be isolated
  - Manually actuated valve located at a safe distance from the equipment to be isolated
  - Mechanically assisted valve at or near the equipment to be isolated
  - Mechanically assisted valve with remote activation capability

Gas Detection [2]

Gas detection is used to determine the presence of undesired vapors and gases at some specified concentration. It is also used to support some action or decision. Sensors need to be located where gas is most likely to accumulate. With gas detectors, the concentration of test gas at point of measurement at a specific time is known, but how much gas is present, how far the gas cloud extends, the concentration profile within the cloud, what other gases are present, or how fast the gas is moving are not known.

Flame/Detonation Arrestors [2]

There are two types of arrestors: flame arrestors and detonation arrestors which are more massive and robust. The arrestor forces the gas velocity to decrease through increasing the diameter and then provides sufficient surface to cool the gas. If the upstream fire continues eventually it could overwhelm the arrestor as the internal parts heat up. Flame arresters absorb kinetic energy from a fluid and prevent deflagration/detonation transition. Common types include crimped ribbon, parallel plate, expanded metal, packed bed, hydraulic, perforated plate, sintered metal, and liquid seal. Criteria for design include vapor composition, operating pressure and temperature, piping configuration, and flow rate. All flame arresters must be tested in their final environment.

Explosion Venting, Mechanical Isolation, and Explosion Suppression [12]

Explosion vent panels are pretty common especially for dust applications. In dust applications there is a possibility of a buildup of solids on the inside panels which can add weight and resistance. Some materials such as hydrogen can't be vented using explosion panels because of its high flame speeds. In general these systems are designed to discharge in an open environment. The panels are designed per NFPA 68. They are lightweight, tethered panels which are non-fragmenting.

Fast acting valves are another means of stopping flame propagation. They are dependent on very quick acting sensors that are able to detect change of pressure in the millisecond range.

Suppression systems such as halons cause the fire to starve because air is displaced by an inert. Having a space that is effectively sealed to minimize leakage is very important.

Certain types of foam or plastic media can be applied to a liquid spill in a dike to restrict vaporization.

Explosion containment rooms are used in special applications, particularly high pressure operations. They are also used in laboratories and pilot plants, sometimes with blow out walls and roofs.

Fire Protection [2]

Fire protection must be a functional, rational, and consistent system across a facility. A "holistic" fire protection strategy must be adopted to deal with all possible exposures that could threaten people, equipment, the operation, and the environment. Compliance to codes and standards is a minimal requirement. There must be an integrated fire protection strategy that includes:

- Prevention: Process selection, equipment layout, good engineering, quality construction
- Detection and response: Isolate fuel source
- Suppression: Prevent fire from spreading—extinguish original fire

All of these activities are essential to success. Obviously the first consideration is to prevent as many opportunities for loss of containment of flammables and possible fires as possible. Foam systems are sometimes necessary to extinguish fires. Fire protection includes:

- System for ensuring the early detection, extinguishment, and protection from fires
- Deluge protection recommended in critical areas such as pump bays
- Deluge systems should be easy to operate and should be augmented with detectors
- Heat actuated sprinkler systems
- Extinguishment in motor control centers and control rooms
- Fireproofing on high value equipment (2–4 h)

A typical fire water distribution system is usually installed underground. Valves are placed so that water supply can get to any point from two directions within the loop. A 4 h supply of firewater is usually specified as recommended by insurance companies. The pumping system should be redundant with both electric and diesel backup pumps. With fire protection systems it is important to ensure the ongoing integrity of all fire protection hardware by preventive maintenance and testing. Ownership must be clearly established to ensure that proper testing and maintenance is done on fire protection systems.

All operating personnel must be familiar with the functionality of fire protection equipment that they may be required to use.

Emergency Response [2]

Emergency response involves scenario-based planning. It requires understanding the hazards and risks and on-site response capabilities. It also requires securing support from outside parties, for example, fire departments, and mutual aid organizations. Emergency response also requires the establishment of safe havens, evacuation routes, command centers, and the development of emergency response procedures. Emergency response training includes emergency drills that must be conducted. These drills include tabletop exercises and full-scale drills. Feedback from drills should result in improvement and modification of emergency procedures as necessary. See Chap. 3 for a more detailed discussion of emergency response.

Management Systems (Risk-Based Process Safety) [2, 13]

Management systems are necessary to ensure that process safety concepts and practices are implemented in an organization. There are several models for process safety management systems. The OSHA process safety management model is a legal requirement in the United States (see section on “Regulations” in this chapter). Risk-Based Process Safety is the model developed by CCPS. It is not a regulatory requirement but is consistent with the OSHA PSM standard and the chemical processing industries’ good practice. The recent book entitled *Risk Based Process Safety,* CCPS, 2007 discusses the model proposed by CCPS that will be used in this discussion of process safety management systems. The concept of Risk Based Process Safety is that each company needs to tailor its process safety management systems to address its risk and risk tolerance. In other words the higher the risk of a major process safety incident, the more robust your management system should be. Also companies with the same risk of a major process safety incident may have different management systems because of different risk tolerance. For example, a company that has a chlorine unloading operation adjacent to another business or residential area should have a more robust management system than a company with a similar unloading operation located in a remote area. Of course hazardous operations need to be located in as remote areas as possible.

CCPS defines process safety management as a management system that is focused on the prevention of, preparation for, mitigation of response to and restoration from catastrophic releases of chemicals or energy from a process associated with a facility. The key concept is “catastrophic” releases of chemicals or energy from a process associated with a facility. A process is a sequence of activities that leads to a desired outcome. That outcome often involves the creation of a marketable product. In practice, processes of concerned include the shipping, handling, storing, mixing, separating, and disposal of chemicals. Risk-based process safety uses risk-based strategies and implementation tactics that are commensurate with the risk-based need for process safety activities, availability of resources, and existing process safety culture. Based on the company’s perception of risk, each element of RBPS needs to be designed and implemented to fit the risk. Each company will have different looking management systems based on their risk perception and culture, but all 20 elements need to be addressed. The goal of RBPS is to design, correct, and improve process safety management activities.

The 20 elements of RBPS are organized under the pillars “commit to process safety,” “understand hazards and risk,” “manage risk,” and “learn from experience.” Each of the 20 elements under the four pillars will be discussed (see Fig. 2.5).

Commit to Process Safety

The first pillar of RBPS is to *Commit to Process Safety*. To commit to process safety, facilities should focus on:

- Developing and sustaining a culture that embraces process safety.
- Identifying, understanding, and complying with codes, standards, regulation, and laws.

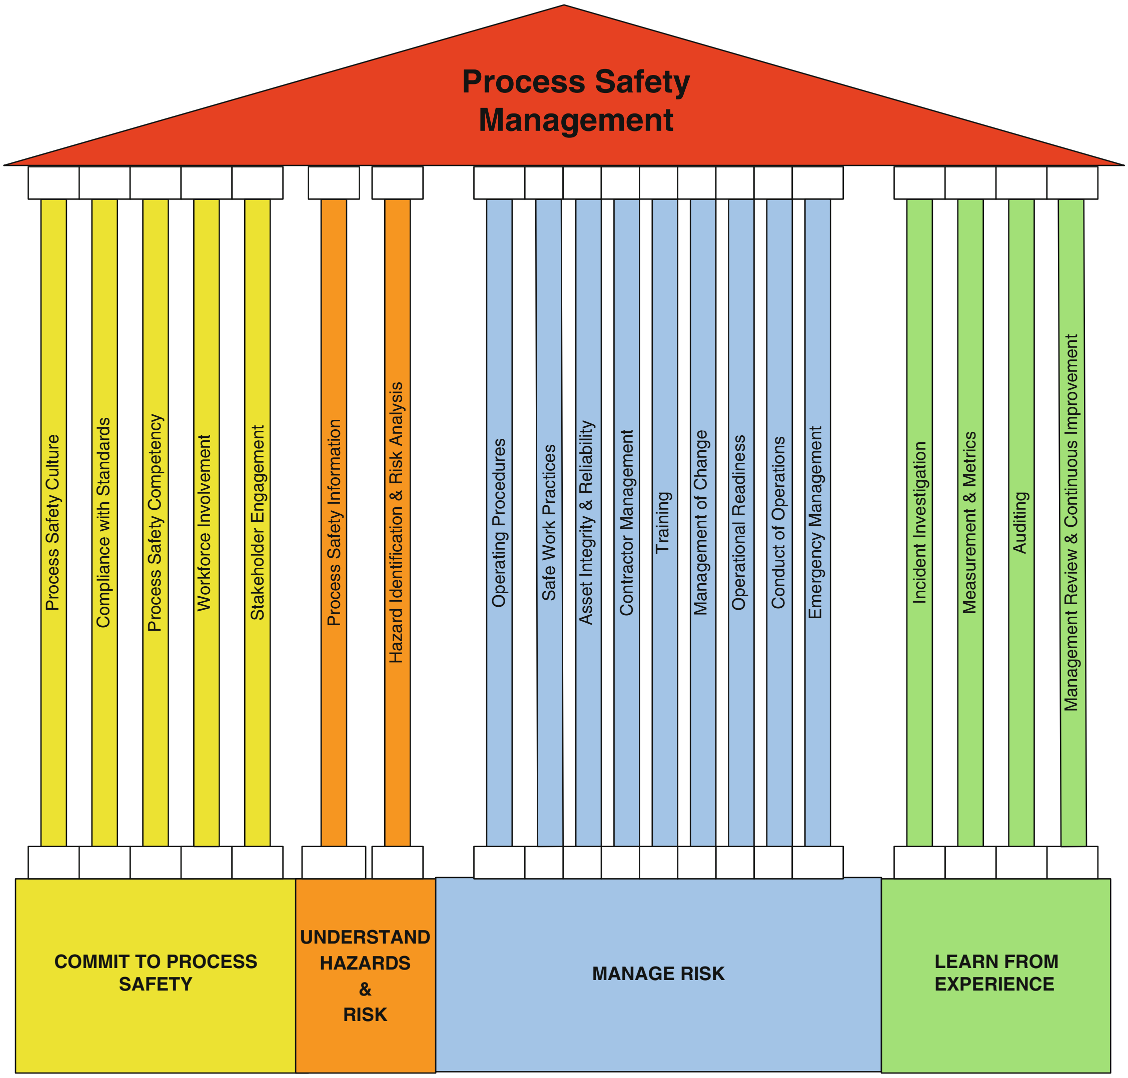

Fig. 2.5 Risk based process safety (David Guss, Nexen Inc. (2008), from CCPS, Process Safety Boot Camp Course (2010) and used with permission)

- Establishing and continually enhancing organizational competence.
- Soliciting input from and consulting with all stakeholders, including employees, contractors, and neighbors.

Process Safety Culture

What is process safety culture? Process safety culture is the combination of group values and behaviors that determine the manner in which process safety is managed. It is often described as how we do things around here, what we expect here, or how we behave when no one is watching. Why is process safety culture important? Investigations of catastrophic events have identified common process safety culture weaknesses that are often factors in other serious incidents. Examples of process safety culture weakness include warning signs such as lack of enforcement of process safety standards, no sense of vulnerability, poor communications, and delayed or no response to process safety issues and concerns.

Human Factors [2]

When examining process safety culture, it is important to understand human factors. This is a very important subject that people sometimes have difficulty in understanding. It encompasses a broad range of topics. Human errors will happen and must be eliminated or the probability or consequences of those errors must at least be reduced when handling hazardous materials. The perception of the application of human factors as ill-defined, difficult to apply, and expensive is a misconception. Those companies that have actively applied human factors have seen a true business value. Human factors look at the ways to identify and control potential human errors and conditions which affect the outcome of human activity. The human is the ultimate variable in every human–machine interface. The potential for human error exists wherever there are several choices or degrees of freedom. There are three groupings of human interactions that all overlap and are intertwined with one another. These are people, facilities, and management systems. The potential for human errors in all these groupings must be examined. The CCPS book *Guidelines for Preventing Human Error in Process Safety* by Center for Chemical Process Safety (CCPS), August 2004, is an excellent source of information on human factors.

Compliance with Standards

The next element under the pillar "Commit to Process Safety" is "Compliance with Standards." A standards system is a system to identify, develop, acquire, evaluate, disseminate, and provide access to applicable standard, codes, regulations, and laws that affect process safety. It addresses internal and external standards; national and international codes and standards; and local, state, and federal regulations and laws. It interacts with every RBPS management system element.

"Recognized and generally accepted engineering practices" or RAGAGEP is a regulatory term that means the engineering practices that are prevalent in the industry must be followed. It is included in the Process Safety Information element as applied to equipment used in the process in the OSHA PSM standard. A standard system as discussed above will help to ensure that RAGAGEP is implemented in the facility.

Why is a standards system important? Knowledge of and conformance to standards helps a company operate and maintain a safe facility and to consistently implement process safety practices. It also minimizes legal liability. Changes in standards must be current so the company can adjust its compliance activities. The standards system also forms the basis of the standards of care used in an audit program to determine management system conformance.

Inherently Safer Concepts [2, 14]

One important accepted practice is inherently safer design. The concept of inherent safety was first coined by Trevor Kletz. Trevor Kletz worked for ICI as a safety consultant and is still active in process safety today. Recently CCPS has updated a guidelines book on inherently safer chemical processes (see references). Inherently safer is a principle that continues to be important in the reduction of overall risk for any company.

In the narrow definition, inherently safer designs permanently and inseparable *reduce or eliminate process hazards* that must be contained and controlled to avoid loss events. To quote Trevor Kletz "The essence of the inherently safer approach to plant design is the *avoidance of hazards* rather than their control by added-on protective equipment" [15].

Process safety strategies include:

- Inherent (hazard elimination or reduction)
- Passive (process or equipment design features that reduce risk without active functioning of any device)
- Active (engineering controls)
- Procedural (administrative controls)

The above is the hierarchy of strategies to control hazards or risk. Least reliable is an administrative approach. From a reliability stand point, engineering controls follow then passive controls such as dikes. Finally, inherent safety is the most reliable. In practice all four strategies are used to design and operate a safe chemical processing facility.

Sometimes what appears to be an inherently safer approach creates its own hazards and risks which may result in lower risk overall but it will not reduce risk to zero. Sometimes the frequency of a loss of containment will be increased by the change. For example, supplying chlorine, a hazardous material, from many small cylinders instead of one large tank increases disconnect frequency, thus the chance of a leak, but the consequences of a release if a leak should occur will be significantly reduced because the quantity release would be less. Another example is a reactor that underwent runaway reaction would have produced much less consequences if it had failed at only a few pounds pressure. Instead the vessel was designed to 50 psig, to decrease the likelihood of a release and when it failed the pressure rise was exponential producing a much greater amount of stored energy and consequently resulted in much greater damage.

Inherently safer principles put forth by Trevor Kletz include:

- Use less hazardous materials
- Minimize inventories
- Reduce operating severity
- Simplify equipment design

The implementation of these principles will result in serious process incidents occurring less frequently. Examples of the application of the principles include:

Intensification: Reduce quantity of hazardous materials.

Substitution: Use of safer materials.

Attenuation: Running at safer operating conditions.

Limitation of effects: Changing equipment layout to reduce consequences.

Simplification: Avoidance of multiproduct operations.

Error tolerance: More robust equipment to tolerate upsets and errors.

Avoid knock-on effects: Open construction, layout.

Prevent incorrect assembly: Piping systems to reduce human error.

Ease of control: Less hands on control. It is extremely important to apply inherently safer principles at the laboratory stage or during the process conceptual design. The earlier inherently safer design concepts can be applied, the easier implementation will be, although, the principles can be applied throughout the life of a plant.

Process Design [2]

Standards and practices are an important aspect of process design. There are many different process safety topics that are part of design. Some are addressed very early in the design process such as layout and spacing, while others are done during detailed design, e.g., bonding and grounding. Some of these safeguards are passive, e.g., grading and drainage and some require engineering control, e.g., system isolation.

The design topics covered briefly in this chapter include:

- Layout and spacing
- Infrastructure
- Grading and drainage
- Equipment selection/sizing
- Design for pressure protection
- Design for mechanical integrity
- Fireproofing/firewalls
- Inerting
- Electrical area classification (EAC)
- Bonding and grounding system isolation
- Review of design alternatives

Process design is a key element in regard to how to contain and control potential loss of containment events.

- *Layout and spacing*

Layout and spacing are critical to safe design. Congestion and confinement are major contributors to high pressures from vapor cloud explosions. Layout and spacing concepts are much easier to apply with a new grass roots facility, but with an existing facility debottlenecking seems to be more prevalent and the job much more difficult.

An I, L, or H pattern provides ease of access and minimal congestion. Layout involves determining the most logical way of configuring the plant given various constraints from the site plot. Every additional foot of piping (and valves) increases the risk of failure. Important strategies include:

- Unit layout in I, L, or H pattern preferred
- High value equipment separated from high hazards if possible
- Major inventory sources well spaced and separated
- Minimize amount of congestion and confinement
- Egress, maintenance and fire fighting access
- Arrange equipment by function
- Arrange piping by category of service
- *Grading and drainage*

Equipment containing large volumes of flammable materials should be located upstream of sloped areas. The rate and quantity of firewater should also be considered in the design of the sewer system or catch basin. The grading plan must be completed prior to plant layout. Key points regarding grading and drainage include:

- Grading should slope away from fuel sources or critical equipment
- Sewer system should be sized to handle storm runoff or maximum release from major equipment failure
- Multiple catch basins reduce the travel time/distance and reduce the surface area for a potential fire
  - Remember sewers are costly; catch basins are not
- Need to segregate incompatible materials
- Sewer design must recognize plugging potential; provide means of clearing
- Sewers must not permit the passage of flammable vapor
  - Use traps
- *Integrated approach to layout, grading, and sewers is required*
- Equipment sizing

Larger vessels are more adiabatic and self-heating and unwanted reactions more difficult to control. Sometimes mixing becomes more difficult in large reactors. Some factors to consider in equipment sizing include:

- Determined by inventory requirements and holdup considerations
- Driven by economics but limited by transportation systems
- Large size equipment is more prone to failure from localized stresses
- Difficult to establish control within all parts of large systems
- Difficult to establish equilibrium in large vessels and reactors

The advantages of small equipment include:

- Reduce hazardous inventory
- Reduce size to save capital and reduce maintenance
- Reduced size gives quicker response—more predictable behavior
- Lower internal stresses

The advantages of larger equipment include:

- Increase size to cushion equipment against upset
- Increased size may reduce number of procedural steps

These are some of the considerations that must be examined. Sometimes goals of the plant and business area are in conflict. The business area wants to have a large inventory so the customer is always able to be supplied on time. The plant wants to minimize storage to have a more inherently safer plant. A facility is probably less prone to human error in a single large system compared to a group of smaller systems.

- *Pressure protection design*

This topic has already been discussed as a mitigative safeguard.

- *Design for mechanical integrity*

Equipment must be designed for mechanical integrity. The design must tolerate continuous exposure to process fluids at normal and upset operating conditions. Normal modes of failure must be anticipated, i.e., impeller wear, corrosion. What tests are necessary to maintain mechanical integrity and how frequently they must be done needs to be established during design. In many cases instruments, like vibration sensors, are designed and alarmed if the machine goes out of its normal operating range. Pressure vessel cycling is another consideration especially for batch reaction systems. Replacement of systems over time and how that can physically be accomplished must be addressed during design. How critical systems must be tested—on-line and off-line—and how frequently testing will occur must also be addressed.

How relief valve testing will be done and access to relief valves is another design consideration. Key concepts to keep in mind regarding design for mechanical integrity include:

- Commit to quality engineering standards
- Material selection to match conditions
- Design to full range of service conditions
- Design for pressure/temperature cycles
- Minimize temperature gradients/local stresses/vibration
- Quality control during fabrication and construction
- Design for ease of testing and maintenance
- Dimensional tolerances in rotating equipment
- *Fireproofing and fire walls*

  Key aspects of fireproofing include:
- Fire hazard zones must be determined based on credible release scenarios
  - Consider drainage and system inventory
- All load-bearing members which reside in a fire hazard zone must be passively protected for 2 h min per UL 1709
- Must extend fireproofing to highest structural member that supports fuel containing equipment—include cross members
- Include whole structure footprint unless clear break point exists
- Fireproofing materials must have good thermal insulation properties and must resist mechanical impact and erosion
- Concrete is an ideal choice for most applications but it can add considerable weight to a structure
- Mixed cementaceous fireproof materials (such as Pyrocrete 241) may be used if they are properly applied
- Contour or surface application around structural steel is recommended to avoid moisture collecting
- All fireproofing applications are subject to verification and approval by UL 1709

Firewalls are solid barriers that shield equipment (*usually high value*) from direct fire radiation and prevent the spread of fires. Firewalls are generally of concrete construction and provide 2–4 h of fire protection. Full partition firewalls may be used to segregate EAC zones.

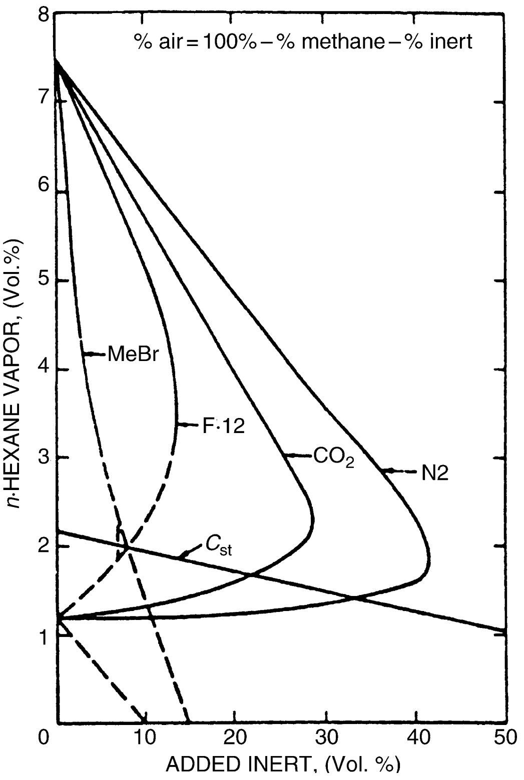

Fig. 2.6 Limits of flammability of various methane–inert gas–air mixtures at 25°C and atmospheric pressure. (Courtesy Bureau of Mines)

Fire stops are barriers installed in pipe racks or conduit runs. They prevent the passage of fuel, air, or fire but permit circuit continuity. Their integrity is a function of design and quality of installation.

Inerting: The addition of inert gases to a mixture of flammable gases and air affects flammability limits. Carbon dioxide causes a greater narrowing of the flammable range than does nitrogen. Water vapor is an acceptable inert gas if the temperature is high enough to exclude much of the oxygen, which requires a temperature of 90–95°C. Because water vapor and carbon dioxide have a higher heat capacity than nitrogen, they are somewhat more effective as inerting agents than nitrogen. Some halogen-containing compounds also can be used for inerting materials at relatively low concentrations. An example of this is the use of Freon-12 (CCl_2F_2). Caution must be used with halohydrocarbons because of the possibility of the halocarbons themselves burning, especially at high pressures. Environmental considerations are making the use of halogenated hydrocarbons for inerting increasingly undesirable. Materials are being developed that are considered environmentally acceptable. Figures 2.6 and 2.7 [16] show flammability envelopes for methane and *n*-hexane for various air–inert mixtures at 25°C and 1 atm. All flammable

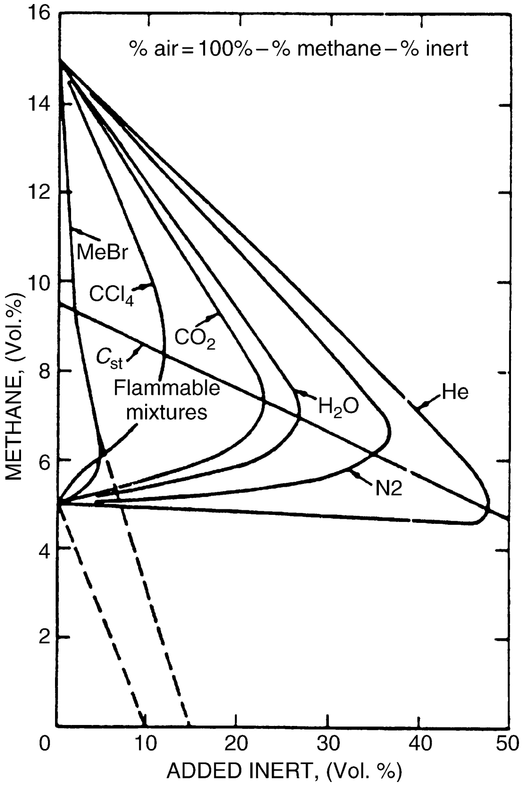

Fig. 2.7 Limits of flammability of various *n*-hexane-inert gas mixtures at 25°C and atmospheric pressure. (Courtesy Bureau of Mines)

envelopes are similar to Figs. 2.6 and 2.7 except in minor detail. The lower limit is virtually insensitive to added inerts. The upper limit, however, decreases linearly with added inert until the critical concentration of inert is reached beyond which no compositions are flammable. In these graphs, C_{st} means the stoichiometric composition.

The limits of flammability are dictated by the ability of a system to propagate a flame front. Propagation does not occur until the flame front reaches about 1,200–1,400 K. Since the typical terminal temperature for hydrocarbons at stoichiometric conditions is about 2,300 K, it can be seen that having only one-half the fuel or oxidizer present will produce about one-half the flame temperature, which is too low to propagate flame.

A useful rule to remember is that the lower flammable limits of most flammable vapors are close to one-half the stoichiometric composition, which can be calculated. Another easy rule to remember is that about 10% oxygen or less in air (assuming the rest is mostly nitrogen) will not support combustion of most flammable hydrocarbon vapors.

The flammability limits of hydrocarbon-type fuels in oxygen and inert gas atmospheres are a function of the inert gas and any fuel or oxygen in excess of that required by the stoichiometry of the combustion process. In systems where fuel content is fixed, inert material having a high heat capacity will be more effective at flame suppression than inert material having a low heat capacity.

Many of the flammable limits reported in the literature are somewhat too narrow, and certain gas compositions regarded as being nonflammable are in fact flammable when given the proper set of circumstances. *In other words, take data on flammability limits from the literature with a grain of salt.* It is best not to design closely on the basis of most available data on flammability limits.

The use of inert gases can cause some serious hazards that must be recognized if inerts are to be used effectively and safely. Considerations in the use of inert gases include:

1. *An inert atmosphere can kill if a person breathes it*: Precautions should be taken to ensure that personnel cannot be exposed to the breathing of inert atmospheres.
2. *Some products need at least a small amount of oxygen to be stored safely*: This includes styrene and some other vinyl monomers, which must have some oxygen in them to make the usual polymerization inhibitor for styrene (t-butyl catechol, or TBC) effective. If pure nitrogen, for example, is used to blanket styrene, the inhibitor will become ineffective. TBC customarily is added to styrene monomer to prevent polymer formation and oxidation degradation during shipment and subsequent storage; it functions as an antioxidant and prevents polymerization by reacting with oxidation products (free radicals in the monomer). If sufficient oxygen is present, polymerization is effectively prevented (at ambient temperatures); but in the absence of oxygen, polymerization will proceed at essentially the same rate as if no inhibitor were present. The styrene may polymerize and can undergo an uncontrolled exothermic reaction, which may generate high temperatures and pressures that can be very hazardous. The inhibitor level of styrene must be maintained above a minimum concentration at all times. The minimum concentration of TBC in styrene for storage is about 4–5 ppm.
3. To be effective, inert atmospheres must be maintained within certain composition limits. This requires the proper instrumentation and regular attention to the system.
4. *Inerting systems can be quite expensive and difficult to operate successfully*: Before the use of inert systems, alternatives should be explored, such as the use of nonflammable materials or operating well outside, preferably below, the flammability range.

Electrical Area Classification [2]: One of the first exercises during design between the electrical engineers and the process engineers results in an electrical classification plot plan diagram. Vehicular traffic in the plant is another source of ignition that should be considered in layout. A plot plan drawing with electrically classified buildings, rooms, etc. is usually developed. More detailed drawings may be needed for special process equipment and discharges. EAC is a system used to control potential electrical ignition sources in close proximity to flammable substances. EAC is usually done by process engineers in conjunction with electrical engineers. It determines electrical hardware which may be used and where it may be located. Non-sparking equipment is defined. Explosion proof enclosures provide small confined enclosure over electrical contacts. Sealing devices must also be specified.

There will be different electrical system requirements depending on the type of material and whether it is a flammable gas or dust. The Zone system is replacing the US Division system.

- Class I—Flammable gas vapor or liquid is present
- Class II—Combustible dust is present
- Group A—Acetylene
- Group B—Hydrogen
- Group C—Cyclopropane, ethyl ether
- Group D—Acetone, butane, hexane, natural gas, fuel oil
- Group E—Combustible metals
- Group F—Carbonaceous materials, including coal dust
- Group G—Flour, starch, plastic
- Division 1 (Zone 0 or 1)—Flammable or combustible concentrations exist under normal operating conditions
- Division 2 (Zone 2)—Flammable or combustible concentrations exist under abnormal operating conditions or have a low likelihood of occurrence

Static Electricity, Grounding and Bonding

Introduction

Many apparently mysterious fires and explosions have eventually been traced to static. In spite of the large amount of information about static electricity, it remains a complex phenomenon not often understood and appreciated. Static electricity is a potential source of ignition whenever there is a flammable mixture of gas or dust.

When two different or similar materials are in contact, electrons can move from one material across the boundary and associate with the other. If the two materials in contact are good conductors of electricity and are separated, the excess electrons in one material will return to the other before final contact is broken. But if one or both of the materials are insulators, this flow will be impeded. If the separation is done rapidly enough, some excess electrons will be trapped in one of the materials. Then both materials are "charged." Electric charges can build up on a nonconducting surface until the dielectric strength is exceeded and a spark occurs. The residual charge could ignite flammable mixtures.

The two materials or phases in initial contact may be a single liquid dispersed into drops, two solids, two immiscible liquids, a solid and a liquid, a solid and a vapor or gas, a liquid and a vapor or gas.

The important thing to keep in mind is that whenever there is contact and separation of phases, a charge may develop that could be disastrous. Three conditions must be met before an explosion caused by static electricity can take place:

1. An explosive mixture must be present.
2. An electric field must have been produced due to the electrostatic charge that had been generated and accumulated in a liquid or solid.
3. An electric field must be large enough to cause a spark of sufficient energy to ignite the mixture.

In designing preventive measures, all three factors should be controlled.

Static electricity is essentially a phenomenon of low current but high voltage and high resistance to current flow. A low-conductivity liquid flowing through a pipeline can generate a charge at a rate of 10^{-9} to 10^{-6} A (A). A powder coming out of a grinding mill can carry a charge at a rate of 10^{-8} to 10^{-4} A. At a charging rate of 10^{-6} A, the potential of a container insulated from earth can rise at a rate of 1,000 V/s and a voltage of 10,000 V or higher can readily be obtained in this way.

Several electrostatic voltages and energies commonly encountered are typified by the following examples:

1. A person walking on dry carpet or sliding across an automobile seat can generate up to 5,000 V in dry weather. An individual having a capacitance of 100 pF, a reasonable figure, could generate a spark energy of 1.25 mJ. This is far more than is needed to ignite some flammable vapor–air mixtures.
2. A person can accumulate dangerous charges up to about 20,000 V when humidity is low.
3. A truck or an automobile traveling over pavement in dry weather can generate up to about 10,000 V.
4. Nonconductive belts running over pulleys generate up to 30,000 V. The voltage generated by a conveyor belt can be as high as 10[5 V; the system can in effect act as a Van der Graaf generator.
5. The energy in the spark from an ordinary spark plug is 20–30 mJ.

The capacitance and the energy for ignition of people and of common objects are important. The capacitance of a human being is sufficient to ignite various flammable gas mixtures at commonly attained static voltages.

There are several hazard determinants relating to static electricity

Capacitance: The capacitance of an object is the ratio of the charge of the object to its potential. The capacitance gets larger as the object gets larger. With a given charge, the voltage gets higher as the capacity of the object gets smaller. For a sphere, capacitance is given by

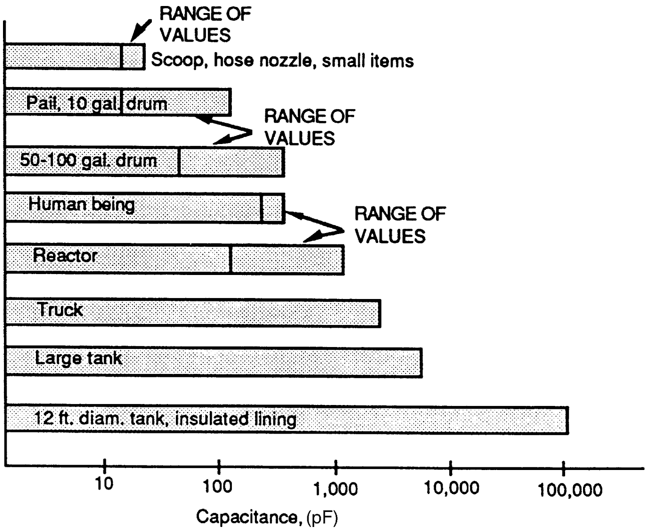

Fig. 2.8 Some typical values of electrical capacitance. (Data from Eichel [21])

$$C = \frac{Q(10^{-3})}{V}$$

The energy stored in a capacitor is [17]

$$W = 0.5\,CV^2(10 - 3) = 500\,Q^2/C$$

where

C = capacitance, pF (1 pF = picofarad = 10^{-12} F)

Q = charge, microcoulombs (1 C = 1 A/s = charge on 6.2×10^{18} electrons)

V = voltage in kilovolts

W = energy, millijoules (mJ)

This energy may be released as a spark when the voltage gets high enough. The minimum sparking potential for charged electrodes is about 350 V and occurs at a spacing of 0.01 mm. Sparks from an equally charged nonconductor are less energetic and may contain only part of the stored energy. These comparatively weak sparks are not likely to ignite dust clouds but can ignite flammable gases (Fig. 2.8).

The energy that can be stored by capacitance of an object can be compared with the minimum ignition energies of flammable gas–air mixtures and of dust–air mixtures to determine the probability that a spark discharge may have sufficient energy to cause ignition. If the charged object is a poor conductor, the calculation of energy available to produce a spark may not be possible because the charge often is not uniformly distributed, and the resistance to flow of current is high. Figure 2.8 shows some typical values of electrical capacitance [18].

Relaxation time: When a liquid is flowing in closed metal pipes, static electricity is not a hazard. When the liquid enters a tank, it may become a hazard. Charges caused by liquid separation during pumping, flow, filtration, and other effects such as splashing and agitation can accumulate on the surface of the liquid in the tank and cause sparking between the liquid surface and the tank or conducting objects in the tank. The charge thus generated can be dissipated by relaxation or via discharge through a spark or corona discharge. The relaxation time is the time required for 63% of the charge to leak away from a charged liquid through a grounded conductive container. The half-time value is the time required for the free charge to decay to one-half of its initial value. The half-time is related to the relaxation time by the relationship

$$T_{\mathrm{h}} = T_{\mathrm{r}} \times 0.693$$

where T_{h} = half-time T_{r} = relaxation time. Relaxation times vary from small fractions of a second up to minutes and even hours for some highly purified hydrocarbons that have very low conductivity.

It is important to recognize that a large charge can accumulate in the liquid even in a grounded container. In fact, it was reported that the majority of accidents attributed to static electricity in the petroleum industry have been with liquid in grounded containers [19].

Relaxation time can be calculated as follows:

$$T_{\mathrm{r}} = E(E_0/k)$$

where

T_{r} = the relaxation time, in seconds; the time for 63% of the charge to leak away

E = relative dielectric constant, dimensionless

E_0 = absolute dielectric constant in a vacuum = 8.85×10^{-14} to less than 1×10^{-18}

K = liquid conductivity, Siemens per centimeter (S/cm)

Siemens (S) are also called mhos

Example: Benzene in a large tank could have a specific conductivity as low as 1×10^{-18} mho/cm and as high as 7.6×10^{-8} S/cm. The corresponding relaxation times for the two conductivities can be calculated as follows. Pure benzene has a dielectric constant of 2.5 to less than 1×10^{-18}. Using the above equation:

1. $T_{\mathrm{r}} = (8.85 \times 10^{-14})(2.5)/(7.6 \times 10^{-8}) = 2.91 \times 10^{-6}$ s
2. $T_r = (8.85 \times 10^{-14})(2.5)/(1 \times 10^{-18})$

   $= 2.21 \times 10^5$ s (this is in excess of 60 h)

Benzene typically contains some water and has a higher conductivity than in the above example and has a much lower relaxation time.

The purity of a liquid has a great effect on its relaxation time, and thus its static hazard potential. In actual practice, relaxation times of a few seconds to an hour are encountered, depending on the purity and dryness of the liquid. This emphasizes the dangers of open sampling of tank contents soon after filling. If it is likely that the liquid being used has a low conductivity, it is important that enough time elapses between activities that can produce a static charge, such as loading a tank, and any activity that could cause a spark, such as sampling from the top of the tank.

In case (2) in the above example, a conductivity of 10^{-18} S/cm is so low that there may be little charge separation and little charge formation, and there may be no hazard even though the calculated relaxation time is extremely long. Materials with a half-time value of less than 0.012 s have been reported not to cause a hazard. A useful rule to remember is that the concept of relaxation is very important because it is possible for liquid in a tank to retain an electric charge for a long time if the liquid is a poor conductor, even if the tank is grounded. The specific conductivity, and therefore the relaxation time, is greatly affected by impurities. For example, the specific conductivity of benzene can vary from as long as 1×10^{-18} to about 7.6×10^{-8} S/cm, depending on its purity. It can vary significantly with the amount of water or other materials dissolved in the benzene [17].

Resistivity: The extent of charge separation is dependent on the resistivity of the liquid. Some materials have a sufficiently high conductivity to render them safe in terms of static buildup. If the resistivity is low, charge separation is easy, but so is charge recombination through the liquid. If the resistivity is high, there may be appreciable charge separation without immediate recombination, leading to a high charge. If the resistivity is extremely high, there may be no charge separation, and there is no buildup of a charge. If the conductivity of a liquid falls in the hazardous range, it is possible to modify it by the use of a very small amount of an additive. Additives usually are a combination of a polyvalent metal salt of an acid such as carboxylic or sulfonic acid and a suitable electrolyte. Additives of this type can impart a conductivity of 10^{-8} S/m (Siemens per meter) in a 0.1% solution in benzene [19].

A useful rule to remember is that when the resistivity of a liquid exceeds 10^{15} Ω centimeters (Ω-cm), or is less than 10^{10} Ω static generation or accumulation is negligible. Between these limits, the net generation of charges increases with the *maximum charge generation at* 10^{3} Ω. Styrene, for example, a commonly used monomer, has a resistivity of 4×10^{13} at 20°C [20], and therefore is capable of building up a potentially hazardous charge.

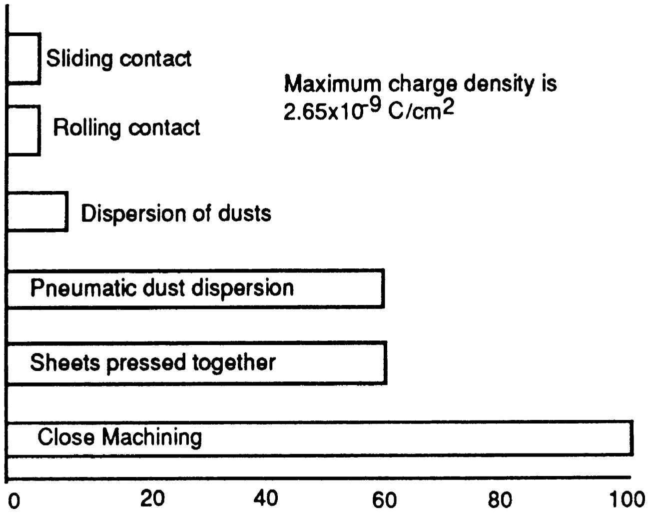

Fig. 2.9 Percentage of maximum theoretical charge produced by various operations. (Data from Eichel [21])

Static charge development: Static electrification of solids can occur in various ways. Different operations will produce the percentages of the theoretical maximum charge density shown in Fig. 2.9 [21].

It should be noted that pure gases do not generate significant static electricity in transmission through pipes and ducts. Gases contaminated with rust particles or liquid droplets produce static, but this is not a problem in a closed, grounded piping system. *If these gases impinge on an ungrounded, conductive object, dangerous charges can accumulate on that object.* Wet steam, which contains water droplets, can develop charges. *If the water droplets contact an ungrounded conductor, that object can develop a static charge.*

Flammable gases may ignite when discharged to air during thunderstorms, even without a direct lightning hit. Dry hydrogen and occasionally other gases may ignite when they are discharged to air in normal weather. This may be so because the electric field developed by the ejected gases can develop a corona discharge which can cause ignition. The minimum ignition energy of hydrogen is only 0.02 mJ. A toroidal ring developed by the National Aeronautics and Space Administration (NASA) is reported to prevent unwanted discharge and subsequent ignition of a vent-stack outlet [22].

Humidification: The conductivity of electrical nonconductors, such as plastics, paper, and concrete, depends on their moisture content. Relatively high moisture in these materials increases conductivity and therefore increases dissipation of static electricity. With relative humidity of 60–70% or higher, a microscopic film of moisture covers surfaces, making them more conductive.

Humidification can and often should be practiced to reduce the hazard of static electricity, but should not be relied on entirely to remove all possibility of static discharge.

In winter, cold air brought into a building and heated to normal room temperature is extremely dry, often less than 5–10% relative humidity. When processing solid materials that can develop a static charge, this air should be humidified to reduce static hazards as well as improve the comfort of personnel.

Filling liquid containers: A fire during top loading of a flammable liquid into a tank constitutes a serious problem if there could be a flammable mixture in the vapor space. Static electricity can be generated by splashing if the liquid is top-loaded, so it is normal practice to fill with a dip pipe positioned so the tip of the dip pipe is near the bottom of the tank. This may not be sufficient to prevent static charge buildup, as a charge may be generated in the bottom of the tank before the pipe tip is fully submerged, and it is possible for the liquid to acquire a charge before it reaches the tank.

Product filters using cotton, paper, felt, or plastic elements are prolific generators of static electricity. It is considered that at least 30 s is necessary to dissipate this charge, although with dry nonconductive liquids, it may require as long as 500 s.

Loading a less volatile liquid into a tank where there was previously a more volatile liquid is particularly hazardous because the more volatile liquid may form a flammable mixture, and the less flammable material is often a poor conductor and will not readily dissipate static charge. This type of loading accounts for 70–80% of severe losses at terminals [19]. This appears to occur most often when the compartments are one-fourth to one-third full, and when the temperature is close to -1°C.

Inerting the tank while it is being filled will reduce the possibility of ignition by static electricity and is highly recommended when it is possible and practical. However, this is not always practical. In any case, if inerts are to be used, they must be added carefully, as the following example illustrates. Two firemen were fatally injured when an explosion occurred as they were attempting to use portable CO_2 fire extinguishers to inert a tank truck. The source of ignition was believed to be a spark from the horn of the extinguisher to the latch on the tank truck. It was found that the voltage on the horn increased as the carbon dioxide "snow" passed down the horn to the outlet side.

Grounding and bonding lines, although very important, will not immediately dissipate the charge on the surface of a nonconducting liquid in a tank. A relaxation time for charge to be dissipated should be allowed after filling or other operations to permit static charge on the liquid surface to dissipate to the dip pipe or tank shell. *The minimum time is 1 min, but longer periods are advisable with some liquids that have extremely low conductivity. Bottom loading may reduce the static electricity hazard but does not eliminate it* [23].

Review of Design Alternatives: Hazards should be considered and eliminated in the process development stage where possible. This would include considerations of alternative processes, reduction or elimination of hazardous chemicals, site selection, etc. By the time the process is developed, the process designers already have major constraints imposed on them. Hazards should also be identified and removed or reduced early in the design. Adding protective equipment at the end of the design or after the plant is operating can be expensive and not entirely satisfactory. Allowing time in the early stages of design for critical reviews and evaluation of alternatives would involve studies such as an early hazard and operability (HAZOP) study, using flowsheets, before final design begins [24]. Fault tree analysis," quantitative risk assessment (QRA), checklists, audits, and other review and checking techniques can also be very helpful. These techniques are extensively discussed in the technical literature and will not be discussed in detail here.

Process Safety Competency

The next element under the pillar "Commit to Process Safety" is "Process Safety Competency." Process safety competency encompasses three interrelated actions; ensuring the appropriate information is available to people who need it, continuously improving knowledge and competency and consistently applying what has been learned. It is important for several reasons. Catastrophic process safety incidents are relatively rare, but losses can be devastating. Because of this learning must be proactive so that lessons must not be forgotten. Only competent people can transform information into knowledge. Knowledge management, not information management, helps organizations understand and manage risks and remain competitive.

The following principles must be followed. Facilities should implement management systems to help identify learning needs that are critical to process safety, support efforts to learn or obtain critical knowledge, maintain knowledge in a manner that helps promote risk-informed decision-making, and share information with other facilities (in some cases even competitors). Activities that help maintain and enhance process safety competency must be executed and evaluated. Results of the evaluation must be shared and plans adjusted as necessary.

Workforce Involvement

The fourth element in the pillar "Commit to Process Safety" is "Workforce Involvement." Workforce involvement includes developing a written plan of action regarding worker participation, consulting with workers on the development of the RBPS management system, and providing workers and their representatives access to all information developed under the RBPS system. In the US PSM standard workforce involvement is called employee participation and is a PSM regulatory requirement. This element provides for a consultative relationship between management and workers at all levels of the organization. It is important because it provides an equitable mechanism for workers to be directly involved in protecting their own welfare. It facilitates access to information only available through the unique experience of operating the process every day. It also provides a mechanism for workers to access necessary information and reinforces the process safety culture.

Stakeholder Outreach

The last element under the pillar "Commit to Process Safety" is "Stakeholder Outreach." Stakeholder outreach involves seeking out individuals or organizations that can be or believe they can be affected by company operations and engaging them in a dialogue about process safety. It also involves establishing a relationship with community organizations, other companies and professional groups, and local, state, and federal authorities. Stakeholders must be provided with accurate information about the company and the facility's products, processes, plans, hazards, and risks. This is important for several reasons. Sharing information with industry peers will promote better process safety for everyone. Sharing information in proactive ways with community and government stakeholders will build trust and commitment. By promoting openness and responsiveness, an effective outreach program will increase all stakeholders' confidence in the company.

Understand Hazards and Risk

The second pillar of RBPS is *Understand Hazards and Risk*. To understand hazards and risk, facilities should focus on:

- Collecting, documenting, and maintaining process safety knowledge
- Conducting hazard identification and risk analysis studies

Process Safety Knowledge

The first element is "process safety knowledge." Process safety knowledge includes written technical documents and specifications, engineering documents and calculations, specifications for design, fabrication, and installation of process equipment, and other written documents such as material safety data sheets (MSDSs). In the OSHA PSM standard process safety knowledge is called "Process Safety Information." To comply with the standard, employers must compile considerable documented process safety information on the hazards of chemicals used in a covered process as well as information on the process technology and equipment before conducting the process hazard analyses required by the standard. Process safety knowledge is important because risk understanding depends on accurate process safety knowledge. Process knowledge also supports other RBPS elements such as procedures, training, asset integrity, management of change, and incident investigation.

Process safety knowledge includes understanding the characteristics that are inherent to each material that is used in a process. Material hazards include flammability and combustibility hazards, reactivity hazards, toxicity hazards, and corrosivity hazards. Each type of hazard will be discussed.

Combustion Hazards

The enchanting flame has held a special mystery and charm the world over for thousands of years. According to Greek myth, Prometheus the Titan stole fire from the heavens and gave it to mortals—an act for which he was swiftly punished. Early people made use of it anyway. Soon the ancients came to regard fire as one of the basic elements of the world. It has since become the familiar sign of the hearth and a mark of youth and blood, as well as the object of intense curiosity and scientific investigation.

Suitably restrained, fire is of great benefit; unchecked or uncontrolled, it can cause immense damage. We respond to it with a powerful fascination coupled with an inbred respect and fear. A good servant but a bad master is Thoreau's "most tolerable third party" [25].

Fire [26]: Fire or combustion is normally the result of fuel and oxygen coming together in suitable proportions and with a source of heat. The consumption of a material by a fire is a chemical reaction in which the heated substance combines with oxygen. Heat, light, smoke, and products of combustion are generated. The net production of heat by a fire involves both heat-producing and heat-absorbing reactions, with more heat being produced than is absorbed. Energy in the form of heat is required:

1. To produce vapors and gases by vaporization or decomposition of solids and liquids. Actual combustion usually involves gases or vapors intimately mixed with oxygen molecules.
2. To energize the molecules of oxygen and flammable vapors into combining with one another and so initiating a chemical reaction.

The amount of energy required to cause combustion varies greatly. Hydrogen and carbon disulfide can be ignited by tiny sparks, or simply may be ignited by static generated as the gases or vapors discharge from pipes into air. Other materials, such as methylene chloride, require such large amounts of energy to be ignited that they sometimes are considered nonflammable. Fire also can result from the combining of such oxidizers as chlorine and various hydrocarbon vapors; oxygen is not required for a fire to take place.

There are exceptions to the general rule that a solid must vaporize or decompose to combine with oxygen; some finely divided materials such as aluminum powder and iron power can burn, and it is generally accepted that they do not vaporize appreciably before burning.

Products of combustion: Heat, light, smoke, and asphyxiating toxic gases are produced by fire. In a hot, well-ventilated fire, combustion usually is nearly complete. Almost all the carbon is converted to carbon dioxide, and all the hydrogen to steam, and oxides of various other elements such as sulfur and nitrogen are produced.

This is not the case in most fires, where some of the intermediate products, formed when large complex molecules are broken up, persist. Examples are hydrogen cyanide from wool and silk; acrolein from vegetable oils; acetic acid from timber or paper; and carbon or carbon monoxide from the incomplete combustion of carbonaceous materials. As the fire develops and becomes hotter, many of these intermediates, which are often toxic, are destroyed (e.g., hydrogen cyanide is decomposed at a significant rate at 538°C).

Small airborne particles of partially burnt carbonaceous materials form smoke, which is often thickened by steam, when there is only partial combustion of fuel.

Solids: Ordinarily, combustible solids do not combine directly with oxygen when they burn. They give off vapor and gaseous decomposition products when they are heated, and it is the vapors or gases that actually burn in the characteristic form of flames. Thus, before a solid can be ignited, it usually must be heated sufficiently for it to give off flammable concentrations of vapors. Glowing, which is combustion in the solid state, is characteristic of materials in the final stages of a fire's decay when flammable gases have been burned away, or when the production of gases and vapors has been suppressed.

Solids with larger surface areas, in relation to their volume, burn more readily than those that are more compact when exposed to heat and oxygen in the air. Common materials such as textiles in the form of fibers or fabrics, foamed rubber, foamed plastics, thin sheets of plastic, paper, corrugated cardboard, combustible dusts, dry grass and twigs, and wood shavings are examples of materials with large surface areas in relation to their volume. In a well-established fire, materials with relatively small surface areas, such as chunks of coal or logs, burn readily.

Combustion is self-propagating; burning materials produce heat which causes more of the solid to produce flammable vapors until either the fuel or oxygen is exhausted, or until the fire is extinguished in some other way.

Dusts: Most combustible solids can produce combustible dusts. Combustible dusts are particularly hazardous; they have a very high surface area to volume ratio. When finely divided as powders or dusts, solids burn quite differently from the original material in the bulk. Dust and fiber deposits can spread fire across a room or along a ledge or roof beam very quickly. Accumulations of dust can smolder slowly for long periods, giving little indication that combustion has started until the fire suddenly flares up, possibly when no one suspects a problem.

Many combustible dusts produced by industrial processes are explosible when they are suspended as a cloud in air. Even a spark may be sufficient to ignite them. After ignition, flame spreads rapidly through the dust cloud as successive layers are heated to ignition temperature. The hot gases expand and produce pressure waves that travel ahead of the flame. Any dust lying on surfaces in the path of the pressure waves will be thrown into the air and could cause a secondary explosion more violent and extensive than the first.

Liquids: A vapor has to be produced at the surface of a liquid before it will burn. Many common liquids give off a flammable concentration of vapor in air without being heated, sometimes at well below room temperature. Gasoline, for example, gives off ignitable vapors above about −40°C, depending on the blend. The vapors are easily ignited by a small spark or flame. Other liquids, such as fuel oil and kerosene, need to be heated until sufficient vapor is produced.

Many liquids can be formed into mists that will burn at temperatures where the vapor pressure is insufficient to produce a flammable mixture of the vapor and air.

For any flammable vapor there are maximum and minimum concentrations of the vapor in air beyond which it cannot burn. When the mixture of vapor in air is too weak, there is insufficient fuel for burning; when the mixture is too strong, there is insufficient oxygen for burning.

If the density of a flammable vapor is greater than that of air, as is normally the case, flammable concentrations may collect at low levels, such as at floor level or in basements, and can travel a considerable distance to a source of ignition, from which flames will then flash back.

Gases: Flammable gases usually are very easily ignited if mixed with air. Flammable gases often are stored under pressure, in some cases as a liquid. Even small leaks of a liquefied flammable gas form relatively large quantities of gas, which is ready for combustion.

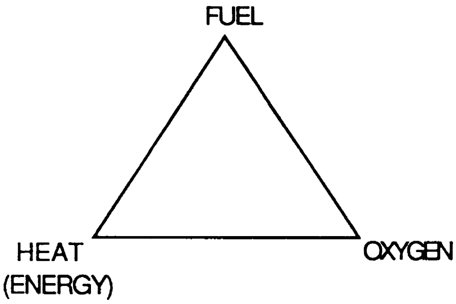

Fig. 2.10 The fire triangle

The fire triangle: The well-known "fire triangle" (see Fig. 2.10) is used to represent the three conditions necessary for a fire:

1. Fuel
2. Oxidizer: oxygen or other gaseous oxidizer such as chlorine; or liquid oxidizer such as bromine; or solid oxidizer such as sodium bromate
3. Energy, usually in the form of heat

If one of the conditions in the fire triangle is missing, fire does not occur; if one is removed, fire is extinguished. Usually a fire occurs when a source of heat contacts a combustible material in air, and then the heat is supplied by the combustion process itself.

The fire triangle indicates how fires may be fought or prevented:

1. Cut off or remove the fuel.
2. Remove the heat or energy—usually by putting water on the fire.
3. Remove the supply of oxygen—usually by foam or inert gas.

Flammability: No single factor defines flammability, but some relevant parameters include:

1. Flash point—often considered the main index of flammability; low flash points usually mean increased flammability.
2. Flammability limits; wide limits mean increased flammability.
3. Autoignition temperature; low temperature means increased flammability.
4. Ignition energy; low ignition energy means increased flammability.
5. Burning velocity; high velocity means increased flammability.

A combustion process is an exothermic reaction initiated by a source of ignition that produces more energy than it consumes. The speed at which the reaction proceeds through the mixture of reactants depends on the concentration of the flammable gas or vapor. This speed is lower at higher ("rich") as well as at lower ("lean") concentrations of the flammable gas than at the stoichiometric mixture. There are lower and upper limits beyond which the reaction cannot propagate through the gas mixture on its own. Some definitions follow:

1. *Flammability limits*: The range of flammable vapor–air or gas–air mixtures between the upper and lower flammable limits. Flammability limits are usually expressed in volume percent. Flammability limits are affected by pressure, temperature, direction of flame propagation, oxygen content, type of inerts, and other factors. The precise values depend on the test method.
2. *Upper flammability limit*: The maximum concentration of vapor or gas in air above which propagation of flame does not occur on contact with a source of ignition.
3. *Lower flammability limit*: The minimum concentration of vapor or gas in air or oxygen below which propagation of flame does not occur with a source of ignition.
   The concentrations at the lower and upper flammability limits are roughly 50 and 200–400%, respectively, of the stoichiometric mixture. The maximum flammability usually (not always) occurs at the stoichiometric mixture for combustion [17, 19].
4. *Flammable limits for mixtures of flammable gases and vapors*: For mixtures of several flammable gases and vapors, the flammable limits can be estimated by application of Le Chatelier's equation, if the flammable limits of the components are known: [19]

$$L = \frac{1}{\sum_{i=1}^{n} (y_i/L_i)} \qquad U = \frac{1}{\sum_{i=1}^{n} (y_i/U_i)}$$

   where

   L = lower flammability limit of the fuel mixture, vol.%.
   L_i = lower flammability limit of fuel component i, vol.%.
   U = upper flammability limit of the fuel mixture, vol.%.
   U_i = upper flammability limit of fuel component i, vol.%.
   y_i = concentration of fuel component i, vol.%.

   This equation is empirical and is not universally applicable, but is useful and a reasonable approximation when actual mixture data are not available.

   It is possible for a mixture to be flammable even though the concentration of each constituent is less than its lower limit.
5. *Methods of measurement*: Flammability limits are determined by measuring the volume percent of a flammable gas in an oxidizing gas that will form a flammable mixture, thus identifying the lower and upper flammable limits as well as the critical oxygen concentration (the minimum oxidizer concentration that can be used to support combustion).
6. *Uniformity of lower limits on a mass basis*: Concentrations of vapors and gases usually are reported in volume percent. As molecular weight increases, the lower limit usually decreases. On a mass basis, the

lower limits for hydrocarbons are fairly uniform at about 45 mg/L at 0°C and 1 atm. Many alcohols and oxygen-containing com pounds have higher values; for example, on a mass basis, ethyl alcohol in air has a lower limit of 70 mg/L [17].

7. *Effect of temperature on flammable limits*: The higher the temperature at the moment of ignition, the more easily the combustion reaction will propagate. Therefore, the reference temperature (initial temperature) of the flammable mixture must be stated when flammable limits are quoted. There are not a lot of data for flammable limits under different conditions of initial temperature. The behavior of a particular mixture under different conditions of initial temperature usually must be determined by tests.
8. *Burning in atmospheres enriched with oxygen*: The flammability of a substance depends strongly on the partial pressure of oxygen in the atmosphere. Increasing oxygen content affects the lower flammability limit only slightly, but it has a large effect on the upper flammability limit. Increasing oxygen content has a marked effect on the ignition temperature (reduces it) and the burning velocity (increases it).

   At the lower explosive limits of gas–air mixtures, there is already an excess of oxygen for the combustion process. Replacing nitrogen by additional oxygen will influence this limit very little [7].
9. *Burning in chlorine*: Chemically, oxygen is not the only oxidizing agent, though it is the most widely recognized and has been studied the most. Halogens are examples of oxidants that can react exothermically with conventional fuels and show combustion behavior. The applicability of flammability limits applies to substances that burn in chlorine. Chlorination reactions have many similarities to oxidation reactions. They tend not to be limited to thermodynamic equilibrium and often go to complete chlorination. The reactions are often highly exothermic. Chlorine, like oxygen, forms flammable mixtures with organic compounds. As an example: a chlorine–iron fire occurred in a chlorine pipeline, causing a chlorine gas release. Chlorine had liquefied in the lines because of the very cold weather, and the low spot was steam-traced. Steam had been taken from the wrong steam line, using 400 psig steam instead of 30 psig steam. The 400 psig steam was hot enough to initiate the reaction. This serves as a reminder that steel and chlorine can react. The allowable temperature for safe use depends upon the state of subdivision of the iron.
10. *Burning in other oxidizable atmospheres*: Flames can propagate in mixtures of oxide of nitrogen and other oxidizable substances. For example, Bodurtha [17] reports that the flammability limits for butane in nitric oxide are 7.5% (lower) and 12.5% (upper).
11. *Flame quenching*: Flame propagation is suppressed if the flammable mixture is held in a narrow space. There is a minimum diameter for apparatus used for determination of flammability limits. Below this diameter the flammable range measurements are narrower and inaccurate.

    If the space is sufficiently narrow, flame propagation is suppressed completely. The largest diameter at which flame propagation is suppressed is known as the quenching diameter. For an aperture of slotlike cross section there is critical slot width.

    The term “quenching distance” sometimes is used as a general term covering both quenching diameter and critical slot width, and sometimes it means only the latter.

    There is a maximum safe gap measured experimentally that will prevent the transmission of an explosion occurring within a container to a flammable mixture outside the container. These data refer to a stationary flame. If the gas flow is in the direction of the flame propagation, a smaller gap is needed to quench the flame. If the gas flow is in the opposite direction, a larger gap will provide quenching. If the gas velocity is high enough, the flame can stabilize at the constriction and cause local overheating. These quenching effects are important in the design of flame arrestors.
12. *Heterogeneous mixtures* [16]. In industry, heterogeneous (poorly mixed) gas phase mixtures can lead to fires that normally would be totally unexpected. It is important to recognize that heterogeneous mixtures can ignite at concentrations that normally would be nonflammable if the mixture were homogeneous. For example, 1 L of methane can form a flammable mixture with air at the top of a 100-L container although the mixture only would contain 1.0% methane by volume if complete mixing occurred at room temperature, and the mixture would not be flammable. This is an important concept because “layering” can occur with any combustible gas or vapor in both stationary and flowing mixtures.

    Heterogeneous gas phase mixtures can lead to unexpected fires if a relatively small amount of flammable gas is placed in contact with a large amount of air without adequate mixing, even though the average concentration of flammable gas in the mixture is below the flammable limit. *Heterogeneous mixtures are always formed at least for a short time when two gases or vapors are first brought together*.
13. *Effect of pressure*: Flammability is affected by initial pressure. Normal variations in atmospheric pressure do not have any appreciable effect on flammability limits.

    A decrease in pressure below atmospheric usually narrows the flammable range. When the pressure is reduced low enough, a flame or an explosion can no longer be propagated throughout the mixture.

An increase in pressure above atmospheric usually (not always) widens the flammability range, especially the upper limit.

14. *Explosions in the absence of air*: Gases with positive heats of formation can be decomposed explosively in the absence of air. Ethylene reacts explosively at elevated pressure, and acetylene reacts explosively at atmospheric pressure in large-diameter piping. Heats of formation for these materials are +52.3 and +227 kJ/g/mol, respectively. Explosion prevention can be practiced by mixing decomposable gases with more stable diluents. For example, acetylene can be made nonexplosive at a pressure of 100 atm by including 14.5% water vapor and 8% butane.

Ethylene oxide vapor will decompose explosively in the absence of oxygen or air under certain conditions when exposed to common sources of ignition if heated to high enough temperatures. One way to prevent the decomposition reaction is to use methane gas to blanket the ethylene oxide liquid. It has also been found that liquid ethylene oxide will undergo a deflagration in the absence of oxygen with a very rapid pressure increase if ignited at a temperature and pressure above a certain level. Fortunately, the conditions required for propagation of the decomposition of liquid phase ethylene oxide are outside the current normal handling and processing ranges for the pure liquid. Propagation has not been observed below 80°C at from 14 to 100 atm pressure [27]. Ethylene oxide also can undergo explosive condensation when catalyzed by a small amount of caustic [28].

Mists and Foams: If the temperature of a liquid is below its flash point, flammable concentrations of vapor cannot exist, but conditions still can exist for flammability if mists or foams are formed. A suspension of finely divided drops of a flammable liquid in air has many of the characteristics of a flammable gas–air mixture and can burn or explode. A mist may be produced by condensation of a saturated vapor or by mechanical atomization. Normally, the diameter of drops in a condensed mist is less than 0.01 mm, whereas in a mechanical spray it usually is greater than 0.1 mm.

The commonly accepted fallacy that liquids at temperatures below their flash points cannot give rise to flammable mixtures in air has led to numerous accidents. Flash points are measured under stagnant conditions in carefully controlled laboratory experiments, but in the real world one works with a wide variety of dynamic conditions that can produce mists and foams.

Flammable mist–vapor–air mixtures may occur as the foam on a flammable liquid collapses [16]. Thus, when ignited, many foams can propagate flame. An additional hazard can arise from the production of foams by oxygen-enriched air at reduced pressures. Air confined over a liquid can become oxygen enriched as pressure is reduced because oxygen is more soluble than nitrogen in most liquids. Thus, the presence of foams on combustible liquids is a potential explosion hazard.

The lower flammability limit for fine mists (<0.01 mm diameter) of hydrocarbons below their flash point, plus accompanying vapor, is about 48 g of mist/m^3 of air at 0°C and 1 atm. Mist can occur in agitated vessels under some conditions, especially when an agitator blade is at or near the liquid–vapor interface in the vessel.

Work on condensed oil mists (drop diameter mostly less than 0.01 mm) has demonstrated that they have flammability characteristics similar to those the mixture would have if it were wholly in the vapor phase at the higher temperature necessary for vaporization. The flammability characteristics are affected by drop size. For larger drop sizes (above 0.01 mm) the lower limit of flammability decreases as drop diameter increases. For mists, the amount of inert gas needed to suppress flammability is about the same as that needed to suppress an equivalent vapor–air mixture of the same material if it were vaporized at a somewhat higher temperature.

A useful rule is that mists of flammable or combustible liquids in air can burn or explode at temperatures below their flash points.

Ignition: Flammable gases and vapors can be ignited by many sources. In the design and operation of processes, it is best not to base fire and explosion safety on the presumption that ignition sources have been excluded. Bodurtha [22] reported that of 318 natural gas fires and explosions, the sources of ignition of 28% were unknown. All reasonable measures should be taken to eliminate possible sources of ignition in areas in which flammable materials are handled.

Autoignition: If the temperature of a flammable gas–air mixture is raised in a uniformly heated apparatus, it eventually reaches a value at which combustion occurs in the bulk gas. This temperature is defined as the spontaneous ignition temperature (SIT) or autoignition temperature (AIT). The gas–air mixture that has the lowest ignition temperature is called by various names, such as the minimum AIT, the minimum spontaneous ignition temperature, and the self-ignition temperature [17]. Usually the AIT reported in the literature is the minimum AIT.

The AIT of a substance depends on many factors, such as:

- Ignition delay
- Energy of ignition source
- Pressure
- Flow effects
- Surfaces
- Concentration of vapors
- Volume of container
- Oxygen content

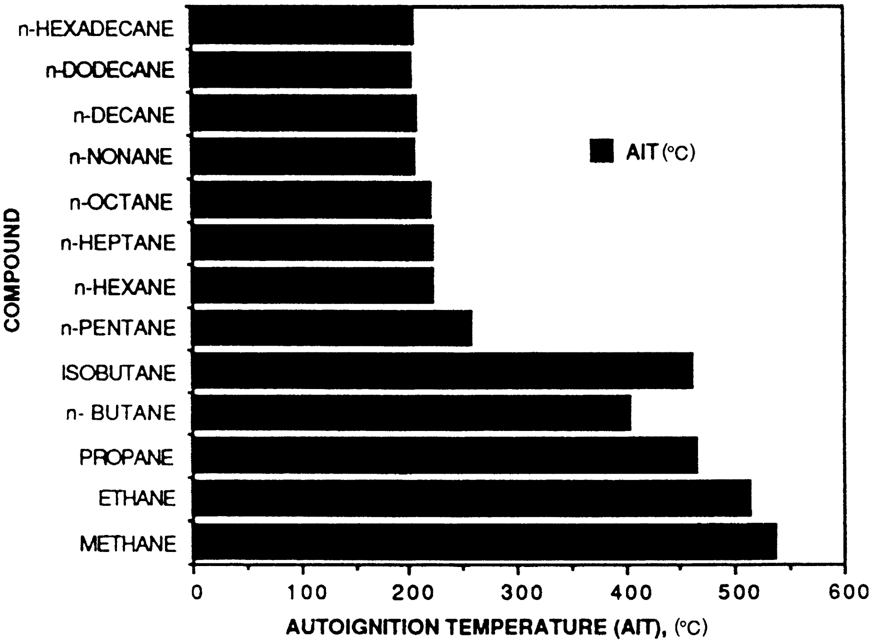

Fig. 2.11 Autoignition temperatures of paraffin hydrocarbons at 1 atm. (Data from Bodurtha [17])

- Catalytic materials
- Flow conditions

Thus, a specific AIT applies only to the experimental conditions employed in its determination. Usually the values quoted are obtained in clean laboratory equipment.

The AIT of a substance may be reduced below ideal laboratory conditions by as much as 100–200°C for surfaces that are insulated with certain types of insulation, or are contaminated by dust.

Mixtures that are fuel-rich or fuel-lean ignite at higher temperatures than do those of intermediate compositions. Also, in a homologous series of organic compounds, the AIT decreases with increasing molecular weight, as shown in Fig. 2.11.

Ignition delay: Ignition of a flammable mixture raised to or above the temperature at which spontaneous combustion occurs is not instantaneous; the time delay between the moment of exposure to high temperature and visible combustion is called the ignition delay. This time delay decreases as the ignition temperature increases. The time delay may be as little as a fraction of a second at higher temperatures, or several minutes close to the AIT.

Environmental effects: It has been found that the AIT becomes lower with increasing vessel size in the range of 35–12 L. An increase in pressure usually decreases AITs, and a decrease in pressure raises AITs. Usually oxygen enrichment of the air tends to decrease the minimum AIT, and a decrease in oxygen content increases the minimum AIT. Low-temperature oxidation can result in "cool flames," which may grow into ignition.

Catalytic materials: Ignition may occur where the temperature is less than the minimum AIT. Catalytic materials, such as metal oxides, can promote oxidation on their surfaces, leading to a high local temperature and subsequent ignition. There is a recorded reactive chemical case [29] in which a solvent at 80°C was being pressurized with a gas phase consisting of a high oxygen concentration. The solvent has a flash point in oxygen of greater than 130°C and normally is considered not to be a flammability hazard. There was an ignition, causing the vessel to rupture its main gasket with major damage to the facility. It was found that a mist had been formed in the vessel by the agitator, and that the source of ignition probably was a trace of palladium catalyst remaining from a previous run.

From this incident, several important lessons can be learned:

1. Ignition of a flammable mixture can result from totally unexpected contamination by trace amounts of catalysts if the oxidizer and fuel are present.
2. Mists of oxidizable liquids may form that can burn or explode at temperatures outside the "normal" flammable range.
3. It can be dangerous to perform experiments with pure oxygen, or air enriched with oxygen, especially under pressure and at elevated temperatures, when oxidizable materials are present.
4. The real criterion regarding flammable mixtures in air should be whether a flammable atmosphere can exist

under the given process conditions, rather than whether a flammable liquid is at a temperature below its flash point.

Cleaning up spills of flammable or combustible liquids: It is customary to clean up small spills of many liquid materials with sand or other noncombustible absorbent material. Some absorbing agents, such as untreated clays and micas, will cause an exothermic reaction with some liquids, especially monomers, which might ignite the liquid if it is flammable or combustible. Before any material is provided to be used to soak up spills of oxidizable material, tests should be made to determine if the material can cause fires with potential spills.

Ignition caused by insulation: Ignition of combustible materials that have been absorbed into commonly used insulating materials is possible at temperatures lower than the AIT for nonabsorbed material. All oxidizable materials oxidize to some extent in air at ambient temperatures, usually at a very low rate. When an absorbent material is absorbed into insulation, it is "spread" over a large area, increasing its access to oxygen. Because the absorbent is an insulator, heat from oxidation is retained rather than dissipated, and the temperature will rise if the heat is produced faster than it can be dissipated. The rate of oxidation increases as the material temperature increases, which produces more heat, compounding the hazard. If the temperature rises enough, the material will ignite ("spontaneous combustion"). This is similar to the classic oily rag and wet haystack phenomenon, which has caused many fires in homes and on farms. In the wet haystack phenomenon, fermentation by microorganisms will create heat. Some air is necessary; too much air will remove too much heat to allow the combustion temperature to be reached. For equipment operating above about 200°C containing combustible liquids with high boiling points, insulation should be impervious to the material handled. To date, only a closed cell foamed glass provides the required degree of protection where oxidizable liquid materials are used above 200°C. Insulation based on glass fiber, silicate, or alumina materials is known to cause hazardous situations and should not be used in this service.

Laboratory tests and actual fires show that Dowtherm A® (a heat-transfer fluid consisting of a eutectic mixture of biphenyl oxide and biphenol) can be ignited if it is soaked in glass fiber insulation and in contact with air at temperatures considerably below the normal AIT. This is also true for stearic acid soaked in glass fiber insulation. Table 2.1 shows the reduction in AIT of Dowtherm A® and of stearic acid soaked in glass fiber insulation.

Ignition of this type generally occurs only with materials having a high boiling point. Usually materials with low boiling points will vaporize and cannot remain soaked in hot insulation. There are exceptions. For example, ethylene oxide has a fairly low boiling point, but if it leaks into insulation, a polymer can be formed that has a high boiling point and can autoignite insulation at low temperatures.

Table 2.1 Reduction in AITs caused by liquids soaking in glass fiber insulation

Material	Normal AIT (°C)	Ignition temperature in glass fiber insulation (°C)
Dowtherm A®	621	260–290
Stearic acid	395	260–290

Ignition caused by impact: Solids and liquids can be ignited by impact. Impact tests are made by having a weight fall freely through a known distance and impacting the sample. Impact can occur, for example, if containers are accidentally dropped. The interpretation of the data from impact tests can be difficult.

Ignition caused by compression of liquids: Liquids can be ignited by sudden compression. This can happen when there is water hammer caused by the pressure surge from quick-acting valves and from the compression in liquid pumps. Sudden compression can occur with liquids, for example if a tank car is bumped rapidly and the liquid goes to one end very quickly, possibly trapping some vapor bubbles that compress and create local hot spots that can cause ignition.

Ignition caused by rubbing friction: Solids can be ignited by frictional sources when rubbed against each other or against another material. The frictional heat produced may be enough to ignite other materials, such as lubricants, that are nearby. A common example of this occurs when bearings run hot, causing oil or grease to vaporize and possibly ignite.

Ignition caused by glancing blows: Friction can cause ignition in other ways. Sparks may occur when two hard materials come in contact with each other in a glancing blow (the blows must be glancing to produce friction sparks). These kinds of sparks are not directly related to frictional impact. Hand and mechanical tools are the most likely sources of friction sparks that occur outside of equipment. The need for nonsparking tools is somewhat controversial; Bodurtha [17] states that it is extremely unlikely that anyone would be using tools in a flammable atmosphere, and it is usually more prudent to control the atmosphere than the tools. Sparkproof tools are not really sparkproof in all situations.

Ignition caused by static electricity: Static electricity is a potential source of ignition wherever there is a flammable mixture of dusts or gases (see previous section).

Ignition caused by compression of gases: If a gas is compressed rapidly, its temperature will increase. Autoignition

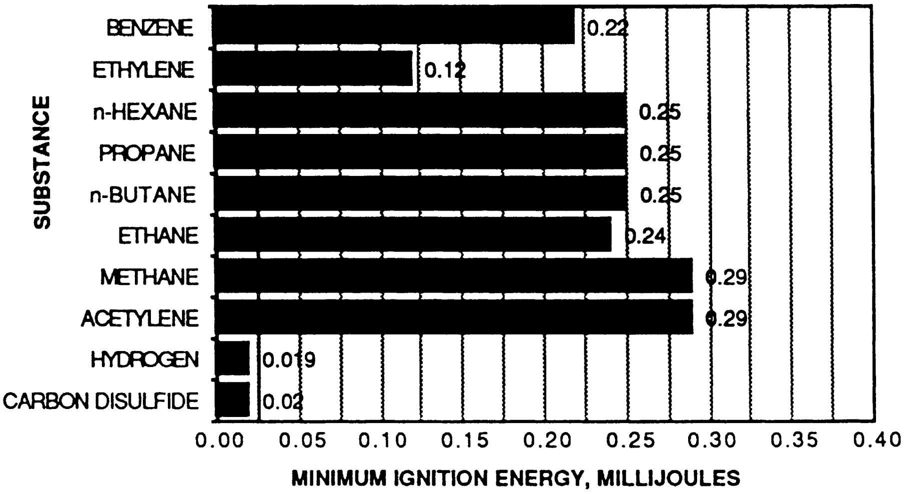

Fig. 2.12 Minimum ignition energy for selected substances (Less [19])

may occur if the temperature of the gas becomes high enough (this is more or less the principle of diesel engines).

An advancing piston of high-pressure gas can compress and heat trapped gas ahead of it. For a perfect gas, the temperature rise due to adiabatic compression is given by

$$\frac{T_2}{T_1} = \left(\frac{P_2}{P_1}\right)^{(k-1)/k}$$

where T_1 and T_2 are the initial and final gas absolute temperatures, P_1 and P_2 are the initial and final absolute pressures, and k is the ratio of heat capacity at constant pressure to the heat capacity at constant volume. For air and many other diatomic gases, $k = 1.4$. Many hydrocarbons have k values of between 1.1 and 1.2. The value of k is a function of temperature and pressure.

Energy levels for ignition: If a flammable gas mixture is to be ignited by a local source of ignition, there is a minimum volume of mixture required to cause a continuing flame throughout the mixture.

For example, to ignite a methane–air mixture in a cold container, a hot patch of 18 mm^2 at 1,000–1,100°C is required in order to heat enough volume of gas to produce a continuing flame [19], even though the auto-oxidation temperature for methane is 540°C. Ignition of a flammable gas–air mixture by electrical discharge can occur only if the electrical discharge is of sufficient energy.

Minimum ignition energy: There is a minimum ignition energy, which usually occurs near the stoichiometric mixture. The minimum ignition energy for some representative substances in air is shown in Fig. 2.12 [19]. The energy required to cause ignition frequently is reported in millijoules (mJ). One joule is 0.24 cal, so 1 mJ is 0.00024 cal, which is a very small amount of energy.

Table 2.2 Comparison of initiation energies of some common substances in air and pure Oxygen [47]

	Relative amount of energy required to initiate combustion (mJ)	
Flammable substance	In air	In pure oxygen
Methane	0.3	0.003
Hydrogen	0.019	0.0012
Acetone	1.15	0.0024
Diethyl ether	0.2	0.0013

A person typically has capacitance of 200 pF (pF), and if charged to 15 kilovolts (kV) could initiate a discharge of 22.5 mJ. This is enough to ignite many flammable mixtures. The energy in ordinary spark plugs is 20–30 mJ.

The hazard of an explosion should be minimized by avoiding flammable gas–air or dust–air mixtures in a plant. It is bad practice to rely solely on elimination of sources of ignition, as it is nearly impossible to ensure this.

Effect of oxygen-enriched atmospheres: The minimum spark energy to cause ignition varies greatly with the amount of oxygen in oxygen-enriched air. Stull [30] showed that with a composition of 10% methane in air, about 0.5 mJ of spark energy is required to initiate a reaction at the lower flammable limit. If the air is enriched with oxygen, the minimum spark energy decreases. If the flammable material is combined with 100% oxygen, the spark energy required is only about 1% of the required energy in air at 21% oxygen! This demonstrates the extremely small amount of energy required to initiate the reaction, as well as the additional ease with which oxygen-enriched atmospheres are initiated. Table 2.2 compares initiation energies of some common substances in air and in pure oxygen.

Effect of pressure: An increase in pressure decreases the amount of energy required to cause ignition. In a mixture of propane, oxygen, and nitrogen, doubling the pressure decreases the minimum energy required to cause ignition by a factor of about 5.

If no other data are available for determination of hazards, minimum ignition energies at ambient temperatures and pressures should be considered as approximately:

- 0.1 mJ for vapors in air
- 1.0 mJ for mists in air
- 10.0 mJ for dusts in air

Explosions

Development of Pressure

Exothermic reactions can lead to high temperatures and in the case of large fires to large loss of property and severe damage from radiant energy. However, in many plant accidents it is the sudden generation of pressure that leads to severe damage, injury, and deaths. Hence, it can be stated that "pressure blows up plants, not temperature." Of course, temperature and pressure are closely related, but it is the pressure effect that is of concern in this section.

The word "deflagration" can be defined in several ways. One definition is "a reaction that propagates to the unreacted material at a speed less than the speed of sound in the unreacted substance." [17] Another definition of deflagration is from Latin meaning "to burn down, or to burn rapidly with intense heat and sparks given off." [28] A deflagration may be an explosion, but not all deflagrations are explosions (a violently burning fire may be a deflagration, but that is not an explosion). On the other hand, not all explosions are deflagrations (a steam boiler may explode, but that is not a deflagration).

An explosion is a sudden and violent release of energy. Usually it is the result, not the cause, of a sudden release of gas under high pressure. The presence of a gas is not necessary for an explosion. An explosion may occur from a physical or mechanical change, as in the explosion of a steam boiler, or from a chemical reaction. The explosion of a flammable mixture in a process vessel may be either a deflagration or a detonation, which differs fundamentally. Both can be very destructive. Detonations are particularly destructive, but are unlikely to occur in vessels.

A detonation is a reaction that propagates to unreacted material at a speed greater than the speed of sound in the unreacted material; it is accompanied by a shock wave and extremely high pressures for a very short time. It is debatable whether the flammable range is the same as the detonable range. Detonation limits normally are reported to be within the flammable limits, but the view is widely held that separate detonation limits do not exist.

Unconfined vapor clouds can both deflagrate and detonate, with a deflagration being much more likely. A detonation is more destructive, but a deflagration also can produce a damaging pressure wave. A deflagration can undergo transition to a detonation in a pipeline, but this is most likely in vessels.

If a flammable mixture may be present in process equipment, precautions should be taken to eliminate ignition sources. However, it is prudent to assume that, despite these efforts, a source of ignition will at some time occur.

Deflagration

The conditions for a deflagration to occur are that the gas mixture is within the flammable range and that there is a source of ignition or that the mixture is heated to its AIT.

For the burning of hydrocarbon–air mixtures:

$$\frac{P_{2\text{MAX}}}{P_1} = \frac{N_2 T_2}{N_1 T_1} = \frac{M_1 T_2}{M_2 T_1}$$

where

T = absolute temperature

M = molecular weight of gas mixture

N = number of moles in gas mixture

P = absolute pressure

1,2 = initial and final states

2MAX = final state maximum value

The maximum pressure rise for a deflagration of flammable mixtures is approximately as follows for initial absolute pressures of 1–40 bar, for initial temperatures of 0–300°C, and for relatively small volumes of a few cubic meters:

$$\frac{P_2}{P_1} = \text{approximately 8 for hydrocarbon} - \text{air mixtures}$$

$$\frac{P_2}{P_1} = \text{approximately 16 for hydrocarbon} - \text{oxygen mixtures}$$

For conventionally designed pressure vessels:

$$\frac{P_b}{P_1} = \text{approximately } 4 - 5$$

where P_b = vessel bursting pressureP_1 = normal design pressureP_2 = pressure caused by deflagration

Therefore, in the absence of explosion relief, the deflagration explosion of a hydrocarbon–air mixture is easily capable of bursting a vessel if it is operating near its design pressure when the deflagration takes place. For reactions operating at or near atmospheric pressure, such as many drying and solids

Table 2.3 Overpressure from Detonations [39]

	Pressure (MPa)	Pressure (lb/in.^{2})
Incident overpressure	3.5	510
Maximum reflected pressure (wave strikes surface head-on)	28	4,100
Load the structure feels (due to acceleration)	56	8,100

MPa means pressure in megapascals

processing operations, it may be practical to construct facilities that will withstand the maximum explosion pressure of most dust–air and flammable gas–air mixtures.

Detonations

Detonation of a gas–air mixture may occur by direct initiation of detonation by a powerful ignition source or by transition from deflagration. This transition occurs in pipelines but is most unlikely in vessels. Two useful rules are:

1. Almost any gas mixture that is flammable is detonable if initiated with a sufficiently energetic source.
2. Detonation of a gas–air mixture is possible in pipelines but is unlikely in vessels.

Bartknecht [31] states that the range of detonability is narrower than the range of flammability. For example, the range of detonability of hydrogen in air is 18–59 vol.%, compared with the flammability of 4–75 vol.%. With flammable gases in air, if the length-to-diameter ratio of a pipe or vessel is more than about 10:1, and the pipe diameter is above a critical diameter, 12–25 mm, a detonation is possible.

Detonation pressure: In the case of the burning of a flammable mixture of gases in a pipe with one end closed, a series of pressure waves traveling at the speed of sound moves through the unburned gas. Later waves traveling through the unburned gas, which has been heated by compression from the earlier waves, speed up because of the higher temperature and overtake the first wave, and a shock wave develops. Flame follows the shock wave and catches up with it, forming a detonation wave. A stable detonation wave may develop, which moves with supersonic speed relative to the unburned mixture, and peak incident (side-on) pressures are of the order of *30 times* the initial absolute pressure.

Reflected pressure: Reflected pressure increases the pressure on a rigid surface if the shock wave impinges on the surface at an angle to the direction of the propagation of the wave. The maximum ratio of reflected pressure to incident (side-on) pressure when a strong shock wave strikes a flat surface head-on is 8:1. Furthermore, acceleration from a suddenly applied force of the detonation wave can double the load that a structure "feels." Table 2.3 shows overpressure that can be expected from typical detonations [32].

Thus, the stable detonation wave may cause enormously high pressures at closed ends of pipes, bends, and tees, where the greatest destruction from a gaseous detonation may occur.

Geometry: The following are some factors to consider when detonation is possible:

1. Large length-to-diameter ratios promote the development of detonations; vessels should be designed with the lowest length-to-diameter ratio practicable if a detonation is possible.
2. Equipment such as tanks (not including pipelines) designed to withstand 3.5 MPa (about 500 psig) usually will be adequate to contain a detonation, with other safeguards, for flammable gases in air at atmospheric pressure.
3. Dished heads survive detonations better than do flat heads because of the more unfavorable incidence of flat heads.
4. If turns in a process line are necessary, two 45° bends or a long sweep elbow will greatly reduce reflected pressure compared with a single 90° elbow.
5. Restrictions such as orifices in pipelines may intensify a detonation by promoting pressure piling, which results when there are interconnected spaces such that the pressure rise in one space causes a pressure rise in a connected space. The enhanced pressure in the latter then becomes the starting pressure for a further explosion.
6. Detonation may be extinguished when it enters a wider pipe from a smaller one, but the detonation may be regenerated somewhere along the longer pipe.
7. Flame arresters, if properly designed, can arrest detonations.

Explosion Violence

The *rate of pressure rise* is a measure of the violence of an explosion. The maximum rate of pressure rise for confined explosions is greatly affected by the volume of the vessel, with the influence of vessel volume on the rate of pressure rise being given by the following equation:

$$(\mathrm{d}p/\mathrm{d}t)_{\max}(V^{1/3}) = \text{a constant } = K_G$$

where$(\mathrm{d}p/\mathrm{d}t)_{\max}$ = maximum rate of pressure rise, bar/sV = vessel volume, m^3K_G = a specific material constant (bar)(m)(s)$^{-1}$This is the *cubic law*, which states that for a given

Table 2.4 K_G values of gases, spark-ignited with zero turbulence, ignition energy ~10 J, $P_{\max} = 7.4$ bar[8]

Flammable gas	K_G (bar)(m)/s
Methane	55
Propane	75
Hydrogen	550

flammable gas, the product of the maximum pressure rise and the cube root of the vessel volume is a specific material constant, K_G.

The cubic law allows the prediction of the course of an explosion of a flammable gas or vapor in a large vessel, based on laboratory tests. It is valid only for the following conditions:

- The same optimum concentration of the gas–air mixture
- Same shape of reaction vessel
- The same degree of turbulence
- The same ignition source

Thus, to characterize an explosion, it is not enough to quote the maximum rate of pressure rise: the volume, vessel geometry [31], turbulence, and ignition energy must also be stated. Table 2.4 lists the K_G values for some common flammable gases measured under laboratory conditions.

It can be seen that the violence of an explosion with propane is about 1.5 times higher than one with methane, and one with hydrogen is about 10 times higher than one with methane. The explosive behavior of propane is representative of many flammable organic vapors in air. Some important relationships among pressure, temperature, turbulence, and vessel shape are discussed below.

1. *Explosion pressure is primarily the result of temperature reached during combustion, not a change in moles.* With complete combustion of propane in air there is a negligible change in moles of gas:

$$C_3H_8 + 5O_2 + \overset{\{...\text{air}...\}}{18.8N_2} = 3CO_2 + 4H_2O + 18.8N_2$$

   Number of moles at start = 24.8. Number of moles after complete combustion = 25.8. *Therefore, explosion pressure usually develops principally from an increase in temperature, not an increase in gas moles, during the combustion process of many materials.*Peak explosion pressure at constant volume occurs near the stoichiometric concentration in air. If only a small part of the total volume of a container is filled by an explosive gas–air mixture at atmospheric pressure, and the remainder of the vessel contains air, an explosion of this mixture can create enough pressure to severely damage containers that are designed to withstand only slight pressure—such as buildings and low-pressure storage tanks.

2. *Initial pressure affects maximum explosion pressure and rate of pressure rise.* If the initial pressure is increased above atmospheric pressure, there will be a proportional increase in the maximum explosion pressure and in the rate of pressure rise. Reducing the initial pressure will cause a corresponding decrease in maximum explosion pressure until finally an explosion reaction can no longer be propagated through the gas mixture.
3. *Initial temperature affects maximum explosion pressure and rate of pressure rise*: The maximum explosion pressure decreases when the starting temperature increases at the same starting pressure because of the lower density and thus smaller mass of material within a confined volume at higher temperatures. The maximum rate of pressure rise, $(dp/dt)_{\max}$, increases as the initial temperature rises because the burning velocity increases with an increase in initial temperature.
4. *Initial turbulence increases the rate of pressure rise*: Initial turbulence greatly increases the rates of explosion-pressure rise [17, 31]. It has been found that with pentane and methane mixtures in air, $(dp/dt)_{\max}$ can be five to nine times more with high initial turbulence than with no turbulence. The maximum explosion pressure is raised by about 20%. The course of explosions of flammable gases with a low normal speed of combustion, such as methane, is influenced by turbulence to a much higher degree than is the course of explosions with a high speed of combustion, such as hydrogen. Test data usually are obtained in equipment with a high degree of turbulence.
5. *Effect of vessel shape and increased initial pressure*: The maximum explosion pressure in confined vessels is not significantly affected by the volume or shape of the vessel in confined explosions for vessels that approximate the "cubic shape," that is, with a ratio of diameter to length (or vice versa) of about 1:1–1:1.5. In closed elongated vessels with central ignition, spherical ignition of the flame front will cause the flame to proceed swiftly in an axial direction. In the process, it compresses the unburned gases ahead of it, causing the violence of the explosion to increase, and pressure oscillations may occur.

Losses from Dust Explosions

Most organic solids, most metals, and some combustible inorganic salts can form explosive dust clouds. In order to have a dust explosion, it is necessary to satisfy certain conditions:

- Suitably sized dust particles
- Sufficient source of ignition energy
- Dust concentration within explosive limits
- Explosible dust
- Oxidizer must be present

If an explosive dust in air that meets the above criteria occurs in a process, an explosion should be considered as inevitable. The process designer should take into account the possibility of dust explosions and design accordingly.

In dust explosions the combustion process is very rapid. The flame speed is high compared with that in gas deflagrations. Detonations normally do not occur in dust explosions in industrial plants.

The sequence of events in a serious industrial dust explosion is often as follows:

1. A primary explosion occurs in part of a plant, causing an air disturbance.
2. The air disturbance disperses dust and causes a secondary explosion, which is often more destructive than the primary explosion.

If the occurrence of a flammable (explosive) dust is inevitable in a particular process, several design alternatives or combinations of alternatives are available:

- Containment (maximum pressure of a dust explosion is usually below 120–150 psig)
- Explosion venting to a safe place
- Inerting (most organic dusts are non flammable in atmospheres containing less than about 10% oxygen)
- Suppression

A fundamental solution to the dust explosion problem is to use a wet process so that dust suspensions do not occur. However, the process must be wet enough to be effective. Some dusts with a high moisture content can still be ignited.

Dust concentrations in major equipment may be designed to be below the lower flammable limit, but this often cannot be depended on in actual operation. Dust concentrations cannot be safely designed to be above an upper flammable limit because such a limit is ill-defined [19].

For a large number of flammable dusts, the lower explosion limit lies between 0.02 and 0.06 kg/m^3. The upper explosion limit is in the range of 2–6 kg/m^3, but this number is of limited importance.

A small amount of flammable gas or vapor mixed in with a flammable dust can cause an explosive mixture to be formed even if both are at concentrations below the explosive range by themselves. These mixtures are called “hybrid” mixtures. The ignition energy to ignite a hybrid mixture is often less than that required for the flammable dust by itself.

Venting is only suitable if there is a safe discharge for the material vented. Whenever an explosion relief venting device is activated, it may be expected that a tongue of flame containing some unburned dust will first be ejected. The unburned dust will be ignited as it flows out of the vent and can produce a large fireball that will extend outward, upward, and downward from the vent. It is essential for protection of personnel that venting is to an open place not used by people. If a duct must be used, the explosion pressure in the enclosure will be increased considerably. Therefore, particular attention must be paid to the design of the enclosure in which the explosion could take place.

The NFPA 68 guide issued in 1998 [33] has nomographs, which can be used to select relief areas required for combustible dusts when test data on the dusts are available. The nomographs in NFPA 68 are considered by many to be the preferred way to design dust explosion relief devices.

Relief venting to reduce dust explosion pressure requires the equipment to be protected to have a certain minimum strength. If the enclosure strength is too low, the enclosure will be damaged or destroyed before the explosion relief device can function. NFPA 68 [33] states that the strength of the enclosure should exceed the vent relief pressure by at least 0.35 psi. For industrial equipment such as dryers and baghouses, it is often desirable to have considerably more strength built into the structure to reduce the size of the vent area required. Also, the supporting structure for the enclosure must be strong enough to withstand any reaction forces developed as a result of operation of the vent.

Inerting is a very good preventive measure against dust explosions. The maximum oxygen concentration at which dust explosions are “just not possible” cannot be predicted accurately, as it depends on the nature of the combustible material; testing is usually required. It has been found that in an atmosphere of 10% oxygen and 90% nitrogen, most combustible organic dusts are no longer explosive. To allow a safety margin, it is good industrial practice to maintain oxygen concentrations below 8%. For metal dusts, the allowable oxygen content is about 4% [6].

Inerting leads to the possibility of asphyxiation by operating personnel if they were exposed to the inert gas. Strict precautions must be taken to prevent exposure of personnel to inerting atmospheres.

Explosion suppression systems are designed to prevent the creation of unacceptably high pressure by explosions within enclosures that are not designed to withstand the maximum explosion pressure [31]. They can protect process plants against damage and also protect operating personnel in the area. Explosion suppression systems restrict and confine the flames in a very early stage of the explosion. Suppression systems require more maintenance than do relief venting devices. Explosion suppression systems are made by only a few manufacturers and are quite expensive. This may be the reason why this type of safe-guard has not been as widely used in industry as one might expect, although its effectiveness has been proved by much practical experience.

Explosion suppression is a proven technology and should be considered as a candidate for explosion protection. The NFPA has published a standard reference on explosion-suppression protection [8]. Manufacturers should be consulted on design, installation, and maintenance.

Even with explosion suppression, it is common for the explosion pressure to reach one atmosphere before it is suppressed. The added pressure surge from the injection of the suppressing agent must also be considered. Therefore, sufficient mechanical strength is always required for enclosures protected by explosion suppression.

Boiling Liquid Expanding Vapor Explosions: Among the most damaging of accidents is a boiling liquid expanding vapor explosion (BLEVE, pronounced BLEV-ee). This occurs when a pressure vessel containing liquid is heated so that the metal loses strength and ruptures. Typically, this happens when the vessel failure results from overheating upon exposure to fire. The failure usually is in the metal contacting the vapor phase; the metal in this area heats to a higher temperature because there is no liquid heat sink to keep the metal temperature from rising rapidly, as there is where metal contacts a liquid phase. A BLEVE can occur with both flammable materials and nonflammable materials, such as water. In all cases the initial explosion may generate a blast wave and missiles. If the material is flammable, it may cause a fire or may form a vapor cloud that then gives rise to a secondary explosion and fireball. Kletz states that BLEVEs can cause as many casualties as can unconfined vapor cloud explosions (UVCEs) [19].

The best known type of BLEVE involves liquefied petroleum gas (LPG). Once a fire impinges on the shell above the liquid level, the vessel usually fails within 10–20 min. In the case of a BLEVE involving a flammable material, the major consequences are, in order of decreasing importance:

- Thermal radiation from the resultant fireball
- Fragments produced when the vessel fails
- Blast wave produced by the expanding vapor/liquid

For example, a BLEVE of a propane sphere with a diameter of 50 ft, holding about 630,000 gal, could cause damage as far away as 13,600 ft, and radiation damage and fragmentation damage would each extend to about 3,000 ft.

In a fire, a tank containing liquid is most vulnerable in the shell at the vapor space because very little heat can be absorbed by the vapor, and the metal in the vapor space can heat up rapidly to a temperature where it will weaken rapidly. The metal contacting the liquid phase will heat up much less rapidly because the liquid can absorb significant amounts of heat, keeping the shell temperature down in that area for a significant amount of time. Thus, there is a dilemma: a partly full vessel may BLEVE sooner than will a full vessel, but a full vessel will have more fuel for the resulting fireball and fire than will a partly empty vessel.

Significant equipment and building damage from radiation is possible from a BLEVE. Wooden structures may be ignited if the radiant heat density at the structure's location exceeds the threshold value for ignition of wood. Severe damage from fragmentation can be expected in the area where 50% or more of the fragments may fall, or typically about 300 ft from the vessel.

A BLEVE can lead to shock waves, projectiles, and thermal radiation. The effects of a shock wave and projectiles were dealt with earlier; by far the most serious consequence of a BLEVE is the radiation received from the fireball. The following calculational procedure is used to determine thermal impact (details are available in CPQRA [34]):

Damage Estimates [17]: Damage estimates deal with the consequences of explosions and thermal radiation to both people and property. Physical models for explosions and thermal radiation generate a variety of incident outcomes: shock wave overpressure estimates, fragment velocities, and radiant flux. These models rely on the general principle that severity of outcome is a function of distance from the source of release. In addition to estimating the damage resulting from an explosion, it is also necessary to estimate how the consequences of these incident outcomes depend on the object of the study. To assess effects on human beings, damage estimates may be expressed as deaths or injuries. If physical property is the object, the damage estimates may be expressed as monetary losses.

Explosion Consequences: A principal parameter characterizing an explosion is the overpressure. Explosion effect modeling generally is based on TNT explosions to calculate the overpressure as a function of distance. Although the effect of a TNT explosion differs from that of a physical or a chemical explosion (particularly in the near-field), the TNT model is the most popular because a large data base exists for TNT explosions.

More recently the explosion multi-energy method was developed by an international group in Europe. This model is the best representation of overpressures at far distances. The mass of vapor in congested volume participates in explosion. This approach requires intricate volume calculation and estimate of congestion. The TNT model overpredicts pressures at the source and underpredicts at longer distances. However, when you have overpressures of 5 psi or so it really doesn't matter as most structures and equipment at that level are destroyed [2].

Several kinds of energy may be released in an explosion; three basic types are: (1) physical energy, (2) chemical energy, and (3) nuclear energy. Nuclear energy is not considered here. Physical energy may take such forms as pressure energy in gases, strain energy in metals, or electrical energy. Chemical energy derives from a chemical reaction. Examples of explosions involving chemical energy are runaway exothermic reactions, including decomposition and polymerization.

Table 2.5 Effect of explosion overpressure on structures (Copyright 1989 by the American Institute of Chemical Engineers, Reproduced by permission of the Center for Chemical Process Safety of AIChE [34])

Pressure (psi)	Damage
0.02	Annoying noise (137 dB if of low, 10–15 Hz frequency)
0.03	Breaking of large glass windows under strain
0.04	Loud noise (143 dB), sonic boom, glass failure
0.10	Breakage of small glass windows under strain
0.15	Typical pressure for glass breakage
0.30	"Safe distance" (probability 0.95 of no serious damage below this value); projectile limits; some damage to house ceilings; 10 % window glass broken
0.40	Limited minor structural damage
0.5–1.0	Large and small windows usually shattered; occasional damage to window frames
0.70	Minor damage to house structures
1.00	Partial demolition of houses; houses made uninhabitable
1–2.00	Corrugated asbestos shattered; corrugated steel or aluminum panels, fastenings fail, followed by buckling; wood panel fastenings of standard housing fail; panels blown in
1.30	Steel frames of clad buildings slightly distorted
2.00	Partial collapse of walls and roofs of houses
2–3.00	Concrete or cinder blocks shattered if not reinforced
2.30	Lower limit of serious structural damage
2.50	50 % destruction of brickwork of houses
3.00	Heavy machines (300 lb), industrial buildings suffered little damage; steel frame buildings distorted and pulled away from foundation
3–4.00	Frameless, self-framing steel panel building demolished; rupture of oil storage tanks
4.00	Cladding of light industrial buildings ruptured
5.00	Wooden utility poles snapped
5–7.00	Nearly complete destruction of houses
7.00	Loaded railcars overturned
7–8.00	Brick panels, 8–12 in. thick, not reinforced, fail by shearing or flexure
9.00	Loaded train boxcars completely demolished
10.00	Probable total destruction of buildings; heavy machine tools (7,000 lb) moved and badly damaged; very heavy machine tools (12,000 lb) survive
300.00	Limit of crater lip

Table 2.5 summarizes the effects of explosion overpressure on structures. With respect to human casualties, heavy building damage usually is equated to a fatal effect, as the people inside the buildings probably would be crushed. People outside of buildings or structures are susceptible to direct blast injury (blast overpressure) and indirect blast injury (missiles or whole body translation).

Relatively high blast overpressures (>15 psig) are necessary to produce a human fatality from a direct blast. Instead, the major threat is produced by missiles or by whole body translation. Fatalities arising from whole body translation are mainly due to head injury from decelerative impact. Injury to people due to fragments usually results from either penetration by small fragments or blunt trauma from large fragments. TNO [22] suggested that projectiles with a kinetic energy of 100 J can cause fatalities. Table 2.6 shows damage to people (physiological damage) as a function of overpressure.

Table 2.6 Physiological damage as a result of overpressure

Effect	Peak overpressure (psi)
Knock down	1.0
Ear drum damage	5.0
Lung damage	15
Threshold for fatalities	35
50 % fatalities	50
99 % fatalities	65

Radiation Consequences: The effect of thermal radiation on people and objects is determined by one of two approaches:

1. Simple tabulations based on experimental results
2. Theoretical models based on the physiology of the skin burn response

Data on time to pain threshold [34] are summarized in Table 2.7. For comparison, solar radiation intensity on a clear, hot summer day is about 320 Btu/h/ft^2 (1 kW/m^2).

Table 2.7 Time to pain threshold for varying levels of radiation [41] (Courtesy American Petroleum Institute)

Radiation intensity (Btu/h/ft^2)	Radiation intensity(kW/m^2)	Time to pain threshold (s)
500	1.74	60
740	2.33	40
920	2.90	30
1,500	4.73	16
2,200	6.94	9
3,000	9.46	6
3,700	11.67	4
6,300	19.87	2

Table 2.8 Effects of thermal radiation (Copyright American Institute of Chemical Engineers, reproduced by permission of the Center for Chemical Process Safety of AIChE [34].)

Radiation intensity (kW/m^2)	Observed effect
37.5	Sufficient to cause damage to process equipment
25.0	Minimum energy required to ignite wood at indefinitely long exposures
12.5	Minimum energy required for piloted ignition of wood, melting of plastic tubing
9.5	Pain threshold reached after 6 s; second-degree burns after 20 s
4.0	Sufficient to cause pain to personnel if unable to reach cover within 20 s; however, blistering of the skin (second degree burns) is likely; 0% lethality
1.6	Will cause no discomfort for long exposure

Other criteria for thermal radiation damage are shown in Table 2.8 [34].

The effect of thermal radiation on structures depends on whether they are combustible or not, and the nature and duration of the exposure. Thus, wooden materials will fail because of combustion, whereas steel will fail because of thermal lowering of the yield stress.

Unconfined Vapor Cloud Explosions: When a large amount of volatile material is released rapidly to the atmosphere, a vapor cloud forms and disperses. If the cloud is ignited before it is diluted below its lower flammability limit, an uncontrolled vapor cloud explosion will occur. This is one of the most serious hazards in the process industries. Both shock waves and thermal radiation will result from the explosion, with the shock waves usually the more important damage producers. UVCEs usually are modeled by using the TNT model [34]. The energy of the blast wave generally is only a small fraction of the energy available from the combustion of all the material that constitutes the cloud; the ratio of the actual energy released to that available frequently is referred to as the “explosion efficiency.” Therefore, the TNT weight equivalent of a UVCE includes an explosion efficiency term, which typically is an empirical factor ranging from 1 to 10%. The explosion effects of a TNT charge are well documented.

Physical Explosions: A physical explosion usually results from the production of large volumes of gases by non-chemical means. The gases necessary for a physical explosion may be those already existing, such as compressed nitrogen released suddenly from a ruptured cylinder, or steam released explosively from a crack in a steam drum.

The following are some settings and situations in which physical explosions have been known to take place:

- Steam boilers
- Hydraulic overfill of tanks or pipes with external applied pressure (as in pressure testing)
- Compressed air tanks
- Deadheaded pumps
- Thermal expansion of tanks or pipes
- Liquid cryogenic fluids on water (such as liquid methane on water)
- Water suddenly mixed with sulfuric acid (also may cause a chemical explosion)
- BLEVE with superheated liquid (flammable or nonflammable) (see next section)
- Explosion of grinding wheel at too high a speed
- Liquid water in molten mgcl$_2$ solution at high temperatures
- Implosions due to vacuum
- Overpressured refrigerant systems
- Molten metals exploding violently on contact with water
- Some molten metals exploding when mixed with each other
- The mixing of two immiscible liquids whose boiling points are not widely separated

Steam boilers are commonly used in power plants and industries of all kinds. They generally are taken for granted now, but in the second half of the nineteenth century boilers blew up with alarming regularity. Records indicate that from 1870 to 1910 there were at least 10,000 boiler explosions in the United States and adjacent areas of Canada and Mexico; that is, more than one recorded explosion every 36 h! By 1910, the rate had jumped to between 1,300 and 1,400 per year. On October 8, 1894, in the Henry Clay Mine in Shamokin, Pennsylvania, 27 boilers disintegrated almost simultaneously! Mainly because of the incorporation of the ASME Boiler Code into laws, boiler explosions have decreased dramatically [35].

When a pressurized vessel ruptures, the resulting stored energy is released. This energy can cause a shock wave and accelerate vessel fragments. If the contents are flammable, ignition of the released gas could produce additional effects. There is a maximum amount of energy in a bursting vessel that can be released, and it is released in the following proportions: [32]

	Distribution of energy when vessel ruptures		
Type of failure	Strain energy	Kinetic energy of fragments	Shock wave energy
Brittle failure	<10%	~20%	up to 80%
Plug ejection	small	up to 60–80%	20–40%

The relative distribution of these energy components will change over the course of the explosion, but most of the energy is carried by the shock wave with the remainder going to fragment kinetic energy. To estimate the damage resulting from the shock wave from a physical explosion, the TNT model is used widely. To determine the TNT equivalent of a physical explosion, the total energy in the system must be estimated. For a physical explosion, if the expansion occurs isothermally, and ideal gas laws apply, then the TNT equivalent of the explosion can be calculated. This energy then can be used to estimate overpressure at any distance from the explosion. The analogy of the explosion of a container of pressurized gas to a point source explosion of TNT is not appropriate in the near-field. Prugh [36] suggests a correction method using a virtual distance R_v from an explosion center.

In addition to shock wave effects, a major hazard of a ruptured gas-filled vessel is from projectiles. To estimate damage from projectiles, both the initial velocity and the range are required. A simplified method for calculating the initial velocity uses the following equation: [37]

$$u = 2.05\left(\frac{PD^3}{W}\right)^{0.5}$$

where
u = initial velocity, ft/s.
P = rupture pressure, psig.
D = fragment diameter, in.
W = weight of fragments, lb.

Clancey [38] gives the following values for initial velocity for the majority of fragments from a TNT explosion:

- Thin case: 8,000 ft/s
- Medium case: 6,000 ft/s
- Thick case: 4,000 ft/s

Once the initial velocity has been determined, the maximum range of the fragment, ignoring air resistance, can be estimated from

$$R_{\max} = \frac{u^2}{g}$$

Where $R_{\max}$ is the maximum range of fragments and g is the acceleration of gravity.

If the above values for typical velocity are substituted into the above equation, a maximum range of 5×10^5 ft is possible. Therefore, it is clearly necessary to include air resistance. To include air resistance, a value of C_D, the drag coefficient, must be estimated. The drag coefficient ranges from 0.48 for a sphere to 2 for flow perpendicular to a flat strip, and for most fragments ranges from 1.5 to 2.0.

If one knows the air density, drag coefficient, exposed area of the fragment, mass of the fragment, and the initial velocity, the maximum range R can be calculated with the aid of Fig. 2.13 [18]. Although this technique gives the maxim-um range, most fragments do not travel the maximum distance but fall at distances between 0.3 and 0.8 of the maximum.

The energy required to impart an initial velocity of u to a fragment is

$$E = \frac{1}{2}mu^2$$

where m is the mass of the fragment (lb)u the initial velocity (ft/s)

Example: A high pressure vessel containing air at 600 bar has ruptured, leading to 15 fragments of approximately equal mass (85 lb), one of which was found as far as 400 ft from the vessel. This fragment has a drag coefficient of 1.5 and an exposed area of 3 ft^2. Assuming that 20% of the explosion energy went to energy of the fragments, estimate the energy of the explosion in weight equivalent TNT. The air density is 0.081 lb/ft^3.

Procedure: Assuming that the fragment found at 400 ft is at the maximum range for the fragments, the scaled fragment range R_s can be calculated:

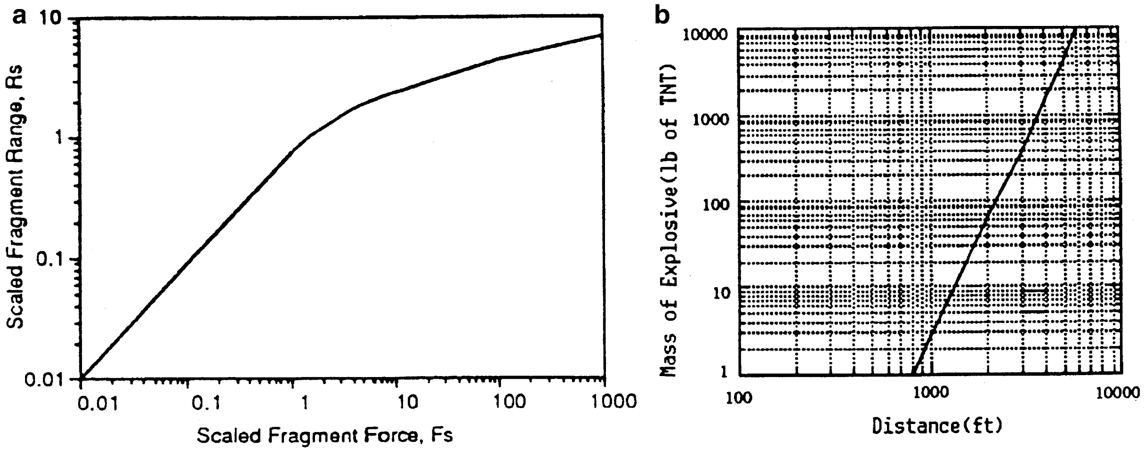
From Fig 2.13, we obtain a scaled force (F_s) of approximately 5. The initial velocity of the fragment then can be calculated as

$$u = \sqrt{\frac{MgF_s}{r_0 C_D A_D}} = \sqrt{\frac{85 \times 32.17 \times 5}{0.081 \times 1.5 \times 3}} = 194\,\text{ft/s}$$

The energy required to give the fragment this initial velocity is

$$E = \frac{1}{2}(85)(194)^2 = 1.6 \times 106\,\text{lb ft}^2/\text{s}^2 = 64\,\text{BTU}$$

Since there were 15 fragments, the total energy of the explosion that went into fragment kinetic energy is 15 × 635.8 BTU = 9,537 BTU. If only 20% of the explosion energy went into fragment kinetic energy, then the total



where: $F_s = \frac{r_o C_D A_D u^2}{Mg}$ $R_s = \frac{r_o C_D A_D R}{M}$

and: r_o = density of air lb/cu ft C_D = drag coefficient

A_D = exposed area of fragment, ft2 R = max range of fragment, ft

M = mass of fragment, lb U = fragment initial velocity, fps

$g = 32.17\ \text{ft. lb.}_m/\text{lb}_f\text{s}^2$

Fig. 2.13 (**a**) Scaled fragment range vs. scaled force. (Baker et al. [18]) (**b**) Maximum horizontal range of blast fragments. (Clancey [38])

explosion energy is 47,680 BTU, which is the equivalent of 23.8 lb of TNT. Using the method of Clancey [38], 2.4 lb TNT can provide a maximum range of 950 ft for projectiles (Fig. 2.13b).

Mechanical Heat

Mechanical motion in fluids becomes kinetic energy and may become heat in devices with rotating parts. Mechanical heat input from rotating agitators, pump impellers, and other mechanical equipment must be taken into account in the design of process equipment, particularly in systems containing reactive chemicals. This section will provide some guidelines for the analysis of individual cases involving pumps and agitated tanks [20, 23, 39].

Some useful rules are as follows.

1. A deadheaded pump is a pump operating full of liquid and with inlet and outlet valves closed.
2. Almost all deadheaded centrifugal pumps with motors of three horsepower or larger are headed for trouble if left deadheaded. (Depending on the horse power, a few minutes may be too long.)
3. The heat input from the rotating impeller in a deadheaded centrifugal pump is always a large value relative to the heat sink of the fluid and the pump.
4. It is not necessary for there to be a chemical reaction in a pump for an explosion to take place. Deadheaded pumps containing only water or brine have blown up.
5. An agitator or a circulating pump left on in a vessel of a reactive chemical may heat up the contents enough to cause a runaway reaction.
6. All centrifugal pumps with motors larger than 3 hp should be protected in some way to prevent deadheading.
7. A temperature alarm in the casing is a minimum form of protection. A better way may be to have the high-temperature alarm wired to the process control computer, to both alarm and shut off the pump. Other systems are available and may be used; they may include (but are not limited to) a relief valve on the pump, a minimum flow valve, and a flow orifice in the recirculating line. A relief valve on a pump relieving back to the pump inlet may not eliminate the problem of heat buildup in a deadheaded pump and usually should be avoided unless other protective measures are used such as a high-temperature device.
8. An ammeter on the pump motor usually is not a reliable means of detecting deadheaded conditions. The low power factors often experienced with pump motors, and the nature of pump curves, often make it difficult to distinguish between normal running and dead headed conditions using an ammeter.
9. For mechanical heat equivalent, the following are recommended: (a) For pumps, use 50% of the connected motor horsepower for centrifugal pumps that are deadheaded, unless better information is available. (b) For agitators, use 100% of the vendor rated shaft input

horsepower for the input shaft (total power less drive and bearing inefficiencies) for the actual material in the vessel.

Vacuum [39]

Ask any chemical engineers who have had some plant experience what they know about vacuum, and they probably will smile and tell a tale about some piece of equipment that tried to turn itself inside out. Usually no one was hurt, and often there is no massive leakage—but not always!

The design for the internal pressure condition of vessels usually is straightforward and well understood. Under vacuum conditions, equipment is subject to external pressure from the atmosphere; and the design for external pressures is more difficult than that for internal pressures. The devious ways in which external pressure can be applied often may be overlooked.

The following are some obvious causes of vacuum collapse:

- Liquid withdrawal by pump or gravity draining
- Removal of gas or vapor by withdrawing with a blower, fan, or jet
- Siphoning of liquids

Less obvious causes include:

- Condensation of vapor
- Cooling of hot gas
- Combination of cooling and condensation of a mixture of gas and condensable vapor

Sometimes obscure causes of vacuum collapse include:

1. Absorption of a gas in a liquid; for example, ammonia in water, carbon dioxide in water, hydrogen chloride in water.
2. Reaction of two or more gases to make a liquid or solid; for example, ammonia plus hydrogen bromide to form ammonium bromide.
3. Reaction of a gas and a solid to form a solid; for example, corrosion in a tank, air plus Fe or FeO forming Fe_2O_3 in the presence of water.
4. Reaction of a gas and a liquid to give a liquid; for example, chlorination, hydrogenation, ethylation.
5. Sudden dropping of finely divided solids in a silo, creating a momentary vacuum that can suck in the sides of the silo.
6. Flame arrestors plugging; for example:
   (a) In styrene service, vapor may condense in flame arrestors, and the liquid formed is low in inhibitor; the liquid may polymerize and plug off the arrestor. Possible solutions: clean the arrestor frequently or use a PVRV (pressure-vacuum-relief valve).
   (b) Liquid service in cold weather: vapor may condense in a flame arrestor and the liquid formed may freeze and plug the arrestor. Possible solution: heat and insulate the arrestor to prevent condensation.
7. Maintenance and testing. It is not a good idea to apply vacuum on a vessel during maintenance or testing without full knowledge of the external pressure rating unless a suitable vacuum relief device is in place and operable.

Protective Measures for Equipment

If equipment may be subject to vacuum, consideration should be given to designing the equipment for full vacuum. This may eliminate the need for complicated devices such as vacuum relief valves and instruments; if they are used, designing the equipment for full vacuum will prevent collapse of the vessel if the instruments or relief valves fail or plug.

A disadvantage of this approach is that it usually is expensive. However, when the total cost of a suitably instrumented vessel not designed for vacuum is compared with the cost of a vessel designed for vacuum but without the extra equipment, the difference may be small or negligible, and the vessel designed for vacuum will be inherently safer. If a vessel is designed for vacuum, precautions should be taken to ensure that internal or external corrosion will not destroy the integrity of the vessel.

Reactivity Hazards [2]

As a nation, we continue to have chemical reactivity incidents that cause harm to people, property and the environment. The Chemical Safety Board's report analyzed 167 incidents from 1980 to 2001 that resulted in a total of 108 fatalities and significant property damage. While this number may seem small in comparison to, say the number of automobile related fatalities annually in the US, it is significant because the data used are admittedly incomplete, leading to the expectation that the "true" impact of chemical reactivity incidents is much higher.

By way of definition, the CCPS Concept Book intentionally uses the term "chemical reactivity hazard" rather than "reactive hazard," "reactive chemical hazard," or "chemical reaction hazard."

A chemical reactivity hazard is defined as a situation with the potential for an uncontrolled chemical reaction that can result in serious harm or loss.

According to the CSB report, in a vast majority of these cases, the information needed to properly assess (and therefore, control) these hazards was known prior to the incident. In 90% + of all incidents studied, the information necessary to have prevented the incident was documented and publicly available.

As the Chemical Safety Board has concluded in its Hazard Investigation, the problem is not reactive chemicals but managing reactive chemicals.

Reactivity of chemicals provides us with much of the materials necessary for modern civilization, but the hazards associated with reactive chemicals must be controlled.

- It's not reactive chemicals, it's reactive chemistry—and the management of its hazards.

- Many reactive chemistry incidents have occurred in operations where there was no intended chemical reaction (storage, blending, distillation, etc.).
- Reactive chemicals can be reactants, intermediates and products.

An approach to reactivity hazard evaluation used by a major chemical company that is a leader in reactive chemical safety includes the following steps.

- Identify all chemicals used in the process (raw materials, intermediates and products).
- Obtain reactivity information and data on the above including inadvertent mixing—testing may be required.
- Use a team approach to identify what can go wrong.
- Determine the consequences of all possible deviations.
- Calculate the worst case scenario.
- Identify and implement appropriate safe guards.

Many reactive chemical incidents take place when there is no chemical reaction intended. Such an incident occurred April 21, 1995 at Napp Technologies in Lodi, New Jersey. The Napp incident involved inadvertent mixing of water with a water reactive chemical (aluminum powder and sodium hydrosulfite) during a blending operation. There were five fatalities, evacuation of 300 people and major property damage and loss of business. Neither aluminum powder or sodium hydrosulfide are included in the OSHA PSM standard.

The first step in managing a reactive hazard is to identify that there is a hazard. This can be done by literature surveys, energy of reaction, chemical structures and bonds, and interaction matrixes. It helps to have someone is your organization that has special expertise on reactive hazards.

It is important to have enough data to describe the hazard and to provide control measures. Special expertise is required to do this right.

There is plenty of literature, vendor information and other resources to help. General types of reactivity testing:

– DOT/UN tests
– Screening tests
– Reaction calorimetry
– Detailed hazard testing
– Special studies

There are numerous testing methods that can be used depending on the hazard information required. If more detailed information is required for engineering calculations, such as relief valve sizing, different methods should be used.

- ASTM CHETAH (Balaraju et al. 2002).

There are standards that can help you construct binary chemical compatibility charts. These charts are useful when you handle a variety of chemicals in an area and are concerned with inadvertently mixing any two chemicals. Factors that should be considered when specifying the mixing scenario include material quantities and temperatures, degree of confinement, atmosphere, and the maximum time the materials may be in contact. Do this for all chemicals including warehousing, cleaning chemicals, etc.

- ASTM 2012–00 Standard Guide for Preparation of a Binary Compatibility Chart.

Chemical Reactivity Worksheet, Version 2.0.2, NOAA/CCPS, last updated August 2010. http://response.restoration.noaa.gov/chemaids/react.html.

It is important to have enough data to describe the hazard and to provide control measures. Special expertise is required to do this right.

- Sufficient data to fully characterize reactive hazards is sometimes available from supplier or other sources.
- Work with someone who knows:
  – The various tests and their limitations
  – When they should be conducted
  – How to interpret and use the results

To summarize, if you handle chemicals, you need a reactive chemicals program. Some important aspects include . . .

- Ownership of the reactive chemistry
- Reactive chemical (life cycle) reviews
- Screening and testing protocols
- Screening and testing facilities
- Capture of reactivity hazard data
- Availability of experts to participate in reviews, be available for consultation

Toxicity Hazards [2]

Toxicity is a life safety issue and there are different ways to express the threat. A particular toxin can represent hazards in more than one type of exposure. Fluorine has both serious skin contact and respiratory issues. Respiratory rate can also contribute to the extent of the exposure. Toxicity is a measure of harm from direct exposure to certain chemical substances. It measures potential life threatening exposures including oral, skin contact and respiratory. Life health risk is a function of type of contact, toxicity and duration of exposure. Reaction of individuals to a specific toxin varies. Toxicity data do not reflect chronic health effects. Examples of highly toxic chemicals include:

- Acetic anhydride
- Acrylamide
- Aniline

- Arsenic compounds
- Benzoyl peroxide
- Barium salts
- Fluorine, Chlorine, Bromine
- Formaldehyde
- Hydrazine
- Hydrogen sulfide
- Mercury compounds
- Nitrobenzene
- Nickel carbonyl
- Oxalic acid
- Phenol
- Phosgene
- Pthalic anhydride
- Propylamines
- Silver salts
- Tetrachlorethane
- Sulfur dioxide

Toxicity includes:

- Acute exposure
  - A single exposure to a toxic substance which may result in severe biological harm or death; acute exposures are usually characterized as lasting no longer than a day and
- Chronic exposure
  - Continuous exposure to a toxin over an extended period of time, often measured in months or years can cause irreversible side effects

Process safety is primarily concerned with acute exposure. Some common terms used to describe toxicity include:

- LC 50—Concentration of a material in air that will kill 50%of the test subjects (typically animals) when administered as a single exposure (typically 1–4 h)
- LC Lo—Lowest concentration reported to have killed animals or humans
- LD 50—Dose required to kill half the members of a tested population
- LD 50—Dose at which 50% of a tested population are killed

There are many ways to define and present acute exposure levels. These definitions and exposure levels have been created with help from organizations like the American Conference of Governmental Hygienists (ACGIH). The data is normally hard to find for acute effects and an even more extensive amount of data, say compared to an IDLH, is necessary to produce a probit relationship which will map out all the combinations of concentration and time for a particular probability of fatality. Probits have application for detailed QRAs.

Some other terms to describe acute toxicity include:

- ERPG—Emergency Response Planning Guidelines
  ERPG 1—1 h exposure mild health effects
  ERPG 2—1 h exposure w/o/ irreversible health effects
  ERPG 3—1 h exposure w/o life threatening health effects
- IDLH—Immediately Dangerous to Life and Health
  Maximum airborne concentration to which a healthy male worker can be exposed up to 30 min and be able to escape without loss of life or irreversible organ damage
- Probit—Dose/Response Algorithm
- EEGL/SPEGL—Emergency Exposure Guidance Levels

Asphyxiants are a special class of toxic gases. Asphyxiants are normally inert gases such as nitrogen, argon, carbon dioxide and others. Nitrogen is the most prevalent in the chemical industry. There are multiple deaths because someone tries to be a hero in a rescue attempt. In some cases where they suspect the cause they think they can hold their breath long enough. Breathing air is normally produced from compressed air. However, air is sometimes manufactured as a mixture of nitrogen and oxygen. These mixtures are normally not acceptable for breathing air but if it is used that way there is always a chance that the ratio of nitrogen to oxygen is not correct. There are approximately 8 deaths/year from N_2 asphyxiation alone in the United States. Contributing causal factors for these incidents include in or near a confined space, inadequate monitoring, mix up of N_2 and breathing air and attempted rescue.

Corrosivity Hazard [2]

Rust is the most simple form of corrosion. Rust can result in a damaged hose clamp that cannot be tightened or removed due to rust deposition. The single biggest concern with corrosion is inside the equipment but external corrosion can also be a major concern. A broken hose clamp can cause a hose to slip off a connection. Corrosion is a chemical reaction between a metal and its environment. Common corrosion (rust) requires air and moisture. The corrosive layer can weakened a pipe or equipment structurally and thus initiate a failure. Corrosion or erosion often occurs in pipe elbows where high velocity can scour corrosion products exposing additional metal to corrosion. Common corrosion rates in pipe wall are 0.1–0.2 mm/year, but corrosion rates may increase tenfold in highly corrosive or erosive service.

The most common example of metal oxidation is rust but other metal oxides can also oxidize (e.g. aluminum). Insulation can absorb moisture and act to dramatically increase the rate of rust formation. High temperature corrosion does not require the presence of a liquid electrolyte such as water. Oxidation is the major type of high temperature corrosion but you can also have sulfidation and carburization. Alloys often rely on the oxidation reaction to produce a protective scale. Galvanic corrosion is an electrochemical process in which one metal corrodes preferentially when in electrical contact with another metal and both metals are immersed in an electrolyte. The galvanic couple is set up and ions move from the anode to the cathode. The presence of electrolyte and a conducting path between the metals may cause corrosion. Underground piping can undergo this problem and sometimes sacrificial anodes such as zinc, magnesium or aluminum are used. One form of microbial corrosion is caused by two types of bacteria one that eats sulfates in the absence of oxygen and nitrates to form hydrogen sulfide (sulfate reducing bacteria) and another that eats the hydrogen sulfide to form sulfuric acid. This can be a problem when city wastewater is used in the plant. The city of Phoenix had problems a few years ago and firewater systems in plants in that area had severe corrosion using that water. The addition of as little as 3 ppm of chlorine eliminated that problem. Corrosion in passivated materials can produce localized pitting if the coating is not completely uniform. Be aware of whether materials passivated by a layer of oxidized material such as aluminum oxide are not in an environment where that passivated layer is continuously scraped away. Corrosion rates are normally in the range of mils/year. Clad vessels are sometimes used if normal materials have too high a corrosion rate for the service and alternative materials are too costly for the thickness needed. Additional thickness needed to compensate for an expected corrosion rate over the lifetime of the equipment Corrosion rates are dependent on piping or vessel materials of construction and chemical conditions including flow, concentration of corrosive chemical(s), temperature, and pressure.

Hazard Identification and Risk Analysis

The other element included in the pillar Understanding Hazards and Risk is Hazard Identification and Risk Analysis (HIRA). HIRA encompasses all activities involved in identifying hazards and evaluating risks to employees, the public and the environment at facilities, throughout the facility's life cycle, to control the risk within the organization's risk tolerance. HIRA addresses three questions:

- What can go wrong?
- How bad is it?
- How likely is it to occur?

HIRA Logic Diagram

The logic diagram (Fig. 2.14) explains the process of how to uncover hazards and how to analyze and address the risks. Note there is a recycle loop at the end. If risks are too high as judged by a company then ways for risk reduction must be sought and the final risk accepted. Risk is a function of the probability and consequences of an undesirable event which could occur as a result of the presence of a hazard. Another way to express risk is to say it is some function of the combination of probability that something might happen and the expected consequences if it does.

HIRA includes the following topics

- Hazard identification
- Qualitative hazard evaluation methodologies
- Quantitative hazard evaluation methodologies
- Consequence analysis
- Probability analysis

Hazard Identification

Hazard identification answers the question "What can go wrong?"

OSHA requires that Process Hazard Analyses (PHAs) be conducted on covered processes. PHAs use qualitative hazard evaluation methodologies.

PHAs include both the identification and evaluation of the hazards (refer to section on "Regulations"). Commonly methodologies used to conduct PHAs include:

- What if
- Checklist
- What if/Checklist
- FMEA (Failure Modes and Effects Analysis)
- FTA (Fault Tree Analysis)
- HAZOP

HAZOP stands for "Hazard and Operability Studies," a set of formal hazard identification and elimination procedures designed to identify hazards to people, processes, plants, and the environment. The techniques aims to stimulate the imagination of designers and operations people in a systematic way so they can identify potential hazards. In effect, HAZOP studies assume that there will be mistakes, and provide a systematic search for these mistakes. In some European countries, HAZOP studies are mandatory and attended by observers from regulatory authorities to ensure that the studies are carried out correctly. The examination of accidents [40] during 1988 at a large US chemical company revealed that the accidents could be classified as follows:

- Spills: 52%
- Emissions: 30%
- Fires: 18%

Of the fires, about 50% occurred during construction, 25% were due to pump seal failure, and the remaining 25% resulted from engineering and operational oversights that a HAZOP study possibly could have prevented.

Of the emissions, 37% were due to piping failure, with lined pipe being the largest contributor. Operational and procedural issues accounted for 53% of the remainder.

Of the spills, 11% were due to equipment failures. Piping failures (especially lined pipe and gaskets) accounted for 30, and 56% were caused by various types of operational errors, noncompliance with procedures, or nonexistent procedures. Material handling was a factor in many spills and emissions. The most frequent type of operational error was a valve being left in an improper position, either open or closed. HAZOP studies probably could have reduced the number and seriousness of the problems experienced. Some investigations have shown that a HAZOP study will result in recommendations that are 40% safety-related and 60% operability-related. Thus, HAZOP is far more than a safety tool; a good HAZOP study also results in improved operability of the process or plant, which can mean greater profitability.

The HAZOP technique can be used to identify human error potential. From a practical point of view, human error and its consequences can occur at all levels of a management structure as well as in the operation of a particular plant or process. Carried out correctly, Technica [41] states that a HAZOP study will identify at least 70–75% of potential operational and safety problems associated with a particular design process, including human error.

The HAZOP technique also can be used for the evaluation of procedures. Procedures may be regarded as a "system" designed to "program" an operator to carry out a sequence of correct actions. Deviations from intent are developed, with the emphasis on "operator action deviation" rather than "physical property deviation." It is the procedure, not the hardware, that is the object of study, but hardware modifications may be recommended to cover potential problems identified from procedure deviations.

Some Tools for Evaluating Risks and Hazards

Dow Fire and Explosion Index: The Dow Fire and Explosion Index (F&EI), developed by The Dow Chemical Company, is an objective evaluation of the potential of a facility for a fire, an explosion, or a reactive chemical accident. Its purpose is to quantify damage from incidents, identify equipment that could contribute to an incident, and suggest ways to mitigate the incident; it also is a way to communicate to management the quantitative hazard potential. It is intended for facilities handling flammable, combustible, or reactive materials whether stored, handled, or processed. The goal of the F&EI evaluation is to become aware of the loss potential and to identify ways to reduce the potential severity in a cost-effective manner. It does not address frequency (risk) except in a general way. The number is useful mainly for comparisons and for calculations of damage radius, maximum probable property damage, and business interruption loss, and to establish frequency of reviews. The method of carrying out an F&EI evaluation is available to the public from the American Institute of Chemical EngineersNew York, NY.

Failure modes and effects analysis (FMEA): FMEA is a systematic, tabular method for evaluating the causes and effects of component failures. It represents a "bottom–up" approach, in contrast with a fault tree, where the approach is "top–down." In large part, HAZOP is a well-developed form of FMEA [19].

Fault tree: A fault tree is a logical model that graphically portrays the combinations of failures that can lead to a particular main failure or accident of interest. A fault tree starts with a top event, which is usually a hazard of some kind. The possibility of the hazard must be foreseen before the fault tree can be constructed. A fault tree helps reveal the possible causes of the hazard, some of which may not have been foreseen [19].

Safety audit: A safety audit is a method of reviewing the actual construction and operation of a facility. Often, safety audits are conducted by a small interdisciplinary team. At least some of the members of the team are not connected with the plant. The audit may be carried out before startup and also is repeated later at intervals of, typically, 1–5 years.

Chemical exposure index: The Chemical Exposure Index is a technique for estimating the relative toxic hazards of chemicals, developed by The Dow Chemical Company. It provides for the relative ranking of toxic chemicals in a given facility, including factors relating to toxicity, quantity volatilized, distance to an area of concern, and physical properties. A description of the method can be found in *Guidelines for Safe Storage and Handling of High Toxic Hazard Materials*, Center for Chemical Process Safety, American Institute of Chemical Engineers [42].

The methods above are described in detail in *Guidelines for Hazard Evaluation Procedures, Third Edition,* CCPS, 2008 and will not be discussed in any more detail in this chapter.

Consequences and Impacts

The next question is "How bad is it?" Evaluating consequences is a very technical subject requiring special training and expertise. There are several good books on the topic in the references. Some general comments will be made here. The first step in evaluating consequences is to select a release scenario. How to choose a scenario is not always well defined. There is a requirement in the Seveso regulations that major hazards must be addressed. The top event of a fault tree may be another starting point. Possible sources of potential release incidents include:

- Hazard evaluation process
  - Scenario based methodologies most useful (e.g., HAZOP)
- Regulatory requirements
- Fault tree analysis
- Company initiative

The next step involves choosing a source model. Source models describe how a material escapes from a process. Use of source models should be referred to experts. If potential release is flammable and/or toxic the following are possible consequences:

- Fires
- Explosions
- Toxic Releases
- Environmental Pollution

The above consequences have already been discussed in the section on “Chemical Hazards”.

Probability

The last HIRA question is “How likely is it to occur?” Generating the frequency or probability of an event requires both technical competence in the calculations and experience. Evaluation methodologies to estimate frequency or probability include:

- Fault tree analysis (FTA)
- Event tree analysis (ETA)
- Level of protection analysis (LOPA)
- Cause–consequence analysis
- Human reliability analysis (HRA)

Detailed description on the methodologies can be found in *Guidelines for Hazard Evaluation Procedures, Third Edition*, CCPS, 2008. Again, there will not be a detailed description of these methodologies in this chapter.

There are always questions about sources of failure data. Experienced analysts can help work through this maze. In some cases frequency information can be obtained from the plant history (e.g., number of times a relief valve has gone off in anger) which comes in at a higher point in the tree. Predicted data relates to establishing a failure rate from the sum of all the individual component failures. PERD is an AICHE CCPS organization (Process Equipment Reliability Data) where companies contribute data and then have access to others data.

Common cause failures must be accounted for when assigning failure rates. See the references at the end of this chapter for other sources of frequency or probability data.

Risk Analysis

Risk is a combination of the consequence if someone is impacted by a hazard combined with the expected frequency of being impacted by that hazard. For instance if a person steps in a hole in the floor what would the consequence be? It depends on a lot of things—including how deep the hole is, the sharpness of the edges of the hole, etc. . . . Risk is often expressed in terms of probability/likelihood and impact/consequence.

Risk Understanding

As Fig. 2.15 illustrates, risk can be managed by managing the probability and the consequence of occurrence. For probability the question asked is—How likely is it? For consequence the question is—What can go wrong. . .and if it does what are the impacts? Answers are often based on our personal past experiences, what has been learned from others experiences, and/or by using some analytical (and perhaps technical) methodologies. Risk estimates are based on exposure to impact, magnitude of impact and probability. The risk estimate must be related to base level of risk. What principal factor determines the magnitude of the risk? If risk is a function of the probability and consequences then risk can be reduced by lowering the probability an incident will occur, reducing the consequences of occurrence, or a combination of both. Lowering the probability of occurrence is the prevention approach. Reducing the consequences of occurrence is the mitigation approach. It is best to try and prevent before trying to mitigate. Risk analysis followed by risk assessment is usually needed to support either approach.

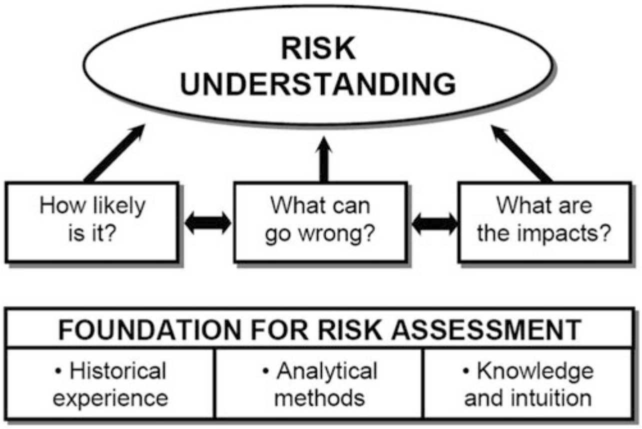

Fig. 2.15 Risk understanding (Copyright 2008 Center for Chemical Process Safety (CCPS) of the American Institute of Chemical Engineers (AIChE), www.aiche.org/ccps, and used with permission”)

Good risk analysis has the following attributes:

- Level of effort commensurate with the risk
- Experienced analysts
- Uncertainties defined
- Options for risk reduction identified
- Risk analysis documented clearly and understandably
- Risk analysis is both defendable and repeatable

There are several approaches to risk analysis including qualitative risk ranking, semi—quantitative analyses using risk matrices, layer of protection analysis (LOPA), and quantitative analysis (QRA). These approaches will not be discussed in detail here. See the references at the end of the chapter.

Quantitative Risk Analysis

Quantitative risk analysis (QRA) models the events, incidents, consequences, and risks, and produces numerical estimates of some or all of the frequencies, probabilities, consequences, or risks [34, 43]. QRA can be done at a preliminary level or a detailed level, and in all cases may or may not quantify all events, incidents, consequences, or risks [36]. QRA is the art and science of developing and understanding numerical estimates of the risk associated with a facility or an operation. It uses highly sophisticated but approximate tools for acquiring risk understanding.

QRA can be used to investigate many types of risks associated with chemical process facilities, such as the risk of economic losses or the risk of exposure of members of the public to toxic vapors. In health and safety applications, the use of QRA can be classified into two categories:

1. Estimating the long-term risk to workers or the public from chronic exposure to potentially harmful substances or activities.
2. Estimating the risk to workers or the public from episodic events involving a one-time exposure, which may be acute, to potentially harmful substances or activities.

QRA is fundamentally different from many other chemical engineering activities (e.g., chemistry, heat transfer), whose basic property data are capable of being theoretically and empirically determined and often established experimentally. Some of the basic "property data" used to calculate risk estimates are probabilistic variables with no fixed values, and some of the key elements of risk must be established by using these probabilistic variables. QRA is an approach for estimating the risk of chemical operations by using the probabilistic approach; it is a fundamentally different approach from those used in many other engineering activities because interpreting the results of QRA requires an increased sensitivity to uncertainties that arise primarily from the probabilistic character of the data.

Safety Risk Criteria [44]

Risk is something that exists every day in our business and private lives. Each one of us has a tolerance level, very often based on our personal experiences. While that may be acceptable for us personally, we need to have a logical and documented way of making risk based decisions in the work place. Let's look at a standard diagram (Fig. 2.7) of how risk based decisions should be made in the work place.

1. First the system that is being analyzed must be understood. So, a system description is required and understood. In some sense, this is compiling the process safety knowledge.
2. Second, hazard identification process must be completed. PHAs are one route to hazards identification. Another way of identifying hazards is to review the process safety information and/or to do a walkthrough of the area.
3. Now, the hazard must be converted to a risk. Remember that risk is a combination of probability that something might happen combined with the consequences if it does.
4. With that in hand, an estimate of the risk can be made.
5. Now it needs to be determined if that risk can be tolerated or if risk must be reduced. So, the risk must be compared to the risk tolerance criteria.
6. If it passes the tolerance test, no changes are needed.
7. If it does not pass the tolerance test, then something must be changed. And that something is either the probability or the consequence.

There are a variety of ways to set the risk tolerance. It can be just a guess based on what is known or believed but that isn't very scientific and is certainly not repeatable or defendable in a court of law. Perhaps it can be copied from someone or some company that we know. That might work, but it may not consider all the things in our company that makes it unique. Or, we can make our own list and criteria based on company culture, beliefs, resources, etc. To do that we probably want to break our decision making process down into small pieces so that each decision has a relatively small impact on the final product. Often performance is evaluated in three areas—safety, environmental, and financial. Failure to pass the tolerance test in any of these areas causes the risk to be unacceptable. There may be other topics that need to be to detail out when making risk tolerance decisions. Whatever they are, write them down and get them universally accepted in your company. They will be the standard that a company will use for critical decisions. Company criteria must be developed so that it is defendable and repeatable. So, what is acceptable (and we really should use *Tolerable* instead of *Acceptable* since Acceptable seems to be an inflammatory word in general public use) This brings us back to our tolerance criteria. The CCPS book entitled *Guidelines for*

Developing Quantitative Safety Risk Criteria, CCPS, 2009 cover this topic in detail.

The benefits of risk management include that it identifies key exposures minimizes surprises, provides an objective basis for allocating resources, improves culture and puts risk to competitive advantage.

Manage Risk

The third pillar of RBPS is *Manage Risk*. To manage risk facilities should focus on:

- Developing written operating procedures
- Implementing an integrated suite of safe work policies, procedures, permits and practices to control maintenance and other non routine work.
- Executing work activities to ensure that equipment is fabricated and installed in accordance with specifications and that it remains fit for duty for service over its entire life cycle.
- Managing contractors, and evaluating work performed by contractors.
- Providing training.
- Recognizing and managing changes.
- Ensuring that units, and the people who operate them, are properly prepared for start ups.
- Maintaining a very high level of human performance.
- Preparing for and managing emergencies.

Operating Procedures

Operating procedures can be written (or electronic) documents that list the steps for a given task and describe the manner in which steps are to be performed. Procedures describe the process, the hazards, tools, protective equipment, and controls; provide instructions for troubleshooting, emergency shutdown, and special situations; describe the tasks necessary to safely start up, operate, and shutdown processes, including emergency shutdown; and provide formatted instructions.

Operating procedures are important because without written operating procedures a facility can have no assurance that the intended procedures and methods are used by each operator or even that an individual operator will consistently execute a particular task in the intended manner. Operating procedures are also a regulatory requirement for PSM covered facilities in the United States (see section on "Regulations"). The implementation of operating procedures requires the identification of when operating procedures are needed, the development of procedures, the use of procedures to improve human performance and the assurance that procedures are maintained.

Safe Work Practices

Safe work practices help control hazards and manage non-routine work. A non-routine activity is any activity that is not fully described in an operating procedure. Safe work practices typically control hot work, stored energy (lock-out/tag out), opening process vessels or lines, confined space entry, and similar operations as well as other routine highly hazardous operations.

Safe work practices are important because non-routine work increases risk and can lead to conditions that make a catastrophic event more likely. Some examples include:

- Piper Alpha (removal of a pressure safety valve for recertification).
- Nitrogen asphyxiation during confined space entry resulted in 80 fatalities from 1992 to 2002.

There are also regulatory requirements regarding safe work practices in the US.

Asset Integrity and Reliability

Asset integrity and reliability is the systematic implementation of activities, such as inspections and tests necessary to ensure equipment will be suitable for its intended application throughout its life. Specifically, work activities focused on preventing catastrophic release of a hazardous material or sudden release of energy and ensuring high availability or (dependability) of critical safety or utility systems that prevent or mitigate the effects of these types of events.

Asset integrity and reliability is important because designing and maintaining equipment fit for its purpose and functions when needed is paramount in maintaining containment of hazardous materials and ensuring that safety systems work when needed. These are two primary responsibilities for any facility. It is a PSM regulatory requirement under the element mechanical integrity. Mechanical integrity requirements emphasize the safety aspect rather than the reliability aspect, but both are important in managing risk.

Contractor (Safety) Management

Contractor (safety) management is a system of controls to ensure contracted services support both facility operations and the company's process safety and personal safety performance goals. It does not address the procurement of goods and supplies or offsite equipment fabrication functions that are covered by the asset integrity quality assurance function. It involves workers located closest to process hazards and more routine tasks such as janitorial and ground keeping services.

It is important because it facilitates the company in achieving the goals of accessing specialize expertise that is not continuously or routinely required, supplementing limited company resources during periods of unusual demand and providing staff increases without the overhead cost of direct hire employees. Companies and contractors must work together to provide a safe workplace that protects the workforce, the community, and the environment, as well as the welfare and interest of the company.

Training and Performance Assurance

Training is practical instruction in job and task requirements and methods. Performance assurance is the means by which workers demonstrate that they understood the training and can apply it in practical situations.

This element is important because a high level of performance is a critical aspect of any process safety program. A less than adequate level of human performance will adversely affect all aspects of operations. Without an adequate training and performance assurance program, a facility can have no confidence that work tasks will consistently be completed to minimum acceptable standards and in accordance with accepted procedures and practices. The implementation of training and performance assurance involves the principles to identify what training (and retraining) is needed, to provide effective training, and to monitor worker performance.

Management of Change

A change is any change (modification) to process chemicals, technology, equipment, or procedures and changes to facilities that affect a covered process except replacement in kind. A replacement which satisfies the design specification is not a change. Management of change (MOC) helps to ensure that changes to a process do not inadvertently introduce new hazards or unknowingly increase the risk of existing hazards. MOC includes a review and authorization process for evaluating proposed adjustments to facility design, operations, and organizations. It is a system to ensure that all introduced changes are thoroughly scrutinized prior to implementation. More than 80% of large losses are related to change. In a MOC system all changes are evaluated, communicated and coordinated prior to execution. A rational basis is required to initiate the process. MOC applies to physical equipment, products, operating conditions, staffing and including organizational changes.

It is important because if a proposed modification is made to a hazardous process without appropriate review, the risk of a process safety incident could increase significantly. The principles of MOC are to identify potential change situations, evaluate possible impacts, decide whether to allow change, and complete follow-up activities.

Operational Readiness

Operational readiness ensures that shut down processes are verified to be in a safe condition before re-start. It is defined more broadly than OSHA PSM prestart up safety review element because it addresses start up from all shut conditions, not only from those resulting from new or changed processes.

Operational readiness is important because experience has shown that the frequency of incidents is higher during process transitions such as startups.

It is important that the process be verified as safe to start. The principles of operational readiness include the following: to conduct appropriate readiness reviews as needed, make startup decisions based on the readiness results, and to follow through on decisions, actions, and the use of readiness results.

Conduct of Operations

Conduct of operations involves the execution of operational and management tasks in a deliberate and structured manner. It institutionalizes the pursuit of excellence in the performance of every task and minimizes variations in performance. Some companies call this Operating Discipline (walk the talk).

It is important for several reasons. A consistently high level of human performance is a critical aspect of any process safety management program. A less than adequate level of human performance will adversely impact all aspects of operations. As operational activities become more complex, an increase in the formality of operations must also occur to ensure safe, and consistent performance of critical tasks. The principles of conduct of operations include the control operational activities, control the status of systems and equipment, development of required skills/behaviors and the monitoring of organizational performance.

Emergency Management

Emergency management includes:

- Planning for possible emergencies
- Providing resources to execute the plan
- Practicing and continuously improving the plan
- Training or informing employees, contractors, neighbors, and local authorities on what to do, how they will be notified, and how to report an emergency
- Effectively communicating with stakeholders in the event an incident does occur

It is important the consequences of any particular incident can be significantly reduced with effective emergency planning and response. Effective emergency management saves lives and protects property and the environment. It also helps reassure stakeholders that, in spite of the incident, the facility is well managed and should be allowed to continue to operate. It is a PSM Regulatory requirement. The principles of emergency management are to prepare for emergencies, and to periodically test the adequacy of plans and level of preparedness. Chap. 3 , Managing an Emergency

Preparedness Program has an in-depth discussion on this topic.

Learn from Experience

The fourth pillar of process safety management is *Learn from experience*.

To learn from experience facilities should focus on:

- Investigating incidents.
- Applying lessons from incidents that occur at other facilities in the company and the industry.
- Measuring performance and striving to continuously improve in areas of significant risk.
- Auditing RBPS management systems and work activities.
- Holding periodic management review to see if things are working and helping to manage risk.

Incident Investigation

Incident investigation is a process for reporting, tracking, and investigating incidents that includes:

- The trending of incident and incident data to identify reoccurring incidents.
- A formal process for investigating incidents including staffing, performing, documenting, and tracking investigations of process safety incidents.
- Managing the resolution and documentation of recommendations generated by the investigations.

Incident investigation is important for the following reasons. It is a way to learn from incidents and communicate lessons learned to internal personnel and other stakeholders. Feedback can apply to the specific incident or a group of incidents sharing similar root causes. Determination of root causes of equipment failures and personnel errors can result in solutions that reduce the frequency and/or consequences of entire categories of incidents. In the United States it is required for facilities covered by the PSM regulation.

The key principles of incident investigation are to:

- Identify potential incidents for investigation.
- Use appropriate techniques to investigate incidents.
- Document incident investigation results.
- Follow through on the results of investigations.
- Trend data to identify repeat incidents that warrant investigation.

Measurement and Metrics

Measurement and metrics establishes performance and efficiency indicators to monitor the near-time effectiveness of RBPS and address which indicators to consider (leading and lagging), how often to collect data, and what to do to ensure effective RBPS. It is important for several reasons. Facilities should monitor the real-time performance managements systems rather than wait for incidents or for infrequent audits to identify management system failures. Performance monitoring allows problems to be identified and corrective actions taken before a serious incident occurs.

The principles of measurement and metrics are to conducts metric acquisition (determine what measurements are needed and collect them) and to use metrics to make corrective action decisions.

Auditing

Auditing is a systematic, independent review to verify conformance with prescribed standards of care. Auditing employs a well-defined review process to ensure consistency and to allow the auditor to reach defensible conclusions. An RBPS management system audit is the systematic review of RBPS management systems to verify suitability and effective, consistent implementation.

Auditing is important because it evaluates RBPS management systems to ensure they are in place and functioning in a manner that protects employees, customers, communities, and physical assets against process safety risk. Audits are an important control mechanism within the overall management of process safety.

The principles of auditing are to conduct the necessary work activities and to use audits to enhance RBPS effectiveness.

Management Review and Continuous Improvement

Management review and continuous improvement include the routine evaluation of whether management systems are performing as intended and producing the desired results as efficiently as possible. It is important because it provides regular checkups on the health of the process safety management systems in order to identify and correct current or incipient deficiencies before they may be revealed by an audit or incident. In other words, if you are management you can expect what you inspect.

The principles of management review and continuous improvement are to conduct review activities and to monitor organizational performance.

Process Safety in Bioprocess Manufacturing Facilities [45]

CCPS defines bioprocess as “A process that makes use of microorganisms, cells in culture, or enzymes to manufacture products or complete a chemical transformation.” Chapters 30, 31 and 32 in this book discuss these processes in some detail. This section discusses the process safety issues associated with these technologies.

Bioprocessing has been used by humans since prehistoric times. Examples include making bread, making cheese, and fermenting alcoholic beverages. Recent advances include the commercialization of recombinant DNA and the production of a variety of protein based therapeutic drugs. Emerging industries and technologies include the production of biofuels from renewable biomass feed stocks such as ethanol biodiesel and polymeric materials. Other emergency technologies include stem cells, gene therapy vectors, and new vaccines.

Bioprocess have many of the same process safety hazards as chemical manufacturing along with other hazards specific to bioprocess. Biohazards can represent extremely low risk (e.g., most recombinant mammalian cell lines used for large scale production of antibody and protein drugs). However in some cases where infectious organisms are used, or where the culture may be susceptible to adventitious contamination (e.g., contamination of human cell lines with a virus), the hazard may be much more significant and the risk to the workers or the public from an accidental release considerably higher. These hazards require the same risk based process safety management systems already discussed.

In addition to the toxic, flammable, or explosive process safety risk that may be present in a bioprocessing facility, risk based process safely management systems must account for biohazard or potentially biohazard materials including the following:

- Biological agent:
  - Pathogenicity
  - Infectious dose
  - Virulence (primary or secondary communicability)
  - Host factors (immunocompetence, pregnancy, underlying medical conditions, extreme age, or immunity
  - Sensitization reactions (allergies, toxins, or biologically active compounds)
  - Incidents of laboratory acquired infections (LAI)
  - Availability of vaccine and/or prophylactic treatment
  - Environmental impact (agent stability—sensitivity to chemical or physical inactivation—survivability and dissemination in the environment)
- Routes/Modes of transmission in the workplace:
  - Respiratory: inhaling of contaminated particles
  - Mucous membrane: splashing, spraying, or droplets in the eyes or mouth
  - Parenteral: penetration through the skin such as cuts, needle sticks, or abrasions
  - Non-intact skin: contact with skin affected with dermatitis, chaffing, hangnails, abrasions, acne, or other conditions that can alter the barrier properties of the skin)
  - Ingestion: swallowing contaminated material
  - Adsorption: adhesion to a surface
- Environmental factors:
  - Climate
  - Geography
  - Proximity to the public
- Procedural and facility factors:
  - Ventilation and laboratory design: directional air, pressure gradients, separation of laboratories from offices, interlocking autoclave and airlock doors
  - Laboratory procedures: use of inherently safer engineered sharps, containment of aerosols, and other means
  - Containment equipment: Class II and III biological safety cabinets, sealed centrifuges, cups and rotors, gasket seals and unbreakable tubes
  - PPE: gloves, safety glasses, lab coats, face masks, respirators or gowns
  - Training: standard microbiological practice, aseptic practices, decontamination, spill cleanup, and handling of accidents
  - Facility sanitation: decontamination, housekeeping, routine cleaning and disinfection, pest and rodent control program
  - Medical surveillance: as dictated by the risk present in the bioprocessing facility

1. For a complete discussion of the topic refer [45].

Regulations[1]

Regulations are a major consideration in the design and operation of chemical facilities. This section provides a description of the significant process requirements. Details of the regulations are available on the Internet or from government agencies, such as the US Department of Labor, or from publications such as those produced by the Thompson Publishing Group and by Primatech, Inc.

Abbreviations used in Government Regulations information:

CFR	Code of Federal Regulations
EPA	Environmental Protection Agency
EPCRA	Emergency Planning and Community Right To Know Act
HAZWHOPER	Hazardous Waste Operations and Response Emergency
HHC	Highly Hazardous Chemicals
MSDS	Material Safety Data Sheet

(continued)

---

[1] This section was prepared with the help of William Carmody, Midland, Michigan. Carmody has had more than 30 years experience in chemical and manufacturing operations for The Dow Chemical Company, Midland, Michigan and six years in Safety and Loss Consulting for Midland Engineering Limited, Midland, Michigan. He has developed entire PSM programs and has conducted many Process Hazard Analyses.

RMP	Risk Management Plans
SARA	Superfund Amendments and Reauthorization Act
TRI	Toxics Release Inventory

Process Safety Management

On February 24, 1992, the US Department of Labor, Occupational Safety and Health Administration (OSHA) promulgated a final rule, 29 CFR Part 1910.119, "Process Safety Management of Highly Hazardous Chemicals."

OSHA administrates regulations whose objectives are primarily involved with protecting workers. This can be regarded as "inside the fence line." This is a safety issue and is addressed in this section. The rule requires employers to effectively manage the process hazards associated with chemical processes to which the rule applies. OSHA is responsible for the Process Safety Management (PSM) program that is used to prevent or minimize the consequences of catastrophic releases of toxic, reactive, flammable, or explosive chemicals. Standard Number CFR 1910.119 contains requirements for preventing or minimizing the consequences of catastrophic releases of toxic, reactive, flammable, or explosive chemicals. It establishes procedures for PSM that will protect employees by preventing or minimizing the consequences of chemical accidents involving highly hazardous chemicals. The requirements in this standard are intended to eliminate or mitigate the consequences of such releases.

PSM applies to a process involving a chemical at or above the specified threshold quantities listed in 1910.119, Appendix A, and also listed in Table 2.9. The requirements of the rule are also applicable to processes that involve a flammable liquid or gas on-site, in one location, in a quantity of 10,000 lb or more, except for hydrocarbon fuels used solely for workplace consumption as a fuel, or flammable liquids stored in atmospheric pressure tanks.

Process means any activity involving a highly hazardous chemical including any use, storage, manufacturing, handling, or the on-site movement of such chemicals, or combination of these activities. For purposes of this definition, any group of vessels that are interconnected and separate vessels which are located such that a highly hazardous chemical could be involved in potential release shall be considered a single process.

The PSM elements required by 29 CFR Part 1910.119 are briefly described in the following.

Employee participation: Employers must develop a written plan of action for how they will implement employee participation requirements. Employers must consult with employees, affected contractors, and their representatives on the conduct and development of process hazard analyses and on other elements of the standard. They must have access to information developed from the standard, including process hazard analyses.

Process safety information: Employers must compile considerable documented process safety information on the hazards of chemicals used in a covered process as well as information on the process technology and equipment before conducting the process hazard analyses required by the standard.

Process hazard analysis (*PHA*): Employers must perform an analysis to identify, evaluate, and control hazards on processes covered by this standard. The PHA shall be appropriate to the complexity of the process and shall identify, evaluate, and control the hazards involved in the process. The OSHA standard specifies a number of issues that the analysis must address, as well as requirements for who must conduct the analysis, how often it must be performed, and response to its findings. Methodologies that are appropriate include:

- What-if
- Checklists
- What-if/checklist
- HAZOP Study
- Failure Mode and Effects Analysis (FMEA)
- Fault tree analysis

The selection of a PHA methodology or technique will be influenced by many factors including the amount of existing knowledge about the process. All PHA methodologies are subject to certain limitations. The team conducting the PHA needs to understand the methodology that is going to be used. A PHA team can vary in size from two people to a number of people with varied operational and technical backgrounds. Some team members may only be a part of the team for a limited time. The team leader needs to be fully knowledgeable in the proper implementation of the PHA methodology that is to be used and should be impartial in the evaluation. The other full- or part-time team members need to provide the team with expertise in areas such as process technology, process design, operating procedures, and practices.

Standard Number: 1910.119 Appendix A (on the Internet).

This is a listing of toxic and reactive highly hazardous chemicals that present a potential for a catastrophic event at or above the threshold quantity.

Operating procedures: Employers must develop and implement written operating instructions for safely conducting

Table 2.9 List of highly hazardous chemicals, toxics, and reactive chemicals (mandatory)

Chemical name	CAS[a]	Threshold quantity
Acetaldehyde	75–07–0	2,500
Acrolein (2-Popenal)	107–02–8	150
Acrylyl chloride	814–68-6	250
Allyl chloride	107-05-1	1,000
Allylamine	107–11–9	1,000
Alkylaluminum	Varies	5,000
Ammonia, anhydrous	7664–41–7	10,000
Ammonia solutions (greater than 44% ammonia by weight)	7664–41–7	15,000
Ammonium perchlorate	7790–98–9	7,500
Ammonium permanganate	7787–36–2	7,500
Arsine (also called arsenic hydride)	7784–42–1	100
Bis(chloromethyl) ether	542–88–1	100
Boron trichloride	10294–34–5	2,500
Boron trifluoride	7637–07–2	250
Bromine	7726–95–6	1,500
Bromine chloride	13863–41–7	1,500
Bromine pentafluoride	7789–30–2	2,500
Bromine trifluoride	7787–71–5	15,000
3-Bromopropyne (also called propargyl bromide)	106–96–7	100
Butyl hydroperoxide (tertiary)	75–91–2	5,000
Butyl perbenzoate (tertiary)	614–45–9	7,500
Carbonyl chloride (see Phosgene)	75–44–5	100
Carbonyl fluoride	353–50–4	2,500
Cellulose nitrate (concentration greater than 12.6% nitrogen)	9004–70–0	2,500
Chlorine	7782–50–5	1,500
Chlorine dioxide	10049–04–4	1,000
Chlorine pentrafluoride	13637–63–3	1,000
Chlorine trifluoride	7790–91–2	1,000
Chlorodiethylaluminum(also called diethylaluminum chloride)	96–10–6	5,000
1-chloro-2, 4-dinitrobenzene	97–00–7	5,000
Chloromethyl methyl ether	107–30–2	500
Chloropicrin	76–06–2	500
Chloropicrin and methyl Bromide mixture	None	1,500
Chloropicrin and methyl Chloride mixture	None	1,500
Commune hydroperoxide	80–15–9	5,000
Cyanogen	460–19–5	2,500
Cyanogen chloride	506–77–4	500
Cyanuric fluoride	675–14–9	100
Diacetyl peroxide (concentration greater than 70%)	110–22–5	5,000
Diazomethane	334–88–3	500
Dibenzoyl peroxide	94–36–0	7,500
Diborane	19287–45–7	100
Dibutyl peroxide (tertiary)	110–05–04	5,000
Dichloro acetylene	7572–29–4	250
Dichlorosilane	4109–96–0	2,500
Diethylzinc	557–20–0	10,000
Diisopropyl peroxydicarbonate	105–64–6	7,500
Dilauroyl peroxide	105–74–8	7,500
Dimethyldichlorosilane	75–78–5	1,000
Dimethylhydrazine, 1,1-	57–14–7	1,000
Dimethylamine, anhydrous	124–40–3	2,500
2,4-dinitroaniline	97–02–9	5,000
Ethyl methyl ketone peroxide (also methyl ethyl ketone peroxide; concentration greater than 60%)	1338–23–4	5,000

(continued)

Table 2.9 (continued)

Chemical name	CAS[a]	Threshold quantity
Ethyl nitrite	109–95–5	5,000
Ethylamine	75–04–7	7,500
Ethylene fluorohydrin	371–62–0	100
Ethylene oxide	75–21–8	5,000
Ethyleneimine	151–56–4	1,000
Fluorine	7782–41–4	1,000
Formaldehyde (formalin)	50–00–0	1,000
Furan	110–00–9	500
Hexafluoroacetone	684–16–2	5,000
Hydrochloric acid, anhydrous	7647–01–0	5,000
Hydrofluoric acid, anhydrous	7664–39–3	1,000
Hydrogen bromide	10035–10–6	5,000
Hydrogen chloride	7647–01–0	5,000
Hydrogen cyanide, anhydrous	74–90–8	1,000
Hydrogen fluoride	7664–39–3	1,000
Hydrogen peroxide (52% by weight or greater)	7722–84–1	7,500
Hydrogen selenide	7783–07–5	150
Hydrogen sulfide	7783–06–4	1,500
Hydroxylamine	7803–49–8	2,500

Trichlorosilane	10025–78–2	5,000
Trifluorochloroethylene	79–38–9	10,000
Trimethyoxysilane	2487–90–3	1,500

[a]Chemical abstract service number

[b]Threshold quality in pounds (amount necessary to be covered by this standard)

activities involved in each covered process consistent with the process safety information. The written procedures must address steps for each operating phase, operating limits, safety and health considerations, and safety systems and their functions. Included must be normal operation, startup, shutdown, emergency operations, and other operating parameters.

Training: The proposal requires training for employees involved in covered processes. Initial training requires all employees currently involved in each process, and all employees newly assigned, be trained in an overview of the process and its operating procedures. Refresher training shall be provided at least every 3 years, and more often if necessary, to each employee involved in the process. After training, employees must ascertain that workers have received and understood the training.

Contractors: Employers must inform contract employees prior to the initiation of the contractor's work of the known potential fire, explosion, or toxic release hazards related to the contractor's work and the process. Contract employees and host employers must ensure that contract workers are trained in the work practices necessary to perform their jobs safely and are informed of any applicable safety rules of the facility work and the process.

Pre-startup safety review: Employers must perform a pre-startup safety review for new facilities and for modified facilities when the modification is significant enough to require a change in the process safety information. The safety review shall confirm that prior to the introduction of highly hazardous chemicals to a process:

1. Construction and equipment is in accordance with design specifications.

2. Safety, operating, maintenance, and emergency procedures are in place and are adequate.
3. For new facilities, a PHA has been performed and recommendations have been resolved or implemented before startup.
4. Modified facilities meet the requirements contained in management of change.

Mechanical integrity: Employers must ensure the initial and on-going integrity of process equipment by determining that the equipment is designed, installed, and maintained properly. The standard requires testing and inspection of equipment, quality assurance checks of equipment, spare parts and maintenance materials, and correction of deficiencies. The following process equipment is targeted in this proposal: pressure vessels and storage tanks; piping systems (including valves); relief and vent systems and devices; emergency shutdown systems; controls, and pumps.

Hot work permit: Employers must have a hot work program in place and issue a permit for all hot work operations conducted on or near a covered process.

Management of change: Employers must establish and implement written procedures to manage changes (except for "replacements in kind") to process chemicals, technology, equipment, and procedures; and, changes to facilities that affect a covered process. Employees involved in operating a process and maintenance and contract employees whose tasks will be affected by a change in the process shall be informed of, and trained in, the change prior to startup of the process or affected part of the process. The procedures shall ensure that the necessary time period for the change and authorization requirements for the proposed change are addressed.

Incident investigation: Employers must investigate each incident that resulted in, or could reasonably have resulted in a catastrophic release of highly hazardous chemical in the workplace. An incident investigation shall be initiated as promptly as possible, but not later than 48 h following the incident. A report shall be prepared at the conclusion of the investigation.

Although not stressed by the regulations, the objective of the incident investigation should be the development and implementation of recommendations to ensure the incident is not repeated. This objective should apply not only to the process involved, but also to all similar situations having the same potential. In major incidents, the Chemical Safety Board's investigation of reports serves as a vehicle to communicate to a much broader audience than the organizations that had the incident.

Emergency planning and response: Employers must establish and implement an emergency action plan for the entire plant in accordance with the provisions of OSHA's emergency action plan to meet the minimum requirements for emergency planning. This is the only element of PSM that must be carried out beyond the boundaries of a covered process.

Compliance audits: Employers must certify that they have evaluated compliance with the provisions of this section at least every 3 years to verify that procedures and practices developed under the standard are adequate and are being followed. The compliance audit shall be conducted by at least one person knowledgeable in the process. The employer shall determine and document an appropriate response to each of the findings of the compliance audit, and document that deficiencies have been addressed.

Trade secrets: Employers must make all information necessary to comply with the requirements of this section available to those persons responsible for compiling the process safety information, developing process hazard analyses, developing the operating procedures, those involved in incident investigations, emergency planning, and response and compliance audits without regard to possible trade secret status of such information. Nothing in this paragraph shall preclude the employer from requiring the persons to whom the information is made available to enter into confidentiality agreements not to disclose the information.

The above elements outline the programs required by PSM. These programs are performance-type standards. They spell out programs and choices and are not limited to specific details. These elements have served to organize and guide the process safety programs of all who are covered by it. They have served to bring direction to training and publications involving process safety. The AIChE's Center for Chemical Process Safety has publications and training programs to support most of these elements.

Risk Management Plans

The EPA is charged primarily with the responsibility to protect the public and the environment. One could regard this as "outside the fence line." Risk management plans (RMPs) are required by the Environmental Protection Agency (EPA). Since protecting the public and the environment is mainly an environmental issue rather than a safety issue, this subject will be covered only briefly in this section.

Congress enacted Section 112(r) of the 1990 Clean Air Act (CAA) to address the threat of catastrophic releases of chemicals that might cause immediate deaths or injuries in communities. It requires owners and operators of covered facilities to submit RMPs to the EPA. The final RMP rule was published in 40 CFR 68 in the Federal Register on June 20, 1996. RMPs must summarize the potential threat of sudden, large releases of certain dangerous chemicals and facilities' plans to prevent such releases and mitigate any damage.

Operators of facilities that are subject to the EPA's RMP must perform offsite consequence analyses to determine whether accidental releases from their processes could put nearby populations at risk. In performing a consequence analysis it is assumed that all or part of a hazardous substance escapes from a process at a given facility. It is then estimated how far downwind hazardous gas concentrations may extend.

Facilities that must prepare and submit RMPs must estimate the offsite consequences of accidental releases. This can be done using tables (such as those provided in CAA 112 (r) Offsite Consequence Analysis) or a computerized model. There are a number of commercially available computer models. Submitters are expected to choose a tool that is appropriate for their facility.

The owners and operators of stationary sources producing, processing, handling, or storing of extremely hazardous substances have a general duty to identify hazards that may result from an accidental release This includes agents that may or may not be identified by any government agency which may cause death, injury, or property damage. In other words, just because a substance is not listed is not an excuse to fail to consider its hazards.

This section with its emphasis on Process Safety does not cover the considerable other safety, design, and operating requirements of other chemical-related regulations. Many of these requirements also include national codes as guidelines or as adopted regulations. Examples of these are in the American Society of Mechanical Engineers (ASME) *2001 Boiler Pressure Vessel Code*, the National Fire Protection Association (NFPA) which covers a wide range of fire safety issues and the American Petroleum Institute (API) *Recommended Practice 520, Sizing, Selection, and Installation of Pressure Relieving Devices in Refineries.*

An extremely hazardous substance is any agent that may or may not be listed by any government agency which, as the result of short-term exposures associated with releases to the air, cause death, injury, or property damage due to its toxicity, reactivity, flammability, volatility, or corrosivity.

Toxics Release Inventory

Two statutes, the Emergency Planning and Community Right-to-Know Act (EPCRA) and Section 6607 of the Pollution Prevention Act (PPA), mandate that a publicly accessible toxic chemical database be developed and maintained by the US EPA. This database, known as the Toxics Release Inventory (TRI), contains information concerning waste management activities and the release of toxic chemicals by facilities that manufacture, process, or otherwise use these materials. The TRI of 1999 is a publicly available database containing information on toxic chemical releases and other waste management activities that are reported annually by manufacturing facilities and facilities in certain other industry sectors, as well as by federal facilities. The TRI program is now under the EPA's Office of Environmental Information. This inventory was established under the EPCRA of 1986 which was enacted to promote emergency planning, to minimize the effects of chemical accidents, and to provide the public. As of November 2001, there were 667 toxic chemicals and chemical compounds on the list.

Hazardous Waste Operations and Emergency Response Standard

The Hazardous Waste Operations and Emergency Response (HAZWOPER) standard, 29 CFR Part 1910.120, applies to five distinct groups of employers and their employees. This includes any employees who are exposed or potentially exposed to hazardous substances—including hazardous waste—and who are engaged in one of the following operations as specified by 1910.120:

- Clean-up operations
- Corrective actions
- Voluntary clean-up operations
- Operations involving hazardous wastes
- Emergency response operations for releases of, or substantial threats of release of, hazardous substances regard less of the location of the hazard.

In addition, with the passage of the Pollution Prevention Act (PPA) in 1991, facilities must report other waste management amounts including the quantities of TRI chemicals recycled, combusted for energy recovery, and treated on- and offsite.

More Information

For more information on Regulations, the books, magazine articles, and Internet references in the reference section can be very helpful. Following the requirements of the many aspects of Regulations can be quite complicated and involve a lot of detail. There is a considerable amount of good assistance available which help can make the subject manageable.

The Principal Reason for Most Chemical Process Accidents

Ask any group of people experienced in chemical plant operations what causes most chemical process accidents, and you will get a variety of answers including: operator error, equipment failure, poor design, act of God, and bad luck. However, in the opinion of representatives of many of the large chemical and oil companies in the United States, these answers are generally incorrect. The Center for Chemical Process Safety, an organization sponsored by the American Institute of Chemical Engineers, includes representatives of many of the largest chemical and oil companies in the United States and the world, and states that "It is an axiom that process safety incidents are the result of *management system failure*." Invariably, some aspect of a process safety management system can be found that, had it functioned properly, could have prevented an incident (or reduced the seriousness of it). "It is a rare situation where an "Act of God" or other uncontrollable event is the sole cause of an incident. Much more common is the situation where an incident is the result of multiple causes, including management system failures. Therefore, it is more appropriate to presume that management system failures underlie every incident so that we may act to uncover such failures and then modify the appropriate management systems, rather than presume that if an "Act of God" appears to be the immediate cause, investigation should cease because there is nothing that can be done to prevent such future incidents" [17].

For example, consider a case where a small amount of hazardous material is spilled while a sample is being taken from a process line. It is not enough to look into the situation and conclude that this is an example of an operator error where procedures were not followed, and then simply to recommend that the employee be instructed to follow procedures in the future. Further investigation may reveal deficiencies in the training system or in the equipment. Still more investigation may reveal deficiencies in the management system that plans resources for training or that provides for proper equipment for sampling. It then may be appropriate to change the management system to prevent repetition of the incident.

Levels of Causes

There are several levels of causes of accidents, usually (1) the immediate cause, (2) contributing causes to the accident or to the severity of the accident, and (3) the "root cause." The root cause is what really caused the accident, and when this is determined, it may be possibly to *prevent* future similar accidents. With the 20–20 hindsight that is available after an accident, the root cause usually can be found. The purpose of the discussion in the next section is to illustrate how knowledge about the root causes of some important accidents can help to keep them from happening again. It will be noted that the root cause is rarely the fault of one person, but instead is the result of a management system that does not function properly.

Following are brief analyses of several case histories that have been of landmark importance in the industrial world, and that have affected the chemical industry all over the world.

Case Histories

Flixborough, England 1974 [19]

On June 1, 1974, an accident occurred in the Nypro plant in Flixborough, England, in a process where cyclohexane was oxidized to cyclohexanone for the manufacture of caprolactam, the basic raw material for the production of Nylon 6. The process consisted of six reactors in series at 155°C and 8.8 bar (130 psig) containing a total of 120 t of cyclohexane and a small amount of cyclohexanone. The final reactor in the process contained 94% cyclohexane. There was a massive leak followed by a large UVCE and fire that killed 26 people, injured 36 people, destroyed 1,821 houses, and damaged 167 shops. It was estimated that 30 t of cyclohexane was involved in the explosion. The accident occurred on Saturday; on a working day, casualties would have been much higher.

The accident happened when the plant had to replace one of six reactors and rushed to refit the plant to bypass the disabled reactor. Scaffolding was jerry-rigged to support a 20-in. pipe connecting reactor four with reactor six, which violated industry and the manufacturer's recommendations. The reactor that failed showed stress crack corrosion. The only drawings for the repair were in chalk on the machine shop floor. Both ends of the 20-in. pipe had expansion joints where they attached to the reactors. The pipe was supported on scaffolding-type supports and was offset with a "dog-leg" to fit the reactors, which were at different levels to promote gravity flow. The safety reviews, if any, were insufficient.

Immediate cause: A pipe replacing a failed reactor failed, releasing large quantities of hot cyclohexane forming a vapor cloud that ignited.

Contributing causes to the accident and the severity of the accident:

1. The reactor failed without an adequate check on why (metallurgical failure).

2. The pipe was connected without an adequate check on its strength and on inadequate supports.
3. Expansion joints (bellows) were used on each end of pipe in a "dog-leg" without adequate support, contrary to the recommendations of the manufacturer.
4. There was a large inventory of hot cyclohexane under pressure.
5. The accident occurred during startup.
6. The control room was not built with adequate strength, and was poorly sited.
7. The previous works engineer had left and had not been replaced. According to the Flixborough Report, "There was no mechanical engineer on site of sufficient qualification, status or authority to deal with complex and novel engineering problems and insist on necessary measures being taken."
8. The plant did not have a sufficient complement of experienced people, and individuals tended to be overworked and liable to error.

Root cause: Management systems deficiencies resulted in:

1. A lack of experienced and qualified people
2. Inadequate procedures involving plant modifications
3. Regulations on pressure vessels that dealt mainly with steam and air and did not adequately address hazardous materials
4. A process with a very large amount of hot hydrocarbons under pressure and well above its flash point installed in an area that could expose many people to a severe hazard

This accident resulted in significant changes in England and the rest of the world in the manner in which chemical process safety is managed by industry and government. One of the conclusions reached as a result of this accident, which has had a wide effect in the chemical industry, is that "limitations of inventory (or flammable materials) should be taken as specific design objectives in major hazard installations."

The use of expansion joints (bellows, in this case) which were improperly installed may have been a principal reason for the accident. This provides additional reasons not to use expansion joints (except in special exceptional circumstances).

Bhopal, 1985 (C&EN Feb 11, 1985; Technica 1989 [41])

On December 3 and 4, 1985, a chemical release causing a massive toxic gas cloud occurred at the Union Carbide India, Ltd, plant in Bhopal, India. (Union Carbide is now a part of The Dow Chemical Company.) The process involved used methyl isocyanate (MIC), an extremely toxic chemical, to make Sevin, a pesticide. According to various authoritative reports, about 1,700–2,700 (possibly more) people were killed, 50,000 people were affected seriously, and 1,000,000 people were affected in some way. The final settlement may involve billions of dollars. It was one of the worst industrial accidents in history. The accident occurred when about 120–240 gal of water were allowed to contaminate an MIC storage tank. The MIC hydrolyzed, causing heat and pressure, which in turn caused the tank rupture disk to burst.

Equipment designed to handle an MIC release included a recirculating caustic soda scrubber tower and a flare system designed for 10,000 lb/h, which would be moderate flows from process vents. It was not designed to handle runaway reactions from storage. The design was based on the assumption that full cooling would be provided by the refrigeration system. The actual release was estimated to be 27,000 lb over 2 h, with the tank at 43°C. At the time of the release the refrigeration had been turned off. The flare tower was shut down for repairs. A system of pressurized sprinklers that was supposed to form a water curtain over the escaping gases was deficient, in that water pressure was too low for water to reach the height of the escaping gas.

There have been conflicting stories of how the water got into the tank, including operator error, contamination, and sabotage.

Immediate cause: The immediate cause was hydrolysis of MIC due to water contamination. The exact source of the water has not been determined.

Contributing causes

1. Flare tower was shut down for repair.
2. Scrubber was inadequate to handle a large release.
3. Chilling system was turned off. (It also was too small.)
4. MIC tank was not equipped with adequate instrumentation.
5. Operating personnel lacked knowledge and training.
6. The inventory of MIC was large.
7. There was a lack of automatic devices and warning systems; it has been reported that safety systems had to be turned on manually.
8. When the plant was built, over 20 years before the accident, there were very few people near it. At the time of the accident, a shanty town had grown up near the plant with a density of 100 people per acre, greatly increasing the potential exposure of people to toxic releases. There was no emergency action plan to notify neighbors of the potential for toxic releases or of what to do if there was a release, nor was there a functioning alarm system.

Root cause: The root cause of the accident appears to be a management system that did not adequately respond to the potential hazards of MIC. There was probably a greater inventory of MIC than was needed. The main process expertise was in the United States. Local management does not appear to have understood the process or the consequences of changes made. This includes plant design, maintenance and operations, backup systems, and community responsibility. (Union Carbide has provided legal arguments alleging that sabotage caused the release; there appears to be enough blame to go around for all those involved in any way in the plant, including government units.)

This accident has become widely known. It is an objective of many chemical process safety programs and government actions to "avoid another Bhopal"—that is, to avoid a severe release of toxic chemicals (usually referring to toxic chemicals in the air). Almost every chemical company in the world has been affected by this incident in one way or another, in the design and operation of chemical plants, in community action programs, and in the activities of such organizations as the American Institute of Chemical Engineers, the Chemical Manufacturers Association (now the American Chemistry Council), and many governmental units.

Phillips Explosion, 1989 [37]

On October 23, 1989, at approximately 1,300, an explosion and fire ripped through the Phillips 66 Company's Houston Chemical Complex in Pasadena, Texas. At the site, 23 workers were killed, and more than 130 were injured. Property damage was nearly $750 million. Business interruption cost is not available but is probably a very large figure.

The release occurred during maintenance operations on a polyethylene reactor. Two of the six workers on the maintenance crews in the immediate vicinity of the reactor leg where the release occurred were killed, together with 21 other employees of the facility. Debris from the plant was found 6 miles from the explosion site. Structural steel beams were twisted like pretzels by the extreme heat. Two polyethylene production plants covering an area of 16 acres were completely destroyed.

The Phillips complex produces high-density polyethylene, which is used to make milk bottles and other containers. Prior to the accident, the facility produced approximately 1.5 billion pounds of the material per year. It employed 905 company employees and approximately 600 daily contract employees. The contract employees were engaged primarily in regular maintenance activities and new plant construction.

The accident resulted from a release of extremely flammable process gases that occurred during regular maintenance operations on one of the plant's polyethylene reactors. It is estimated that within 90–120 s more than 85,000 lb of flammable gases were released through an open valve. A huge flammable vapor cloud was formed that came into contact with an ignition source and exploded with the energy of 4,800 lb of TNT. The initial explosion was equivalent to an earthquake with a magnitude of 3.5 on the Richter scale. A second explosion occurred 10–15 min later when two isobutane tanks exploded. Each explosion damaged other units, creating a chain reaction of explosions. One witness reported hearing ten separate explosions over a 2-h period.

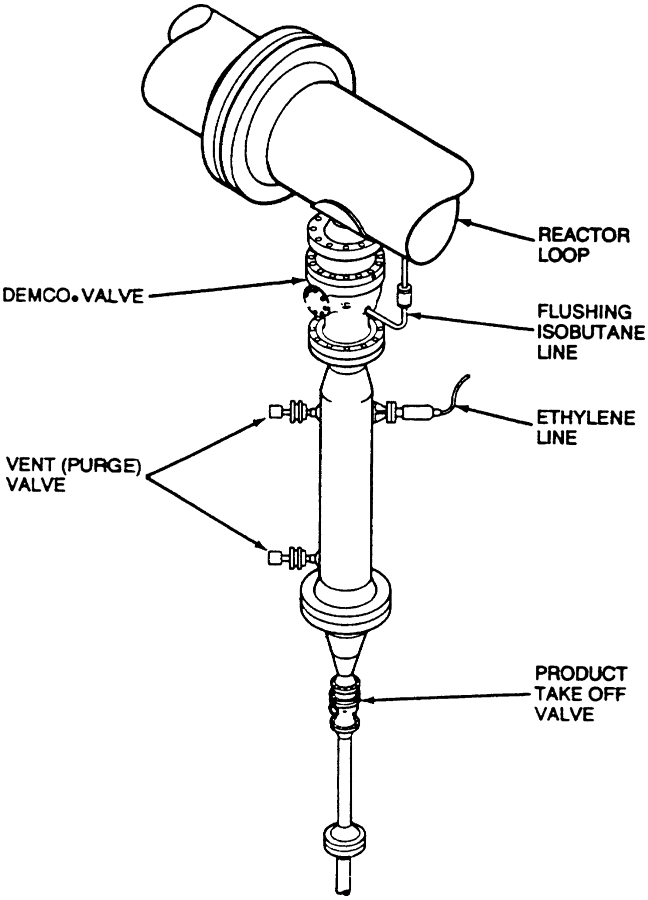

Fig. 2.16 Typical piping settling leg arrangement

In the process used by Phillips at this site to produce high-density polyethylene, ethylene gas is dissolved in isobutane and, with various other chemicals added, is reacted in long pipes under elevated pressure and temperature. The dissolved ethylene reacts with itself to form polyethylene particles that gradually come to rest in settling legs, where they are eventually removed through valves at the bottom. At the top of the legs there is a single ball valve (DEMCO® brand) where the legs join with other reactor pipes. The DEMCO valve is kept open during production so that the polyethylene particles can settle into the leg. A typical piping settling leg arrangement is shown in Fig. 2.16.

In the Phillips reactor, the plastic material frequently clogged the settling legs. When this happened, the DEMCO valve for the blocked leg was closed, the leg disassembled, and the block removed. During this particular maintenance process, the reactor settling leg was disassembled and the block of polymer removed. While this maintenance process was going on, the reaction continued, and the product settled in the legs that remained in place. If the DEMCO valve were to open during a cleaning-out operation, there would be nothing to prevent the escape of the gas to the atmosphere.

After the explosion it was found that the DEMCO valve was open at the time of the release. The leg to be cleaned had been prepared by a Phillips operator. The air hoses that operated the DEMCO valve were improperly connected in a reversed position such that a closed DEMCO valve would be opened when the actuator was in the closed position. In addition, the following unsafe conditions existed:

1. The DEMCO valve did not have its lock out device in place.
2. The hoses supplied to the valve actuator mechanism could be connected at any time even though the Phillips operating procedure stipulated that the hoses should never be connected during maintenance.
3. The air hoses connecting the open and closed sides of the valve were identical, thus allowing the hoses to be cross-connected and permitting the valve to be opened when the operator intended to close it.
4. The air supply valves for the actuator mechanism air hoses were in the open position so that air would flow and cause the actuator to rotate the DEMCO valve when the hoses were connected.
5. The DEMCO valve was capable of being physically locked in the open position as well as in the closed position. The valve lockout system was inadequate to prevent someone from inadvertently opening the DEMCO valve during a maintenance procedure.

Established Phillips corporate safety procedures and standard industry practice require back-up protection in the form of a double valve or blind flange insert whenever a process or chemical line in hydrocarbon service is opened. According to OSHA, Phillips had implemented a special procedure for this maintenance operation that did not incorporate the required backup. Consequently, none was used on October 23.

The consequences of the accident were exacerbated by the lack of a water system dedicated to fire fighting, and by deficiencies in the shared system. When the process water system was extensively damaged by the explo-sion, the plant's water supply for fighting fires was also disrupted. The water pressure was inadequate for fire fighting. The force of the explosion ruptured water-lines and adjacent vessels containing flammable and combustible materials. The ruptured water lines could not be isolated to restore water pressure because the valves to do so were engulfed in flames. Of the three backup diesel pumps, one had been taken out of service and was unavailable, and another soon ran out of fuel. It was necessary to lay hoses to remote sites—settling ponds, a cooling tower, a water treatment plant, and so on. Electric cables supplying power to regular service pumps were damaged by fire, and those pumps were rendered inoperable. Even so, the fire was brought under control within 10 h.

In the months preceding the explosion, according to testimony, there had been several small fires, and the alarm had sounded as many as four or five times a day. There had been a fatality at the same plant doing a similar operation about 3 months before this incident. Some of the employees in the area where the release occurred may not have heard the siren because of the ambient noise level, and may not have known of the impending disaster. Employees in the immediate area of the release began running as soon as they realized the gas was escaping.

The large number of fatalities was due in part to the inadequate separation between buildings in the complex. The site layout and the proximity of normally high-occupancy structures, such as the control and finishing building, to large-capacity reactors and hydrocarbon vessels contributed to the severity of the event.

The distances between process equipment were in violation of accepted engineering practices and did not allow personnel to leave the polyethylene plants safely during the initial vapor release; nor was there sufficient separation between reactors and the control room to carry out emergency shutdown procedures. The control room, in fact, was destroyed by the initial explosion. Of the 22 victims' bodies recovered at the scene, all were located within 250 ft of the vapor release point.

OSHA's investigation revealed that a number of company audits had identified unsafe conditions but largely had been ignored. Thus, a citation for willful violations of the OSHA "general duty" clause was issued to Phillips with proposed penalties of $5,660,000. In addition, proposed penalties of $6,200 were issued for other serious violations. A citation for willful violations with proposed penalties of $724,000 was issued to Fish Engineering and Construction, a Phillips maintenance contractor. Other financial penalties have been proposed. In the investigation it became apparent that Fish had become accustomed to tolerating safety and health violations at the site by its personnel and Phillips personnel, as well as participating in those violations by knowing about them and not taking direct positive action to protect its employees.

Since 1972, OSHA has conducted 92 inspections in the Dallas region at various Phillips locations; 24 were in response to a fatality or a serious accident. OSHA determined that Phillips had not acted upon reports by its own safety personnel and outside consultants who had pointed out unsafe conditions. OSHA also had conducted 44 inspections of the Fish Company, seven of them in response to a fatality or a serious accident.

One of the major findings by OSHA was that Phillips had not conducted a PHA or equivalent (such as HAZOP) in its polyethylene plants.

Immediate cause: There was a release of flammable process gases during the unplugging of Number 4 Reactor Leg on Reactor 6 while undergoing a regular maintenance procedure by contractor employees. The unconfined flammable vapor cloud was ignited and exploded with devastating results.

The immediate cause of the leak was that a process valve was opened by mistake while the line was open. The valve was open to the atmosphere without a second line of defense such as another valve or a blind flange.

Contributing causes to the accident and the severity of the accident.

1. Procedures to require backup protection in the form of a double valve or a blind flange insert were not used. The lockout system was inadequate.
2. Air hoses were improperly connected in the reversed position.
3. The air hoses for the open and closed side of the valve were identical, allowing the hoses to be cross-connected.
4. The DEMCO valve actuator mechanism did not have its lockout device in place.
5. There was not a water system dedicated to fire fighting, and there were deficiencies in the system shared with the process.
6. The site layout and proximity of high-occupancy structures contributed to the severity.
7. There was inadequate separation of buildings within the complex. Especially, there was inadequate spacing between the reactors and the control room.

Root causes: The root causes of the accident and its extreme severity appear to be failures of the management system, as shown by the following: [37]

1. According to OSHA, Phillips had not conducted a PHA or equivalent (such as HAZOP) in its polyethylene plants.
2. It was found by OSHA that the contractor, Fish Engineering, had a history of serious and willful violations of safety standard, which Phillips had not acted upon. The same contractor also had been involved in a fatal accident at the same facility 3 months earlier.
3. A report by OSHA stated that Phillips had not acted upon reports issued previously by the company's own safety personnel and outside consultants. Phillips had numerous citations from OSHA since July 1972. OSHA discovered internal Phillips documents that called for corrective action but which were largely ignored.
4. Safe operating procedures were not required for opening lines in hazardous service.
5. An effective safety permit system was not enforced with Phillips or contractor employees, especially line opening and hot work permits.
6. Buildings containing personnel were not separated from process units in accordance with accepted engineering principles, or designed with enough resistance to fire and explosion.
7. The fire protection system was not maintained in a state of readiness:
    (a) One of the three diesel-powered water pumps had been taken out of service.
    (b) Another of the three diesel-powered water pumps was not fully fueled, and it ran out of fuel during the fire fighting.
    (c) Electric cables supplying power to regular service fire pumps were not located underground and were exposed to blast and fire damage.

Summary

As the tragic case histories illustrate, the importance of the risk based process safety practices presented in this chapter to prevent and mitigate potential catastrophic process safety incidents in the future becomes alarmingly apparent, and the necessity for risk based process design is clear. The case histories also reveal significant flaws in the management systems necessary to ensure that good process safety practices are followed. Even a process designed according to principals of process safety can be transformed into one with a high potential for disaster if risk based process safety management systems are not in place to ensure that good process safety practices are followed throughout the life cycle of the process.

Because there is always risk when equipment, instrumentation, and human activity are involved, there is no way to make a plant completely safe. However, facilities can be made risk tolerant by careful examination of all aspects of design and management, using modern techniques that are now available. If the process safety performance and public image of the chemical processing industries is to improve, risk based process design coupled with risk based process management is imperative.

Managing an Emergency Preparedness Program

3

Thaddeus H. Spencer and James W. Bowman

Introduction

Prevention, Prediction, and Preparation

The preceding chapter explored many technical aspects of chemical process safety and some safety management systems that form the foundation of a comprehensive emergency preparedness program. Clearly, the first step in preparing for emergencies is to identify and mitigate the conditions that might cause them. This process starts early in the design phase of a chemical facility, and continues throughout its life. The objective is to *prevent* emergencies by eliminating hazards wherever possible.

Although hazard elimination is the goal, experience has taught us that guaranteed, failure-free designs and devices have so far eluded human kind, despite astonishing advances in knowledge and technology. Even the most "inherently safe" chemical facility must prepare to control potentially hazardous events that are caused by human or mechanical failure, or by natural forces such as storms or earthquakes.

The process of careful, structured analysis and evaluation used to eliminate hazards during design and construction will also allow a chemical facility to accurately *predict* unplanned events that may create emergencies, and to effectively *prepare* to manage them should they occur. A comprehensive emergency preparedness program has all of these elements: *prevention, prediction*, and *preparation*.

The fundamental need to predict and prepare for a failure of some kind is familiar to everyone. Fortunately, most of the failures that we encounter create little more than inconveniences in our lives. Others have much more serious potential. Such a failure can trigger an emergency, a term that Webster defines as "an unforeseen combination of circumstances or the resulting state that calls for immediate action." If the immediate action is ineffective, the emergency will escalate to a full-blown crisis.

Certainly most if not all of us in our personal experiences have had many opportunities to reconfirm the wisdom of the admonition, "Plan for the best, but prepare for the worst." As a result, we prepare ourselves for human and mechanical failure in a variety of ways, some so simple and familiar that we scarcely are aware that we are managing a personal emergency preparedness program.

To varying degrees, each of us has assessed our personal vulnerability to a specific emergency and the potential consequences to family and property. In some cases the required immediate action may be minor, but elsewhere the same combination of circumstances will demand significant resources to avoid a crisis of major proportions. The loss of household electric power in an urban condominium may only turn out the light, but on a farm, where electricity pumps the well water, milks the cows, refrigerates the produce, and irrigates the land, loss of power can bring disaster to the unprepared.

In an industrial environment, the consequences of human or mechanical failure can be far greater, even threatening the lives of employees and neighbors. Therefore, emergency prevention and preparedness efforts must have high priority, receiving continuous attention from every employee, including those at every level of management and supervision.

In the chemical industry, emergency preparedness programs have long been recognized as vital elements in protecting people, property, and the environment from harm. Few chemical facilities are without an emergency response plan (ERP). Still, when the alarms sound and the emergency is real, the response often does not proceed as planned. Too often, preparation for the unlikely event has been inadequate. As a result, many chemical facility managers are taking a fresh and critical look at their existing emergency preparedness programs in cooperation with their

communities, and placing a still higher priority on being truly prepared for emergencies. This is consistent with the aggressive approach to other aspects of safety management that has made the chemical industry one of the safest industries.

Although the commitment to *prevent* the events that lead to injuries and emergencies of all kinds remains the first priority in safety management, we must "prepare for the worst." In this chapter we will explore how chemical facilities and their neighbors can better *predict* and *prepare* for unplanned events that threaten lives, property, and the environment—events that call for immediate and coordinated action.

Need for Emergency Preparedness Programs

The need for more effective management of emergency preparedness programs by chemical facilities and their host communities became painfully clear to the world in the 1980s—a decade marred by tragic events linked to the manufacture and distribution of chemical products. These events revealed serious deficiencies, not only in training people to react effectively during an emergency, but also in managing the systems employed to identify, evaluate, and mitigate hazards that may cause an emergency.

The chemical industry has vigorously responded to these problems in a variety of ways. In some cases well before thecrisis of the 1980s, individual chemical units took aggressive action to increase the reliability of their operations, to communicate these actions to their neighbors, and to involve the communities in the process of emergency response planning. This proactive interaction at the local level proved fruitful in promoting the active partnership needed to solve mutual problems and to respond to public concerns. In 1986, these individual initiatives were institutionalized by the industry in the Chemical Manufacturers Association's (now the American Chemistry Council [ACC]) "Community Awareness/Emergency Response (CAER)" program, which has in turn become a major element of the more recent "Responsible Care" program.

The proven success of these activities provides a powerful reason for giving high priority to open and cooperative management of an emergency preparedness program. By implementing such a program, a chemical facility builds important bridges to its neighbors and fosters positive perceptions. Involving the host community provides an opportunity to demonstrate a sincere commitment to the protection of people and the environment, and a route to the mutually profitable solution of real problems through meaningful two-way communication with the public.

Much of what had been voluntary prior to 1986 became law in the United States with the enactment of the Superfund Amendments and Reauthorization Act (SARA). The Emergency Planning and Community Right-to-Know portions of the Act (known as Title III, or EPCRA) place specific organizational, planning, communication, and training responsibilities on the public and private sectors, as do the accidental release provisions of the Clean Air Act (CAA) amendments enacted in 1990. Other laws, such as OSHA's 29 CFR 1910.114, Process Safety Management of Highly Hazardous Chemicals, also require ERPs. In addition, various state and local regulations must be considered, understood, and reflected in a complete emergency preparedness program.

These laws and regulations, which will be covered later in this chapter, should be viewed as describing only the minimum requirements. Beyond the legal and self-protective reasons for chemical facilities to improve their management of emergency response programs lie other important driving forces. One of these is the moral and ethical responsibility to employees and the public to work toward elimination of events destructive to the quality of life. In practice, full recognition of this responsibility requires actions in prevention, prediction, and preparation that go beyond the letter of the law.

The financial benefits of good emergency preparedness program management are important as well. Emergencies are always expensive. Uncontrolled emergencies can become financially devastating crises. Nervous communities, fearful of the dangers dimly perceived through industrial fences, can and have put some chemical operations out of business. Creating and maintaining a comprehensive emergency preparedness program does not come free. However, the investment is proving to be money well spent by most chemical facilities.

Preventing and Predicting Emergencies: Getting Started

The objective of a comprehensive emergency preparedness program is the protection of people, property, and the environment from unplanned hazardous events. Organizations handling hazardous materials recognize that the process of creating an effective program starts with the identification, evaluation, reduction, and control of hazards (commonly called risk management), and proceeds through the preparation, drilling, and maintenance of plans and procedures designed to contain an emergency situation should one occur.

To assure an effective emergency preparedness program, chemical facilities need to make periodic, formal assessments of their vulnerability to and preparedness for emergencies. Managers must be involved in developing and monitoring key indicators that will help in assessing an organization's ability to prevent or deal with an emergency. Awareness of any program weaknesses revealed by examining these indicators leads to corrective action to ensure that the potential for incidents decreases, and emergency

EMERGENCY PREVENTION	EMERGENCY RESPONSE PLANNING
1. Frequent management presence in operating areas.	1. Emergency manual that documents the areas or processes with emergency potential and describes the emergency response plan.
2. Proper storage and identification of hazardous materials.	2. Regular emergency response plan training, and drills each quarter.
3. Formal and systematic inspections of key equipment, safety devices, and safety interlocks.	3. Liaison with the community for response coordination.
4. Audits for compliance with safety rules and procedures.	4. Emergency response management organization with documented functional tasks and assigned personnel.
5. Periodic critical reviews of existing operating and maintenance procedures.	5. Systems to recognize and report an emergency in a timely manner.
6. Training programs updated to meet current needs.	6. Documentation of hazardous chemicals with potential to leave the site, and evacuation plan for affected areas.
7. Control systems for maintenance hot work and changes in process and equipment.	7. Adequate emergency response equipment.
8. Systematic process hazards reviews during design, start-up, and routine operations.	8. Proper method to account for personnel during and after an emergency.
9. Formal reviews all of events that could or did cause serious process incidents.	9. Procedures to review and modify the emergency plan following drills or actual emergencies.

Fig. 3.1 Emergency preparedness checklist

preparedness improves. Sample checklists including some of these key indicators are shown in Fig. 3.1.

Central to all emergency preparedness programs is a written ERP. An ERP obviously is a key element of emergency preparedness, yet it is only one procedural part of a systematic process that includes the following sequential steps:

Identify and evaluate hazards
Mitigate hazards wherever possible
Identify and evaluate remaining hazards
Identify and evaluate resources
Develop emergency procedures and ERP
Train facility personnel
Communicate plans to the public
Integrate with community ERPs
Conduct and critique drills
Review and revise ERPs
Do it again

The creation and maintenance of an ERP requires the allocation of valuable resources, as well as strong leadership from a manager. No one else in the organization has the authority to commit the resources required. Only the power of the manager's office can overcome the organizational inertia that is often encountered.

Many people do not like to "prepare for the worst." They may harbor sincere doubts about the value of planning for events that they consider unlikely to occur. Some people are complacent after years free of serious accidents, and honestly believe that "It can't happen here." Others may be concerned that an open discussion of potentially disastrous events will needlessly upset employees and neighbors. These and other "start-up" problems could make trouble for a manager initiating (or reviving) an emergency preparedness program.

Managers need to find ways to stimulate employee interest and enthusiasm in the planning process. This is best done through the involvement of employees. One strategy that minimizes problems is the early involvement of those employees who serve as emergency responders in their communities. Some of them have witnessed the tragic consequences of failing to heed early danger signs and being unprepared for events. Thus, they can be willing and able catalysts in the emergency response planning process.

Open communication with all employees early in the process is also important. Sharing objectives and encouraging contributions stimulates thoughtful discussion, leads to more complete hazard recognition and mitigation, and ensures a greater chance of effective action when the emergency alarms do sound. Armed with facts, employees acting as informal ambassadors to the community can reduce the potential for public alarm over a facility's preparations to deal with serious but low-probability events.

Hazard Identification and Mitigation

As shown in Fig. 3.2, emergency preparedness begins with the identification and mitigation of hazards. When properly done, the systematic analysis and evaluation of chemical process hazards stimulate actions that eliminate the potential for many emergency situations and pinpoint the situations that remain. The direction of these analytical and corrective efforts is an integral part of managing a comprehensive emergency preparedness program.

Process Safety Management Team

Hazard identification and mitigation are the responsibility of a facility's line organization—the same people who are responsible for all other organizational performance parameters. However, a line organization often needs support in identifying and mitigating complex chemical process hazards, support that can be effectively provided through the formation of a standing team functioning under the manager's direction. This team, called a Process Safety Management Team (PSMT), includes representatives of each unit of a facility from various levels of the organization. They meet on a regular basis (usually monthly) and report frequently to the manager on the status of their activities.

Identifying Hazards: PSR Teams

Supported by the PSMT, the line organization develops a structured approach for performing process hazard analyses on a repetitive basis. One effective way to do this is to organize knowledgeable facility personnel into ad hoc Process Safety Review (PSR) teams. These teams, supplemented by outside specialists as required, are responsible for studying all processes, identifying all potential hazards, and recommending appropriate corrective or control measures.

The makeup of a PSR team is critical to the success of this process. The effectiveness of the team depends on the skills, knowledge, and cooperative effort of its members, and the leadership ability of its chairperson. Each member must be familiar with the process being studied, and have at least a working knowledge of the basic engineering principles and chemistry involved. The team should include supervisors from operations and maintenance and a technical support person. Knowledgeable process operators and maintenance personnel would be valuable team members as well. Others who could contribute to the team's work include design engineers, specialists in electrical and instrument systems, safety engineers, reaction kinetics consultants, and equipment vendors.

The selection and training of PSR team members must be carefully monitored. Most managers make this the responsibility of the standing PSMT, which also may assist a PSR team in choosing the most appropriate hazards evaluation method for a specific process.

Review Methods

There are many structured methods for carrying out effective reviews of process hazards. The four most commonly used methods are:
What if/checklist
Failure mode and effect analysis
Hazard and operability study (HAZOP)
Fault tree analysis

What If/Checklist. The most frequently used method of process hazard review, the what if/checklist, is effective in reviews of relatively uncomplicated processes from raw materials to final product. The team formulates and answers "What if?" questions at each handling or processing step to evaluate the effects of component failures or procedural errors. They use a checklist to ensure that all important subjects are addressed. This method should be used as the first step in all process hazard reviews.

Failure Mode and Effect Analysis. When the team studies a specific item of equipment, such as a reaction vessel, they often use the failure mode and effect analysis method. Its semi-quantitative approach assists in prioritizing hazards.

HAZOP. The HAZOP procedure systematically questions every part of a process to discover how deviations from the intention of the design can occur, and to determine if the consequences of such deviations are hazardous.

Fault Tree Analysis. Fault tree analysis, the most complex of the commonly used methods, is employed to determine the possible causes of a preselected undesired event. Through the use of logic diagrams and failure rate data, the team can make a quantitative evaluation of the frequency of the undesired event.

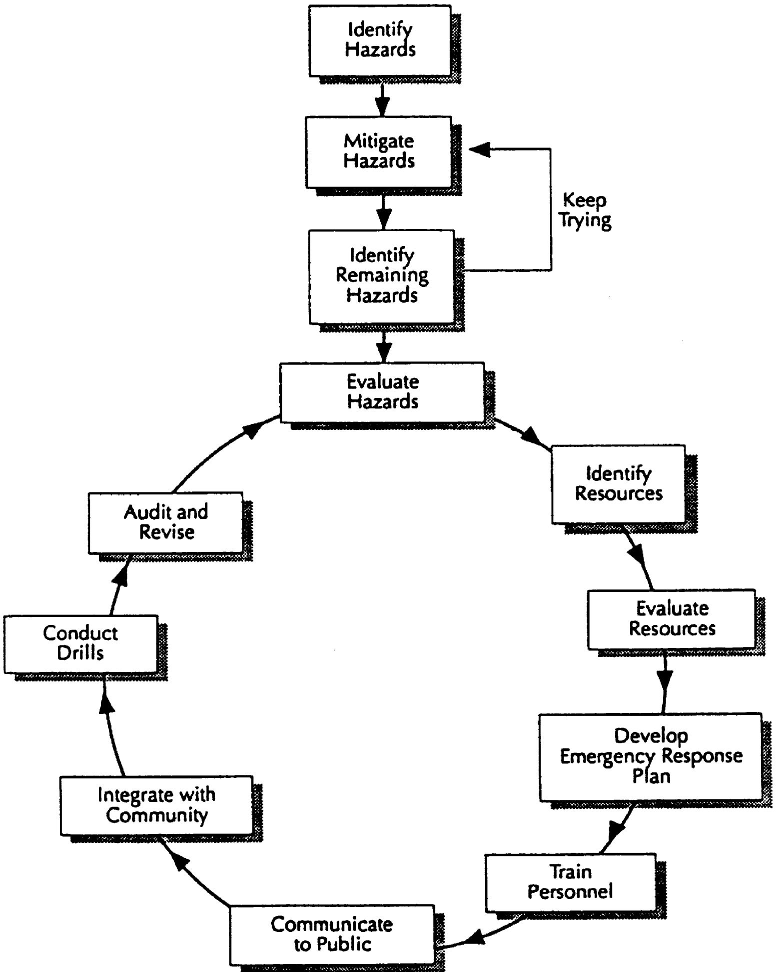

Fig. 3.2 Elements of a comprehensive emergency preparedness program

Recommendations and Reports

Regardless of the method used, the PSR team's most important responsibility is to alert management to serious hazards that may have been overlooked or given inadequate attention. To fulfill this responsibility, a PSR team must take the following steps:

1. Identify the hazards that could cause explosion, fire, release of toxic materials, serious injury, or inappropriate exposure to chemicals.
2. Evaluate the magnitude of the hazards for the areas of probable involvement; the consequences of an event in terms of injuries, environmental harm, and property damage; and, qualitatively or quantitatively, the probability of the hazards' occurrence.
3. Develop practical recommendations to eliminate or control the hazards identified.

The PSR team reviews in detail up-to-date reference material such as:

☐ Architectural drawings
☐ Equipment layout drawings
☐ Process schematics
☐ Instrument diagrams
☐ Chemical and physical characteristics of process materials
☐ Equipment design specifications
- Operating procedures
☐ Process conditions
☐ Emergency shutdown procedures

When a facility has more than one chemical process, the PSMT develops a priority order for reviews and recommends a review frequency to the facility manager. The frequency usually ranges from once every 2–3 years for high-hazard-class processes such as explosives manufacture or acetylene purification, to once every 5–7 years for low-hazard-class processes such as alcohol purification, steam generation, and operations involving combustible materials.

Changes not anticipated in the original design of equipment often pose serious problems. Some examples of such changes are:

☐ Introduction of different raw materials
☐ Changes in temperatures, pressures, speeds
☐ Deterioration of equipment

At the completion of each PSR, the team prepares a written report that defines needs, makes recommendations to remedy problems, and recommends priorities for the correction of deficiencies. Following review and acceptance of the report, the facility manager assigns responsibility for corrective action to the appropriate operating personnel. The PSMT then assists the manager in monitoring the status of the recommendations from all PSRs.

Mitigating Hazards: Release Detection and Mitigation

The release of flammable or toxic chemicals from uncontrolled pressure relief vents or as a result of equipment failure may present a serious threat to employees or neighbors who fail to guard against exposure. Every chemical facility must address this potential problem and prepare to protect people from these hazards by working toward reducing the potential hazard and its consequences. Typically, the line organization and PSR teams are responsible for hazard mitigation. They conduct a hazard study that includes the following activities:

1. Detailed appraisal of the potential for an accidental release of toxic gas or vapor.
2. Evaluation of instruments and other methods for detecting such leaks.
3. Provisions for rapid alerting of threatened personnel, and for communicating with emergency responders.
4. Identification of buildings in which people might be trapped by such a release.
5. Assessment of the capability of buildings or rooms to prevent the infiltration of gas or vapor.
6. Evaluation of plans for building evacuations, including the provision and maintenance of appropriate personal protective equipment.

Early *detection* of a chemical leak is necessary in order to limit its effect on people and the environment. The most fundamental method for detecting a chemical release is the systematic patrol of operating units by personnel trained to recognize potentially hazardous vapors using odor or visual observations. The frequency and scope of the patrols will vary with the nature of the process equipment and materials; however, every facility should have documented patrol procedures in place.

When particularly hazardous vapors are present, the patrol procedures should include special provisions to protect the patrollers from the fumes. For example, in facilities producing or consuming hydrogen sulfide, operators may carry emergency respiratory equipment to escape any unexpected fumes that they may encounter, and patrol in pairs or individually, under constant surveillance.

Many chemical facilities supplement operator patrols with an instrumented detection system. Such a system may be a necessary resource when a hazards study concludes that the system will substantially increase the available escape or emergency response time, or where:

1. The harmful substance is odorless or deadens the sense of smell at hazardous concentrations.
2. The harmful substance is toxic at concentrations undetectable by smell.
3. Large numbers of people may be exposed quickly.
4. Ventilation systems might draw toxic fumes into a building before other means of detection could trigger protective action.

At the core of an instrumented leak detection system is a gas detector. There are many kinds of detectors on the market with varying degrees of sensitivity and selectivity. All require careful regular testing and maintenance.

An engineering study of many site-specific factors is required before one makes a choice and designs an appropriately instrumented system. Some generally accepted guidelines are:

1. Early warning of a leak is enhanced if the sensors can be placed near the process equipment subject to leakage.
2. Air movement characteristics are critical in achieving reliable detection.
3. Most detectors respond to several gases or fumes, so the possible presence of all airborne substances affecting the detection system must be considered.
4. When it is necessary to monitor work areas or the intakes to ventilation systems, a highly sensitive system is desirable.

Most detection systems are designed not only to report the presence of hazardous fumes through instrument readouts but to sound an alarm and automatically initiate corrective or protective action. In an office or shop, for example, the system can be designed to shut down all ventilating fans and close exterior air inlet dampers.

When process safety reviews have identified chemical releases as potential sources of facility emergencies, the organization must provide the training and materials needed to ensure a prompt and appropriate reaction to *mitigate* the hazards. Some countermeasures that are effective in limiting the spread of a hazardous material spill or release should be included in the design of chemical process equipment, and described in emergency response procedures. The following discussion of relea e mitigation is largely excerpted from *Guidelines for Vapor Release Mitigation*, prepared by

R. W. Prugh and R. W. Johnson for the Center for Chemical Process Safety of the AIChE (copyright 1988 by the American Institute of Chemical Engineers, reproduced by permission of the Center for Chemical Process Safety of the AIChE).

"Water, steam, and air curtains and water sprays are primarily effective in dispersing and/or diluting vapors with air to reduce the severity of effects of a hazardous vapor release. In some cases, vapors can be partially 'knocked down' or absorbed after release."

"Ignition source control and deliberate ignition are also possible vapor release countermeasures." "For areas around processes handling flammable vapors, ignition source control is practiced to reduce the probability of vapor ignition if a leak occurs." "Administrative controls are exercised on plants where flammable materials are processed. Such controls may include hot work permits, restricted smoking areas, not allowing lighters or matches on the site, and electrical grounding and bonding procedures."

"Deliberate ignition is a countermeasure against spills of highly toxic materials which are also flammable, such as hydrogen sulfide, hydrogen cyanide, and methyl mercaptan. Igniting nontoxic flammable materials such as hydrocarbons may present hazards outweighing possible advantages." In any case, deliberate ignition must be carefully planned and executed so that the resulting fire is truly controllable.

"Practical methods for combating vapor from liquid leaks are dilution, neutralization, or covering. All three reduce the vaporization rate of the pool. Water dilution is effective for spills of water-miscible or water-soluble material. Spraying water into the spill reduces the vapor pressure by reducing the concentration of the liquid." "For acidic spills, limestone or soda ash is often used" to react with the spilled liquid to produce a less volatile salt or ester. "A foam cover can be effective in reducing vaporization from spills," and "dense liquids can be covered with lighter immiscible nonreactive liquids" to accomplish the same thing.

Preparing for Emergencies: Identifying and Evaluating Resources

The process of hazard identification, evaluation, and mitigation, when sustained over a period of time and coupled with other good safety management practices, can prevent most process-related emergencies. However, the potential for various low-probability process-related events will remain. Should one occur, there must be resources available to promptly bring the event under control. These resources include designated personnel, plans, systems, and facilities that are needed for effective action and communication. The facility line organization is responsible for providing and maintaining these resources.

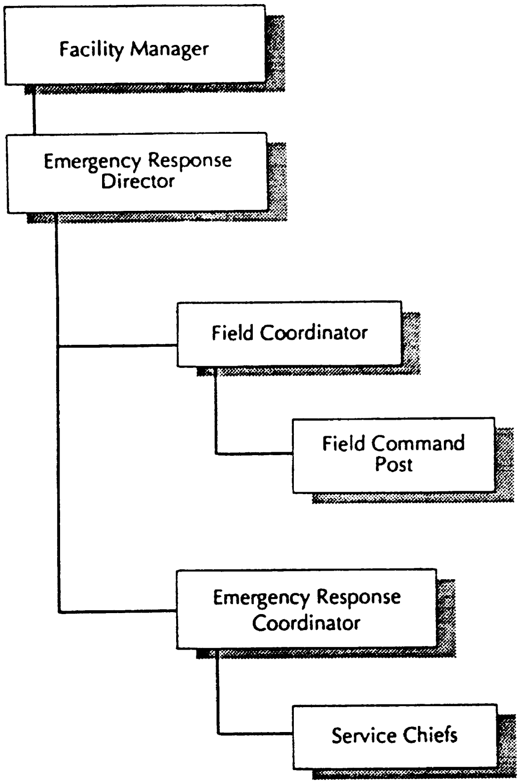

Fig. 3.3 Generic emergency management organization

Personnel

Emergency Preparedness Team. As with the PSMT and the PSR team, the efforts of the line will benefit from the support of a standing Emergency Preparedness Team functioning under the direction of the facility manager. This team, which includes representatives of each unit of the facility, leads the development and maintenance of an ERP for the facility, and monitors specific procedures and training for handling emergency situations of all kinds. It should meet on a regular basis (usually monthly), and report frequently to the manager on the status of its activities.

Emergency Management Organization (EMO). Emergencies demand rapid, well-coordinated decisions, communications, and action to bring them under control as swiftly as possible. There must be a formal EMO whose purpose is to achieve this objective. The structure of the organization is not critical as long as it is capable of rapid assembly, carries out its assigned responsibilities, and meets the needs of the facility. A generic EMO is shown in Fig. 3.3; the EMO is described below, in the section on "Developing an Emergency Response Plan."

Fire Brigades. Most chemical facilities of any size have established fire brigades as a key resource in their emergency preparedness programs. By virtue of its training and familiarity with the equipment and the physical layout of a site, the brigade can be a major factor in *preventing* incidents as well as in minimizing injuries and property damage due to fire, explosion, or other causes.

The size and the structure of a fire brigade vary, depending on the hazards present, the size of the facility, and the level of internal fire-fighting capability desired; and large, multi-process facilities usually have several unit or area brigades. Each brigade has a designated captain and an alternate. The training of brigade members must be commensurate with the duties and the functions that they are expected to perform, and thus depends on the fire prevention plan option selected by site management. (Fire prevention plans are discussed later in this section).

It is best to have a written statement establishing the brigade and its duties, specifying its size and organizational structure, and outlining the type, amount, and frequency of training provided. In the United States, OSHA has promulgated minimum standards for fire brigades, which may be found in 29 CFR 1910.156.

Plans

Work Unit Plans. In a large facility, each work unit has emergency procedures for its own area of operations, and these work unit plans form the foundation of the facility ERP. Thus, the facility's emergency response can be no more effective than the recognition and response capabilities of the employees in the facility work units.

The primary objectives of these unit plans are (1) to control and contain any emergency condition within the unit, and (2) to provide protection for unit personnel and equipment from events originating outside the unit. Unit plans specify who has authority to take emergency action, and how escalation to a full facility emergency occurs. Subjects that must be covered include:

☐ Unit emergency command and coordination
☐ Communications within the unit
☐ Communications with other units
☐ Emergency assessment
☐ Unit evacuation and personnel accounting
☐ Emergency shutdowns
☐ Communications with the facility management
☐ Criteria and procedures for securing resources from outside the unit

Unit plans clearly assign primary responsibility for initial emergency assessment and reaction to the lead unit employee on site at the time of the event. Among the factors to be considered by that individual in making the initial assessment are:

☐ Previous experience with similar situations
☐ How long the situation has existed
☐ What might occur "If . . ."
☐ Properties and hazards of materials involved
- Other complicating situations

Using the information gained from the assessment, unit personnel take whatever immediate action is required to protect people and property on and off the site.

Work unit plans should contain guidelines for assuring uniformity in the assessment of and reaction to unusual events. An effective approach is to develop an emergency classification system that includes criteria for classification and guidance for the appropriate response actions for each level of emergency that is defined.

For example, an emergency judged to be controllable within the unit, with no evacuation outside the unit and no impact in the community, is a Level One Emergency. Small releases of hazardous materials usually fall into this category. Appropriate response items to consider would include:

☐ Protection of unit personnel
☐ Shutdown or isolation of affected equipment
☐ Notification on- and off-site
☐ Containment and cleanup

Similarly, other events are categorized by their potential or actual severity. Preplanned response checklists are prepared for each one. An incident that requires response by facility personnel outside the affected unit but has no impact on the community is a Level Two Emergency. A Level Two Emergency requires activation of the facility ERP. If some community impact becomes probable, the emergency is a Level Three Emergency. That level of emergency triggers additional response requirements, including interaction with the community.

The unit plan must be formal and in writing. Because the emergency procedures of each individual operating area or work unit form the foundation of the facility ERP, they should be reviewed by the Emergency Preparedness Team for completeness and consistency across the site before they are included in the facility ERP.

Fire Prevention Plan. One of the most basic resources that all chemical facilities must have is a fire prevention plan. To be fully effective, this plan must be in writing, and it must be reviewed with all employees on an established schedule.

A comprehensive fire prevention plan includes the following subjects:

1. Major facility fire hazards
2. Storage and handling practices for combustible and flammable materials
3. Identification of potential ignition sources
4. Procedures to maintain systems and equipment installed to control ignition sources
5. Names and titles of those responsible for the system and equipment maintenance and the control of fuel source hazards

6. Procedures to minimize accumulations of flammable and combustible waste materials
7. Plans for communicating to all employees the fire hazards and their specific responsibilities in the event of fire

Fire response options open to facility managers range from a plan to evacuate all employees without attempting fire fighting on any scale, to full involvement of an established fire brigade in fighting advanced-stage structural fires. The fire prevention plan must specify which option applies to the facility. The option selected determines the type and extent of education and training required, as well as the type of equipment needed on the site.

Fire prevention and response information may be covered in other written facility documents (such as job descriptions, rules, or procedures) and communicated to employees on the same schedule as the fire prevention plan.

Evacuation Plans. Many emergency events require the evacuation of at least some facility personnel, if only for precautionary reasons. This presents other needs, which must be addressed in the evacuation plan. Personnel who are directed to evacuate their normal work stations need visible wind direction indicators to help them move away from a dangerous gas cloud drifting downwind of the release point. If the building is enveloped in the cloud, however, they will need personal protective equipment in order to evacuate the building safely. When there are processes that must be rapidly shut down and/or isolated as evacuation proceeds, the plan must include written procedures and appropriate means to ensure incident-free action.

Headcount Plan. The evacuation plan also must establish gathering points for all personnel in order to identify those who are missing.

Alarm Systems

The procedure for accounting for personnel, called the headcount, must work effectively and rapidly in the first minutes of the emergency to determine if anyone is missing or known to be injured. Communications to the fire brigades or other first responders must be quick and accurate so that search and rescue operations and medical aid can be successfully implemented.

Each work unit in a facility must have its own plan for headcounts as a part of its emergency preparedness program. This plan must be in writing, and it must be practiced frequently enough to ensure good execution in a time of real emergency. It should include:

☐ A designated assembly point for each employee
☐ An alternate assembly point, should the primary location be inaccessible
☐ A procedure for counting at each assembly point
☐ A designated unit headcount coordinator and backup
☐ Primary and alternate phone numbers where coordinator may be reached
☐ Phone numbers for reaching the personnel chief, who coordinates and summarizes the site-wide accounting

Headcount procedures must include guidelines for accounting for visitors to the facility at the time of the emergency. These visitors may include truck drivers, vendors, and contractors. Some guidelines are:

1. All visitors must sign in and out, preferably at one designated gate.
2. Visitors will have a designated host employee responsible for their safety whenever possible.
3. Everyone temporarily on the facility must report to the assembly point of the unit he or she is in at the time of the emergency.
4. Unit procedures must include reporting these “extra” people by name to head-count headquarters.
5. The personnel chief of the EMO must have access to the log at the visitors’ gate.

Another essential resource that every chemical facility must have is an effective alarm system, which initiates action by endangered personnel and emergency responders.

A satisfactory facility emergency alarm system must meet three additional requirements. It must, at a minimum, immediately alert *all* the people on the site. (A single signaling device should be adequate for small sites; however, large facilities may require many devices placed to reach all occupied areas of the site.) The system must function even when the facility has a general power failure. Alarm activation controls should be located so that an emergency condition is unlikely to prevent access to them.

On most older chemical facilities, the basic component of the emergency warning system is the fire alarm. It is essential that there be different signals to distinguish between an actual fire and other threatening events, as the action taken in response to a toxic gas release, for example, may be quite different from that taken in response to a fire. On multi-process sites, the signals also should identify the work unit involved.

Depending upon the number of people at a facility and their familiarity with response and evacuation procedures, it may be necessary to supplement signals with verbal instructions delivered by public address equipment, radios, or automated telephone systems. For reliability at any time of day, a system using verbal instructions must be located in a regularly manned job station such as a control room or gate house.

Any alarm system used must communicate clearly the nature of the emergency event and its severity. In a Level One Emergency some people may have to be evacuated in order to ensure their safety, but by and large the emergency can be contained within the unit. In that case, information usually may be given to unaffected employees through normal telephone communications.

In the event of a Level Two or a Level Three Emergency, each facility must have an easily recognizable signal that clearly communicates that a major incident has occurred. Some facilities have alarm boxes that will automatically sound this signal when pulled. Others have boxes that require manual operation. Still others rely on a telephone message to trigger the signal.

In some facilities, the “major” emergency alarm is a steady blast on the facility steam whistle. Others use sirens or special bells. Whatever is chosen, the alarm must reach everyone on the site, triggering activation of the facility ERP and the initiation of a head-count procedure.

It is essential that every employee on a chemical facility knows how, where, and when to turn in an appropriate and effective emergency alarm. The specifics will vary considerably, but the procedure for turning in an alarm is similar in all cases.

Employees first need to know how to report a fire. On most facilities, this is done by using a fire alarm box or by telephoning a central station such as a guard house from which the fire alarm can be sounded. Chemical facilities need to have well-developed training and drill programs in place to be sure that response procedures and equipment are maintained.

When fire alarms are supplemented by verbal instructions, the facility personnel who are contacted need to know the location and the nature of the fire, the action under way to control it, and the actions required (if any) by those not involved. There are many commercially available communications systems that deliver this information efficiently, even on large sites.

Facilities for Protection and Communication

Safe Havens. When accidental releases of a toxic gas occur or threaten to occur, the immediate protection of on-site personnel is of paramount importance. One resource available for this purpose is a building or room that by the nature of its construction and its heating and ventilating characteristics can prevent the infiltration of intolerable concentrations of the toxic substance. The best location for a safe haven is determined by an engineering study. That location then is documented in the work unit and facility ERPs.

Safe havens may be rare on some sites; however, many buildings can provide personnel with temporary protection until the incident has been analyzed and a decision made on the need for evacuation. To qualify as a designated temporary safe haven, a building must be reasonably well sealed against air infiltration, with adjustable ventilation systems that can reduce or close off exhaust vents and outside makeup air. Emergency procedures should state how long a building can be considered a safe haven under specified exposure conditions.

Main Emergency Control Center (MECC). Using a list of safe havens developed by the work units, the Emergency Preparedness Team helps management select one building or room to be used as a control center in case of a major emergency. This MECC should be as remote from potential hazards as possible in order to serve as a reasonably safe haven to those involved in directing, coordinating, and communicating activities for the duration of an emergency.

MECCs need to have basic information readily available and maintained in an up-to-date, standby condition. Such a collection would include:

- ☐ Copies of the facility ERP
- ☐ Facility maps and diagrams
- ☐ Process material isolation points
- ☐ Fire control maps and diagrams
- ☐ Maps of the surrounding area
- ☐ Aerial photos of the facility and the surrounding area
- Names, addresses, phone numbers for: —all facility employees—off-site company people to be notified—groups and organizations who may be notified—community officials who may be notified
- ☐ Material Safety Data Sheets (MSDSs) for facility materials
- ☐ MSDSs for the materials of neighboring chemical facilities
- ☐ Copies of mutual aid agreements
- ☐ Highlights of the facility’s history, products, and performance

The MECC should have the following basic equipment:

- ☐ Adequate telephones and lines
- ☐ Unlisted telephone and/or a hotline
- ☐ Two-way radios
- ☐ Fume path projector
- ☐ FAX machine
- ☐ Regular radio with tape recorder
- ☐ Regular television with recorder and playback video cassette recorders
- ☐ Chart pads and stands
- ☐ Battery-powered lighting
- ☐ Personal protective equipment
- ☐ Hand-held tape recorders

Alternate Control Centers. Recognizing the unpredictable nature of a developing emergency, it is advisable to select at least one alternate on-site main control center. Both the MECC and the alternate on-site center should have backup power supplies.

The presence of substantial quantities of explosive or toxic materials on-site may justify establishing yet a third location off-site, in case of a complete evacuation of the facility. This could be a fixed location in the nearby community, or a mobile unit such as a truck or van properly equipped for managing an emergency. Some of the supplies and equipment for the alternate off-site main control center may have to be packed in a readily transported kit rather than being on standby at the alternate off-site location.

Media Headquarters. In an emergency, it is essential to maintain regular contact with the public and the media. A separate location for communications will allow that contact to continue without interfering with the operations of the MECC or overloading its communications system. There, the public affairs chief and the facility manager can receive media representatives and provide periodic updates on the emergency situation. The media headquarters should be equipped with several direct outside telephones and the facilities to make the reporters comfortable for the duration of the emergency. Permanently mounted facility plot plans or aerial photographs are helpful resources, as are handouts describing in general terms the facility and its products.

Developing an ERP

Following the identification and evaluation of the resources available to the facility, the Emergency Preparedness Team, under the direction of the manager, develops the written ERP for the entire facility. The Emergency Preparedness Team is responsible for ensuring that the written facility ERP informs all employees of their roles in an emergency and the hazards to which they may be exposed.

An ERP must be tailored to a specific facility, reflecting its unique conditions and individual needs. Among the variables that affect the details of a plan are:

☐ Materials used, produced, or stored
☐ Nature of the operations
☐ Available employee skills
☐ Geographic location
☐ Proximity to other facilities
☐ Available emergency resources
☐ Mutual aid agreements

No two ERPs will be exactly alike, nor is there one best outline. The plan of a production facility will differ from that of a warehouse. However, every plan must include:

☐ Initial alarm procedures
☐ Emergency escape procedures and routes
☐ Emergency operating and shutdown procedures for critical operations
☐ Accounting procedures for all on-site personnel
☐ Rescue and medical duties for specified personnel
☐ Procedures for communicating the emergency inside and outside the organization
☐ Structure, duties, and resources of the EMO, including the names or titles of people with detailed knowledge of the plan and its assigned duties
☐ Reference material

Plan Design

The ERP is a working plan, applicable to any event with emergency potential occurring at any time and at any location on the facility. It should be written concisely, with diagrams and checklists used wherever possible, so that it may be effectively used for guidance during an actual emergency. To accomplish this, it is helpful to divide the ERP into several major sections, which are in turn divided by subject.

For example, an ERP may be broken down into three sections: the EMO, Action Plans, and Reference Material.

The first section documents the structure, duties, resources, and communications systems for the facility EMO, and the conditions that will trigger the EMO's response. It includes plans for site-wide notification and response.

The second section includes detailed action plans for each particular type of emergency. This section includes summaries or outlines of the emergency procedures developed by each work unit of a facility, and may contain considerable process-oriented information.

The third section consists of reference material on plan philosophy, training, plan maintenance, drills, and similar supportive data that usually are not needed at the time of an emergency. Members of the EMO and others with assigned response duties should be able to quickly locate and refer to the appropriate action guidelines, to determine that key functions are being performed.

Using this approach, the outline of an ERP for a multiprocess chemical facility would look like this:

Section I
A. Table of Contents
B. EMO Structure and Tasks
C. Notification: On-Site
D. Accounting for Personnel
E. Headcount Center
F. EMO Center
G. Emergency Scene
H. Notification: Off-site
Section II
A. Table of Contents
B. Work Unit 1
  1. Emergency types
  2. Action checklists
  3. Responsibilities
  4. Communications
  5. Shutdown procedures
C. Work Unit 2 (same as above)
Section III
A. Table of Contents
B. Plan Philosophy and Objectives
C. Training Programs
D. Drills and Tests

E. Return to Normal
F. Appendices
  1. Special situations (e.g., bomb threats)
  2. Hazardous material data
  3. (Others as required)

EMO Structure

Perhaps the most essential element of an ERP is the establishment of the organization that will manage an emergency response once the event has developed beyond a Level One Emergency. The EMO must be capable of rapid assembly, and must be able to carry out all of its assigned responsibilities.

The EMO is composed of the facility manager, the emergency response coordinator, the field coordinator, and various service chiefs. The number of service chiefs and their duties will vary. There need not be a separate individual in charge of each service, and small facilities may combine two or more services under one individual, as long as each function is performed.

The facility manager, in cooperation with the Emergency Preparedness Team, assigns people, by their title or function at the facility, to the EMO, with designated alternates for each EMO function. The duties and responsibilities of each EMO function are defined and documented in the ERP. Because there must be a functional EMO in place regardless of when a facility emergency occurs, designated shift personnel take specific EMO responsibilities until the primary members can reach the site.

All the positions established for the EMO should have written position descriptions, which may be placed in the third section of the ERP as an appendix to the plan. In the first section of the ERP, the EMO summary need only include a concise checklist for each position, with diagrams showing relationships and major communication flow paths.

Facility Manager. In the EMO, the facility manager has the overall responsibility for protecting people on-site, facility property, the environment, and the public during and after an emergency. With the assistance of the public affairs and communications chiefs, the manager usually serves as the spokesperson for the facility and the company, communicating with representatives of the media and other concerned audiences.

Emergency Response Coordinator. The designated emergency response coordinator, who may also serve as the chairperson of the Emergency Preparedness Team, directs all emergency control activities from the MECC. All other service chiefs on the EMO report to the coordinator. Using information from the emergency scene and from the service chiefs, the coordinator makes the key decisions on what should be done, and coordinates activities on and off the site. The coordinator reports to the manager, who should be available nearby for overall guidance and counsel.

Field Coordinator. The job of the field coordinator is to correct the emergency situation as rapidly as possible with minimum risk to those in or near the affected area. He or she establishes a field command post as close to the scene of the emergency as can be safely done. The post often is in or near a radio-equipped building or vehicle, thus permitting rapid establishment of communications between the command post and the emergency response coordinator.

Ideally, the field coordinator is familiar with the operations and materials involved in the emergency; so she or he often is the highest-ranking supervisor of the affected area who is available at the time of the event. That supervisor may remain as field coordinator for the duration of the emergency, or may be relieved by another designated member of management.

In the latter case, the area supervisor may become a service chief with greater hands-on involvement, with the field coordinator concentrating on marshaling required resources and maintaining effective communications. The choice depends to a great extent on the size and complexity of the facility, and the resources available for the EMO.

Public Affairs Chief. Working in close coordination with the facility manager, the public affairs chief releases appropriate information to the news media, regulatory personnel, government officials, and other public groups and individuals. No information is to be made public by anyone other than the facility manager without specific direction from the public affairs chief. The objective is to provide full and accurate statements in a timely fashion, so that public attention is focused on facts and useful information rather than on rumors and speculation.

The public affairs chief also establishes and monitors the media headquarters, which is isolated from the EMCC to avoid interference with operations there. The public affairs chief's function includes assisting the manager in the preparation of formal statements and background information to be distributed to reporters. It also may include arranging with local radio and television stations to make periodic announcements during an emergency so that the public and the employees not on the site are properly informed. The public affairs chief also arranges to monitor and perhaps record the broadcasts of local radio and television stations in order to determine what additional statements or clarifications to the public may be required.

Communications Chief. The communications chief establishes and maintains communications capability with appropriate people on and off the site. This chief must be familiar with the various communicating systems available, including telephones, public address systems, two-way radios, and messengers. The job includes recommending and coordinating revisions or additions to the communicating systems during an emergency, and assisting the facility manager and the public affairs chief with any communications as needed.

Engineering Chief. The engineering chief's primary responsibility is to maintain electrical power for vital services. These services include on-the-scene portable lighting, continuous fire pump operation, and a steady supply of nitrogen, steam, and process cooling water. Another key duty is to assemble repair groups capable of isolating damaged sections of pipelines, electrical lines, and other necessary equipment in order to contain problems and maintain or restore operations outside the affected area. Because these repair groups must be drawn largely from site personnel such as electricians, welders, riggers, and pipefitters, the position of engineering chief should be filled by someone from the facility maintenance organization.

Emergency/Fire Chief. The emergency/fire chief is responsible for fire-fighting and fume control activities. The best person for this job has good knowledge of and access to the fire-fighting, rescue, and fume control resources available on and off the site. On a small facility this may be the captain of the fire brigade. The job includes direction of designated facility personnel, and coordination with any outside forces brought in to bring the fire or fume condition under control. The environmental chief may assist in determining optimum courses of action based on actual or threatened adverse effects on air and water emissions from the facility.

Medical Chief. The medical chief ensures that the proper medical care is provided to people on the facility who have been injured or exposed to toxic materials. When facilities have medical professionals on the site, one of them carries out this function. This chief's responsibilities include establishing field stations to treat affected personnel, and, in cooperation with the transportation chief, providing transportation for injured people to other medical facilities.

The medical chief also participates in discussions with community officials and appropriate facility personnel regarding actual or potential medical problems for people outside the site boundaries. Representatives from nearby local hospitals, ambulance services, fire departments, police forces, and emergency management groups also may be involved in these discussions. The medical chief communicates any action or contingency plans developed in the discussions to the emergency response coordinator and the public affairs chief.

Environmental Chief. The environmental chief oversees all activities designed to minimize adverse effects on the quality of air and water as a result of an emergency. The function includes coordinating air and water quality monitoring on and off the site during and after the emergency, and assisting the emergency/fire chief in selecting the optimum approach to abating a fire or fume condition. The environmental chief also provides assistance in projecting the path and concentration of a fume release, using computer modeling (if available) or maps with plastic overlays, and developing an effective plan of action.

Personnel Chief. The personnel chief is responsible for accounting for all personnel on the facility at the time of the emergency. Unit emergency programs must include training on how this is accomplished. Unit supervisors initiate the process with headcounts at designated rally points. The success of rescue and medical activities depends on how quickly and thoroughly this information is obtained and reported to the personnel chief.

The personnel chief also coordinates communication with relatives of injured or deceased employees, and makes certain that this is completed before any names are released publicly. This requires close coordination with the public affairs chief and the manager.

The personnel chief need not be located at the MECC, but it is imperative that the personnel chief be in close touch with other members of the EMO. Telephones in the headcount center should have answering and message recording equipment to capture any unit reports arriving before the headquarters is staffed.

Security Chief. The security chief makes sure that entry to and egress from the facility are properly controlled. This involves securing gates; limiting entry to authorized personnel; registering all who pass through gates; meeting visitors, including representatives of the media, and escorting them to proper locations; and controlling all traffic on the site. The function also includes communicating with local police so that access to the facility is maintained, and crowd control procedures are enforced. Usually, the individual serving as security/chief at the time of the emergency also is responsible for initiating procedures to summon key facility personnel and urgently needed outside agencies.

Transportation Chief. The transportation chief coordinates and controls all transportation on the facility. This includes directing the assembly of available vehicles and crews, and identifying needs beyond site capabilities such as cranes, trackmobiles, and bulldozers that must be obtained from outside organizations. The function also includes providing suitable transportation for facility employees who monitor the effects of emergencies beyond site boundaries, or interact with community officials at an off-site location.

Training Personnel

Having a written facility ERP that is supported by established work unit emergency plans and procedures it is an important part of the manager's job to ensure that unplanned events will be promptly controlled with minimum risk to people, property, and the environment. There is much important work to be done, however, before the ERP is anything more than a paper resource. Facility personnel must be trained to use the ERP effectively. There must be frequent drills to test the plan and the people against the standards established by management as well as those established by law.

Within the facility, there are three groups of people who require training. First, there are members of the fire brigade, who must be trained to fight fires at the level specified by facility management. Next are the employees who have been assigned active roles in controlling emergencies of all types. This group includes members of the EMO and their alternates, plus designated support people such as headcount coordinators, guards, and emergency repair personnel. Finally, everyone else on the facility must have a basic understanding of the ERP, and must know how to respond when specific alarms sound.

The facility manager is responsible for ensuring that the appropriate training and retraining are done in a timely and effective manner. An employee should be trained when he or she is hired, at least annually thereafter, and when the employee's work area changes or the plan is revised. Most managers make this primarily a line organization function. They expect facility supervisors to use all available resources and means of education to accomplish the tasks. Some specialized training assistance, however, must be provided, particularly for the members of a fire brigade.

Fire Brigade Training

Training programs for fire brigades have two major objectives. One is to inform the brigade members of new hazards at their facility and innovations in fire-fighting techniques and equipment. The other objective is to provide hands-on training for developing skills in emergency operations and using equipment, including:

☐ Portable fire extinguishers
☐ Hoses and accessories
☐ Portable lighting
☐ Forcible entry tools
☐ Ladders
☐ Salvage equipment
☐ First-aid supplies
☐ Replacement parts
☐ Personal protective equipment
☐ Transportation equipment

A comprehensive training program for fire brigades must include classroom and hands-on training.

Outside resources can provide valuable assistance in the education and training of brigade members. Local fire departments and state fire schools are usually enthusiastic partners in such efforts. Often they are the key to securing adequate resources at a reasonable cost. In industrialized communities, mutual aid agreements may include cooperative training provisions with other chemical facilities, which provide opportunities for even more effective use of available resources. All mutual aid agreements should require cross-training in special hazards at the other facilities.

EMO Training

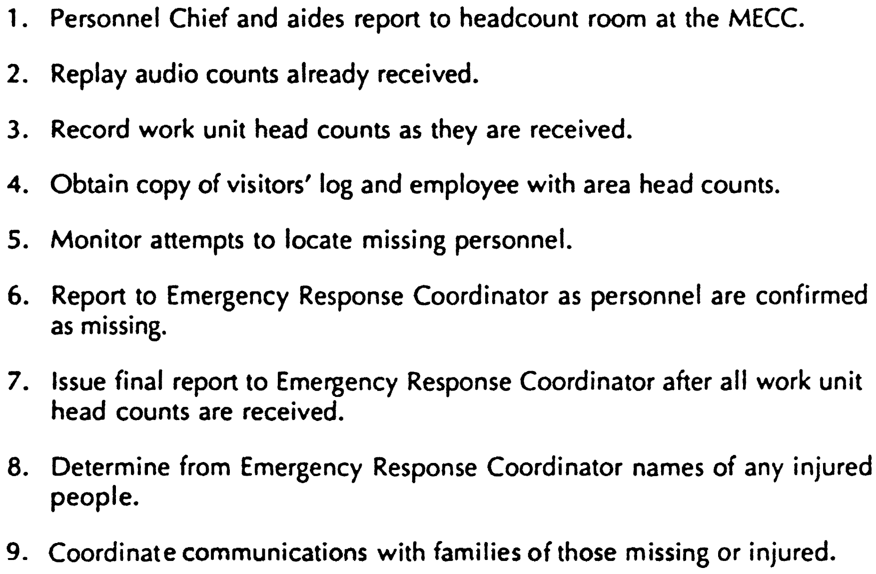
Training for personnel assigned to the facility EMO can be led by the emergency response coordinator, who meets periodically with each member of the EMO to review and refine position descriptions and the associated functional checklists. An example of such a checklist is shown in Fig. 3.4. The meetings may be followed by limited drills involving only the people and responsibilities included in the individual EMO function. Some facility managers assign specific emergency response training duties to each member of the EMO.

For example, the engineering chief organizes, equips, and trains the repair groups who will be called on to physically stabilize a situation at the time of an emergency. The emergency/fire chief could be given the responsibility for maintaining a trained force of fire and fume fighters, which includes competent leadership on all shifts.

Employee Training

There are many ways to be sure that all employees understand the ERP. The Emergency Preparedness Team can assist in the assessment of existing training programs, alerting the organization to training weaknesses and suggesting or providing creative ways to overcome those deficiencies. Unit supervisors must periodically review the ERP in scheduled group safety meetings or with individuals. Key plan elements can be reproduced on wallet-size cards, desktop displays, or telephone stick-ons. Individual or group discussions of how to react in given situations can detect weaknesses in procedures, training, or understanding.

Training programs for the three groups of employees discussed here should be documented, reviewed regularly, and included in a reference section of the facility ERP. But



1. Personnel Chief and aides report to headcount room at the MECC.
2. Replay audio counts already received.
3. Record work unit head counts as they are received.
4. Obtain copy of visitors' log and employee with area head counts.
5. Monitor attempts to locate missing personnel.
6. Report to Emergency Response Coordinator as personnel are confirmed as missing.
7. Issue final report to Emergency Response Coordinator after all work unit head counts are received.
8. Determine from Emergency Response Coordinator names of any injured people.
9. Coordinate communications with families of those missing or injured.

Fig. 3.4 Personnel chief functional checklist

no matter how comprehensive the training programs may be, their effectiveness is unknown until a drill of the ERP is conducted and its systems and procedures are tested.

Facility Drills

To evaluate the effectiveness and completeness of an ERP, a facility must conduct periodic announced and unannounced Level Two and Level Three emergency drills. These are in addition to the more frequent Level One unit drills that are held to ensure that the more limited response procedures of a work unit are complete and well understood. Major internal emergency drills should be held at least four times each year, and scheduled to involve each working shift at least once a year.

To gain the maximum benefit from the drills, assigned observers should witness all aspects of response activity, and gather soon after to participate in a verbal evaluation of actions taken. These observers should include members of the Emergency Preparedness Team. This process is enhanced by capturing on-scene action on videotape or in still photographs. Critiquing can be extremely valuable in identifying necessary plan changes, training needs, and resource deficiencies of all kinds. The process of critiquing must be controlled and managed. The leader must be sure to identify the strengths as well as the weaknesses that were revealed in the drill. The objective is to stimulate actions for positive change, not to assign blame.

Drills should be held on weekends and at night occasionally to test segments of the organization that work at times when all of the specialized resources of the facility are not immediately available. Initially, limited scale drills can test segments of the ERP, such as manning the MECC with the shift personnel that are available and carrying out a headcount without involving daytime employees.

As the proficiency of the organization increases, drill scenarios can become more complex. Complicating factors approaching worst real-life conditions should be introduced periodically, including:

☐ Telephone switchboard overload
☐ Absence of key EMO members
☐ Arrival of major TV network anchorperson
☐ Simulated mass casualties
☐ Two-way radio failure
☐ Evacuation of primary and backup MECCs
☐ Major community impact

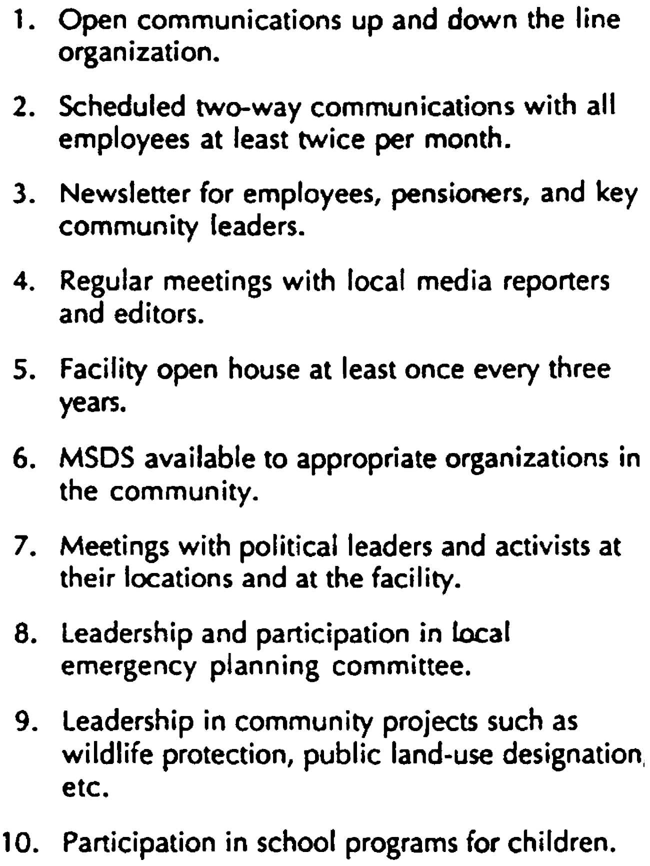
The Emergency Preparedness Team, with approval of the manager, designs the drill scenarios, monitors the organization's performance, provides leadership for critiquing, and recommends corrective actions. The team also develops and monitors a plan for involving the community in the important task of integrating a facility's ERP into the public emergency preparedness programs of the region.

Involving the Community

Of major concern to the chemical industry is the public perception that facility managers have little concern for the welfare of their neighbors. Managers themselves have contributed to such false impressions by failing to interact with their communities in a consistent and meaningful way.

The public clearly wants to know more about the risks presented by a chemical facility. Increasingly, the public wants to help decide which risks are acceptable and which are not.

Recognizing that industrial facilities exist only with the consent of their host communities, most industrial organizations are assigning a high priority to building



1. Open communications up and down the line organization.
2. Scheduled two-way communications with all employees at least twice per month.
3. Newsletter for employees, pensioners, and key community leaders.
4. Regular meetings with local media reporters and editors.
5. Facility open house at least once every three years.
6. MSDS available to appropriate organizations in the community.
7. Meetings with political leaders and activists at their locations and at the facility.
8. Leadership and participation in local emergency planning committee.
9. Leadership in community projects such as wildlife protection, public land-use designation, etc.
10. Participation in school programs for children.

Fig. 3.5 Risk communication checklist

stronger bridges with their neighbors. The chemical industry in particular is finding that the involvement of the community in the process of emergency preparedness planning presents an excellent opportunity for constructive two-way communications. This has proved particularly productive if these communications are part of an aggressive and continuous risk communications process.

Communications

Each chemical facility needs to create opportunities for sharing information with its surrounding community; it should not wait for these opportunities to occur. Facility managers in particular should be active in the process, and should monitor the performance of their organizations. Some items that should be on a manager's checklist for risk communications are shown in Fig. 3.5.

The process should start with employee communications. In its employees, a facility has an important, informal communication link with its community that is often ignored. Employees deserve to know at least as much about their facility as their neighbors, and they deserve to know it first. They should be aware through communications (if not through actual involvement) of the facility's entire emergency preparedness program, from prevention to preparation. The employees also should be familiar with the products made and their end uses. They should understand the potential hazards of the processes and materials with which they work, and how to protect themselves and the public from those hazards.

Other communication channels should be developed and regularly used. Scheduled meetings with representatives of community emergency service groups are useful for exchanging information and objectives concerning emergency preparedness, for promoting the sharing of resources, for gaining familiarity with one another's physical facilities and people, for identifying problems, and for recommending action for their solution.

In the 1980s, some chemical facilities and their communities formalized this approach and broadened participation in their meetings to include public officials and representatives of regulatory agencies and the media. Operating as Hazardous Material Advisory Councils (HMACs) and meeting regularly with established leadership and agendas, these groups quickly became key resources in organizing a community's efforts to better understand the potential for hazardous material incidents and to protect against them. Typically the responsibilities of an HMAC include coordinating a regional risk assessment, assisting the development of a community response plan specific to hazardous materials, and assisting with educational programs for various segments of the public.

The Responsible Care program of the American Chemistry Council embraces HMACs as one good way to communicate relevant and useful information that responds to public concerns for safety, health, and the environment. However, managers are finding many other ways to interact with the public to achieve a fuller measure of community awareness and involvement in affairs of mutual interest. Among the many options from which a manager may choose are the following:

- Hosting facility tours featuring emergency prevention and mitigation procedures
- Speaking at community meetings (service clubs, schools, governing bodies, etc.)
- Sending newsletters to selected neighbors
- Preparing informative brochures or newspaper inserts
- Appearing on local TV or radio

An open and sincere comprehensive risk communication process led by the facility manager creates a better-informed public that is able to understand real risks (vs. perceptions) and is likely to respond effectively in case of an actual emergency.

Integrating Plans

Most communities have long had written ERPs designed for natural events such as floods and windstorms; some communities have had written plans dealing with emergencies created by people, such as bomb threats and civil disturbances; but, until recently, few had specific plans for responding to emergencies involving hazardous materials. As a result, the consequences of accidental chemical releases have been in many cases tragically magnified by the undisciplined reactions of people near the release source. It has been reported, for example, that when the alarms sounded at Bhopal, residents of the nearby homes ran toward the plant rather than taking action to protect themselves from the enveloping fumes.

It is not enough to train the personnel of a chemical facility to implement an ERP effectively. Appropriate people in the community, especially near neighbors, need to understand the elements of an ERP that are designed to protect them and the role they play in making the plan work. There must be a continuous effort to integrate the facility ERP into community emergency planning at local and district levels. Drills involving external resources that test all the plan elements against the standards mutually established with the community and those imposed by laws and regulations are necessary to ensure successful implementation of the plan.

Off-Site Warning

Designing an effective off-site warning system presents some major challenges. Despite excellent ongoing communications between a chemical facility and its neighbors, there is no positive way to ensure that the general public will respond quickly and appropriately to a warning alarm of any kind. Thus, it is essential that the selected warning system be developed with the close cooperation of the community. Even then, it is difficult to predict such factors as the inclination of people to be warned and the degree of public confidence in the validity of an alarm.

No off-site warning system will assure complete coverage of the intended audience. Best results are achieved by combining two or more systems for sequential alerting—the first to trigger preplanned immediate action by the public at greatest risk, followed by other communications that provide further information and guidance to a larger audience. Some of the systems most commonly used are:

- ☐ Facility fixed-sound sources, such as sirens and whistles
- ☐ Mobile alerting by police or fire personnel, either from vehicles with loudspeakers or door-to-door
- ☐ Fixed public address systems in the community or in the facility
- ☐ Automated telephone calling
- ☐ Alert radios energized by a special signal to produce a warning tone followed by broadcast messages
- ☐ Strobe lights in situations where the noise level is a problem
- ☐ Local radio stations and the emergency broadcast system
- ☐ Local TV stations

More sophisticated and less commonly used warning systems include helicopters equipped with loudspeakers, modified cable TV installations, and computer networks between a chemical facility and community emergency response groups.

Local Emergency Plans

Existing plans for a coordinated response to emergencies in a community vary greatly in content and organization, but the plans have two common objectives. They are to:

- ☐ Define authority and responsibilities of various emergency service participants
- ☐ Describe the interaction between those participants, government, and industry

In creating their plans, most communities draw on the Integrated Emergency Management System (IEMS) developed by the Federal Emergency Management Agency (FEMA).

A local plan has many of the same elements as a chemical facility ERP. It includes:

- ☐ An EMO, with designated functional responsibilities
- ☐ The location of the emergency operating center and its resources
- ☐ Guidelines for classifying emergencies
- ☐ Activation and declaration checklists
- ☐ Communications requirements and available systems
- ☐ Evacuation and sheltering plans
- ☐ Methods for securing added resources
- ☐ Descriptions of local hazards

Most local plans are written to be nonspecific as to the cause of the emergency, with various appendices describing the details of response to specific events. These appendices are based on the results of risk assessments made by the community with the cooperation of industry.

One such appendix should relate to emergencies caused by fixed facility or transportation incidents in which hazardous materials are involved. Chemical facilities must provide substantial support to the community in preparing this portion of the local emergency plan, and provide resources and training leadership that are not available elsewhere in the community. Where a HMAC exists, there is an effective forum for doing this. In any case, a chemical facility manager should seek ways to help the community prepare for and recover from incidents of this nature.

Local Emergency Planning Committees

An important contribution to community and industry cooperation in emergency preparedness was the passage in 1986 of the SARA, which contained an emergency planning and community right-to-know provision. Title III, or EPCRA, as this portion of SARA is commonly called, is intended to encourage and support hazardous materials emergency planning efforts at the state and local level, and to provide citizens and local agencies with appropriate information concerning potential hazards in their communities.

The major portions of Title III require

☐ A statewide organization for planning emergency action and receiving hazardous chemical information
☐ Notification to the community of emergency releases of chemicals
☐ Reports of hazardous chemical inventories and copies of MSDSs to be furnished to the community
☐ An annual inventory of hazardous chemical releases to the environment

Drills and Critiques

The optimum frequency of major drills involving personnel outside a chemical facility is dependent upon a number of variables:

☐ Location of the facility
☐ Dependence upon community emergency agencies
☐ Size and complexity of the facility
☐ Site and off-site risk assessments
☐ Population patterns

An important element of emergency preparedness is the establishment of an appropriate major drill frequency in cooperation with off-site agencies. A reasonable goal is to hold one such drill each year. The scenario might include an on-site, internally generated hazardous material emergency 1 year and a transportation emergency somewhere in the adjacent community the following year.

For facilities and communities just beginning to test their plans, desktop or simulated drills are effective for identifying procedural problems that need to be corrected before they proceed to full-scale drills. In these simulations, staffing of the appropriate emergency center would occur, but the emergency service groups would not actually mobilize at the scene of the incident.

As people gain confidence in the completeness and the effectiveness of the ERP, it becomes important to measure the performance of all who are involved. Monitors record and later report on all aspects of response actions, including:

Elapsed times before critical actions occur
Actions and coordination of responding groups
Actions of uninvolved personnel
Alarm and communication effectiveness
Emergency control center management
Control at the emergency scene
Accounting for personnel
Medical aid for simulated casualties
- Off-site notifications

Handling media representatives—real or simulated

Following each drill there must be an organized critique that provides the information needed to strengthen the plan and/or its implementation. All the people actively involved should be represented at the critique, and a written report of conclusions and recommendations should be widely distributed. It then is the responsibility of the facility Emergency Preparedness Team and the local emergency planning committee (LEPC) to coordinate and assist in solving any problems identified—a process that begins emergency preparedness activities again: identifying hazards; evaluating and strengthening resources; modifying the emergency plan; training people; communicating and integrating plans; and testing them once again.

Laws, Regulations, and Support

Laws

A number of legal requirements must be incorporated in a facility's ERP. Emergency prevention, preparedness, and response planning are regulated at the federal, state, and, occasionally, local levels. At the federal level, these laws include

☐ Clean Air Act (CAA)
☐ Clean Water Act (CWA)
☐ Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA)
☐ Emergency Planning and Community Right-to-Know Act (EPCRA, or SARA Title III)
☐ Energy Reorganization Act (Nuclear Regulatory Commission)
☐ Hazardous Materials Transportation Act (HMTA)
☐ Occupational Safety and Health Act (OSHA)
☐ Resource Conservation and Recovery Act (RCRA)
☐ Toxic Substances Control Act (TSCA)
☐ U.S. Coast Guard requirements
☐ Environmental Protection Agency (EPA) regulations

A list of these laws and their *Code of Federal Regulations* (CFR) citations appears in the bibliography at the end of the chapter. States may have their own laws and regulations that also govern emergency response planning. References to these laws may be found in the Bureau of National Affairs (BNA) *Environment Reporter*.

These laws and their regulations are enforced by all levels of governmental agencies. A knowing or willful violation has serious implications for both companies and individuals, who may be held civilly or criminally liable for noncompliance. The penalties can be severe, ranging from daily-assessed fines to imprisonment. Thus, it is prudent to know the regulations that apply to the facility, and to ensure that the regulatory requirements are met.

The regulations regarding emergency planning and response are comprehensive, covering every aspect from prevention to reporting. RCRA's regulations cover the entire process, from planning to training to formal reports on the facility's response to an emergency involving hazardous waste. Other regulations focus on a specific aspect of emergency response, or part of the facility's operations. For example, the TSCA requires that spills or releases that contaminate the environment be reported orally and in writing within a certain time frame. All but one of the laws put the burden of planning on the facility. EPCRA, the exception, requires state and local agencies to prepare an ERP for the community. Facilities that meet criteria specified in EPCRA regulations have to assist in the development of the plan; however, they are not responsible for creating it.

The OSHA Process Safety Management regulation (29CFR 1910.119) and the EPA's Risk Management Plan regulation require significant attention to emergency planning and response. Inevitably, some of the regulations and requirements overlap. Most chemical facilities are subject to more than one law, and could be expected to prepare separate plans for specific parts of their facility. RCRA's Contingency Plan, for example, must be developed and maintained apart from other ERPs. The key to managing all the requirements and satisfying the regulations in an efficient, coordinated manner is first to understand the requirements and how they apply to the facility, and then to look for the common denominators among the requirements. The finished product, or master plan, will satisfy all the common denominators that apply, and will avoid duplication of effort. It also can be used as the basis for plans that must be maintained separately or that have requirements in addition to the common denominators.

Meeting the Requirements

Regulations governing emergency response planning can be broken down into four general categories:

☐ Preparation
☐ Plans
☐ Reports and other communications
☐ Drills and evaluations

Figure 3.6 shows a matrix-type summary of the major federal laws and their requirements for emergency planning and response. Such a matrix is very helpful in determining what the requirements are and how they apply to a facility. It could be further tailored to cover only the requirements that apply to a specific site or operation.

Prevention and Preparation

Some regulations require that a facility conduct a risk assessment and/or other preparatory activities. The RCRA calls it a preparedness and prevention plan. A facility subject to the RCRA must determine how structures, processes, and operations can be changed in order to minimize the possibility of an emergency involving hazardous waste. The facility also has to determine the communications and alarm systems that will be used in the event of such an emergency. The CWA includes prevention in its requirements for the Spill Prevention, Containment, and Countermeasure (SPCC) Plan. The 1990 amendments to the CAA added an accident prevention plan for extremely hazardous substances (EHSs).

Plans

At the very least, a facility is required to develop a plan describing how it will respond to an incident that threatens human health and/or the environment. Generally, the plan includes notification, evacuation, protection of employees, and control of the incident. This ERP usually must be in writing. For example, the OSHA requires a minimum of three plans: emergency response, emergency action, and fire prevention. The CAA requires that the state implementation plan have an emergency air pollution episode plan.

Communications

There are two aspects to emergency communications: the actual equipment used to communicate information about the incident and the types of communications or information-sharing required. The RCRA has specific requirements for the types of emergency communication equipment (alarm systems, phone or radio communications) that must be present. Under the EPCRA, facilities must provide information about their operations and substances used or stored on site when the Local Emergency Planning Committee (LEPC) or State Emergency Response Commission (SERC) requests it. If the facility uses or stores extremely hazardous substances (EHSs) in reportable quantities, it must appoint a representative to the LEPC.

	RCRA	OSHA	DOT/HMTA	EPCRA	CERCLA
PREVENTION AND PLANNING	Preparedness & prevention plan Contingency Plan (CP) in writing: Emergency coordinator, Evacuation, Access, Equipment, Communications	Emergency Response Plan : For entire site; For employees who respond to uncontrolled releases of hazardous substances, including hazardous wastes Emergency Action Plan: Evacuation for employees in case of incidental chemical release; How to report an incident Fire Prevention Plan	Incident prevention and response	Local Emergency Planning Committee prepares emergency response plan for community State Emergency Planning Commission (SERC) oversees.	National Contingency Plan (NCP) Facility plan for response and cleanup of oil or hazardous substance must meet NCP Standards
REPORTS	Incidents in transit Transporter must: Notify National Response Center (NRC) at once; Submit written report within 15 days to DOT; Coordinate with DOT. Hazardous waste emergency on site: Immediately-NRC Follow-up, in writing to EPA RA within 15 days UST releases	Process hazards review	Report six specific hazardous material incidents, at once to DOT/NRC; written follow-up at once to NRC Spill of RQ into navigable waters	Releases of extremely hazardous substances over reportable quantity (RQ) EHS stored on site in quantities ≥ RQ	Release of RQ or 1 pound of hazardous substance-to NRC, immediately
INFORMATION	Maintain copy of CP at site Provide copy to local emergency response organization Establish alarm and communication systems for emergency notification.	MSDS to employees and emergency response organization	Emergency response information available during transportation and at facilities where hazardous materials are loaded or stored.	As required by LEPC and SERC Designate representative to LEPC. Coordinate internal plans or make them available to LEPC.	
TRAINING, DRILLS, AND EVALUATION	Emergency response must be documented and records retained Initial and annual review Evacuation drill	Initial and annual refresher training for employees involved in emergency response; varies with roles– All employees trained in Emergency Action Plan; initially and with every change to plan. Training in MSDS information			

Fig. 3.6 Emergency prevention, planning, and response

CWA	CAA	TSCA	NUREG 054	USCG	EPA
Spill Prevention Control and Countermeasure (SPCC) Plan Shows how facility will: prevent, respond, follow-up to oil spills in harmful quantities. Must be in writing	State Iplementation Plan (SIP) must include an Emergency Air Pollution Episode plan Accident Prevention Program for EHS States may require prevention and emergency response plan		Emergency response plan, including: Emergency planning zones; Prevention, mitigation, and limitation of core damage and consequences of release Subject to annual review		Risk management plan
Release of RQ of oil or hazardous substance to NRC, immediately.	Announce uncontrolled releases of pollutants over certain set levels Releases ≥ RQ to NRC	Emergency incidents of environmental contamination At once to EPA, Written follow-up within 10 days	Notify state and local officials: Change in condition Protective action recommendations Notify community within 15 minutes. 100% notification within 15 miles.	All spills into navigable waters of oil, hazardous substances, ≥ RQ, at once, to US Coast Guard or to NRC	Worst case scenarios
Keep copy of SPCC at site available to EPA RA during normal working hours. Submit SPCC amendments to EPA RA and state water pollution control agency					Emergency response plan
Train: SPCC responders Employees who operate, maintain equipment			Annual training On-site Off-site Annual graded emergency response exercises		Training required for all employees in emergency response plan

Several laws require that a copy of the ERP be made available to employees and representatives of government agencies during working hours. The OSHA requires that facilities provide material safety data sheets (MSDS) for all hazardous substances present on the site.

Reports

Reports are another important communications aspect of the ERP. Most laws insist on prompt notification of the proper agencies immediately after an incident occurs. These reporting requirements can be complex, particularly in view of the fact that many laws have their own lists of hazardous substances and reportable quantities. The CERCLA requires that releases of a reportable quantity of what it defines as a hazardous substance must be reported immediately to the National Response Center (NRC). The EPCRA requires facilities that store and/or release reportable quantities of substances on its EHS list to report that information to the LEPC and the SERC. EPA's Risk Management Plan requires prior disclosure of possible "worst case" incident scenarios.

Written follow-up reports are often a requirement. The HMTA has identified six specific hazardous material incidents that must be reported immediately and again in writing. The RCRA gives managers 15 days after a hazardous waste emergency to submit a written report to the EPA.

Training, Drills, Audits, and Evaluations

An emergency plan is relatively useless unless the employees affected by it are trained in its use. The RCRA, OSHA, HMTA, CWA, and the Energy Reorganization Act require annual and refresher training. In addition, the facilities must keep records of the training, and must make them available to the appropriate agency when they are requested. Some laws go so far as to require practice drills. Nuclear power plants must conduct on- and off-site training, and go through annual graded emergency response exercises. The plan and the response executed according to the plan then are evaluated so that the plan can be improved.

Sources of Assistance

Seeing all the requirements together can be overwhelming. Fortunately, there are agencies, associations, and programs that can assist in the preparation of a comprehensive emergency prevention and response plan.

The federal government and the agencies responsible for the laws that govern emergency response planning provide 800-number hotlines and manuals that describe various aspects of emergency prevention, planning, and response.

The volunteer or professional emergency responders in the community have valuable practical experience that can be put to work in developing the facility ERP. Working with them also establishes a forum for communications and understanding with the community.

The ACC Community Awareness and Emergency Response (CAER) program provides comprehensive guidelines for the development and implementation of an ERP. The CAER program has been expanded to include all aspects of the chemical industry in an initiative called Responsible Care.

Other services of the ACC include CHEMTREC, a 24-h emergency response service for people who respond to emergencies involving chemicals; CHEMNET, a mutual aid agreement between chemical producers and emergency response contractors; and workshops and videotape training programs for first responders and other emergency response personnel.

Additional sources of assistance and information include other professional associations, such as the American Institute of Chemical Engineers, and publications, seminars, workshops, and videotapes offered by educational organizations. Considerable information is available on the Internet through web sites such as www.fema.gov which is maintained by the FEMA.

A bibliography; a list of laws, regulations, and standards; and a compilation of suggested reading material follow.

Applied Statistical Methods and the Chemical Industry

4

Stephen Vardeman and Robert Kasprzyk

Introduction

The discipline of statistics is the study of effective methods of data collection, data summarization, and (data based, quantitative) inference making in a framework that explicitly recognizes the reality of nonnegligible variation in real-world processes and measurements.

The ultimate goal of the field is to provide tools for extracting the maximum amount of useful information about a noisy physical process from a given investment of data collection and analysis resources. It is clear that such a goal is relevant to the practice of Industrial chemistry. The primary purposes of this chapter are to indicate in concrete terms the nature of some existing methods of applied statistics that are particularly appropriate to industrial chemistry, and to provide an entry into the statistical literature for those readers who find, in the discussion here, reasons to believe that statistical tools can help them be effective in their work.

This chapter will begin with some simple ideas of modern descriptive statistics, including numerical and graphical data summarization tools, and the notions of fitting equations to data and using theoretical distributions. Next, some tools for routine industrial process monitoring and capability assessment, concentrating primarily on the notion of control charting, will be presented. This will be followed by a more extensive discussion of common statistical data collection strategies and data analysis methods for multifactor experimental situations met in both laboratory and production environments. This section will touch on ideas of partitioning observed variation in a system response to various sources thought to influence the response, factorial and fractional factorial experimental designs, sequential experimental strategy, screening experiments, and response surface fitting and representation. Next come brief discussions of two types of special statistical tools associated specifically with chemical applications, namely, mixture techniques and nonlinear mechanistic model building. A short exposition of chemical industry implications of relationships between modern business process improvement programs and the discipline of statistics follows. The chapter concludes with a reference section listing sources for further reading.

Simple Tools of Descriptive Statistics

There are a variety of data summarization or description methods whose purpose is to make evident the main features of a data set. (Their use, of course, may be independent of whether or not the data collection process actually employed was in any sense a "good" one.) To illustrate some of the simplest of these methods, consider the data listed in Table 4.1. These numbers represent aluminum impurity contents (in ppm) of 26 bihourly samples of recycled PET plastic recovered at a Rutgers University recycling pilot plant.

A simple plot of aluminum content against time order, often called a *run chart*, is a natural place to begin looking for any story carried by a data set. Figure 4.1 shows such a plot for the data of Table 4.1, and in this case reveals only one potentially interesting feature of the data. That is, there is perhaps a weak hint of a downward trend in the aluminum contents that might well have been of interest to the original researchers. (If indeed the possible slight decline in aluminum contents is more than "random scatter," knowledge of its physical origin, whether in actual composition of recycled material or in the measurement process, presumably would have been helpful to the effective running of the recycling facility. We will save a discussion of tools for rationally deciding whether there is more than random scatter in a plot like Fig. 4.1 until the next section).

Fig. 4.1 A run chart for 26 consecutive aluminum contents

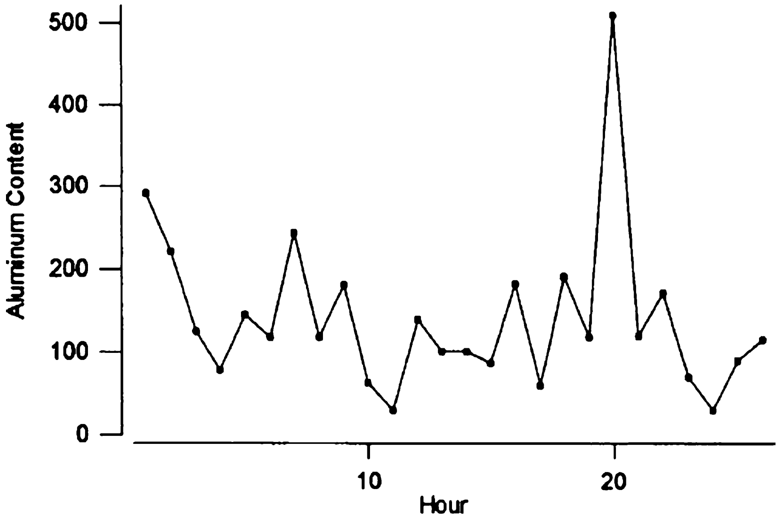

Fig. 4.2 A histogram for 26 aluminum contents

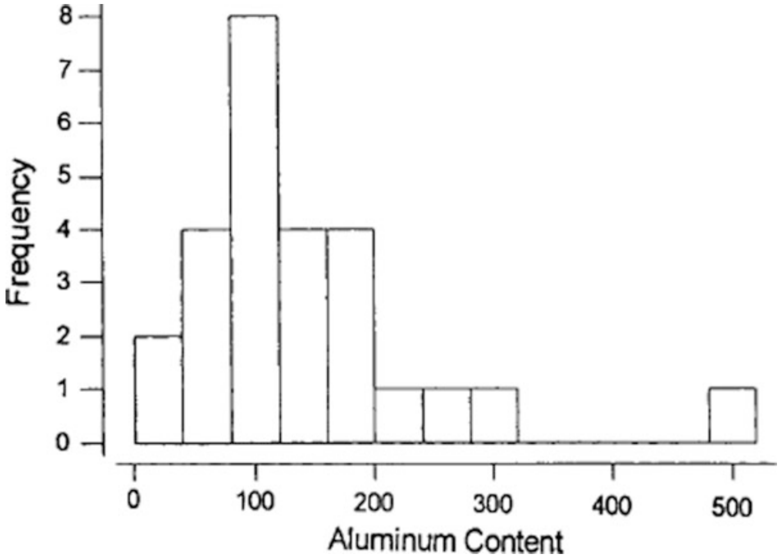

The run chart is a simple, explicitly dynamic tool of descriptive statistics. In those cases where one decides that there is in fact little information in the time order corresponding to a data set, there are a variety of simple, essentially static, statistical tools that can be used in describing the pattern of variation in a data set. Figures 4.2, 4.3, 4.4 and 4.5 show graphical representations of the data of Table 4.1 in, respectively, *histogram*, *stem and leaf plot*, *dot plot*, and *box plot* forms.

The histogram/bar chart idea of Fig. 4.2 is likely familiar to most readers, being readily available, for example, through the use of commercial spreadsheet software. It shows how data are spread out or distributed across the range of values represented, tall bars indicating high frequency or density of data in the interval covered by the base of the bar. Figure 4.2 shows the measured aluminum contents to be somewhat asymmetrically distributed (statistical jargon is that the distribution is "skewed right"), with a "central" value perhaps somewhere in the vicinity of 120 ppm.

Histograms are commonly and effectively used for final data presentation, but as working data analysis tools they suffer from several limitations. In one direction, their appearance is fairly sensitive to the data grouping done to make them, and it is usually not possible to recover from a histogram the exact data values used to produce it, should

[a] Based on data in Albin [32]

one wish to try other groupings. In another direction, histograms are somewhat unwieldy, for example, not being particularly suitable to the comparison of, say, 10 or 12 data sets on a single page. The graphical devices of Figs. 4.3, 4.4, and 4.5 are less common than the histogram, but address some of these shortcomings.

The stem and leaf diagram of Fig. 4.3 and the dot plot of Fig. 4.4 carry shape information about the distribution of aluminum contents in a manner very similar to the histogram of Fig. 4.2. But the stem and leaf and dot diagrams do so without losing the exact identities of the individual data points. The box plot of Fig. 4.5 represents the "middle half" of the data with a box divided at the 50th percentile (or in statistical jargon, the median) of the data, and then uses so-called whiskers to indicate how far the most extreme data points are from the middle half of the data.

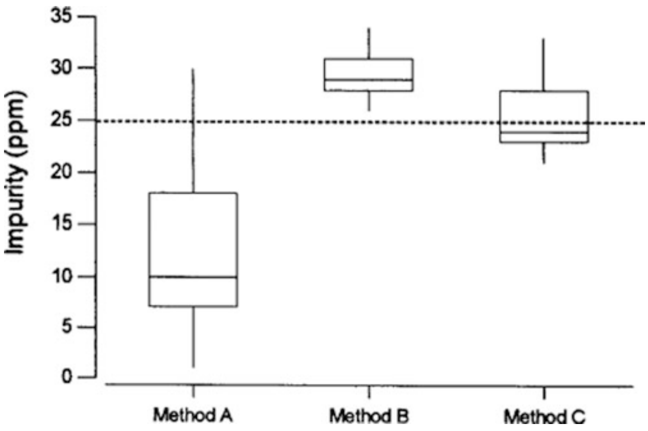

Fig. 4.6 Side-by-side box plots for three laboratory test methods

Box plots preserve much of the shape information available from the other displays (e.g., portraying lack of symmetry through differing sizes of box "halves" and/or whisker lengths), but do so in a way that is conducive to simultaneous representation and comparison of many data sets on a single graphic, through the placement of box plots side by side. Figure 4.6 illustrates this point with a graphical comparison of three laboratory test methods to a standard.

A total of 90 samples of a stock solution known to contain 25 ppm of an impurity were analyzed by a single lab team using three different test methods (30 of the samples being allocated to each of the three methods), and the box plots in Fig. 4.6 portray the measured impurity levels for the different methods. The figure shows quite effectively that Method A is neither precise nor accurate, Method B is quite precise but not accurate, and Method C is somewhat less precise than B but is accurate. This kind of knowledge can form the basis of an informed choice of method.

Figures 4.2, 4.3, 4.4, 4.5, and 4.6 give only a hint of the spectrum of tools of statistical graphics that are potentially helpful in data analysis for Industrial chemistry. For more details and much additional reading on the subject of modern statistical graphics, the reader is referred to the book by Chambers et al. [1] listed in the references section.

Complementary to graphical data summaries are *numerical summarizations*. For the simple case of data collected under a single set of conditions, the most commonly used measures deal with the location/center of the data set and the variability/spread of the data. The (*arithmetic*) *mean* and the *median* are the most popular measures of location, and the *variance* and its square root, the *standard deviation*, are the most widely used measures of internal variability in a data set.

For n data values $y_1, y_2, \ldots, y_n$ the median is

$$\tilde{y} = \text{the ``middle'' of } \frac{n+1}{2} \text{th ordered data value} \tag{4.1}$$

and the mean is

$$\bar{y} = \frac{1}{n}\sum_{i=1}^{n} y_i \tag{4.2}$$

The reader is invited to check that upon ordering the $n = 26$ values in Table 4.1, the 13th smallest value is 119 and the 14th smallest value is also 119, so that the only sensible interpretation of (4.1) for the aluminum content data is that

$$\tilde{y} = \text{the } 13.5\text{th ordered data value} = \frac{119 + 119}{2} = 119 \text{ ppm}$$

On the other hand, from (4.2) the mean of the aluminum contents is

$$\begin{aligned}\bar{y} &= \frac{1}{26}(291 + 222 + 125 + \cdots + 30 + 90 + 115)\\ &\approx 142.7 \text{ ppm}\end{aligned}$$

The median and mean are clearly different measures of location/center. The former is in the middle of the data in the sense that about half of the data are larger and about half are smaller. The latter is a kind of "center of mass," and for asymmetrical data sets like that of Table 4.1 is usually pulled from the median in the direction of any "skew" present, that is, is pulled in the direction of "extreme" values.

The variance of n data values $y_1, y_2, \ldots, y_n$ is essentially a mean squared deviation of the data points from their mean. In precise terms, the variance is

$$s^2 = \frac{1}{n-1}\sum_{i=1}^{n}(y_i - \bar{y})^2 \tag{4.3}$$

and the so-called standard deviation is

$$s = \sqrt{s^2} = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(y_i - \bar{y})^2} \tag{4.4}$$

For the example of the aluminum contents, it is elementary to verify that

$$\begin{aligned}s^2 &\approx \frac{1}{26-1}[(291 - 142.7)^2 + (222 - 142.7)^2 + \cdots\\ &\quad + (115 - 142.7)^2]\\ &\approx 9{,}644(\text{ppm})^2\end{aligned}$$

so that

$$s = \sqrt{s^2} \approx 98.2 \text{ ppm}$$

An appropriate interpretation of s is not completely obvious at this point, but it does turn out to measure the spread of a data set, and to be extremely useful in drawing quantitative inferences from data. (In many, but not all, circumstances met in practice, the *range* or largest value in a data set minus the smallest value is on the order of four to six times s.) The variance and standard deviation are time-honored and fundamental quantifications of the variation present in a single group of measurements and, by implication, the data-generating process that produced them.

When data are collected under several different sets of conditions, and those conditions can be expressed in quantitative terms, effective data summarization often takes the form *of fitting an approximate equation* to the data. As the basis of a simple example of this, consider the data in Table 4.2. The variable x, hydrocarbon liquid hourly space velocity, specifies the conditions under which information on the response variable y, a measure of isobutylene conversion, was obtained in a study involving the direct hydration of olefins.

Table 4.2 Seven liquid hourly space velocity/mol% conversion data Pairs[a]

Liquid hourly space velocity, x	Mole % isobutylene conversion, y
1	23.0, 24.5
2	28.0
4	30.9, 32.0, 33.6
6	20.0

[a] Based on a graph in Odioso et al. [33]

For purposes of economy of expression, and perhaps some cautious interpolation between values of x not included in the original dataset, one might well like to fit a simple equation involving some parameters $\underline{b}$, say,

$$y \approx f(x|\underline{b}.) \tag{4.5}$$

to the data of Table 4.2. The simplest possible form for the function $f(x|\underline{b})$ that accords with the "up then back down again" nature of the conversion values y in Table 4.2 is the quadratic form

$$f(x|\underline{b}) = b_0 + b_1 x + b_2 x^2 \tag{4.6}$$

and a convenient method of fitting such an equation (that is linear in the parameters b) is *the method of least squares*. That is, to fit a parabola through a plot of the seven (x, y)

pairs specified in Table 4.2, it is convenient to choose b_0, b_1, and b_2 to minimize the sum of squared differences between the observed conversion values y and the corresponding fitted values y on the parabola. In symbols, the least squares fitting of the approximate relationship specified by (4.5) and (4.6) to the data of Table 4.2 proceeds by minimization of

$$\sum_{i=1}^{7} \left[y_i - \left(b_0 + b_1 x_i + b_2 {x_i}^2\right)\right]^2$$

over choices of the coefficients b. As it turns out, use of standard statistical "regression analysis" software shows that the fitting process for this example produces the approximate relationship

$$y \approx 13.64 + 11.41x - 1.72x^2$$

and Fig. 4.7 shows the fitted (summarizing) parabola sketched on the same set of axes used to plot the seven data points of Table 4.2.

The least squares fitting of approximate functional relationships to data with even multidimensional explanatory variable x typically goes under the (unfortunately obscure) name of *multiple regression* analysis, and is given an introductory treatment in most engineering statistics textbooks, including, for example, the ones by Devore [2], Vardeman and Jobe [3], and Vardeman [4] listed in the references. A lucid and rather complete treatment of the subject can also be found in the book by Neter et al. [5].

A final notion that we wish to treat in this section on descriptive statistics is that of representing a distribution of responses and/or the mechanism that produced them (under a single set of physical conditions) by a *theoretical distribution*. That is, there are a number of convenient theoretical distributional shapes, and it is often possible to achieve great economy of expression and thought by seeing in a graphical representation such as Figs. 4.2, 4.3, 4.4, and 4.5 the possibility of henceforth describing the phenomenon portrayed via some one of those theoretical distributions. Here we will concentrate on only the most commonly used theoretical distribution, the so-called *Gaussian* or *normal* distribution.

Figure 4.8 is a graph of the function of x

$$g(x) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right) \qquad (4.7)$$

where $g(x)$ specifies the archetypical "bell-shaped curve" centered at the number μ, with spread controlled by the number σ (and is in fact usually called the Gaussian probability density with mean μ and standard deviation σ).

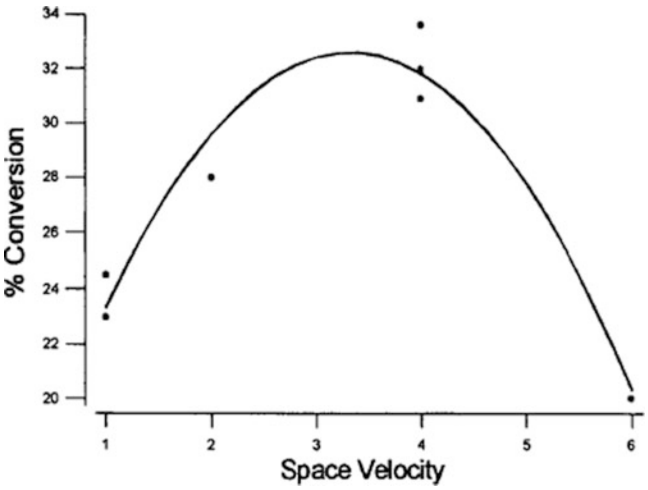

Fig. 4.7 A scatter plot of seven space velocity/mol% conversion data pairs and a fitted parabola

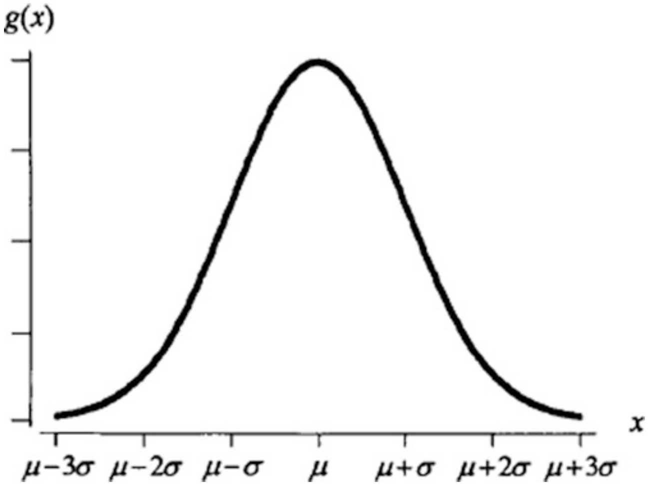

Fig. 4.8 The Gaussian probability density with mean μ and standard deviation σ

Figure 4.8 can be thought of as a kind of idealized histogram. Just as fractional areas enclosed by particular bars of a histogram correspond to fractions of a data set with values in the intervals represented by those bars, areas under the curve specified in (4.7) above particular intervals might be thought of as corresponding to fractions of potential data points having values in those intervals. (It is possible to show that the total area under the curve represented in Fig. 4.8, namely, $\int_{-\infty}^{\infty} g(x)\,\mathrm{d}x$, is 1.) Simple tabular methods presented in every elementary statistics book avoid the need to regularly use numerical integration in evaluating such areas. These methods can, for example, be used to show that roughly 68% of a Gaussian distribution lies between $\mu-\sigma$ and $\mu+\sigma$, roughly 95% lies between $\mu-2\sigma$ and $\mu+2\sigma$, and roughly 99.7% lies between $\mu-3\sigma$

Table 4.3 Twenty-six logarithms of aluminum contents

Fig. 4.9 A stem and leaf plot for the logarithms of 26 aluminum contents

and $\mu + 3\sigma$. Part of the convenience provided when one can treat a data-generating process as approximately Gaussian is that, given only a theoretical mean μ and theoretical standard deviation σ, predictions of fractions of future data values likely to fall in intervals of interest are thus easy to obtain.

At this point let us return to the aluminum content data of Table 4.1. The skewed shape that is evident in all of Figs. 4.2, 4.3, 4.4, and 4.5 makes a Gaussian distribution inappropriate as a theoretical model for (raw) aluminum content of such PET samples. But as is often the case with right skewed data, considering the *logarithms* of the original measurement creates a scale where a normal distribution is more plausible as a representation of the phenomenon under study. Thus, Table 4.3 contains the natural logs of the values in Table 4.1, and the corresponding stem and leaf plot in Fig. 4.9 shows the transformed data to be much more symmetrically distributed than the original data. The possibility opened up by this kind of transformation idea is one using statistical methods based on the normal distribution to reach conclusions about $\ln y$ and then simply exponentiating to derive conclusions about the original response y itself. The applicability of statistical methods developed for normal distributions is thereby significantly broadened.

In addition to providing convenient conceptual summarizations of the nature of response distributions, theoretical distributions such as the normal distribution form the mathematical underpinnings of methods of formal quantitative *statistical inference*. It is outside our purposes in this chapter to provide a complete introduction to such methods, but thorough and readable accounts are available in engineering statistics books such as those of Devore [2] and Vardeman and Jobe [3]. Here, we will simply say that, working with a Gaussian description of a response, it is possible to quantify in various ways how much information is carried by data sets of various sizes. For instance, if a normal distribution describes a response variable y, then in a certain well-defined sense, based on $n = 26$ observations producing a mean $\bar{y}$ and a standard deviation s, the interval with end points

$$\bar{y} - 2.060s\sqrt{1 + \frac{1}{26}} \tag{4.8}$$

and

$$\bar{y} + 2.060s\sqrt{1 + \frac{1}{26}} \tag{4.8a}$$

has a 95% chance of predicting the value of an additional observation. For instance, applying formula (4.8) to the log values in Table 4.3, the conclusion is that the interval from 3.45 to 6.10 ln(ppm) has a 95% chance of bracketing an additional log aluminum content produced (under the physical conditions of the original study) at the recycling plant. Exponentiating, the corresponding statement about raw aluminum content is that the interval from 31 to 446 ppm has a 95% chance of bracketing an additional aluminum content. Methods of statistical inference like that represented in (4.8) are called *prediction interval* methods. The book by Hahn and Meeker [6] provides a thorough discussion of such methods, based not only on the Gaussian distribution but also on other theoretical distributional shapes as well.

Tools of Routine Industrial Process Monitoring and Capability Assessment

Probably the two most basic generic industrial problems commonly approached using statistical methods are those of (1) monitoring and maintaining the stability/consistency of a process and (2) assessing the capability of a stable process. This section provides a brief introduction to the use of tools of "control" charting in these enterprises.

Working at Bell Labs during the 1920s and 1930s, Walter Shewhart developed the notion of routinely plotting data from an industrial process in a form that allows one to separate observed variability in a response into two kinds of variation. The first is that variation which appears to be inherent, unavoidable, short-term, baseline, and characteristic of the process (at least as currently configured). This variation Shewhart called *random* or *common cause variation*. The second kind of variability is that variation which appears to be avoidable, long-term, and/or due to sources outside of those seen as legitimately impacting process behavior. He called this variation *assignable* or *special cause variation*.

Shewhart reasoned that by plotting summary statistics from periodically collected data sets against time order of collection, one would be able to see interpretable trends or other evidence of assignable variation on the plots, and could intervene to eliminate the physical causes of that variation. The intention was to thereby make process output stable or consistent to within the inherent limits of process precision. As a means of differentiating plotted values that should signal the need for intervention from those that carry no special message of process distress, he suggested drawing so-called control limits on the plots. (The word "control" is something of a misnomer, at least as compared to common modern engineering usage of the word in referring to the active, moment-by-moment steering or regulation of processes. The nonstandard and more passive terminology "monitoring limits" would actually be far more descriptive of the purpose of Shewhart's limits.) These limits were to separate plausible values of the plotted statistic from implausible values when in fact the process was operating optimally, subject only to causes of variation that were part of standard conditions.

By far the most famous implementations of Shewhart's basic logic come where the plotted statistic is either the mean, the range, or less frequently, the standard deviation. Such charts are commonly known by the names *x-bar charts*, *R charts*, and *s charts*, respectively. As a basis of discussion of Shewhart charts, consider the data given in Table 4.4. These values represent melt index measurements of specimens of extrusion grade polyethylene, taken four per shift in a plastics plant.

Figure 4.10 shows plots of the individual melt indices, means, ranges, and standard deviations from Table 4.4

Table 4.4 Measured melt indices for ten groups of four specimens[a]

Shift	Melt index	$\bar{y}$	R	S
1	218, 224, 220, 231	223.25	13	5.74
2	228, 236, 247, 234	236.25	19	7.93
3	280, 228, 228, 221	239.25	59	27.37
4	210, 249, 241, 246	236.50	39	17.97

10	228, 238, 220, 230	229.00	18	7.39

[a] Based on data from page 207 of Wadsworth et al. [7]

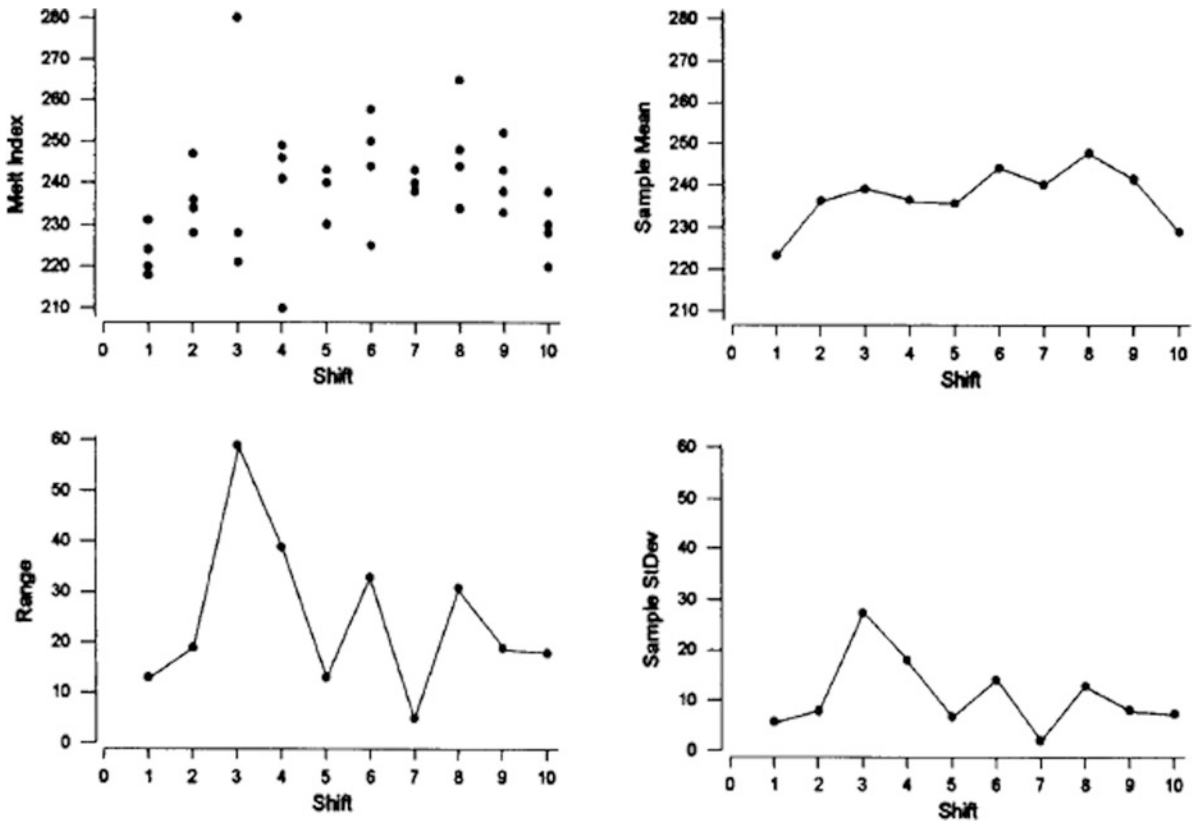

Fig. 4.10 Plots of melt index, $\bar{Y}$, R, and s against shift number

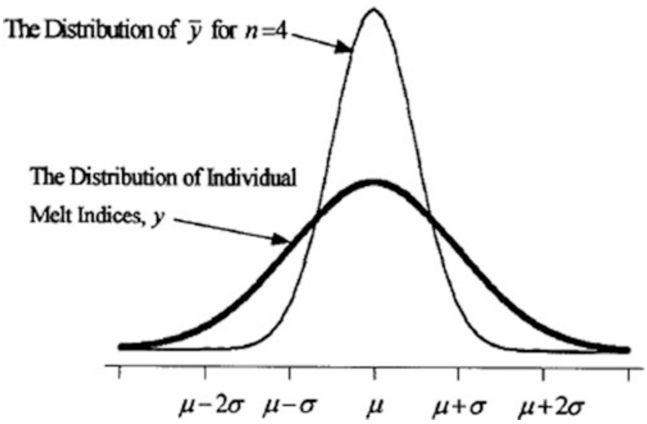

Fig. 4.11 The distribution of individuals, Y, and sample means, $\bar{Y}$

against shift number. The last three of these are the beginnings of so-called Shewhart $\bar{x}$, R, and s control charts.

What remain to be added to the plots in Fig. 4.10 are appropriate control limits. In order to indicate the kind of thinking that stands behind control limits for Shewhart charts, let us concentrate on the issue of limits for the plot of means. The fact is that mathematical theory suggests how the behavior of *means* $\bar{y}$ ought to be related to the distribution of *individual* melt indices y, provided the data-generating process is stable, that is, subject only to random causes. If individual responses y can be described as normal with some mean μ and standard deviation σ, mathematical theory suggests that averages of n such values will behave as if a different normal distribution were generating them, one with a mean $\mu_{\bar{y}}$ that is numerically equal to μ and with a standard deviation $\sigma_{\bar{y}}$ that is numerically equal to $\sigma/\sqrt{n}$. Figure 4.11 illustrates this theoretical relationship between the behavior of individuals and the behavior of means.

The relevance of Fig. 4.11 to the problem of setting control chart limits on means is that if one is furnished with a description of the typical pattern of variation in y, sensible expectations for variation in $\bar{y}$ follow from simple normal distribution calculations. So Shewhart reasoned that since about 99.7% (most) of a Gaussian distribution is within three standard deviations of the center of the distribution, means found to be farther than three theoretical standard deviations (of $\bar{y}$) from the theoretical mean (of $\bar{y}$) could be safely attributed to other than chance causes. Hence, furnished with standard values for μ and σ (describing individual observations), sensible control limits for $\bar{y}$ become

$$\begin{aligned}\text{Upper control limit (UCL) for } \bar{y} &= \mu_{\bar{y}} + 3\sigma_{\bar{y}}\\ &= \mu + 3\frac{\sigma}{\sqrt{n}}\end{aligned}$$

and

$$\begin{aligned}\text{Lower control limit (LCL) for } \bar{y} &= \mu_{\bar{y}} - 3\sigma_{\bar{y}}\\ &= \mu - 3\frac{\sigma}{\sqrt{n}}\end{aligned} \tag{4.9}$$

Returning to the context of our example represented by the data of Table 4.4, Wadsworth et al. [7] state that the target value for melt index in the original application was in fact 235. So if standard process behavior is "on target" behavior, the value $\mu = 235$ seems appropriate for use in (4.9). No parallel value for σ was provided by the authors. Common practice in such situations is to use the data in hand (the data of Table 4.4) to produce a plausible value for σ to use in (4.9). There are many possible ways to produce such a value, but to understand the general logic behind the standard ones, it is important to understand what σ is supposed to measure. The variable σ is intended as a theoretical measure of baseline, short-term, common cause variation. As such, the safest way to try to approximate it is to somehow use only measures of variation *within* the groups of four values in Table 4.4 *not* influenced by variation *between* groups. (Measures of variation derived from considering all the data simultaneously, e.g., would reflect variation between shifts as well as the shorter-term variation within shifts.) In fact, the most commonly used ways of obtaining from the data in hand a value of σ for use in (4.9) are based on the averages of the (within-group) ranges or standard deviations. For example, the ten values of R given in Table 4.4 have a mean

$$\bar{R} = \frac{1}{10}(13 + 19 + 59 + \ldots + 19 + 18) = 24.9$$

and some standard mathematical theory suggests that because the basic group size here is $n = 4$, an appropriate multiple of $\bar{R}$ for use in estimating σ is

$$\frac{\bar{R}}{2.059} \approx 12.1 \tag{4.10}$$

(The divisor above is a tabled factor commonly called d_2, which increases with n.)

Finally, substituting 235 for μ and 12.1 for σ in (4.9) produces numerical control limits for $\bar{y}$:

$$\text{LCL} = 235 - 3\frac{(12.1)}{\sqrt{4}} = 216.9$$

and

$$\text{UCL} = 235 + 3\frac{(12.1)}{\sqrt{4}} = 253.1$$

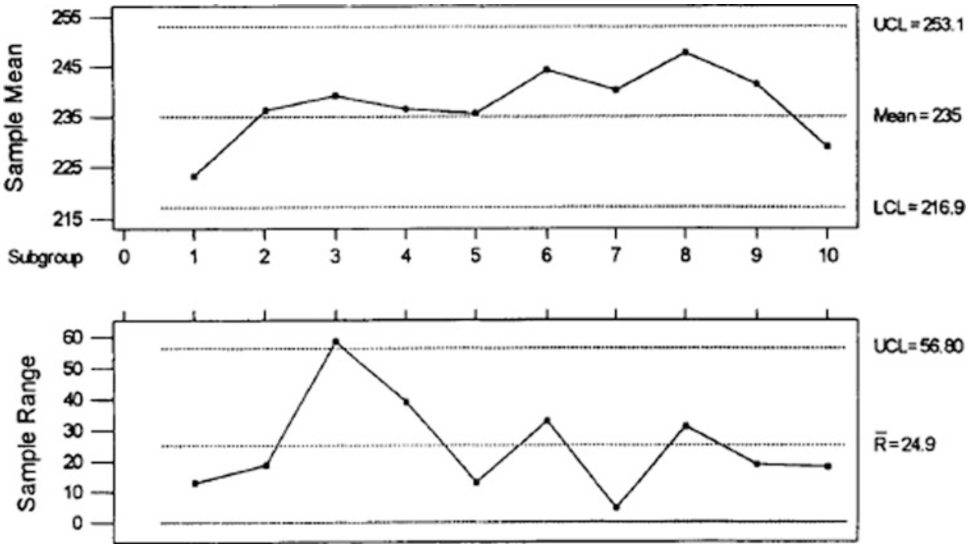

Fig. 4.12 Control charts for $\bar{Y}$and R based on melt indices

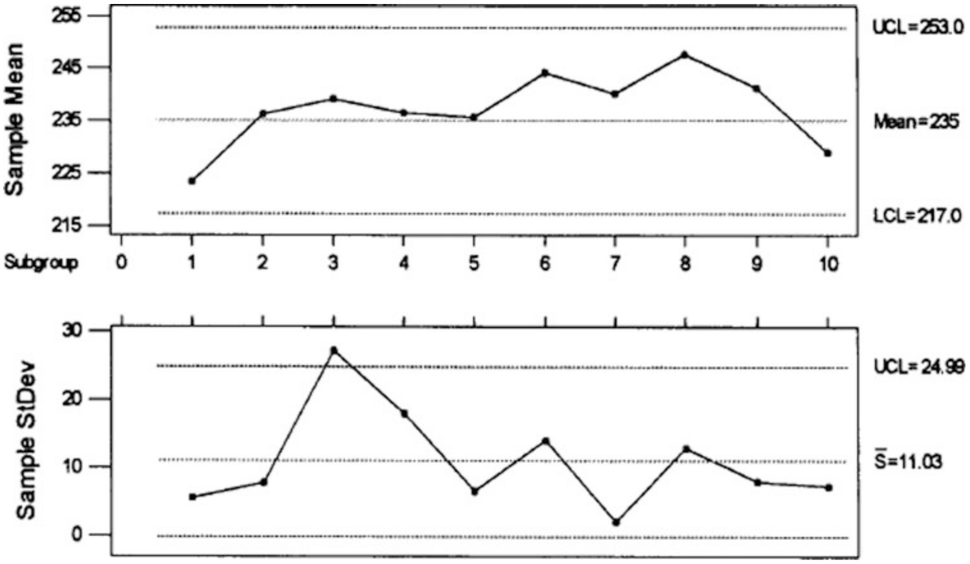

Fig. 4.13 Control charts for $\bar{Y}$and s based on melt indices

Comparison of the $\bar{y}$ values in Table 4.4 to these limits reveals no "out of control" means, that is, no evidence in the means of assignable process variation. Figures 4.12 and 4.13 show control charts for all of $\bar{y}$, R, and s, where control limits for the last two quantities have been derived using standard calculations not shown here.

The *R and s* charts in Figs. 4.12 and 4.13 are related representations (only one is typically made in practice) of the shift-to-shift behavior of melt index *consistency*. It is seen that on both charts, the shift #3 point plots above the upper control limit. The strong suggestion thus is that melt index consistency was detectably worse on that shift than on the others, so that from this point of view the process was in fact *not stable* over the time period represented in Table 4.4. In practice, physical investigation and hopefully correction of the origin of the instability typically would follow, as well as some reconsideration of our earlier assessment of 12.1 as a plausible figure to represent the inherent short-term variability of melt index. (If shift #3 could be treated as a special case, explainable as an unfortunate but correctable situation that was not expected to reoccur, there might be reason to revise $\bar{R}$ downward by deletion of shift #3 from the calculation, and thereby to reduce one's view of the size of baseline process variability. Notice that, in general, such a

[a] Based on data from page 190 of Burr [8]

downward revision of $\bar{R}$ might well also have the effect of causing one to need to rethink his or her assessment of the constancy of the melt index mean.)

There is a variation on the basic "$\bar{x}$ and R chart" idea that we wish to illustrate here next, because of its frequent use in chemical industry applications. That is the making of a so-called x and *MR* chart pair. The motivation for this modification of the ideas outlined thus far in this section is that in many chemical process monitoring contexts the natural "group size" is $n = 1$. A mean of $n = 1$ observation(s) is simply that observation itself, and the limits of (4.9) make perfectly good sense for the case of $n = 1$. That is, the analog of an $\bar{x}$ chart for $n = 1$ cases is clear, *at least if one has an externally provided value for* σ. But what, if anything, to do for an $n = 1$ counterpart of the R chart and how to develop an analog of (4.10) in cases where σ is not a priori known are perhaps not so obvious. Table 4.5 contains data representing moisture contents in 0.01% of bihourly samples of a polymer, and the question at hand is what besides simply the bihourly y values might be plotted in the style of a Shewhart control chart for such data.

The final column of Table 4.5 gives 19 so-called moving ranges of pairs of successive moisture contents. It is often argued that although these *MR* values are actually affected not only by variation within a 2-h production period but by some variation between these periods as well, they come as close to representing purely short-term variation as any measure available from $n = 1$ data. Accordingly, as a kind of $n = 1$ analog of an R chart, moving ranges are often charted in addition to individual values y. Further, the average moving range is used to estimate σ in cases where information on the inherent variability of individuals is a priori lacking, according to the formula

$$\text{Estimated } \sigma = \frac{\overline{\text{MR}}}{1.128}$$

where $\overline{\text{MR}}$ is the mean of the moving ranges (and plays the role of $\bar{R}$ in (4.10)), and 1.128 is then $n = 2$ version of the factor d_2 alluded to immediately below (4.10).

In the case of the data of Table 4.5,

$$\overline{\text{MR}} = \frac{1}{19}(16 + 4 + 5 + \ldots + 16 + 18) \approx 8.2$$

so that a (possibly somewhat inflated due to between period variation) data-based estimate of within-period variability σ for use, for example in limits (4.9), is

$$\frac{8.2}{1.128} \approx 7.2$$

Figure 4.14 shows both an x (individuals) chart and an *MR* (moving range) chart based on these calculations. As no standard value of moisture content was provided in Burr's text [8], the value $\bar{y} = 28.55$ was used as a substitute for μ in (4.9). The MR chart limits are based on standard $n = 2$ (because ranges of "groups" of two observations are being plotted) R chart control limit formulas. Figure 4.14 shows no evidence of assignable variation in the moisture contents.

Statistical research in the last decade has cast serious doubt on the wisdom of adding the *MR* chart to the x chart in $n = 1$ situations. The price paid for the addition in terms of "false alarm rate" is not really repaid with an important increase in the ability to detect process change. For a more complete discussion of this issue see Sect. 4.4 of Vardeman and Jobe [9].

The use of Shewart control charts is admirably documented in a number of statistical quality control books including those by Vardeman and Jobe [9], Wadsworth et al. [7], Duncan [10], Burr [8], Grant and Leavenworth [11], and Ott et al. [12]. Our purpose here is not to provide all details necessary for their use, but only to give the reader an introduction to the overall function that they serve. It should be said, however, that in recent years other statistical process monitoring tools such as the so-called CUmulative SUM (CUSUM) schemes and Exponentially Weighted Moving Average (EWMA) schemes have been developed as competing methodologies, and can in some circumstances be practically more effective than the original Shewhart charts. Indeed, many computerized controllers for real-time chemical process monitoring and adjustment now employ some

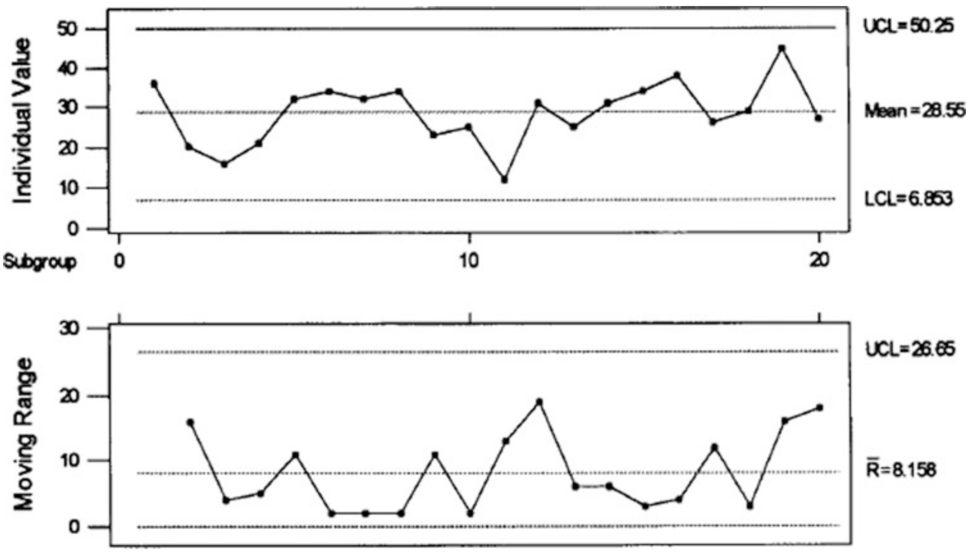

Fig. 4.14 Control charts for *Y* and *MR* based on moisture contents of 20 polymer samples

form of CUSUM or EWMA logic. For more on these topics, including their integration with model-based process controllers, the reader is referred to Sects. 4.1 and 4.2 of Vardeman and Jobe [9] and Vander Wiel et al. [13].

Shewhart's basic conceptualization of common and special cause variation not only leads to control charts as quantitative, rational tools to guide one in knowing when (and when not!) to intervene in an industrial process to correct potential ills, but also provides a framework for considering the question of what is the best/most consistent performance one can hope for from a particular version of a process. That is, it provides a framework for discussing process capability assessment.

If $\hat{\sigma}$ is some (standard deviation type) estimate of the baseline variation inherent in an industrial process (obtained, e.g., from a calculation such as (4.10) or from data taken from the process after eliminating all physical sources of assignable variation), it essentially specifies what is possible in terms of consistency of process output. There are, however, several common ways of using such an estimate to produce related measures of process capability.

For one thing, remembering again the fact that an interval from $\mu-3\sigma$ to $\mu+3\sigma$ (i.e., of length 6σ) will bracket about 99.7% of a normal distribution, the figure 6σ is sometimes stated as "the process capability." This usage would say that in the context of the polyethylene melt index example of Table 4.4 the $\hat{\sigma} = 12.1$ figure from (4.10) implies a melt index process capability of approximately $6(12.1) \approx 72.6$. If properly monitored, the process appears capable of producing almost all individual melt indices in a 73-point range.

Where there are stated specifications for individual measurements y, σ is sometimes turned into a kind of index comparing it to the difference in upper and lower engineering specifications. For example, one such *process capability index* is

$$C_{\mathrm{p}} = \frac{\mathrm{USL} - \mathrm{LSL}}{6\sigma}$$

where *USL–LSL* is the difference in specifications. Fairly obviously, the larger the value of C_{p}, the more comfortably (properly targeted) process output values will fit in an interval from *LSL* to *USL*.

Another process capability measure that is frequently used in the industrial chemistry sector is

$$C_{\mathrm{pk}} = \mathrm{minimum}\left\{C_{\mathrm{pu}} = \frac{\mathrm{USL} - \mu}{3\sigma}, \qquad C_{\mathrm{pl}} = \frac{\mu - \mathrm{LSL}}{3\sigma}\right\}$$

where μ is an overall process average for an in-control/stable/predictable process, and σ is as before. This measure is clearly similar to C_{p}, but it takes into account the placement of the process mean in a way that is ignored by C_{p}. A large value of C_{pk} indicates that not only is the process short-term variation small enough for the process output values to potentially fit comfortably between *LSL* and *USL*, but that the process is currently so targeted that the potential is being realized.

Statistical Methods and Industrial Experimentation

One of the most important areas of opportunity for the new application of statistical methods in the chemical industry in the twenty-first century is that of increasing the effectiveness of industrial experimentation. That is, it is one thing to bring an existing industrial process to stability (a state of "statistical" control), but it is quite another to determine how to make fundamental changes in that process that will improve its basic behavior. This second activity almost always involves some form of experimentation, whether it be in the laboratory or in a plant. As we indicated in the introduction, efficient methods and strategies of such data collection (and corresponding analysis) are a central concern of applied statistics. In this section, we hope to give the reader some insight into the kinds of statistical tools that are available for use in chemical industry experimentation.

We will here take as our meaning of the term "experimentation" the observation of a (typically noisy) physical process under more than one condition, with the broad goal of understanding and then using knowledge of how the process reacts to the changes in conditions. In most industrial contexts, the "conditions" under which the process is observed can be specified in terms of the settings or so-called levels chosen for several potentially important process or environmental variables, the so-called factors in the experiment. In some cases, the hope is to identify those (often largely unregulated) factors and combinations of factors that seem to most influence an observed response variable, as a means of targeting them for attention intended to keep them constant or otherwise to eliminate their influence, and thereby to improve the consistency of the response. In other situations the hope is to discover patterns in how one or more critical responses depend on the levels of (often tightly controlled) factors, in order to provide a road map for the advantageous guiding of process behavior (e.g., to an increased mean reaction yield) through enlightened changing of those levels.

This section is organized into two subsections. In the first, we will illustrate the notion of variance component estimation through an example of a nested or hierarchical data collection scheme. In the second, we will discuss some general considerations in the planning of experiments to detail the pattern of influence of factors on responses, consider so-called factorial and fractional factorial experimental designs, illustrate response surface fitting and interpretation tools and the data requirements they imply, and, in the process, discuss the integration of a number of statistical tools in a sequential learning strategy.

[a] Based on data taken from Wernimont [34]

Identifying Major Contributors to Process Variation

A statistical methodology that is particularly relevant where experimentation is meant to identify important unregulated sources of variation in a response is that of variance component estimation, based on the so-called ANalysis Of Variance (ANOVA) calculations and random effects models. As an example of what is possible, consider the data of Table 4.6. Shown here are copper content measurements for some bronze castings. Two copper content determinations were made on each of two physical specimens cut from each of 11 different castings.

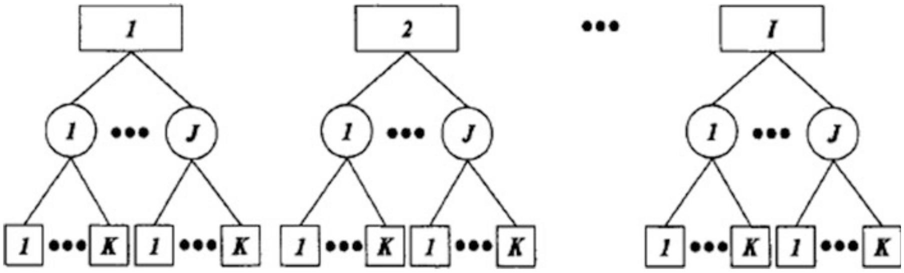

Fig. 4.15 A balanced hierarchical data structure

The data of Table 4.6 were *by design* collected to have a "tree type" or so-called hierarchical/nested structure. Figure 4.15 shows a diagram of a generic hierarchical structure for *balanced* cases like the present one, where there are equal numbers of branches leaving all nodes at a given level (there are equal numbers of determinations for each specimen and equal numbers of specimens for each casting).

An important goal in most hierarchical studies is determining the size of the contributions to response variation provided by the different factors, that is, the different levels of the tree structure. (In the present context, the issue is how variation between castings compares to variation between specimens within a casting, and how they both compare to variation between determinations for a given specimen. If the overall variability observed were considered excessive, such analysis could then help guide efforts at variation reduction by identifying the largest contributors to observed variability.) The structure portrayed in Fig. 4.15 turns out to enable an appealing statistical analysis, providing help in that quantification.

If one lets

y_{ijk} = the copper content from the kth determination of the jth specimen from casting i

$\bar{y}_{ij.} = \frac{1}{2}\sum_k y_{ijk} =$ the mean copper content determination from the ith casting

$\bar{y}_i\cdot\cdot = \frac{1}{2}\sum_j \bar{y}_{ij}\cdot =$ the mean copper content determination from the ith casting

and

$\bar{y}_{\ldots} = \frac{1}{11}\sum_i y_{i\cdot\cdot} =$ the overall mean copperdetermination

it is possible to essentially break down the variance of all 44 copper contents (treated as a single group) into interpretable pieces, identifiable as variation between $\bar{y}_{i\cdot\cdot}$s(casting means), variation between $\bar{y}_{ij\cdot}$s(specimen means) within castings, and variation between $\bar{y}_{ijk}$s (individual measurements) within a specimen. That is, it is an algebraic identity that for 44 numbers y_{ijk} with the same structure as those in Table 4.6

$$\begin{aligned}(44-1)s^2 &= \sum_{i,j,k}(y_{ijk}-\bar{y}_{\ldots})^2\\ &= \sum_{i,j,k}(\bar{y}_{i\cdot\cdot}-\bar{y}_{\ldots})^2+\sum_{i,j,k}(\bar{y}_{ij\cdot}-\bar{y}_{i\ldots})^2\\ &\quad+\sum_{i,j,k}(y_{ijk}-\bar{y}_{ij\cdot})^2 \qquad (4.11)\end{aligned}$$

The sums indicated in (4.11) are over all data points; so, for example, the first summand on the right is obtained for the copper content data by summing each $(\bar{y}_{i\cdot\cdot}-\bar{y}_{\ldots})^2$ a total of 2 × 2 = 4 times, one for each determination on a given casting. With the obvious meaning for the s and the substitution of the total number of data values for 44, the identity in (4.11) applies to any balanced hierarchical data structure. It is a so-called ANOVA identity, providing an intuitively appealing partitioning of the overall observed variability in the data, an *analyzing of the* (*observed*) *variation*.

Some tedious arithmetic "by hand," or use of nearly any commercially available statistical package that includes an ANOVA program, shows that for the copper content data of Table 4.6 the numerical version of (4.11) is approximately

$$5.1385 = 3.2031 + 1.9003 + 0.0351 \qquad (4.12)$$

Although we will not provide any details here, the reader is alerted to the fact that it is common practice to present the elements of an identity such as (4.12) in a tabular form called an "ANOVA table." The use for the elements of (4.12) that we wish to illustrate here is their role in estimating casting, specimen, and determination "variance components."

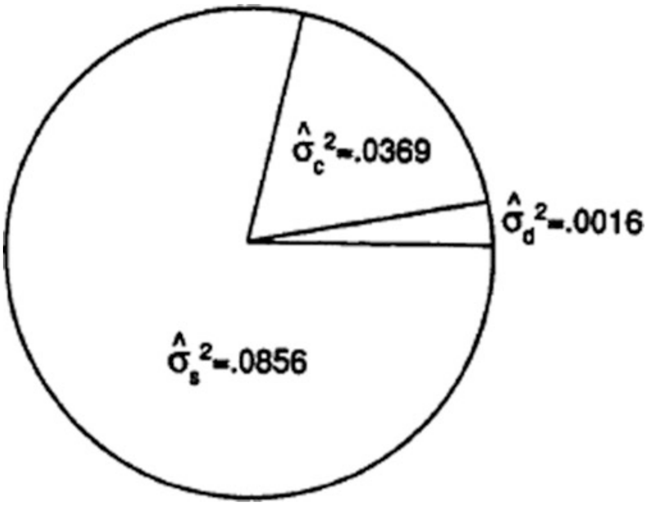

Fig. 4.16 Three estimated variance components for copper contents

That is, if one models an observed copper determination as the sum of a *random* casting-dependent *effect* whose distribution is described by a variance σ_c^s, a *random* specimen-dependent *effect* whose distribution is described by a variance σ_s^2, and a *random* determination-dependent *effect* whose distribution is described by a variance σ_d^2, the elements of (4.12) lead to estimates of the *variance components* σ_c^2, σ_s^2, and σ_d^2 in the model. Note that in such a random effects model of the data-generating process, copper measurements from the same casting share the same casting effect, and copper measurements from the same specimen share the both same casting and the same specimen effects. The individual σ^2 values are conceptually the variances that would be seen in copper contents if only the corresponding sources of variation were present. The sum of the σ^2 values is conceptually the variance that would be seen in copper contents if single determinations were made on a number of different castings.

Standard statistical methodology for estimation of the variance components (which we will not detail here but can, e.g., be found in Sect. 4.5 of Vardeman and Jobe [9] or Chap. 11 of Hicks and Turner [14]) produces

$$\sigma_d^2 = \frac{0.0351}{11 \cdot 2 \cdot (2-1)} \approx 0.0016(\%)^2$$

as an estimate of σ_d^2,

$$\hat{\sigma}_s^2 = \frac{1}{2}\left(\frac{1.9003}{11 \cdot (2-1)} - 0.0016\right) \approx 0.0856(\%)^2$$

as an estimate of σ_s^2, and

$$\begin{aligned}\hat{\sigma}_c^2 &= \frac{1}{2 \cdot 2}\left(\frac{3.2031}{(11-1)} - \frac{1.9003}{11 \cdot (2-1)}\right)\\ &\approx 0.0369(\%)^2\end{aligned}$$

as an estimate of σ_c^2. Figure 4.16 is a pie chart representation of these three estimated variance components as fractions of their sum (the variance predicted if single determinations were made on single specimens from each casting), and graphically identifies inhomogeneity between specimens cut from a single casting as the biggest contributor to observed variation.

On the standard deviation scale the estimates translate to $\hat{\sigma}_d \approx 0.04\%$, $\hat{\sigma}_s \approx 0.29\%$, $\hat{\sigma}_c \approx 0.19\%$. So, for example, the data of Table 4.6 indicate that even if castings and specimens were all exactly alike, it would still be reasonable to expect measured copper contents to vary according to a standard deviation of about 0.04%, presumably due to unavoidable measurement error.

Variance component estimation methodology is not limited to balanced hierarchical experiments, but they do provide an important and straightforward context in which to introduce the technology. More detailed information on the case discussed here and extensions to other kinds of data structures can be found in books by Vardeman [4], Neter et al. [5], Mason et al. [15], and Hicks and Turner [14].

Discovering and Exploiting Patterns of Factor Influence on Responses

Having discussed statistical methodology particularly appropriate to studies whose primary purpose is simply to identify factors with the largest influence on a response, we will now consider methods aimed more directly at detailed experimental quantification of the pattern of factor influence on one or more responses. As an example, we will use a "sanitized" account of some statistical aspects of a highly successful and economically important process improvement project. (Data presented here are not the original data, but resemble them in structure. Naturally, details of the project not central to our expository purposes and those of a proprietary nature will be suppressed.) A more complete version of this case study appears as Chap. 11 of Vardeman [4].

The process monitoring, capability assessment, and variance source identification ideas discussed thus far are almost logical prerequisites for industrial experimentation to detail the nature of dependence of response variables on factors of interest. When an industrial process has been made to operate in a stable manner, its intrinsic variability reduced to the extent practically possible, and that baseline performance quantified and understood, the prospects of success are greatly enhanced for subsequent efforts to understand the effects of potential fundamental process changes.

Preliminary work by various groups left a project team with a batch production process behaving in a stable but unsatisfactory fashion. Obvious sources of variation (both in the process itself and "upstream") had been identified and, to the degree practically possible, eliminated. The result was a process with an average output *purity* of 88% and an associated purity standard deviation of around 5%, and an average *yield* of 43% and an associated yield standard deviation of around 5% as well. The project team was charged with finding ways to increase the purity and yield means to, respectively, 95% and 59% while it is hoped, also further reducing the standard deviations. To accomplish this, the team recognized the need for an improved understanding of how various process variables under their control influenced purity (which we will call y_1) and yield (which we will call y_2). Experimentation to provide this was authorized, and, in particular, attention was focused on four factors consisting of three reactant concentrations and the process run time. We will call the Reactant A mole ratio x_1, the Reactant B mole ratio x_2, the Reactant C mole ratio x_3, and the run time (in hours) x_4.

The choice of experimental factors (what to vary in data collection) is a nontrivial matter of fundamental importance that is best handled by people with firsthand process knowledge. There are a number of popular techniques and tools (such as so-called cause and effect diagrams, discussed for instance in Sect. 2.1 of Vardeman and Jobe [9]) for helping groups brainstorm and reach a consensus on such matters. Further, in cases where a priori knowledge of a process is scarce, relatively small preliminary screening experiments can help reduce a large list of potential factors to a smaller list apparently worthy of more detailed study. (The fractional factorial plans that will be illustrated shortly often are recommended for this purpose).

Once a particular set of experimental factors has been identified, questions about exactly how they should be varied must be answered. To begin with, there is the choice of levels for the factors, the matter of how much the experimental factors should be varied. Particular experimental circumstances usually dictate how this is addressed. Widely spaced (substantially different) levels will in general lead to bigger changes in responses, and therefore clearer indications of how the responses depend upon the experimental factors, than will closely spaced (marginally different) levels. But they may do so at the expense of potentially creating unacceptable or even disastrous process conditions or output. Thus, what may be an acceptable strategy in a laboratory study might be completely unacceptable in a production environment and vice versa.

Given a set or range of levels for each of the individual experimental factors, there is still the question of exactly what combinations of levels actually will be used to produce experimental data. For example, in the process improvement study, standard process operating conditions were $x_1 = 1.5$, $x_2 = 1.15$, $x_3 = 1.75$, and $x_4 = 3.5$, and the project team decided on the ranges

$$1.0 \leq x_1 \leq 2.5, 1.0 \leq x_2 \leq 1.8, 1.0 \leq x_3 \leq 2.5, \tag{4.13}$$

and

$$2.0 \leq x_4 \leq 5.0$$

as defining the initial limits of experimentation. But the question remained as to exactly what sets of mole ratios and corresponding run times were appropriate for data collection.

A natural (but largely discredited) strategy of data collection is the one-variable-at-a-time experimental strategy of picking some base of experimental operations (such as standard operating conditions) and varying the level of only one of the factors away from that base at a time. The problem with such a strategy is that sometimes two or more factors act on responses jointly, doing things in concert that neither will do alone. For example, in the process improvement study, it might well have been that an increase in either x_1, or x_2 alone would have affected yield very little, whereas a simultaneous increase in both would have caused an important increase. Modern strategies of industrial experimentation are conceived with such possibilities in mind, and attempt to spread out observations in a way that gives one some ability to identify the nature of the response structure no matter how simple or complicated it turns out to be.

There are several issues to consider when planning the combinations of levels to include in an experiment. We have already said that it is important to "vary several factors simultaneously." It is also important to provide for some replication of at least a combination or two in the experiment, as a means of getting a handle on the size of the experimental error or baseline variation that one is facing. The replication both verifies the reproducibility of values obtained in the study and identifies the limits of that reproducibility. Also, one must balance the urge to "cover the waterfront" with a wide variety of combinations of factor levels against resource constraints and a very real law of diminishing practical returns as one goes beyond what is really needed in the way of data to characterize response behavior. In addition, the fact that real-world learning is almost always of a sequential rather than a "one shot" nature suggests that it is in general wise to spend only part of an experimental budget on early study phases, leaving resources adequate to follow up directions suggested by what is learned in those stages.

It is obvious that a minimum of two different levels of an experimental factor must appear in a set of experimental combinations if any information is to be gained on the effects of that factor. So one logical place to begin thinking about a candidate design for an industrial experiment is with the set of all possible combinations of two levels of each of the experimental factors. If there are p experimental factors, statistical jargon for such an arrangement is to call it a (complete) $2 \times 2 \times 2 \times \cdots \times 2$ or 2^p factorial plan. For example, in the process improvement situation, an experiment consisting of the running of all 16 possible combinations of

$$\begin{aligned} x_1 &= 1.0 \quad \text{or} \quad x_1 = 2.5 \\ x_2 &= 1.0 \quad \text{or} \quad x_2 = 1.8 \\ x_3 &= 1.0 \quad \text{or} \quad x_3 = 2.5 \end{aligned}$$

and

$$x_4 = 2.0 \quad \text{or} \quad x_4 = 5.0$$

would be called a complete $2 \times 2 \times 2 \times 2$ or 2^4 factorial experiment. Notice that in geometric terms, the (x_1, x_2, x_3, x_4) points making up this 2^4 structure amount to the 16 "corners" in four-dimensional space of the initial experimental region defined in (4.13).

A complete factorial experimental plan is just that, in some sense "complete." It provides enough information to allow one to assess (for the particular levels used) not only individual but also joint or interaction effects of the factors on the response or responses. But when in fact (unbeknownst to the investigator) a system under study is a relatively simple one, principally driven by only a few individual or low-order joint effects of the factors, fewer data actually are needed to characterize those effects adequately. So what is often done in modern practice is initially to run only a carefully chosen part of a full 2^p factorial, a so-called fractional factorial plan, and to decide based on the initial data whether data from the rest of the full factorial appear to be needed in order to adequately characterize and understand response behavior. We will not discuss here the details of how so-called 2^{p-q} fractional factorials are intelligently chosen, but there is accessible reading material on the subject in books by Box et al. [16], and by Vardeman and Jobe [3].

In the process improvement study, what was actually done in the first stage of data collection was to gather information from one-half of a full 2^4 factorial (a 2^{4-1} fractional factorial) augmented by four observations at the "center" of the experimental region (thereby providing both some coverage of the interior of the region, in addition to a view of some of its corners, and important replication as well).

The data in Table 4.7 are representative of what the group obtained.

Table 4.7 Data from an initial phase of a process improvement study

x_1	x_2	x_3	x_4	Purity, y_1(%)	Yield, y_2(%)

2.50	1.8	2.50	5.0	83.7	52.8
1.75	1.4	1.75	3.5	87.7	54.7
1.75	1.4	1.75	3.5	89.8	52.8
1.75	1.4	1.75	3.5	86.5	53.3
1.75	1.4	1.75	3.5	87.3	52.0

The order in which the data are listed is simply a convenient systematic one, not to be confused with the order in which experimental runs were actually made. The table order is far too regular for it to constitute a wise choice itself. For example, the fact that all $x_3 = 1.0$ combinations precede the $x_3 = 2.5$ ones might have the unfortunate effect of allowing the impact of unnoticed environmental changes over the study period to end up being confused with the impact of x_3 changes. The order in which the 12 experimental runs were actually made was chosen in a "completely randomized" fashion. For a readable short discussion of the role of randomization in industrial experimentation, the reader is referred to Box [17].

For purposes of this discussion, attention is focused on the yield response variable, y_2. Notice first that the four y_2 values from the center point of the experimental region have $\bar{y} = 53.2$ and $s = 1.13$ (which incidentally already appear to be an improvement over typical process behavior). As a partial indication of the logic that can be used to investigate whether the dependence of yield on the experimental factors is simple enough to be described adequately by the data of Table 4.7, one can compute some estimated "main effects" from the first eight data points. That is, considering first the impact of the variable x_1 (alone) on yield, the quantity

$$\begin{aligned} \bar{y}_{\text{high}_{x_1}} - \bar{y}_{\text{low}_{x_1}} &= \frac{1}{2}(45.9 + 46.0 + 51.2 + 52.8) \\ &\quad - \frac{1}{4}(35.1 + 4.0 + 41.4 + 10.0) \\ &= 26.35 \end{aligned}$$

is perhaps a sensible measure of how a change in x_1 from 1.00 to 2.50 is reflected in yield. Similar measures for the other variables turn out to be

$$\begin{aligned} \bar{y}_{\text{high}_{x_2}} - \bar{y}_{\text{low}_{x_2}} &= -15.20 \\ \bar{y}_{\text{high}_{x_3}} - \bar{y}_{\text{low}_{x_3}} &= 6.10 \end{aligned}$$

and

$$\bar{y}_{\text{high}_{x_4}} - \bar{y}_{\text{low}_{x_4}} = 0.45$$

These measures provide some crude insight into the directions and magnitudes of influence of the experimental variables on y_2. (Clearly, by these measures $x_1 = 2.50$ seems preferable to $x_1 = 1.00$, and the run time variable x_4 seems to have little impact on yield.) But they also provide strong evidence that the nature of the dependence of yield on the experimental factors is too complicated to be described by the action of the factors individually. For example, if it *were* the case that the separate actions of the experimental factors were adequate to describe system behavior, then standard statistical theory and the data indicate that the mean response for the $x_1 = 1.00$, $x_2 = 1.0$, $x_3 = 1.00$, and $x_4 = 2.0$ set of conditions would be around

$$\hat{y} = \bar{y}_{\text{corners}} - \frac{1}{2}(-26.35) - \frac{1}{2}(-15.20) - \frac{1}{2}(6.10) - \frac{1}{2}(0.45) = 27.45$$

(where $\bar{y}_{\text{corners}}$ is standing for the mean of the first eight yields in Table 4.7). But the observed yield of 35.1 is clearly incompatible with such a mean and the standard deviation value (of $s = 1.13$) derived from the repeated center point. Also, other simple evidence that (at least linear and) separate action of the four factors is not enough to describe yield adequately is given by the large difference between $\bar{y}_{\text{cornere}} = 35.8$ and the observed mean from the center point $\bar{y} = 53.2$. (As it turns out, calculations that we will not show here indicate the *possibility* that individual action of the factors *plus joint action* of the Reactant A and Reactant B mole ratios is sufficient to describe yield. But in any case, the point is that the data of Table 4.7 provide evidence that the pattern of dependence of yield on the experimental variables is not simple, and thus that completion of the 2^4 factorial is in order).

After a complete analysis of the first round of experimental data, the project team "ran the second half fraction" of the 2^4 factorial, and data similar to those in Table 4.8 were obtained. (Again, no significance should be attached to the order in which the observations in Table 4.8 are listed. It is not the order in which the experimental runs were made).

Table 4.8 Data from a second phase of a process improvement study

x_1	x_2	x_3	x_4	Purity, y_1(%)	Yield, y_2(%)
1.00	1.0	1.00	5.0	64.0	35.3
2.50	1.0	1.00	2.0	91.9	47.2
1.00	1.8	1.00	2.0	6.5	3.9
2.50	1.8	1.00	5.0	86.4	45.9
1.00	1.0	2.50	2.0	63.9	39.5
2.50	1.0	2.50	5.0	93.1	51.6
1.00	1.8	2.50	5.0	6.8	9.2
2.50	1.8	2.50	2.0	84.6	54.3

The data from the second phase of experimentation served to complete the project team's 2^4 factorial picture of yield and confirm the tentative understanding drawn first from the initial half fraction. It is seen that the combinations listed in Table 4.8 are in the same order as the first eight in Table 4.7 as regards levels of experimental variables x_1, x_2, and x_3, and that the corresponding responses are very similar. (This, by the way, has the happy practical implication that run time seems to have little effect on final purity or yield, opening the possibility of reducing or at least not increasing the standard run time.) Thorough data analysis of a type not shown here left the project team with a clear (and quantified version of the) understanding that Reactant A and B mole ratios have important individual and joint effects on the responses, and that, acting independently of the other two reactants, Reactant C also has an important effect on the responses. However, it did *not* yet provide a solution to the team's basic problem, which was to reach a 59% mean yield goal.

The data of Tables 4.7 and 4.8 do hold out hope that conditions producing the desired purity and yield can be found. That is, though none of the 16 corners of the experimental region nor the center point appeared to meet the team's yield goal, the data do show that there is substantial *curvature* in the yield response. (The joint effect of x_1 and x_2 amounts to a kind of curvature, and the nonlinearity of response indicated by a large difference between and $\bar{y}_{\text{corners}} \approx 35.8$ and $\bar{y} = 53.2$ at the center of the experimental region also is a kind of curvature.) If one could "map" the nature of the curvature, there is at least the possibility of finding favorable future operating conditions in the interior of the initial experimental region defined in (4.13).

It ought to be at least plausible to the reader that 2^4 factorial data (even supplemented with center points) are not really sufficient to interpolate the nature of a curved response over the experimental region. More data are needed, and a standard way of augmenting a 2^p design with center points to one sufficient to do the job is through the addition of so-called star points to produce a central composite design. Star points are points outside the original experimental region whose levels of all but one of the p experimental factors match those of the center point. Figure 4.17 shows graphical representations of central composite designs in $p = 2$ and $p = 3$ factors.

The project team conducted a third phase of experimentation by adding eight star points to their study and obtained data similar to those in Table 4.9.

The data in Tables 4.7, 4.8, and 4.9 taken together turn out to provide enough information to enable one to rather

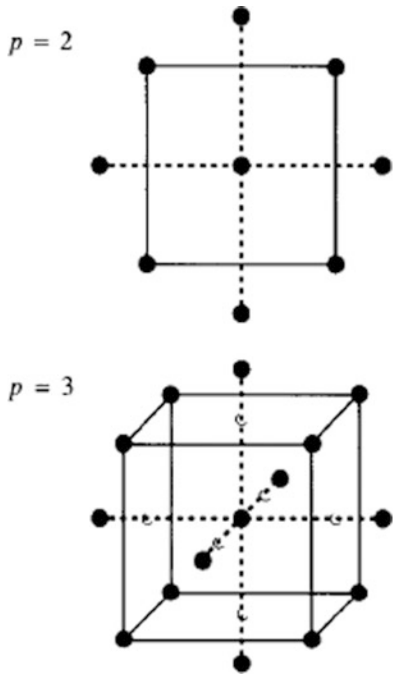

Fig. 4.17 $p = 2$ and $p = 3$ central composite designs

Table 4.9 Data from a third phase of a process improvement study

x_1	x_2	x_3	x_4	Purity, $y_1(\%)$	Yield, $y_2(\%)$
0.6895	1.4	1.75	3.5	20.8	13.0
2.8105	1.4	1.75	3.5	95.9	54.3
1.75	0.8344	1.75	3.5	99.9	62.4
1.75	1.9656	1.75	3.5	65.9	41.2
1.75	1.4	0.6895	3.5	64.4	32.7
1.75	1.4	2.8105	3.5	64.8	40.3
1.75	1.4	1.75	1.379	88.1	52.7
1.75	1.4	1.75	5.621	88.9	50.5

thoroughly quantify the "curved" nature of the dependence of y_2 on x_1, x_2, x_3, and x_4. A convenient and often successful method of accomplishing this quantification is through the least squares fitting of a general *quadratic response surface*. That is, central composite data are sufficient to allow one to fit an equation to a response that involves a constant term, linear terms in all the experimental variables, quadratic terms in all of the experimental variables, and cross-product terms in all pairs of the experimental variables. Appropriate use of a multiple regression program with the project data represented here produces the fitted equation

$$\begin{aligned} y_2 \approx\ & 15.4 + 37.9x_1 - 66.2x_2 + 48.8x_3 \\ & + 0.97x_4 - 16.1x_1^2 - 0.03x_2^2 \\ & - 13.6x_3^2 - 0.046x_4^2 + 26.5x_1x_2 \\ & + 0.344x_1x_3 - 0.217x_1x_4 \\ & + 1.31x_2x_3 - 0.365x_2x_4 + 0.061x_3x_4 \end{aligned}$$

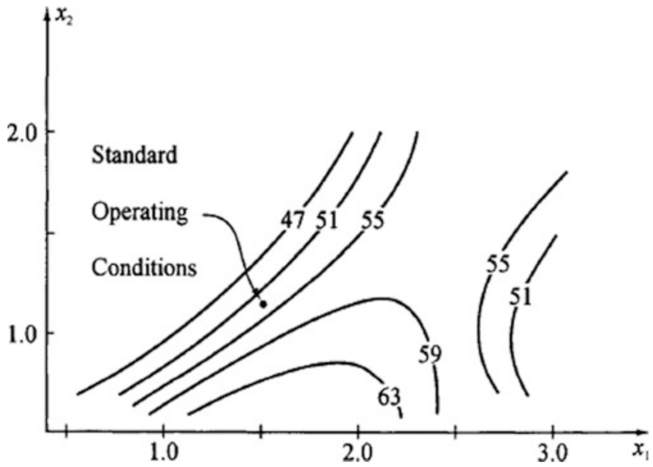

Fig. 4.18 A contour plot of fitted yield when $x_3 = 1.75$ (from *Statistics for Engineering Problem Solving* (*1st Ed.*) by S. B. Vardeman © 1994. Reprinted with permission of Brooks/Cole, a Division of Thomson Learning; http://www.thomsonlearning.com. FAX 800-730-2215)

This may not seem to the reader to be a particularly helpful data summary, but standard multiple regression tools can be used to deduce that an essentially equivalent, far less cluttered, and more clearly interpretable representation of the relationship is:

$$\begin{aligned} y_2 \approx\ & 13.8 + 37.8x_1 - 65.3x_2 + 51.6x_3 \\ & - 16.2x_1^2 - 13.6x_3^2 + 26.5x_1x_2 \end{aligned} \qquad (4.14)$$

Equation (4.14) provides an admirable fit to the data in Tables 4.7, 4.8, and 4.9, is in perfect agreement with all that has been said thus far about the pattern of dependence of yield on the experimental factors, *and* allows one to do some intelligent interpolation in the initial experimental region. Use of an equation like (4.14) ultimately allowed the project team to determine that an increase of x_1 only would, with minimal change in the existing process, allow them to meet their yield goal. (In fact, the single change in x_1 proved to be adequate to allow them to meet all of their yield *and* purity goals!)

Graphical representations similar to those in Figs. 4.18 and 4.19 for (4.14) with $x_3 = 1.75$ (the standard operating value for x_3) were instrumental in helping the team understand the message carried by their data and how yield could be improved. Figure 4.18 is a so-called contour plot (essentially a topographic map) of the fitted equation, and Fig. 4.19 is a more three-dimensional-looking representation of the same surface. Both types of display are commonly used tools of modern statistical experiment design and analysis. The contour plot idea is particularly helpful where several responses are involved, and by overlaying several such plots one can simultaneously picture the various implications of a contemplated choice of process conditions.

Special Statistical Tools for Chemical Applications

The statistical methods discussed thus far are of a quite general nature, routinely finding application beyond the bounds of the chemical industry. In this section, we will briefly highlight two statistical methodologies whose most important applications are to chemical problems. That is, we will touch on some of the ideas of mixture experiments and the role of statistics in mechanistic modeling.

Mixture Experiments

In many situations in industrial chemistry, some important measured property of a product is a function of the proportions in which a set of p ingredients or components are represented in a mixture leading to the product. For example, case studies in the literature have covered subjects ranging from octanes of gasoline blends, discussed by Snee [18] to strengths of different formulations of ABS pipe compound, treated in Koons and Wilt [19] to aftertaste intensities of different blends of artificial sweeteners used in an athletic sport drink, discussed by Cornell [20] to moduli of elasticity of different rocket propellant formulations, considered by Kurotori [21]. For experimenting in such contexts, special statistical techniques are needed. These tools have been discussed at length by Cornell [22, 23], and our purpose here is not to attempt a complete exposition, but only to whet the reader's appetite for further reading in this area.

The goal of mixture experimentation is to quantify how proportions $x_1, x_2, x_3, \ldots, x_p$ of ingredients 1 through p affect a response y. Usually, the hope is to fit some kind of approximate equation involving some parameters $\underline{b}$, say

$$y \approx f(x_1, x_2, \ldots, x_p | \underline{b})$$

to a set of n data points ($x_1, x_2, \ldots, x_p, y$), for the purpose of using the fitted equation to guide optimization of y, that is, to find the "best" blend. The logic of data collection and equation fitting is complicated in the mixture scenario by the fact that

$$x_1 + x_2 + \ldots + x_p = 1 \tag{4.15}$$

The linear constraint (4.15) means that (p way) factorial experimentation is impossible, and that special measures must be employed in order to use standard regression analysis software to do least squares equation fitting. We will briefly describe in turn some approaches to experimental design, equation fitting, and presentation of results for the mixture problem under its fundamental constraint (4.15).

In the case of $p = 3$ (a three-component mixture problem), the set of all possible combinations of values for x_1, x_2, and x_3 satisfying (4.15) can be conveniently represented as an equilateral triangular region. Figure 4.20 shows such a region and the so-called simplex coordinate system on the region. The corners on the plot stand for cases where the "mixture" involved is actually a single pure component. Points on the line segments bounding the figure represent two-component mixtures, and interior points represent genuine three-component mixtures. For example, the center of

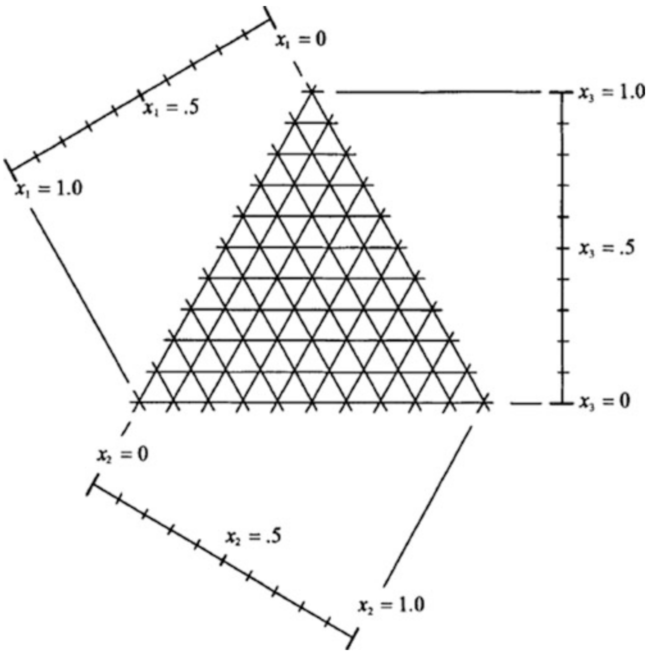

Fig. 4.20 The set of points with $x_1 + x_2 + x_3 = 1$ and a simplex coordinate system (from *Statistics for Engineering Problem Solving* by S. B. Vardeman © 1994. Reprinted with permission of Brooks/Cole, a Division of Thomson Learning; http://www.thomsonlearning.com. Fax 800-730-2215)

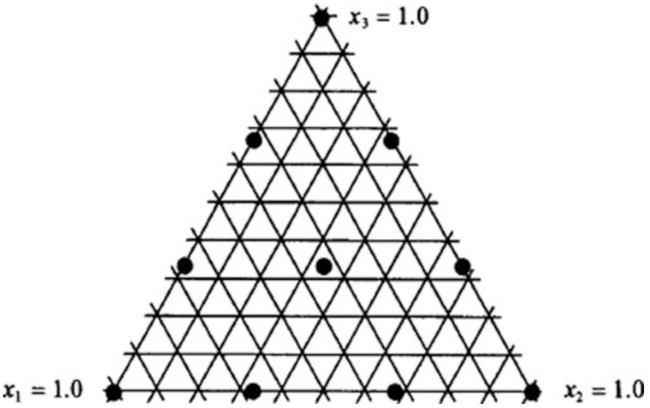

Fig. 4.21 A $p = 3$ simple lattice design

the simplex corresponds to a set of conditions where each component makes up exactly one-third of the mixture.

One standard mixture (experimental) design strategy is to collect data at the extremes (corners) of the experimental region along with collecting data on a regular grid in the experimental region. Figure 4.21 shows a $p = 3$ example of such a so-called simplex lattice design, and Table 4.10 lists the (x_1, x_2, x_3) points involved. (As in the cases of the data in Tables 4.7, 4.8, and 4.9, the order used in the listing in Table 4.10 is not one that would be used in sequencing data collection runs. Instead, a randomly chosen order often is employed).

Table 4.10 (x_1, x_2, x_3) points in a particular $p = 3$ simplex lattice design

x_1	x_2	x_3
1	0	0
0	1	0
0	0	1
$\frac{1}{3}$	$\frac{2}{3}$	0
$\frac{2}{3}$	$\frac{1}{3}$	0
$\frac{1}{3}$	0	$\frac{2}{3}$
$\frac{2}{3}$	0	$\frac{1}{3}$
0	$\frac{1}{3}$	$\frac{2}{3}$
0	$\frac{2}{3}$	$\frac{1}{3}$
$\frac{1}{3}$	$\frac{1}{3}$	$\frac{1}{3}$

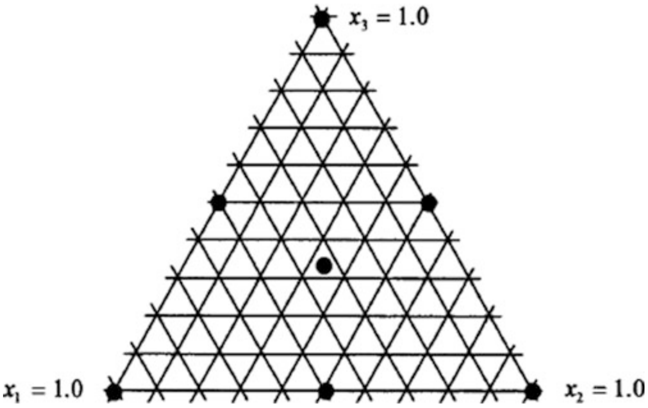

Fig. 4.22 A $p = 3$ simplex centroid design

Another standard mixture experiment strategy is the so-called simplex centroid design, where data are collected at the extremes of the experimental region and for every equal-parts two-component mixture, every equal-parts three-component mixture, and so on. Figure 4.22 identifies the blends included in a $p = 3$ simplex centroid design.

Often, the space of practically feasible mixtures is smaller than the entire set of $x_1, x_2, \ldots, x_p$ satisfying (4.15). For example, in many contexts, "pure" mixtures do not produce viable product. Concrete made using only water and no sand or cement obviously is a useless building product. One common type of constraint on the proportions $x_1, x_2, \ldots, x_p$ that produces quite simple experimental regions is that of lower bounds on one or more of the individual proportions. Cornell [22], for example, discusses a situation where the effectiveness in grease stain removal of a $p = 3$ bleach mixture was studied. Past experience with the product indicated that the proportions by weight of bromine, x_1, of powder, x_2, and of HCl, x_3, needed to satisfy the constraints:

$$x_1 \geq 0.30, x_2 \geq 0.25, \text{ and } x_3 \geq 0.02 \tag{4.16}$$

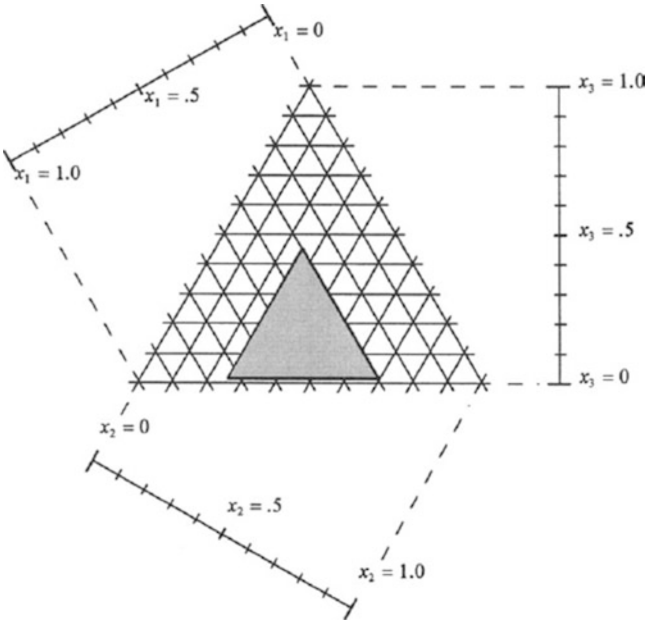

Fig. 4.23 The $p = 3$ simplex and a set of feasible bleach mixtures

for effective action of the product (i.e., the mixture needed to be at least 30% bromine, at least 25% powder, and at least 2% HCl by weight).‘

The effect of adding the lower bound constraints (4.16) to the basic mixture constraint (4.15) can be pictured as in Fig. 4.23. There, a triangular subregion of the basic $p = 3$ simplex depicts the feasible (x_1,x_2,x_3) points. The choice of experimental mixtures for such an experimental region can be made by direct analogy to or rescaling of designs such as the simplex lattice and simplex centroid designs illustrated above to cover the entire simplex. (It is common to refer to the rescaling process as the use of pseudo-components).

Constraint systems more complicated than simple lower bounds produce irregularly shaped experimental regions and less obvious methods of choosing $(x_1, x_2, \ldots, x_p)$ points to cover the experimental region. When $p = 3$, it is possible to sketch the region of feasible points on a simplex plot and use it to help guide the choice of mixture experiment strategy. Figure 4.24 illustrates the kind of region that can arise with other than exclusively lower bound constraints.

When more than three components are involved in a mixture study, such plots are, of course, no longer possible, and other more analytic methods of identifying candidate experimental mixtures have been developed. For example, McLean and Anderson [24] presented an algorithm for locating the vertices of an experimental region defined by the basic constraint (4.15) and any combination of upper and or lower bound constraints

$$0 \leq a_i \leq x_i \leq b_i \leq 1$$

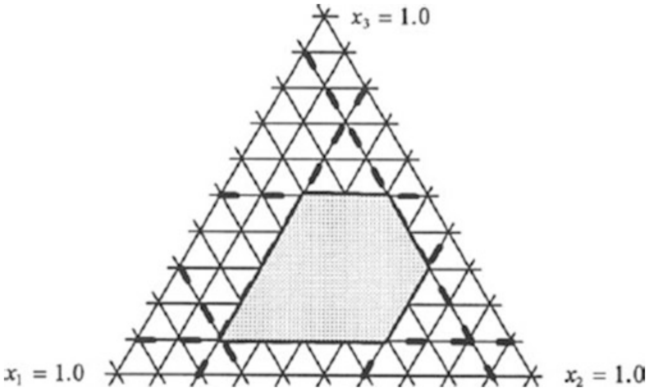

Fig. 4.24 An irregularly shaped experimental region in a $p = 3$ mixture study

on the proportions x_i. Cornell [22, 23] discusses a variety of algorithms for choosing good mixture experiment designs under constraints, and many of the existing algorithms for the problem have been implemented in the MIXSOFT software package developed by Piepel [25].

Empirical polynomial descriptions of (approximately) how a response y depends upon proportions $x_1, x_2, \ldots, x_p$ are popular mixture analysis tools. The process of fitting polynomials to mixture experiment data in principle uses the same least squares notion illustrated in the fitting of a parabola to the data of Table 4.2. However, the mechanics of using standard multiple regression analysis software in the mixture context is complicated somewhat by the basic constraint (4.15). For example, in view of (4.15) the basic ($p + 1$ parameter) linear relationship

$$y \approx b_0 + b_1x_1 + b_2x_2 + \ldots + b_px_p \tag{4.17}$$

is in some sense “overparameterized” in the mixture context, in that it is equivalent to the (p parameter) relationship

$$y \approx b_1x_1 + b_2x_2 + \ldots + b_px_p \tag{4.18}$$

if one identifies the coefficients in (4.18) with the sums of the corresponding coefficients in (4.17) and the coefficient b_0. As a result, it is the “no intercept” relationship (4.18) that is typically fit to mixture data when a linear relationship is used. In a similar way, when a second-order or (multivariable) quadratic relationship between the individual proportions and the response variable is used, it has no intercept term and no pure quadratic terms. For example, in the $p = 3$ component mixture case, the general quadratic relationship typically fit to mixture data is

$$\begin{aligned} y \approx\ & b_1x_1 + b_2x_2 + b_3x_3 + b_4x_1x_2 \\ & + b_5x_1x_3 + b_6x_2x_3 \end{aligned} \tag{4.19}$$

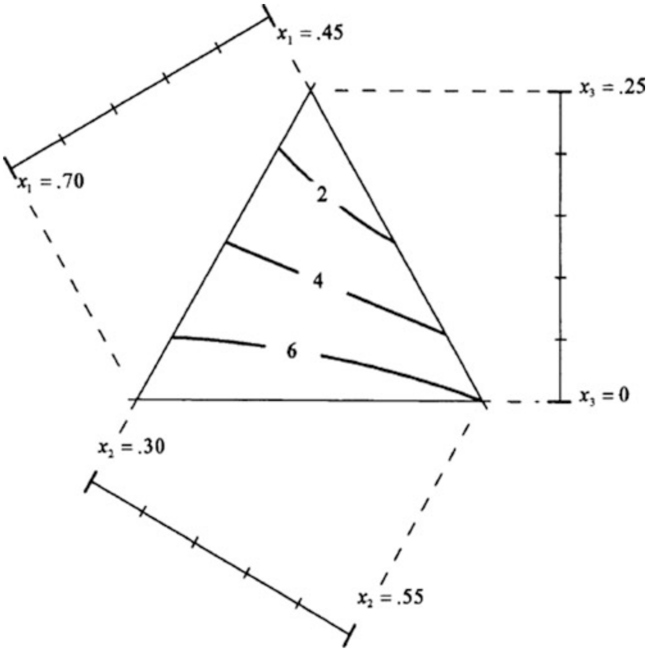

Fig. 4.25 A contour plot made on the $p = 3$ simplex (from *Statistics for Engineering Problem Solving* by S. B. Vardeman © 1994. Reprinted with permission of Brooks/Cole, a Division of Thomson Learning: http://www.thomsonlearning.com. Fax 800-730-2215)

(Any apparently more general relationship involving an intercept term and pure quadratic terms can by use of (4.15) be shown to be equivalent to (4.19) in the mixture context.) Relationships of the type of (4.19) are often called Scheffé models, after the first author to treat them in the statistical literature. Other more complicated equation forms are also useful in some applications, but we will not present them in this chapter. The interested reader is again referred to Cornell [22, 23] for more information on forms that have been found to be tractable and effective.

We should point out that the ability to fit equations of the form (4.18) or like (4.19), or of an even more complicated form, is predicated on having data from enough different mixtures to allow unambiguous identification of the parameters $\underline{b}$. This requires proper data collection strategy. Much of the existing statistical research on the topic of mixture experiment design has to do with the question of wise allocation of experimental resources under the assumption that a particular type of equation is to be fit.

One's understanding of fitted polynomial (and other) relationships often is enhanced through the use of contour plots made on coordinate systems such as that in Fig. 4.25. (This is even true for $p \geq 3$ component mixture scenarios, but the use of the idea is most transparent in the three-component case.) A plot like Fig. 4.25 can be a powerful tool to aid one in understanding the nature of a fitted equation and finding regions of optimum fitted response.

The mixture experiment counterpart to conventional screening/fractional factorial experimentation also is possible. So-called axial designs have been developed for the purpose of providing screening-type mixture data for use in rough evaluation of the relative effects of a large number of mixture components on a response variable. The same kind of sequential experimental strategy illustrated in the process improvement example is applicable in mixture contexts as well as contexts free of a constraint such as (4.15).

Mechanistic Model Building

The kinds of equations most easily fit to multi-factor data using standard (least squares) regression analysis techniques are polynomial equations such as (4.6), (4.14), (4.18), and (4.19). These are particularly convenient because they are linear in their parameters, b. But they are probably best thought of as empirical "mathematical French curve" descriptions of the relation of a response, y, to the explanatory variables, x. Polynomial equations function as extremely useful summaries of observed patterns in one's data, but they do not typically provide direct insight into chemical mechanisms that produce those patterns, and the fitted parameters, b, do not often have direct physical meanings. Their use is particularly appropriate where there is little a priori knowledge of mechanisms involved in a process that might aid in its description, and/or no such knowledge is really essential to achieving one's goals.

Sometimes, however, it is desirable (on the basis of possible reaction kinetics or for other reasons) to posit theoretical descriptions of process outputs in terms of explanatory variables. That is, physicochemical principles often lead (through differential or integral equation descriptions of a system) to equation forms for a response that, like

$$y = \frac{K_1 K_A K_B P_A P_B}{(1 + K_A P_A + K_B P_B)^2}$$
$$y = C_0 \exp(-Kt)$$

and

$$y = \frac{K_1 x}{1 + K_2 x}$$

are nonlinear in the parameters. Although such equations or models may be less tractable than empirical polynomial equations, the parameters involved more often than not *do* have direct physical interpretations. Further, when such a model can be verified as being an adequate description of a process (thereby confirming scientific understanding) and the parameters involved are estimated from process data, such mechanistic models can provide much safer extrapolations beyond an experimental region than the cruder empirical polynomial models.

The process of research in chemical systems is one of developing and testing different models for process behavior. Whether empirical or mechanistic models are involved, the discipline of statistics provides data-based tools for discrimination between competing possible models, parameter estimation, and model verification for use in this enterprise. In the case where empirical models are used, techniques associated with "linear" regression (linear least squares) are used, whereas in mechanistic modeling contexts "nonlinear" regression (nonlinear least squares) techniques most often are needed. In either case, the statistical tools are applied most fruitfully in iterative strategies.

Reilly and Blau [26] and Chap. 16 of Box et al. [16] provide introductions to the general philosophy of using statistical methods in mechanistic modeling contexts, as well as a number of useful references for further reading.

Fairly sophisticated and specialized statistical software is needed in the practical application of nonlinear regression methods to mechanistic modeling for industrial chemistry applications. The techniques implemented in such software are discussed in Seber and Wild [27], Bates and Watts [28], Bard [29], and Riley and Blau [26].

Modern Business Process Improvement and the Discipline of Statistics

The modern global business environment is fiercely competitive in all sectors, including the chemical sector. It is by now widely recognized that corporate survival in this environment depends upon constant improvement in all business processes, from billing to production. Companies have adopted a variety of programs and focuses aimed at facilitating that improvement. A decade ago, efforts organized around a *Total Quality Management* banner (with liberal references to emphases of consultants like W. E. Deming, J. M. Juran, and A. Feigenbaum) were popular. More recently, programs keyed to ISO 9000 [30] certification criteria and Malcolm Baldridge Award [31] criteria have become prominent. And currently probably the most visible programs are the so-called *Six Sigma* programs.

In one sense there is nothing new under the sun, and all successful business process improvement programs (including those in the chemical sector) must in the end reduce to organized problem-solving disciplines. So it is not surprising that programs quite different in name are often very alike in fundamental content. And as they must necessarily make use of empirical information (data), they must have significant statistical components. To make this connection to statistics slightly more explicit, we proceed to provide a few additional details on the Six Sigma movement. (Further material on the subject is easy to find using an Internet search engine, as there are many consultants eager to sell their advice and Six Sigma training. The American Society for Quality at http://www.asq.org offers many entries into the subject. And a search at amazon.com for "Six Sigma" books already produced 6,666 hits in May 2004. Fashions change quickly enough that it seems pointless to provide more detailed recommendations for follow up on the subject).

The phrase "Six Sigma" originated at Motorola in the late 1980s. Programs there and at General Electric in the mid-1990s are widely touted as important contributors to company profits and growth in stock values. The name is now commonly used in at least three different ways. "Six Sigma" refers to

- A goal for business process performance
- A discipline for improvement to achieve that performance
- A corporate program of organization, training, and recognition conceived to support the process improvement discipline

As a goal for business process improvement, "Six Sigma" is equivalent to "$C_{\mathrm{pk}} = 2$." What is perhaps confusing to the uninitiated is that this goal has connections (through normal distribution tail area calculations) to small ("parts per million") fractions defective relative to two-sided specifications on y. Six Sigma proponents often move between the "small process variation" and "parts per million" understandings with little warning.

Six Sigma process improvement disciplines are typically organized around the acronym "MAIC." The first step in an MAIC cycle is a Measure step, wherein one finds appropriate process responses to observe, identifies and validates measurement systems and collects baseline process performance (process monitoring) data. The second step is an Analyze step. This involves summarizing the initial process data and drawing appropriate inferences about current process performance. The third step in an MAIC cycle is an Improve step, where process knowledge, experimentation, and more data analysis are employed to find a way to make things work better. Finally, the four-step cycle culminates in a Control (process monitoring) effort. The object here is to see that the newly improved performance is maintained after a project team moves on to other problems.

Six Sigma corporate organization, training, and recognition programs borrow from the jargon and culture of the martial arts. People expert in the process improvement paradigm are designated "black belts," "master black belts," and so on. These people lead project teams and help train new initiates ("green belts") in the basics of the program and its tools (including statistical tools). The emphasis throughout is on completing projects with verifiable large dollar impact.

Having made the point that improvement in all business activities is of necessity data-driven, it is hopefully obvious that the emphases and methods of the subject of statistics are useful beyond the lab and even production. Of course, for broad implementation, it is the most elementary of statistical methods that are relevant.

Conclusion

We have tried in this chapter to give readers the flavor of modern applied statistical methods and to illustrate their usefulness in the chemical industry. Details of their implementation have of necessity been reserved for further more specialized reading, for which the interested reader is encouraged to consult the references given in this chapter.

Overview

Literature sources on green chemistry and green engineering are numerous. The objective of this chapter is to familiarize readers with some of the green engineering and chemistry concepts, approaches, and tools. In order to do this, the chapter is organized into five sections as follows.

Section "Introduction to Green Chemistry and Green Engineering" provides an introduction to green chemistry and green engineering. Section "Pollution Prevention Heuristics for Chemical Processes" provides examples of pollution prevention heuristics for chemical processes. Heuristics of the two most important unit operations, reactors and separators, are covered. Section "Understanding and Prediction of the Environmental Fate of Chemicals" introduces readers to the concept of environmental fate and transport and prediction of environmental fate properties. Understanding of environmental fate and transport is important for exposure assessment and also is essential for evaluating environmental performance of processes and products during process development and design.

Section "Environmental Performance Assessment for Chemical Process Design" covers the environmental performance assessment for chemical processes design and introduces a three-tier approach to green engineering design of processes incorporating green chemistry, pollution prevention, environmental fate and transport, and life-cycle approach. Finally, Section "Life-Cycle Assessment" provides more background and examples on life-cycle assessment which is an essential principle of green engineering.

Introduction to Green Chemistry and Green Engineering

The Pollution Prevention Act of 1990 (42 U.S.C. 13101–13109) established a national policy to prevent or reduce pollution at its source whenever feasible. The Pollution Prevention Act also provided an opportunity to expand beyond traditional EPA programs and devise creative strategies to protect human health and the environment. The pollution prevention (P2) hierarchy established by this act is illustrated later in Table 5.1. Shortly after the passage of the Pollution Prevention Act of 1990, the EPA's Office of Pollution Prevention and Toxics (OPPT) launched a model research grants program called "Alternative Synthetic

Pathways for Pollution Prevention." This program provided grants for research projects that include pollution prevention in the design and synthesis of chemicals. The grant program eventually resulted in the establishment of the Green Chemistry Program around 1991 and 1992. Over the years, this program has catalyzed the development of many green chemistry approaches and environmentally benign chemical syntheses.

Green chemistry is the use of chemistry to reduce pollution at the source. More specifically, green chemistry is the design of chemical products and processes that reduce or eliminate the use or generation of hazardous substances. It is an overarching philosophy of chemistry, rather than a discipline of chemistry such as organic or inorganic. In fact, green chemistry is usually multidisciplinary, drawing on a broad range of expertise. Green chemistry, also called *sustainable chemistry*, offers lower-hazard alternatives to traditional technologies. Green chemistry and green engineering are partners in achieving sustainability.

Green engineering research was begun in the early 1990s to support environmental risk assessment of new chemicals. OPPT staff realized that the risk-based tools used to assess human health and environmental risk of new chemicals, when combined with traditional engineering design, could result in "greener" processes. This recognition eventually resulted in the establishment of the green engineering program which has catalyzed the green engineering movement, including many educational initiatives, research programs, and development of environmentally beneficial processes and products.

Environmental risk or environmental impact is an essential concept of green engineering (http://www.apa.goviogpugreenengmeaning) [1]. There are numerous literature references on environmental risk assessment and some are included in the list of references in this chapter. Risk assessment considers the extent of harm a chemical and its uses pose to human health and the environment. Mathematically, it is expressed as a function of hazard and exposure:

$$\text{Risk} = f(\text{hazard and exposure})$$

A hazard is anything that will produce an adverse effect on human health and the environment. In environmental risk assessment, the hazard component generally refers to toxicity. Exposure is the quantitative or qualitative assessment of contact to the skin or orifices of the body by a chemical. Traditional pollution prevention techniques focus on reducing waste as much as possible; however, risk assessment methods used in pollution prevention can help quantify the degree of environmental impact for individual chemicals. This approach provides a powerful tool that enables engineers to better design processes and products by focusing on the most beneficial methods to minimize all aspects of risk.

By applying risk assessment concepts to processes and products, one can accomplish the following:

- Estimate the environmental impacts of specific chemicals on people and ecosystems.
- Prioritize chemicals that need to be minimized or eliminated.
- Optimize design to avoid or reduce environmental impacts.
- Assess feed and recycle streams based on risk and not volume within a chemical process.
- Design "greener" products and processes.

Historically, scientists, engineers, and policy makers have focused their energy on minimizing exposure as the easiest way to minimize risk to humans or to the environment. Green chemistry focuses on the hazard or toxicity component of the equation instead of exposure. In reducing hazard, risk is reduced in a more reliable and frequently cost-effective manner. Exposure controls, such as personal protective equipment, thermal oxidizers, or treatment plants, are frequently expensive. Also, there is always a risk that an exposure control can fail. Such failure can be mitigated and minimized, but it cannot be eliminated. If instead, hazard is reduced, risk is minimized more reliably. To be sure, there are not yet technologies to eliminate the use or generation of all hazardous substances, so exposure controls are still needed, but to the extent that future technological developments can minimize hazard, the need for treatment or remediation will also be minimized.

Chemistry is an inherently creative discipline. Chemists routinely create new molecules and new methods to make molecules. Green chemistry taps this creativity. The 12 Principles of Green Chemistry [2], originally published in *Green Chemistry: Theory and Practice* [3], provide a roadmap for implementing green chemistry. Green chemistry techniques and principles are very powerful, especially for development of new chemicals and processes.

Green engineering (see Fig. 5.1) provides a system-based framework for evaluating and improving the environmental performance of chemical processes and products (both new and existing) by integrating consideration of health and environmental risk, green chemistry, and pollution prevention approaches into traditional engineering design.

As defined previously, risk is a function of hazard and exposure. In the environmental risk context, hazard is a

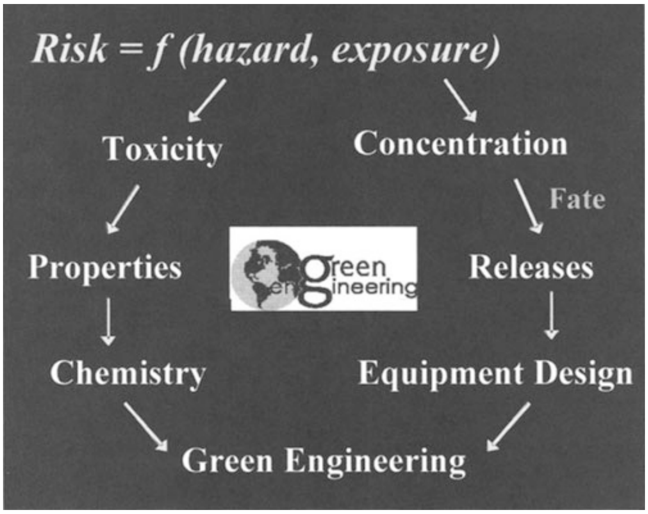

Fig. 5.1 Green engineering is a holistic approach to green process development and design

function of toxicity which is affected by physical/chemical and environmental fate properties and hence chemistry. Green chemistry reduces the risk or environmental impact of processes or products by focusing on the hazard component.

Exposure is a function of concentration and also is affected by the environmental fate properties of a chemical. Concentration is a function of the environmental release that is affected by the equipment or unit operations.

Environmental fate is an important subject area of environmental engineering discipline, especially in the modeling and design of treatment systems. It is also an important component of green engineering. Environmental fate properties can be useful for designing greener chemicals and performing environmental performance assessment of processes.

Green engineering minimizes risk or environmental impact by addressing both the exposure component or unit operations and the hazard or chemistry of the process or product (Fig. 5.2).

Figure 5.3 provides an example for a green engineering process. The left-hand side is a conventional process for making methyl acetate which involves a reactor and a series of distillation steps. The right-hand side is a greener process which involves a combined unit operation, reactive distillation. The green process is superior to the conventional process in many aspects, including chemistry, exposure, release, energy, and economics.

There have been a number of green engineering concepts, approaches, and tools that have been developed since the introduction of green engineering in the mid-1990s. Many of the green engineering approaches, concepts, and tools have been compiled into a standard textbook, *Green Engineering: Environmentally Conscious Design of Chemical Processes* by Allen and Shonnard [5]. These concepts, approaches, and tools can also be found via accessing the EPA Green Engineering Web site at www.epa.gov/oppt/greenengineering. The Web site contains links to many computerized green design tools that can be downloaded free of charge.

Twelve Principles of Green Chemistry[1]

1. Prevent waste: *Design chemical syntheses to prevent waste, leaving no waste to treat or clean up*. As commonsensical as this sounds, many chemists do not consider the waste generated by the syntheses they design. Coproducts (substances that are formed in stoichiometric amounts during a reaction) and by-products (substances that are formed unintentionally, usually in side reactions) are an inconvenience with which others are expected to deal.
2. Design safer chemicals and products: *Design chemical products to be fully effective, yet have little or no toxicity*. Although much is understood about the hazard of various substances, chemists frequently neglect toxicity as a design criterion when they are evaluating the performance of a chemical substance. Because hazardous materials are so routinely used in the laboratory, hazard becomes a trivial matter. Hazard should be explicitly considered and minimized during chemical design.
3. Design less hazardous chemical syntheses: *Design syntheses to use and generate substances with little or no toxicity to humans and the environment*. A holistic view of a synthetic pathway often allows a chemist to change factors and minimize hazard in a number of steps simultaneously. A safer synthesis may simply reduce the number of isolations and purifications, or it may allow a cascade of changes where a new first step fosters changes down the line.
4. Use renewable feedstocks: *Use raw materials and feedstocks that are renewable rather than depleting*. Renewable feedstocks are often made from agricultural and forest products or are the wastes of other processes; depleting feedstocks are made from fossil fuels (petroleum, natural gas, or coal) or are mined. Also the oxidation state of renewable feedstocks is often close to that of the desired product, thus simplifing and reducing the number and extent of chemical transformations necessary in a synthetic pathway.
5. Use catalysts, not stoichiometric reagents: *Minimize waste by using catalytic reactions*. Catalysts are used in small amounts and can carry out a single reaction

Minimize Risk Involves Reducing Both the Hazard (i.e. Toxicity) and Exposure

Risk = f (hazard, exposure)

Human Health & Ecosystem Effects

Concentration in Air, Water Soil (g/m³)

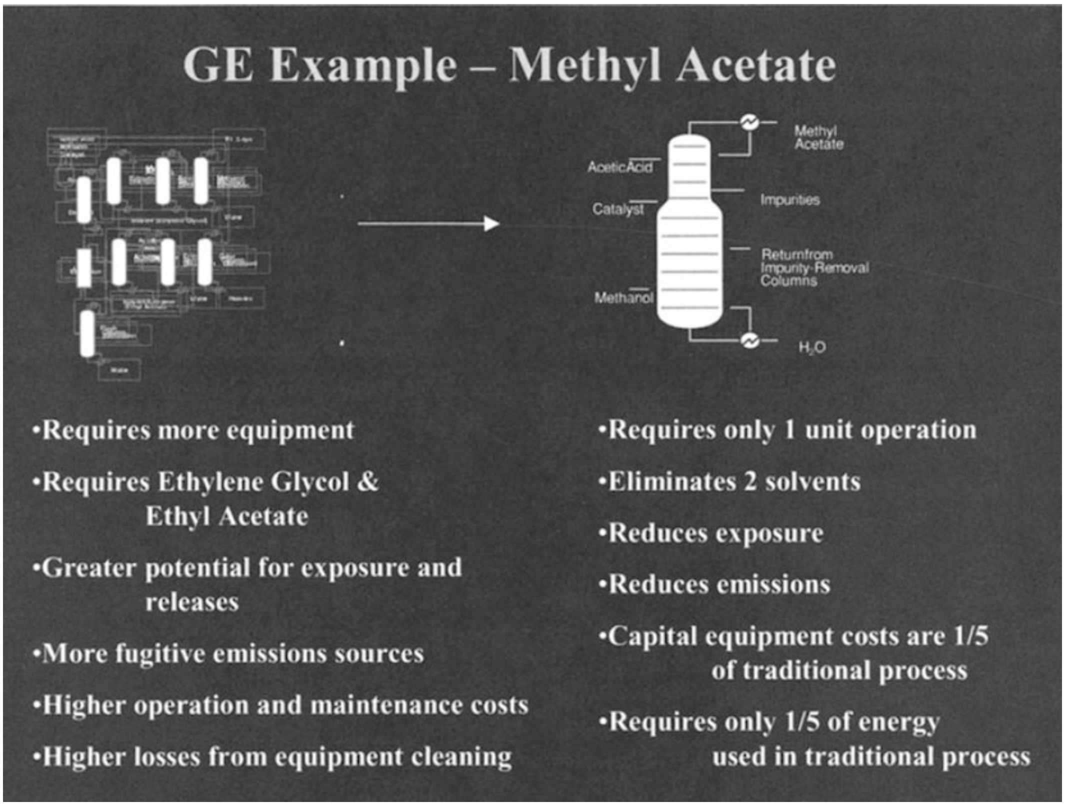
P/C and Fate Chemistry

Duration (min,sec)

Emission Rates (g/sec)

Equipment Design

Fig. 5.2 Green engineering addresses both the hazard and exposure components of the risk equation (P/C = physical chemical properties)



GE Example – Methyl Acetate

- Requires more equipment
- Requires Ethylene Glycol & Ethyl Acetate
- Greater potential for exposure and releases
- More fugitive emissions sources
- Higher operation and maintenance costs
- Higher losses from equipment cleaning

- Requires only 1 unit operation
- Eliminates 2 solvents
- Reduces exposure
- Reduces emissions
- Capital equipment costs are 1/5 of traditional process
- Requires only 1/5 of energy used in traditional process

Fig. 5.3 Green engineering example: conventional vs. greener process using reactive distillation technologies for the production of high-purity metal acetate (adapted from Malone and Russ [4] and modified) many times. They are preferable to stoichiometric reagents, which are usually used in excess and work only once. Even oxidations and reductions, which require a change in oxidation state and therefore an ultimate electron sink or source can be improved by using a catalyst. If reduction using hydrogen gas or oxidation with oxygen can be selectively catalyzed, the hazard and amount of waste generated is minimized.

6. Avoid chemical derivatives: *Avoid using blocking or protecting groups or any temporary modifications if possible*. Derivatives use additional reagents and generate waste. By definition, any group that is added and removed is waste. Reuse of protecting groups is uneconomical, leading to substantial amounts of waste when they are used. Reactants or reaction conditions may be tailored to maximize selectivity for the desired moiety.
7. Maximize atom economy: *Design syntheses so that the final product contains the maximum proportion of the starting materials. There should be few, if any, wasted atoms*. Reactions should also be designed to minimize the *E*-factor (ratio of the mass of all reaction waste to the mass of the desired product). Being aware of all the reaction inputs and outputs helps the designer maximize the benefit of the new chemistry. Materials efficiency not only minimizes environmental impact, but maximizes cost efficiency.
8. Use safer solvents and reaction conditions: *Avoid using solvents, separation agents, or other auxiliary chemicals. If these chemicals are necessary, use innocuous chemicals*. More and more research demonstrates reactions may not require solvents to proceed in clean and quantitative yields. When solvents are required, water, CO_2, ethanol, or other low-toxicity alternatives are preferred to traditional organic solvents.
9. Increase energy efficiency: *Run chemical reactions at ambient temperature and pressure whenever possible*. Shorter reaction times also help minimize energy use. Designers should be cognizant of the conditions necessary to carry out their transformations.
10. Design chemicals and products to degrade after use: *Design chemical products to break down to innocuous substances after use so that they do not accumulate in the environment*. This is arguably one of the hardest principles to apply, despite the existence of sound experimental evidence of what groups degrade well in the environment. The trick, of course, is how the substance “knows” it is at the end of its useful life. Products must be stable long enough to be available before and during use. Degradation may be triggered by a change in the conditions: presence or absence of water, light, oxygen, microorganisms, or other environmental factors.
11. Analyze in real time to prevent pollution: *Include in-process real-time monitoring and control during syntheses to minimize or eliminate the formation of by-products*. It is possible to monitor reactions and to adjust the reaction parameters, such as feedstock ratios, temperature, pressure, etc., to maximize the selectivity for the desired product.
12. Minimize the potential for accidents: *Select chemicals and their physical forms to minimize the potential for chemical accidents, including explosions, fires, and releases to the environment*. Whenever possible, select however energy forms of substances to minimize the energy needed as well as the energy content in case of accident. Avoid substances that are corrosive, highly reactive, or acutely toxic. Inherently safer chemistry reduces the risk from accidents as well as intentional harm.

Principles of Green Engineering

Green engineering is the design, commercialization, and use of processes and products that are feasible and economical yet, at the same time, minimize generation of pollution at the source and risk to human health and the environment. Green engineering embraces the concept that decisions to protect human health and the environment can have the greatest impact and cost-effectiveness when applied early to the design and development phase of a process or product.

There exist a number of green principles, including green engineering principles that have been developed. Most of these principles have overarching themes and objectives. For example, some were developed to help with design. The Green Engineering Principles[2] presented below were developed at the Green Engineering: Defining the Principles Conference held in Sandestin, Florida in May 2003 and attended by more than 65 individuals, primarily engineers of various disciplines and scientists. The attendees used as a starting point various existing compilations of green and sustainability related principles in developing these nine Principles of Green Engineering. Examples of existing principles used in this exercise were the Hannover Principles, Twelve Principles of Chemistry, CERES Principles, and Twelve Principles of Green Engineering proposed (Anastas and Zimmerman 2003). This list, along with the previously described Green Chemistry Principles, is intended

---

[2] The preliminary principles forged at this multidisciplinary conference are intended for engineers to use as a guidance in the design or redesign of products and processes within the constraints dictated by business, government, and society such as cost, safety, performance, and environmental impact.

to be used in tandem as guidance or rules for design and development of green processes and products. The Green Engineering Principles, described below, parallel many of the concepts and approaches covered in the textbook *Green Engineering: Environmentally Conscious Design of Chemical Processes* [5].

1. *Engineer processes and products holistically, use systems analysis, and integrate environmental impact assessment tools.* These concepts resonated in a number of green and sustainable principles and are addressed at length in Allen and Shonnard [5]. Evaluate and reduce the environmental health and safety impacts of designs, products, technologies, processes, and systems on ecosystems, workers, and communities continually and "holistically." Avoid risk shifting (e.g., reducing releases to one environmental medium may increase risk to another medium and/or worker exposure and safety).
2. *Conserve and improve natural ecosystems while protecting human health and well-being.* Reduce, reuse, and recycle the materials used in production and consumption systems, and ensure that residual waste can be assimilated by ecological systems. Rely on natural energy flows. Design processes and products to create cyclical material flows.
3. *Use life-cycle thinking in all engineering activities.* This is an important concept of green engineering. Life-cycle approaches have been widely used by many companies to assess and improve the environmental performance of their products and processes. It is essential that one consider the environmental impacts throughout the product or process life cycle from extraction through manufacturing, use, and disposal.
4. *Ensure that all material and energy inputs and outputs are as inherently safe and benign as possible.* This principle addresses the hazard component of the risk equation. Risk will be minimized if material and energy sources are inherently benign and safe.
5. *Minimize depletion of natural resources.* This principle resonates in many existing lists of principles. It reminds the engineer of the need to reduce and recycle the materials used in production and consumption systems. Conserve energy and improve the energy of internal operations and of the goods and services. Make every effort to use environmentally safe and sustainable energy sources.
6. *Strive to prevent waste.* It is always better and more economical to prevent waste from occurring in the first place.
7. *Develop and apply engineering solutions, while being cognizant of local geography, aspirations, and cultures.* Successful implementation of green engineering solutions can be affected by such factors as availability of resources and geography. It is important that these factors are considered in selecting the green engineering solutions that are most effective for certain localities or regions.
8. *Create engineering solutions beyond current or dominant technologies; improve, innovate, and invent (technologies) to achieve sustainability.* This principle encourages engineers to be creative and innovative in design and development of green engineering solutions. Think "outside the box" for development of green and sustainable technologies.
9. *Actively engage communities and stake-holders in development of engineering solutions.* This is important to ensure that stakeholders are supportive of the engineering solutions.

Engineers and chemists, as designers of products and processes, have a central role in designing chemical processes that have a minimal impact on the environment. Green chemistry and green engineering approaches and tools should be used to design new processes and modify existing processes. Green engineering broadens the scope of engineering design to encompass critical environmental issues and is an important framework for achieving goals of sustainable development.

Pollution Prevention Heuristics for Chemical Processes

Introduction

This section discusses pollution prevention (P2) guidelines and heuristics in chemical process industries useful in process/product development and design stages. The heuristics can also be used for analysis of existing processes but it should be noted that the number of available options is somewhat limited at this stage because the design decisions are already locked in. Therefore, for existing processes, these rules provide some guidelines for maintenance procedures and for making retrofitting decisions.

The outline of this section is as follows: First is a listing and discussion of the general hierarchical rules to be evaluated during the process design stage. Then, because reactors and separators form the heart of a chemical process, specific aspects of P2 heuristics as applied to reactors and separators are discussed in somewhat more detail.

It is appropriate at this point to define what is meant by a heuristic and indicate the pattern of discussions in the other sections of this chapter. A heuristic is commonly defined as a general "rule of thumb," or procedure to arrive at a solution in the absence of a detailed analysis. More specifically, it is a set of rules, often based on common knowledge, used to guide thinking towards a final solution. In our case, the final goal is P2, and heuristics guide us towards achieving this goal.

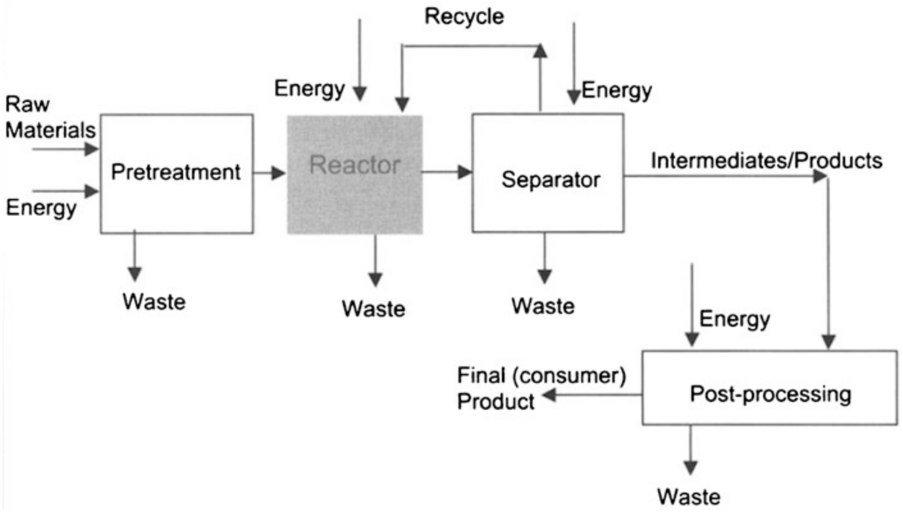


Fig. 5.4 Overall flowsheet showing the various sections for P2 analysis

In this section, the heuristics are often presented as questions rather than as affirmative rules. The rules are then often obvious answers to the questions, and, hence, often no explanation is necessary nor is any provided. However, if an elaboration or clarification is needed, this is provided immediately following the question. The question format of presenting the heuristics is very useful, for instance, in brainstorming sessions during process evaluation and design.

Hierarchical Rules for Waste Minimization

General rules for P2 follow the Pollution Prevention Act of 1990 (42 U.S.C. 13101–13109) and are applicable to any manufacturing activity. This act clearly identifies the waste management hierarchy, and we list them in Table 5.1 for completeness. The P2 Hierarchy specific to a chemical process is derived from this set of principles.

A simplified overall schematic of a chemical process is shown in Fig. 5.4 and forms a block diagram to analyze pollution prevention strategies. A flowsheet can be broken down into the following sections: (1) Pretreatment section, (2) reactor section, (3) separation section, and (4) postprocessing section. The reactor and separator are usually coupled, and, hence, the P2 decisions are often to be made together for this section. Also it may be noted that the blocks cannot be treated in isolation and any design changes made in one section may affect the other. The blocks are, therefore, only convenient partitions for outlining a general strategy. Any decision made for one section has to be reexamined in the overall context, and reconsideration may often be needed. The rule "think outside the box" is very relevant here. With this background setting, we can discuss the hierarchical approach to evaluate P2 opportunities.

Table 5.2 P2 hierarchy for flowsheet analysis or process design

1.	Batch or continuous mode
2.	Input–output structure of the flowsheet
3.	Recycle structure of the flowsheet
4.	Reaction systems
5.	Separation systems
6.	Postprocessing and product sections (e.g., tableting, product drying, etc.)
7.	Energy systems (boilers, cooling towers, heat exchangers, etc.)
8.	Auxiliary equipment (piping, storage tanks, etc.)

The hierarchical rules for analyzing a flowsheet or designing a new process were first formulated by Douglas [6] and then modified by Rossiter and Klee [7], and these form a starting point in this section. The steps are outlined in Table 5.2, which is an extended version of the original suggestions by Rossiter and Klee [7]. The key idea in forming such a hierarchy is that decisions made in earlier steps do not generally affect the design/changes to be made in the later steps and, hence, the rules can be followed on a "top to bottom" basis. This prunes the decision tree and makes the process synthesis task somewhat simpler. Each of the hierarchical steps is now discussed in detail together with the heuristics to be followed for each step.

Batch or Continuous?

The general guidelines are as follows:

1. *What is the annual rate of production?* For capacities of the order of 500 t/year or less, use batch. For capacities of more than the order of 5,000 t/year, use a continuous process.
2. *Does the system involve resource conservation and recovery act* (*RCRA*) *hazardous chemicals?* If so, try to use continuous processes even if the scale is relatively small. Continuous processes generate waste at a constant rate.

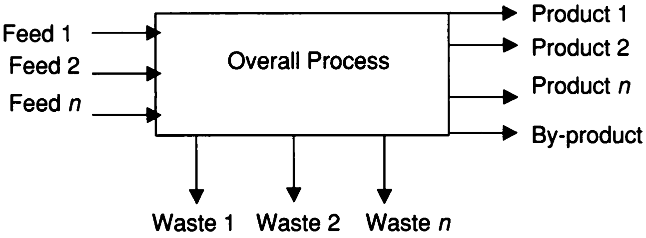

Fig. 5.5 Input–output structure of flowsheet

The composition of the waste is also constant with time and, hence, the treatment is easier. In contrast, batch processes generate wastes intermittently with a large rate of generation for a short period (during the peak point in production). As a result, continuous processes are easier to monitor and control. Batch processes also generate additional waste due to the need for cleaning the equipment between two batches. Hence, the capacity alone may not be the deciding factor in choosing between batch and continuous operation.

It may be noted that raw material substitution is easier in batch processes. Therefore, if one anticipates a varying range of feedstocks then batch processes may have some merit. In a similar note, if the same equipment is used to make a wide range of products (e.g., dyestuffs) then a batch process may be more suitable.

Input–Output Structure

Input–output analysis focuses on the overall structure of the flowsheet, and the recycle streams are not considered here in as much as they do not appear in the overall flow streams. Hence, this structure is essentially an overall mass balance for the entire process. A simplified representation of the input–output structure is shown in Fig 5.5. The main purpose of this analysis is to identify the amount of raw materials used, useful products, and waste formed.

At this stage one can define a process efficiency parameter as:

Process efficiency = MMass of raw ma/Mass of raw materials used which can be used as an indicator of the P2 success scorecard. The goal is to improve the process efficiency, and any changes can be benchmarked against the level of existing efficiency.

The heuristics to be considered at this stage are as follows:

Are any impurities in the feed tied to the waste streams? If so, try source reduction.

Is there a scope for better raw material selection? This would achieve a source reduction which is number 1 in the P2 list given in Table 5.1.

Do the products have a toxic component? Can this be minimized by proper raw material selection?

Can value be added to the waste? Are there any raw materials that are suitable for in-process recycling? In-process recycling is covered under item 2 in the P2 list.

Can wastes be used in the process recycling? Are there waste agencies nearby to take these away? This concern is addressed in item 3 of the P2 hierarchy.

Are wastes generated due to reactor inefficiency? Some guidelines for improving the reactor performance are discussed below under "Heuristics for Green Reactor Design."

Are wastes generated as a result of separation inefficiency? Some guidelines for improving the separation processes are discussed in a later section titled "The P2 Rules for Separations Devices."

Recycle Structure of the Flowsheet

At this level of analysis, the focus is on the recycle streams. The pertinent questions to be addressed at this stage are as follows.

Is there a scope to redirect any output waste streams back to the reactor feed to reduce waste? Can the recycle to reactor be fed directly to the reactor or is a separate reactor needed for this purpose? Often the streams leaving the reactor have trace impurities (formed as by-product in a side reaction) that can be harmful to the catalyst. Hence a separate reactor may be more suitable for such cases. In some cases, the streams can be recycled back to the existing reactor but only after a pretreatment step to remove the trace contaminants and catalyst poisons.

Can any impurity be recycled to extinction? This is possible if the impurities are formed by a reversible reaction while the main reaction is irreversible.

Is the recycle affecting the purge streams? If so consider raw material pretreatment. Nonreactive materials in the feed stream are responsible for the purge and reducing their quantity would reduce the purge. For example, if oxygen-enriched air is used instead of air in a typical partial oxidation process, the quantity of the purge and the associated waste can be reduced.

Can any waste from separation units be reprocessed? Can any waste from separation be reused in any other part of the process?

Has the scope for water recycle been examined completely? Often the possibility of reuse of stripped sour water, wastewater from utility blowdown, etc. exists, and these are often overlooked.

Reaction Systems

Having examined the recycle nature of the flowsheet and the relevant decisions made, the focus shifts to the reaction section. Some of the common issues related to reactor design to be addressed at this stage are as follows:

Are wastes formed from the side reactions? Often the side reactions can be minimized by simple changes in operational procedure. For example, temperature sensitivity of the side reactions can be examined and if the rate of the side reaction increases more with temperature than the main reaction, then lowering the reactor temperature will reduce the waste.

Are the side reactions leading to waste formed in a reversible step of the reaction? If so, there is scope to recycle wastes to extinction.

Is the catalyst used the best available or is there a scope for catalyst replacement?

Is there a scope for solvent substitution? If so, how would it affect the other steps? Additional information on solvent selection is discussed later.

Separation Systems

Having addressed issues related to the overall flowsheet and the reaction system, attention is now focused on the separation systems. Separation systems offer considerable scope for waste minimization. They can be generally classified into the following categories.

1. Gas–liquid separation
2. Gas–solid separation
3. Liquid–liquid separation
4. Liquid–solid separation

General heuristics related to separation systems are indicated here. Detailed heuristics with respect to each individual type of separation are addressed in "Separations Devices."

Some of the key questions to be addressed are the following.

1. *Are any waste streams produced as a result of poor separation?*
2. *Is the separation sequence optimum?* Separations that are easy are done first, followed by the less energy-intensive ones. The final separation step is usually assigned to the most difficult step because the overall quantity of stream to be treated would be minimum by then.
3. *Is the current separation the most suitable or should other methods of separation be considered?* For example, distillation is commonly the workhorse in the chemical industry and is often the immediate choice. Other separation methods, such as pervaporation, can be sometimes more effective especially if the volatility differences are small. Pervaporation is a membrane-based process with the difference that the permeate appears as a vapor, thus permitting solute recovery and recycle. For example, benzene can be recovered from hydrocarbon streams using this method in fairly high concentrations and in a usable form ready for recycle. Many alternative separation methods must be considered, and one should not simply bank on past experience or expertise.
4. *Is the current separation most efficiently designed or are there alternative designs that can reduce energy consumption and lead to less waste?* Examples may be in solvent extraction where a simple switch of solvent may lead to a nonhazardous waste. Also, conventional distillation is often used, but, currently, new design concepts, such as divided wall distillation [8], may prove to be more beneficial for certain processes. Replacing a conventional packing by a more efficient, structured packing may improve the treatment of waste gases in absorption columns.
5. *Is the choice of the mass separation agent (MSA) both cost-effective and environmentally benign? Can any improvements be possible in this choice?* Caffeine extraction from coffee beans is an example. Chlorinated solvents were used as mass separating agents, which posed both a health risk to workers and global harm due to ozone depletion. Supercritical CO_2 and, more recently, supercritical water have replaced these as MSAs.
6. *Have mass integration possibilities been evaluated? Are mass exchange networks (MENs) in place in the flowsheet?* Mass exchange network (MEN) synthesis has been addressed in the book by El-Halwagi [9], and application of this method to water management has been addressed in a paper by Liu et al. [10]. These aspects should be looked at carefully during the process synthesis stage, as they offer considerable scope for solvent or MSA reduction.
7. *Can the separation and reaction sections be suitably combined?* Combining reaction and separation in one unit can have some advantages. It often removes the equilibrium barrier, and, in some cases, complete recycle of unreacted feed is achieved in the same vessel. This question is more important in the design stage of new processes and is somewhat difficult to address in retrofitting existing processes. Membrane separations provide another area where reaction and separation can be combined.
8. *Can any hazardous waste be removed before discharging into a POWT (publically owned water treatment) facility?*

Postprocessing and Product Section

Postprocessing forms an additional important step in the manufacture of many consumer-oriented products, in contrast to commodity chemicals. Examples include tablets, pills, toothpaste, creams, and a wide variety of common products. The chemical industry has traditionally focused on commodity chemicals (process engineering), but, recently, the emphasis has shifted to product engineering. The postprocessing of chemicals to make consumer-used products can often be a major source of pollutants. Hence, careful attention has to be paid to this part of the process as well. Also, this part of the overall plant may involve batch processing, whereas the rest of the process may be continuous processing. Some heuristics are listed below.

Are fines created as a result of product drying? If so, select a different type of dryer. High air velocities or thermal degradation of solids lead to fine formation in drying equipment. These can be avoided by choosing the proper type of dryer depending on the properties of the solid.

Is the blending operation optimized or is it creating some wastes? Can any waste from this operation be recycled?

Is the cleaning operation in between batches optimized? Is there a possibility of wash-solvent recycle here without affecting the overall product quality?

Can process equipments be coordinated to minimize vessel cleaning and to reduce the associated wastes?

How will the products be packaged? Will containers be available for recycle? Are any additional wastes generated as a result of the container reuse policy?

Energy Systems

Energy costs are a major part of the operating costs in chemical processes and, hence, any reduction in energy consumption leads to an increased profitability. Further increased energy use has a direct bearing on the greenhouse gas emissions and, thus, the optimization of the energy systems is also important from a P2 point of view. Some heuristics to be discussed at this stage of analysis are the following:

Is the process fully optimized for energy use?

Are the heat integration networks in place and is there further scope in reducing the energy costs?

Can cleaner fuels be used to reduce SO_2 emissions? If so, at what cost?

Do the steam systems operate at the needed pressure rather than at the available boiler pressure? Too large a pressure leads to a higher condensation temperature for steam. This causes an unnecessarily large temperature differential for heat transfer. Fouling and other problems arise as a consequence, reducing the energy efficiency. In other words, use utilities at the lowest practical temperature. A simple solution to reduce the steam temperature is the use of a thermocompressor. This device uses high-pressure steam to increase the pressure of low-pressure steam to form steam at a desired intermediate pressure.

Are the heat exchangers routinely maintained to reduce fouling? Are the state-of-the art cleaning methods used to reduce sludge formation?

Is the wastewater from high-pressure cleaning of heat exchangers treated separately and not with all the other water streams? These often carry fine particles that provide a large surface area for oil and water to stabilize creating an oily sludge in the wastewater which is difficult to separate.

Can the cooling tower blowdown be reduced? Often pretreatment of fresh water to the cooling tower to reduce calcium salts can be helpful to reduce the scaling and thereby reduce the blowdown. Ion-exchange or even more expensive options, such as reverse osmosis, may prove to be beneficial in this regard depending on the quality (hard or soft) of the feed water.

Auxiliary Equipments

These include pumps, compressor, and storage tanks. The pumps, valves, flanges, etc. can often be a major source of pollution due to fugitive emissions (unintentional release of process fluids). Storage tanks also contribute to pollution by breathing and standing losses. Hence, sufficient attention should be paid to the design and maintenance of this equipment from a P2 standpoint, and this auxiliary equipment should not be taken for granted. The following guidelines are useful.

Can welded pipes be used instead of flanged pipes? This will reduce the fugitive emissions.

Can the total amount of equipment and number of connections be reduced?

Are tanks properly painted? A tank freshly painted will reduce the breathing losses by 50% as shown in an example by Allen and Rosselot [11].

Has the EPA recommended estimates for fugitive emissions done on a periodic basis? Are any improvements noted over a period of time?

Heuristics for Green Reactor Design

Green design of a reactor can be approached in the following hierarchical manner with the top of the hierarchy being the least cost-effective solution.

- Minor modifications in operating conditions and better "housekeeping" practices in existing processes.
- Additional "end-of-the-pipe" clean-up of wastes. (The goal here is to recycle and recover.)
- Major retrofitting of existing processes. Waste reduction and enhanced recycle. Goal is zero emissions and "total recycle."
- Development and installation of more efficient new process technologies that minimize waste and pollution.
- Process intensification concepts and new reactor design concepts.

The last two items in the above list involve considerable R&D and hence present a long-term strategy for waste minimization in reactors. These items should be looked into carefully at the early stage of process design. The first three can be attempted in existing processes.

The minor modifications can be addressed by looking at some of these issues.

A. Source reduction
   - Use nonhazardous raw materials.
   - Use renewable resources.
   - Use benign solvents.
   - Reduce use of solvents.

B. Routine maintenance
   - Temperature control.
   - Pressure control.
   - Vent and relief system tuning.
   - Routine calibration of instruments.
   - Routine cleaning of steam jackets, coils, and other reactor cooling auxiliaries.

C. Operational changes
   - Reduce by-products and generate less waste.
   - Produce products easy to separate.
   - Use heat integration.
   - Evaluate the effect of temperature on side-product formation rate. Can an increase in temperature be beneficial or should one decrease the temperature?
   - Evaluate the role of mass transport for multiphase systems. In some cases an increased mass transfer may favor by-product formation, and reducing the degree of agitation, for instance, may be helpful.
   - Evaluate the role of mixing of reactants. Is a premixed feed better?
   - Evaluate the role of catalyst. Is there a better or more stable catalyst?
   - Is the temperature profile in batch or semi-batch the optimum? Can the temperature peak be minimized?

D. Design changes
   - Recycle unreacted materials.
   - Consider a separate reactor for recycle to minimize catalyst deactivation.
   - Do not overdesign. Overdesign is not only capital consuming but also leads to increased energy costs that translate into greenhouse gases in the environmental context.

The above rules can be applied to an existing process. For new plants it may be necessary to revamp the entire process and use alternative benign production technologies. Some approaches to investigate here are as follows:

Improve atom efficiency.

Improve energy efficiency.

Novel chemistry, e.g., solid-catalyzed routes to replace liquid-phase routes or simple quantitative organic chemistry-based routes.

Novel solvents, e.g., CO_2 expanded systems, ionic liquids, etc.

Novel reactor concepts, e.g., periodic operation, membrane reactors, etc.

Reaction + separation combination, e.g., catalytic distillation, extractive reactions. Biphasic catalysis.

A more detailed description of the role of chemical reaction engineering is available in the paper by Tunca et al. [12], along with some examples and recent trends. Another useful source is the EPA Green Chemistry Web site (www.epa.gov/oppt/greenchemistry).

The P2 Rules for Separations Devices

Some heuristics related to specific methods of separation are as follows.

Distillation Columns

Distillation columns are the workhorse of separations in the chemical industry, and these are very common and offer considerable scope for P2. Some important questions to be addressed in this context are listed below.

1. *Does the system form an azeotrope?* If so, is an entrainer used? Can one replace the entrainer by a more benign agent? Can the azeotrope be broken by other methods such as pervaporation (see paper by Wynn 2001) or membrane separation and then continue with distillation to get the final purity?
2. *Is the reflux ratio in distillation column optimized?* Increase in reflux ratio increases the product purity. However, this causes a larger pressure drop in the column, and increases the reboiler temperature and the reboiler heat duty. Hence, there is a delicate balance among these factors, and often the reflux ratio has to be continuously adjusted to meet the change in feed composition and other day-to-day variations.
3. *Is the feed location optimum*? Simply relocating the feed may cause a more pure product and may be a simple strategy to reduce waste formation. It has both economic and environmental benefits.
4. *Is there a scope for combining reaction and distillation in one piece of equipment*?

Gas–Liquid Separation

These include absorption columns to remove a gaseous impurity as well as stripping columns to remove a VOC from a liquid (usually wastewater). Note that these involve an MSA. For example, for stripping of VOC from wastewater, steam or air is used as the MSA. Hence, appropriate choice of MSA is an important consideration in the context of P2 for gas–liquid separations. Some important heuristics are as follows.

Are the off-gas specifications within the regulations? If not try to switch to more efficient structured packings.

Are the desorption systems at the optimum pressure?

Can the solvent losses be minimized? Should one use alternate solvents that have better heat stability over the repeated absorption–desorption cycle?

Gas–Solid Separations

Gas–solid systems are encountered in a number of processes, such as fluid bed dryers, fine capture from gaseous effluents to meet the PM_5 air quality criteria, etc. Efficient design of these systems will improve the air quality.

Another example of gas–solid separation is the adsorption process. The regeneration of adsorbent is often not complete due to pore diffusion limitations and other factors. Furthermore, the eventual replacement of spent adsorbent leads to solid wastes. Optimization of adsorbent pore structure is one option that can be examined here. The process of regeneration also leads to waste formation and needs to be set at optimum conditions.

Liquid–Liquid Separations

These systems are common in liquid extraction and also in a multiphase reactor with an organic and an aqueous phase. Common sources of pollution are incomplete separation and contamination due to trace organics in the aqueous phase. An example is in alkylation reactions (e.g., *n*-butane reaction with olefins to form isooctanes). Strong acids, such as sulfuric and hydrofluoric acids, are used as catalysts, and the recovery and the recycle of acid need to be optimized in order to reduce the waste generation.

Liquid–Solid Separations

These are encountered in processes such as filtration that involve flow through a membrane. The prevalence of this in the chemical industry has not, however, diminished the challenges in proper design of these systems. A wide range of membranes is available for separation of a solid from a liquid. Fouling is the major challenge in membrane processes and is the most common source of pollution. Membrane systems need periodic cleaning and are another source for pollution generation in terms of waste water. Some heuristics to consider at this stage of design are listed below.

Is the membrane hydrophobic or hydrophilic?

Has the proper selection of membrane tied to the property of the slurry?

Can fouling be reduced by maintaining a higher shear rate at the interface?

In summary, the hierarchical process review and the various heuristics presented here provide a systematic method for identification of waste formation and the appropriate strategies to minimize waste in process industries. Maximum benefit of using this approach is realized at the process development and process synthesis stage followed by the process design stage. Some of the guidelines can also be used in the retrofitting state for existing processes. Additional P2 methods, technologies, and practices are found in the compilation by Mulholland and Dyer [13].

Understanding and Prediction of the Environmental Fate of Chemicals

Introduction

To understand the fate of a chemical once released into the environment requires knowledge of not only how the environment is modeled but also the intimate connection among a chemical's structure, its physicochemical properties, and its behavior under a given set of conditions. The behavior of a chemical in the environment falls under one of two categories: *translocation*, resulting in the movement of the chemical either within a compartment or between compartments, and *transformation*, resulting in the alteration of the chemical's structure. In predicting the persistence of a chemical in the environment, three broad questions are asked:

1. Will it move, and, if so, where will it go?
2. Will its structure be altered?
3. How long will it persist?

The first question is answered by understanding the susceptibility of the chemical to translocation, whereas the second question is answered by understanding the chemical's susceptibility to transformation. Once these two questions are answered, then the third question, requiring rates of translocation and/or transformation, can be answered, thus providing a foundation upon which subsequent assessments of risk to the environment and public health can be performed.

The goals of this section are to introduce methods of modeling chemical movement within and between environment compartments, to define specific translocation and transformation processes, to provide a basic understanding of the association among chemical structure, physicochemical properties, and susceptibility to specific translocation and transformation processes, and to provide methods of accessing and estimating physicochemical properties and environmental fate of chemicals.

Translocation of Chemicals in the Environment

Modeling the Environment

Before assessing how a chemical moves in the environment, the relevant media, or compartments, must be defined. The environment can be considered to be composed of four broad compartments—air, water, soil, and biota (including plants and animals)—as shown in Fig. 5.6. Various approaches to modeling the environment have been described [14–16]. The primary difference in these approaches is the level of spatial and component detail included in each of the compartments.

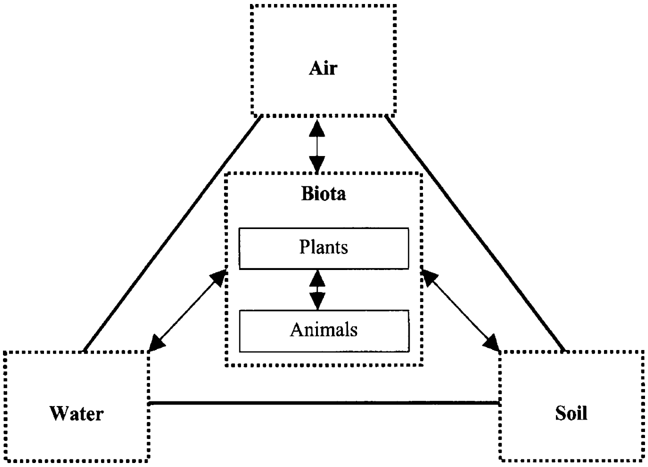

Fig. 5.6 Potential exchange routes of chemicals among the environmental compartments

For example, the most simplistic model considers air as a lumped compartment. A more advanced model considers air as composed of air and aerosols, composed of species such as sodium chloride, nitric and sulfuric acids, soil, and particles released anthropogenically [17]. A yet more complex model considers air as composed of air in stratified layers, with different temperatures and accessibility to the earth's surface, and aerosols segmented into different size classes [16]. As the model complexity increases, its resolution and the data demands also increase. Andren et al. [16] report that the simplest of models with lumped air, water, and soil compartments is suitable for chemical fate evaluations at very large scales (global), whereas the more complex models, with greater levels of segmentation and spatial differences within each compartment, are best suited for problems involving regional to site-specific studies.

Regardless of the model complexity chosen, the transport and partitioning of a chemical between water and air, air and soil, and biota and all compartments must be assessed. Furthermore, each of these compartments may contain different air, liquid, and vapor phases, and chemical partitioning among these phases must be determined. The driving force of transport of chemicals within and between compartments is a difference between chemical potential, the tendency of a chemical to undergo physical or chemical change, in one region compared to the other. When thermal, mechanical, or material equilibrium has been upset in the compartment(s) in question, the chemical moves in response. Despite the awareness that nonequilibrium conditions are at the heart of net chemical transport, modeling of partitioning of chemicals is commonly performed by assuming equilibrium conditions using estimates of liquid–vapor, solid–liquid, and solid–vapor partition coefficients [18]. These coefficients and other properties estimating environmental partitioning, along with properties enabling prediction of environmental transport of chemicals, are briefly discussed in the following sections. For greater detail on transport and fate of chemicals in the environment, the reader is encouraged to refer to numerous resources that are dedicated solely to this topic [19–21].

Translocation Processes in Air

As characterized in Fig. 5.7, once a chemical is released into the atmosphere, it is rapidly transported by the average wind and subjected to dispersion, defined as spreading as a result of thermal or density gradients and/or turbulence, and advection, defined as movement as a result of mass flow in the wind. These processes occur within the planetary boundary layer up to approximately 1 km above ground level [16]. Individual contaminant molecules are also prone to move within air along high-to-low concentration gradients. This type of transport is known as diffusion. These three processes combined result in the same effects: movement of the contaminant away from the source by dilution of the contaminant concentration in the release plume and spreading of the contaminant over a larger area.

While in the air compartment, the contaminant "solubilizes" in the vapor–liquid phase or is associated with aerosol particles by adsorption. It is also prone to desorption from the aerosol particles into the vapor phase. Relevant properties of the air used to model transport of partitioning of a contaminant in the air compartment include temperature, turbulence, wind speed, size and composition of aerosol particles, etc. [16, 19]. Relevant properties of the contaminant that measure its tendency to partition among the vapor, liquid, and solid phases in the air include its aqueous solubility (S_{aq}), vapor pressure (VP), Henry's (K_H), and a variety of coefficients measuring sorption on solids. These properties will be discussed in more detail in subsequent sections.

The net dispersive, advective, and diffusive transport of contaminants in the air is greatly influenced by the degree of deposition to the soil, water, and biota. Deposition occurs in three steps: (1) turbulent diffusion through the surface layer of the atmosphere, (2) diffusion through a laminar sublayer just above the surface, and (3) the ultimate disposition of the chemical on the surface [17]. As discussed previously with the first step, the second step is also affected by properties of the atmosphere and terrain, including turbulence, wind speed, and temperature, along with the size and composition of the particles composing the aerosols [16, 19]. Dry deposition of the contaminant occurs in the absence of precipitation and involves contaminants with and without association with particles. Wet deposition results from condensation of aerosol particles or equilibrium partitioning of the "dissolved" contaminant from the air to the liquid phase. Relevant chemical properties that enable prediction of the tendency of the

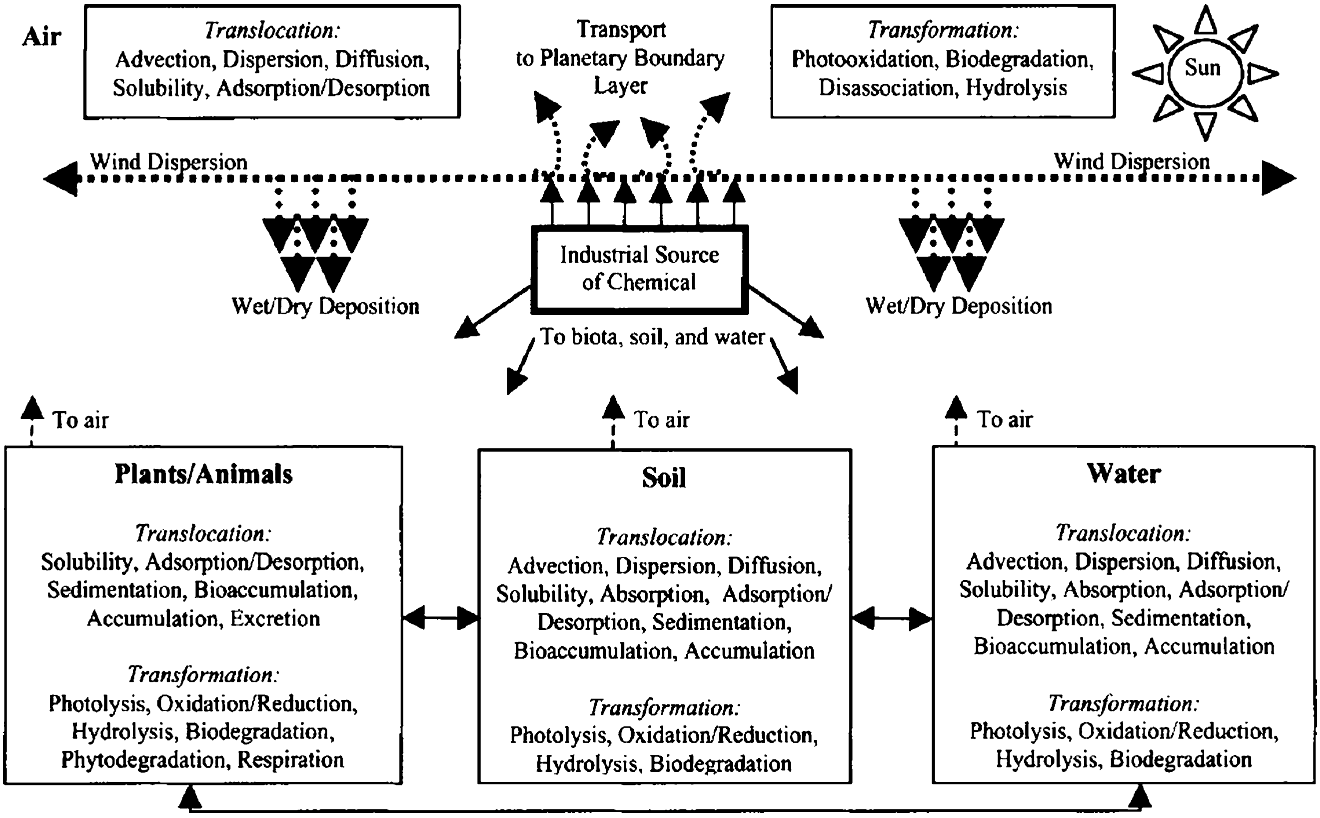

Fig. 5.7 Translocation and transformation processes possible in air, soil, water, and biota (adapted from Bishop [21])

contaminant to undergo deposition include aqueous solubility (S_{aq}), vapor pressure (VP), Henry's constant (K_H), and various sorption coefficients on solids. The last step of deposition is the behavior of the chemical once it has reached the water, soil, or biota surfaces, where it may return to the atmosphere in its original form or in an altered structure.

Translocation Processes in Water

Like the transport of a chemical in air, movement of a chemical in water is governed by the flow characteristics of the water itself (advection) and by the degree of diffusion within the water body. Two different types of diffusion can exist in water bodies. Eddy diffusion (or eddy dispersion) results from the friction caused by the water flow over the sediment or soil bottom surfaces. The vertical and horizontal flow resulting from eddy diffusion is more random and temporal than advective flow and thus extends over a smaller region. Horizontal eddy diffusion tends to be greater than vertical flow, and the contaminant is therefore transported to a greater extent horizontally from a point of discharge [22, 23]. A contaminant is also prone to transport by molecular diffusion, generated by concentration gradients. As a general rule, unless the water body is stagnant and uniform in temperature, molecular diffusion plays a minor role in transporting contaminants in comparison to eddy diffusion [23, 24]. Temperature plays a significant role in determining the degree of eddy and molecular diffusion of a contaminant, particularly in water bodies with stratified layers, such as lakes. As described previously in air translocation processes, the net result of the advective and diffusive transport of a contaminant in water is dilution away from the point of discharge and spreading of the contaminant plume into regions of greater area.

A contaminant can partition from the aqueous phase to solid, air, and biota media, and the presence of each of these media can greatly influence the extent of transport of the contaminant. With a porous solid phase with which the contaminant does not interact, transport of the contaminant is governed by the same laws of mass transport, involving advection and diffusion, that apply in aqueous media free of solids. However, interaction of the contaminant with the solid medium greatly inhibits its movement in the aqueous phase. When contaminant mixtures are present, those with less interaction with the solid medium move along with the aqueous medium, whereas those with greater attraction to the solid medium are retained in proportion to their degree of interaction [23].

As shown in Fig. 5.7, partitioning between the aqueous and solid phases may result from absorption, adsorption/desorption, and sedimentation processes. The contaminant may be taken up into the interior of a solid by means of diffusion in a process known as absorption. As previously described in air–solid partitioning, the contaminant may also be taken up by the surface of the solid, known as adsorption, and its release from the surface of the solid is known as desorption. Adsorption of a chemical to soil or sediment particles may be a result of electrostatic or hydrophobic attraction between the contaminant and the solid surface [23]. Once associated with solid particles, the contaminant may also settle to the sediment surface. This process, known as sedimentation, typically occurs in water bodies with laminar flow, such as a wetland. The increase in contaminant concentration in the solid phases as a result of any of these partitioning processes is known as accumulation [14].

The contaminant's aqueous solubility and density greatly influence its final disposition in water–solid systems. Dense nonaqueous phase liquids (DNAPLs) are chemicals with densities greater than water and typically low aqueous solubilities. DNAPLs naturally partition away from the aqueous phase and towards the solid phase, often pooling on top of an impermeable solid layer. On the other hand, light nonaqueous phase liquids (LNAPLs) possess densities less than water and have a tendency to pool on the water's surface where they may be prone to volatilization and photolysis reactions. Various liquid–solid partition coefficients have been developed to predict a contaminant's tendency to associate with the solid phase. These include the octanol–water partition coefficient (K_{ow}), the soil–water distribution ratio (K_{d}), the organic carbon partition coefficient (K_{oc}), the organic matter–water partition coefficient (K_{OM}). These will be discussed in detail in sections to follow.

Transport of a contaminant from water to air is influenced primarily by wind velocity [16]. The contaminant's density, vapor pressure, and aqueous solubility also factor into its tendency to be introduced into the air phase, and its Henry's constant (K_{H}) provides a good indication of this tendency. Biota have a strong attraction to hydrophobic contaminants, and, as a result, uptake of contaminants, by partitioning into plants and animals, known as bioaccumulation, has been reported to be a dominant mechanism of removal [16, 25]. The tendency of a chemical to be taken up into biota is quantified by the bioconcentration factor (BCF), as measured by the ratio of its concentrations in biota and water.

Translocation Processes in Soil

Contaminants in the soil compartment are associated with the soil, water, air, and biota phases present. Transport of the contaminant, therefore, can occur within the water and air phases by advection, diffusion, or dispersion, as previously described. In addition to these processes, chemicals dissolved in soil–water are transported by wicking and percolation in the unsaturated zone [26]. Chemicals can be transported in soil air by a process known as barometric pumping that is caused by sporadic changes in atmospheric pressure and soil–water displacement. Relevant physical properties of the soil matrix that are useful in modeling transport of a chemical include its hydraulic conductivity and tortuosity. The diffusivities of the chemicals in air and water are also used for this purpose.

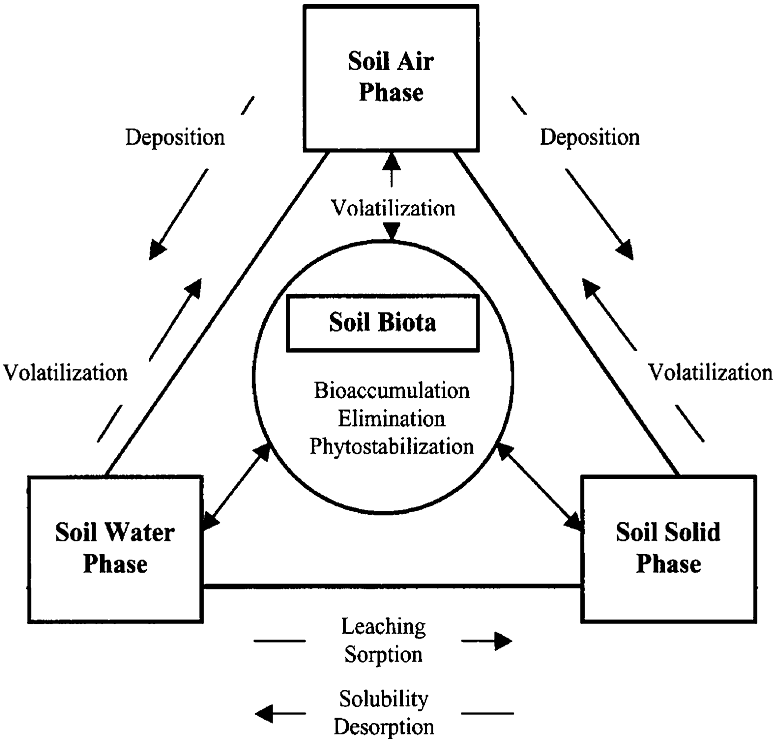
As shown in Fig. 5.7, any of the translocation processes described previously in air and soil compartments may also occur in soil. Figure 5.8, adapted from Baum [26], shows the potential intermedia exchanges that occur among the soil, air, water, and biota phases within the soil compartment. Exchange between air and water and air and solid phases may involve volatilization or deposition. Interchange between the water and solid phases may involve leaching (movement of the chemical in water through the soil column), absorption into the solid matrix, adsorption onto the solids, or desorption into the aqueous phase. Partitioning from any of the solid, water, or air phases to biota results in the bioaccumulation of the contaminant. Biota can use various means of elimination of the contaminant or its metabolites. Volatilization of the contaminant or its metabolites from plants to the air phase may occur, as well as excretion of the contaminant or its metabolites from roots or foliage to the surrounding soil and water phases in the root zone. The root zone may also serve to "stabilize" the contaminant in the soil, a process known as phytostabilization [27], resulting in accumulation of the contaminant in the soil phase. Relevant physicochemical properties of the contaminant that provide an indication of the degree of these partitioning processes include aqueous solubility (S_{aq}), vapor pressure (VP), Henry's constant (K_{H}), soil partitioning coefficients, and the BCF.

Translocation Processes Involving Biota

As mentioned previously and shown in Fig. 5.8, movement of a chemical in a system containing plants or animals may involve exchange with the air, soil, and water phases. Bioaccumulation results when the plant or animal uptakes the contaminant. In plants, the contaminant may be, in turn, released to the air by means of volatilization or to the soil with subsequent accumulation by phytostabilization, adsorption, and sedimentation or transport to the aqueous phase by advective, diffusive, or dispersive processes. Excretion of the contaminant or a metabolite from animals may also be received by any compartment.

Partitioning between a plant and air depends on the properties of the chemical, such as vapor pressure (VP), properties of the plant, and the temperature. Andren et al. [16] report that partitioning from the air to plants occurs primarily through the foliage, and only compounds with mobility in the phloem can partition to the stem and trunk

Fig. 5.8 Intermedia translocation processes involved in the soil compartment (adapted from Baum [26])



of the plant. As a general rule, hydrophilic compounds have higher phloem mobility, and, therefore, the octanol–water partition coefficient (K_{ow}) is a good indicator of the tendency of a chemical to be transported into a plant via its foliage. Uptake and release to/from the water and soil phases and the relevant parameters used to measure the tendency for these processes were discussed in the previous section. Of all the compartments of the environment, the least information is known concerning the translocation processes involving biota [16]. Also, the BCFs cannot be considered equilibrium constants as the other partitioning coefficients are because biota are "reactive sorbents" where the contaminant may be transformed upon uptake. These and other transformation processes involved in each of the environmental compartments are discussed in the following sections.

Transformation of Chemicals in the Environment

The primary mechanisms of degradation of chemicals in soil, water, sediment, air, and biota environments are classified as biotic (biodegradation, phytodegradation, and respiration) or abiotic (hydrolysis, photolysis, and oxidation/reduction), as shown in Fig. 5.7. Biodegradation, the transformation of chemicals by microorganisms, has potential to occur in any environmental compartment that contains moisture to support microbial processes; therefore, it can occur in all compartments, including in the root zone of plants. Phytodegradation, the transformation of chemicals by green plants, and respiration, the metabolism of chemicals by animals, occur wherever these biota reside, and, as discussed previously, they interact with each of the other compartments of the environment. Hydrolysis, the reaction with water, can occur in any compartment containing water, whereas nonbiological oxidation/reduction reactions are most dominant in the air phase [21]. Photolysis, the reaction of a chemical with ultraviolet radiation from the sun, occurs on surfaces exposed to sunlight, including soil, water, air, and plants. Compounds not susceptible to any of these degradation processes will have a tendency to be persistent in the environment. These reactions and their kinetics are discussed in more detail below.

Biotic Transformation Processes

Biodegradation. Because of the abundance and species diversity of environmental microorganisms and their ability to adapt to many different conditions and to degrade a wide range of substrates, biodegradation plays a major role in the transformation of contaminants [28]. The rate of biodegradation is influenced by numerous factors, including availability of nutrients, pH, temperature, level of oxygen, moisture content, and chemical structure. The degradation of the contaminant is catalyzed by enzymes, and most biodegradation processes are composed of a series of steps mediated by different enzymes. If the chemical is completely degraded to carbon dioxide, methane, water, and other inorganic compounds, it is said to be mineralized.

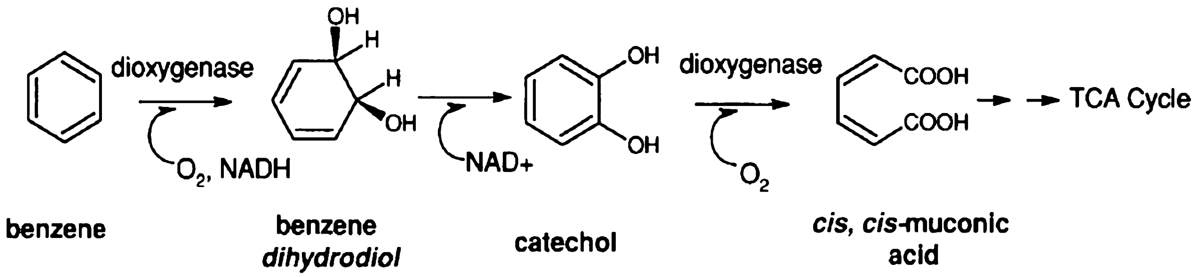


Fig. 5.9 The *ortho*-cleavage pathway of benzene oxidation by dioxygenase enzymes [29]

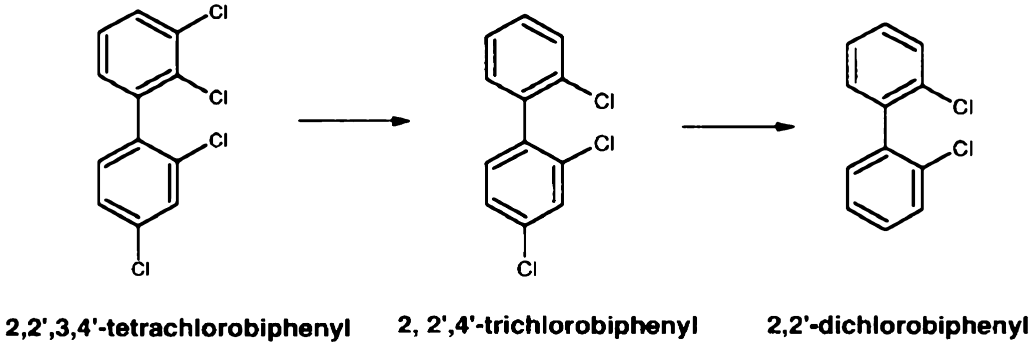

Fig. 5.10 Pathway of reductive dehalogenation of PCBs [31]

However, the contaminant is often converted to a chemical structure more complex than these mineralization products, and, in many cases, these incomplete degradation products, called daughter products or metabolites, are more toxic than the parent compound.

Some chemical compounds serve as a source of carbon and/or energy for the degrading microorganism, whereas in other cases they are not but are, rather, “cometabolized.” For example, methanotrophs, or methane-oxidizing bacteria, are known to oxidize aliphatic and aromatic compounds by cometabolism as long as methane is available to provide a source of carbon and energy. These bacteria are obligately aerobic because oxygen is necessary for their growth and metabolism; however, many other types of microorganisms cannot function in the presence of oxygen, and they are known as obligately anaerobic bacteria. Furthermore, bacterial populations exist that can function with or without oxygen, and they are known as facultative aerobes or facultative anaerobes.

Biodegradation reactions can be classified as aerobic or anaerobic, with oxidations and reductions dominating within these two classes, respectively. Oxidations occur in aerobic pockets in groundwater aquifers, near the soil surface, and aerobic zones of lakes and streams, for example. Dioxygenase and monooxygenase enzymes mediate oxidation reactions, yielding hydroxylated metabolites and possibly ring-cleavage products resulting from the activity of ring-cleaving diooxygenase enzymes. Figure 5.9 shows one of the known pathways of oxidation of benzene involving a consortium of microorganisms expressing diooxygenase enzymes that cleave the benzene ring between the two hydroxyl groups of the catechol, called *ortho*-cleavage. As implied by the TCA cycle endpoint in Fig. 5.9, the microorganisms involved in this pathway gain energy from the degradation of benzene. It is important to note that typical intermediates of biologically mediated oxidation reactions are more polar than the parent compound, thus with different environmental behavior.

More oxidized compounds, such as chlorinated benzenes, are susceptible to biologically mediated reduction in environments under anaerobic conditions, such as in lake and river sediments. It is known that highly polychlorinated biphenyl (PCB) congeners, for example, are susceptible to reductive dehalogenation, the result of the interaction of syntrophic microbial communities that are active under methanogenic and sulfate-reducing conditions [30]. Previous studies of Hudson River sediments have reported that the more chlorinated PCB congeners (with more than 3–4 chlorine atoms) are transformed to lesser chlorinated congeners by a series of dechlorination steps where the chlorine atoms are replaced by hydrogen atoms [31]. As shown in Fig. 5.10, preferential removal of the chlorine atoms in the *meta*- and *para*-positions on the ring occurs before the *ortho*-chlorines are removed, resulting in accumulation of the *ortho*-substituted congeners in the environment [32].

As a result of a large body of studies, heuristics of biodegradation have been developed. Table 5.3 provides

Table 5.3 Chemical characteristics conferring susceptibility to biodegradation

general guidelines for prediction of the tendency of a chemical to be biodegraded [21]. More detailed information about the specific biodegradation pathways and kinetics for individual groups of compounds and microorganisms can be found in numerous references [33–35].

Phytodegradation. The transformation of contaminants by plants is believed to play a major role in contaminant removal from the biosphere, particularly considering that plants cover approximately 146,000,000 km^2 of terrestrial surface [28]. Plants generally degrade chemicals by first uptaking them and subsequently transforming them to products that are conjugated or bound to the cell wall or stored in vacuoles [36]. Some plants use reductive dehalogenation and oxidation transformation pathways of degradation similar to those pathways followed by microorganisms in biodegradation. Compound classes that have been reported to be degraded in aqueous systems by plants include halogenated hydrocarbons [37, 38], nitroaromatics [39, 40], organophosphate pesticides [41], and polycyclic aromatic hydrocarbons [42, 43]. At this time, there are few rules of thumb to enable prediction of phytodegradation of contaminants because the study of phytodegradation is relatively recent.

Abiotic Transformation Processes

Hydrolysis. Compounds that possess an electrophilic atom (electron-poor) have a tendency to undergo hydrolysis reactions with electron-rich water or hydroxide ion (OH^-). The reaction forms a product with a hydroxyl group replacing a group that leaves the parent compound. The products are more polar than the parent compound, thus indicating different environmental behavior that must be evaluated, as also reported for products of biological oxidation. Hydrolysis is observed anywhere water is present, thus indicating that it can occur in any environmental compartment, given the presence of compounds susceptible to this reaction. This is considered a dominant pathway of transformation of compounds with hydrolyzable groups in aquatic systems [28]. These reactions are extremely pH^- sensitive, as they are often catalyzed by H^+ or OH^- ions. For example, Bishop [21] reports that the rate of hydrolysis of insecticide carbaryl increases logarithmically with pH, where the rate at pH 9 is ten times greater than at neutral pH and 100 times greater than at pH 6.

Numerous functional groups have been reported to be hydrolyzable, and examples of compound classes that are susceptible to hydrolysis are provided in Table 5.4. The chemical structure of the compounds greatly affects the rates of hydrolysis as shown in Table 5.4, with half-lives measured at pH 7 and 25°C ranging from seconds to thousands of years. A detailed discussion of degradation of contaminants via hydrolysis can be found in Schwartzenbach et al. [44], Larson and Weber [23], and Wolfe and Jeffers [45]. Ney [14] has set a low range of hydrolysis half-lives falling below 30 days and a high range above 90 days. As shown in Table 5.5, compounds considered to be hydrolyzed rapidly are not prone to bioaccumulation, accumulation, food-chain contamination, or adsorption, and are not generally considered persistent, whereas the opposite is true for compounds not hydrolyzed rapidly. Half-lives of various contaminants undergoing hydrolysis reaction have been reported to be significantly higher than those undergoing microbial transformation and phytotransformation [27]. For example, tetrachloroethylene (PCE), a common solvent used in dry cleaning, possesses a half-life of over 10 years if subjected to hydrolytic conditions at neutral pH. In contrast, PCE's half-lives due to microbial transformation (using a density of 10^5 organisms per liter) and phytotransformation (using *Spyrogyra* spp. at a density of 200 g wet weight per liter) have been reported to be 35 and 5 days, respectively.

Photolysis. Photochemical transformations of chemicals, also known as photolysis, result from the uptake of light energy (quanta) by organic compounds. These reactions can occur in the gas phase (troposphere and stratosphere), the aqueous phase (atmospheric aerosols or droplets, surface waters, land–water interfaces), and the solid phase (plant tissue exteriors, soil and mineral surfaces) [23]. Photolysis may be direct, where the structure of the chemical absorbing the light energy is "directly" transformed, or indirect, where photosensitizers, such as quinones and humic acids, absorb light energy and then transfer it to a contaminant whose structure is altered in the process [46]. Chemical reactions that affect structural change of photochemically excited contaminants include fragmentation, intramolecular rearrangement, isomerization, hydrogen atom abstraction, dimerization, and electron transfer from or to the chemical [44].

Functional groups such as unsaturated carbon–carbon bonds and aromatic rings lend greater susceptibility to photolytic reactions, and compound classes such as nitrosamines, benzidines, and chlorinated organics are more readily photolyzed [28, 46]. In order for photolysis to be

Table 5.4 Comparison of hydrolysis half-lives of representative chemicals in classes susceptible to hydrolysis at pH 7 and 25 °C [14, 23, 44]

Hydrolyzable compound class	Representative compound(s)	Half-life, $t_{1/2}$
Monohalogenated hydrocarbons R–X	CH_3Cl $(CH_3)_2CHCl$ $(CH_3)_3C–Cl$	340 days 38 days 23 seconds
Polyhalogenated hydrocarbons $R–X_n$	CH_2Cl_2 $CHCl_3$ $CHBr_3$ $BrCH_2–CH_2Br$	700 years 3,500 years 700 years 4 years
Carboxylic acid esters 	$R_1 = CH_3–, R_2 = –CH_2CH_3$ $R_1 = CH_3–, R_2 = –C(CH_3)_3$ $R_1 = CH_3–, R_2 = C_6H_5–$	2 years 140 years 38 days
Dialkyl phthalates 		100 years (pH 8)
Amides 	$R_1 = CH_3–, R_2 = –H, R_3 = –H$ $R_1 = CH_3–, R_2 = CH_3–, R_3 = –H$ $R_1 = –CH_2Cl, R_2 = –H, R_3 = –H$	4000 years 4,000 years 40,000 years
Carbamates 	$R_1 = CH_3–, R_2 = CH_3–$ $R_3 = –CH_2CH_3$ $R_1 = –H, R_2 = C_6H_5–, R_3 = –C_6H_4NO_2$	1.5 year 50,000 years 25 seconds
Phosphoric acid triesters 	$R_1 = CH_3–, R_2 = CH_3–$ $R_1 = C_6H_5–, R_2 = C_6H_5–$	1.2 years 320 days
Thiophosphoric acid triesters 	$R_1 = CH_3CH_2–, R_2 = C_6H_5NO_2–$ $R_1 = CH_3CH_2–, R_2 =$ 	89 days 23 days

considered to be a significant gas-phase destruction mechanism for a chemical, it must absorb light energy beyond a wavelength of 290 nm [28]. Specific compounds that do absorb greater than 290 nm include 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD), 1,2,3,7,8-pentachloro-*p*-dioxin, octachloro-*p*-dioxin, dibenzo-*p*-dioxin, hexachlorobenzene, and various polychlorinated dibenzofurans, and polychlorinated and polybrominated biphenyls [40, 47–51]. The kinetics of photolysis of herbicides in natural waters and soil surfaces were compared by Konstantinou et al. [52], who reported faster rates in soils than in lake, river, marine, and ground waters and significant enhancement of rates in the presence of increasing dissolved organic matter. Applying the same general rule as described for hydrolysis (Table 5.5), if the photolytic half-life of a contaminant is less than 30 days, it is not considered to be persistent; however, if the photolysis half-life is greater than 90 days, the contaminant poses risk to accumulation, bioaccumulation, and food-chain contamination [14].

Oxidation/reduction reactions. Reactions of chemicals via abiotic oxidation or reduction involve a transfer of electrons and result in a change in oxidation of the state of the product compared to its parent compound. As a general rule, reduction reactions are prevalent in soil sediments, while oxidation reactions are more important in surface waters and in the atmosphere [28].

The contaminant that is oxidized serves as the donor of electrons that are transferred to oxidizing agents including O_2, ferric (III) iron, and manganese (III/IV) in aquatic/soil systems and ozone (O_3), hydrogen peroxide (H_2O_2), and free radicals, such as the hydroxyl radical, in the atmosphere. Reduction reactions result in the transfer of electrons from an electron donor to the contaminant. Examples of electron

Table 5.5 Heuristics for hydrolysis half-lives and susceptibility of contaminants to translocation and transformation processes [14]

Process	Rapid hydrolysis ($t_{1/2} < 30$ days)	Slow hydrolysis ($t_{1/2} > 90$ days)
Accumulation	Not likely	Yes
Bioaccumulation	Not likely	Yes
Food-chain contamination	Not likely	Yes
Persistence	Negligible	Yes
Adsorption	Negligible	Maybe
Dissipation	Yes	Negligible to slowly

Table 5.6 Useful properties of the chemical, the medium, and transport/kinetics for assessment of environmental fates of contaminants [14, 18, 53]

Chemical	Medium	Transport and kinetics

Specialized Henry's constant, K_H Octanol–water partition coefficient, K_{ow} Bioconcentration factor, BCF Soil–water distribution ratio, K_d Organic matter–water partition coefficient, K_{om} Organic carbon–water partition coefficient, K_{oc}	*Water*: Number of active cells, redox potential, activity, velocity, etc. *Soil*: Hydraulic conductivity, tortuosity, composition, etc.	

donors present in the environment include pyrite (FeS), ferrous carbonates, sulfides, and natural organic matter. As described previously for biologically mediated reduction reactions, highly oxidized contaminants, such as PCE and highly chlorinated PCBs, can be reduced abiotically provided that they are in intimate contact with electron donors. Unfortunately, the kinetics of abiotic oxidation/reduction reactions have not been described for many contaminants [28].

The Connection Between Chemical Properties and Environmental Fate

As indicated previously, the final disposition of a chemical in the environment is dependent on the environmental conditions, characteristics of the media involved, and the various physicochemical properties of the contaminants. Table 5.6 provides a listing of properties describing the chemical, medium, and potential for translocation and transformation. This section focuses on chemical properties that are frequently used to assess the fate of a contaminant in air, water, soil, or biota. The goals of this section are to provide brief descriptions of relevant properties of a contaminant and to directly link specific ranges of these properties to predicted fate in the environment.

Traditional Chemical Properties

Traditional chemical properties including boiling point, T_b, melting point, T_m, density, ρ, surface tension, γ, vapor pressure, VP, and aqueous solubility, S_{aq}, have use in many systems beyond environmental applications; however, they provide strong indication of partitioning among the air, water, soil, and biota compartments in the environment. When combined with more specialized physicochemical properties to be discussed below, these traditional chemical properties can provide a very powerful means of answering the basic questions of where will a chemical go, what reactions will it undergo, and how long will it persist in the environment.

A chemical's T_b, the temperature at which its vapor pressure equals the ambient pressure, and T_m, the temperature at which its solid and liquid forms are in equilibrium at ambient pressure, are easily located in references and databases. As a result, many of the correlations that have been constructed for property estimations use these parameters as independent variables. The T_b of a chemical can nonetheless provide an indication of the partitioning between gas and liquid phases [53], with the higher values denoting a lower tendency to exist in the vapor phase. The surface tension, γ, of a chemical, the ratio of the work done to expand the surface divided by the increase in the surface area, is often used to estimate the VP of liquids in aerosols and in soil capillaries [28]. The VP of a chemical is the pressure of a pure chemical vapor that is in equilibrium with the pure liquid or solid, and it provides an indication of the tendency of a chemical in its pure liquid or solid phase to volatilize. Chemicals with high vapor pressures will be likely to escape to air and thus exist in higher concentrations in the air phases of environmental compartments than those with low vapor pressures. Ney [14] suggests that the VP of a chemical is considered high if greater than 0.01 mmHg, whereas low VP is considered to be below 10^{-6} mmHg. The S_{aq} of a chemical is another property that can be directly used to assess translocation and transformation potential of a chemical. By definition, the S_{aq} of a chemical is its concentration in a saturated water solution. A chemical possessing high S_{aq}, defined by Ney [14] as greater than 1,000 ppm, is more likely to be mobile in the aqueous environment than a chemical with a low S_{aq}, defined as less than 10 ppm.

Specialized Chemical Properties

Chemical properties that reflect the tendency of a chemical to partition between phases have been constructed specifically for environmental fate applications. These specialized properties are known as partition coefficients. The parameter that is a measure of a chemical's tendency to partition between water and air is known as the dimensionless Henry's constant (K_H), determined by the ratio of the equilibrium concentrations of the chemical in air and in water, respectively. The Henry's law constant (H), describing the ratio of the chemical's partial pressure in solution to its concentration in solution at equilibrium, is often used to describe chemical partitioning between air and water. K_H is simply the ratio of H to the product RT, where R is the gas constant and T is the temperature. Compounds with high H values (greater than 10^{-1} atm m^3/mol) will prefer the air phase and tend to volatilize from the aqueous phase in water, soil, air, and biota compartments, whereas compounds with low H values (less than 10^{-7} atm m^3/mol) prefer to escape the air phase into the aqueous phase [53].

Partitioning of a chemical between the aqueous and nonaqueous phases is frequently measured by the octanol–water partition coefficient, K_{ow}. K_{ow} of a chemical is the ratio of its concentration in *n*-octanol, frequently used to represent a model phase of living and nonliving natural organic material, to its concentration in water. This parameter which ranges from 10 to 10^7 is a measure of the partitioning of a chemical between hydrophobic and hydrophilic phases in all environmental compartments. A high K_{ow} value (characterized as greater than 1,000) indicates that a chemical has a tendency to be less mobile in the aqueous phase, more greatly adsorbed to solids, and bioaccumulate [14, 16, 53]. K_{ow} values are frequently used to determine another parameter, the BCF, which is the ratio of a chemical's concentration in the tissue of a living organism to its concentration in water. A chemical with a high BCF (greater than 1,000) will be more likely partitioned from water into the fatty tissues of fish and humans, for example, and thus is more likely to bioaccumulate and yield food-chain contamination effects. Chemicals with low potential for bioaccumulation typically have BCF values less than 250 [53].

Various coefficients are helpful in measuring the potential of a chemical to partition between the aqueous and solid phases. These parameters are valuable in predicting the potential of a chemical to adsorb to the solid phase. The soil–water distribution ratio, K_d, of a chemical is the ratio of its equilibrium concentration sorbed onto a solid phase to its equilibrium concentration in solution. Because most sorption of neutral, nonpolar chemicals occurs primarily on the organic matter in soil and sediments, the organic matter–water partition coefficient, K_{om}, is frequently used as a measure of a chemical's tendency to partition from water to solid phases. The useful parameter of K_{oc}, the organic carbon–water partition coefficient, has been introduced to describe the ratio of the equilibrium concentration of a chemical associated with the organic carbon content of soil to that associated with the water phase. K_{oc} is roughly 1.724 times greater than K_{om} because the organic matter sediment is roughly 1.724 times larger than the organic carbon content [28]. With all of these partition coefficients, higher values indicate that a chemical has a greater tendency to leave the aqueous phase and sorb to soils and sediments. Log K_{oc} values of chemicals are considered high when greater than 4.5 and low when less than 1.5 [53].

Sources of Chemical Property and Fate Data

Handbooks. Tabulations of traditional properties of chemicals (T_b, T_m, ρ, S_{aq}) are often available in publications by fine-chemical manufacturers (e.g., Fisher Scientific, Web page: www.fishersci.com). Other collections of these parameters, surface tension, the specialized partition coefficient values, and kinetics of transformations include Windholz et al. [54], Howard et al. [55], Dean [56], Lide [57], Mackay et al. [58], Howard and Meylan [59], Tomlin [60], Yaws [61], and Verschueren [62].

Software and online sources of chemical properties. Larson et al. [28] and Andren et al. [16] provide a thorough listing of electronic databases and online search engines for environmental fate properties. Very useful online databases for these parameters include Syracuse Research Corporation's (SRC's) (Syracuse, NY) Environmental Fate Database (EFDB) and the Hazardous Substances DataBank available at http://toxnet.nlm.nih.gov/. The SRC Web site also provides access to its DATALOG database that provides a literature search engine for numerous chemical properties. In addition, direct photolysis rates and half-lives of contaminants in the aquatic environment can be obtained from the US EPA's GCSOLAR software, available at http://www.epa.gov/ceampubl/swater/gcsolar/. A very useful software for estimating physical/chemical and environmental fate properties is the EPI Suite software [1].

Estimation methods. Numerous references focus on the theory and application of estimating physicochemical properties of chemicals. Lyman et al. [63], Neely and Blau [64], Howard and Meylan [59], Baum [26], and Allen and Shonnard [53] provide thorough descriptions of the methods available for manually calculating chemical properties.

Heuristics for Predicting Environmental Fate

Once the properties and fate data are obtained for a chemical, its general disposition in the environment can be estimated. Many of the properties described previously have been divided into ranges from low to high that enable estimation of tendencies of a chemical to undergo various translocation and transformation processes. Table 5.7 summarizes expected behavior of chemicals using values of VP, S_{aq}, K_{ow}, and K_{oc}. These findings are summarized below with general heuristics for predicting environmental fate of chemicals. These general trends in environmental fate can be combined with transformation kinetics to provide an assessment of exposure for any chemical.

Environmental Performance Assessment for Chemical Process Design

Introduction

The chemical industry contributes significantly to economic development, yet faces many environmental and societal challenges that require a rethinking of traditional approaches in the commercialization of processes and products. The generation of toxic, hazardous, and global change by-products of chemical processes is but a few examples of these challenges. A more comprehensive evaluation of economic, environmental, and societal consequences, at times spanning the entire product or process life cycle, is needed to achieve sustainable growth. Coincident with this will be an enlargement in the data and computational requirements for these assessments. Computer-aided analysis tools will therefore be needed to efficiently link process/product design with critical environmental and societal impacts in a larger systems analysis.

Fortunately, much progress has been made recently in developing environmental assessment methods and computer-aided tools to accomplish these goals. Table 5.8 shows a description of key factors for the environmentally conscious design of chemical processes for which computer-aided tools are useful. These tools fall into two categories: those providing information on environmental fate and impacts and those intended to improve process environmental performance. As will be shown, some tools provide information early in design whereas others are employed at later stages. These environmental factors and assessment tools should be incorporated into the design of chemical processes and products as illustrated in Fig. 5.11. The computer-aided tools in Fig. 5.11 include what has thus far been employed in traditional design: process simulation, design heuristics, and optimization. Added to these conventional design tools is a set of environmental evaluation methods and tools that inform the design activity on a range of potential impacts. The Green Engineering approach uses these environmental assessments in a hierarchical fashion during process and product design. A hierarchical approach for evaluating environmental performance during process design will be described in a later section.

Overview of Environmental Issues

Before beginning a series of case study evaluations, we will need to establish a set of environmental performance measures to use in design. These performance measures must reflect societal attitudes on the importance of several environmental impact categories. This is naturally a subjective judgment, but a consensus is emerging in the professional literature and in regulatory agencies on a set of environmental "midpoint" indicators for this purpose [53, 65–69]. Table 5.9 features several environmental impact categories, a description of the causes, and midpoint/endpoint effects.

Environmental Impact Assessment: Tier I–Tier III

Figure 5.12 illustrates a design hierarchy in the synthesis and evaluation of chemical processes, integrating the design approach of Douglas [70] with environmental risk assessment methods [53]. Environmental evaluation progresses from simple ("Tier I") assessments early in design when process information is limited to detailed flowsheet evaluations later in the design process. Different assessment approaches are needed in early design as opposed to those applied later in flowsheet evaluation. In early design, a large number of design choices are considered, and a simple and

Table 5.7 Rules of thumb of chemical property ranges guiding prediction of environmental fates [14, 53]

Property	Activity predicted	Heuristic
VP (mm Hg) Low: $<10^{-6}$ Medium: 10^{-6}–0.01 High: 0.01	Translocation Volatilization Accumulation Bioaccumulation Adsorption	1. Chemicals with high VP are more likely to volatilize into the air phase and less likely to accumulate, bioaccumulate, and adsorb to solids
S_{aq} (ppm) Low: <0.1 Medium: 0.1–10,000 High: $>10,000$	Translocation Mobility in water and soils Accumulation Bioaccumulation	2. High S_{aq} confers a greater tendency for a chemical to be mobile in the aqueous environment and is less likely to accumulate, bioaccumulate, volatilize, and be persistent
	Volatilization Adsorption	3. Chemicals with high S_{aq} are prone to biodegradation and respiration processes
	Transformation Biodegradation Respiration	4. Chemicals with low S_{aq} have a greater tendency to be immobilized via adsorption and less likely to be leached in soil
H (atm m^3/mole) Low: $<10^{-7}$ Medium: 10^{-7}–10^{-1} High: $>10^{-1}$	Translocation Mobility in air/water Volatilization	5. Chemicals with high H values have a greater tendency to escape the aqueous phase into the air phase, are less mobile in the aqueous environment, and less biodegradable but more mobile in the air environment
	Transformation Biodegradation	6. Chemicals with higher molecular weight tend to experience a decrease in both VP and S_{aq}. Thus, VP is a better measure of tendency to volatilize for these chemicals
K_{ow} Low: $<3,000$ Medium: 3,000–20,000 High: $>20,000$	Translocation Accumulation Bioaccumulation Adsorption Transformation Biodegradation Respiration	7. A chemical with a low K_{ow} indicates that it has high water solubility, aqueous mobility and is not susceptible to bioaccumulation, accumulation, or sorption to solids but is susceptible to biodegradation and metabolism by plants and animals
K_{oc} Low: <30 Medium: 30–32,000 High: $>32,000$	Translocation Accumulation Bioaccumulation Adsorption Transformation Biodegradation Respiration	8. Chemicals with high K_{oc} will adsorb to organic carbon and is likely to bioaccumulate and accumulate and less likely to biodegrade or to be metabolized by plants and animals
BCF Low: <250 Medium: 250–1,000	Translocation Accumulation Bioaccumulation Adsorption	9. Chemicals with high BCF values will bioaccumulate and yield food-chain contamination
High: $>1,000$	Transformation Biodegradation Respiration	10. A high BCF value implies a high K_{ow} value, and thus the same heuristics applying for K_{ow} apply for BCF
Half-lives of hydrolysis (days) Low: <30 Medium: 30–90 High: >90	Translocation Accumulation Bioaccumulation Adsorption	11. Compounds considered to be hydrolyzed rapidly are not prone to bioaccumulation, accumulation, food-chain contamination, or adsorption, and are not generally considered persistent, whereas the opposite is true for compounds not hydrolyzed rapidly
	Transformation Hydrolysis	12. In general, for all transformation reactions, if half-lives are high, the chemical is not considered to be susceptible to bioaccumulation, accumulation, food-chain contamination, or adsorption, and are not generally considered persistent

efficient methodology is needed. Design choices in early design might include the selection of raw materials, solvents, reaction pathways, and heat or mass separating agents, and the number of choices may be very large. Later in design, we consider the environmental performance of a small number of process flowsheets. The purpose of this section is to present applications of this tiered approach in the comparison of alternative design choices, emphasizing the methodologies and computer-aided tools.

Early Process Design Evaluations: "Tier I" Assessment

Early design is arguably the most important stage in the hierarchy for conducting environmental assessment. Environmental burdens of chemical processes are largely "locked in" by choices made during early design and attempts to improve environmental performance after a chemical process is operational are expensive and disruptive. Given the importance of early design assessment and the need to

Table 5.8 Description of environmental factors and prediction/analysis methods

Environmental factors	Description
Environmental properties of chemicals	Equilibrium distribution of chemicals among air, water, solid phases in the environment Degradation rates in air, water, and soil/sediment Toxicological properties Structure–activity relationships based on chemical structure Online databases
Emission estimation from process units	Emission factors for major process units Emission correlations for fugitive sources, storage tanks, material transfer and handling Emissions for process heating and utilities
Environmental fate	Fate models for wastewater treatment Fate models in a multimedia environment
Environmental performance metrics	Models to characterize environmental impacts
Process intensification and integration	Integration of heat and power Mass integration to prevent waste Pinch analysis, source sink diagrams
Process optimization	Mixed integer nonlinear programming Multi-criteria optimization

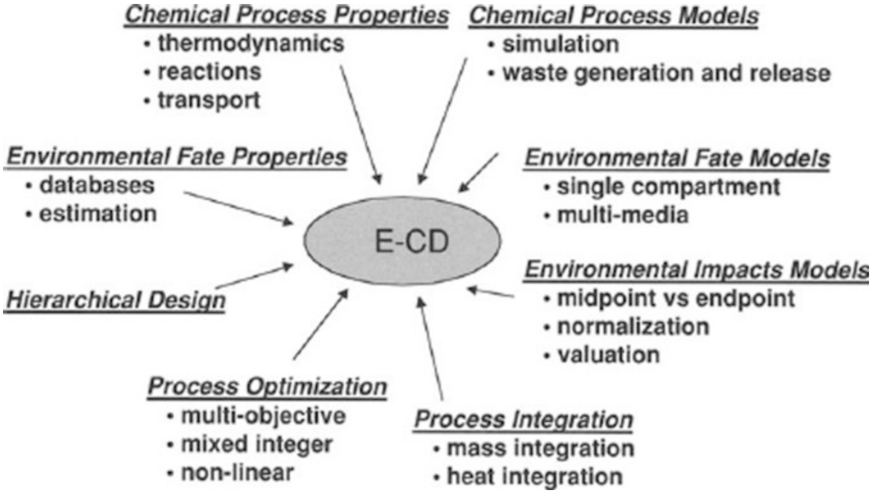

Fig. 5.11 The linking of environmental assessment methods and tools to the design of environmentally conscious chemical processes. *E-CD* environmentally conscious design

provide information on a large number of choices, streamlined yet accurate assessment methods are a high priority.

Solvent selection. Solvent selection is often conducted in early design of chemical processes. A method to match desirable solvent properties (solubility parameters, for example) while simultaneously avoiding undesirable environmental impacts (persistence, toxicity, volatility, etc.) would improve design performance. PARIS II is a program combining such solvent design characteristics. Solvent composition is manipulated by a search algorithm aided by a library of routines with the latest fluid property prediction techniques, and by another library of routines for calculating solvent environmental performance requirements [71].

Reaction pathway selection. Reaction pathway selection is another very important early design activity. High conversion of reactants, selectivity to desired products, and avoiding by-product reactions are among the 12 Green Chemistry principles from Anastas and Warner [3] described previously. Atom and mass efficiency are Green Chemistry performance measures that aid in early design assessment. Atom efficiency is the fraction of any element in the starting material that is incorporated in the product. The rationale is that reactions with high atom efficiencies will be inherently less wasteful. For example, in the reaction of phenol with ammonia to produce analine ($C_6H_5 - OH + NH_3 \rightarrow C_6H_5 - NH_2 + H_2O$), atom efficiencies of C, H, O, and N are 100%, 77.8%, 0%, and 100%, respectively. Mass efficiency for this reaction is defined as the ratio of mass in the product with mass in the reactants. For this example mass efficiency is

$$\begin{aligned}\text{Mass in Product} &= (6\text{C})(12) + (7\text{H}) \times (0\text{O}) \times 16) + (1\text{N}) \\ &\quad \times (14) \\ &= 93 \text{ g}\end{aligned}$$

Table 5.9 Environmental causes and midpoint/endpoint effects

Impact category	Initiating event	Environmental processes	Midpoint effects	Endpoint effects	Impact indicator(s)
Global climate change	Emission of greenhouse gases (CO_2, CH_4, N_2O, CFCs)	Absorption of infrared radiation	Increase in atmospheric temperature, sea level increase	Increases in human diseases and mortality Climate warming Ecological damage	Global warming potential (GWP)
Stratospheric ozone	Emission of ozone depleting compounds (CFCs, halons)	Chemical reaction release of C1 and cBr in stratosphere	Catalytic destruction of ozone in stratosphere	Skin and crop damage, damage to materials	Ozone depletion potential (ODP)
Acidification	Release of oxides of sulfur and nitrogen (SO_x, NO_x)	Chemical oxidation and deposition of acid compounds	Acidic precipitation and lowering of pH in lakes and soils	Ecosystem changes and plant/animal death	Acidification potential (AP)
Smog formation	Emission of smog precursors	Photochemical conversion to ozone and other species	Elevated ozone and aerosols in urban atmospheres	Reduced plant growth, human morbidity and mortality	Photochemical ozone creation potential (POCP)
Human cancer and noncancer effects	Release of toxic and carcinogenic compounds	Environmental fate and transport, exposure pathways	A dose to humans in excess of acceptable levels	Increases in human mortality and morbidity	Human toxicity potential (HTP)
Ecological toxicity	Release of toxic and carcinogenic compounds	Environmental fate and transport, exposure pathways	A dose to animals in excess of acceptable levels	Increases in animal mortality and morbidity	Ecological toxicity potential (ETP)
Resource consumption	Utilization of natural resources from the Earth	Extraction processes	Disruption of natural environments	Unsustainable depletion of resources	Fossil energy, land use area, mineral resource use

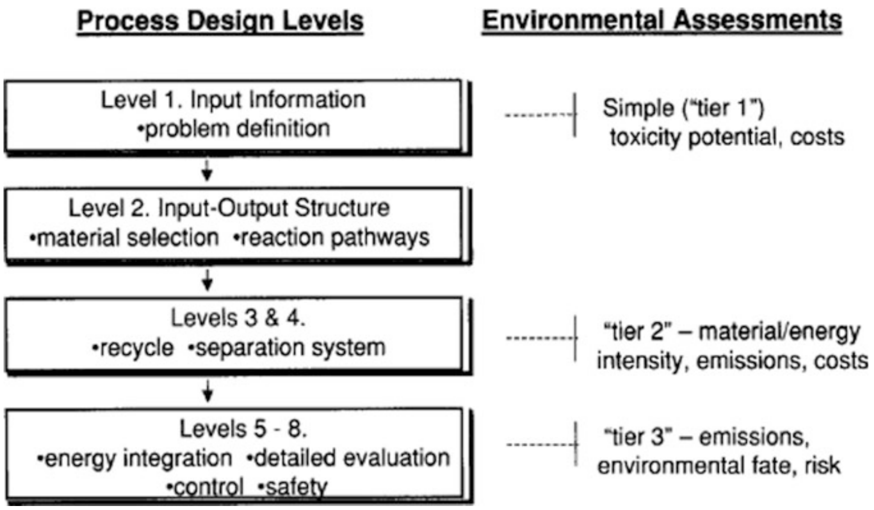

Fig. 5.12 A hierarchical structure to environmental evaluation of chemical process design

$$\begin{aligned}\text{Mass in Reactants} &= (6\text{C})(12) + (9\text{H}) \times (1) + (1\text{O}) \times 16) \\ &\quad + (1\text{N}) \times (14) \\ &= 111\ \text{g}\end{aligned}$$

$$\text{Mass Efficiency} = 93/111 \times 100 = 83.8\%$$

A higher atom and mass efficiency is desirable when comparing alternative reaction choices. A clear example of this is the production of maleic anhydride (MA) starting from either benzene or *n*-butane [72]. Benzene or *n*-butane is partially oxidized in the vapor phase in the presence of air and a solid catalyst at high temperature and pressure.

$$\text{Benzene route: } 2C_6H_6 + 9O_2 \rightarrow 2C_4H_2O_3 + H_2O + 4CO_2$$

$$n\text{-Benzene route: } C_4H_{10} + 7/2O_2 \rightarrow C_4H_2O_3 + 4H_2O$$

Mass efficiencies for these routes are 44.4% and 57.6% for the benzene and *n*-butane routes, respectively.

This simplistic analysis indicates that *n*-butane is the "greener" reaction route. But further analysis at this early design stage can shed more light on the differences in environmental performance. We will focus on raw material cost and CO_2 generation in this screening comparison because of concerns of economics and global climate change. It is necessary to bring in differences in conversion and selectivity at this stage. The benzene route has typical conversions of 95% and selectivity to MA of 70%, with approximately equimolar amounts of CO and CO_2 generated as by-products. For the *n*-butane route these values are 85% and 60%, respectively. Assuming 1 mole of MA produced, 1/0.70 mole of benzene or 1/0.60 mole of *n*-butane is needed. The raw material costs are as follows:

$$\begin{aligned}&\text{Benzene: } (1\ \text{mole}/0.70\ \text{mole}) \times (78\text{g/mole})\\&\quad\times (0.000280/\text{g}) = 0.0312\ \$/\text{mole of MA}\end{aligned}$$

$$\begin{aligned}&n\text{-Butane: } (1\ \text{mole}/0.60\ \text{mole}) \times (58\ \text{g/mole})\\&\quad\times (0.000214/\text{g}) = 0.0207\$/\text{mole of MA}\end{aligned}$$

This result shows that the *n*-butane route costs less for the raw material than the benzene route due to the lower price of *n*-butane, even though the molar yield of MA from *n*-butane is less. This simplistic economic analysis is of relevance because raw material costs often dominate. The generation of CO_2 in the reactor is estimated as follows:

$$\begin{aligned}&\text{Benzene: } [1\ \text{mole MA} \times (2\ \text{mole CO}_2/\text{mole MA})]\\&\quad + [(1\ \text{mole Benzene}/0.70\ \text{mole MA}) \times (0.965 - 0.7)\\&\quad \times 6/2] = 3.071\ \text{mole CO}_2/\text{mole of MA}\end{aligned}$$

$$\begin{aligned}&n\text{-Butane: } (1\ \text{mole } n\text{ - Benzene}/0.60\ \text{mole MA})\\&\quad \times (0.85 - 0.6) \times 4/2 = 0.833\ \text{mole CO}_2/\text{mole of MA}\end{aligned}$$

The first [] term in the Benzene calculation accounts for the two carbons that are liberated when MA is formed, and the second [] term is for conversion to by-products, with 1/2 going to CO_2 and the other to CO. MA from benzene generates almost four times as much CO_2 in the reactor than the *n*-butane route. Additional CO_2 is generated when unreacted benzene or *n*-butane and by-product CO is incinerated in the pollution control equipment from the process. The total CO_2 emission including pollution control is calculated as shown next.

$$\begin{aligned}&\text{Benzene: } 3.071 + (1.071)(0.99) + (0.0714)(0.99)(6)\\&\quad = 4.595\ \text{moles CO}_2/\text{mole of MA}\end{aligned}$$

$$\begin{aligned}&n\text{-Butane} : 0.833 + (0.833)(0.99) + (0.25)(0.99)(4)\\&\quad = 2.688\ \text{mole CO}_2/\text{mole of MA}\end{aligned}$$

The second term in each summation is CO converted to CO_2 in the pollution control device; the third is due to unconverted feedstock. These screening calculations verify that the *n*-butane route emits approximately 1/2 the CO_2 compared to the benzene pathway. Based on the economic and environmental screening, the benzene route would be excluded from further consideration. More detailed calculations based on optimized flowsheets confirm these screening calculations are accurate [72].

Table 5.10 provides another example of the type of assessment that chemical engineers will need to perform with limited information [73]. A process engineer evaluating two alternative synthesis routes for the production of methyl methacrylate can use data on persistence, bioaccumulation, toxicity, and stoichiometry to quickly evaluate potential environmental concerns. These data can be estimated using group contribution methods when measured values are not available. The estimates of persistence, bioaccumulation, toxicity, and stoichiometry can then be combined to provide preliminary guidance. In this case concerns about the health and safety issues associated with sulfuric acid dominate, and the isobutylene route appears preferable because it requires less acid. Although more detailed data are available for these two processes, this level of data is typical of what might be available for new process chemistries.

Evaluations During Process Synthesis: "Tier II" Assessment

"Tier II" environmental assessment is employed for flowsheet synthesis on a smaller number of design alternatives. This provides an opportunity to evaluate the impacts of separation and other units in the process in addition to the reactor. Identification of emission sources and estimation of release rates are also part of this assessment. Inclusion of additional environmental and sustainability metrics (energy intensity [energy consumption/unit of product], water intensity, toxic release intensity, etc.) are hallmarks of "Tier II" assessment. More information on "Tier II" assessment is provided in the text by Allen and Shonnard [53].

Detailed Evaluation of Process Flowsheets: "Tier III" Assessment

After a process flowsheet has been established, it is appropriate for a detailed environmental impact evaluation to be performed. The end result of the impact evaluation will be a set of environmental metrics (indexes) representing the major environmental impacts or risks of the entire process.

Table 5.10 Stoichiometric, persistence, toxicity and bioaccumulation data for two synthesis routes for methyl methacrylate [53, 73]

Compound	Pounds produced or pounds required per pound of methyl methacrylate[a]	Atmospheric half-life or aquatic half-life[b]	1/TLV[c] (ppm)[c]	Bioconcentration factor[d] (conc. in lipids/conc. in water)
Acetone-cyanohydrin route				
Acetone	−0.68	52 days/weeks	1/750	3.2
Hydrogen cyanide	−0.32	1 year/weeks	1/10	3.2
Methanol	−0.37	17 days/days	1/200	3.2
Sulfuric acid[e]	−1.63		1/2 (est.)	
Methyl methacrylate	1.00	7 h/weeks	1/100	2.3
Isobutylene route				
Isobutylene	−1.12	2.5 h/weeks	1/200 (est.)	12.6
Methanol	−0.38	17 days/days	1/200	3.2
Pentane	−0.03	2.6 days/days	1/600	81
Sulfuric acid[e]	−0.01		1/2 (est.)	
Methyl methacrylate	1.00	7 h/weeks	1/100	2.3

[a] A negative stoichiometric index indicates that a material is consumed; a positive index indicates that it is produced in the reaction. A screening environmental index is used for comparison in "Tier I" assessment; Environmental index $= \sum |\nu_i| * (\mathrm{TLV}_i)^{-1}$

[b] The atmospheric half-life is based on the reaction with the hydroxyl radical; aquatic half-life via biodegradation is based on expert estimates. From: EPISuite software (http://www.epa.gov/oppt/greenengineering/software.html) or ChemFate Database (http://www.syrres.com/eswc/chemfate.htm)

[c] TLV is the threshold limit value, and the inverse is a measure of inhalation toxicity potential for a chemical. Values taken from NIOSH Pocket Guide to Chemical Hazards (http://www.cdc.gov/niosh/npg/npg.html), and the Specialized Information Service of the National Library of Medicine (NLM) (http://sis.nlm.nih.gov/)

[d] Bioconcentration factor is an indicator of a chemical's potential to accumulate through the food chain. From the EPISuite software (http://www.epa.gov/oppt/greenengineering/software.html) or ChemFate Database (http://www.syrres.com/eswc/chemfate.htm)

[e] The lifetime of sulfuric acid in the atmosphere is short due to reactions with ammonia

A number of indexes are needed to account for potential damage to human health and to several important environmental compartments.

In quantitative risk assessment [74], it is shown that impacts are a function of dose, dose is a function of concentration, and concentration is a function of emission rate. Therefore, emissions from a process flowsheet are a key piece of information required for impact assessment during process design. A number of computer-aided tools are available to generate pollutant emissions to air using process flowsheet information. Emission factors are used to calculate emission rates from major units (distillation columns, reactors, other columns, furnaces, boilers, etc.) based on process flows and utilities [75]. Fugitive sources (valves, pumps, flanges, fittings, sampling valves, etc.) number in the thousands for a typical chemical process and together contribute to facility air emissions. A compilation of emission estimation methods for chemical processes is found in Chap. 8 of Allen and Shonnard [53].

As previously discussed, the concentrations in the relevant compartments of the environment (air, water, soil, biota) are dependent upon the emission rates and the chemical/physical properties of the pollutants. A fate and transport model transforms emissions into environmental concentrations. Although single compartment fate models are often used to predict concentrations downwind or downgradient from emissions sources—for example, an atmospheric dispersion model, a groundwater fate model, or river model—most applications of risk assessment to the design of chemical processes employ a multimedia compartment model (MCM). MCMs predict regional pollutant transport and fate, with a typical scale of 100 × 100 km of the earth's surface. Mechanisms of diffusive and convective transport as well as degradation reactions are applied to separate well-mixed environmental compartments (air, water, soil, sediment). Steady-state concentrations in each compartment are expected to match actual environmental concentrations within an order of magnitude. An illustrative example calculation using the "Level III" model of Mackay [76] is presented in Chap. 11 of Allen and Shonnard [53].

Finally, information regarding toxicity or inherent impact is required to convert the concentration-dependent doses into probabilities of harm (risk). Based on this understanding of risk assessment, the steps for environmental impact assessment are grouped into three categories, (1) estimates of the rates of release for all chemicals in the process, (2) calculation of environmental fate and transport and environmental concentrations, and (3) the accounting for multiple measures of risk using toxicology and inherent environmental impact information. Computer-aided software packages integrating these three calculation steps are available and have been linked to commercial process simulation packages [72, 77, 78]. Figure 5.13 shows the information flows occurring in the software tool EFRAT (Environmental Fate and Risk Assessment Tool), which links with the simulation package HYSYS. Flowsheet stream and utility information from

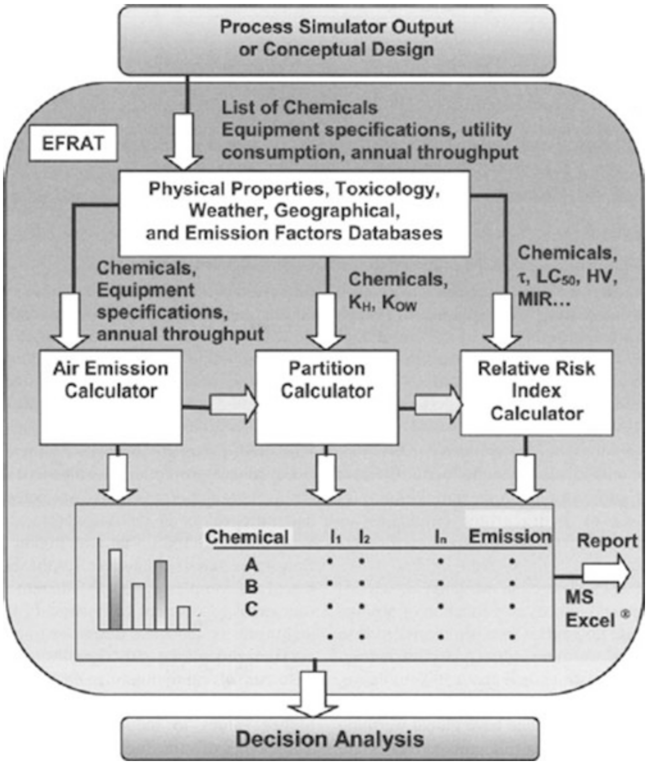

Fig. 5.13 Information flow diagram for EFRAT and relation to HYSYS™ (Shonnard and Hiew [77], Copyright American Chemical Society and reproduced by permission)

HYSYS is automatically transferred to EFRAT once the flowsheet is “synchronized” with EFRAT. Emission factors and correlations within EFRAT estimate release rates to the air, an MCM predicts environmental partitioning, and finally a relative risk assessment module in EFRAT generates nine environmental risk indicators. A version of EFRAT is available free of charge for education purposes [79].

Figure 5.14 provides an example of the type of decision that a process designer would face in flowsheet evaluation. In this simple example, absorption with a regenerable solvent is used to capture (and recycle or sell) toluene and ethyl acetate, which might otherwise be emitted into the atmosphere. To increase the fraction of the hydrocarbons that are absorbed, the circulation rate of the solvent can be increased, but this will increase the duties of the reboiler, condenser, and pumps in the system, increasing energy use and increasing atmospheric emissions (primarily of criteria pollutants, sulfur and nitrogen oxides, particulates, carbon monoxide, and of the greenhouse gas CO_2). The process engineer will need emission estimation tools to evaluate such trade-offs, and will need to evaluate the potential environmental and economic costs associated with different types of emissions, in this example the relative costs of hydrocarbon emissions as opposed to emissions of criteria pollutants and CO_2.

Figure 5.15 shows the variation of several environmental indices as a function of absorption solvent flow rate. There is a sharp decrease in the global warming index (I_{GW}) with increasing solvent flow rate until about 50 kgmoles/h, due mostly to toluene recovery. (Note that toluene and ethyl acetate have global warming impacts assuming that all emitted VOCs are oxidized to CO_2 in the environment and that the VOCs are of fossil origin.) Thereafter, increasing utility-related emissions of greenhouse gases (primarily CO_2) drive this index up faster than its rate of decrease by further recovery of ethyl acetate. The smog formation index (I_{SF}) decreases sharply with absorber solvent flow rate in the range of 0–50 kgmoles/h, again due to recovery of toluene. Afterwards, there is a slow decline in I_{SF} with increasing solvent flow rate above 50 kgmoles/h as ethyl acetate is recovered. The acid rain index I_{AR} increases in nearly direct proportion to solvent flow rate. Utility consumption and its associated sulfur and nitrogen oxide emissions (precursors to acid rain) drive the I_{AR} up with higher solvent flow rates. These flowsheet results begin to reveal the complex trade-offs inherent in environmental assessment of chemical processes and products. Does the design engineer operate the process at 50 kgmoles/h for the absorber solvent to minimize emission of CO_2 and global warming impacts or operate at higher values to reduce smog formation? These types of value judgments are commonly encountered in the decision-making process. Notwithstanding the complexity, environmental metrics inform the design activity on potential environmental impacts of the process.

Hybrid Screening Evaluations: Combining “Tier I”–“Tier III” Life-Cycle Assessment

Early design assessments similar to those presented in previous sections of this chapter have the following limitations: (1) they tend to focus on the reaction step and neglect the impacts of downstream units, (2) the assessment includes one or a small number of environmental indicators, and (3) the early assessment typically does not consider impacts beyond the process boundary, for example, the environmental burdens associated with the life cycle of materials used in the process. In this section we will explore some approaches to address these limitations.

Combining “Tier I” with Tier “III.” In the next example, the maleic anhydride process from an earlier section is reexamined by including the effects of units downstream from the reactor. Figure 5.16 shows the major emission sources from the process: the reactor, absorption unit, and distillation. Emission factors along with stream flow rates in the reactor are used to estimate releases of benzene, *n*-butane, CO, and MA. The emission from the reactor is estimated

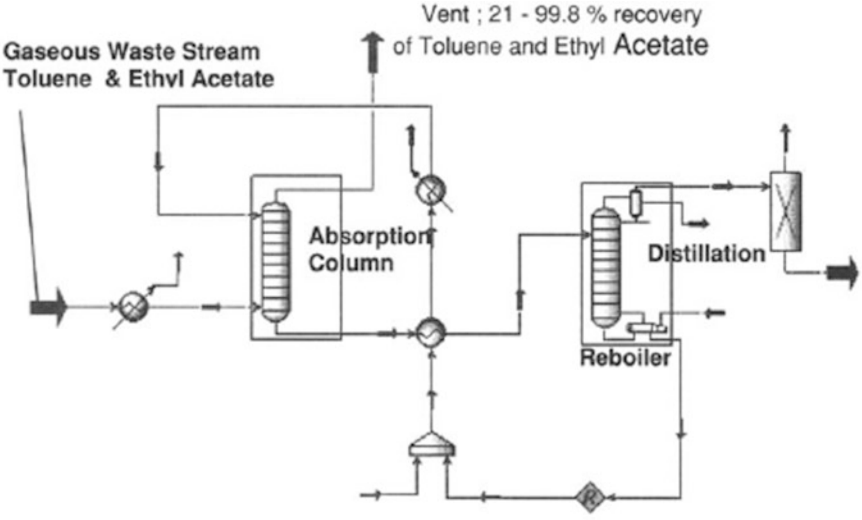

Fig. 5.14 Absorption with a regenerable solvent is used to capture toluene and ethyl acetate (Shonnard and Hiew [77], Copyright American Chemical Society and reproduced by permission)

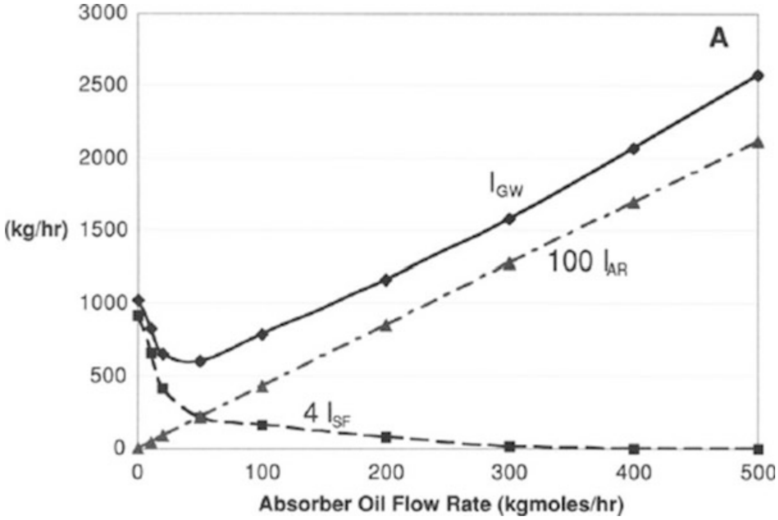

Fig. 5.15 Variation of environmental indexes with absorber oil flow rate for global warming (L_{GW}), smog formation (I_{SF}), and acid rain (I_{AR}) (Shonnard and Hiew [77], Copyright American Chemical Society and reproduced by permission)

using an average emission factor (EF_{av}, 1.50 kg emitted/10^3 kg throughput [53], chapter 8, eqn. 8-4) using the equation

$$E = M_{voc} EF_{av}$$

In this equation, M_{voc} is the mass flow rate (kilograms per unit time) of the volatile organic compound in the reactor, and it is taken as the average mass flow rate through the reactor. The emissions from the absorber column originate from the offgas vent and this stream contains unreacted raw material, by-products, and product. Raw material, especially benzene, and one of the by-products, CO, are toxic. To include the effects of pollution control at this early design stage, it is assumed that unreacted raw material, by-products, and unrecovered product exiting the reactor are incinerated to CO_2 with 99% destruction efficiency with the remaining 1% released to the environment. The recovery of MA in the separation system is assumed to be 99%, with the remaining 1% going to pollution control.

Based on the process description above, Table 5.11 can be generated which contains the total emission of each pollutant. Emissions are converted to impact indicators using the environmental fate and impact assessment tool EFRAT [79]. A comparison of environmental indicators for MA production from either benzene or *n*-butane is shown in Table 5.12. All of the environmental indices in the *n*-butane process are less than or equal to those in the benzene process. This table reveals that the benzene route is estimated to have greater environmental impacts than the *n*-butane route. This early assessment is more rigorous than the approach in the previous section titled “Early Process Design Evaluations” because more indicators were used and the effects of units downstream of the reactor were included.

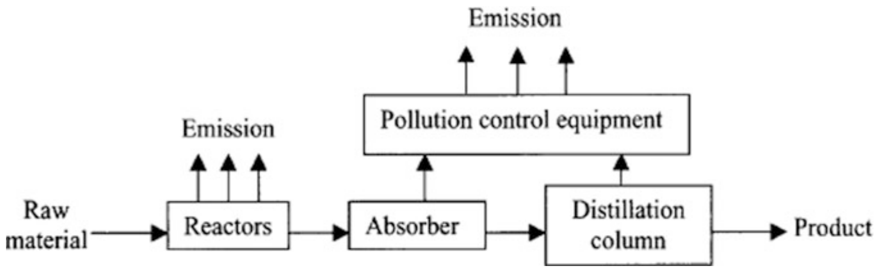

Fig. 5.16 Major emission sources from the maleic anhydride process

Table 5.11 Stream flow rates and emission rates for screening evaluation of environmental impacts from two alternative reaction routes for maleic anhydride production

	Benzene process (kg/mole of MA)				
	Benzene	CO	CO_2	Maleic anhydride	Total
Total process emission rate	1.4×10^{-4}	3.23×10^{-4}	2.03×10^{-1}	8.33×10^{-5}	2.04×10^{-1}
	n-Butane process (kg/mole of MA)				
	n-Butane	CO	CO_2	Maleic anhydride	Total
Separation unit (w/pollution control)	2.3×10^{-4}	2.51×10^{-4}	1.18×10^{-1}	8.33×10^{-5}	1.18×10^{-1}

Table 5.12 Environmental indices of both routes (all the values are in units of kg/mole of MA)

Chemical	I_{FT}	I_{ING}	I_{INH}	I_{CING}	I_{CINH}	I_{OD}	I_{GW}	I_{SF}	I_{AR}
Benzene	6.8×10^{-6}	3.3×10^{-3}	4.6×10^{-2}	1.4×10^{-4}	1.4×10^{-4}	0.0	2.0×10^{-1}	2.5×10^{-5}	0.0
n-Butane	3.0×10^{-6}	3.1×10^{-3}	3.8×10^{-2}	0.0	0.0	0.0	1.2×10^{-1}	4.4×10^{-6}	0.0

Including life-cycle assessment at the early design stage. In this example, a comparison is made between a new wood pulp bleaching process and a conventional process in order to uncover advantages and limitations of the "Green Chemistry" innovation [80]. In the production of most paper, wood is chemically treated with NaOH and Na_2S at high temperature (170°C [81]) to remove lignin and some hemicellulose, yielding pulp with a small residual of lignin that must be removed by bleaching to achieve a high brightness paper. Conventional bleaching utilizes ClO_2 and NaOH in sequential processes (Fig. 5.17). This process generates approximately 0.5 kg of chlorinated organics per ton of bleached pulp, and even though these water pollutants are less persistent, bioaccumulative, and toxic than those generated using Cl_2 (earlier bleaching agent), they are still of concern. Furthermore, the need to raise and lower the stream temperature consumes a large amount of energy and cooling water.

The 1999 Green Chemistry Challenge Award was given to Professor Terrence J. Collins of Carnegie Mellon University for the development of "Tetraamido-macrocyclic ligand" TAML™ activators [82]. These organic amine compounds contain a catalytic iron center that activates hydrogen peroxide at minute concentrations in the bleaching process (50 g/ton pulp). Although information is lacking about the toxicity of the TAML™ Oxidant Activators, it is known that the temperature of the TAML™ peroxide process is 50°C compared to 70°C for chlorine dioxide bleaching (Fig. 5.18). We will use these temperature differences as the basis of the green engineering analysis in comparing conventional ClO_2 bleaching with TAML™ process, with energy over the life cycle being the sustainability indicator.

Let us assume that the chlorine dioxide bleaching process has the sequence *DEDED* ($D =$ chlorination with ClO_2, $E =$ extraction with NaOH) in which the pulp is cold-water drum washed between *DE* stages giving a drum exit temperature of 50°C. TAML™ peroxide bleaching process is assumed to follow a sequence *PPPD* ($P =$ peroxide). Thus, two of the *DE* stages are replaced with two *PP* stages in which there exists a 20°C difference between the stream temperatures. Furthermore, assuming a 10% consistency for the pulp (9 t water/ton pulp), we can estimate an energy savings of Energy Saved/ton pulp $= 2$ stages $\times$ $(20 \times 9/5)°$ F/stage $\times$ (2,200 Btu/ton water $\times$ 9 t water/ton pulp) $= 1.426 \times 10^6$ Btu/ton pulp. (Note, the contribution of the pulp to the energy analysis is neglected, being a minor component).

According to Department of Energy statistics the average energy consumed per ton of pulp is 39.4×10^6 Btu/ton pulp

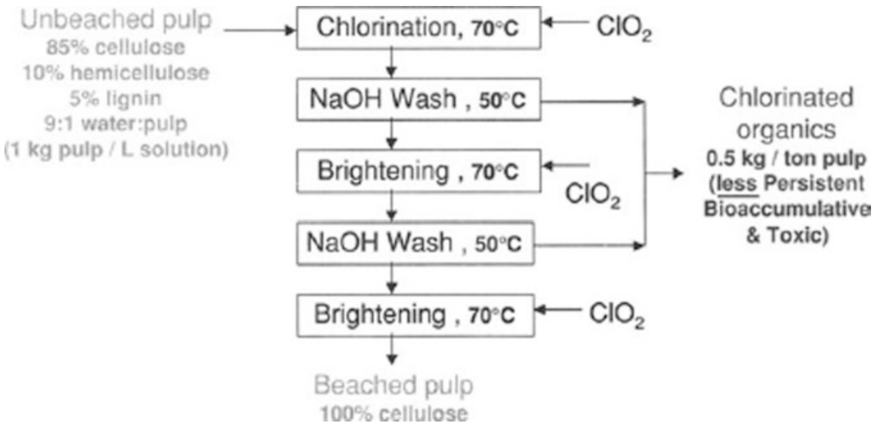

Fig. 5.17 Chlorine dioxide process for bleaching of unbleached wood pulp

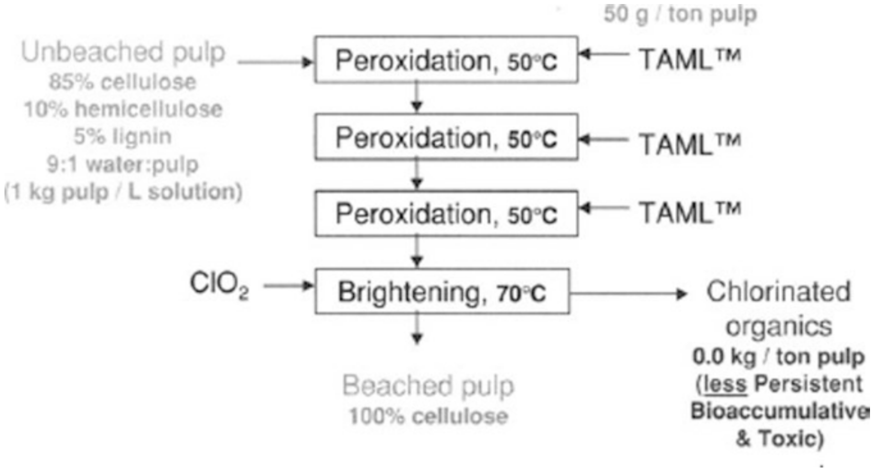

Fig. 5.18 Wood pulp bleaching process using TAML™ activators and hydrogen peroxide

[81]. Given that roughly 1/2 of the pulp in the United States is bleached, this energy savings is about 2% of the annual energy consumed for production of pulp. This significant energy savings was cited in the application for the 1999 Green Chemistry Award [82]. This analysis included the energy differences between these bleaching processes in terms of the stream heating requirements. The next section will present a more complete energy efficiency analysis of the TAML™ peroxide bleaching processes by including the effects of producing and delivering the bleaching agents to the process. Figure 5.19 shows the chain of material flows in the production of ClO_2, H_2O_2, NaOH, and TAML activator. Table 5.13 shows the primary energy intensity for each of the materials in the chain of materials for ClO_2 and H_2O_2 bleaching of pulp.

The overall energy change for substituting H_2O_2 bleaching for ClO_2 bleaching is obtained by combining the net energy change from producing the chemicals and then subtracting the in-process energy savings. This yields a total decrease in energy consumption for the TAML™ H_2O_2 bleaching process of $(1.15 \times 10^7 - 1.87 \times 10^6$ Btu/ton pulp$) - 1.426 \times 10^6 = -8.63 \times 10^6$ Btu/ton pulp.

The energy decrease as a percentage of the energy consumption rate of the pulp and paper industry is $0.5 \times 8.63/39.394 \times 100 = 11.0\%$.

This Green Engineering screening level energy analysis of the Green Chemistry award for TCF (total chlorine free) bleaching of pulp points out a potential energy benefit by implementing the TAML™ process in the US pulp and paper industry of approximately 11.0% over the "cradle-to-gate" life cycle for pulp. This conclusion is based upon a screening-level analysis that is uncertain, and more detailed analysis of the life-cycle energy burdens must be completed before the energy implications are fully understood. One step in the life cycle for ClO_2 production was not included for lack of data, the process energy for converting $NaCl0_3$ to ClO_2. This screening assessment is expected to underestimate the energy savings for implementing this new technology. However, the analysis points to the need for including all relevant life-cycle stages in the evaluation, not only the in-process changes, as was done previously. The energy burdens of the chemicals in the supply chain for each bleaching alternative are more significant than the in-process energy improvements.

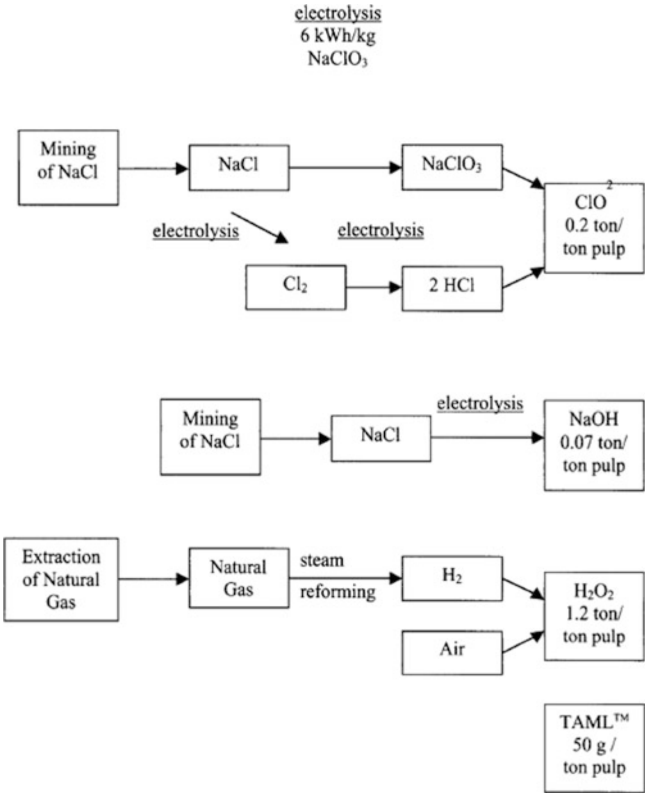

Fig. 5.19 Material flow chain for pulp bleaching chemicals

Conclusions

Environmental performance assessment is a powerful tool for moving the chemical industry toward sustainability. It provides important insights to the process designer on potential environmental impacts of alternative choices at several stages in the design process. Computer-aided tools further enhance the environmentally conscious engineering design activity. These tools for solvent selection, reaction pathway analysis, emission estimation, environmental property estimation, fate modeling, and life-cycle assessment will find increased use in the chemical industry. They will be particularly effective in decision-making when coupled with economic and societal criteria. Application of these tools for comparison of traditional processes and products to innovative alternatives is already taking place in fields such as bio-based products, recycle of wastes, elimination of toxic compounds, green chemistry, benign solvents, and material flow analysis.

Life-Cycle Assessment

Introduction

Products and processes all have a natural life cycle. For example, the life cycle of a product starts from the extraction of raw materials for its production and ends when the product is finally disposed. In the production, use, and disposal of this product, energy is consumed and wastes and emissions are generated. A life-cycle assessment is an analysis in which the use of energy and materials are quantified and the potential

Table 5.13 The subitems in calculating the energy requirement in ClO_2 and H_2O_2 bleaching

	Energy in original units	Energy (Btu/ton ClO_2 or ton NaOH)
ClO_2 bleaching		
Mining NaCl	1.3 MJ/kg NaCl	9.69×10^5 Btu/ton ClO_2
Electrolysis of NaCl to $NaClO_3$	17.1 kWh/kg $NaClO_3$	8.35×10^7 Btu/ton ClO_2
HCl production	2.5 MJ/kg HCl	2.32×10^6 Btu/ton ClO_2
HCl production electricity	0.043 kWh/kg HCl	1.44×10^5 Btu/ton ClO_2
Total from ClO_2		8.69×10^7 Btu/ton ClO_2
NaOH production	21.3 MJ/kg NaOH	1.83×10^7 Btu/ton NaOH
Total ClO_2 bleaching		(1.87×10^7 Btu/ton pulp)
H_2O_2/TAML bleaching		
H_2O_2 production		9.60×10^6 Btu/ton H_2O_2
TAML production		1.0×10^8 Btu/ton TAML™
Total H_2O_2/TAML bleaching		1.15×10^7 Btu/ton pulp

Energy intensities are taken from the SimaPro 6.0 software and other sources [80]

1 Btu = 0.0010551 MJ

1 Btu = 0.0002931 kWh

1 kWh = 3.6 MJ

Example calculation: The energy required to produce 1 t of ClO_2 is therefore (0.867 kg NaCl/kg ClO_2)×(1.3 MJ/kg NaCl) × (2,000/2.205 kg/ton)×(947.8 Btu/MJ + (24,478 kWh/ton of ClO_2) ×(3,411.8 Btu/kWh for electrolysis of NaCl solution (1.08 t HCl/ton ClO_2) × (2.5 MJ/kg HCl) × (2,000/2.205 kg/ton) × (947.8 Btu MJ) + (1.08 t HCl/ton ClO_2) × (0.043 kWh/kg HCl) × (2,000/2.205 kg/ton) × (3,411.8 BtukWh) = $9.69 \times 10^5 + 8.35 \times 10^7 + 2.32 \times 10^6 + 1.44 \times 10^5 = 8.69 \times 10^7$ Btu/ton ClO_2.

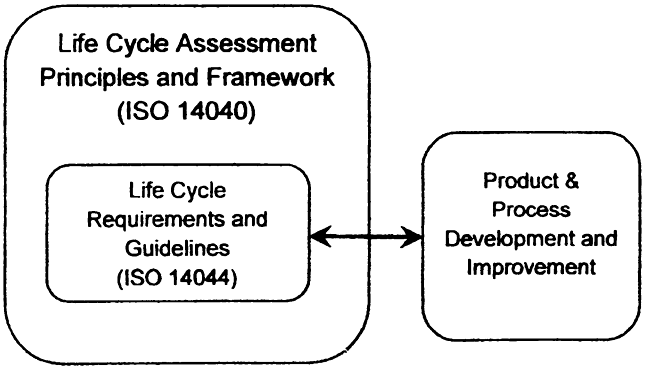

Fig. 5.20 ISO standards for life-cycle assessment [90–95]

environmental and societal impacts are predicted. Life-cycle thinking is progressively being adopted by industry as an essential tool for analyzing processes and products. For example, 3M instituted a life-cycle management policy in 2001, requiring reviews of all new products and prioritized reviews of existing products [83]. BASF is using eco-efficiency analysis of a life-cycle assessment to compare products they produce and examine their economic and ecological characteristics [84, 85]. This section presents a review of methods used for life-cycle assessment and then gives examples of assessments conducted on chemical products and processes.

Life-cycle assessment methodology has been used since the 1960s with early studies that focused solely on energy usage and solid waste issues. This focus continued in life-cycle assessments performed during the oil crisis in the 1970s [86, 87]. The unique aspect of all of these initial studies was the early development and use of life-cycle data inventories with less emphasis on environmental risk impacts of the associated processes studied. A method published by the Royal Commission on Environmental Pollution in 1988, employing the “Best Practicable Environmental Option,” attempted to minimize the environmental burdens at the LCA practitioner’s manufacturing plant, but this method did not analyze the entire lifecycle of the product or process in question [88]. However, even today, life-cycle assessments that focus primarily on mass and energy balances (e.g., Beaver [89]) provide useful life-cycle information.

Life-cycle assessments capturing the full life of a process or product came into fruition in the late 1980s but were performed primarily by private companies, thus leaving into question the specific methodology used and the biased nature of the results. In 1993, the Society of Environmental Toxicology and Chemistry (SETAC) addressed the concern of no common framework for LCA methodology by introducing principles on how to conduct, review, use, and present the findings of a life-cycle assessment. The International Organization of Standardization (ISO) introduced Standards 14040 (principles and framework) [90] and 14041 (goal and scope definition and inventory analysis) [91] on life-cycle assessments in 1997 and 1998, respectively, and Standards 14042 (impact assessment) [92] and 14043 (interpretation) [93] in 1999 and 2000 respectively. These were updated in 2006 to life-cycle assessment Standards 14040:2006 (principles and framework) [94], these were updated in 2006 to life-cycle assessment standard 14040: 2006 (in) [94] and Standards 14041 through 14043 were condensed into the new Standard 14044: 2006 (requirements and guidelines) [95]. Figure 5.20 illustrates the Life-cycle Assessment according to ISO Standards 14040 and 14044.

Life-cycle impact assessments typically consist of four steps [53]. The first step includes the definitions of the system boundary, scope, and the functional unit. The second step consists of an inventory of the inputs and outputs of the system. Figure 5.21 depicts the various components of life-cycle inventory (LCI). As the earliest life-cycle assessments were previously described, many life-cycle assessments end at this stage, and conclusions are made on minimizing mass and energy usage. To increase the information gained by using life-cycle assessment, the relative hazards of the chemicals used in and emitted from the process must be included. The linking of the inputs and outputs determined in step 2 to their inherent risk to the environment and public health is the third step of LCA. The fourth and final step of LCA is interpreting the results and recommending process improvements [96]. SETAC has defined a different, but similar, fourth step which is termed “improvement assessment” which includes ways to improve the impact assessment [86]. There are several good reference texts that give detailed procedures on life-cycle assessment [97–99].

Life-cycle assessments are typically conducted on end products, but can also be used proactively for process selection, design, and optimization. Figure 5.22 illustrates the various steps involved in product and process life cycle. Some debate exists on the relative value of life-cycle assessments applied to products vs. processes. Burgess and Brennan [87] state that a life-cycle assessment conducted on a product is also valid for the processing steps involved in the manufacture of the product and that the purpose of conducting an LCA on a process is different than on a product. On the contrary, Chevalier et al. [100] state that a life cycle conducted on a process is more thorough than a life cycle conducted on a product. A life-cycle assessment on a process is usually conducted in the research and development phase to determine if there are other options, such as replacing a solvent with a less environmentally harmful solvent, for comparison to processes used by competitors, to reduce liability, and for marketing and policy-making purposes [87]. Regardless of whether a process or product is evaluated, the basic steps of LCA remain the same. These steps are presented in more detail to follow.

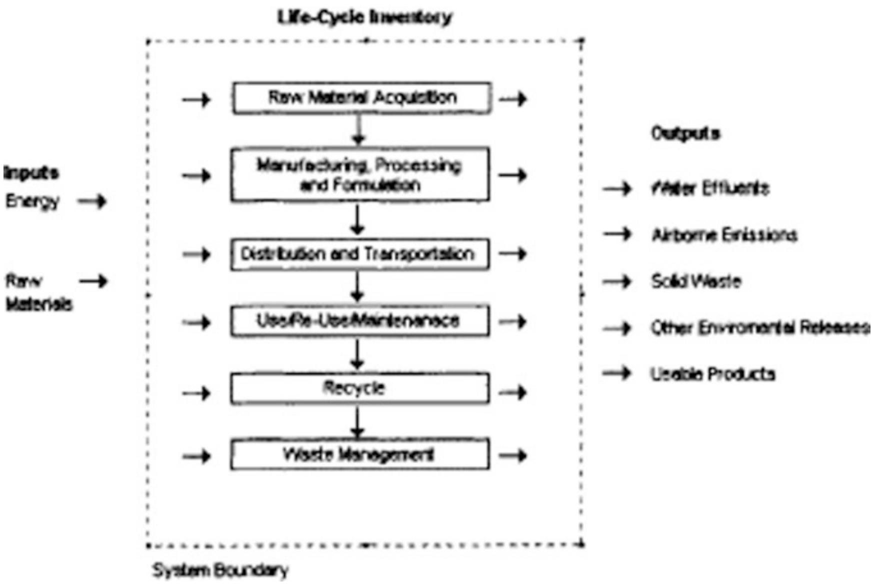

Fig. 5.21 Components of a life-cycle inventory

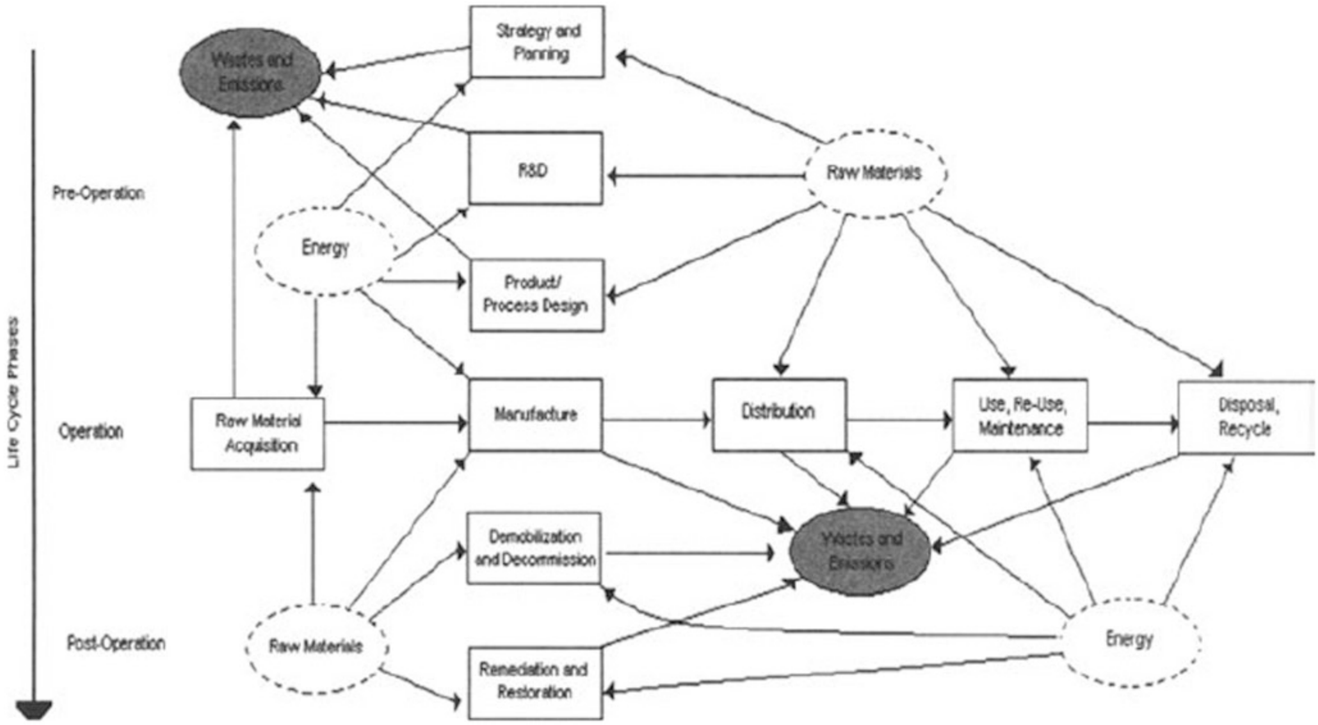

Fig. 5.22 Product and process life cycles [53]

Goal and Scope of LCA

Defining a boundary for a life-cycle assessment varies depending on the methodology used. As previously described, ISO 14040 standardized life-cycle impact assessments in 1997 [101, 102] and established that a life-cycle assessment should be conducted in terms of elementary flows. This approach is typically understood as a cradle-to-grave approach, involving raw material extraction through the disposal of the product, including all of the relevant supply chains [103]. The standard was further refined by ISO 14041 [91], which established a "streamlining" approach to LCA that allowed omission of certain processes, inputs, and outputs if these processes are deemed insignificant. Burgess and Brennan [87] state that assumptions concerning the boundary conditions are necessary to maintain manageability and to ensure that the law of diminishing returns can be observed after three upstream processes. However, according to the ISO standards, these data must be collected before they can be disregarded.

Scoping and goal definition is often thought of as the most important process of an LCA, and care must be taken to establish appropriate boundaries that are consistent with the objectives of a study. Suh et al. [104] warn that including a scientific basis for excluding and including processes in system boundaries is essential and emphasizes the difficulty in doing so, particularly if the practitioner is not familiar with the specific process under study.

The functional unit is defined as the basis upon which all data and impacts are presented and compared and typically relates to the "function" of the product studied. For example, the basis for comparing plastic and paper grocery bags can be the number of bags required to carry a certain amount and type of grocery items. Another example of a functional unit directly reflecting the product function is used when comparing cloth and disposable diapers, accounting for the number of diapers required for each diapering. A common functional unit used in LCAs involving product manufacture is "per mass of product"; however, there are other appropriate functional units that may be more relevant to the specific product effectiveness studied.

Methods of Life-Cycle Inventory

The inventory stage involves the collection of all the data that will be used in the life-cycle analysis. The quality of the data is an important part of the LCI process, and, as with any model, the results of an LCA are only as good as the data inputs. There are two basic sources of data for an LCA, primary and secondary in nature. Primary data are derived directly from the process in question. These are the most accurate data that can be applied to an LCA and, as a result, are the most desirable. However, in many cases, data are proprietary and are not readily available to the public [87], thus necessitating the LCA practitioner to seek secondary sources of data, including databases, peer-reviewed literature, etc., that may not be as accurate and are not often accompanied with error estimates. Because of the frequent use of secondary data, debate within the LCA community has arisen on how to best capture and report error and subsequently interpret results of LCAs.

There are four main methods of conducting an LCI, each differing in its degree of detail. These methods are economy scale, life-cycle scale, equipment scale, and a hybrid LCI [103], listed from the most general to the most detailed in approach. The most general analysis, at the economy scale, contains all the information from cradle-to-grave of a product or process but is not specific for an individual process. On the other hand, the most detailed method, the hybrid LCI approach, is typically used for gate-to-gate (within the grounds of a manufacturing facility) analysis. A brief summary of each LCI method, along with its advantages and disadvantages, is presented below.

The "economy scale" method of LCI typically uses national statistics about resource use and emissions from a specified sector and considers the entire economic system. With this method the boundary is defined from the cradle-to-the-grave of the product. The most well-known method in this category is provided in the EIOLCA software developed at Carnegie Mellon University (2005). There are two disadvantages to this approach. First, an assumption must be made that there is a linear relationship between the dollars spent on the product in question and its environmental impact. In many cases, this is a good assumption, such as in processes involving obtaining a higher purity chemical. This assumption, however, is not valid for other industries with equivalent products having different perceived values, such as automobiles. There is also another drawback to using this type of method because the data typically used are a composite for the entire industry. This assumption may be valid assuming that the company is average in its performance; however, this assumption does not account for industries that are leaders or laggards in areas such as sustainability, operation efficiency, or whether they are using state-of-the-art processes.

The second LCI approach that can be used is at the life-cycle scale, involving focus on a specific sector. Industry uses this approach most frequently in developing LCIs. Although the data using the life-cycle-scale approach are more detailed than the data offered in economic-scale approach, they do not include specific information about individual processes, equipment, or other materials that could be considered negligible.

Another method for conducting an LCI is the equipment-scale approach, most frequently used in a "gate-to-gate" analysis of various processes. Full life-cycle assessments do not often include this LCI approach even though the most accurate data can be obtained from this method. The drawback of using this method is that it is very time and resource intensive. Another issue with this LCI approach is that a comparison with other products is relatively difficult to obtain in as much as a gate-to-gate inventory does not account for how the given raw materials are being produced. This type of method is usually supplemented with data from the other LCI methods.

The hybrid LCI approach combines the features of the economic, life-cycle, and equipment-scale approaches in an attempt to overcome the shortcomings of the previous methods. This approach may involve combining the economy scale with the life-cycle scale to give a cradle-to-grave analysis with more detailed information on the specific industry. A hybrid LCI may also combine the life-cycle scale LCI approach with the equipment-scale approach [104]. The advantage of this method is that it fills the gaps that are left from the life-cycle scale with data from the economic-scale, thus yielding a full "cradle-to-gate" life cycle. This type of life cycle also has the same limitations of the economy-scale approach, as described above.

There are several other methods that can be used for an LCI which include a limited LCI [89]. This method only considers metrics such as mass, water usage, energy, toxics emitted, and overall pollutants emitted. In-depth calculations are used, but all of the common metrics are not used as stated by Allen and Shonnard [53]. Another method for life-cycle assessment was proposed by Lei et al. [105], coined by the authors as "the Most of the Most." This approach consists of finding the most significant impact factors and then selecting the most significant stages of the life cycle. Although this method was designed to consider the whole process life cycle, it severely limits the size of an LCA.

Life-cycle assessment can also be conducted using the concept of exergy, which is defined as the available energy for the specific process. This method reduces the amount of double counting involved in a process [106]. According to Cornelissen and Hirs [107], an exergetic life-cycle assessment is a good tool to use in the area of depletion of natural resources, as life-cycle assessments are weak in evaluating this impact. An exergetic analysis compares the irreversibility of products, and the product with the lower irreversibility is more sustainable [108]. Cornelissen and Hirs [107] compared coal, green wood, and dried wood in an exergetic life-cycle assessment. According to this study, it appears as though using waste wood as chipboard rather than as an energy source results in less depletion. It was also found that using green wood for electricity production rather than for making chipboard gives less depletion of resources compared to using waste wood for electricity production. This difference is because the green wood needs to be dried prior to being used in chipboard production. Ukidwe and Bakshi [103] stated that the exergetic life-cycle assessment does not account for various ecological resources and suggests that a thermodynamic life-cycle assessment can be used in place of an exergetic LCA.

If there is only limited information that can be obtained for a specific process, then this information must be estimated. Jimenez-Gonzalez et al. [109] have proposed several rules of thumb. This methodology includes determining the inlet temperature and pressure, reflux ratio, fugitive losses, and a way to account for any water in contact with other chemicals as contaminated. They mention that using this approach produces results within a 20% error [110].

Streamlined life-cycle analysis has been used in cases such as in the fine chemical and pharmaceutical industry where there may be an extensive list of raw materials consisting of unique compounds where data does not exist. GlaxoSmithKline developed the Fast Life-cycle Assessment for Synthetic Chemistry, FLASC™ software tool to allow quick screening of synthesis routes from drug discovery chemistry through manufacturing [111]. Grinter [112] shows how the method was used to analyze alternative processes used to make radafaxine. The method measures the life-cycle environmental impact of materials used in the processes and provides an overall FLASC™ score.

Impact Assessment and Analysis

There are three steps recommended in a complete impact analysis: classification, characterization, and valuation. Classification involves grouping of chemical emissions into impact categories. Typical impact categories include global warming, ozone depletion, smog formation, human carcinogenicity, atmospheric acidification, aquatic and terrestrial toxicity, habitat destruction, eutrophication, and depletion of nonrenewable resources. Xun and High [113] offer that these categories can be subdivided into four classes of metrics: generic for both chemical and site, chemical specific (not accounting for environmental conditions), chemical specific in a generic environment (such as a chemical's global effects), and site and chemical specific (such as releases into a specific waterway).

The characterization step of impact assessment in LCA involves quantifying the specific impact category chosen. For example, the mass or dollar amount of material emitted is multiplied by the potential for the compound to cause the chosen impact. This provides a weighted factor for the specific impact category. When comparing two similar products and one product is higher for all impact categories, no further analysis is needed. This is rarely the case, however, thus necessitating valuation. The valuation step consists of determining which impact categories are the most significant. An example of a valuation step, the total amount of ocean and land that is needed to "buffer" the various environmental impacts may be calculated [53], the so-called "critical volume" approach. It is also possible to conduct the valuation step in terms of a monetary value. Burgess and Brennan [87] state that developing a standard for assigning relative weights to the categories is difficult because there is no clear consensus on how to carryout the valuation process. One method to approach valuation uses weighting of impact categories based on their relevance to a specific country [66, 114]. These authors also show how weighted factors can be used to determine which factor contributes most using societal factors. They use a process called Eco-Efficiency to determine which process causes the least environmental impact at the lowest normalized cost.

LCA in Practice

Typical life-cycle assessments are conducted during the product review stage of a process, after the plant, prototypes, and detailed designs of the product have been performed. However, Mueller et al. [115] state that life-cycle evaluation should be conducted starting at the planning stage of product development. They illustrate this using an example of multifunctional chip cards that are used in a wide variety of electronics. They determine the amount of material used for each board, how much is recycled, how much is incinerated, the toxic emissions, and the energy required to mine/produce the material. Their results show that the board is nearly 50% PVC, which accounts for two-thirds of the toxic emissions, but only 8.1% of the total energy required for its production. The most energy-intensive material in a multifunctional chip card is silver oxide, comprising only 2.5% of the product by weight, but requiring the most energy to produce. If LCA were applied at the product design stage of a chip card, alternatives to PVC and silver oxide could be explored and compared in terms of their contribution to emissions and energy requirements.

There have been a number of studies on fuels used for electricity generation. One of these studies focuses on the use of natural gas, heavy oil, or coal in cogeneration of electricity [116]. Using a numerical "eco-load total standardized" evaluation system, these authors found that coal had the lowest eco-load of all alternatives considered. In another LCA study, Goralczyk [117] compares hydroelectric, photovoltaic cells, wind turbines, oil, coal, and natural gas and quantifies that electricity from hydropower had the least environmental impact. Schleisner [118] focuses on wind farms in an LCI study that focuses on the materials used to manufacture the windmills and reports that 2% of the electricity generated during the windmill's lifetime is used to manufacture the windmill components.

A life-cycle assessment for various forms of production of hydrogen has also been conducted. Koroneos et al. [119] examine six methods used to manufacture hydrogen: photovoltaic cells, solar thermal energy, wind power, hydroelectric power, biomass degradation, and natural gas steam reforming. These authors show that wind power yields the lowest environmental impacts for greenhouse gas formation, acidification, eutrophication, and smog formation, whereas photovoltaic cells result in the largest total environmental impact. As a result of this study, these authors recommend the use of wind power, hydropower, and solar thermal power to produce hydrogen because these are the "most environmentally friendly methods."

Life-cycle assessments have also been conducted on transportation fuels. Furuholt [120] has conducted a study comparing the production of diesel, gasoline, and gasoline with MTBE in Norway. The factors that were considered in this study were global warming, photo-oxidant formation, acidification, eutrophication, fossil energy, and solid waste. The impacts in the environmental categories listed above were conducted on the basis of 1 MJ of energy. In both analyses it was found that gasoline with MTBE contributes the most to the impact categories. It was also found that diesel fuel and gasoline have approximately the same scaled values for acidification, eutrophication, and solid waste, but gasoline without additives has 1.5 times the global warming, 2.6 times the photochemical oxidant formation, and uses 1.5 times the fossil energy as diesel.

Another study on automobile fuel options was conducted by MacLean and Lave [121]. This study focused on light-duty vehicles and the CO_2 equivalent gases released during manufacture, gasoline refining, operation, maintenance, and other services. The authors cite that 73% of the greenhouse equivalent gases are released during operation and propose viable alternatives to the use of gasoline in vehicles. They emphasize that, although battery-powered vehicles have zero emissions, there are other factors that give this alternative a negative environmental impact, such as the use of heavy metals. Hybrid vehicles are also discussed as an alternative, but they state that the higher sales price of the Toyota Prius is not justified by fuel savings, emissions reductions, or a combination of the two. Diesel fuel, another fuel alternative, has a well-to-tank efficiency of 24%, whereas gasoline only has a 20% efficiency. There are also many drawbacks to the use of diesel, including higher NO_x and particulate matter emissions, possibly carcinogens. MacLean and Lave also cite that fuel cell vehicles are 20 years away from wide-scale use. Ethanol is a viable option as a fuel source, and there are two renewable processes that can be used to obtain ethanol. The first method is from plant cellulosic material. The well-to-tank efficiency for this material ranges from 80 to 95%, and the emissions are 15 g CO_2 equivalent gases/MJ. Ethanol can also be manufactured using corn. This process releases six times as much CO_2 equivalent gases/MJ as the previous process.

The life-cycle for the production of biodiesel from renewable feedstock has been studied. Biodiesel is a renewable fuel that can replace traditional petroleum-derived diesel fuels. It is typically made through a transesterification reaction of triglycerides derived from fats, oils, and alcohols. Narayanan et al. [122] used an analytical hierarchy process method to determine that soybean oil was the most sustainable raw material when compared to rapeseed, sunflower, and beef tallow. Dinh et al. [123] incorporated environmental, economical, safety, raw material, and fuel performance criteria in comparing biodiesel production routes. Algae received better sustainable development scores in their study than did soybean, rapeseed, jatropha, and palm oil. This was due to the lower green house gas emissions, water usage, and land area needed.

Other than fuels, life-cycle assessments have been performed on other sectors of the transportation industry. One study focused on the catalytic converters for passenger cars [124]. The goal of this life-cycle assessment was to compare the life-cycle impacts of a catalytic converter and the environmental benefits in terms of emission reductions through the exhaust pipe. The study on catalytic converters involved a cradle-to-grave approach, but excluded the mining and transportation of raw materials because no data were available. The criteria used for environmental loads were global warming potential, waste, eutrophication, acidification, resource use, and photochemical ozone creation potential. It was found from this study that waste and global warming are drastically increased, but acidification, eutrophication, and photochemical ozone creation potential are drastically decreased as a result of converter use. Auxiliary power units for diesel trucks were compared by Baratto and Diwekar [125]. The environmental criteria used were the same criteria as mentioned by Allen and Shonnard [53], but also included the toxicity to humans, terrestrial species, and aquatic species. It was found the auxiliary power unit had the least impact for all the categories. An economic analysis was also conducted, and it was found that the payback period was a little over 2 years.

Eagen and Weinberg [126] conducted a life-cycle assessment on two different anodizing processes, differing in the mixture of boric and sulfuric acid or chromic acid used. Boric and sulfuric acid are shown to be a better choice than a mixture of boric and chromic acid. Tan et al. [127] have conducted a cradle-to-gate life-cycle assessment of an aluminum billet, which included the mining of bauxite, the processing of the alumina, and the final casting process for three plants located in Australia. Four different scenarios were analyzed—a base case, a reduction of scrap metal, a more sustainable practice for the smelter, and the latter with clean coal technology—and they conclude that implementation of the last case, clean coal technology, decreases all emissions considered and decreases the global warming potential by 21%.

Life-cycle assessments have been conducted on processes involved in the pharmaceutical industry. A study conducted by Jodicke et al. [128] focuses on one processing step of an intermediate using either a metal catalyst or bio-catalyst. These authors show that the solvents used in the extraction of the product play a large role in the environmental impacts. Jimenez-Gonzalez et al. [129] conducted a cradle-to-gate life cycle for a pharmaceutical product of GlaxoSmithKline. The metrics used for this study were eutrophication, acidification, greenhouse gases, photochemical ozone creation, energy, and mass requirements. This study reports that eutrophication, ozone creation, total organic carbon, energy, and raw materials are most affected by this process, whereas greenhouse gas formation and acidification are most affected by energy use requirements. The manufacturing process is broken down further and shows the impact of solvents, chemicals, and internal drug manufacture on the environmental criteria listed above. Solvent selection also contributes significantly to the impact of the manufacture of a pharmaceutical product. Solvents contribute 75% to the energy use, 80% of the mass (excluding water), and 70% of the ozone depletion. Energy also contributes 70% to resource depletion and 90% to greenhouse gas emissions. Jimenez-Gonzalez and Overcash [130] compared two processes for making sertraline: the THF and TOL processes. These two processes were analyzed from the lab scale to the production scale. In comparing energy usage between the lab and production scales energy usage decreased by about 70%. It was also found that there is no significant energy difference during the final production stage of the product with regard to the two different processes. The results of an eco-efficiency analysis on Vitamin B2 production was reported by Wall-Markowski et al. [131]. In this study they compared vitamin B2 produced from three fermentation processes and one chemical process. One of the three bioprocesses outperformed the others in both economic and ecological indicators. Based on the results of this study BASF recently started vitamin B2 production using a one-step fermentation from vegetable oil.

Assessments of green designs for solvent recovery in the pharmaceutical industry have been evaluated by Slater et al. [132, 133]. These studies have evaluated the life-cycle impact of using various separation processes for solvent purification and reuse within active pharmaceutical ingredient (API) synthesis [134]. Membrane pervaporation has been proposed as a “green drying” alternative to entrainer-based constant volume distillation in one step of the synthesis of an investigational Bristol-Myers Squibb oncology drug [135]. The life-cycle assessment for this study compared the two process routes to dehydrate a batch process vessel that contained the solvent tetrahydrofuran. The pervaporation membrane system allows for a 95% reduction in greenhouse gas emissions through purifying and reusing the solvent within the process step. This avoids the emissions associated with purchasing the tetrahydrofuran entrainer used in constant volume distillation and its disposal. In addition, the economics are favorable, since tetrahydrofuran is a relatively costly solvent. Life-cycle assessments have also been performed for various separation strategies in the recovery of isopropanol in the Pfizer celecoxib synthesis [136]. The case study evaluated seven different process routes which included combinations of distillation, molecular sieve adsorption, and membrane pervaporation. A proposed process of using distillation and pervaporation to recover isopropanol reduced CO_2 life-cycle emissions by 95% from the base case of solvent incineration. This study showed that the emissions generated by operating the separations equipment are small when compared to the overall life-cycle emissions reduced from virgin solvent manufacture and waste incineration. This study also evaluated the life-cycle emissions reduced from concentrating waste solvents for sale as a generic solvent.

Life-cycle assessments have also been conducted on seawater desalination technologies. One study was conducted by Raluy et al. [137] used SimaPro 5.0 software [138] for the analysis portion. Three desalination technologies were compared: multi-effect distillation, multistage flash, and reverse osmosis. The study focused on the environmental criteria of CO_2, NO_x, nonmethane volatile organic compounds (NMVOC), and SO_x. The analysis focused on integrating the distillation process and flash process with a cogeneration plant and with reverse osmosis. This study also compared different regions with the primary difference related to the type of fuel used for electricity production. It was found that in models using the average of the European countries, as well as in models of Spain and Portugal alone, that the multistage flash had the least environmental burdens. However, the French and Norwegian models showed that reverse osmosis had the least environmental negative effects using Eco-indicator 99, Ecopoint 97, and CML 2 baseline impact-assessment methods that accompany the software. Raluy et al. [137] also stated that using a hybrid plant cuts down energy usage by 75%.

There have also been a number of LCA studies performed on industrial paint coatings. One study done by Shonnard et al. [114] compared five different coating processes for wooden doors. It appears from this analysis that the UV coating process has the least risk potential, raw material consumption, emissions, and energy consumption. Papasavva et al. [139] also conducted a life-cycle assessment on paints used in the automotive industry. This study focused on three types of coating materials: primer, basecoat, and clear coat. Three primers were investigated, one solvent-based and two powders (acrylic and polyester). The two basecoats that were used were waterborne and white and pewter in color, respectively. The two clear coats were both acrylic, but one was a solvent-based and the other, powder-based. The white basecoat was chosen for the article because the energy required to produce either basecoat was approximately the same. The criteria used by Papasavva et al. were material requirements, energy consumption, atmospheric emissions, water emissions, solid waste emissions, particulate matter, SO_x, NO_x, CO, VOC, and CO_2. They show that there is a trade-off among environmental factors. These authors report that using the combination of powder primer, water basecoat, and powder clearcoat (PP2–WB1–PC2) results in the least energy requirement, water consumption, solid waste, and VOC emissions. However, this combination of surface coatings exceeded the other scenarios in PM, SO_x, and CO_2 equivalent air emissions. An interesting finding by Dobson [140] is that use of water-based and solvent-based paints yielded the same environmental impacts as incineration of the VOCs.

The pulp and paper industry is another industry where life-cycle assessment methodology has been applied. One example is a paper by Lopes et al. [141], who compared the two major fuels used in the pulp and paper industry: fuel oil and natural gas. The environmental categories were the same categories listed by Allen and Shonnard [53]. The use of methane in place of fuel oil decreases all of the environmental parameters except photochemical ozone formation, which does not vary between fuel options.

Other life-cycle assessments have been conducted on postconsumer-use recycling. One of these studies by Rios et al. [142] focused on the end-of-life recycling of plastics used in electronics. The focus of this paper was on the separation and sorting of various types of plastics for recycling. Another study [53] compared PET bottles to glass bottles with and without recycling. It was found that recycling the PET bottles has the least environmental impact and the same normalized cost as the glass bottle. Song and Hyun [143] focused on the recycling aspects of PET bottles for 11 different scenarios and showed that as the percent of bottles collected increases, the energy used for collection also increases. They cited that the recycle pathway which produces the least CO_2, SO_x, and NO_x was the closed loop and landfill pathway, and the pathway which produced the least solid waste was the pathway for pyrolysis and incineration. Ekvall [144] conducted a life-cycle analysis for recycling newsprint in Sweden. Shiojiri et al. [145] conducted a life-cycle assessment on sulfur hexafluoride. There were different ways to use and to recycle the sulfur hexafluoride. From the study conducted on sulfur hexafluoride "energy consumption as well as global warming risk can be reduced by using a mixture of SF_6 with nitrogen as an insulating gas compared to SF_6," but the other environmental impacts will increase due to transportation to the recycling plant.

There have been life-cycle assessments conducted on waste management. Jimenez-Gonzalez et al. [109] conducted a partial LCI on three different waste treatments for pharmaceutical waste: waste-water treatment, incineration, and solvent recovery. Life-cycle assessment has been used to analyze technologies for the treatment of wastewater produced in the extraction of oil and gas in the energy industry [146]. The study evaluated environmental impacts of 20 processes such as dissolved air, rotating biological contactors, air stripping, dual media filtration, membrane filtration, and ion exchange used in successive stages of water treatment. The impact assessment included an analysis of various end-use options for the reused water in both agricultural and industrial scenarios. The study showed that dissolved air flotation, adsorption, dual media filtration, and reverse osmosis produce a low environmental impact for a treatment system. Chevalier et al. [100] compared two flue gas treatment processes for waste incineration using life-cycle assessment.

Other life-cycle assessments have been done on consumer textile products. One example is a life-cycle assessment on the production of clothing for the production of various indigo dyes for dying denim [114]. A 2D plot was used with the axis being cost and normalized environmental impact. It was found that dying the denim electrochemically in a 40% vat solution has the least environmental impact and cost compared to dying the denim using indigo plants.

The consumer products industry has embraced life-cycle assessment in promoting sustainability. Procter & Gamble has performed life-cycle assessment of its product line which includes laundry detergents, paper towels, disposable diapers, shampoos, personal care products, cosmetics, bathroom tissues, liquid dish wash, and liquid fabric softener [147]. Their study was able to determine the stage in the life-cycle that makes the greatest impact on the energy footprint of these products. In the case of laundry detergents, the energy demand is mainly a result of the product use in the home-heating of water to do the laundry. Therefore, a laundry detergent designed to be used in cold water would have the greatest impact on the environment. Tide Cold Water (US market) and Ariel Cool Clean (European market) were formulated as sustainable innovation products. An estimated 34 million tons of CO_2 per year would be saved in the United States if everyone switched to cold water washing. Life-cycle analysis also shows that materials contribute the next highest impact on the carbon footprint. Through production concentration, a.k.a., compaction, savings in packaging and transportation are achieved.

There have also been life-cycle assessments conducted on the food industry. In the study by Cederberg and Mattson [148] organic milk farms were compared to conventional milk farms. They show an increase in global warming in methane due to organic farming, but a decrease in other compounds such as carbon dioxide and N_2O. Most of the acidification potential for these farms was caused by the release of ammonia from manure. The eutrophication parameter was estimated for this study and was based on the manure application rate and a higher phosphorous surplus on conventional farms. They stated that organic farming reduces pesticide use, global warming, acidification, and eutrophication. Zabaniotou and Kassidi [149] conducted a study on two types of egg packaging material, recycled paper and polystyrene. The functional unit for this study was done on a packaging basis instead of a product mass basis. The environmental factors used in the study for egg containers were global warming, ozone depletion, acidification, eutrophication, particulate matter, heavy metals, carcinogenic substances, and photochemical ozone creation potential. This study concluded that polystyrene packages contribute more to acidification potential, winter and summer smog formation, whereas recycled paper egg packages contribute more to heavy metal and carcinogenetic substances impact. Another study on food packaging was conducted by Bohlmann [150], which focused on a comparison of polypropylene and biodegradable packaging. The functional unit for this case study was the packaging required to fill 1,000 kg of yogurt. The environmental criteria used for this comparison were energy and greenhouse gases. It appears as though the biodegradable package consumes less energy, but has slightly higher greenhouse gas emissions. Bohlmann cited that the greenhouse gas emissions are equivalent if the biodegradable packaging is fully decomposed in the landfill.

Anderson et al. [151] report a life-cycle assessment on tomato ketchup, in an attempt to identify “hot spots” in the life cycle of the product. In this study, it was found that the food-processing stage contributes the most to greenhouse gases, human toxicity, and acidification. They also suggest that the major contributor to eutrophication is the agriculture sector of the economy.

Conclusions

Life-cycle assessment is an important green engineering tool for analyzing processes and products. This tool is currently being used by industry to improve the environmental and economic performance of products and processes. Examples have been given in this chapter of life-cycle assessment methods as well as many studies done on chemical processes and products. Through the use of life-cycle assessment tools industry will move to sustainable production of current and new products.

Industrial Catalysis: A Practical Guide

6

Robert J. Farrauto

The Importance of Catalysis

Every student of chemistry, material science, and chemical engineering should be schooled in catalysis and catalytic reactions. The reason is quite simple; most products produced in the chemical and petroleum industry utilize catalysts to enhance the rate of reaction and selectivity to desired products. Catalysts are also extensively used to minimize harmful byproduct pollutants in environmental applications. Enhanced reaction rates translate to higher production volumes at lower temperatures with smaller and less exotic materials of construction necessary. When a highly selective catalyst is used, large volumes of desired products are produced with virtually no undesirable byproducts. Gasoline, diesel, home heating oil, and aviation fuels owe their performance quality to catalytic processing used to upgrade crude oil.

Margarine, cakes, chocolate, salad oils, and other everyday edible products are produced from natural oils via catalytic hydrogenation. Polyethylene and polypropylene plastics, commonly used in packaging of foods, films, fibers, liquid containers, etc., require catalysts for cost-effective high volume production. Because of highly active and selective catalysts, polyester fibers used in clothing can be produced at reasonable prices for the mass market. Catalysts enhance the production of ammonia-based fertilizers that enrich the earth's nutrient deficient soils for efficient agriculture. Catalytically produced ethylene oxide is a precursor to antifreeze. Formaldehyde is produced catalytically and used as a preservative and as a component in some polymer resins.

It is good to keep in mind the importance of catalysts in protecting the environment. They are frequently installed in the exhaust ducts from chemical operations to convert volatile organic compounds (VOC) generated during manufacturing operations, into harmless products. Catalysts also provide the environmental benefit of clean air by abating pollutants generated from stationary and mobile combustion sources. In many locations around the industrialized world, coal- and gas-fired power plants have special catalysts installed in the ducts to eliminate pollutants dangerous to our health. Many gas-fired compressors that pump natural gas through millions of miles of pipelines are also equipped with exhaust catalysts to clean emissions at moderate conditions. Even fastfood restaurants are being equipped with catalysts to eliminate odors from the cooking process. The most widely used treatment of exhaust pollutants is that of the catalytic converter present in the exhaust manifold that cleans emissions from the internal combustion engines of gasoline- and diesel-fueled automobiles and trucks. As modern commercial passenger jets fly above 30,000 feet, there is a need to destroy the few ppm ozone that enters the airplane with make-up air to ensure passenger and crew comfort and safety. Radiators on select vehicles have a catalytic coating deposited on their surface that decomposes harmful groundlevel ozone as the vehicle is driven.

All of this gives the consumer the benefits of readily available high-quality products at reasonable prices. From food to clothing to medicines to clean energy, catalysts play a major role in products people use in everyday life.

The forthcoming description of catalysts and catalytic processes should only serve as a primer towards understanding the basic principles with some examples of applications in the field of petroleum processing, alternative fuels, chemical production, and environmental air purification. Table 6.1 gives a list of some of the many commercial catalytic applications.

How Does a Catalyst Work?

A catalyst increases the reaction rate or activity relative to an uncatalyzed process by providing a less energetic pathway for conversion of reactants to products. In this regard the

Table 6.1 Some commercial catalytic reactions

Reaction name	Example of chemical reaction	Major catalyst components	Commercial applications
Petroleum processing			
Cracking	$C_{16}H_{34}=C_8H_{18} + C_8H_{16}$	Faujasite Zeolite	Naphtha, heating oil
Hydrodesulfurization	$RS + H_2=H_2S + RH$	Co, Mo/Al_2O_3 (S)	Sulfur-free fuels
Naphtha reforming	$C_6H_{12}=C_6H_6 + 3\ H_2$	Pt, Re/Al_2O(Cl)	High-octane gasoline
Alkylation	$C_3H_6 + C_4H_{10}=C_7H_{16}$	Liquid acids	Gasoline
Hydrogenation of functional groups			
Double bonds	$H_2R=R'–R''H_3 + H_2=H_3R–R'HR''H_3$	Ni or Pd or Ru on carriers	Air stable compounds, edible/non-edible oils
Aldehydes	$RCHO + H_2=RCH_2OH$	Pd or Ru or Ni on carriers	Alcohols
Selective oxidations			
Nitrogen dioxide for nitric acid	$4NH_3 + 5O_2=4NO_2 + 6H_2O$	Pt, Rh gauze	Fertilizer, explosives
Sulfuric acid	$SO_2 + 1/2O_2=SO_3$	V_2O_5 on TiO_2	Dissolving minerals
Ethylene oxide	$CH_2=CH_2 + 1/2O_2=C_2H_4O$	Ag on alpha Al_3O_3	Antifreeze, polyester, fibers, bottles
Formaldehyde	$CH_3OH + 1/2O_2=CH_2O + H_2O$	Bi, Mo or Ag	Monomers, preservatives
Synthesis gas/H_2			
Synthesis gas	$CH_4 + H_2O=3\ H_2 + CO$	Ni/Al_2O_3	Production of chemicals
Water gas shift	$CO + H_2O=H_2 + CO_2$	Fe, Cr and Cu, Zn, Al	High purity H_2
Pollution control			
Automotive (TWC)	CO, HC + $O_2=CO_2 + H_2O$ CO + $NO=1/2N_2 + CO_2$	Pt, Rh or Pd on $Al_2\ O_2$ on a Monolith	Clean emissions
Stationary reduction of NO_x	$2NO_2 + 4NH_3 + O_2=3N_2 + 6H_2O$	V_2O_5/TiO_2 on a monolith and metal exhanged zeolite	Reduction of NO_x from power plants
Polymerization	$nCH_2=CH_2=(–CH_2–)_{n+1}$	Cr/SiO_2 or $TiCl_4$ + alkyl aluminum halide	Plastics

catalyst provides a chemical and energetic shortcut by lowering the energy barrier (i.e., activation energy) of reactants going to products. If no catalyst were present, higher temperature would be required to initiate the reaction. Higher temperatures often lead to undesirable byproducts and sometimes decomposition of one of the reactants. Therefore, by initiating the reaction at a lower temperature, the process is more controlled and the desired product can be produced. This is the most important advantage for catalytic processes that is exploited in many product applications.

The catalyst is not consumed in the process; it accelerates but does undergo various chemical changes during the process by interacting with the reactants and products. Mechanistically some or all of the reactants adsorb onto active sites of the catalyst where bonds are rapidly made or broken. For a heterogeneous solid catalyst processing a liquid and/or gas, the adsorption of reactants is called chemisorption that has the kinetics and reaction energies equivalent to a chemical reaction. Frequently chemisorbed species decompose to an intermediate that is rapidly converted to other intermediates or the final product. After the reaction is complete, the catalyst returns to its original state. In this regard there is no net change of the catalyst. Therefore, a very small amount of catalyst can process many molecules.

What Are the Catalytic Metals and Metal Oxides?

Most catalytic metals and metal oxides are derived from Group VIII of the periodic table. Of special importance are Fe, Co, Ni, Rh, Pd, and Pt, but also of importance are Cu and Ag in Group 1b, V in Group Vb, and Cr and Mo in Group V1b. Three of the precious metals Rh, Pd, and Pt are extensively used in many industries due to their extremely high activity and selectivity. They are rare in nature and very expensive, and thus spent catalysts are routinely recycled, purified, and reused. However, the so-called base metals Fe, Co, Ni, Cu, V, Cr, and Mn but especially Ni and Cu are used for specialty chemical applications. Base metal catalysts usually have modest activities, but are much less expensive and in certain cases more selective than the precious metals. Therefore, it is always desirable to search for less expensive base-metal catalysts whenever possible. This has been especially the case for replacing precious metal-containing automotive emission control catalysts, but because of lower activity and stability in the severe environment of an automobile exhaust they are only used as promoters.

More examples of the efficient use of catalytic metals and metal oxides will be given in the applications section of this brief review.

The Structure of Heterogeneous Catalysts

The process of chemisorption of reactants requires adsorption on the surface of the catalyst. Therefore to maximize the rate, the catalytic surface area should also be maximized. This is achieved by dispersing the catalytic species onto a high surface area inorganic carrier. An ideal dispersion of Ni on Al_2O_3 is shown in Fig. 6.1.

Ideally every Ni atom should be accessible to the reactants for maximum efficiency in the conversion process. Although this is possible when the catalyst is first prepared, the dynamics of the catalytic reactions lead to some agglomeration. Catalyst scientists, however, have developed procedures and stabilizers to minimize the extent of agglomeration and therefore dispersed catalysts can be classified as nanomaterials with sizes only slightly greater than 1 nm or 10 Å.

The carrier can be thought of as a sponge with pores from 1 to 100 nm (10–1,000 Å) in diameter. If one were to measure the internal surface area of just 20 g with an internal surface area of 200–300 m^2/g, it would be equivalent to about 1 football field. Carriers such as Al_2O_3, SiO_2, TiO_2, CeO_2, ZrO_2, C, and combinations of these materials are commonly used. All have different surface properties and are used in applications dependent on the requirement for acidity, inertness to solubility, interactions with reactants, affinity for catalytically active components, and resistance to components in the gas phase. High surface area Al_2O_3 is not well suited for combustion reactions in which SO_2/SO_3 are present due to the formation of $Al_2(SO_4)_3$. In such cases, high area TiO_2 and/or ZrO_2 are used because of their inertness. Carbons are mostly used for supporting precious metals in hydrogenation reactions. In addition to their chemical role, precious metal recovery is achieved simply by burning the carbon.

The most common carrier is gamma alumina (γ-Al_2O_3). It has an internal area of >200–300 m^2/g. Its surface is highly hydroxylated (i.e., Al-O^-H^+). The H^+ sites provide acidity required for many reactions and exchange sites for catalytic metal cations.

Zeolites are combinations of Al_2O_3 and SiO_2 that are crystalline structures with precisely defined pore structures in the molecular size range (0.4–1.5 nm or 4–15 Å). A related group of materials known as mesoporous silica–alumina has extended the range of pore sizes attainable in ordered SiO_2–Al_2O_3 supports to 4 nm (40 Å). They are commonly used in the chemical and petroleum industry due to their surface acidity and ability to exclude molecules larger than the pore diameter. For this reason, they are often referred to as molecular sieves. Their surfaces contain Al–OH groups with acidic and exchangeable H^+. In the application section some of these materials will be more thoroughly discussed.

Rate-Limiting Steps for a Supported Catalyst

Supporting a catalytic component introduces a physical size constraint dictated by the pore size of the carrier. Thus, a key consideration is the accessibility of the reactants to the active

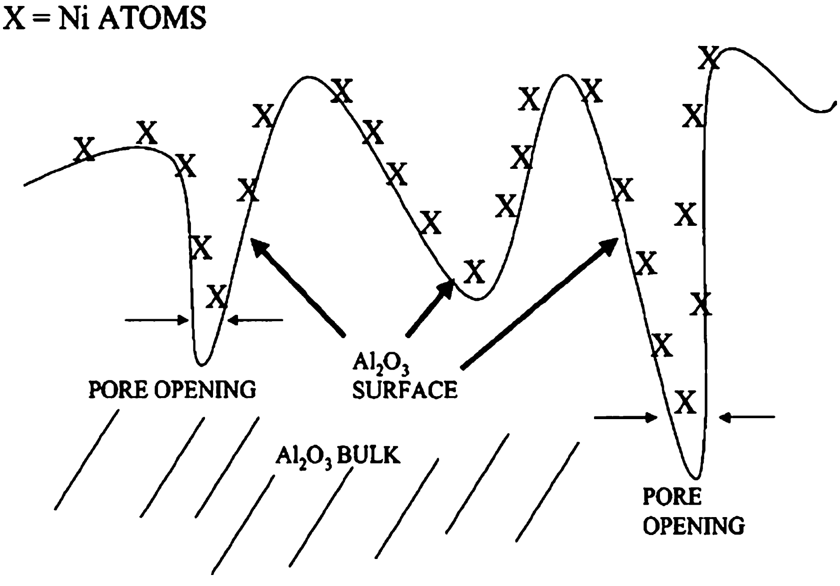

Fig. 6.1 Ideal dispersion of an active catalyst species on a porous carrier. Example given is Ni on Al_2O_3

catalytic sites within the high surface area carrier. Consider a hydrogenation reaction in which Ni is located in extremely small pores (i.e., 1 nm or 10 Å). The H_2 molecule has easy access, but a large molecule, having a size comparable to the diameter of the pore, would experience great resistance moving towards the active sites. If large amounts of Ni are present in pores and are not accessible to the molecules to be hydrogenated, the reaction rate will not be enhanced to its fullest potential. Thus, the carrier with its geometric sizes and its pore size distribution must be carefully designed to permit the reagents and products to move in the pores with minimum resistance.

Following are the seven fundamental steps in converting a reagent molecule(s) to its product(s) using a supported heterogeneous catalyst.

1. Bulk diffusion of all reactants to the outer surface of the catalyzed carrier from the external reaction media
2. Diffusion through the porous network to the active sites
3. Chemisorption onto the catalytic sites (or adjacent sites) by one or more of the reactants
4. Conversion and formation of the chemisorbed product
5. Desorption of the product from the active site
6. Diffusion of the products through the porous network to the outer surface of the catalyzed carrier
7. Bulk diffusion of the products to the external fluid

Steps 1, 2, 6, and 7 depend on the physical properties of the catalyzed carrier and are not activated processes (no intermediate chemical complex is formed). For this reason, we use the term apparent activation energy which is a term useful for comparing temperature dependence as will be described later. Steps 3–5 are chemically activated (with intermediate complexes formed during conversion to products) and depend on the chemical nature of the interaction of the reactants and products with the active sites [1–3]. Step 1 is referred to as bulk mass transfer. It describes the transfer of reactants from the bulk fluid to the surface of the catalyzed carrier. When this step is rate limiting, reactant molecules arriving at the external surface of the catalyst are converted instantaneously resulting in zero concentration of reactants at the surface. Thus, the internal surface of the catalyst is not used. Such as mass transfer controlled process is nonactivated and we assign an apparent activation energy of less than 2 kcal/mol. Rates vary only slightly with temperature ($T^{3/2}$) which, as will be shown below, allows it to be distinguished from other rate-limiting steps. Step 7 is similar to Step 1 except that the products diffuse from the external surface of the catalyst particle into the bulk fluid. The temperature dependence of this phenomena is relatively weak and has an apparent activation energy similar to that observed in Step 1 when it is rate limiting. When only the external surface of the catalyst particle is participating in the catalysis, it is said to have a low effectiveness factor. The effectiveness factor is defined as the actual rate divided by the maximum rate achievable when all catalytically active sites participate in the reaction. In the case of bulk mass transfer, the effectiveness factor approaches zero.

Steps 2 and 6 are both pore diffusion processes with apparent activation energies between 2 and 10 kcal/mol. This apparent activation energy is stated to be about 1/2 that of the chemical rate activation energy. The concentration of reactants decreases from the outer perimeter towards the center of the catalyst particle for Step 2. In this case some of the interior of the catalyst is being utilized but not fully. Therefore, the effectiveness factor is greater than zero but considerably less than one. These reactions are moderately influenced by temperature, but to a greater extent than bulk mass transfer.

Steps 3, chemisorption of the reactant(s), 4, chemical reaction forming the adsorbed product, and 5, desorption of the product(s) from the active site(s) are dependent on the chemical nature of the molecule(s) and the nature of their interaction with the active site(s). Activation energies are typically greater than 10 kcal/mol for kinetically or chemically controlled reactions. Chemical kinetic phenomena are controlling when all transport processes are fast relative to the reactions occurring at the surface of the active species so the effectiveness factor is one. All available sites are being utilized and the concentration of reactants and products is uniform throughout the particle. These reaction processes are affected by temperature more than either transport mechanisms. Figure 6.2 shows the conversion vs. temperature and concentration profiles of a reagent (R) for the three regimes of rate control.

Because of the significant differences in temperature dependence the kinetically limited reactions can be distinguished from pore diffusion that in turn can be differentiated from bulk mass transfer. This is shown in Fig. 6.2 in which conversion of reactants is measured against temperature. The first evidence of conversion is the sharply increasing slope that indicates kinetic control, whereas pore diffusion shows a lower change in slope as the temperature increases. The bulk mass transfer process shows little change in conversion with increasing temperature. Thus, at low temperature the reaction is controlled by chemical reactions (3, 4, or 5) and pore diffusion limited reactions exist when the supply of reactants to the active sites within the particle is limiting the rate (2 or 6). Finally, at the highest temperature, chemical reactions at the external surface are faster than bulk mass transfer (1 or 7) and the reaction is considered limited by bulk mass transfer.

The corresponding concentration of reactant R is also shown for each regime. The concentration of R is constant within the catalyst for kinetically limited reactions. The concentration of reactant gradually decreases within the catalyst particle for the pore diffusion limited case because the rate is limited by transport through the porous network.

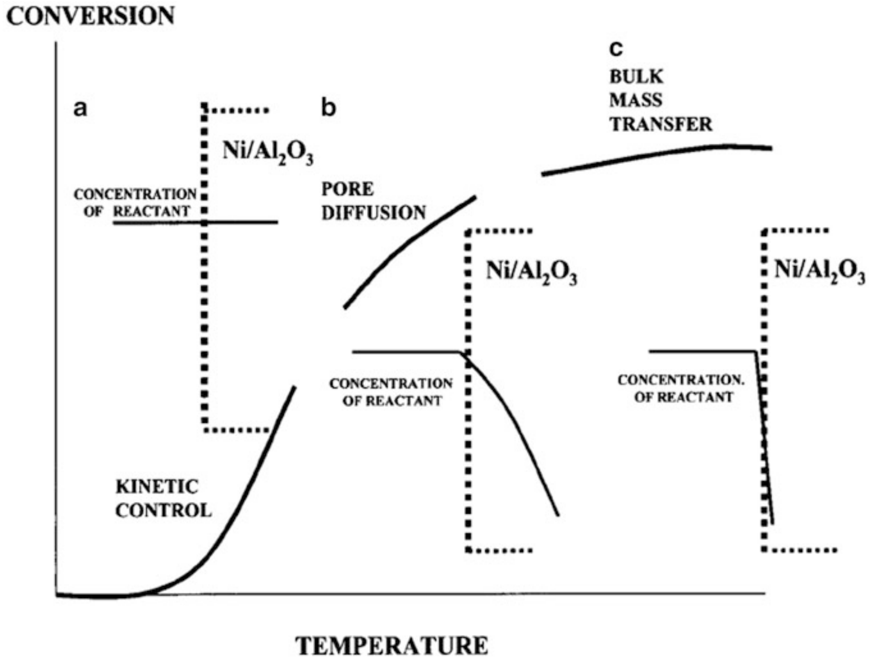

Fig. 6.2 Conversion of a reactant vs. temperature. The concentration of reactants [*R*] within the porous catalyst structure. Concentration of *R* is (**a**) uniform for kinetic control, (**b**) decreasing within the catalyst for pore diffusion control, and (**c**) zero immediately at the surface of the catalyst for bulk mass transfer

For bulk mass transfer limited cases, the concentration of R is zero at the gas/solid interface.

Activation Energies and Rate-Limiting Steps. The heterogeneous catalyzed NH_3 synthesis from N_2 and H_2 will be used to illustrate the relationship between rate and activation energy. There are a series of steps in the Fe catalyzed process.

The process steps within the pore structure of the catalyst are

1. Diffusion of N_2 and H_2 to the active Fe site within the catalyst pore structure
2. Chemisorption of H_2 on the active Fe surface
3. Dissociation of chemisorbed H_2 to H atoms on the Fe site
4. Chemisorption of N_2 on the Fe site
5. Dissociation of N_2 to N atoms on the Fe surface
6. Surface reaction between adsorbed N and H atoms forming chemisorbed NH_3
7. Desorption of NH_3 from the surface
8. Diffusion of the NH_3 into the bulk gas

Dissociation of chemisorbed N_2 (Step 5) is the slowest and thus is rate limiting.

$$N_2\text{—Fe(active site)} \rightarrow 2\text{N—Fe}$$

The overall rate of reaction is determined by the slowest of these steps. In other words, the overall reaction cannot be faster than the slowest step. The slow step and hence the overall reaction rate is characterized by the apparent activation energy.

An important detail is that an individual rate-limiting step may be endothermic, whereas the overall reaction is exothermic as in this case. This is illustrated in Fig. 6.3. The chemisorption of N_2 is exothermic and its dissociation is endothermic (1A). However, the overall reaction of N_2 + H_2 to NH_3 is exothermic (1B). The overall activation energy and kinetics are dictated by the slow step. The reaction heat liberated (ΔH_{25}°C) $= -11$ kcal/mole is the thermodynamic value associated with the overall reaction.

It is very important to understand that the catalyst only promotes the rate of a reaction and cannot change the equilibrium concentrations of reactants and products. It cannot make a thermodynamically unfavorable reaction occur. It increases the rate at which equilibrium is achieved while always respecting the thermodynamics of the equilibrium constant and the enthalpy (ΔH) and free energy (ΔG) of the overall reaction. Process conditions (T&P) are changed to give more favorable thermodynamics and rates.

Consider an everyday example of how we are all influenced by rate-limiting steps. If you are driving on a one-lane road behind a slow-moving truck, your speed and that of those behind you is no greater than that of the truck although you certainly have the potential to increase your rate. Thus, the time required to arrive at your destination is controlled by the speed of the truck. Taking an analogy, we can liken the truck to a slow chemical reaction step where the overall reaction rate, and the time required to achieve products, is no faster than the speed of the conversion at the surface of the catalyst. Returning to our highway story if you take a bypass road you can increase your rate of speed and

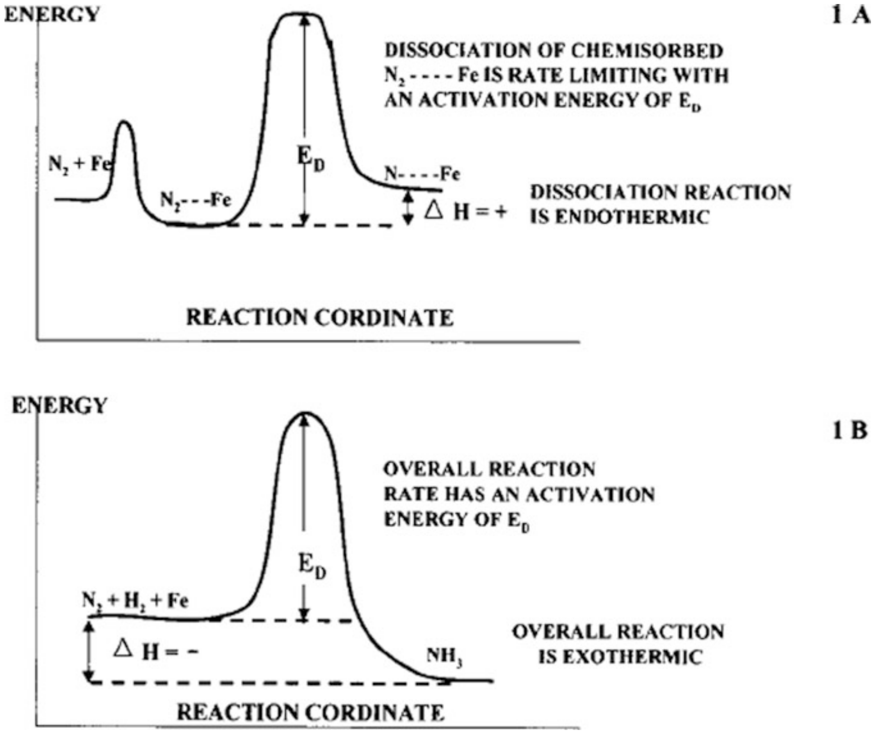

Fig. 6.3 Activation energy diagram for NH_3 synthesis: (1A) chemisorbed N_2 dissociation (rate-limiting step); (1B) overall reaction for NH_3 synthesis

decrease the time needed for you to arrive at your destination. The new road is analogous to a catalyst that provides a different pathway to the final product. It is likely, however, that you will again be limited by another obstacle (narrowing of the new road due to construction) that will slow you and the others behind you, as you maneuver through it. This may be likened to pore diffusion where you are limited by the width of the passage. Mass transfer control can be thought of as reaching the maximum speed your vehicle can safely achieve within the local speed limits. The activation energy reflects the slow step and the kinetics of the overall reaction rate.

Selectivity

In many processes, multiple reaction pathways are possible and it is the role of the catalyst and reaction conditions to maximize the rate along the desired path. Selectivity is defined as the amount of desired product divided by reactant converted. A practical example of the catalyst directing reactants to a selective product is shown by the oxidation of ammonia to nitric oxide, which is used in the production of fertilizers.

$$4NH_3 + 5O_2 \rightarrow 4NO + 6H_2O;$$
$$\Delta H_{25} = -54.2 \text{ kcal/mole } NH_3$$

The operating temperature of the process is 900°C and both the standard free energy of $\Delta G_{25} = -57.2$ kcal/mol of NH_3 and the equilibrium constant of $K_{NO} = 10^{10}$ are very favorable.

However, the decomposition pathway to N_2 is even more thermodynamically favorable with $\Delta G_{25} = -77.9$ kcal/mol of NH_3 and an equilibrium constant of $K_{N2} = 10^{15}$ at 900°C.

$$4NH_3 + 3O_2 \rightarrow 2N_2 + 6H_2O;$$
$$\Delta H_{25} = -75.5 \text{ kcal/mol of } NH_3$$

The presence of a PtRh gauze catalyst catalyzes the reactants along the NO pathway with a selectivity of 98%. Therefore, although the free energy is more favorable and the equilibrium constant for the N_2 reaction is 10^5 times greater, the highly selective PtRh catalyst promotes the NH_3 oxidation reaction to NO. In contrast, the presence of Pd favors the N_2 product. In each case the catalyst respects the equilibrium constant, but directs the reactants to specific products.

A second reaction that is currently receiving a great amount of attention because of low-temperature fuel cells is the purification of traces of CO present in a H_2 stream. The fuel cell directly converts chemical energy (H_2 and O_2) to electricity bypassing the mechanical (pistons, turbines, etc.) and combustion steps associated with conventional power generation. The mechanical step limits efficiency and combustion generates pollutants (CO, HC, and NO_x). The heat and power generated from the fuel cell hold promise for powering vehicles and for providing heat and electricity to residential and commercial buildings with the only product being H_2O. H_2 and CO are produced by catalytic steam reforming of a hydrocarbon (e.g., natural gas). The subsequent water gas shift reaction generates more H_2 from the $CO + H_2O$ reaction. Traces of CO exiting the shift reactor must be removed from the H_2 because it poisons the anode of the low-temperature fuel cell. The H_2 content of the gas is about 75%, and the CO is about 0.1% (balance is H_2O and CO_2). Although both standard state free energies are similar, a highly selective Pt containing catalyst promotes the oxidation of the CO with minimum oxidation of the H_2 purifying the latter for a low-temperature fuel cell.

$$CO + \frac{1}{2}O_2 \rightarrow CO_2 \ \Delta G_{25} = -61 \text{ kcal/mole}$$
$$\Delta H_{25} = -68 \text{ kcal/mole}$$
$$H_2 + \frac{1}{2}O_2 \rightarrow H_2O \ \Delta G_{25} = -57 \text{ kcal/mole}$$
$$\Delta H_{25} = -55 \text{ kcal/mole}$$

A small amount of air is injected into the reactor. The inlet H_2/CO ratio is 750, whereas the exit ratio must be 75,000. Thus, the free energy for CO oxidation is becoming less favorable (more positive) as CO is reduced below 10 ppm. An effective catalyst [4] currently in use commercially is Pt on Al_2O_3 promoted with a small amount of Fe. It operates at an inlet of 90°C and reduces the CO to less than 0.001% with a selectivity of well over 50% depending on management of the exothermic heat of reaction. This is quite remarkable given the increasingly large excess of H_2 as the reaction approaches completion. The same catalyst, but without the Fe, requires 170°C to achieve the same conversion of CO but with a selectivity less than 25%.

Catalyst Preparation

In the example given above, a small amount of Fe is added to a Pt on Al_2O_3 catalyst. The catalyst is prepared by a very unique procedure that must be strictly adhered to in order to achieve the desired results. The Pt and Fe must be in such close proximity that the CO chemisorbs on the Pt and the O_2 on the Fe after which they react to form CO_2 [4]. Simply reproducing the composition will not give acceptable performance. The specific details of catalyst preparation may be confidential and are most often covered by patents and trade secrets.

Some general guidelines for supported catalyst preparations are presented below; however, the reader should consult the many references and patents available on the subject [5]. Even by doing so the precise details used by industry to optimize the catalyst will often not be found.

Known amounts of salt(s) of catalytic metals are dissolved in aqueous solutions and impregnated into carrier materials. The wet mass is dried at 110°C and calcined in air at 300–500°C, releasing the decomposable salt components and depositing the metal oxide on the surface within the depths of the porous carrier. For many oxidation reactions, the catalyst is now ready for use, but for hydrogenation it is necessary to reduce the impregnated metal oxide or salt chemically. Usually this is accomplished by flowing H_2, under conditions consistent with the maximum temperature of use for the reaction of interest.

The carrier can be in the form of a powder used for slurry reactions or a particulate such as a sphere, cylinder, or tablet (typically a few mm in diameter) used in fixed bed reactors. The size and shape depend very much on what is anticipated to be the rate-limiting step. For example, for a reaction limited by pore diffusion, it is customary to use a smaller particle in the shape of a star, trilobe, or wagon wheel to decrease the diffusion path while increasing the external geometric surface area.

Mechanical strength and solubility under reaction conditions must be considered in the selection. Although it is often stated that the carrier is inert, there are many cases where this is not the case. Some carriers provide acid or basic sites that act as cocatalysts with the metal or metal oxides performing other functions. Petroleum reforming (discussed later) requires a hydrogenation function, provided by the metal, to dissociate H_2 and the carrier provides the acid site to enhance isomerization reactions.

Multi-channel ceramic monoliths (Fig. 6.4) are now the primary choice as support structures to carry the active catalytic species for cleaning emissions from various sources of pollution [6]. Figure 6.4 shows the shapes used for both automotive and stationary pollution abatement applications.

The largest application is the automotive catalytic converter that converts carbon monoxide (CO), hydrocarbons (HC), and nitric oxides (NO_x) to nontoxic compounds. The monolith structure offers high cell densities and thus geometric surface area upon which the catalyst is deposited permitting smaller reactor sizes, high mechanical strength, excellent thermal shock resistance, and low-pressure drop [6]. A powdered carrier, usually stabilized Al_2O_3, is impregnated with catalyst precursor salts. A slurry of the impregnated carrier is prepared and milled to some desirable particle size. The monolith is dipped into the slurry and "washcoated" onto the walls of all of the channel surfaces (see Fig. 6.4). Air is blown through the channels to remove excess slurry. It is then dried and calcined in air at about 500°C. The finished structure now contains the proper amount of catalyst uniformly deposited throughout the channel length. The washcoat thickness is greatest at the corners or fillets of the cell due to its sharp angle. The reactants flow through the channels and catalysis occurs on the washcoated walls. There are many other variations of

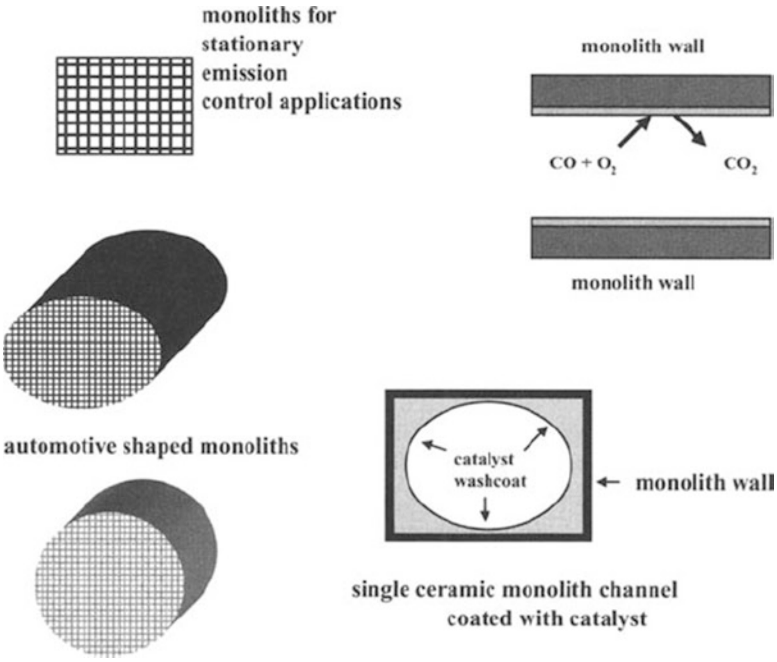

Fig. 6.4 Typical ceramic monolith geometries used for environmental emission control for vehicle and stationary applications

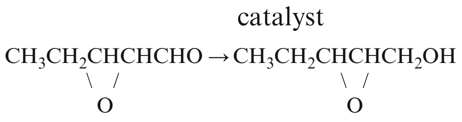
preparing monolith catalysts with different carriers and compositions. There are monoliths made of metal, some of which have parallel channels and others with nonparallel channels designed for tortuous flow to enhance mass transfer.

A Heterogeneous Catalytic Reaction: An Example

There is a great desire to use naturally occurring and renewable biomass for producing useful products. Furfural is extracted from cornhusks and contains an aldehyde functional group. If this group is selectively hydrogenated to the corresponding alcohol, the product furfuryl alcohol can be used to make corrosion-resistant resins for preparing polymers to make molds for shaping products. This reaction is selectively carried out with a Cu, Cr_2O_3 catalyst (copper chromite powder) in a slurry phase stirred batch reactor (see “Reactor Types” below) at 3,000 psig and 150°C.



$$\underset{\backslash\ /\ \ \mathrm{O}}{CH_3CH_2CHCHCHO} \xrightarrow{\text{catalyst}} \underset{\backslash\ /\ \ \mathrm{O}}{CH_3CH_2CHCHCH_2OH}$$

Hydrogen gas is dissociatively chemisorbed onto the surface of the Cu-containing catalyst producing highly active hydrogen atoms. The high pressure is needed to ensure adequate solubility of the H_2 in the furfural liquid. The aldehyde functional group forms a weak bond with these active adsorbed atoms and is hydrogenated to the finished product. In the absence of the catalyst, the diatomic hydrogen molecule would have to be dissociated in the gas phase at a much higher temperature leading to the decomposition of the aldehyde group.

Active Catalytic Sites

Not all catalytic sites are equal. Ideally each catalytic site is an atom having equal activity. This is never the case for a supported heterogeneous catalyst. One of the great mysteries in catalysis is the exact nature of the active site. Some catalytic species may be so well dispersed that they have no defined structure or are amorphous (no long-range structural order), whereas others may be highly crystalline. Amorphous catalytic components have greater catalytic surface area because fewer atoms are buried within a large crystal. However, the nature of the carrier and the catalytic species and the method used to deposit it on the carrier gives rise to a very heterogeneous surface with different sites having different surface energies and different activities. For example, it is believed that defects in the crystal structure produce highly energetic and active sites for catalytic reactions. This may be true but the more crystalline the catalytic site, the lower is the number of surface atoms and the lower is its catalytic surface area. All this being said, there are reactions that favor certain catalyst crystalline sizes and are said to be structure sensitive. The above discussion points to the mystery of catalysis. The goal of finding a universal model describing the nature of the active catalytic site still eludes us today and will undoubtedly be the subject of fundamental research for years to come.

Reactor Types

There are many different reactor designs, but the two most commonly used are fixed bed and batch slurry phase. For a fixed bed reactor, a given volume of solid particulate or monolith supported catalyst is fixed in a heated tube located within a furnace and liquid and/or gaseous reactants flow through the bed. This type of process is commonly used for large continuous-volume production where the reactor is dedicated to making only one product such as a bulk chemical or petroleum product.

Monolithic supports are commonly used for environmental applications and will be discussed in more detail later [6]. Batch reactors are used mostly for small-scale production such as the hydrogenation of intermediates in the production of medicines in the pharmaceutical industry. The catalyst powder is mixed in a precise amount of reactant in a pressurized-stirred autoclave. A gaseous reactant, usually H_2, is introduced at elevated pressures and the reaction proceeds with continuous monitoring of the H_2 consumed. The catalyst is separated from the product via filtration and is often used again depending on its retained activity and selectivity.

For the production of gasoline and other fuels by catalytic cracking of oils, a fluid bed reactor is used. This is a hybrid of a fixed bed and slurry phase reactor. The catalyst is fluidized as it interacts with the feed to be processed. This application is so important that it will be highlighted in the application section of this review.

Kinetics

The overall kinetics of a heterogeneous catalytic reaction can be controlled by any of the seven steps listed above [7–10]. We can distinguish which is rate controlling by determining the temperature dependence of the reaction. Once we know this we can design the catalyst to enhance the rate of the slowest step.

For example, bulk mass transfer (Steps 1 and 7) can be enhanced by increasing the turbulence of the reactants by increased stirring for a batch process or by increasing the linear velocity (see below) in the case of a fixed bed reactor. Increasing the geometric surface area of the catalyst also favors a reaction limited by bulk mass transfer. This is accomplished by decreasing the particle size of a particulate or by increasing the number of channels in a monolithic structure. Turbulence can be introduced in a monolith channel by modifying the surface from smooth to rough. Because kinetically controlled reactions have a stronger temperature dependence than transport controlled reactions, they are affected the most by increasing temperature. Pore diffusion resistance is decreased by increasing the pore size of the carrier or by using a smaller diameter carrier. One may also deposit the active catalytic species nearer the surface of the carrier to decrease the diffusion path length. The rate of a reaction limited by pore diffusion is moderately enhanced with temperature.

For chemically controlled reactions, one must modify the catalyst itself by increasing the number of active sites (increasing the catalytic surface area) or finding a crystal size that is more active for a given reaction. Often the activity is increased by the addition of promoters to the catalyst (i.e., Fe addition to Pt described under "Selectivity") that enhance the activity. Having the highest activation energy, it is affected more than the transport regimes by increasing the temperature. Many examples of this will be given in the example section of this chapter.

General Kinetic Rate Equations. The rate of a bi-molecular reaction is given by

$$\text{Rate} = d[A]/d(t) = -[k_F(A)^a(B)^b - k_{REV}(D)^d(E)^e]$$

Rate is the disappearance of reactants with time expressed as the derivative—$d[A]/d(t)$. $[A]$ and $[B]$ are the concentrations of reactants and $[C]$ and $[D]$ are the concentrations of the products. The exponents $a, b, c,$ and d are the reaction orders for each compound. The rate constants are k_F for the forward and k_{REV} for the reverse reaction. For those cases where the reaction is far away from equilibrium, the reverse rate is negligible and this term is dropped from the rate expression.

To determine the rate constant and the reaction order at a specific temperature, it is often convenient to increase the concentration of one reactant at least 20 times that of the other to maintain it relatively constant during the reaction. Thus, with a high concentration of reactant B one my write $k_F\ [B]^b = k_F{}^*$

$$d[A]/\mathrm{d}t = -k_F{}^*(A)^a$$

If the reaction order is to be determined, one may take the natural log of the rate equation and obtain

$$-\ln(d[A]/\mathrm{d}t) = \ln k_F{}^* + a\ln[A]$$

A plot of the $-\ln(d[A]/\mathrm{d}t)$ vs. $\ln[A]$ will produce a straight line with a slope equal to a and intercept $\ln k_F{}^*$

If one assumes $a = 1$ and integrates the rate expression

$$\int d([A]/[A]) = -k_F{}^* \int d(t)$$

Integration from the initial concentration A_o to A at anytime and from $t = 0$ to t

$$\ln([A_o]/[A]) = k_F{}^*t$$

$$[A] = [A_o - xA_o] \quad \text{where } x \text{ is the fraction converted}$$

Plotting $A_o \ln[1/(1-x)]$ vs. t will give a straight line with a slope equal to $k_F{}^*$ *Kinetics for Fixed Bed Continuous Reactions*. For continuous flow reactors, we use the term space velocity (*SV*) defined as the volumetric flow rate at *STP* divided by the volume of catalyst. That ratio yields the reciprocal of the residence or space-time (t)

$$\mathrm{SV}(\mathrm{h}^{-1}) = \frac{\text{flow rate cm}^3/\text{h(STP)}}{\text{catalyst volume}(\text{cm}^3)}$$

$$\frac{1}{\mathrm{SV}} = \text{residence time or space-time}$$

Thus, the rate equation for continuous flow reactions is

$$\ln([A_o]/[A]) = k_F{}^*t = k_F{}^*/\mathrm{SV}$$

The linear velocity (*LV*) or superficial velocity is an important engineering term because it relates to pressure drop and turbulence. This parameter is often increased in fixed bed reactors to enhance bulk mass transfer and heat transfer.

$$\mathrm{LV(cm/h)} = \frac{\text{flow rate cm}^3/\text{h(STP)}}{\text{frontal area of catalyst}(\text{cm}^2)}$$

Kinetics of a Slurry Phase Reaction in a Batch Process. This example is for the liquid phase hydrogenation of nitrobenzene to aniline with a powdered catalyst. These reactions typically are controlled by the supply of H_2 to the active sites.

$$3H_2 + C_6H_5NO_2 \rightarrow C_6H_5NH_2 + 2H_2O$$

H_2 must be

1. Transported from the bulk gas phase and dissolved in the liquid nitrobenzene.
2. Diffuse to the outside of the catalyst particle and into the pore structure.
3. H_2 and nitrobenzene react at the catalytic site.
4. Products diffuse through the pores and into the bulk liquid.

Steps 1, 2, and 4 are mass transfer phenomena while step 3 is kinetic.

At steady state the rate of mass transfer of reactants $(Rate)_M$ is equal to the kinetic rate $(\mathrm{Rate})_R$. This assumes Step 4 is fast and not rate limiting.

$$(\mathrm{Rate})_{\mathrm{net}} = (\mathrm{Rate})_{\mathrm{MT}} = (\mathrm{Rate})_{\mathrm{R}}$$

$$(\mathrm{Rate})_{\mathrm{MT}} = k_m(\mathrm{H}_{2g} - \mathrm{H}_{2s})/\mathrm{H}_{2g}$$

$$= 1 - (\mathrm{H}_{2s}/\mathrm{H}_{2g})$$

where H_{2g} = H_2 concentration in the gas

H_{2s} = H_2 concentration at catalyst surface

k_m = Mass transfer rate constant

$$(\mathrm{Rate})_{\mathrm{R}} = k_R(\mathrm{H}_{2s}Q)/H_{2g}$$

where k_R = kinetic rate constant

Q = the amount of catalyst

Equating $(\mathrm{Rate})_{\mathrm{MT}}$ and $(\mathrm{Rate})_{\mathrm{R}}$ and rearranging one obtains

$$(\mathrm{Rate})_{\mathrm{net}} = \frac{k_R k_m Q}{k_R Q + k_m}$$

Taking the inverse for the general rate equation and dividing both sides by $k_R\ k_m Q$, one obtains

$$(\mathrm{Rate})_{\mathrm{net}}{}^{-1} = k_M{}^{-1} + (k_R Q)^{-1}$$

A plot of inverse $(\mathrm{Rate})_{\mathrm{net}}$ vs. the inverse of Q yields a straight line with the slope equal to the inverse of k_R and the intercept the inverse of k_m. This is shown in Fig. 6.5.

When the amount of catalyst Q is large $k_R Q$ ≫ k_m

$$(\mathrm{Rate})_{\mathrm{net}} = k_m$$

The rate is limited by mass transfer because the reactants are consumed immediately at the outer surface of the catalyst. For small amounts of catalysts k_m ≫ $k_R Q$

$$(\mathrm{Rate})_{\mathrm{net}} = k_R Q$$

The reaction is kinetically controlled limited by the amount of catalyst.

Arrhenius Equation. The general rate constant (k) is an exponential function of temperature as described by the Arrhenius equation

$$k = k_o \exp^{(-E/RT)}$$

where

E = Activation energy for chemical control ("apparent" for diffusion limited processes)

R = Universal gas constant

T = Absolute temperature

k_o = Absolute rate constant

Taking the natural log of the equation gives

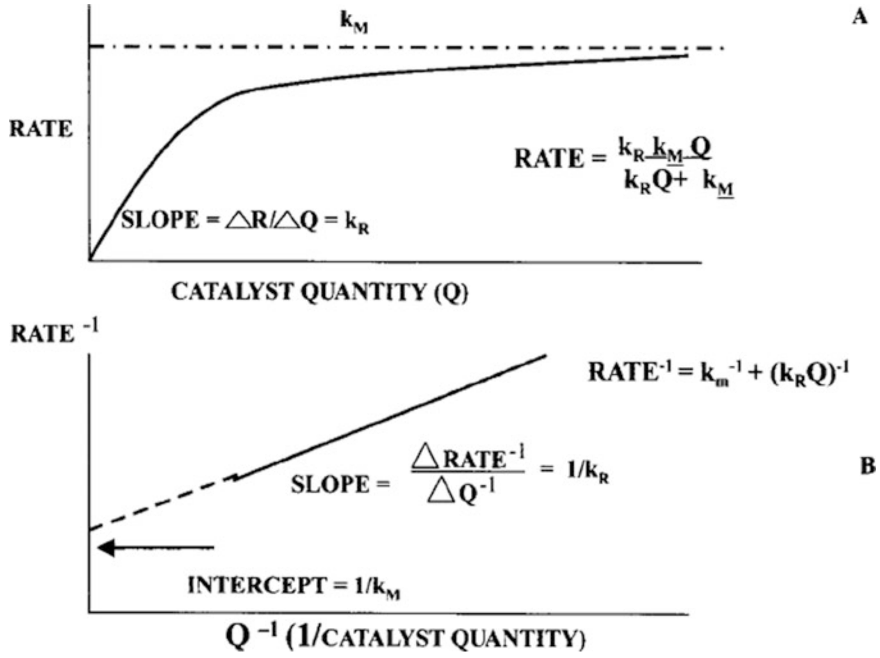


Fig. 6.5 Kinetics for slurry phase/batch reaction: (**a**) rate vs. quantity of catalyst; (**b**) line plot of the rate expression

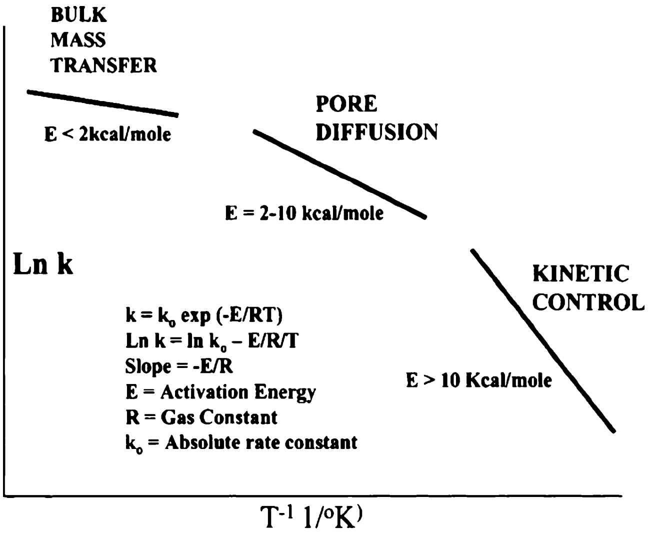

Fig. 6.6 Arrhenius profile for three regimes of rate control with activation energies (E)

$$\ln(k) = \ln(k_o) - E/RT$$

The plot of ln (k) vs. T^{-1} gives a straight line with a slope equal to $-E/R$ and intercept the absolute rate constant k_o as shown in Fig. 6.6. The lowest slope represents reactions controlled by bulk mass transfer, and the largest is for chemical or kinetic control. This method allows for the comparison of different rate-limiting steps, but it must be clearly understood that diffusion processes are not activated and thus we use the term apparent activation energy for them only to allow comparisons to activated processes such as chemically controlled processes.

Rate Models

The Langmuir-Hinshelwood kinetic model describes a reaction in which the rate-limiting step is reaction between two adsorbed species such as chemisorbed CO and O reacting to form CO_2 over a Pt catalyst. The Mars-van Krevelen model describes a mechanism in which the catalytic metal oxide is reduced by one of the reactants and rapidly reoxidizd by another reactant. The dehydrogenation of ethyl benzene to styrene over Fe_2O_3 is another example of this model. Ethyl benzene reduces the Fe^{+3} to Fe^{+2}, whereas the steam present reoxidizes it, completing the oxidation-reduction (redox) cycle. This mechanism is prevalent for many reducible base metal oxide catalysts. There are also mechanisms where the chemisorbed species reacts with a gas phase molecule and the combination rapidly converts to the final product. There are many kinetic models that describe different mechanisms and the reader is directed to some outside references [7–10].

Catalyst Deactivation

The first indication of catalyst deactivation is a significant change in the activity/selectivity of the process. Catalyst deactivation occurs in all processes, but it often can be controlled if its causes are understood. This subject is very extensive and the reader is encouraged to seek additional information in references given here [11, 12]. In the following we will present some of the most common deactivation modes especially for heterogeneous catalysts. These are pictorially shown in cartoon form in Fig. 6.7.

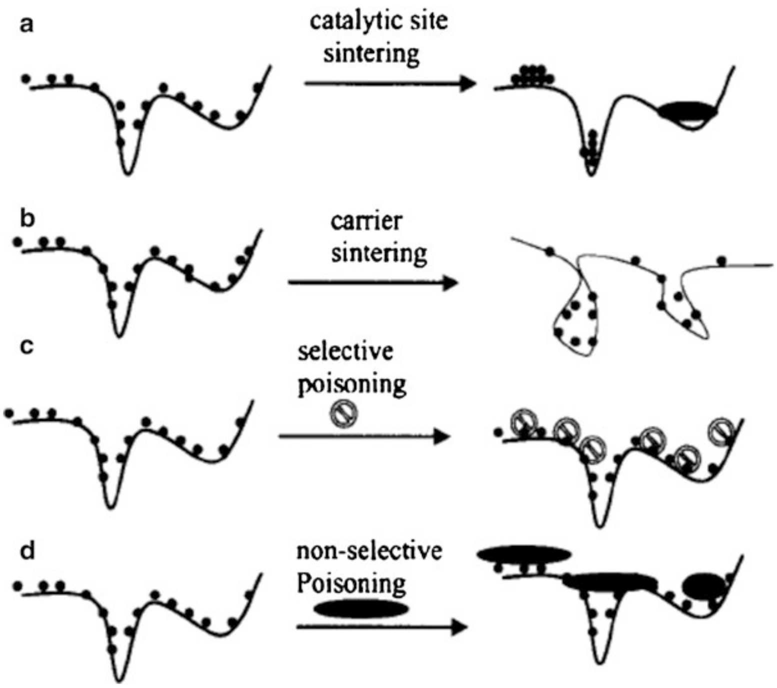

Fig. 6.7 Idealized poisoning mechanism: (**a**) sintering of the catalytic components, (**b**) sintering of the carrier, (**c**) selective poisoning, and (**d**) nonselective poisoning

Sintering of the Active Components. Catalytic scientists go to great lengths to disperse the active catalytic species over the surface of a carrier to maximize the number of sites available to the reactants. Small particles or crystallites have a high surface-to-volume ratio that is a highly unstable thermodynamic condition. The simple principle of Ostwald ripening indicates that small crystallites tend to grow to larger ones to bring the surface to volume condition to a favorable low free energy state. Thermal sintering occurs when small particles of active catalyst migrate over the surface of the carrier and agglomerate to form larger particles. There are other mechanisms of sintering, but conceptually this is the easiest to understand. The net effect is the loss of catalytic surface area that leads to loss of activity. The most frequently encountered cause is high temperature. This condition is encountered in Pt-, Pd-, and Rh-containing catalytic converters present in automobile exhausts where temperatures close to 1,000°C are commonly experienced. An oxidizing environment promotes the sintering of Pt by the formation of highly mobile or volatile Pt oxides. PdO, on the other hand, tends to form a stronger bond with the Al_2O_3 surface and thus sintering is not significant at modest temperatures. In contrast, it does sinter more readily in reducing environments. A catalytic species strongly bound to the surface is less likely to sinter. For this reason, a carrier such as SiO_2, which contains few OH groups on the surface relative to Al_2O_3, leads to sintering of the supported metal or metal oxide more readily. Catalyst companies have incorporated "rare earth stabilizers" into the formulations to minimize the rate of growth of the metal and metal oxide components. Stabilizers slow the rate of sintering, but do not completely prevent it due to the thermodynamic nature of the phenomenon. The goal is to minimize the rate to acceptable levels to ensure acceptable life of the catalyst.

Carrier Sintering. The purpose of the carrier is to provide a high surface area upon which the catalytic components can be dispersed. The high surface area leads to sintering by collapse of the pore structure that subsequently blocks (or occludes) the active sites by preventing access of the reactant. For some carriers such as Al_2O_3, there are changes to the crystal structure that occur as the temperature is increased. The most common is the conversion of high surface area (gamma) γ-Al_2O_3 (200 m^2/g) to low area (alpha) α-Al_2O_3 (1–5 m^2/g) at temperatures greater than about 800°C. This process occludes the catalytic components within the carrier and prevents the reactants from having access. The easiest analogy to understand is the truck that breaks down at the tunnel entrance; it prevents other vehicles from entering. High temperatures and steam are two of the most significant contributors to carrier sintering. Catalyst companies have incorporated metal oxides, such as Ba and La in precise percentages, into the carrier to minimize the sintering rate.

Poisoning. Specific components present in the reactant feed can adsorb selectively onto active catalytic sites rendering them inactive, in much the same way as CO can react with Fe-hemoglobin in the blood. For heterogeneous catalysts, sulfur compounds are the most universal poisons for both base metal catalysts and to a lesser extent precious metals.

Sulfur compounds present in petroleum, chemical, and environmental streams adsorb on the surface of Ni, Cu, Co, etc. forming metal sulfides that have little or no activity. In general, poisoning by sulfur compounds is irreversible. For this reason, upstream processes are used to reduce the sulfur to acceptable levels.

Sulfur oxides (SO_2 and SO_3) present in flue gases from upstream combustion operations adsorb onto the catalyst surface and in many cases form inactive metal sulfates. It is the presence of sulfur compounds in petroleum-based fuels that prevent the super-sensitive base metal catalysts (i.e., Cu, Ni, Co, etc.) from being used as the primary catalytic components for many environmental applications. Precious metals are inhibited by sulfur and lose some activity, but usually reach a lower but steady state activity. Furthermore, the precious metals are reversibly poisoned by sulfur compounds and can be regenerated simply by removing the poison from the gas stream. Heavy metals such as Pb, Hg, As, etc. alloy with precious metals and permanently deactivate them. Basic compounds such as NH_3 can deactivate an acidic catalyst such as a zeolite by adsorbing and neutralizing the acid sites.

Water is a reversible poison in that it will weakly adsorb (physically adsorb) on sites at low temperature, but readily desorbs as the temperature is increased.

One interesting example of different selective poisoning mechanisms is that of SO_3 deactivation of Pt on Al_2O_3 used for abating emissions from combustion reactions. The Pt oxidizes the SO_2 to SO_3 and the latter adsorbs onto the Al_2O_3 forming a sulfate. Slowly the carrier surface becomes so sulfated that it occludes the Pt within the pores and the catalyst slowly deactivates. By using a nonsulfating carrier such as TiO_2 or ZrO_2, deactivation can be prevented. In contrast, SO_3 directly adsorbs on Pd sites and deactivation occurs rapidly.

Poisoning is not always bad. There are situations where a catalyst is intentionally poisoned to decrease activity towards an undesirable reaction. In the hydrodesulfurization and -demetallization of a petroleum feedstock, the catalyst is presulfided prior to introducing the feed to decrease its activity and minimize cracking reactions that will produce unwanted gases. Another is the use of ammonia to slightly poison a Pt catalyst used in the hydrogenation of fats and oils to decrease undesirable oversaturation.

Nonselective poisoning or masking is caused by debris depositing on the surface of the catalyst physically blocking sites. Corrosion products from the reactor walls and contaminants such as dust, oil, etc. can be eliminated by careful filtration upstream, but this mechanism of deactivation is a constant problem in many applications. Regeneration is possible for precious metal oxidation catalysts designed to abate VOC from flue gases. The reactor is bypassed when the activity begins to decline to unacceptable levels. High-velocity air is passed through the catalyst bed and loosely held debris is dislodged. In some cases chelating solutions are used to solubilize the metal contaminants such as Fe without destroying the catalyst. Coking is a common phenomenon when petroleum and/or high molecular weight chemical compounds are processed. Hydrogen-deficient-hydrocarbons are formed from undesirable side reactions and block access to the catalytic sites deep within the pores of the catalyst. This deactivation mode has been positively integrated into the fluid catalytic cracking process for converting heavy oils to useful products. The coked catalyst is regenerated with air in a separate reactor and the heat liberated used to preheat the feed as it enters the cracker.

Catalyst Characterization

The goal of catalyst characterization is to relate the physical and/or chemical properties of the catalyst to performance. Some of the most important catalytic properties are physical surface area, pore size distribution, active catalytic surface area, the morphology or crystal structure of the carrier and active components, the location of the active components within the carrier, and the presence of surface contaminants or poisons on the surface. Fortunately, there are many instrumental tools readily available in modern laboratories to measure these properties for fresh and spent catalysts. There are many reference books and monographs available that describe the strengths and limitations of the instrumental methods used in characterizing catalysts [13, 14].

The chemical composition can be measured by traditional wet and instrumental methods of analysis. Physical surface area is measured using the N_2 adsorption method at liquid nitrogen temperature (BET method). Pore size is measured by Hg porosimetry for pores with diameters larger than about 3.0 nm (30 Å) or for smaller pores by N_2 adsorption/desorption. Active catalytic surface area is measured by selective chemisorption techniques or by X-ray diffraction (XRD) line broadening. The morphology of the carrier is viewed by electron microscopy or its crystal structure by XRD. The active component can also be measured by XRD, but there are certain limitations once its particle size is smaller than about 3.5 nm (35 Å). For small crystallites, transmission electron microscopy (TEM) is most often used. The location of active components or poisons within the catalyst is determined by electron microprobe. Surface contamination is observed directly by X-ray photoelectron spectroscopy (XPS).

Making the characterization measurements is of critical importance in the diagnostics of the catalysts, but interpreting those most responsible for changes in activity or selectivity requires experience and good comparative kinetics for fresh and aged materials. It should be standard practice to compare fresh and aged catalytic performance with the changes observed in your characterization diagnostics. Measuring rate-limiting steps and activation energies will provide invaluable insight into the major causes of deactivation.

Homogeneous Catalytic Reactions

In a homogenous catalytic reaction, the reactants and catalysts are in the same phase. The catalyst is a metal (Rh, Co, Ni, etc.) chelated with organic ligands (often phosphine-containing) soluble in the reaction media, and because no support is used, pore diffusion does not exist. However, bulk mass transfer is a concern especially when the reaction is a hydrogenation because H_2 must be dissolved in the liquid and make contact with the catalyst. This is accomplished by using high pressure and vigorous stirring. Homogeneous catalysis is most often used in the pharmaceutical industry where the desired selectivity can only be achieved with active complexes. A significant issue is separation of the catalyst from the final product to achieve the required purity. Furthermore, recovery of the catalyst is most often necessary especially for expensive precious metal containing complexes such as Rh. Distillation is sometimes used, provided there is a significant difference in vapor pressure of the product from the catalyst. The catalyst is also recovered by ion exchange with a suitable sequestering agent such as an amine compound. The efficiency of the separation allows for catalyst reuse and is essential for an economic process.

An example will be given in "Commercial Applications."

Commercial Applications

There are literally hundreds of commercial catalytic processes carried out for high and low volume premium products. Only a few have been selected below as examples of everyday products essential for a high-quality life. Table 6.1 also presents listings of some of the major catalytic processes, but the reader is directed to references given in this review for a more complete listing [10].

Petroleum Processing

Hydro-Demetallization (HDM) and -Desulfurization (HDS) of Heavy Oils. The hydrocarbon petroleum fractions separated by distillation contain varying amounts of inorganic impurities such as nickel, vanadium, and sulfur-containing compounds, all of which must be removed to make high-quality products both functionally and environmentally. The high-boiling fractions contain the highest concentration of metals and sulfur [15, 16]. Metals, if present in gasoline or diesel, will create significant engine wear and the sulfur would produce sulfur oxides during combustion and ultimately sulfuric acid in the atmosphere. Furthermore, they will deactivate the catalysts used in the petroleum upgrading processes and in their ultimate application as a fuel will damage the performance of the abatement catalyst.

Crude oil contains about 0.01% metals and up to 5% sulfur present in large aromatic structures. These levels are highly dependent on the origin of the crude. For example, California crude is relatively low in sulfur but higher in metals than crude from Kuwait. Any process to remove them must be economical with little destruction of the hydrocarbons and minimum consumption of H_2. The catalyst is Co, Mo/Al_2O_3 with particles a few mm in diameter. Although sulfur is usually a poison for catalytic reactions, it is used here in a positive function to control selectivity. It is presulfided to decrease activity towards excessive consumption of H_2 that leads to unwanted saturation of aromatic molecules.

$$\begin{aligned}
&\mathrm{SCo,\ Mo/Al_2O_3}\\
&\mathrm{R-M+H_2 \rightarrow M+R-H}\\
&\mathrm{R'S+H_2 \rightarrow R-M+H_2S}\\
&\mathrm{R\ and\ R'} = \text{organic host of metals and sulfur}\\
&\mathrm{M} = \text{metal (Ni or V)}
\end{aligned}$$

R and R′ = organic host of metals and sulfur M = metal (Ni or V)

The hydrogenation process is carried out at 500°C and pressures in excess of 30 atm in fixed bed reactors containing catalysts with varying physical properties to accommodate the metal deposition that occurs during the reaction. In some cases moving bed reactors are used where spent catalyst is continuously removed and fresh catalyst added.

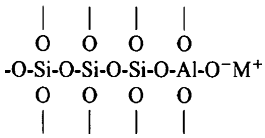
The first reactor contains the Co, Mo deposited on a low surface area Al_2O_3 with large pores to allow deep penetration of the metals into the particle. The second bed will treat a feed with less metal so its pore size is smaller and surface area slightly larger. The metal penetration here is less deep than in the first bed and allows for some hydrodesulfurization. The final bed contains the highest surface area and smallest pores and is designed to perform most of the desulfurization.

The catalyst is regenerated frequently during its useful life, but once spent it is leached and the metals recovered.

Catalytic Cracking for the Production of Useful Fuels. Gasoline and diesel fuel, home and commercial heating oil, kerosene, jet fuel, etc. are all produced by catalytically cracking fractions of distilled crude oil. Crude oil is distilled in large vertical towers where the various fractions present are separated according to their boiling ranges. The light gases (C_3 and C_4 propane and butane, respectively) are distilled first and the light/heavy naphtha fraction (C_5 to C_{10} pentanes to branched cyclopentanes), the precursors to gasoline, distill between roughly 70 and 200°C. Diesel fuel and heating oils (No. 1 and 2) are collected between 200 and 340°C. The remaining heavy hydrocarbons (called vacuum distillates) are used for lubricants and road construction.

The composition and molecular weight distribution of the crude oil depends on its origin, but generally less than 50% is within the molecular and boiling range for transportation and heating fuels. Thus, the role of the cracking process is to break or crack the higher molecular weight fractions into lower molecular weight compounds to be used for more useful products. Therefore, the catalyst is at the heart of the refining industry.

Cracking Catalysts. The catalysts used for cracking are called zeolites [17, 18]. They are SiO_2–Al_2O_3 materials in which Si, in its tetrahedral SiO_2 structure, is replaced with Al cations. They are produced by reacting sodium silicate with a water-soluble salt of Al followed by hydrothermal treatment in an autoclave. The zeolite is unique in that it has a well-defined crystal structure with a precise pore size (or aperture) ranging typically from 0.3–4 nm or 3–40 Å. This unique pore structure is responsible for separating molecules in accordance with their cross-sectional area. A molecule smaller than the aperture can enter the interior although a larger one cannot. Hence, the term molecular sieve is often used to describe zeolites. The composition and pore size can be varied giving rise to a large number of different zeolites with different pore sizes and crystal structures. They are usually identified by the Si/Al ratio, the crystal structure, and the size and shape of the pore. The Si^{+4} is bonded to 4 O^{-2} and each is bonded to another Si^{+4} establishing charge neutrality. Substituting Al^{+3} for Si cation upsets charge neutrality and requires another positive charge to satisfy the oxygen ions.



$$\begin{array}{c} | \quad\ \ | \quad\ \ | \quad\ \ | \\ \text{O} \quad \text{O} \quad \text{O} \quad \text{O} \\ \text{-O-Si-O-Si-O-Si-O-Al-O}^{-}\text{M}^{+} \\ \text{O} \quad \text{O} \quad \text{O} \quad \text{O} \\ | \quad\ \ | \quad\ \ | \quad\ \ | \end{array}$$

Neutrality is satisfied by a cation (e.g., M^+), which is usually Na^+ derived from the salts used in the synthesis. When the cation is exchanged with a proton, an acid site is created. This is the key active site for catalytic cracking reactions. The first exchange is with NH_4^+ which when heat-treated decomposes to NH_3 and the H^+ is retained on the zeolite. The acid zeolite is designated HZ.

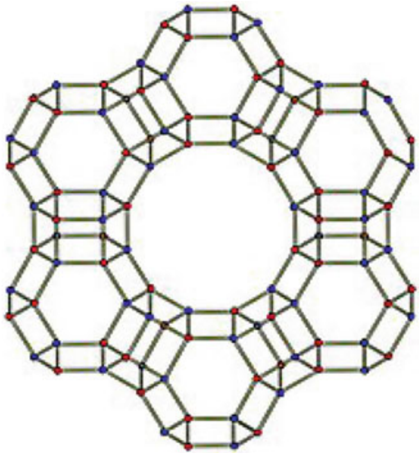


Fig. 6.8 Faujasite zeolite

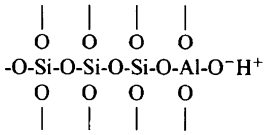

$$\begin{array}{c} | \quad\ \ | \quad\ \ | \quad\ \ | \\ \text{O} \quad \text{O} \quad \text{O} \quad \text{O} \\ \text{-O-Si-O-Si-O-Si-O-Al-O}^{-}\text{H}^{+} \\ \text{O} \quad \text{O} \quad \text{O} \quad \text{O} \\ | \quad\ \ | \quad\ \ | \quad\ \ | \end{array}$$

The active zeolite for cracking reactions is called Faujasite and is classified as an X zeolite (HX). It has a Si/Al ratio of 1.0–1.5 with a pore or aperture size of 0.74 nm or 7.4 Å forming an aperture composed of 12 oxygen anions as shown in Fig. 6.8. The midpoint of each line represents an O^{-2} bonded to either Si^{+4} or Al^{+3}. It is the AlO^- site that requires a metal cation for charge balance. For cracking catalysts these sites are H^+. The higher the Al content (lower Si/Al), the greater the number of acid sites, but the lower the thermal stability. The zeolite is embedded within an amorphous SiO_2–Al_2O_3 structure that initiates the cracking of the large molecules, but also captures impurities such as organic compounds containing Ni and V that will severely deactivate the zeolite. Having its own acid sites, it also functions to break large molecules into smaller sizes where the zeolite can polish them to desired products. Catalyst particle sizes vary between 50 and 100 μm depending on the fluidization dynamics of the process.

During the fluidized catalytic cracking (FCC) process, a C–C bond is broken and a proton transferred from the catalyst to the molecule forming a positively charged carbocation. This ion can react with other hydrocarbons transferring its proton generating new carbo cations. Ultimately the large molecule is cracked to a smaller alkane and alkene with the regeneration of the protonated zeolite completing the catalytic cycle.

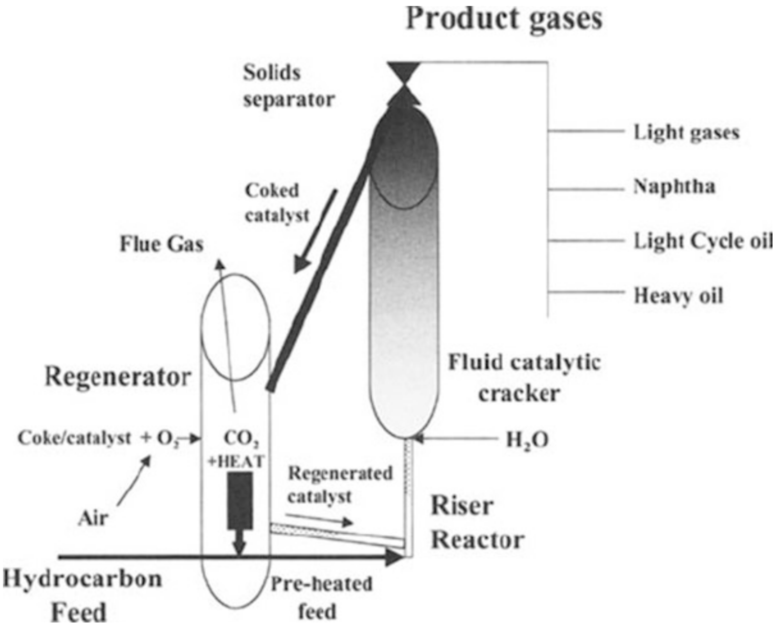

Fig. 6.9 Schematic of Fluid Catalytic Cracking (FCC) reactor with catalyst regenerator

Paraffin cracking: $C_{16}H_{34} \overset{HX}{\rightarrow} C_8H_{18} + C_8H_{16}$

Catalyst HX

Dealkylation: $C_6H_5 - CH_2CH_3 \overset{HX}{\rightarrow} C_6H_5H + CH_2 = CH_2$

Catalyst HX

Excessive extraction of H leads to the formation of hydrogen-deficient, high-boiling hydrocarbons called coke. Coking reactions are catalyzed by acid. The coke masks the surface and blocks the pore of the catalyst preventing access of the feed molecules leading to a loss in activity.

Cracking is carried out in a fluid bed process as shown in Fig. 6.9. Catalyst particles are mixed with feed and fluidized with steam upflow in a riser reactor where the reactions occur at around 500°C. The active life of the catalyst is only a few seconds because of deactivation caused by coke formation. The deactivated catalyst particles are separated from the product in a cyclone separator and injected into a separate reactor where they are regenerated with a limited amount of injected air. The regenerated catalyst is mixed with the incoming feed which is preheated by the heat of combustion of the coke.

Zeolites play a major role as catalysts and/or adsorbents in the petroleum, chemical, and lately in a growing number of environmental applications. The reader should consult references available [18].

Naphtha Reforming for High-Octane Gasoline. Gasoline is volatilized and injected into the cylinders of the internal combustion engine where it is ignited under compression by a spark plug in the power stroke. Maximum power occurs when the cylinder reaches top dead center (maximum compression) and the mixture ignited by the spark plug. A high-octane gasoline is formulated not to preignite before reaching top dead center during compression to avoid the pinging or "knocking" sound that detracts from power. Before the mid-1970s, tetraethyl lead was added to quench preignition reactions, but because lead is no longer permitted the gasoline must be formulated to resist combustion until initiated by the spark. High-octane compounds such as aromatics and branched-paraffins are used in place of lead compounds. Today oxygenates are added to boost octane allowing decreases in carcinogenic aromatics.

Fuel-quality gasoline is made by a process called catalytic reforming [19, 20] in which molecules in the gasoline boiling range (called naphtha) are isomerized, dehydrogenated, and aromatized to make high-octane products. The most widely used reforming catalyst is Pt, Re on chlorinated Al_2O_3 particles (3–5 mm diameter). The Pt is the active component primarily for dehydrogenation and aromatization reactions and the Cl adds to the acidity of the carrier and is the active site for isomerization. The Re is believed to minimize coke formation. Dehydroisomerization requires both metal and acid functions. Some reactions are endothermic (dehydrogenation and dehydroisomerization) and others are exothermic (isomerization and dehydroaromatization). One can see below that the reactions lead to an increase in octane number

The dehydrogenation of cyclohexane to benzene and H_2 increases the octane number from 75 to 106.

$$C_6H_{12} + \text{HEAT} \xrightarrow{\text{Pt site}} C_6H_6 + 3H_2$$

Isomerization of *n*-butane to *i*-butane increases octane from 94 to 101.

$$CH_3CH_2CH_2CH_3 \xrightarrow{\text{acid site}} CH_3\,\overset{CH_3}{CH}CH_3 + HEAT$$

Heptane has a defined octane number of 0 and when dehydroaromatization occurs toluene is formed with an octane number of 116.

$$CH_3CH_2CH_2CH_2CH_2CH_2CH_3 \xrightarrow{\text{Pt + acid site}} C_6H_5CH_3 + 4H_2 + HEAT$$

The formation of benzene by the dehydroaromatization coupled with isomerization of methyl cyclopentane also increases octane from 76 to 106.

$$CH_3{-}C_5H_9 + HEAT \xrightarrow{\text{Pt + acid site}} C_6H_5H + 3H_2$$

The reforming process operates with three or four reactors in series. The feed is delivered to the first reactor at 500°C that is charged with the smallest amount of catalyst (5% of the total and the highest space velocity) to perform the easy but highly endothermic dehydrogenation reactions. To minimize coke formation, a small amount of H_2 is recycled from the product. The products and unreacted feed are then reheated to 500°C and fed to a second bed containing about 15% of the total catalyst charge where isomerization reactions occur. The unreacted feed and product are then reheated to 500°C where the more difficult dehydroisomerization reactions take place with 20% of the total catalyst charge. The final reactor contains 60% of the total catalyst charge and performs dehydrocyclization. Swing reactors are in place to allow the process to continue as each bed is being regenerated by coke burn-off. After regeneration, the catalyst must be rejuvenated by the addition of chloride. The final step is reduction of the metal to its active state.

Alternative Fuels

A secure energy supply and the need for reduction of greenhouse gas emissions will continue to be a technological goal for the world throughout the next few decades. It has become apparent that we need a fossil free energy supply. Solar, wind geothermal, tidal, etc. are natural sources of energy that are beginning to be utilized for stationary power generation. The promise of a hydrogen economy and fuel cell vehicles is also on the horizon. These technologies are slowly being introduced; however, we need a transitional approach for liquid fuels for vehicular applications. Biofuels, derived from plants, are already making an impact partially replacing fossil fuels in both gasoline and diesel applications [21]. In the US, ethanol is commonly added (10%) to gasoline, while bio diesel additions to fossil derived diesel can range from 2 to 100% depending on the locations and country of use.

Ethanol is derived primarily for corn, and other starchy plants, by the well known fermentation process where enzymes (nature's catalysts) accelerate the conversion of starch to ethanol. Bio diesel is synthesized by the homogeneous alkali catalyzed transesterification of triglyceride oils derived from plants such as soy and canola. Both alternative fuels are derived from edible plants which conflict with the food chain.

For this reason, there is a strong interest in utilizing non-edible portions of the plant, called lignin-cellulose as a source of fuel, especially ethanol. One of the main issues is the efficient penetration of the lignin (un-reactive aromatic polymer) portion of the plant which exists as a protective fiber surrounding the hemi cellulose and cellulose (sugar polymers of glucose), both of which are somewhat reactive towards enzymatic catalyzed fermentation to ethanol. This problem has stimulated the chemical and biochemical approach of developing new pretreatment techniques, including new enzymes, which can breakdown the lignin without destroying the ability to ultimately ferment the cellulose to ethanol. Alternatively, the thermal-chemical approach of gasification or pyrolysis of lignin-cellulose to produce gases and bio oils is being explored as a source of fuel. The gaseous and liquid products will require more traditional heterogeneous catalysts for upgrading to useable fuels.

Biodiesel can be derived also from non-edible plants such as jathropa and pennycress, both of which are rich in triglyceride oils relative to edible plants. These plants grow on arid lands during summer and winter seasons with little need for fertilizers. Research in harvesting and utilizing these plants is in progress with catalysts being used to upgrade the products to useful fuels.

Catalysts for Controlling Automotive Emissions

Oxidation Catalysts to Abate Unburned Hydrocarbon and CO Emissions

Catalytic converters were first installed in U.S. cars in 1976 [22, 23]. They were passive devices in that they were simply placed in the exhaust with no communication with the engine or its control strategy. It catalyzed the oxidation of the unburned hydrocarbons (C_yH_n) and carbon monoxide (CO) emitted during the incomplete combustion of the fuel. In some vehicles, excess air was pumped into the exhaust to ensure sufficient oxygen to complete the catalytic oxidation. This resulted in about a 90% reduction of these two pollutants relative to the uncontrolled uncatalyzed vehicle.

$$CO + \frac{1}{2}O_2 \rightarrow CO_2 + HEAT$$
$$C_yH_n + (1 + n/4)O_2 \rightarrow yCO_2 + n/2H_2O + HEAT$$

The presence of the catalyst provides a lower-energy chemical path than that offered by a thermal reaction. A catalyst accelerates oxidation of hydrocarbon/carbon monoxide/air mixtures that lie outside the flammability range required for thermal reactions. In the exhaust of the automobile, the composition of the pollutants is far below the flammability range, yet the oxidation reactions occur by the catalyst providing a lower-energy chemical path to that offered by the thermal reaction. An excellent example is the oxidation of CO with and without a catalyst. Without a catalyst, the rate-limiting step is O_2 dissociation at 700°C followed by reaction with gas phase CO. In the presence of the Pt catalyst, O_2 dissociation is rapid and the rate-limiting step becomes the surface reaction between adsorbed O atoms and CO that occurs below 100°C.

Two approaches were used in the design of the converters, both of which were positioned in the exhaust physically under the driver's seat. Both used precious metals (Pt and Pd) as the active catalytic components dispersed on Al_2O_3 (stabilized against carrier sintering with 1–2% CeO_2 and sometimes alkaline earth metal oxides).

One major automobile company used catalyzed Al_2O_3 beads (4 mm in diameter) and a spring-loaded pancakelike vessel to decrease the linear velocity and thus pressure drop. This design decreases back pressure that detracts from the power by offering less resistance to flow. Another used a new ceramic monolithic structure with hundreds of parallel channels (see Fig. 6.4). Upon the walls was deposited a coating of stabilized Al_2O_3 containing the active precious metals. The cordierite structure ($2MgO–5SiO_2–2Al_2O_3$) has a melting point over 1,300°C sufficiently high to withstand the expected temperatures in the exhaust. It was extruded and had excellent resistance to breakage due to thermal shock experienced during the transient operation of the vehicle. The cellular structure had between 200 and 400 cells per square inch (cpsi) parallel to the flow. With channel diameters of 0.059 in. (200 cpsi) and 0.044 in. (400 cpsi), they had open frontal areas of about 70%, offering little resistance to flow and thus low back pressure. It was incorporated into the exhaust system with retainer rings and surrounded by layers of insulation to minimize breakage due to vibration and heat. The regulations required that the converter have a life of 50,000 miles. To ensure this life, it was necessary to remove the tetraethyl lead, used to boost octane, in gasoline because the Pb poisoned the Pt and Pd by alloy formation.

Oxidation catalysts were used until 1979 in both the particulate (bead) form and monolith structure. Road experience demonstrated that the particulate beds were not mechanically stable and were breaking apart. In contrast, the washcoated monoliths were found to be highly reliable so they became the structure of choice.

Three-Way Catalytic Conversion

In 1980, additional regulations imposed by the U.S. Environmental Protection Agency (EPA) required control of NO_x (NO, NO_2, N_2O) emissions. Its removal coupled with the continuing need to remove CO and C_yH_n proved to be quite challenging because the latter had to be oxidized and the former reduced. Thus, it appeared two separate environments were needed. This problem was solved by the development of the three-way catalyst or TWC capable of catalyzing the conversion of all three pollutants simultaneously, provided the exhaust environment could be held within a narrow air-to-fuel range. This is shown in Fig. 6.10.

This range was defined between the fuellean and fuel-rich sides of the stoichiometric point, where the amount of O_2 is precisely sufficient for oxidizing both the CO and C_yH_n. This control required an O_2 sensor that is discussed below.

In the TWC, the Pt functions primarily as the catalyst for the oxidation reactions and the Rh catalyzes the NO_x reduction.

$$CO + NO(\text{or } NO_2) \rightarrow \frac{1}{2}N_2 + CO_2$$

$$H_2 + NO(\text{or } NO_2) \rightarrow \frac{1}{2}N_2 + H_2O$$

$$C_yH_n + (2 + n/2)NO(\text{or } NO_2) \\ \rightarrow (1 + n/4)N_2 + yCO_2 + n/2H_2O$$

The second reaction requires H_2 that is produced catalytically by the steam reforming reaction that occurs when excess C_yH_n is present.

$$C_yH_n + (n - 2)H_2O \rightarrow (n + 1)H_2 + yCO_2$$

O_2 Sensor. The control of the exhaust composition was essential to maintain the air-to-fuel ratio close to stoichiometric for simultaneous conversion of all three pollutants. This control came about with the invention of the O_2 sensor [23, 24]. The sensor head of this device was installed in the exhaust immediately at the inlet to the catalyst and was able to measure the O_2 content instantly and precisely.

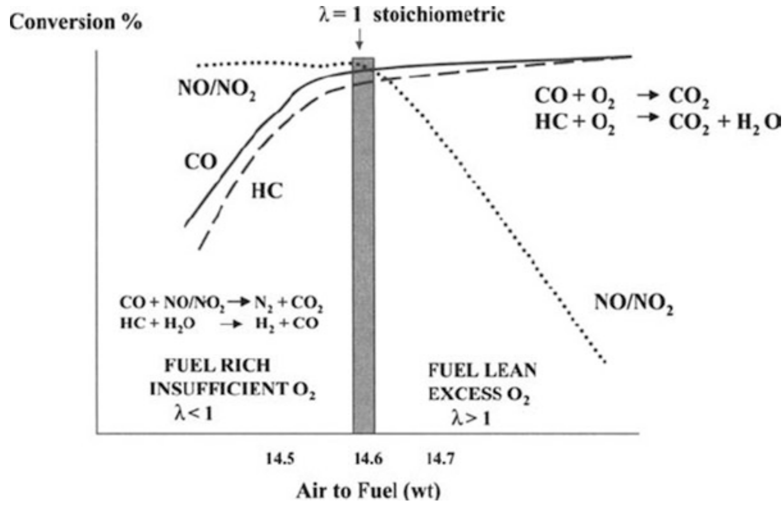

Fig. 6.10 Three-way catalytic (TWC) converter profile for conversion vs. air-to-fuel ratio

It generates a voltage consistent with the Nernst equation in which the partial pressure of O_2 $(PO_2)_{exhaust}$ in the exhaust develops a voltage (E) relative to a reference. The exhaust electrode was Pt deposited on a solid oxygen ion conductor of yttrium-stabilized zirconia (ZrO_2). The reference electrode, also Pt, was deposited on the opposite side of the electrolyte, but was physically mounted outside the exhaust and sensed the partial pressure $(PO_2)_{ref}$ in the atmosphere. E_o is the standard state or thermodynamic voltage. R is the universal gas constant, T the absolute temperature, n the number of electrons transferred in the process, and F the Faraday constant.

$$E = E_o + RT/nF[\ln (PO_2)_{ref}/(PO_2)_{exhaust}]$$

The CO and C_yH_n catalytically react with the O_2 at the surface of the Pt electrocatalyst. When the O_2 content is below stoichiometric, the electrode surface is depleted of O_2 causing an increase in the $(PO_2)_{ref}/(PO_2)_{exhaust}$ generating a large voltage. When the O_2 is higher than stoichiometric, the voltage is decreased. Thus, the electrodes must also function as catalysts. The voltage signal generated continuously fluctuates as the O_2 content is adjusted from sub to excess stoichiometric. Naturally, the exhaust electrode had to be resistant to exhaust poisons and temperature variations, so it was engineered with great care.

The voltage signal is fed back to the air/fuel intake system of the engine through an electronic control unit that controls the ratio necessary to maintain the proper window in the exhaust. Given the finite time necessary for the feedback system to function, it creates a perturbation of the O_2 content in the exhaust. The TWC catalyst had to be engineered to respond to these changes. The catalyst was composed of Pt, Rh on stabilized Al_2O_3 on a ceramic monolith, but an oxygen storage component (OSC) capable of storing and releasing O_2 was added. When the engine momentarily delivers less O_2 than the stoichiometric amount, the hydrocarbons present reduce the OSC. During higher O_2 spikes, the excess is stored on the OSC according to the fuel lean reaction below.

$$\text{Fuel rich:}\quad 2CeO_2 \rightarrow Ce_2O_3 + \frac{1}{2}O_2$$

$$\text{Fuel lean:}\quad Ce_2O_3 + \frac{1}{2}O_2 \rightarrow 2CeO_2$$

The current OSC material is CeO_2–ZrO_2 (proprietary promoters are added to stabilize it against sintering) where the oxidation state of the cerium is sufficiently labile to respond to the requirements for the OSC. The ZrO_2 is added to enhance thermal stability of the OSC.

U.S. federal regulations require that the driver be alerted to a malfunctioning catalyst through a signal on the dashboard. Currently, there is no instrumentation commercially available to sense the effectiveness of the catalyst to meet the onboard diagnostic requirement. An indirect solution is to place a second O_2 sensor at the exit of the catalytic converter. If the OSC in the catalyst is working properly, its voltage signal would have virtually no fluctuations because the O_2 content would be always zero. If the OSC is not functioning properly, O_2 will break through at the exit and the sensor would undergo similar fluctuations as the inlet sensor. Comparing these two signals generates the diagnostic that informs the operator of a malfunction.

A modern converter with dual O_2 sensors (one at the inlet and one at the outlet) is shown as Fig. 6.11.

Modern Catalytic Converter Systems

Modern TWC-equipped vehicles are required to meet minimum emission standards for 150,000 miles [23, 24]. It should be understood that after this time period the catalyst

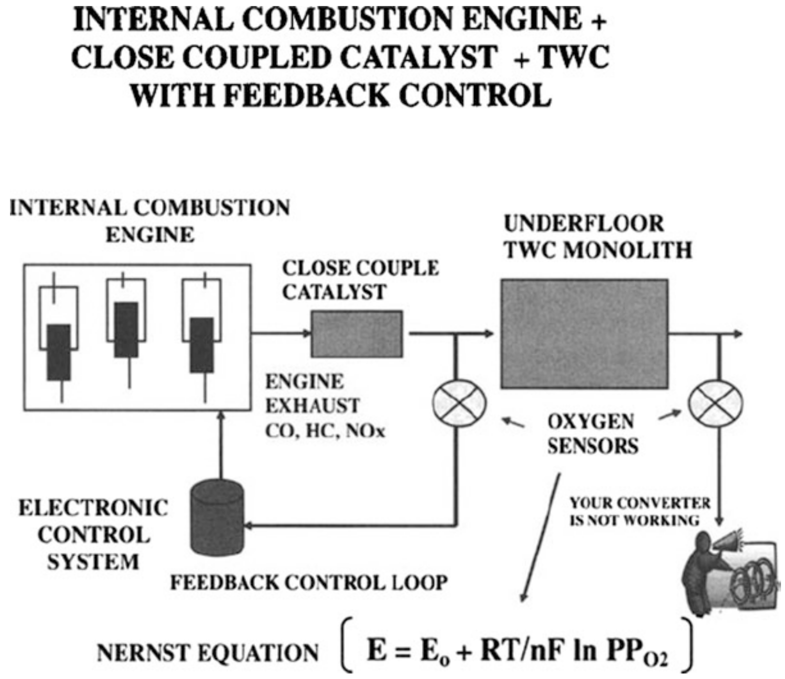

Fig. 6.11 Schematic of a exhaust system with a close couple and TWC catalyst. The system is equipped with dual O_2 sensors, one at the inlet and one at the outlet of the TWC converter

is still extremely active, but has lost sufficient activity that it no longer meets the stringent EPA standards. The source of deactivation is sintering of the catalytic metals, especially the OSC and the carrier due to the extremely high temperatures (900–1,000°C) experienced in the exhaust. The steam produced from combustion enhances the degree of sintering. There are proprietary stabilizers added to the formulations that minimize the extent of sintering. Poisoning effects by sulfur and oil components (Zn, P, Ca, S, etc.) have been minimized by reductions in fuel sulfur and careful design of the washcoat to prevent contact of the poisons with the catalytic components. These catalyst improvements, coupled with enhanced engine control, have resulted in lifetimes of at least 150,000 miles.

At start-up, the catalyst is cold and there is a substantial emission of hydrocarbons. It is during the first 1 or 2 min of cold-start operation that the vehicle can fail the federal test procedure. Here the reaction is kinetically controlled. Once it gets sufficiently warm, the reaction exotherm quickly raises the temperature and the reaction becomes limited by bulk mass transfer. The space velocity varies between 5,000 (idle) and 75,000 h^{-1} at high speed. So manufacturers had to design the catalyst for kinetic control and bulk mass transfer conditions. The cold-start issue was addressed by positioning a small oxidation catalyst (close coupled) up against the exhaust ports of the engine to ensure rapid heat up and light-off. This is shown in Fig. 6.11. The newest cordierite monoliths have lower weights for faster light-off and high geometric areas (600–900 cpsi) to ensure adequate bulk mass transfer area and lower pressure drop to meet modern driving demands and ever-increasing regulations.

It is truly remarkable that catalysts can function so well in the exhaust of the modern high-speed vehicle. This fact has raised confidence in industry to use different monolithic (ceramic and metal) structures as supports for catalysts for other environmental applications such as diesel exhausts, power and chemical plants, restaurants, and even on widebody aircraft.

Controlling Emissions from Diesel Engines

The diesel engine was invented by Rudolph Diesel in the latter part of the nineteenth century. Due to significant benefits in fuel economy, they have enjoyed a surge in popularity in recent years, particularly in Europe where they represent approximately 50% of new cars sold. Although improved fuel efficiency is the key driver, improvements in the drivability of diesel vehicles as well as a reduction in their tailpipe emissions have also helped improve their image and spurred further growth. Unlike gasoline emissions that are mainly gaseous in nature, diesel emissions from passenger cars, buses, and trucks contain solid, liquid, and gaseous components. Both diesel fuel and operation of the engine differ significantly from gasoline spark ignited engines and therefore their emission profiles are much more complicated. Diesel fuel has a boiling range from 200 to 350°C. The four-stroke engine compresses air and at maximum compression (top dead center) injects liquid fuel into the mixture where combustion occurs spontaneously driving the piston downward in the work stroke. Diesel engines operate with a large excess of air ($\lambda \gg 1$)

and therefore three-way catalysts, which operates at ($\lambda \sim 1$), will not catalyze the reduction of NO_x. Furthermore, the reduction of total particulate matter (TPM) must be addressed with new technology [23].

Based on the combustion characteristics of lean burn compression ignition diesel engines, the focus of emission regulations is on two key tailpipe pollutants—TPM and NO_x. Both of these are produced in high quantity during combustion. Since diesel fuel is less volatile than gasoline and is injected directly into the cylinder as a liquid, combustion initiates before the fuel has had sufficient time to vaporize and mix completely with the air. As a result, combustion begins at the gas–liquid interface of the fuel spray and then progresses towards the center. This "diffusion combustion" phenomenon results in the production of significant amounts of NO_x at the fuel liquid–gas interface where the local temperature and oxygen concentrations are high. In contrast, high amounts of soot (dry carbon) are generated in the interior of the spray where the temperature and oxygen concentrations are lower. As a result, both soot and NO_x are produced simultaneously in large amounts from diesel engines. This relationship between combustion temperature-particulates and NO_x is called the NO_x-particulate trade-off. When NO_x emissions are high (e.g., at high combustion temperatures), particulate emissions are low. In contrast, NO_x emissions are low (e.g., at lower combustion temperature), but the particulate emissions are high.

Also shown on this profile are the emission standards to be met for different countries and years. Clearly, regulations are requiring that both particulate and NO_x emissions be reduced to close to zero by 2010 and beyond in the US with other countries following closely.

Due to the adverse health effects associated with diesel soot and the ozone forming potential of NO_x, both are the major focus for emissions regulations. Although CO and HC are also regulated, the amounts produced by diesel engines are generally low enough not to be a major obstacle for meeting emission regulations. This is particularly true for heavy duty diesel applications.

The solids emitted from diesel engines are essentially dry soot (carbon rich particles). The liquids are primarily unburned diesel fuel and lubricating oils (commonly referred to as soluble organic fraction or SOF) and to some extent sulfates originating from the combustion of the sulfur compounds present in the diesel fuel. The combination of solid and liquid pollutants is referred to as particulates or TPM. Note that H_2SO_4 derived from the combustion of sulfur compounds in diesel fuel is included since it is a liquid at the collection conditions for TPM. The gaseous pollutants are CO, HC, and NO_x.

Total Particulate Matter
- Dry soot
- Liquids (oil, fuel) called SOF
- H_2SO_4

Gases
- CO, HC, NO_x

Diesel Oxidation Catalysts

The diesel oxidation catalyst (DOC) has two primary functions (1) to oxidize the CO and HC's emitted from the engine and (2) oxidize injected diesel fuel to generate heat for regenerating the particulate filter (to be discussed next). This catalyst is primarily a mixture of Pt and Pd on stabilized Al_2O_3 deposited on a ceramic monolith.

Regulations for dry soot reduction required an additional solution. This led to the introduction of the wall flow or diesel particulate filter (DPF). A DPF is primarily a cordierite honeycomb structure with alternating adjacent channels plugged at opposite ends. Exhaust enters the open channels, but only the gaseous components can pass through the porous wall exiting via the adjacent channel. Soot that is entrained in the exhaust stream is trapped on the wall while the gaseous components pass unrestricted. Periodically (e.g., every 1,000 km of driving), the filter is heated to a temperature high enough (ca. 550°C) to combust the soot and regenerate the filter. This heat is generally provided by oxidizing the diesel fuel injected into the DOC generating at least 550°C to initiate combustion of the soot. Alternatively, for vehicles without a DOC, fuel is injected into the cylinders during the exhaust stroke to promote combustion in the exhaust manifold, thereby raising the exhaust and DPF temperature. For the light duty market, DPF are usually silicon carbide or aluminum titanate.

A DPF may also contain a Pt containing catalyst (i.e., a catalyzed soot filter or CSF) to assist with the combustion of soot and to oxidize CO generated during the soot regeneration process.

Controlling NO_x in Diesel Engines

The US and European standards require the reduction of all three phases of diesel emissions (i.e., solids, liquids, and gases). In particular, reduction of NO_x will offer considerable challenges due to the lean nature (large excess air) of the exhaust. Two of the most promising technologies for controlling NO_x at the tailpipe are Selective Catalytic Reduction (SCR) and lean NO_x Traps (LNT). Both utilize catalytic processes to eliminate NO_x by chemically reducing it to N_2.

SCR relies on the reduction of NO_x by ammonia (NH_3) over either a vanadia (V_2O_5) supported on titania or metal-exchanged zeolite-based catalyst. The major desired reactions are below

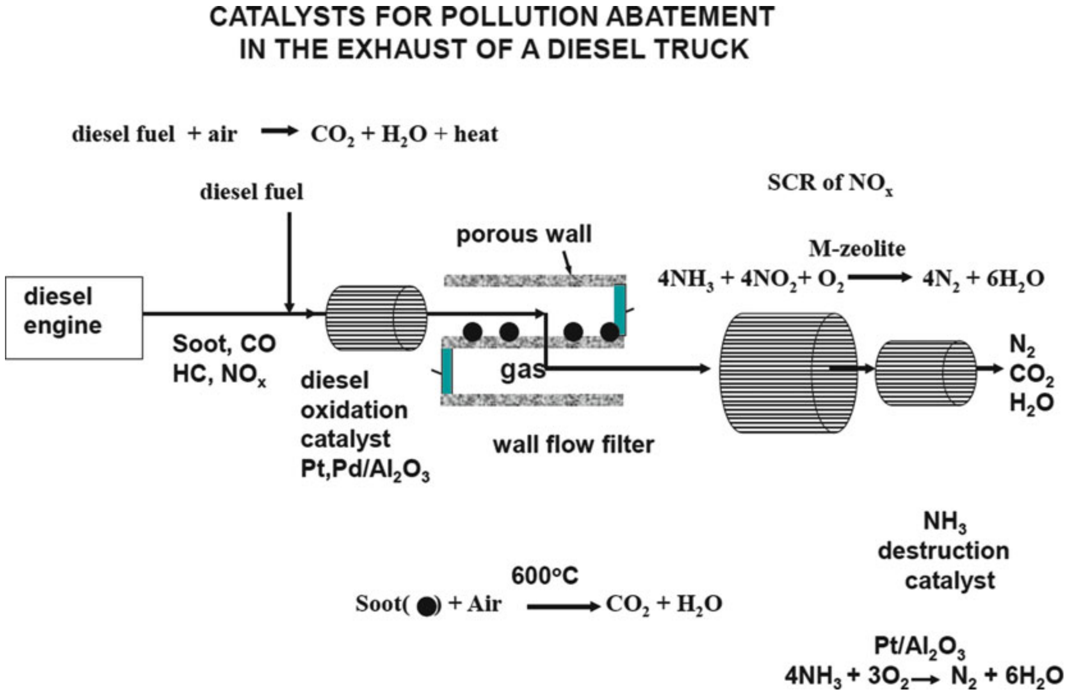

Fig. 6.12 Simplified diesel exhaust after-treatment system for heavy duty trucks. A diesel oxidation catalyst, wall flow filter, selective catalytic reduction, and ammonia decomposition catalyst

$$4NH_3 + 4NO + O_2 \xrightarrow{\text{catalyst}} 4N_2 + 6H_2O$$

$$4NH_3 + 2NO_2 + O_2 \xrightarrow{\text{catalyst}} 3N_2 + 6H_2O$$

Although commonly used in stationary source applications, SCR is relatively new for vehicle applications. Since handling gaseous ammonia is not practical in automobiles or trucks, an ammonia surrogate such as urea is utilized to generate ammonia in-situ in the vehicle exhaust. Typically, a solution of urea and water is injected into the exhaust stream before the SCR catalyst, and in the presence of water vapor, is hydrolyzed to ammonia which can participate in the SCR/NO_x reduction reactions. In addition, an ammonia "cleanup" catalyst (often referred to as an AMOX catalyst) may be required to remove any ammonia "slip" that may pass through the SCR catalyst unconverted. Clearly, integration of the SCR catalyst within the exhaust system is a challenge. Depending on the specific application, an oxidation catalyst (DOC), a CSF, an SCR catalyst, and an ammonia destruction catalyst (AMOX) may all be required to meet the combined CO, HC, and NOx regulations especially for heavy duty trucks. Sophisticated engine controls are required to ensure proper operation of all components within the system. The schematic in Fig. 6.12 shows the catalytic unit operations for meeting 2010 diesel emission standards using an SCR system.

The second promising technology for controlling NO_x at the tailpipe is LNT. The technology utilizes a Pt and Rh-based TWC catalyst in combination with an NO_2 trapping agent (e.g., an alkaline earth compound such as BaO). During the normal lean operation mode of the diesel engine, NO is oxidized to NO_2 over the Pt catalyst and the NO_2 is adsorbed by the BaO within the catalyst washcoat. Periodically (e.g., every 60–120 s), the trap is regenerated by introducing a "rich pulse" of reductant (e.g., diesel fuel) into the exhaust stream or by switching the engine operating mode to stoichiometric or rich for 1–2 s. This rich pulse provides the necessary chemical reductant to convert the adsorbed nitrate to nitrogen over the Rh catalyst.

Pt

$$\text{Lean mode:}\quad NO + \frac{1}{2}O_2 \rightarrow NO_2$$
$$NO_2 + BaO \rightarrow BaO\text{----}NO_2$$

Rh

$$\text{Rich mode:}\quad BaO\text{---}NO_2 + CO(H_2) \rightarrow N_2 + H_2O + CO_2$$

LNT technology has been successfully demonstrated in light duty vehicle applications; however, its primary disadvantages are high Pt levels are required to maintain sufficient catalyst durability and a fuel penalty (ca. 3–5%) results from the periodic trap regeneration. In addition, the

SO_x derived from the fuel-borne sulfur forms $BaSO_4$ that is much more stable than the corresponding nitrates and are not removed during the stoichiometric or rich operation mode. Therefore, the trap becomes progressively poisoned by sulfates. Complicated engine control strategies are being developed to desulfate the poisoned trap by operating the engine at a high temperature (>550°C) and rich of the stoichiometric air/fuel ratio for a short period of time. In addition, the air-to-fuel ratio must be carefully controlled to avoid the formation of H_2S during excessive rich conditions. LNT technology has the capability of removing up to 90% of the NO_x in the exhaust. Having lower sulfur fuels available will favor high NO_x conversion levels and also reduce the requirements for desulfation. Improvements in catalyst and engine control technologies hold promise for the future.

Catalytic Hydrogenation of Vegetable Oils for Edible Food Products

Triglycerides

Plant-derived oils such as soy, cottonseed, peanut, canola, corn, etc. are natural sources of edible products such as baking dough for cakes, cooking oils, salad dressing, chocolates, margarine, etc. Non-edible products such as lubricants, creams, lotions, etc. can also be produced depending on the processing of the oils. Natural oils are composed of long chains of fatty acid esters called triglycerides as shown in Fig. 6.13. The triglyceride chains are polyunsaturated, the degree of which influences their stability against oxidation in air.

Catalytic hydrogenation of the double bonds improves the stability against air and raises the melting point such that solids can be produced. Thus, the precursor to chocolate candy, margarine, or a cake mix is liquid oil that upon hydrogenation becomes an edible solid at room temperature. The more double bonds hydrogenated (the more saturated) the higher istowards air but often more injurious to our health by deposition of cholesterol in our blood the melting point, the lower is the reactivity vessels. The goal of a good catalyst coupled with the proper process conditions is to produce a reasonably healthy product with the desired melting point range with sufficient air stability to permit good shelf life.

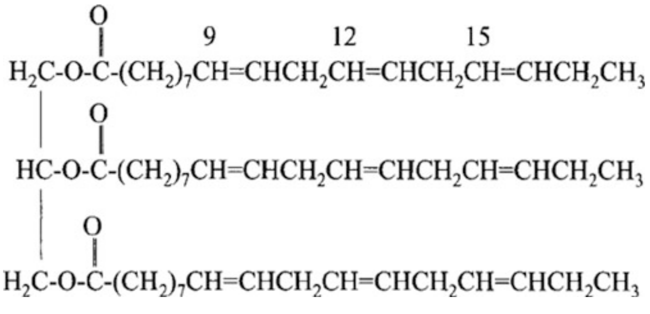

Fig. 6.13 Unsaturated fat molecule. Example shown is linolenic oil

Oils are classified by the length of the glyceride chain and degree of polyunsaturation. Typically nature produces oils with each chain length between 12 and 22 carbons with up to three unsaturated bonds usually all in the *cis*-form. Triglycerides with 18 carbons per length and three double bonds at positions 9, 12, and 15 counting from the first carbon in the ester group are called linolenic and designated C18:3. This structure is shown in Fig. 6.13. The outermost double bond is so reactive towards air that oils with three double bonds in the alkyl chain are rare. Therefore, the most prevalent in nature have double bonds at positions 9 and 12 and are referred to as linoleic (C18:2). Its reactivity is about half that of linolenic. The least reactive is oleic (1/20 that of linolenic) with only one double bond per length at position 9 (C18:1). Stearic is the term used for glycerides with all bonds saturated (C18:0). Not surprisingly, this form has virtually no reactivity towards air, has a high melting point, and is unhealthy.

The source of the oils plays a major role in producing a product with the desired melting point, stability, and health consequences. Cotton, sunflower, corn, and soy bean oils are a mixture of the four basic triglycerides with 50–70% C18:2 being the most dominant followed by 20–30% C18:1 with less than 1% C18:3. Less than 10% are other saturated oils such as C16:0. Palm kernel and coconut oils have almost 80% saturated triglycerides (C12:0, C14:0, and C16:0), have high melting points, and are stable against air but not healthy. They are used for protecting the skin against excessive sun exposure. Olive oil has up to 80% C18:1 and is therefore relatively healthy.

The most common oil hydrogenation catalysts are 20–25% Ni on Al_2O_3 and SiO_2. The nickel salts are either impregnated or co-gelled with a carrier precursor such as a soluble Al or Si salt. The catalytically active state of Ni is the reduced (metallic) form. The activation step is performed during manufacture at which time the catalyst is coated with a fatty gel to protect it from air oxidation during shipment.

Less than 1% by weight of catalyst is added to the batch reactor where the fatty protective gel slowly dissolves and the hydrogenation reaction commences. Temperatures of 100°C and H_2 pressures of 3–5 atmospheres are used to ensure adequate dissolution of the H_2 into the feed stream. Reactions are carried out between 100 and 160°C. Stirring is vigorous to maximize bulk gas diffusion to the catalyst surface. The catalyst particles are small to minimize pore diffusion resistance and increase liquid–solid mass transfer area.

Cu supported on Al_2O_3 is less active than Ni and this property is used to “brush” hydrogenate. Only minimum hydrogenation occurs maintaining the melting point but sufficient to improve stability against air. This is sometimes used for producing salad oils.

The reaction profile is generally sequential with hydrogenation first occurring on the most active double bonds followed by those less active [24–26]. Time distribution shows the linoleic form decreasing as the oleic form increases. After extended reaction time, the stearic begins to form as the oleic is slowly hydrogenated. Thus, one can design the process to control the product distribution in a predictable manner.

Hydrogenation of the linoleic form with a melting point of −13°C will produce a oleic product with a melting point of 5.5°C very suitable for consumption. During the partial hydrogenation process, it is most desirable to minimize isomerization to the *trans* isomer (the hydrocarbon groups are *trans* to each other across the remaining unsaturated bonds) because this structure raises the "bad" cholesterol or LDL (low-density lipids). A partially hydrogenated *cis*-structure may have a melting point of 6°C, whereas its *trans* isomer melts at 40°C. The *trans* isomer is more readily formed at high reaction temperatures, high Ni catalyst loadings, and at low hydrogen pressures (low concentration of H_2 at the catalyst surface). Pt containing oil hydrogenation catalysts produce considerably less *trans* than Ni; however, the high activity causes excessive hydrogenation of the double bonds. To minimize this effect, NH_3 is intentionally added to the feed or catalyst to poison its activity towards hydrogenation. By so doing, a low *trans* oil is produced without excessive saturation of the double bonds. In 2006, the U.S. Food and Drug Administration required labels that report the amount of *trans* components present in edible products.

Catalyst deactivation is mainly caused by mechanical attrition due to the rigorous stirring. In most cases, adsorption guard beds are used upstream to remove most of the impurities such as sulfur and phosphorous often found in the feed. Recognizing that some poisons may break through, the catalyst has an average pore size sufficiently large to admit the triglycerides but smaller than the average size of the organic compounds containing P and S. The spent catalyst is separated from the product by filtration. Given the increasing cost of Ni, it is recovered, refined, and used to make fresh catalyst.

Fertilizers and Hydrogen Generation

General Reactions

Ammonium nitrate (NH_4NO_3) and urea ($CO(NH_2)_2$) are two major sources of the world's fertilizers. The nitrate is produced by reaction of ammonia and nitric acid.

$$NH_3 + HNO_3 \rightarrow NH_4NO_3$$

Urea is produced by the reaction of NH_3 with CO_2 and its subsequent decomposition.

$$2NH_3 + CO_2 \rightarrow NH_2CO_2NH_4$$

Heart

$$\rightarrow CO(NH_2)_2 + H_2O$$

Ammonia is produced by the catalytic hydrogenation of N_2 with H_2

$$3H_2 + N_2 \rightarrow 2NH_3$$

Hydrogen is produced by a series of catalytic reactions, the first of which is hydrocarbon reforming, and the second is water gas shift. Considering natural gas (CH_4) as the starting hydrocarbon

$$\begin{gathered} CH_4 + H_2O \rightarrow 3H_2 + CO \\ CO + H_2O \rightarrow H_2 + CO_2 \end{gathered}$$

Nitric acid is produced by the selective catalytic oxidation of NH_3 and its subsequent hydration

$$\begin{gathered} 2NH_3 + \frac{7}{2}O_2 \rightarrow 2NO_2 + 3H_2O \\ \frac{3}{2}NO_2 + \frac{1}{2}H_2O \rightarrow \frac{3}{2}HNO_3 + \frac{1}{2}NO \end{gathered}$$

Each catalytic step will be discussed in this section.

Hydrogen Generation for the Production of NH_3

Producing H_2 from hydrocarbons such as natural gas is currently practiced in the chemical industry [27–30] under steady state conditions with carefully controlled catalytic unit operations. The overall process is as shown in Fig. 6.14.

Traces of organic sulfur compounds such as mercaptans, thiosulfides, and alkyl sulfides are added to natural gas to impart odor for safety detection of leaks. Because sulfur compounds are poisons to the downstream catalysts, they must be removed. The technology of choice is hydrodesulfurization or HDS.

$$RH - S + H_2 \rightarrow H_2S + RH_2$$

The reaction is carried out at about 300–400 psig and 300–400°C, but these conditions vary with the hydrocarbon feed. The catalyst is 3% Co, 15% Mo deposited on spheres

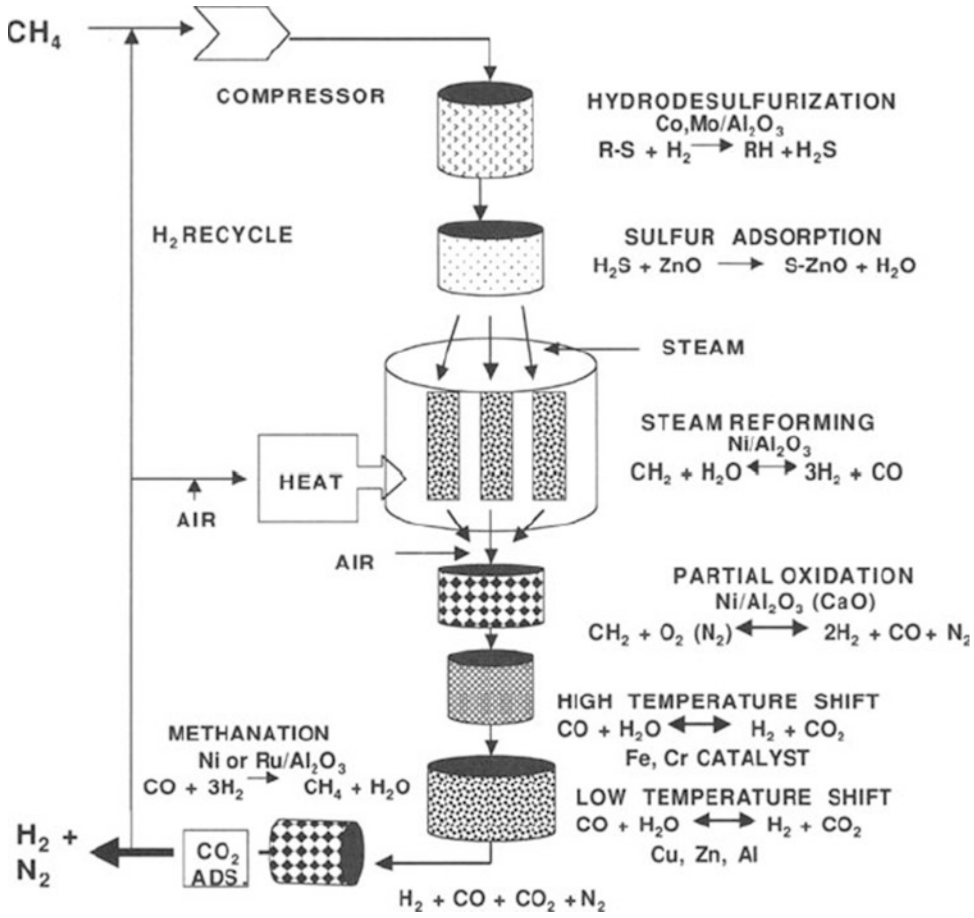

Fig. 6.14 The catalytic synthesis of hydrogen from natural gas for ammonia synthesis using hydrodesulfurization, steam reforming, partial oxidation, water gas shift, methanation, and CO_2 scrubbing

(25–75 m^2/g) Al_2O_3 with diameters of 2–3 mm. The catalyst is presulfided to decrease its activity towards undesirable side reactions such as coking.

The H_2S produced is removed downstream from the HDS reactor by adsorption on ZnO particles at about 400–500°C.

$$H_2S + ZnO \rightarrow ZnS + H_2O$$

Primary reforming of the sulfur-free natural gas (i.e., CH_4) is the first step to produce a H_2-rich gas.

$$CH_4 + H_2O \rightarrow CO + 3H_2$$

The reaction is highly endothermic and thus is favored at high temperatures. The maximum temperature achievable is limited by metallurgy of the reactor. Given the increase in gas volume, the reaction is favored by low pressures.

The catalyst is approximately 30% Ni with about 14% CaO on highly densified alpha alumina (α-Al_2O_3) with a surface area about 2–5 m^2/g. The CaO reacts with the Al_2O_3 forming $CaAl_2O_4$ for added mechanical strength under the severe operating conditions of 800°C and 300–400 psig and a steam environment up to 75%. The reaction rate is limited by a combination of heat transfer and pore diffusion, the latter due to the inadequate accessibility of the reactants to the catalyst interior. To counter pore diffusion limitations, the catalyst is manufactured as a donut with two to three holes to increase the external contact area and decrease the diffusion path. The space velocity is between 1,000 and 2,000 h^{-1}. The active catalyst is Ni metal, so it must be reduced carefully with H_2 prior to introducing the feed. The reaction is carried out in a series of tubular parallel reactors located in a large fired box furnace to provide the necessary heat.

Deactivation is due mostly to the slow accumulation of sulfur that breaks through the upstream HDS/ZnO guard beds. Sulfur irreversibly decreases the activity of the Ni that allows the methane decomposition rate to become significant leading to the accumulation of hydrogen-deficient carbon or "coke." This builds up within and between catalyst particles, leading to its fracture and an increase in pressure drop. During process shut down, the catalyst must be "passivated" to protect against air oxidation of the Ni and a subsequent fire due to its strong exotherm creating a safety hazard at the plant site. This is accomplished by periodically injecting small amounts of air and carefully oxidizing the surface of the Ni while monitoring the exotherm.

Equilibrium limits conversion of the CH_4, so partial oxidation or secondary reforming of the unreacted CH_4 is used to generate more heat and H_2 in a secondary reforming step. The addition of air also serves the purpose of providing the required N_2 for the subsequent ammonia synthesis reaction. Secondary steam reforming also uses a high-temperature resistant Ni containing catalyst that must retain its strength after prolonged exposure to close to 1,200°C due to the oxidation in the front end of the bed. The catalyst used is α-Al_2O_3 impregnated with about 18–20% Ni and 15% CaO.

$$2CH_4 + N_2 + 2O_2 \rightarrow CO + 3H_2 + CO_2 + H_2O + N_2$$

The exit from the secondary reformer contains about 10–12% CO, is cooled to about 350°C, and fed to a high-temperature water gas shift (HTS) reactor.

$$CO + H_2O \rightarrow H_2 + CO_2$$

The particulate catalyst is composed of 90% Fe and 10% Cr. The Cr minimizes sintering of the active Fe phase. The catalytic reaction is limited by pore diffusion, so small particles are used. The exit process gas contains about 2% CO as governed by the thermodynamics and kinetics of the reaction. This reaction is slightly exothermic and thermodynamics favor low temperatures that decrease the reaction rate. It is therefore necessary to further cool the mix to about 200°C where it is fed to a low-temperature shift reactor (LTS) containing another particulate catalyst composed of 30–35% Cu, 45% ZnO, and 13–20% Al_2O_3. The catalyst is active in the reduced form, so it must be carefully activated with H_2 avoiding excessive overheating which will cause sintering. The Zn and Al_2O_3 are added to stabilize the Cu because it is sensitive to sintering. The CO is decreased to its thermodynamic limit as imposed by the temperature and gas compositions. Typically, the CO is reduced to less than about 0.5%. The catalyst deactivates by traces of sulfur and sintering of the active Cu phase. Because of the necessity to operate at low temperatures, the reaction rate is slow and large volumes and low space velocities (1,500–2,500 h^{-1}) are used.

The active Cu-containing catalyst is also very air sensitive (like the Ni reforming catalyst) and will spontaneously oxidize generating uncontrolled reaction heats. Thus, it must be passivated before discharged and exposed to air. A small amount of air is added to the reactor and the temperature monitored. This process is continued until the exotherm is small enough that the catalyst can be safely removed from the reactor.

The remaining CO, which poisons the downstream ammonia synthesis catalyst, is removed by methanation using either a Ni or Ru on Al_2O_3 catalyst at 300°C

$$CO + 3H_2 \rightarrow CH_4 + H_2O$$

The CO_2 is scrubbed in an amine solution.

Ammonia Synthesis

The Haber process for the synthesis of ammonia from H_2 and N_2 has been practiced since the beginning of the twentieth century always with a massive Fe catalyst [31].

$$N_2 + 3H_2 \rightarrow 2NH_3$$

It is mildly exothermic, so the reaction is thermodynamically favored at lower temperatures but at high pressures due to the contraction of gaseous product volume. To obtain reasonable rates, the process is operated at about 450°C and pressures approaching 5,000 psig at a space velocity of 10,000–15,000 h^{-1}. The process is operated in a recycle mode, so ammonia is continuously removed aiding the equilibrium.

The active catalyst is 75–80% Fe metal, 10% Fe_2O_3, 4% Al_2O_3, less than 5% alkali and alkaline earth (Li, Ca, and Mg), with 1% SiO_2 added to minimize sintering of the Fe. The promoters are added to a melt of magnetite (Fe_2O_3). The solid mass is then ground to 1 mm particles, charged to the fixed bed reactor, and slowly reduced with H_2 at 500°C. The reduction generates active Fe metal with some porosity due to liberation of oxygen forming H_2O. The surface area is increased from about 1 m^2/g to about 20 m^2/g. The small particle size of the finished catalyst is necessary to minimize pore diffusion limitations. Special precaution is necessary during discharge from the reactor because air exposure will spontaneously oxidize the Fe surface generating large quantities of heat.

The catalyst is poisoned by CO, CO_2, and H_2O, so they must be rigorously removed upstream in the hydrogen synthesis process. Oxygen-containing molecules are permanent poisons. Other poisons such as sulfur, arsenic, halides, and phosphorous must be carefully removed upstream in as much as they too are permanent poisons.

Nitric Acid Synthesis

Nitric acid is produced by the selective oxidation of NH_3 over a gauze catalyst composed of 90%Pt, 10%Rh (some gauze is 90% Pt, 5% Rh, and 5% Pd) [32]. This reaction was used in the “Selectivity” section to demonstrate the high efficiency with which PtRh leads to NO production as opposed to more thermodynamically favored N_2.

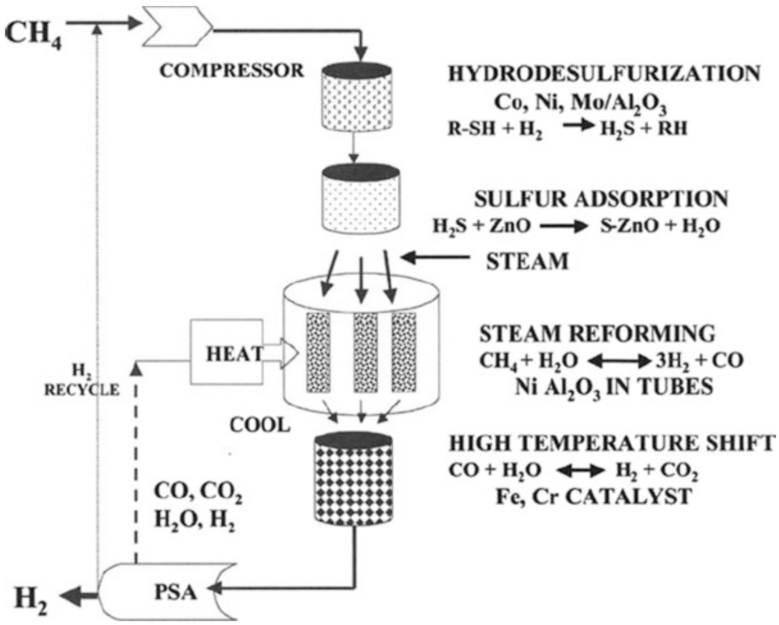

Fig. 6.15 The catalytic synthesis of hydrogen from natural gas using hydrodesulfurization, steam reforming, water gas shift, and pressure swing absorption (PSA)

$$4NH_3 + 5O_2 \xrightarrow{PtRh} 4NO + 6H_2O$$

$$4NH_3 + 3O_2 \rightarrow 2N_2 + 6H_2O$$

The low-pressure process (15–30 psig) produces NO with a selectivity of 98% and the high-pressure process (150 psig) has a selectivity of 94%. The high-pressure plant allows for a smaller reactor (and gauze) diameter (3 ft) compared to 12 ft for the low-pressure process.

The feed is composed of 10–12% NH_3 in air and is fed to the reactor at an inlet temperature of about 250°C and a space velocity approaching 50,000 h^{-1}. For a high-pressure plant, the exotherm generates an outlet temperature of 900°C. The NO product is cooled and noncatalytically converted to NO_2, its thermodynamically favored state at low temperatures, which reacts with H_2O forming HNO_3.

The finished alloy catalyst is manufactured by a knitting process to form a wire gauze that looks like a door screen. The Rh is added to impart mechanical strength during the wire drawing operations. During reaction, the catalyst undergoes an unusual morphology change. The Pt forms an oxy–nitrogen species and volatilizes from the gauze. The smooth wires become roughened and sprout resembling cauliflower. The surface area of the gauze increases by 20 times. The loss of Pt enriches the surface with Rh and the catalyst slowly loses activity. After approximately 90 days of operating a high-pressure plant, the Pt content of the gauze is reduced to 50%. The volatile Pt is captured downstream on a "getter gauze" made of Pd. The Pd surface catalytically decomposes the gaseous oxy–nitro Pt species and a Pt–Pd alloy forms that allows for easy recovery of the precious metals. The spent catalyst is returned to the supplier where the precious metal is recovered for future use.

Another source of deactivation is Fe contamination originating from the corrosion of upstream equipment depositing on the gauze resulting in decomposition of the NH_3 to N_2. Another source is from the Fe-containing ammonia synthesis catalyst.

Although the largest use for nitric acid is NH_4NO_3 fertilizers, it is also used for explosives and nylon polymers.

Pure Hydrogen Generation with Pressure Swing Adsorption Purification

For applications in which N_2 is not needed, such as H_2 or alcohol production, pressure swing adsorption (PSA) is used. The process flow diagram is shown in Fig. 6.15.

There is a renewed interest in hydrogen generation for the developing hydrogen economy with the anticipated use of fuel cells as a power source for vehicles [33]. The fuel cell generates electricity by electrochemically oxidizing H_2 and reducing O_2. Because it directly converts chemical to electrical energywithout using the traditional mechanical steps of piston-driven engines and turbines, it promises to be more efficient, cleaner, decrease our dependence on oil, and generate less greenhouse gas. The small-scale generation of H_2 for cost-effective refueling stations is a major issue that is aggressively being studied. Ultimately, it will be derived from water by electrolyzers using natural sources such as solar, wind, and geothermal energy. Until these technologies are available, natural gas reforming is a likely source because infrastructures exist in many cities in the world. The fuel cell powered vehicle will require an infrastructure similar to gasoline and diesel service stations. High-pressure H_2 will have to be available to refuel the vehicles.

Such demonstration stations are now being built in various parts of the world. PSA is used for final H_2 purification. The partial oxidation and the LTS are eliminated. There is therefore a loss of some hydrogen production, but the final H_2 is not diluted with N_2. The PSA purification unit replaces the methanator and CO_2 scrubber and produces pure H_2. Some of the H_2 is recycled for HDS and some combusted to provide the heat for steam reforming.

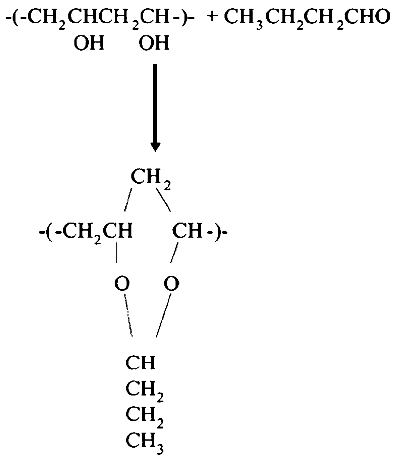
Given the need for smaller size reformers to be operated in local communities, safety will be an elevated concern. These reformers must contain nontoxic and air-insensitive catalysts, thus eliminating Ni, Cu, and Cr from consideration. A major research effort is underway to redesign the entire H_2 generation process system using modern materials such as monoliths and precious metal catalysts [33].

For fuel processors directly integrated to a residential fuel cell, H_2 must be maximized and no pressure is available for PSA. In these cases, a high- and LTS catalyst will be required. Hydrogen purification to reduce the CO to less than 10 ppm will be managed by preferential oxidation [34].

Production of Butyraldehyde: A Homogeneous Catalytic Reaction

Butyraldehyde

The incorporation of an inner layer of poly(vinyl butyral) or (PVB) in the glass of an automobile windshield protects against serious head injuries when a passenger strikes it during an accident. The strongly adherent coating is optically transparent and maintains the glass intact (anti-shattering agent) when a foreign object hits the surface. Thus, the glass does not shatter when a stone strikes its surface. PVB is produced by reaction of polyvinyl alcohol (PVA) with linear butylraldehyde ($CH_3CH_2CH_2CHO$).



Another important application of butyraldehyde is in the production of oxo-alcohols for use as plasticizers used to improve mixing of solid compounds that must be molded or extruded into specific shapes. The hydrogenation catalyst is Ni/Al_2O_3.

$$CH_3CH_2CH_2CHO + H_2 \xrightarrow{Ni/Al_2O_3} CH_3CH_2CH_2CH_2OH$$

Butylraldehyde is produced by a homogeneous catalytic process called hydroformulation in which CO and H_2 are added to liquid propylene using a soluble cobalt-containing complex catalyst $Co(CO)_6$. The reaction is carried out with a butanol solvent

$$\begin{aligned} &CH_3CH = CH_2 + H_2 + COCo(CO)_6 \\ &\quad \rightarrow 80\% CH_3CH_2CH_2CHO + 20\% CH_3CHCHO \\ &\quad + CH_3CHCHOCH_3 \end{aligned}$$

The conditions needed to catalyze the reaction are very severe; pressure = 3,000–4,500 psig and 150°C. The high pressure maintains the propylene in solution, ensures sufficient solubility of the H_2 and CO, and maintains the Co-carbonyl complex stable against decomposition. The product distribution is 4:1 linear to branch.

Much less severe conditions can be used with the Wilkinson homogeneous catalyst rhodium tricarbonyl triphenyl phosphate, $HRh(CO)_3(PC_6H_5)_3$. Pressures equal to 225 psig and temperatures of 100°C selectively produce the more useful linear form [35]. The milder conditions more than compensate for the more expensive Rh (1,000 times that of Co). The aldehyde product is distilled leaving the catalyst in the solvent ready for reuse.

Homogeneous catalysts are structurally well- defined complexes and, because they are soluble in the reaction mix, are not subject to pore diffusion limitations as are heterogeneous catalytic materials. They are almost always highly selective towards desired products. The main consideration is that the complex be stable and reactor conditions chosen such that all the gaseous reactants are adequately dissolved and mixed in the liquid phase. Homogeneous catalysts are easily characterized by standard instrumental methods for compound identification such as XRD or spectroscopy. Deactivation is associated with attack by traces of carboxylic acidic byproducts and impurities in the feed such as O_2 and chlorides that attack the ligand groups.

Polyethylene and Polypropylene for the Production of Plastics

Polyethylene

Specially prepared plastics are rapidly replacing traditional metal components because of their strength, transparency, resilence, lighter weight, and greater corrosion resistance.

The largest volume products are polyethylene and polypropylene. Each has its own contributions to the marketplace where the former is primarily used for low-strength applications such as milk and food containers. Polypropylene is used when enhanced strength, higher melting temperatures, and greater resistance to chemicals such as chemical holding tanks and automobile bumpers are required.

There are two prevalent methods of producing polyethylene, both of which involve heterogeneous catalysts. A slurry phase process utilizes chromium oxide deposited on SiO_2 dispersed in a solvent such as cyclohexane at 80–150°C and a pressure between 300 and 500 psig. The process operates in a recycle mode with a residence time of 2–3 h. The product containing the solvent and polymer is flashed leaving the polymer. The catalyst is usually left in the polymer because its concentration is extremely low. The operating conditions are adjusted to produce both high- and low-density polyethylene. The active site is Cr^{+2} produced by the reduction of Cr^{+6} by ethylene. The reaction mechanism proposed is that the polymer coordinates with one of the Cr^{+2} sites and the incoming ethylene coordinates with another site. Insertion of the ethylene into the double bond of polymer propagates its growth.

A second method of production utilizes the Ziegler–Natta $TiCl_4$ catalyst with liquid cocatalysts such as an alkyl aluminum halide. This is a reactive catalyst that must be prepared at the exclusion of air and water. The alkyl group of the cocatalyst coordinates with the Ti^{+3} site. The polymer grows by insertion of the ethylene into the double bond of the adsorbed polymer on another site.

Polypropylene

The most modern production route for polypropylene (PP) is also the Zeigler–Natta catalyst [36–38]. The catalyst is $TiCl_4$ supported on $MgCl_2$ along with aluminum alkyl halide cocatalyst such as diethyl aluminum fluoride $(CH_3CH_2)_2AlF$. The $MgCl_2$ is milled to a very disordered but active structure and the $TiCl_4$ is added. Production of the PP can be carried out in a fluidized gas phase reactor between 50 and 100°C and 100–600 psig. Ethyl benzoate is also used as part of the catalyst preparation and functions to reduce the $TiCl_4$ to active $TiCl_3$. The role of the alkyl component of the cocatalyst is to coordinate with the Ti^{+3} site where it inserts into the adsorbed polypropylene continuing the chain growth. The amount of catalyst used is so small it is retained in the final polymer product with no negative consequences. Unreacted gases are removed and recycled at the completion of the process. The most desirable product for the largest market is the isotactic form in which all CH_3 groups are on the same side of the polymer chain. Typically, it has a density of 0.9 g/cm^3, a melting point of 170°C, and an average molecular weight of 500,000. The polypropylene product is mixed in a separate reactor with ethylene to make a block polymer with enhanced mechanical properties.

Water, CO, and O_2 are the most significant poisons and are carefully removed upstream of the process.

The catalyst preparation and the process are far more complicated than presented here, so the reader is encouraged to refer to more detailed references [36–38].

Catalyst Challenges

Catalysts will have additional challenges as we move forward in the twenty-first century. In this author's mind, one of the most critical is the need to balance our rapidly expanding energy needs with the environment. Catalysts are already playing a dominant role in pollution abatement and in the production of specialty petroleum and chemical products. The main challenge will be to use bio-renewable energy sources (Chap. 33) as well as solar, wind, geothermal, etc. with the specific goal of freeing us from the use of fossil fuels. The hydrogen economy coupled with the fuel cell holds great promise as one road to meet this challenge [39]. Catalysts will play a key role in this pursuit, although the road map is not yet complete. This will be an exhilarating ride as we find our way to clean energy.

Another area of great importance is the application of biocatalysis using enzymes to produce a growing number of pharmaceutical agricultural products and fuels such as ethanol. This subject is outside the scope of this review so other sections of this Handbook (see Chap. 31) should be consulted.

Environmental Chemical Determinations

7

William L. Budde

Introduction

Environmental chemical determinations are identifications and measurements of the concentrations of elements, compounds, or ions in environmental media. In a chemical determination equal importance is given to the correct identification of the substance, and to its accurate and precise measurement. There has been a tendency in some environmental work to place more emphasis on making accurate and precise measurements, and to give less attention to ascertaining the correctness of the identification of the substance being measured.

Air, water, soil, and sediment are broad categories of environmental media and each of these can be divided into several subcategories, for example, ambient air, indoor air, industrial or workplace air, and vapor emissions from mobile or stationary combustion sources. Body fluids and tissue are also relevant environmental media because they are often analyzed to determine human, animal, and plant exposure to environmental chemicals.

Significance of Environmental Chemical Determinations

Accurate and precise identifications and measurements of specific chemical substances are fundamental to environmental studies and protection programs. Determinations are required to understand natural background concentrations of chemicals in the environment, the nature and extent of environmental pollution by anthropogenic chemicals, trends in concentrations of these substances, the transport and fate of chemical substances, and the causes of variations of concentrations in time and space. Accurate and precise determinations are also required to assess human health and ecological risks caused by exposure to natural and anthropogenic substances, establish air and water quality standards, develop pollution-control strategies, evaluate the effectiveness of pollution prevention and treatment technologies, and monitor compliance with and the effectiveness of discharge and other government regulations. These data are also needed to develop, calibrate, and verify mathematical models used to predict the impact of changes in concentrations of specific substances in the environment. Environmental chemical determinations are also required to set priorities and make cost estimates for the remediation of abandoned hazardous waste sites.

In addition to specific chemical substances, a variety of other determinations is very important and is often required for environmental studies and protection programs. These include identifications and measurements of bacteria, viruses, protozoa, and minerals such as asbestos fibers. Measurements of meteorological conditions, particulate matter in air by size, water turbidity, biological oxygen demand, chemical oxygen demand, and radioactivity are also very important. These and other similar determinations are beyond the scope of this chapter and the reader should consult other reference books for information about these topics.

Chemical Analysis Strategies

A wide variety of chemical analytical strategies is used in environmental analysis programs. In order to develop an appropriate strategy for a specific program, the objectives of the program must be thoroughly defined and understood by all participants. An analytical strategy for the program can then be developed by selecting and combining the most appropriate analytical methods and other key elements that will provide the results needed to fulfill the objectives of the

program. Some of the major issues and strategies that must be considered in developing a specific strategy for an analysis program are described in this section.

Samples and Sampling Strategies

The goals of the environmental program will usually define the specific types of samples that must be acquired and analyzed, for example, ambient air, drinking water, ground water, soil, sediment, blood, sweat, urine, tissue, etc. The sampling strategy is a broad but detailed plan for the acquisition of the samples needed for the project. Sampling techniques and procedures are the actual physical processes used to acquire the samples. Sample preservation protects the integrity and validity of the samples before, during, and after the actual sampling process. Sampling strategies, techniques, and sample preservation are major factors contributing to the success or failure of environmental chemical determinations.

The sampling strategy defines in detail what, where, when, and how the environmental samples will be acquired. This plan should specify all details including the number of sampling stations for air, water, soil, sediment, or fish samples; the locations of the sampling stations; the time of the day of sampling; the frequency of sampling; the depth of sampling for water, soil, and sediment samples; the meteorological conditions and altitude for air sampling; and, the need for replicate samples taken at the same time and place. For body fluids and tissue samples myriad details must be considered including the number of persons contributing or the kinds of wildlife-related samples that must be collected. The plan should specify a series of discrete samples, a composite sample from contributions at various intervals, or a continuous flow of sample over a period of time. A sampling strategy that does not provide appropriate and representative samples seriously jeopardizes the value of the chemical determinations.

The sampling techniques and procedures define the type of sampling equipment, the containers used for the samples, the procedures used to clean the sample containers and sampling equipment, the calibration of sampling equipment, and sample compositing procedures if composite samples are required. Sample preservation must ensure that the chemical composition of the sample at the time of analysis is the same as it was at the time and place of sampling and is not the result of physical or chemical changes caused by the conditions of shipment and storage prior to chemical analysis. Significant research has been conducted to find sample containers that resist adsorption or degradation of sample components. Samples are often shipped and stored at low temperatures, and treated with various chemical reagents, to retard microbiological degradation of the analytes or to prevent chemical reactions that can change the composition of the sample. Appropriate sampling techniques and preservation procedures are required to provide valid samples and valid chemical determinations.

Determination of Total Elements or Total Related Substances

A standard analysis strategy is the determination of the total amount of an element in a sample where the element is present in several or more elemental forms, compounds, ions, oxidation states, or physical phases. This strategy was developed before chromatographic and other techniques were available to separate the individual substances containing the element of interest. It is widely used in environmental studies and government regulatory programs. However, the meaning of *total* is variable because some analytical methods do not include all the physical phases or chemical forms in the determination. The sample preparation procedures in individual analytical methods define exactly which elemental forms, compounds, ions, oxidation states, and physical phases are included in a total measurement. A similar strategy is the determination of the total amount or total concentration of a group of closely related compounds or ions without specifying the relative or absolute concentrations of the individual substances. Closely related substances usually have some common physical or chemical properties, elemental composition, or structure.

The broadest definition of, for example, total mercury (Hg) in a sample is the sum of the elemental Hg^0, the Hg in all inorganic compounds of Hg^1, the Hg in all inorganic compounds of Hg^2, and the Hg in all organic compounds in which Hg is bonded to C, O, N, S, or some other element. All phases are included because some species may be present in the vapor phase (Hg^0), some soluble in water, and some insoluble in water or present in the particulate phase of an air sample. More limited definitions of total are often used in analytical methods that separate physical phases or chemical forms that contain the element of interest.

If a water sample contains both soluble and insoluble manganese (Mn) compounds and ions, and it is filtered to separate the dissolved and insoluble fractions, and the filtrate and insoluble residue are analyzed separately, the results can be expressed as total dissolved Mn and total suspended or insoluble Mn. Phosphorus (P) can be determined colorimetrically as the ortho-phosphate ion, PO_4^{-3}, in aqueous samples after a reaction that forms an intensely blue-colored derivative. However polyphosphate ions and other ions and compounds containing P do not form this derivative. Total P in a sample can be determined with the same colorimetric procedure after acid hydrolysis and oxidation of all ions and compounds containing P to PO_4^{-3}. In some elemental analyses the sample is treated with reagents designed to make available for measurement some fraction of an element or elements but not the total amount. For example, a soil sample may be treated with water at pH 3 to simulate the leaching process of acid rain. A total elemental analysis of the filtrate provides information about just those elements solubilized by the mild acid treatment. This can be called the determination of total mild acid leachable elements.

The measurements of total organic carbon (TOC) and total organic halogen (TOX) in a sample are used to assess many types of environmental samples. The analytical methods for TOC employ procedures to physically separate the inorganic carbon, that is, carbonate, bicarbonate, cyanide, and other inorganic substances containing C, from the organic compounds and ions in the sample. The TOC is then measured by oxidation of the organic compounds and ions to carbon dioxide which is determined by one of several techniques. The analytical methods for TOX use procedures to separate inorganic halogen-containing ions from halogen-containing organic compounds and then determine the total halogens in the organic compounds.

Some analytical methods have been developed for the determination of groups of closely related compounds or ions. The classic example is the measurement of combined phenolic materials colorimetrically after a reaction that forms a red derivative with many phenols. However, different phenols form derivatives with somewhat different visible absorption spectra and various phenols have different reactivities with the derivatizing reagent. Therefore this method is calibrated with pure phenol and the measurement gives just an estimate of the total phenols in the sample. For this reason this method is probably no longer widely used and phenols are usually determined as individual compounds with other analytical methods. Subgroups of complex mixtures of congeners are sometimes measured together for convenience of interpretation or for government regulatory programs. These determinations give concentrations of, for example, total tetrachlorobiphenyls, total pentachlorobiphenyls, etc. Similar determinations of chlorinated dibenzo-*p*-dioxins and chlorinated dibenzofurans at each level of chlorination are specified in some analytical methods.

Determination of Specific Substances

Before the development of efficient chromatographic separation techniques and selective and sensitive detectors, analytical methods for the determination of specific analytes in environmental samples were very limited. Those methods depended on highly selective chemical reactions that are relatively rare and difficult to discover, or on very selective physical measurements such as atomic absorption or emission techniques for elemental analytes. Therefore only a relatively few analytical methods for the most common and amenable organic and inorganic compounds or multi-element ions were developed. It would have been essentially impossible, and enormously costly, to develop, test, document, and implement a large number of nonchromatographic analytical methods for a wide range of often similar organic and inorganic analytes.

Vapor phase or gas chromatography (GC) and high-performance liquid chromatography (HPLC) provided capabilities for the separation of microgram (10^6) and smaller quantities of often similar individual substances in complex mixtures. A variety of GC and HPLC detectors were developed and, depending on the detector, the separated substances could be determined with good to excellent sensitivity and with fair to excellent reliability. It was soon recognized that determinations of a broad range of specific chemical substances was not only practical but also essential to achieve the goals of many environmental studies and protection programs.

Gas chromatographic techniques were first applied during the 1960s to synthetic organic compounds and natural products which are often complex mixtures of organic compounds. The earliest applications of these techniques in environmental research were GC-based determinations of petroleum hydrocarbons in polluted air and chlorinated hydrocarbon pesticides in several types of samples. Analytical chemists and environmental scientists concerned about organic pesticides, industrial organic chemicals, and other organic compounds emphasized the development of analytical methods for the determination of specific organic compounds. In contrast, the emphasis in elemental and inorganic analyses during the 1960–1980s was, with a few exceptions, on determinations of the total amounts or concentrations of specific elements in a sample without regard to the specific compounds or ions containing those elements. With the recognition that toxicity and other environmentally significant properties varied widely with the specific compound or ion, inorganic analytical chemists later focused on chromatographic separations of individual species. The term *speciation* came into use, mostly by inorganic chemists, to distinguish this type of analysis from the conventional determinations of the total amounts or concentrations of the elements in a sample.

There are two general strategies for the determination of specific organic or inorganic compounds and ions in environmental samples [1]. The target analyte (TA) strategy dominated analytical chemistry before the development of chromatographic separation techniques and is by far the most commonly used with contemporary separation and detection techniques. The broad spectrum strategy became feasible with the development of high-resolution chromatographic separation techniques and spectroscopic detectors.

Target Analyte (TA) Strategy. Target analytes are known substances with known chemical, physical, and other properties. They are either known or thought to be in samples and they must be determined to meet the objectives of the environmental analysis program. The TA strategy is the analysis of the sample with an analytical method that is designed and optimized to determine the target analyte or a group of similar and separated target analytes. If the target analytes are a diverse group with sufficiently different chemical and physical properties, they are divided into subgroups according to their similar properties. Several optimized analytical methods and separate environmental samples are used to determine the analytes in the subgroups.

The TA strategy has many advantages that favor its widespread application. Sample preparation procedures can be designed to separate the target analytes from the sample matrix with maximum efficiency, and to concentrate them in a suitable solvent for further chromatographic separation. Some interferences can be separated from the analytes during sampling or sample processing by pH adjustments, chemical derivatization, evaporation of non-target substances, or other techniques. Chromatographic separation and detection techniques can be selected to give the best practical resolution of analytes, selective detection, and the lowest detection limits. The detector can be calibrated for quantitative analysis with standard solutions of the target analyte or analytes, and the analytical method tested, perfected, and validated using test sample matrices fortified with known concentrations of the target analyte or analytes.

The target analyte strategy is widely accepted, understood, and used in analytical chemistry, environmental research, environmental protection programs, and in many other fields of investigation. It is used in most environmental quality surveys and government regulatory compliance monitoring programs. Many analytical methods for a variety of target analytes have been developed, tested, documented, and implemented [1–4]. Cost estimates for analyses are readily made and analytical costs are not difficult to control. The target analyte strategy is used in the vast majority of chemical analyses reported in the scientific literature.

The Broad Spectrum (BS) Strategy. The objective of the BS strategy is to discover the substances present in the sample and to measure their concentrations without a predetermined list of target analytes [1]. As a starting point, the BS strategy may follow the general scheme of a target analytical method, but with minimum sample processing to allow a broad variety of generally similar substances to reach the chromatographic separation and the detector. Procedures to remove target analyte interferences are minimized or not used to avoid discarding interesting and potentially important components. If the sample is very complex, it is usually divided into fractions that are likely to contain components with similar properties. Several or more different types of chromatographic separations may be required for the various fractions depending on the components of the sample and the breadth of information desired. The chromatographic detectors are generally spectroscopic detectors that can provide information about the composition and structure of the sample components. This information is used to identify known substances, unexpected substances, and even unknown substances. The most important and widely used detector for the broad spectrum strategy is the mass spectrometer [1], but infrared, nuclear magnetic resonance, and other spectroscopic techniques are sometimes used.

The identification of all or most substances in one or more chromatograms, even with extensive spectroscopic data, can be a challenging and difficult process. The available data may not be sufficient to even tentatively identify all the components, especially if pure authentic samples of suspected substances are not available in the laboratory. Calibration of a broad spectrum method for quantitative analysis is delayed until the desired components are identified. For these reasons, and the general preoccupation with target analytes, the BS strategy is much less common than the target analyte strategy.

The BS strategy is obviously important for the discovery of unknown naturally occurring substances and anthropogenic chemicals in the environment. However, BS strategies are more difficult than TA strategies to develop, document, and implement. Cost estimates for analyses are difficult to make because the number of substances found, identified, and measured is not known until after the samples are analyzed. Therefore, analytical costs are difficult to control. Because of the potential costs, the instrumentation requirements, the technical skills needed, and time required, the BS strategy is not often employed especially by programs with limited objectives and budgets. A strategy sometimes used in environmental studies is to develop a target analyte method that can meet the objectives of the study and give some attention to other chromatographic peaks to identify potentially new or unexpected substances.

Single-Analyte and Multi-Analyte Methods

Traditional analytical methods, which were generally developed prior to the widespread application of GC and HPLC techniques, were nearly always designed for a single target analyte, for example, the colorimetric determination of PO_4^{-3}. With the development of GC and HPLC separation techniques, the determination of several or more similar compounds or ions in a sample was feasible and multi-analyte analytical methods were developed and documented. However, analytical chemists did not generally attempt to include more than about 10–20 target analytes in a method. This strategy was necessary because early GC and HPLC columns were not very efficient and most GC and HPLC detectors were either not selective or had limited selectivity. Sample preparation procedures designed to reduce or eliminate interferences continued to be very important. Analytical methods for chlorinated hydrocarbon pesticides with a GC separation and an electron capture detector require appropriate sample preparation. These multi-analyte pesticide methods are sometimes called multi-residue methods because the pesticides are residues in crops and other samples.

As more efficient high-resolution chromatographic separation techniques were developed, and spectroscopic detectors came into widespread use, the number of target analytes in multi-analyte methods was increased. The separation of most or all target analytes is often feasible and spectroscopic detectors usually provide sufficient information to make correct identifications of target analytes even when some are not fully separated. Well-tested and documented analytical methods for 80–100 or more analytes in some types of samples are presently available [1, 2]. Multi-analyte methods significantly reduce the cost of an analysis on a per analyte basis and add support to the already strong justification for high-resolution chromatographic separations and spectroscopic detectors.

Remote Laboratory Analyses and Field Analyses

Chemical analyses can be conducted in a laboratory remote from the locations where the samples are taken or in the field near the sampling sites (on-site). On-site analyses can be conducted in a field laboratory which may be a temporary building or a truck trailer, van, or recreational vehicle equipped with utilities services and analytical equipment. Another type of field laboratory is within a materials or fluids processing facility. Alternatively, field analyses can be conducted with mobile or portable instrumentation carried in a small van, sport utility vehicle, moved with a hand cart, or carried by a person. Each of these strategies has some advantages and some disadvantages.

The remote laboratory has the advantages of providing carefully controlled temperature, humidity, ventilation, and background conditions with adequate space and utilities to support a large array of major analytical instrumentation and a staff of skilled analytical chemists and technicians working in a convenient, comfortable, and safe environment. The major disadvantage is that environmental samples must be carefully preserved, shipped, and stored prior to analysis. Furthermore, the analytical results may not be available for several days or weeks because of the time required to transport the samples to the laboratory, incorporate the analyses into work schedules, and service the multiple clients of a remote laboratory.

Field determinations have the major advantage of greatly reducing the time between acquisition of the samples and the availability of the analytical results. This may allow utilization of the results quickly which can provide significant cost savings in the field operations that utilize the analytical information. For example, the rapid availability of results from field determinations can be used to fine-tune a sampling strategy to obtain the most significant samples for detailed remote laboratory analysis. Similarly, the results from field determinations can be used to direct the work of construction crews or well drillers using heavy and costly equipment. Mobile or portable instrumentation can provide rapid and low-cost results from a large number of samples taken over a broad geographic area in a short period of time.

The analytical methods that are feasible in the field may be significantly limited compared to what is feasible in a remote permanent laboratory. If a field laboratory is located in a temporary building or a large truck trailer, and adequate utilities and personnel are available, many of the kinds of analytical methods that are routinely implemented in a remote laboratory may be feasible in the field. However, because of space and power limitations, a broad variety of instrumentation is usually not available and the number of different analytical methods that can be implemented is smaller than in a remote permanent laboratory. Mobile or portable instrumentation is usually more limited and generally sample analyses are less complete and detailed than in a field or remote laboratory.

Discrete Samples and Continuous Monitoring

Field analyses can be conducted with discrete or composite samples similar to the samples used in a remote laboratory, or by continuous monitoring of substances in a flowing stream of gases or liquids. Continuous monitoring is required when the results are needed within a period of time that is shorter than the time required to acquire and to analyze conventional discrete samples. Continuous monitoring is often required to determine substances in a processing facility and provide rapid feedback of results that are used in process-control strategies. If continuous determinations are made with sufficient speed to permit changes in sampling or other strategies while the determinations are in progress, these are called real-time analyses.

Continuous environmental monitoring in the field is needed when the substances present and their concentrations are changing rapidly. Discrete samples taken at inappropriate times will give results that do not correctly assess the variable conditions in the atmosphere or a flowing stream. Sample compositing may provide a better assessment, but continuous monitoring and integration of the determinations over time gives the best assessment. The determination of the sources of fugitive emissions that are rapidly dispersed in the atmosphere or in a flowing water stream requires continuous and sometimes mobile continuous monitoring. The concentrations of air pollutants, such as CO, NO_x, SO_2, and O_3, that vary widely with sunlight, automobile traffic, wind speed, wind direction, and other meteorological conditions are monitored continuously.

Sampling and analytical equipment used in processing facilities and in the field have some of the same requirements. However, equipment used in a facility may have fewer constraints in regard to size, weight, and power requirements than mobile and portable field equipment. Standard chromatographic separation techniques are generally too slow for continuous measurements although GC separations, especially fast GC, are used for process control.

Analytical Quality Assurance and Control

Analytical quality assurance (QA) is a broad program of actions designed to ensure that the chemical determinations are of known and acceptable quality. The QA program encompasses all aspects of the chemical analysis from the design of the sampling strategy to the documentation of the results. Analytical quality control (QC) is the implementation of specific actions designed to control the quality of the determinations at some defined level of acceptance. All physical measurements have some degree of variability and uncertainty and the QA/QC program should define the limits of these. The quality of analytical determinations is judged by the attributes, or figures of merit, of an analytical method, which include selectivity, sensitivity, detection limits, signal/noise, recovery, accuracy, bias, precision, and validation. These attributes are determined using a variety of special measurements and fortified samples (QA/QC samples) which are described in the analytical method. The time relationship between the analyses of the environmental samples and the determination of the quality attributes is critical in estimating the quality of the environmental determinations.

Published environmental chemical determinations are often used in ways that are not anticipated by the original investigators. The determinations may be used by other investigators to estimate human or ecological exposure, assess the level of industrial discharges, or to develop environmental quality standards or discharge limitations. Therefore the results of the QA/QC measurements, and their time relationships to the analysis of environmental samples, should be permanently attached to the environmental sample results. These QA/QC data should demonstrate that the environmental data were obtained under controlled conditions that provide credibility to the results. Other users of the data, sometimes years in the future, should be able to assess the quality and applicability of the information and take into account the variability and uncertainty in the determinations.

Development and Documentation of Analytical Methods

The complete development and documentation of an analytical method usually occurs over a period of several years or more. The germ of most new methods is often a research project in which a determination is needed. Organizations that specialize in developing and manufacturing analytical instrumentation frequently play a major role in supporting the development of new analytical methods. But instrumentation alone does not constitute an analytical method. The general acceptance and widespread use of methods depends on many factors including the needs for research or environmental monitoring of various substances, the cost and complexity of instrumentation, the required laboratory or field skills, and especially government regulations. There is a high degree of variability in the completeness, documentation, testing, and validation of published analytical methods.

Research Methods

The basic concepts and fundamentals of most analytical methods are usually first published in scientific journals, for example, The American Chemical Society publications.

Analytical Chemistry, Environmental Science and Technology, and the *Journal of the American Chemical Society*. These descriptions are usually brief and often just summarize the techniques and procedures of the method. Research reported in scientific journals is often focused on a detailed investigation of a narrow subject area, and new analytical techniques and procedures developed for the research are rarely tested in a broader context. Analytical quality assurance and control are often minimal or not described. Techniques and procedures described in scientific research journals are the beginnings of analytical methods, however, they usually require considerable development, modifications, and testing before they become widely accepted analytical methods.

Methods in Development

Academic research groups, industrial laboratories, and government agencies interested in conducting environmental surveys or monitoring programs often adapt research techniques and procedures to the broader needs of the survey or program. During this stage considerable experimentation is underway to evaluate equipment, instrumentation, chemical reagents, and other materials used in the method. The incipient method may be tested with many potential analytes and sample matrices. Modifications are implemented to minimize or eliminate problems discovered during the development process. Techniques and procedures are developed for identifications of analytes, calibration of instruments for quantitative analysis, and analytical quality assurance and control. Methods in development may be described in a series of draft versions that are not usually formally published but may appear in bound or unbound technical reports. These methods are described in more detail than in scientific journal articles, and descriptions often contain detailed information about required equipment, supplies, reagents, instrumentation, and personnel skills. The technical reports and draft method descriptions are often distributed informally through personal contacts, scientific conferences, or the Internet.

Methods Published by Standard-Setting Organizations

Standard-setting organizations that publish analytical methods for environmental analyses include The American Society for Testing and Materials (ASTM) [4], The American Public Health Association (APHA) [3], The American Water Works Association (AWWA), The Water Environment Federation (WEF), The International Standards Organization (ISO), and the Association of Official Analytical Chemists (AOAC). These organizations assemble working committees of experts that consider developed, widely used, and generally accepted analytical methods for publication as standardized analytical methods. Requirements of individual organizations vary and these may include a description of the method in a specific editorial format and the availability of multi-laboratory validation data for the proposed analytical method. Some of these organizations also sponsor or participate in multi-laboratory validation studies of proposed analytical methods. When an analytical method is published by one of these organizations it usually has been thoroughly tested and used by many laboratories and analysts, and is widely known and accepted by specialists in that type of determination. Published methods are reviewed periodically, updated as needed, and may eventually be replaced by entirely new methods.

Methods Published or Referenced in Government Agency Regulations

The US Environmental Protection Agency (USEPA) and other federal, state, and local government agencies in the United States may require chemical analyses to determine compliance with air quality, water quality, liquid waste discharge, solid waste disposal, and other environmental regulations. The analytical methods specified for these purposes may be methods in development, methods published by standard-setting organizations, or new methods documented in the regulatory proposals [2]. The USEPA has promulgated two types of analytical methods. Some regulations, for example, some drinking water and waste water regulations, require either analytical methods designated in the regulations or approved alternative test methods for compliance monitoring. Other regulations, for example, some USEPA solid waste regulations, include or reference analytical methods that are suggested or optional but allow any other appropriate analytical methods.

Characteristics of Analytes, Samples, and Sampling Techniques

The physical and chemical properties of analytes and the nature of the sample have a major impact on, and often limit, the sampling and other procedures and techniques that can be employed in an analytical method. Major issues that must be considered when developing an analytical method are the volatilities, thermal stabilities, photochemical stabilities, polarities, water solubilities, and chemical reactivities of the sample components or target analytes; the physical state of the sample; and the nature of the sample matrix. Analytes, whether organic or inorganic, can be broadly divided into three categories based partly on vapor pressure (VP), or volatility, at ambient temperature and on some other physical and chemical properties. There are major differences in the procedures and techniques used to acquire and process condensed-phase and vapor-phase samples.

Sampling ground water requires expert selection of procedures and techniques to avoid significant analytical errors.

Volatile Analytes

Volatile analytes are usually defined as those having vapor pressures (VPs) greater than about 0.1 Torr at 25°C and an external pressure of 760 Torr (1 Torr 1 mm of Hg or 133 pascals (Pa)). Figure 7.1 shows the structures, molecular weights (MW), boiling points (BP), and VPs of three representative volatile compounds of environmental interest. Most volatile analytes have MWs below 200 but a low MW does not guarantee that an analyte will be volatile. Many substances have MWs below 200 but they are not volatile because they are ionic or have polar groups of atoms or engage in hydrogen bonding with other molecules. Some compounds have high VPs, for example, MTBE in Fig. 7.1, but reduced volatility in water because of their high water solubilities. Boiling points of volatile substances range

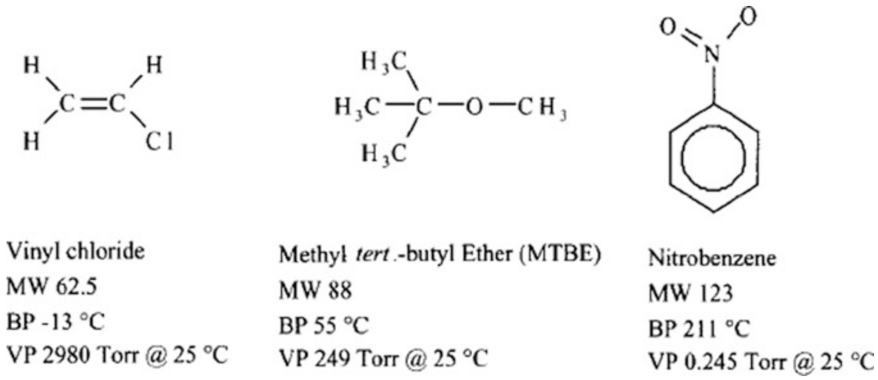

Fig. 7.1 The structures, molecular weights (MW), boiling points (BP), and vapor pressures (VP) of three representative volatile compounds of environmental interest

from below 0°C to above 200°C. Some compounds with BPs at the upper end of this range are surprisingly volatile. For example, nitrobenzene in Fig. 7.1 has a BP of 211°C but still has a VP of 0.245 Torr at 25°C. At normal room temperatures the distinctive odor of nitrobenzene vapor is readily detected by most people.

Semivolatile Analytes

Semivolatile analytes are usually defined as those having VPs in the range of 0.1 Torr to about 10^9 Torr, but this range is approximate and some substances with VPs in this range are considered volatiles or even nonvolatiles (next section). For example, Hg^0 has a VP of 2 10^3 Torr at 25°C, but is often considered a volatile analyte. Most semivolatile analytes have molecular weights in the range of 100–500, but a MW in this range does not guarantee that a compound is a semivolatile. However, because semivolatiles nearly always have higher MWs and contain more atoms than the volatiles, they have a significantly larger number of isomers, congeners, and chiral forms. Semivolatiles are usually devoid of structural groups that are susceptible to thermal decomposition below about 300°C, or cause high polarity, or impart high water solubility, or are very chemically reactive. Figure 7.2 shows the structures, MWs, some melting points (MPs), and VPs of four representative semivolatile compounds of environmental interest. Both benzo[a]pyrene and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin have VPs at the low end of the semivolatile range, but they have little or no polarity and tend to behave as do other semivolatiles with higher VPs. The VPs of semivolatile compounds are generally insufficient to give vapor concentrations at ambient temperatures that can be detected by a distinctive odorb.

The large number of potential congeners and isomers of some semivolatile compounds is illustrated in Table 7.1, which shows the numbers of possible chlorinated biphenyl, chlorinated dibenzo-*p*-dioxin, and chlorinated dibenzofuran congeners and isomers. The total number of chlorinated congeners of each parent compound is the sum of the possible isomers at each level of chlorination. Dibenzofuran has more possible chlorinated congeners and isomers than chlorinated dibenzo-*p*-dioxin (Fig. 7.2) because it has just one-ring oxygen and a less symmetrical structure. If F, Br, I, CH_3, or any other uniform substituent replaces Cl, the same numbers of possible congeners and isomers would exist. If different atoms or groups of atoms were mixed as substituents on these parent compounds, a significantly larger number of different substances, congeners, and isomers are possible.

Nonvolatile Analytes

All other compounds and essentially all ions are classified as nonvolatile. Substances in this category have VPs lower than about 10^9 Torr or have structural groups that are susceptible to thermal decomposition below about 300°C, or that cause high polarity, or that impart high water solubility, or that are very chemically reactive. Figure 7.3 shows the structures, MWs, some MPs, and VPs of six representative compounds of environmental interest from this group. All these examples except the herbicide glyphosate have reported VPs in the semivolatile range, but they do not behave as typical semivolatile compounds. Nitroglycerine and *N*-nitrosodiphenylamine undergo thermal decomposition at temperatures well below 300°C. The pesticide carbofuran and the herbicide diuron are more thermally stable, but they also tend to decompose below 300°C and on hot surfaces. The polarities of the functional groups of this class of compounds cause adsorption on polar surfaces and dipole–dipole interactions with other molecules. Nearly all carboxylic acids, for example, the herbicide 2,4-D in Fig. 7.3, are susceptible to decarboxylation at elevated temperatures and they interact with basic substances or basic surfaces which reduces their volatility. Similarly, basic substances such as amines and some other nitrogen compounds interact with acids and acidic surfaces which reduce their volatility.

Condensed-Phase Samples

If only semivolatile and nonvolatile components are of interest, or the sample only contains these categories of analytes, sampling procedures for most condensed-phase samples are not difficult and require only a few precautions. These include the materials used for sample containers, the cleaning of sample containers, and the preservation of the sample. Water samples for elemental analyses are treated with acid at the time of sampling, or well before analysis, to reduce the pH to 2. This ensures the solubility of metal-containing ions which can precipitate or adsorb on container walls at a pH 2. Glass containers are not used for elemental analysis samples because aqueous acid solutions can leach trace elements from glass. Samples are taken in plastic containers which provide the added benefits of reduced weight compared to glass, little or no breakage during handling and shipping, and single-use containers that can be disposed of at a plastic recycling facility. However, samples for the determination of organic analytes are taken in glass containers to prevent background contamination of the samples by organic compounds that can leach from plastic materials. These samples are often preserved by addition of acid to make the sample pH 2 to retard microbiological degradation of some analytes. Acid leaching of glass containers generally has no effect on the concentrations of organic analytes.

Condensed-phase samples containing volatile analytes require special techniques because the volatile components are elusive and can be readily lost during sampling and

sample processing. Water samples must be taken with little or no agitation of the sample and poured into the container so there is no air space, often called a headspace, between the top of the sample and the air-tight seal of the container. This prevents vaporization of volatile components into the headspace during shipment and storage which reduces the concentration in the aqueous phase. Aliquots of water samples are removed from sample containers by inserting a syringe needle through the inert air-tight septum seal and drawing water into a gas-tight syringe. Solid samples, for example, soils and sediments, may also contain volatile components trapped in pores or dissolved in associated water and these components are easily lost during sample handling. Solid and semisolid samples are carefully and quickly placed in wide-mouth sample containers that are sealed in the field and not opened during any subsequent processing of the sample. Volatile components are usually partitioned into water, organic solvents, or the vapor phase and the extracts are analyzed using techniques developed for liquid- or vapor-phase samples. Water or an organic solvent are added to the sample containers through inert and air-tight septum seals with a syringe.

Ground water sampling is a significant challenge because water must be lifted to the surface through a bore hole from depths ranging from a few meters to 75 m or more. The lifting process can disturb the equilibrium between dissolved analytes and analytes associated with particulate matter, and significantly change the temperature and pressure of the water sample. These factors can cause changes in concentrations of analytes and raise questions about the representativeness of the sample. Volatile components of ground water samples are particularly susceptible to losses caused by temperature and pressure changes and degassing of the sample. Several types of down-hole water samplers are available and several types of pumps are used to purge a well and lift a stream of ground water to the surface. The materials of construction of the down-hole samplers, pumps, tubing used with pumps, and well casings can also have an impact on the concentrations of analytes in the sample. Considerable research has been conducted to evaluate the materials and techniques used to sample ground water, however, uncertainties remain because there is no satisfactory ground water standard of reference for comparison of various techniques.

Semivolatile analytes in vapor-phase samples are often associated with particulate matter or aerosols that are collected on glass or quartz fiber filters in a flowing air stream [1]. However some semivolatile analytes that have higher VPs, for example, 3,3′,5,5′-tetrachlorobiphenyl in Fig. 7.2, can slowly vaporize from a particle trapped on a filter in the flowing air stream, and will be lost unless captured by an in-stream sampling device. Small glass or metal tubes containing polyurethane foam are often used to capture vaporized semivolatile analytes. Other solid-phase adsorbents, which are described in the next section, are also used to trap semivolatile analytes vaporized from particulate filters.

Vapor-Phase Samples

There are two general approaches to sampling air, or vaporous emissions from stationary (stack) and mobile (automobile, truck, etc.) sources, for the laboratory determination of volatile analytes [1]. Bulk vapor-phase samples can be taken in the field in various containers and transported to a remote or field laboratory for analysis. Containers used for bulk vapor-phase samples include flexible polyvinyl fluoride (Tedlar™) bags, evacuated glass or metal reservoirs, and thermally insulated cryogenic collection vessels. Alternatively, the volatile analytes can be separated from the main components of air in the field and just the analytes and their collection devices transported to the laboratory. The principal techniques used to separate volatile analytes from air in the field are cryogenic traps, impingers, and solid-phase adsorbents.

Bulk Vapor-Phase Samples. Flexible plastic sample bags are generally limited to vapor-phase samples that can be analyzed within a short time after sample collection. This limitation is due to potential losses of analytes by surface adsorption and surface chemical reactions. Transportation of inflated bags over long distances to a remote laboratory is cumbersome and can result in total losses of samples due to punctures and other accidents. Plastic bags are used in some laboratory operations, for example, to collect automobile exhaust and vaporized fuel, and for samples that can be conveniently transported to a laboratory.

Evacuated stainless steel canisters are widely used collection devices for ambient air samples [5]. Sample canisters have smooth and inert internal surfaces and few or no active sites that adsorb volatile analytes or catalyze chemical reactions. The 1–6 L canisters are easily transported to a remote or a field laboratory. Canisters are leak tested and cleaned in the laboratory prior to use, evacuated to about 5 10^2 Torr or less, and transported to the sampling site where samples are taken by opening the sampling valve. Composite samples can be taken over time and/or space and an in-line pump can be used to pressurize the container with either additional sample air or pure air if sample dilution is required. Pressurized samples are useful when longer-term composite samples are taken or when larger samples are needed to lower detection limits.

Condensation of an entire air sample with liquid nitrogen or liquid helium has been used for many studies. However, this technique is expensive to implement and requires specialized portable equipment for handling cryogenic fluids in the field.

Separated Analytes. Cold trapping is used to separate volatile analytes from the main components of air in the field. Air is drawn by a pump through an inert, often nickel, metal tube immersed in a fluid at a very low temperature, for example, 150°C. The tube may be packed with some inert material such as Pyrex™ glass beads and the temperature is sufficient to condense most analytes but insufficient to condense oxygen or nitrogen.

Plugging of the condensation tube with ice or other solids can be a major problem when sampling large volumes of humid air. This problem is addressed by the employment of air dryers that trap moisture but allow the nonpolar volatile analytes to pass into the cold stage of the trapping system. However, the more polar and water-soluble analytes are also removed by efficient air drying systems. Another potential problem is that some analytes may react during subsequent processing with trapped ozone, nitrogen oxides, or other substances present in the air. A practical limitation of the cold trapping technique is the requirement for liquid nitrogen or liquid argon in the field during extended sampling periods.

Impingers are used to extract various substances from vapor-phase samples [1]. An impinger is a closed glass or metal vessel with an inlet tube that extends to near the bottom of a liquid and an outlet tube well above the surface of the liquid. The impinger may contain various aqueous or nonaqueous liquids including solutions of derivatizing agents. Vapor is drawn by a pump into the inlet tube and bubbled through the liquid which dissolves soluble analytes or the analytes react with reagents in solution to form soluble compounds. The liquid may also condense various substances, including water vapor, and collect fine particulate material that passes through a coarse filter or another separation device. A important advantage of an impinger compared to some bulk air sampling techniques is that hundreds of liters of air can be drawn through the device over a period of several hours. Sampling trains with multiple collection devices in series are used to collect different fractions of a vapor-phase sample. Components of sampling trains can include particulate filters of several types and sizes, particle-size separation devices, multiple impingers, and solid-phase adsorbents.

Solid-phase adsorbents are simple and inexpensive devices used to separate volatile analytes from the principal components of air in the field [1]. A porus solid-phase adsorbent is placed in a glass or metal tube which is taken to the field where air is drawn through the adsorbent to trap the analytes. The adsorbent tube is then sealed and returned to the laboratory for analysis. Many types of solid-phase adsorbents are used including alumina, activated carbons of various types, charcoal, graphitized carbon black (Carbopack™ B and C), carbon molecular sieves, GC packing materials such as Chromosorb™ 101 and 102, ethylvinylbenzene-divinylbenzene copolymer (Porapak Q™), styrene-ethylvinylbenzenedivinylbenzene terpolymer (Porapak P), silica gel, 2,6-diphenyl-*p*-phenyleneoxide (Tenax-GC™), styrene-divinylbenzene copolymers (XAD-1™, XAD-2™, and XAD-4™), and acrylic ester polymers (XAD-7™ and XAD8™). Adsorbent trapping is applicable to a wide variety of nonpolar and some polar volatile analytes.

Some adsorbents do not bind analytes strongly, which is an advantage for subsequent processing, but may result in the gradual release of some volatile analytes during long vapor sampling periods. Long sampling periods are often required, for example, with ambient air, because of generally lower analyte concentrations compared to vapor-phase samples from stationary or mobile sources of air pollutants. Breakthrough of the more volatile polar and nonpolar analytes from the adsorbent is controlled by placing additional adsorbents in the tube or additional sampling tubes in a sampling train. Analytes adsorbed on solid-phase materials may also react with substances in the air, for example, nitrogen oxides and ozone, to produce products not in the original sample. Long air sampling times also risk oxidation of some adsorbents and the production of background substances and other artifacts. These potential problems are usually evaluated during analytical method development and controlled by using appropriate quality control procedures.

Processing of Samples Before Determination of the Analytes

Some processing of samples before the determination of the analytes is often required to achieve optimum analytical method performance. Sample processing also defines exactly what elemental forms, compounds, ions, oxidation states, and physical phases are included in the determination of specific substances, or in the total amount of an element or a group of related substances in a sample. The degree of sample processing that is either appropriate or needed depends on a variety of considerations including:

The chemical analysis strategy, that is, a total target analyte, or broad spectrum determination
The physical phases of the sample that are included in the determination
Whether the samples will be analyzed in a remote or a field laboratory or with laboratory, mobile, or portable instrumentation
The complexity of the sample matrix
The number of target analytes
The diversity of properties of the target analytes
The nature and concentrations of analyte interferences
The detection limits required
The efficiency of the chromatographic separation used in the analytical method
The selectivity of the chromatographic detector or the nonchromatographic measurement technique
The willingness to risk severe contamination of a GC or HPLC column, or some other critical instrument component, by a concentrated or high background environmental sample

Some sample matrices, for example, ambient air or drinking water, are analyzed without sample processing with some analytical methods. Volatile compounds in ambient air collected in canisters or volatile compounds trapped from ambient air on solid-phase adsorbents are determined directly. Similarly, the total concentrations of some elements in low turbidity drinking or surface water samples preserved at a pH 2 can be determined without further sample processing. Common inorganic anions, for example, Cl, Br, NO_3, etc., are determined in surface, ground, drinking, and some other water samples without sample processing. However, many sample matrices and analytical methods require at least some, and sometimes considerable, sam- *CHROMATOGRAPHIC ANALYTICAL* ple processing prior to the determination of *METHODS* the analytes.

Semivolatile organic analytes trapped on air filters or on solid-phase adsorbents or in water, soil, and other solid samples are extracted with an organic solvent, or a solvent mixture, and the extracts are concentrated by evaporation of the solvent before the determination of the analytes. Solid samples are often extracted with the classical Soxhlet apparatus or with a variety of other techniques including several that use organic solvents at elevated temperatures and pressures. If a sample is highly concentrated, for example, an industrial wastewater or a soil from a hazardous waste land fill, fractionation of the solvent extract before determination of the analytes is usually required. Fractionation is often accomplished with open-column liquid chromatography or preparatory-scale HPLC. The determination of total elements in particulate matter collected on air filters, in most water samples, or in solids requires an acid digestion of the sample to ensure that the elements are in water-soluble chemical forms for the measurement. The vigor of the digestion also determines the recovery of the elements from sediment and other insoluble material.

Invariably the analytical method developer is required to make compromises between the amount and complexity of the sample processing and the separating power, selectivity, and other attributes of the chromatographic or nonchromatographic determination. These compromises are often strongly influenced by the projected cost and time required for various method options and by the desired quality, detail, and reliability of the results. Major issues usually are the availability of laboratory or field equipment and instrumentation, the experience and skill of the staff in using the equipment, and other laboratory or field infrastructure required to complete the analyses of the samples. Most research and standard analytical methods contain many compromises that may not be clearly defined in the method description, but should be understood by the user.

Nearly all contemporary analytical methods designed for specific compounds or ions in environmental samples employ some type of chromatographic separation. Gas chromatography is the dominant technique for the separation of volatile and semivolatile analytes (Figs. 7.1 and 7.2 and Table 7.1). Reverse-phase HPLC is used for the separation of nonionic analytes that are thermally unstable, nonvolatile, or reactive and not amenable to GC (Fig. 7.3). High-performance ion exchange chromatography and capillary electrophoresis (CE) are used for the separation of ionic substances. Analytes, either fully or partially separated, are sensed by in-line chromatographic detectors that produce electronic signals that are usually converted into digital form and stored in computer data systems. The computer systems, which are used with nearly all contemporary chemical analytical instrumentation, typically have software to control the operation of the instrument, acquire and store raw data, and reduce the data to more usable analytical information.

Chromatographic Separation Techniques

Gas Chromatography. The basic components of a gas chromatograph are a carrier gas system, a column, a column oven, a sample injector, and a detector. Very pure helium is the near-universal carrier gas for environmental and many other analyses. Open tubular GC columns are constructed of fused silica with low-bleed stationary phases of varying polarity chemically bonded to the silica surface. Columns are typically 30–75 m in length and have inside diameters (ID) in the range of about 0.25–0.75 mm. The column oven is capable of precise temperature control and temperature programming at variable rates for variable times.

Analytes are introduced into GC columns with several techniques. An aliquot of a relatively concentrated vapor or air sample, for example, from a plastic bag or a canister, can be introduced into a short section of tubing of known volume, called a sample loop, and subsequently purged with carrier gas into the GC column. Volatile analytes in ambient air samples in a canister or trapped on a solid-phase adsorbent are usually concentrated and focused in a cryogenic trap or a secondary adsorbent trap, then thermally vaporized into the GC carrier gas stream. However, in some analytical methods, volatiles trapped on an absorbent are thermally desorbed directly into the GC column. Aliquots of organic solvent extracts from various aqueous and solid samples are usually injected with a syringe into the carrier gas stream in a heated injection port. Both manual and automated syringe injection systems (autoinjectors) are used and the latter are generally very reliable, precise, and have the capacity to process many samples unattended.

Mixtures of analytes are separated by repeated equilibrations between the vapor state, where the analytes are entrained in the flowing carrier gas toward the detector, and the absorbed or dissolved state, where they are attracted to the stationary phase on the wall of the column by generally weak molecular forces. Analytes that tend to favor the absorbed state move more slowly through the column to the detector than do analytes that favor the vapor state. Complete separations of a few nanograms (10^9) or less of each of 40–50 or more analytes in 30 min or less is not uncommon.

HPLC. The basic components of a high-performance liquid chromatograph are a high-pressure mobile-phase delivery system, a metal column packed with fine particles containing the stationary phase, a sample injector, and a detector. A high-pressure pump is used to force the mobile-phase solvent or solvent mixture through the packed column. The term *high performance* is often used to distinguish this technique from open-column liquid chromatography conducted at atmospheric pressure with gravity flow of the mobile phase. Columns vary in diameter from 1 to 5 mm ID, or larger, and from a few cm in length to 30 cm or more. Column packings consist mainly of silica particles, usually 3–10 m in diameter, coated with low-bleed stationary phases of varying polarity chemically bonded to the silica surface. Organic polymers are also used as stationary phases in analytical separations. Automated or manual syringe injections of aliquots of liquid samples and known-volume sample loops are used for sample injection.

The dominant HPLC technique is the reverse-phase configuration in which a nonpolar or slightly polar stationary phase is used with a more polar mobile phase that is often water, methanol, acetonitrile, or mixtures of these solvents. The normal-phase configuration, which was developed before reverse phase, uses a more polar stationary phase and a nonpolar mobile phase, but it is not often used in contemporary HPLC. A vast array of organic compounds containing a variety of functional groups are retained on nonpolar or slightly polar stationary phases, and are sufficiently soluble in more polar mobile phases to give excellent separations. Analytes are retained on the column by an equilibrium process in which the dissolved molecule is alternately associated with the stationary phase, through weak noncovalent bonding interactions, and the mobile phase where it is transported toward the detector.

Isocratic elution is the use of a mobile phase that has a constant composition throughout the elution of analytes from the column. Gradient elution is the gradual changing of the mobile phase composition as the analytes elute from the column. Gradient elution is frequently used to enhance analyte resolution and shorten the time required for a separation. The pH of typical mobile phases can be adjusted over a reasonable range to improve resolution and selectivity. Various buffer substances, salts, and ion pair reagents can be used to control pH, ionic strength, and to facilitate the separation of some analytes. Reverse-phase HPLC is more complex than GC because of the number of operational parameters including column dimensions, column packings, mobile phases, gradient elution, and various mobile-phase additives.

High-Performance Ion Exchange Chromatography. Ion exchange is another form of HPLC that uses a stationary phase consisting of a cross-linked synthetic organic polymer, often called a resin, with SO_3H or NH_2 groups attached to phenyl or other aromatic rings on the polymer backbone. Mobile phases are usually water or water and a miscible organic solvent. In basic solution the SO_3H groups of a cation exchange resin are ionized and consist of $-SO_3$ groups and associated counter ions, for example, Na. Cationic analytes are retained on the cation exchange column by displacing the resin counter ions in an equilibrium process. The cationic analytes are subsequently eluted with a mobile phase containing a high concentration of counter ions or counter ions of a higher charge, for example, Ca. Isocratic and gradient elutions are used with gradients in both solvent composition and counter ion concentration. Mobile-phase pH is a very important operational parameter that can have a significant impact on the retention or elution of various ionizable analytes from a resin.

In an acid solution the amino groups of an anion exchange resin are protonated and exist as NH_3 groups and associated counter ions, for example, Cl. Analyte anions are retained on the column by displacing the resin counter ions in an equilibrium process. The anion analytes are subsequently eluted with a higher concentration of counter ions or some type of gradient elution. Anion exchange chromatography is widely used for the separation of inorganic anions and chelated metal anions in aqueous samples. With some natural or industrial water samples that contain high concentrations of ions such as Na, Ca, Mg, Cl, and SO_4, cation and anion analytes may not be retained on the column and this can result in poor analyte recoveries.

Other Chromatographic and Related Techniques. Supercritical fluid chromatography (SFC), capillary electrophoresis (CE), and several related separation techniques are occasionally used in environmental chemical determinations. The CE technique is very important in biochemistry and molecular biology because of the very high resolving power that can be achieved, the high speed of separations compared to HPLC, and its ability to separate charged species such as proteins, peptides, and deoxyribonucleic acid fragments. These techniques have considerable potential for environmental analyses and may emerge as very important techniques in the future.

Chromatography Detectors

Online detectors for GC, HPLC, and other chromatographic separation techniques are conveniently divided into three general classes:
Nonselective detectors
Selective detectors
Spectroscopic detectors

Nonselective detectors respond to most or all changes in the composition of the carrier gas or mobile phase and are capable of detecting nearly all entrained or dissolved analytes. The GC flame ionization and thermal conductivity detectors and the HPLC refractive index detector are examples of nonselective detectors. Nonselective detectors provide no direct information about the identity of the analytes except the time of arrival, the time of maximum concentration, and the time of return to pure carrier gas or mobile phase. Thus the peak shape of the analyte is usually well defined, the measurement of peak area or height can be precise, but the information needed to identify the analyte that caused the change is weak. Identifications are based on comparisons of measured retention times of separated analytes with retention times of expected analytes measured under the same chromatographic conditions. Although measured retention times can be very precise, especially with fused silica capillary GC columns and multiple internal standards, there is a high probability of coelution of two or more analytes in most environmental samples. This is because the peak capacity of a chromatogram, which is the number of analytes that can be fully separated, is limited. For most environmental samples the peak capacity is much smaller than the number of possible analytes that respond to a nonselective detector. Therefore, there is a significant risk of misidentifications or false positives.

Selective detectors respond to only certain classes of analytes and they are often used in environmental chemical determinations. The electron capture, photoionization, electrolytic conductivity, and flame photometric GC detectors are selective for limited groups of analytes. Selective HPLC detectors include electrochemical detectors and the single wavelength ultraviolet–visible (UV–VIS) absorption and fluorescence detectors. Preinjection or postcolumn online chemical reactions are used to convert nonresponsive analytes into derivatives that respond to a selective detector. The information produced by a selective detector about the nature of the analyte is improved, compared to the nonselective detector, but still is not strong because the most significant piece of information obtained is the retention time. Although the range of potential analytes that responds to a selective detector is much narrower than the range that responds to a nonselective detector, multiple potential analytes still can have the same retention time. The nature of the sample is a factor in considering whether multiple analytes could be present that may have the same retention time.

Spectroscopic detectors measure partial or complete energy absorption, energy emission, or mass spectra in real-time as analytes are separated on a chromatography column. Spectroscopic data provide the strongest evidence to support the identifications of analytes. However, depending on the spectroscopic technique, other method attributes such as sensitivity and peak area measurement accuracy may be reduced compared to some nonselective and selective detectors. The mass spectrometer and Fourier transform infrared spectrometer are examples of spectroscopic detectors used online with GC and HPLC. The diode array detector, which can measure the UV–VIS spectra of eluting analytes is a selective spectroscopic detector because only some analytes absorb in the UV–VIS region of the spectrum. The mass spectrometer, which can use a variety of ionization techniques, is probably the most widely used GC and HPLC detector for environmental chemical determinations [1]. All detectors respond, to some extent, to natural background substances in environmental samples and sample extracts. Background chemical noise is highest in the most contaminated environmental samples and at the highest instrument sensitivities, but spectroscopic detectors are best equipped to distinguish chemical noise from environmental analytes.

Nonchromatographic Analytical Methods

Analytical methods that do not employ a chromatographic separation of analytes are widely used for some environmental determinations. These methods generally depend on highly selective physical measurements or selective chemical reactions. Atomic absorption spectrometry (AAS), atomic emission spectrometry (AES), and mass spectrometry (MS) are most often used for determinations of the elements, but electrochemical and colorimetric techniques are sometimes used. Derivatives of analytes, which are sometimes called complexes, that strongly absorb in the UV–VIS spectrum are employed in colorimetric methods for the elements and some compounds and multi-element ions. Ozone, nitrogen oxides, and some other substances in air are determined by selective chemical reactions that produce measurable light emission (chemiluminescence). Fluorescence spectrometry is used in some methods, especially with fiber optics technology, for remote monitoring. Immunoassays have been developed for a few analytes and they are especially useful in field analyses.

Elemental Analysis

Atomic emission and atomic absorption techniques are highly selective because the number of elemental analytes is small and each has a unique atomic spectrum. Frequencies are selected for measurements to maximize selectivity and sensitivity, minimize interferences, and correct for interferences when necessary. Mass spectrometry is the separation and measurement of ions in the gas phase by their mass-to-charge ratios. Elemental analyses by mass spectrometry provides high selectivity, sensitivity, and the ability to correct for interferences when necessary [1]. Colorimetric and electrochemical techniques were used more frequently for elemental determinations before the development of the three major spectroscopic techniques. Their use has decreased significantly because of inherent limitations in selectivity, sensitivity, susceptibility to interferences, and the need for chemical processing to prepare energy-absorbing derivatives.

Atomic Absorption. During the 1960s, flame AAS became the dominant technique for determinations of the elements in low concentrations in water samples and aqueous extracts of other samples. Aqueous sample aerosols are injected directly into the flame and precise determinations of many elements can be made. However, instrument detection limits for some important elements, for example, As, Cr, Pb, Sb, Se, and Tl, in water and other matrices are 50 g/L, and often much greater, and AAS is limited to measuring one element at a time. The high-temperature graphite furnace sample introduction system provided instrument detection limits of 5 g/L for most elements, and allowed automation of sample processing, but was still limited to measuring one element at a time. Other AAS sample introduction techniques, especially chemical reduction and elemental Hg vaporization (cold-vapor) and conversion of As and Se to volatile hydrides, provided similarly low detection limits. The graphite furnace and Hg cold-vapor techniques are often referred to in the scientific literature as flameless AAS methods.

Atomic Emission. Elemental analysis with AES had been practiced since the mid-1930s using flames and arc or spark discharges to vaporize and atomize samples and excite the atoms for optical emission. The AES technique provided rapid simultaneous or sequential multi-element determinations, but the flames and arc or spark discharges had significant limitations. Interferences from electrode and other sample components were not uncommon, elemental measurements were often imprecise, detection limits were not sufficiently low, and liquid samples were difficult to analyze. The increasing demand for rapid, selective, and sensitive multi-element determinations led to the development of the inductively coupled plasma (ICP) sample vaporization, atomization, and excitation source which met the analytical requirements and gave new life to AES. The ICP allowed the direct injection of aqueous aerosols into a 5,500–8,000°K argon ion plasma and elemental measurements with minimal or no interferences from background components or other analytes. Analytical methods utilizing ICP/AES are widely used for the determination of multiple elements in environmental samples.

Mass Spectrometry. The ICP technique also produces gas-phase elemental ions and the ICP was quickly adapted as an ion source for mass spectrometry. This combination became one of the most useful and important techniques for rapid multi-element analyses of gases, liquids, and solids [1]. The argon ICP is a very efficient ion source that produces mainly singly charged ions. It is estimated that 54 elements, all metals, are ionized with 90% or greater efficiency. Only C, H, N, a few electronegative elements, and the noble gases are ionized with efficiencies less than 10%. A small number of elements, for example, As, B, Be, Hg, I, P, S, Se, and Te have estimated ionization efficiencies in the 10–90% range. Although Ar has a low ionization efficiency, it is present in the ion source in great quantity and gives a few significant ions at m/z 40 ($Ar^{\cdot}$) and m/z 80 ($Ar_2^{\cdot}$). Other background ions, for example, m/z 41 (ArH) and m/z 56 ($ArO^{\cdot}$), are formed from sample components, usually water, and mineral acids that are used to ensure dissolution of some analytes.

These ions obscure ions from some elements, but techniques are available to circumvent most of these interferences.

Organic and Inorganic Compounds and Ions

Colorimetric determinations are selective for specific substances, for example, the PO_4^{-3} ion, because of selective color-forming chemical reactions between reagents and target analytes. Several of these techniques continue to be important for the determination of a few inorganic anions. However, ion-exchange chromatographic techniques are increasingly used for determinations of multiple ions in environmental samples. Some electrochemical techniques, for example, ion-selective electrodes, are selective because the materials of construction, for example, ion-selective membranes, and operating parameters are carefully chosen so the devices respond only to specific analytes. Ion-selective electrodes are widely used for the determination of pH and a few other inorganic ions, for example, F^-. Immunoassay methods, which are very widely used and enormously important in clinical analyses, have been developed for a small number of organic compounds, for example, several triazine pesticides. However, many chemicals of environmental interest have MWs and shapes that are too small and similar for effective application of immunochemical techniques.

The further development of nonchromatographic analytical methods based on these and other techniques has been impeded by fundamental limitations in selectivity, and sometimes sensitivity, for a wide variety of similar substances, for example, those in Table 7.1 and Figs. 7.1–7.3. The cost of developing, testing, and documenting a large number of specialized methods, often for just one or a few analytes, is generally prohibitive compared to the cost of chromatographic methods that allow the determination of multiple generally similar analytes in an environmental sample.

Glossary

Accuracy The degree of agreement between the measured concentration of a substance in a sample and the true value of the concentration in the sample.

Analysis The process of investigation of a sample of the physical world to learn about its chemical components, composition, structure, or other physical or chemical characteristics. Generally only samples are analyzed and individual elements, compounds, and ions are separated from one another, identified, measured, or determined. A pure compound or multi-element ion is analyzed only when it is investigated to determine its components, composition, structure, or other physical or chemical characteristics.

Analyte A general term for any element, compound, or ion that is present in a sample or is targeted for determination in a sample.

Analytical method The complete process used to determine an analyte or analytes in a sample. The analytical method documents all the individual steps in the process from sampling to reporting the results.

Analytical method attributes Measures of the quality, reliability, and uncertainty of the determinations obtained with an analytical method. Typical analytical method attributes are selectivity, sensitivity, detection limits, signal/noise, recovery, accuracy, bias, precision, and validation. *Analytical method attributes* are sometimes called *figures of merit*.

Bias The systematic error in a measurement of the amount or concentration of an analyte in a sample.

Congeners Compounds or ions that are members of a series of related substances that differ only by the number of hydrogens that have been substituted by the same atom.

Derivatives Compounds or ions that are produced by chemical reactions of analytes. An analytically useful derivative has physical or chemical properties that are not possessed by the analyte but that can be employed to determine the analyte.

Detection limit The minimum quantity or concentration of an analyte that can be detected with an analytical method or technique. There are no generally accepted standard criteria for detection and detection limits often depend on the sample matrix. Therefore detection limits must include the criteria for detection and the nature of the sample matrix. A technique with a higher analyte sensitivity does not always provide a lower detection limit because interfering sample matrix components may also be observed with higher sensitivities.

Determination The identification and the measurement of the concentration of an analyte in a sample.

Isomers Two or more compounds or multi-element ions that have the same elemental composition but different structures.

Precision The degree of random variation in repetitive measurements of the concentration of an analyte in a sample. Precision is usually measured by the standard deviation or the relative standard deviation of the measurements.

Procedure A specific part of an analytical method that is concerned with one aspect of the method, for example, the liquid–liquid extraction of groups of similar analytes from a water sample.

Qualitative analysis The process of only identifying the analytes in a sample.

Quantitative analysis The process of both identifying and measuring the concentrations of the analytes in a sample.

Recovery The amount of analyte measured in a sample matrix as a fraction of the amount of the same analyte that was added to the sample. If the analyte is present in the sample before the addition, the native amount is subtracted from the measured quantity before calculating the recovery.

Sample matrix The general nature of the sample and its components that can have a significant impact on the performance of an analytical method. For example, sea water and fresh water sample matrices are significantly different and this difference can affect the performance of an analytical method.

Selectivity Is a qualitative estimate of how well the analyte identification procedure is able to distinguish an analyte in a sample from one or many similar analytes with similar, or even some of the same, physical or chemical properties.

Sensitivity Is the electronic or other measurable signal produced by the analytical method or measurement technique per unit amount of analyte.

Signal/Noise Is the ratio of analyte electronic or other measurable signal to the mean background matrix signal.

Technique Is a specific way of manipulating a sample or substance or measuring a substance. One or more techniques may be used within each procedure and several procedures may be used within an analytical method.

Validation Is the determination of the attributes, or figures of merit, of an analytical method for one or more analytes in one or more sample matrices by one or more analysts in one or more analytical laboratories and the acceptance of the attributes as reasonable and useful by the users of the data. There are many levels of analytical method validation ranging from the validation of a method for a single analyte in a single matrix by a single analyst in a single laboratory to a multi-analyte, multi-matrix, multi-analyst, and multi-laboratory validation.

Nanotechnology: Fundamental Principles and Applications

8

Ranjit T. Koodali and Kenneth J. Klabunde

Introduction

Research in nanotechnology has seen an explosive growth during the past decade, fueled by significant investment in research and development and the appearance of a cornucopia of consumer-based products. As of August 2009, an inventory conducted by the Project on Emerging Nanotechnologies has identified over 1,000 nanotechnology consumer products [1]. Based on current growth rates, it is estimated that nano-related goods could be in the range of $1–2.5 trillion market by 2015 globally.

This chapter is not intended to be a comprehensive summary of nanotechnology; however, the basic principles and selected applications will be discussed for the reader to gain an appreciation and basic understanding of the importance of nanotechnology and how it has already made an impact in our day-to-day lives. The reader is also advised to refer to some excellent books published in the past few years that could provide more detailed and specific information [2–20].

What Is Nano?

The prefix *nano* literally means one billionth of a meter and one nanometer is thought to be a “magical point on the dimensional scale” [18]. This is because these are the smallest solid materials that can be fabricated since anything smaller than nanometer would essentially be a small molecule or an atom and not condensed matter. Thus, nanostructures (materials with one dimension in the range between 1 and 100 nm) are the smallest solid things possible to make. To put things in context, ten hydrogen atoms make up one nanometer. A better appreciation of the nanoscale may be obtained from Fig. 8.1 which contains images of manmade and natural substances spanning several length scales. For example, the width of a human hair is between 60 and 120 μm.

The corresponding manmade devices are microelectromechanical (MEMS). MEMS is a mature field of nanotechnology and finds extensive uses in manufacturing and assembly processes. MEMS deals with devices primarily in the 10–100 μm range. Advances in the fields of nanotechnology and MEMS have led to the creation of Nanoelectromechanical Systems (NEMS), a field that bridges and borrows principles from both nanotechnology and MEMS.

Nanotechnology is a broad encompassing area incorporating principles of sciences, engineering and technology to understand, control, manipulate, and construct matter in the 1–100 nm dimension range. A widely accepted definition is the one proposed by the National Nanotechnology Initiative (NNI), a Federal research and development program approved by the Congress in 2001. This defines nanotechnology only if all three following aspects are involved: (1) research and technology development at the atomic, molecular, or macromolecular levels, in the length scale of approximately 1–100 nm range, (2) creating and using structures, devices, and systems that have novel properties and functions because of their small and/or intermediate size, and (3) ability to control or manipulate on the atomic scale. Thus, one can define nanotechnology to be a technology based on the manipulation of individual atoms and molecules to build complex structures that have unique physical, chemical, and/or biological properties different from bulk properties. Estimates based on key indicators such as publications, patent applications, products, and research and development funding suggest that the average growth in this area has been 23–35% since 2000. In 2008 alone, over 15,000 manuscripts in the broad area of

nanoscience/nanotechnology have been published, compared with ~5,000 in the year 2000, illustrating robust growth in this fertile area of research.

Nanotechnology is a technology that is expected to create products or devices that are lighter, robust, safer, reliable, and durable. At the core of nanotechnology is what is called "molecular technology" or "molecular manufacturing." Molecular technology refers to manufacturing processes using molecular machinery, i.e., obtaining molecule-by-molecule control of products and by-products via positional chemical synthesis. Most of the current technologies rely on bulk technology or a top-down approach such as the ancient technology of chipping a large rock to smaller particles or the modern technology of making Silicon chips for microprocessors. In contrast, nanotechnology builds materials and products from the bottom-up. Nanotechnology handles individual atoms or molecules with control and precision.

History

The term *nano-technology* was coined by the Japanese scientist Norio Taniguchi in 1974 and then by Eric Drexler (who was unaware of the usage of the term by Taniguchi) who popularized the concept of nanotechnology [21, 22]. However, the dawn of nanotechnology was envisioned by the late Nobel laureate Richard Feynman much earlier [23]. In his seminal talk at the annual meeting of the American Physical Society in December 1959, titled *There's plenty of room at the bottom—An Invitation to Enter a New Field of Physics*, Feynman discussed the advantages that could be obtained through precise control of atoms. Feynman, had stated in his talk "*But I am not afraid to consider the final question as to whether, ultimately—in the great future—we can arrange the atoms the way we want; the very atoms, all the way down.*" There is no doubt that the seeds for the foundation of nanotechnology was laid by Feynman more than 50 years ago.

The far-reaching idea proposed by Feynman in 1959 did not immediately spur research in this area and it took time before scientists had the ability to synthesize new materials and image them by microscopic tools. In 1985, a team of scientists at Rice University, Houston, USA discovered fullerenes (Buckyballs), a new allotrope of carbon in which all the C atoms were arranged in closed shells. The American Chemical Society (ACS) honored the discovery of fullerenes as a National Historic Chemical Landmark in 2010. A book written by Eric Drexler in 1986 titled *Engines of creation—The coming era of nanotechnology* created considerable excitement in the scientific community [22]. In his book, Drexler had stated that "*Our ability to arrange atoms lies at the foundation of technology and for better or for worse; the greatest technological breakthrough in history is still to come*." The publication of this book sparked imagination in the minds of scientists. Coupled with technological progress in instrumentation, research in the area of nanotechnology attracted the attention of several scientists. Throughout the late 1980s and early 1990s, research in the area of nanoscience and nanotechnology blossomed and scientists were able to synthesize novel materials. In September 1989, IBM Fellow, Don Eigler realized the vision of Feynman, by being able to move and control individual atoms. In November of the same year, the research team at IBM showed that they could use a Scanning Tunneling Microscope (STM) tip to move atoms, and they spelled out the letters "IBM" using 35 individual Xenon atoms on a nickel surface. This pioneering work opened new vistas and heralded the coming of nanotechnology. This was made possible by the invention of the STM and the Atomic Force Microscope (AFM) in 1986 and 1989, respectively. In 1991, Iijima reported the synthesis of carbon nanotubes, cylindrical structures that have novel properties such as extraordinary strength, efficient thermal conductivity, and high electrical conductivity.

In the United States in 1998, several federal agencies formed a group called "Inter-agency Working Group on Nanotechnology (IWGN)" to discuss future plans in the area of nanotechnology and sponsor research funding in this area. IWGN was the forerunner to the current NNI established in 2001 to foresee research and development in nanotechnology and to forecast future directions. The federal government initiative includes activities ranging from basic and fundamental nanoscience to the development of specific nanotechnology devices and applications. They include the design and manufacture of nanostructured materials that are correct and precise at the atomic or molecule level. These advances are aimed at applications such as cost-effective manufacture of nanoscale microelectronics, more efficient and cost-effective energy conservation and storage devices, and biological sensors with applications to both health care and chemical and biological threat detection. In 2003, the US Congress passed the Twenty-first Century Nanotechnology Research and Development Act which provided statutory funding for NNI. In pursuance to the environmental and safety concerns, the Environmental Protection Agency (EPA) issued guidelines in 2009 to better understand the impact of manufactured nanomaterials.

Nanotechnology has now become a mature field with the appearance of over 1,000 verified products that incorporate some element or aspect of nanotechnology. The various product categories containing nanotechnology are health and fitness, computers and electronics, home and garden, food and beverage, and consumer appliances. The health and fitness accounts for most of the products and it includes cosmetics (137 products), clothing (155), personal care (193), sporting goods (93), sunscreens (33), and filtration units (43).

A New Realm of Matter

Chemistry is the study of atoms and molecules whose dimensions are generally less than one nanometer (e.g., a carbon-carbon single bond length is only 0.154 nm), while the majority of physics, particularly the area of condensed matter, deals with solids that are essentially an infinite array of bound atoms or molecules greater than 100 nm. A considerable gap exists between these two extreme regimes. The regime called the nanoscale regime lies intermediate between the realms of quantum chemistry and solid state or condensed matter physics and deals with particle sizes of 1–100 nm. In this regime, classical laws of physics or quantum chemistry rules are not strictly applicable. Hence, this regime represents a new realm of matter in which the size scale creates/imparts unique physicochemical properties [6]. For example, the melting point of gold (Au) nanoparticle is lower than the melting point of the bulk Au metal and does not necessarily vary linearly with particle size. Also, a nanoscale wire may not necessarily obey Ohm's law that is the foundation and cornerstone of the electronics industry. Thus, the nanoscale size imparts unique and often unpredictable physical, chemical, and/or biological properties distinct from the bulk.

The field of nanomaterials is not unique to manmade substances; nature has been utilizing nanomaterials for millions of years. Several biological systems contain several nanoscale materials. For example, bones, teeth, and shells are molecular composites of proteins and biominerals that have superior strength and toughness. Human bones contain minerals with particle sizes in the nanoscale regime. Another example is found in certain aquatic bacteria that are able to orient themselves using the Earth's magnetic field. This is possible because they contain chains of nanosized, single-domain magnetite (Fe_3O_4) particles. Another example is the teeth of herbivorous mollusks. Their teeth have an intricate structure that contains nanocrystalline needles of goethite (FeO(OH)). It is quite a marvel that nature produces such tough materials out of protein constituents as soft as human skin and mineral constituents as brittle as a classroom chalk. In fact, nature can be considered as providing model systems for developing technologically useful nanomaterials. According to Dickson, *Life itself could be considered as a nanophase system!* [24]

Synthesis

In this section, we will briefly examine the various synthetic methods available for the preparation of nanomaterials. Our focus in this section will be on metals (Gold and Silver) and metal oxides (Magnesium oxide and Calcium oxide), the two important classes of materials that have received considerable attention because of their widespread applications.

Several innovative and "bottom-up" approaches have been developed to prepare nanomaterials with desired physical and chemical properties. In this chapter, we shall discuss two methods that have been developed and successfully commercialized in the author's laboratory for the production of nanoparticles.

The first method, called Solvated Metal Atom Dispersion (SMAD) method, allows the preparation of gram scale and higher quantities of metal nanoparticles such as Au, Ag, Cu, Pd, etc., metal supported catalysts, bimetallic alloy materials such as Au-Ag, Au-Cu, Pt-Sn, Ag-Au, Mn-Co, etc., and also semiconductors such as CdSe, CdS, PbS, etc., that have uniform particle sizes in nanoscale dimensions. A further important aspect of the SMAD method is that it leads to the production of high purity materials (with no formation of by-products) and most importantly the materials produced are highly monodisperse (uniform particle sizes).

Solvated Metal Atom Dispersion Method for the Preparation of Nanoparticles

Before we discuss the SMAD method, we will briefly discuss other methods for the preparation of nanoparticles with emphasis on Au nanoparticles. A popular method of preparation of Au nanoparticle was first reported by Turkevich in 1951. This method relied on the use of a reducing agent, citrate ions, to reduce Au^{3+} ions in aqueous solution. The original recipe reported by Turkevich led to the synthesis of Au nanoparticles that were spherical in shape with a particle diameter of ~20 nm [25]. An improvement in the synthetic method was reported in 1973 in which Au nanoparticles with varying particle sizes (16–147 nm) could be prepared by careful control of the experimental conditions. A new method was developed by Brust and Schiffrin in which a thiol containing compound was simultaneously added to the citrate and gold ions [26]. This work is considered to be important in the development of Au nanoparticles since the synthesis was facile and led to the formation of Au nanoparticles that were thermally stable and considerably resistant to oxidation by air. The Brust-Schiffrin method led to the formation of Au nanoparticles ranging in diameter from 1.5 to 5.2 nm. Another key feature of this synthetic method was the ability to isolate and re-disperse the Au nanoparticles in common organic solvents without decomposition or irreversible aggregation of the nanoparticles. Although this work led to the development of other stable Au nanoparticles, a drawback of this method was the inability to prepare them in large amounts, i.e., gram *or* kilogram scale. It is usually challenging to prepare gram scale amounts of pure nanomaterials that are monodisperse.

The importance in the preparation of metal nanoparticles lies in the fact that metal supported catalysts are among the important class of synthetic materials developed in the past 50 years. Approximately, 20 % of the US national gross product is dependent on the use of these catalysts. Thus, the preparation of metal-supported catalysts is very vital to the economy of any nation. It is worthwhile to briefly review the traditional methods of preparation of metal-supported catalysts.

Metal ion reduction has been the principal procedure for preparing metal-supported catalysts. In this method, metal nitrates or metal halides are dissolved in water and added to a high surface area solid support such as alumina or silica. Then, water is evaporated and the dispersed metal salt solution is converted into the oxide form by drying the slurry in air. Finally, the metal oxide is reduced to the metallic state by passing a stream of hydrogen gas to give the final metal-supported catalyst. During the reduction step, the reduced metal atoms sinter to form larger particles leading to difficulties in controlling their particle sizes. The advantages of this method of preparation are the ease of preparation, easy scale-up for industrial applications, and the relative low cost involved. However, there are several disadvantages: (1) incomplete reduction of the metal ions to the metallic state, (2) sintering of the metal atoms during the high temperature treatment leading to broad particle size distribution, and (3) difficulty in reducing two metal particles simultaneously to prepare bimetallic particles supported oxide catalysts [27, 28].

A second popular method of preparation of metal supported catalysts is decomposition of organometallic compounds on catalyst supports. In this procedure, stable organometallic compounds are adsorbed from either solution or gas phase onto a catalyst support. Controlled thermolysis of the organometallic compounds leads to loss of the organic ligand molecules and the metal particles grow on the support surface. In principle, by using an organometallic cluster compound, it is possible to form a well-defined cluster of metal atoms on the support surface; however in practice, the removal of the ligands in a well-organized manner to deposit metal nanoparticles with pre-determined particle sizes that are highly uniform has been a challenge. Cluster aggregation and decomposition are frequently encountered and are the major disadvantages of this approach. A related method that has been employed is the use of plasma discharge to decompose the organometallic compound in a controlled manner. However, this method suffers from the disadvantage that only a limited number of organometallic compounds can be utilized for the preparation of metal supported catalysts; this severely limits the range of nanomaterials that can be synthesized.

A novel approach was developed in 1976 and makes use of weakly stabilized metal atoms or “solvated metal atoms” [29]. The nature of the solvent and the metal determine the stability of the metal solvate. Such metal solvates are normally thermally unstable and hence can be used as precursors to metal nanoparticles. On warming the metal solvates, metal cluster nucleation takes place and in the presence of a support, both nucleation and particle growth occur that lead to the formation of a highly dispersed metal-supported heterogeneous catalyst. This preparation method has been termed by the authors as “Solvated Metal Atom Dispersed” (SMAD) procedure. The numerous advantages of this method are: (1) unusual metal morphologies that are highly reactive are often encountered since the metal particle deposition occurs at low temperature, (2) very high dispersion of the zero valent metal is achieved, (3) no reduction step is necessary and sintering or agglomeration of metal particles is avoided, (4) many metal–solvent combinations can be used, (5) bimetallic metal or alloy particles can be prepared, (6) metal particles are securely anchored to catalyst support by the reaction of solvated atoms with surface hydroxyl groups, and (7) handling of toxic organometallic compounds can be avoided. However, careful and skillful operation of the experimental setup is required, and although a number of metal–solvent combinations can be used, only some of the combinations have been found to be of synthetic utility.

SMAD catalysts have been generally prepared in the following manner. An aluminum oxide coated tungsten crucible is first degassed by placing it into a reaction vessel and heating to ~1,400°C in vacuum overnight. Then, after cooling the crucible the reactor is filled with air and a gram scale quantity of metal is placed in the crucible. About 100 mL of organic solvent (usually a non-polar solvent such as toluene or pentane) is degassed and placed in Schlenk tubes and attached to the SMAD reactor. This whole system is sealed under vacuum and the reactor flask is immersed in liquid nitrogen and evacuated for few hours (typically at least 3 h) reaching final pressures of nearly 1×10^{-3} Torr. After approximately 30 min, the solvent is deposited on the cold walls of the reactor flask forming a layer of frozen solvent. At the same time, the crucible is slowly heated to the evaporation temperature of the metal. The metal vapor and solvent are co-deposited for a period of 3 h. After the deposition of the solvent layer and the evaporation of the metal are completed, the frozen matrix is warmed from $-196°$C to room temperature until the solvent melts to form a solvent-solvated metal solution. The solution is stirred and warmed further in the presence of a support (silica or alumina, ~20 g preheated at 500°C for 3 h in dry air and cooled and transferred to the reaction chamber and placed in vacuum prior to the metal vapor reaction). After reaching room temperature, the mixture is siphoned in vacuum and placed under an atmosphere of nitrogen in glassware to prevent any oxidation of the metal. The solvent is then slowly removed under vacuum and the resulting powder is then outgassed at room temperature to 1×10^{-5} Torr and used without any further treatment as catalyst. The metal concentration, temperature, and time of impregnation have an effect on the final size and shape of the nanoparticle. Support effects are not pronounced, but the presence of acid sites and higher specific surface areas of the support tend to allow better dispersion of the metal particles. The following section describes some recent results obtained for the preparation of Au, Ag, and semiconductor nanoparticles (CdS, PbS, CdSe, etc.) using the SMAD method.

Gold Nanoparticles

Gold has received the attention of mankind since ancient times and continues to be an important metal. Au nanoparticles or colloids had been inadvertently incorporated into glass several centuries ago. The Lycurgus cup is a classic and outstanding work of Roman technology belonging to the fourth century. The cup shows a spectacular color change from green to red depending on whether light is reflected or transmitted. This dichroic property has been attributed to the presence of both Au and Silver (Ag) nanoparticles in trace amounts that had been inadvertently introduced into the glass during the manufacturing process by the Romans. Transmission electron microscopic (TEM) studies conducted in recent years indicate the presence of 50–100 nm of Au and Ag nanoparticles, key to producing the unusual optical effect. Thus, the process of making metallic nanoparticles is not entirely new. The stained glass windows found in many churches built during the medieval period is attributed to the presence of gold nanoparticles. Thus, the first nanotechnologists were glass workers, although they were not fully sure what caused the various colors.

An interesting feature is the arrangement of ligand-stabilized, monodisperse particles into regular and periodic two- or three-dimensional structures called nanocrystalline superlattices (NCSs). The formation of such two-dimensional (2D) or three-dimensional (3D) NCS leads to the formation of materials characterized by very different properties compared to those of the discrete species. The collective interactions of the individual nanoparticles in the NCS and the individual particles themselves lead to the manifestation of unique properties compared to the bulk particles [30].

Several methods have been reported for the synthesis of 2D and 3D NCSs [31]. The most common method is to reduce the metal salt in the presence of stabilizing agents [32]. However, they invariably end up in the formation of by-products and an additional step is required for the isolation of samples. Thus, the traditional methods of preparation are quite tedious and time consuming and the possibility of scale-up is fraught with more difficulties and challenges. An important advantage of the SMAD method is the possibility of scaling up the process and the ability to coat substrates uniformly with continuous electrically conductive metals [33]. Industrial applications of nanoparticles require their preparation in large quantities and reproducible quality. Thus, the SMAD method seems to be a very facile method for the preparation of large-scale quantities of metal nanoparticles.

Colloidal solutions of gold in acetone have been well documented in the literature. A combination of two solvents such as acetone and toluene was used in the preparation of Au nanoparticles by the SMAD method [34]. Acetone, being a polar solvent, solvates the nascent Au metal clusters during the warming stage of the SMAD method and acts as a stabilizing agent. After the removal of acetone from the system, the Au nanoparticles are stabilized by dodecanethiol molecules, which enable their dispersion in non-polar solvents such as toluene. A second step called the digestive ripening is carried out in the presence of the surface active agent and a solvent (typically toluene) [35, 36]. This step is the key for the formation of highly monodisperse Au nanoparticles from the polydisperse Au–toluene–thiol colloid [37, 38]. In this step, the Au–toluene–thiol colloid is heated to reflux under Ar atmosphere for a couple of hours. This leads to a narrowing of the particle size distribution and monodisperse colloids are obtained. This particle narrowing is caused by the transfer of gold atoms/clusters from particle to particle until a thermodynamic equilibrium is achieved between the formation of more gold–sulfur bonds as shown by the following equations:

$$\text{Au vapor} + \text{acetone} \xrightarrow{77\text{K}} (\text{Au})(\text{acetone})\ \text{solvate} \tag{8.1}$$

$$\text{Au(acetone)} + \text{C}_{12}\text{H}_{25}\text{SH} \rightarrow (\text{Au})_x(\text{HSC}_{12}\text{H}_{25})_y \tag{8.2}$$

$$(\text{Au})_x(\text{HSC}_{12}\text{H}_{25})_y \xrightarrow[\text{reflux}]{\text{toluene}} (\text{Au})_{5000}(\text{HSC}_{12}\text{H}_{25})_{300} \tag{8.3}$$

Although, the exact mechanism of the digestive ripening is not fully clear at this moment, the process probably involves dissolution of surface atoms or clusters of atoms by the ligand (dodecanethiol) molecules [39]. Hence, it is hypothesized that reactive sites such as corners and edges (since these are the most energetic ones) are probably the first that are prone to dissolution-reprecipitation process. The dry product (usually obtained as a fine powder) is then obtained by cooling the colloidal solution to room temperature and precipitating by adding absolute ethanol. The final dry product consists of Au nanoparticles stabilized by dodecanethiol molecules that are readily soluble in non-polar solvents such as toluene or hexane. Treatment with a long-chained thiol in refluxing toluene causes a remarkable particle size narrowing such that each final gold nanoparticle is 4.6 ± 0.1 nm (about 5,000 atoms/particle and 300 $\text{C}_{12}\text{H}_{25}\text{SH}$ ligands/particle). A remarkable property of these colloidal solutions is their tendency to organize into 2D and 3D NCSs [34]. The TEM figures of the Au colloids obtained after digestive ripening and cooling to room temperature show remarkable features. After just 15 min, these Au nanoparticles organize and form predominantly 3D NCSs and some 2D NCSs when deposited on a support. Interestingly these NCSs are stable and even after 2 months, distinct 2D structures are seen.

High-resolution TEM studies indicate that the Au nanoparticles prepared by the SMAD procedure lack faceting, have defective core structures, and behave like “hard spheres.” They self-assemble and organize into hcp-type superlattices with long-range translational order. The Au nanoparticles have predominantly spherical shapes and the TEM of the Au nanoparticles showed reproducibly hcp structures indicating the versatility of the SMAD method [40]. An interesting observation from this study was the fact that Atomic Force Microscopy (AFM) studies conducted on Au nanoparticles deposited on surfaces indicated an fcc-type superlattice packing indicating that the superlattices can undergo reconstruction when deposited onto surfaces. An AFM image of Au superlattice surface is shown in Fig. 8.2.

Silver (Ag) Nanoparticles

Silver nanoparticles are of great importance due to their ability to efficiently interact with light because of plasmon resonances [15]. These are due to the collective oscillations of the conducting electrons in the metal [41]. Ag nanoparticles are envisaged to be vital components of optical and photonic devices in the future and have already been

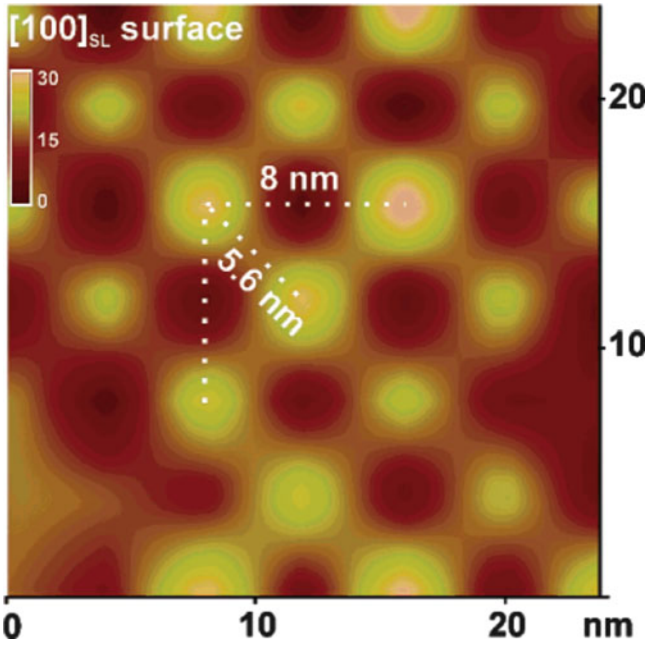

Fig. 8.2 Tapping-mode AFM image of a superlattice surface of Au nanoparticles synthesized by the SMAD method (Stoeva et al. [40], Fig. 13, by permission of American Chemical Society)

incorporated in a variety of consumer products because of their excellent antimicrobial properties.

Over the years, several methods have been reported for the synthesis of Ag nanoparticles. These include the Creighton method [42] in which sodium borohydride is used for the reduction of silver nitrate, or the Lee-Meisel method [43] in which silver nitrate is reduced by sodium citrate. The most common source of silver ions is silver nitrate; however, other silver salts such as silver perchlorate, silver sulfate, or silver 2-ethylhexonate have also been used. The high reduction potential of Ag ions (0.799 V) allows it to be reduced by several inorganic and organic compounds. Several reducing agents have been employed for the reduction of silver ions, $NaBH_4$, sodium citrate, ascorbic acid, ethanol, pyridine, *N*,*N*-dimethylformamide, hydrazine hydrochloride, poly(ethylene glycol), etc. Unlike Au, Ag is more prone to oxidation. Thus, for the long-term stability of the Ag nanoparticles, surfactants have been used as protecting agents [44]. Surfactants such as sodium 2-diethylhexyl sulfosuccinate (AOT), cetyltrimethylammonium bromide (CTAB), and stabilizers like poly(vinyl pyrrolidone) (PVP) have been successfully employed for stabilization of Ag nanoparticles and to also direct the formation of Ag nanoparticles into different shapes such as plates, rods, discs, etc. [45]. All the above methods, in general, produce nanoparticles of Ag; however, very careful control of conditions is necessary in order to obtain Ag nanoparticles with narrow particle size distribution. Scalability and the purity of the Ag nanoparticles are also a problem. The preparation of metallic silver nanoparticles is a challenge because of its relative ease of oxidation compared to Au nanoparticles as stated previously. Very often, after several days of standing under ambient conditions, the surface of the Ag nanoparticles becomes oxidized due to the formation of a thin oxide layer coating.

A key requirement for applications is a reproducible and reliable method that can produce large quantities of Ag nanoparticles with a narrow size distribution. The SMAD method has the potential for preparation of large-scale quantities; a 5,000-fold scale up is possible by the SMAD method compared to the inverse micelle method of production of metal nanoparticles. Gram scale quantities of monodisperse spherical Ag nanoparticles have been successfully prepared using the SMAD method followed by digestive ripening [46]. Two different capping agents or stabilizing agents were evaluated and it was found that the use of dodecanethiol led to Ag nanoparticles with a mean diameter of 6.6 ± 1 nm, while trioctyl phosphine capped particles were 6.0 ± 2 nm. Like the Au nanoparticles, the Ag nanoparticles were also found to organize into 2D and 3D superlattices with a well-defined geometry through self-assembly in solution. 2D arrays were found when either dodecanethiol or trioctyl phosphine were used as ligands; interestingly, only circular 3D superlattices were observed when trioctyl phosphine was used as the protecting ligand and triangular 3D superlattices were observed when dodecanethiol was used as the protecting ligands. The synthetic procedure for the preparation of Ag nanoparticles was similar to that used for Au; however, some changes were needed to prevent the oxidation of Ag. Ag nanoparticles are normally resistant to the formation of 3D structures and the structures reported earlier in the literature were found to be amorphous. Thus, the observation of crystalline 3D Ag superlattice structures formed via the SMAD method and subsequent digestive ripening is unique. The versatility of SMAD method is indicated by its successful application for the preparation of bimetallic nanoparticles. Noble metal intermetallic particles containing Au and Ag or Au and Cu are formed in gram quantities via digestive ripening in as little as 1 h. Highly monodisperse particles of 5.6 ± 0.5 nm diameters for Au–Ag and 4.8 ± 1.0 nm diameter for Au–Cu are formed and they undergo facile self-assembly to form 3D superlattice ordering [47].

Semiconductor Nanoparticles

Semiconductors are an important class of materials that are ubiquitous in our daily lives. Microprocessors, LEDs, transistors, and solar cells are all made of semiconducting materials. The size-dependent properties of semiconductor nanoparticles were first reported by several groups in the early 1980s. In their pioneering works, Brus, Henglein, and

Grätzel independently developed liquid phase synthesis of stable semiconductor nanoparticles suspended in solvents such as acetonitrile and water [48–50]. Several nanocrystalline semiconductors such as II-VI materials (CdS, HgS, and CdSe), I-VII materials (AgBr, AgCl), and III-V materials (GaAs) that are narrowly dispersed have been prepared. The strategy adopted by Brus was to separate the temporal growth and nucleation sites so that a highly crystalline and monodisperse semiconductor could be obtained. This is important since the presence of amorphous phase and/or trace amounts of impurities can significantly alter the physicochemical properties of these materials. Thus, synthetic strategies developed should be facile, reproducible, and most importantly lead to consistent and predictable electronic properties. A typical synthesis of a semiconductor nanoparticle is conducted in the following manner. A room-temperature solution containing the inorganic precursors is rapidly injected into a preheated solvent (350°C) to facilitate rapid nucleation at the same time. This process is called "burst nucleation" since all the particles nucleate almost simultaneously. This is followed by lowering the temperature to around 300°C and this allows for a slow growth of the nanocrystals until all the reactants are consumed. The size and shape of the semiconductor nanocrystals can be controlled by adjusting the ratio of the concentration of the inorganic precursors and the concentration of the stabilizing or capping agents (surfactants, dendrimers, and polymers). This type of synthesis is called the bottom-up method. In contrast, in the top-down method, the macroscopic or bulk material is "machined" down to nanometer length scale by laser ablation–condensation or lithographic techniques.

In bulk semiconductors, the conduction band and the valence band are separated by a band gap. On excitation, the electrons are promoted to the conduction band and holes are produced in the valence band. The charge carriers (electrons and holes) are separated by distances that encompass a number of ions or molecules that constitute the semiconductor material. This separating distance is called the Bohr radius and normally has dimensions on the nanometer scale. When the size of the semiconductor material becomes similar to the Bohr radius or smaller, it leads to a situation in which the charge carrier excitons have a restricted space or volume to move and thus their motion is confined. Like the motion of an electron in a box, the kinetic energy and the excitation energy of the electron increase as the size of the box decreases. Similarly, the band gap of the semiconductor increases as the size of the particles becomes smaller than their Bohr radius. Along with the band-gap, the color and emission of the nanoparticle change with change in the size of the nanoparticle. The physical, chemical, and optical properties of semiconductor nanoparticles thus are sensitive to both the size and shape of the nanoparticles. The surface-to-volume ratio increases as the semiconductor nanoparticle decreases in size and since the properties of the semiconductor depend on the size and shape of the nanoparticle, semiconductor nanoparticles exhibit very different properties compared to bulk semiconductors [51]. Several applications are envisaged for the use of these semiconductor particles; these include photovoltaics, nanoelectronics, and optoelectronics. Other applications where these semiconductor nanoparticles find extensive use are in the fields of photovoltaics and photocatalysis [52, 53].

The SMAD method has been successfully developed to synthesize gram scale quantities of high-purity metal sulfide semiconductor nanoparticles such as ZnS, PbS, CdS, SnS, and CdSe [54, 55]. The advantages of the SMAD method compared to other methods reported in the literature are: (1) gram scale quantities of stable nanocrystalline (1–10 nm) particle sizes can be prepared without any stabilizers with relative ease, (2) the synthesis is very reproducible and yields are typically >90%, (3) the nanoparticles have fairly uniform particle size distribution and hence are highly monodisperse, (4) no purification step is necessary and hence easy work-up affords high-purity metal sulfide nanoparticles, and (5) the surfaces of the metal sulfide nanoparticles are "clean," i.e., no oxide coating is found on the surface of the nanoparticles. In addition, the SMAD method for the synthesis of metal sulfide nanoparticles allows one to tune the particle size and hence its band gap by appropriate choice of solvents and warm-up time of the matrix consisting of frozen solvent and metal sulfide vapors. The textural properties such as specific surface area and pore volume of the nanoparticles are much higher compared to the commercial samples. For example, ZnS prepared by the SMAD method using pentane as the solvent leads to the production of ZnS nanoparticles with surface area as high as 237 m^2/g whereas a commercial ZnS (Fluka) has a surface area of only about 10 m^2/g. Similarly PbS and CdS nanoparticles prepared by the SMAD method have surface areas ~120 m^2/g. In the case of CdSe nanoparticles prepared by the SMAD method, broad photoluminescence (PL) was observed; however, the digestive ripening process led to an increase in the fluorescence intensity and very narrow PL spectra. Figure 8.3 shows the variation in luminescence with change in time of reflux.

Thus, the SMAD method of preparation of metal sulfide nanoparticles leads to the production of high surface area metal sulfides with unique physicochemical and optical properties.

Metal Oxide Nanoparticles

Metal oxides are ubiquitous in catalysis and are key components in several catalytic reactions. They function directly as catalytic reactive centers or serve as high surface

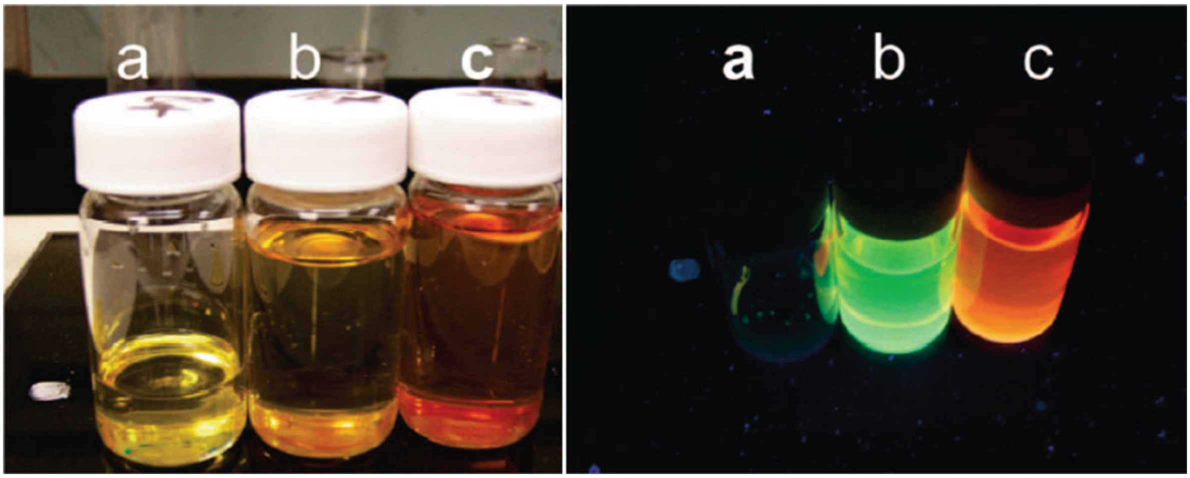

Fig. 8.3 Luminescence of CdSe samples prior to digestive ripening (*left*) and after digestive ripening (*right*). ((**a**–**c**) refer to samples before reflux, after 1 h reflux, and after 16 h of reflux. Reprinted with permission from Cingarepu et al. Chem. Mater. 2009, 21, 1248–1252, Fig. 2 copyright (2009) American Chemical Society)

area supports to disperse active metal centers or as promoters to enhance the rate of catalytic reactions. Many commercial catalysts consist of zero valent metal atoms dispersed finely on a high surface area metal oxide support such as silica or alumina.

Surface chemistry is of importance in numerous processes such as catalysis, corrosion, and adsorption. When the particles sizes are in the 1–10 nm range, a whole new field of surface chemistry is realized. In recent years, it has been possible to successfully produce nanocrystalline metal oxides of MgO, CaO, ZnO, TiO_2, CuO, CeO_2, and other binary metal oxides by a specially designed sol–gel-based process developed in the author's laboratory [56, 57]. The results obtained so far indicate that: (1) the intrinsic reactivities are higher per unit surface area for nanocrystals compared to microcrystals and (2) consolidation of the nanoparticles into pellets does not significantly lower the surface reactivity and the surface area when moderate pressures are used. The high surface area of the nanomaterial ensures that a high percentage of the atoms are on the surface. Thus, reactant–surface interactions can reach stoichiometric ratios. For spherical Fe atoms it has been calculated that for a 3 nm particle, 50% of the atoms lie on the surface while a 20 nm particle has less than 10% of the atoms on the surface. Another important feature that has larger practical implications is that the nanoparticles exhibit higher intrinsic chemical reactivities as the particle size becomes smaller. The reason for the dramatic increase in the activities is most probably due to changes in crystal shape and the presence of defect sites.

Until a few years ago, the crystal shape of solid materials was of academic curiosity only and shape was not considered to have a significant effect on the chemical properties and reactivities of a material. However, recent results obtained in the author's laboratory clearly indicate that the shape of nanocrystals influences the chemical reactivity significantly. For example, it has been shown that 4 nm sized nanocrystalline MgO particles adsorbs as much as six molecules of SO_2 per nm^2 at room temperature and 20 Torr pressure [58]. On the other hand, microcrystalline MgO adsorbs only two molecules of SO_2 per nm^2 under similar conditions. Similarly, an MgO nanocrystalline aerogel (AP-MgO) material adsorbs four times as much CO_2 as the MgO microcrystals. There are not only differences in the amounts of gaseous molecules adsorbed on these surfaces, but also the mode of surface binding can be different in the nanocrystalline materials. For example, SO_2 binds more predominantly as a monodentate species on the AP-MgO crystal but favors a bidentate geometry on conventionally prepared (CP-MgO) microcrystals. Clearly, these results indicate that the shape and size of the crystals affect the adsorptive properties of the MgO surfaces. Thus, the modified sol–gel process leads to the production of a new family of porous inorganic metal oxides that exhibit unique physicochemical properties [59].

Modified Aerogel Procedure

Aerogels are porous materials that have nanoscale dimensions and have low density and high surface area [60]. They are widely used as insulators and increasingly as heterogeneous catalysts. An aerogel procedure involving supercritical drying was first reported by Kistler in 1932 for the preparation of high surface area silica. However the procedure developed by Kistler was time consuming [61]. Teichner and his co-workers used organic solvents that dramatically decreased the processing time from weeks to hours [62].

A further modification of the aerogel method involved the addition of large amounts of aromatic hydrocarbons such as toluene to the alcohol–alkoxide mixture [63]. The addition of toluene dramatically increased the surface area of the resulting metal oxide and although the exact reason is not fully understood, it is believed that incorporation of a less polar solvent such as toluene could reduce the surface tension at the pore walls and thus minimize pore collapse and retain the high porosities of the "wet gel."

The modified aerogel procedure (MAP) for the preparation of inorganic metal oxides has four steps. Let us consider the preparation of MgO by MAP. The first step is the preparation of Mg alkoxide by the reaction of Mg metal with alcohols such as methanol or ethanol. The second step is the hydrolysis of the Mg alkoxide conducted in the presence of a non-polar solvent such as toluene. The third step is the supercritical or hypercritical drying procedure. In this step, the gel obtained in the hydrolysis step is placed in an autoclave and the wet gel is heated at a controlled rate so that the pressure and the temperature exceed the critical temperature (T_c) and the critical pressure (P_c) of the solvent entrapped inside the pores of the gel. The supercritical conditions vary depending on the nature of the solvent employed. The autoclave is slowly heated from room temperature to the critical temperature and after about 15 min of standing at T_c, the solvent is vented quickly through a port to give a dry solid powder. This drying procedure preserves the texture of the wet gel by avoiding the collapse of the pores and hence a highly porous, low-density material having very high specific surface area and large pore volume is obtained. In the final and fourth step, the metal hydroxide, obtained previously is heated under vacuum or air (typically at 500°C) to convert it into metal oxide. This step also gets rid of surface carbonates and/or other species such as alkoxy groups adsorbed on the surface.

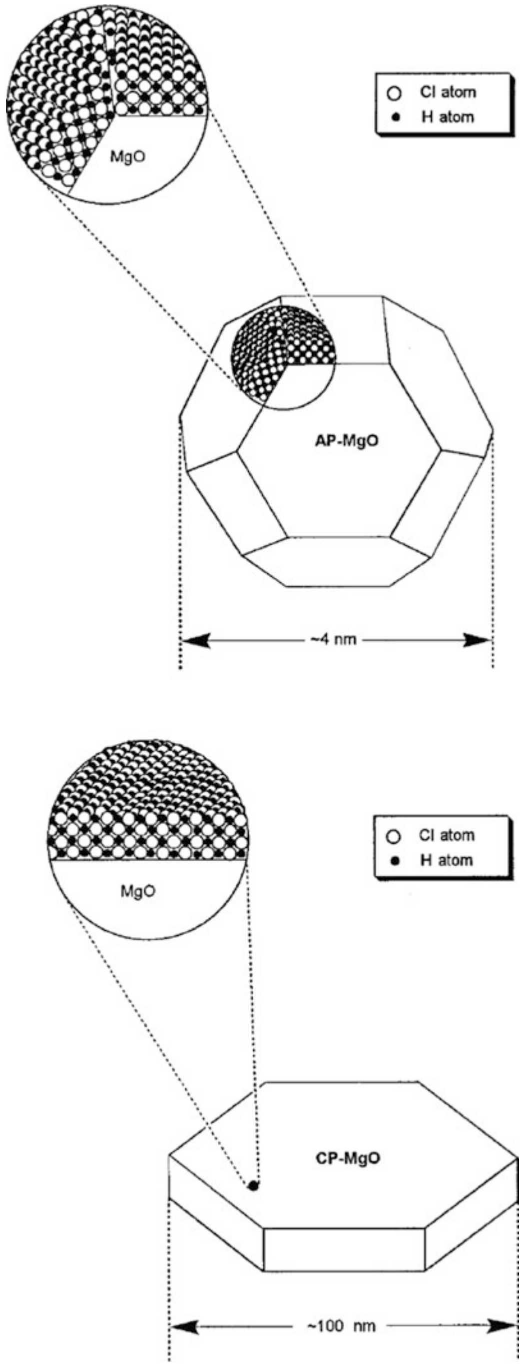

Fig. 8.4 Models of AP-MgO and CP-MgO crystallites. Insets illustrate multilayer HCl adsorption, suggesting more disorder in the AP-MgO case (reprinted with permission from Klabunde et al. [65], Fig. 5 copyright (1996) American Chemical Society)

The following section describes some of the properties of the metal oxide nanoparticles prepared by the MAP. The crystallite sizes of the metal oxide nanoparticles prepared by MAP are remarkable. For example, MgO have crystallite sizes ~4 nm, AP-CaO ~7 nm, AP-TiO_2 ~10 nm, AP-Al_2O_3 ~2 nm and AP-ZrO_2 ~8 nm [64–68]. The specific surface area of AP-MgO obtained is ~500 m^2/g, whereas a MgO sample that is conventionally prepared (referred to as CP henceforth) has specific surface area of ~200 m^2/g, while the specific surface area of a commercial (referred as CM) MgO sample is only around 30 m^2/g. The surface areas of AP-CaO, CP-CaO, and CM-CaO are typically ~150, ~100, and ~1 m^2/g, respectively. Similarly, AP-Al_2O_3 possesses specific surface areas as high as 810 m^2/g, while a commercial Al_2O_3 has a surface area of only about 100 m^2/g. These examples clearly indicate that the MAP results in the formation of ultrafine particles that have very high specific surface areas compared to commercial samples. Also, as the particle size decreases, the surface area increases and the reactivity is considerably enhanced. The increased reactivity is not simply due to the increased surface areas alone. These nanoparticles contain numerous defect sites such as crystal corners, edges, kinks, and ion vacancies. Figure 8.4 illustrates the differences in AP and CP MgO. The high

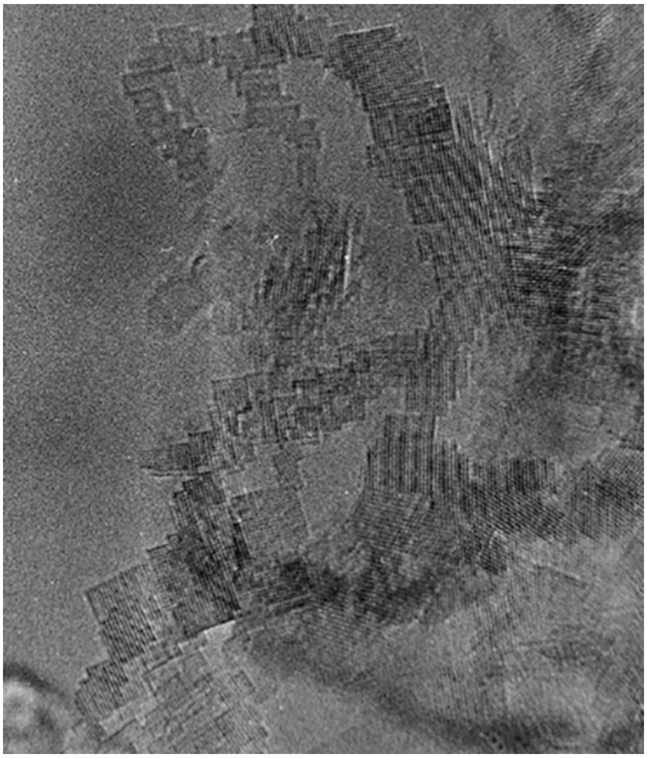

Fig. 8.5 High-resolution transmission electron microscopic image of aerogel prepared AP-MgO (reprinted with permission from Richards et al. [69], Fig. 2 copyright (2000) American Chemical Society)

reactivities of the polyhedral-shaped MgO and CaO are attributed to the higher percentage (~20%) of defect sites such as corner and edges on the surfaces of AP-MgO and AP-CaO. In contrast, a conventionally prepared CP-MgO possesses less than 0.5% of defect sites while a commercial sample of MgO and CaO essentially contains very little defect sites since it is highly crystalline. In addition, surface hydroxyl groups which can be either isolated or lattice bound add to the rich surface chemistry exhibited by these metal oxide nanoparticles.

The MAP process leads to the formation of free flowing ultrafine powders rather than rigid monoliths. TEM studies of AP-MgO show porous web-like aggregates in the range of about 1,400 nm. These are formed by the interaction of the 4 nm (average) polyhedral crystallites and their overall size distribution is narrow. A high-resolution TEM image of AP-MgO is shown in Fig. 8.5.

The TEM picture clearly shows that the cube-like crystallites aggregate into polyhedral structures that have numerous edge and corner sites. Also, interesting is the formation of pores between the crystalline structures that are visible at this magnification. Essentially, the TEM picture is an atomic resolution image of MgO nanocrystallites with lattice planes of Mg and O ions clearly revealed.

An interesting behavior is exhibited by the MgO when the loose powders of it are consolidated into pellets. AP-MgO powder has a low density of 0.30 cm^3/g. Upon compression at low pressure (3,000 psi) this increases to 0.58 cm^3/g, and at 20,000 lb, the density increases to 1.0 cm^3/g. The surface area of AP-MgO powder is 364 m^2/g. Upon compaction at a low pressure of 1,000 psi, the surface area was found to reproducibly increase to ~370 m^2/g [69]. On compaction at higher pressures of 5,000 and 20,000 psi, the specific surface area was found to be 366 and 342 m^2/g, respectively. Another interesting aspect is that these powders exhibit adsorption/desorption isotherms typical of bottleneck pores. However, after compression at 1,000 psi, the samples of $Mg(OH)_2$ and MgO exhibit bottleneck and cylindrical pores, open at both ends. For comparison purposes the conventionally prepared (CP) samples too were subjected to compaction and their textural properties measured. The CP samples of MgO and CaO were more susceptible to collapse of pore volume, especially the CaO samples. However, the AP-CaO exhibited more resistance. The AP oxides, due to their polyhedral nanocrystal shapes and their tendencies toward forming porous web-like aggregates, are the most resistant to collapse under pressure. The CP oxides, due to their more ordered hexagonal platelet shapes, more easily compress into denser structures.

The aerogel-prepared metal oxide nanoparticles constitute a new class of porous inorganic materials because of their unique morphological features such as crystal shape, pore structure, high pore volume, and surface areas. Also, it is possible to load catalytic metals such as Fe or Cu at very high dispersions on these oxide supports and hence the nanocrystalline oxide materials can also function as unusual catalyst supports. Further, these oxides can be tailored for desired Lewis base/Lewis acid strengths by incorporation of thin layers of other materials or preparation of mixed metal oxides [70, 71].

Mixed Metal Oxide Nanoparticles

Many methods have been reported for the synthesis of mixed metal oxides. Generally they have been prepared by co-precipitation of metal hydroxides followed by high temperature treatment; solid-state physical mixing of hydroxides, oxides, or nitrates followed by high temperature treatment or by hydrolysis of bimetallic bridged alkoxides. However, all these methods of preparation lead to partial segregation of the individual oxides as final products. This is because the starting precursors tend to hydrolyze at different rates leading to phase segregation. Further, the very high temperature treatment leads to sintering of the particles resulting often in low surface area oxide materials. The MAP method avoids the problems inherent in the synthetic methods and provides an ideal way to prepare intermingled mixed metal oxide nanoparticles that are essentially mixed at the molecular level. In the MAP method, a large portion of a spectator solvent (toluene) is added that greatly enhances gelation rates, thereby increasing the chances that the two hydrolyzing metal alkoxides gel together. This results in the formation intermingled mixtures or gels that are essentially molecular in nature. This technique was used to prepare a series of intimately intermingled mixed metal oxide nanoparticles [72, 73]. These mixed oxides were composed of alkaline earth oxide and alumina. It was found that only aerogel-prepared AP-$MgAl_2O_4$ and AP-$BaAl_2O_4$ showed peaks in the powder X-ray diffractometry (XRD) studies indicating high crystallinity. In the XRDs for AP-$MgAl_2O_4$ and AP-$BaAl_2O_4$, it was possible to identify peaks corresponding to MgO and BaO. This clearly indicates that the samples are intimately mixed. The intimately intermingled mixed metal oxide samples retain the high surface area and relatively large pore volumes when compared with the individual metal oxides. High-resolution TEM studies clearly indicate the extent of the intermingling of the two oxides. Individual and aggregated Al_2O_3 boehmite planes mixed with AP-MgO nanocrystals could be observed. This gives a clear indication that the MgO and Al_2O_3 are intimately mixed throughout the entire material resulting in some unique structures. The presence of MgO "guest" planes in the "host" AlO(OH) planes has led to an increase in the distance between the planes. Typically in AP-Al_2O_3 the spacing between planes is 6 Å. MgO is now sandwiched between the boehmite planes and the spacing has increased to 15 Å.

Thus, an interesting facet of the MAP procedure is that one can engineer and tune acid/base sites in them. The intimately intermingled MgO-Al_2O_3 nanostructures discussed earlier exhibit enhanced capacity/activity over the pure forms of either AP-Al_2O_3 or AP-MgO. The enhanced reactivity is attributed to the Lewis base nature of the very small and very well dispersed MgO crystallites that are "housed" within the large pores of Al_2O_3. In addition, such intimately intermingled mixed oxides are highly thermally stable with minimal sintering after heating up to 700°C.

Selected Applications

As stated earlier, catalytic processes contribute to at least 20% of the GDP of the USA. Thus, an important application of nanostructured materials lies in the field of heterogeneous catalysis. It is beyond the scope of this chapter to discuss the numerous applications of nanoparticles as catalysts. However, we shall confine our discussion to a select few examples that demonstrate the importance of nanoparticles in the field of environmental catalysis.

Catalysis: Dechlorination and Dehydrochlorination

The disposal and destruction of chlorinated compounds is a subject of great importance. The cost of complete elimination of chlorinated compounds is quite staggering and it is estimated to be over $100 billion/year. In 1993 some environmental agencies had proposed the need for a "chlorine free economy" [74]. The most widespread group of chlorocarbons includes polychlorinated biphenyls (PCBs) and cleaning solvents such as CCl_4 and C_2Cl_4. The most common method used to destroy chlorocarbons is high temperature thermal oxidation (incineration). The toxic chlorinated compounds seem to be completely destroyed at high temperatures; however, there is great concern about the formation of toxic by-products such as dioxins which are far more toxic than the chlorinated compounds themselves. The desired reaction is the complete oxidation of chlorocarbons to water, CO_2, and HCl without the formation of any toxic by-products.

Chlorocarbons are destroyed during reactions with nanocrystalline metal oxides by becoming mineralized as environmentally benign metal chlorides and CO_2 gas [66, 75, 76]. The process can be written as

$$2MO + CCl_4 \rightarrow CO_2 + 2MCl_2 \tag{8.4}$$

From a purely thermodynamic perspective, the reaction of metal oxides with chlorocarbons with MgO and CaO are energetically favorable according to the following equations:

$$\begin{gathered} 2MgO_{(s)} + CCl_4 \rightarrow 2MgCl_{2(s)} + CO_{2(g)} \\ \Delta H^0 = -334\ \text{kJ/mol} \end{gathered} \tag{8.5}$$

$$\begin{gathered} 2CaO_{(s)} + CCl_4 \rightarrow 2CaCl_{2(s)} + CO_{2(g)} \\ \Delta H^0 = -573\ \text{kJ/mol} \end{gathered} \tag{8.6}$$

CaO and MgO can destroy chlorocarbons such as CCl_4, $CHCl_3$, and C_2Cl_4 at temperatures around 400–500°C in the absence of an oxidant, yielding mainly CO_2 and the corresponding metal chlorides. Also, it has been demonstrated that if MgO or CaO nanoparticles were coated with transition metal oxides (e.g., Mn_2O_3, Fe_2O_3, CoO, or NiO), the reactivity could be enhanced substantially and a kinetic advantage could be obtained [77]. The dehydrochlorination is represented as shown by (8.7) below:

$$R\text{-}CH_2\text{-}CH_2\text{-}Cl \rightarrow R\text{-}CH = CH_2 + HCl \tag{8.7}$$

Nanoscale AP-MgO and AP-CaO were found to be superior to conventionally prepared CP-CaO, CP-MgO, and commercial CaO and MgO catalysts for the dehydrochlorination of several toxic chlorinated substances. The interaction of 1-chlorobutane with nanocrystalline MgO at 200–350°C results in both stoichiometric and catalytic dehydrochlorination of 1-chlorobutane to isomers of butene and simultaneous topochemical conversion of MgO to $MgCl_2$ [78]. During the course of the study, it was found that the surface of MgO was converted to $MgCl_2$ and a steady performance of the catalyst was observed only after the formation of the surface $MgCl_2$ phase. Also, a decrease in the surface area during the transformation of MgO to $MgCl_2$ was found due to aggregation of the nanoparticles. The study demonstrates that multi-component systems comprising nanoparticles of $MgO/MgCl_2$ have unusual catalytic properties in acid–base reactions.

Destructive Adsorption of Chemical Warfare (CW) Agents

Chemical warfare agents constitute one of the biggest threats to mankind along with biological warfare agents such as bacteria, fungi, and viruses. The huge stockpiles of CW nerve agents in the USA and Russia and other nations such as North Korea is a matter of grave concern to the public in these countries. The CW agents are known to irreversibly react with the enzyme acetylcholinesterase (AChE) which prevents the enzyme from controlling the central nervous system and hence cause irreversible damage to humans. Hence, many methods have been attempted to decontaminate or neutralize these CW agents [79]. However, only a few reactions are feasible for practical neutralization. Examples of CW agents include VX [*O*-ethyl S-(2-diisopropylamino) ethylmethyl-phosphonothioate], GD (pinacolyl methylphosphono-fluoridate), and HD [bis(2-chloroethyl) sulfide].

The traditional method of decontaminating CW agents is to neutralize them in basic media in solution phase. An approach in this direction has been to use oxidizing reagents such as aqueous bleach (NaOCl or $Ca(OCl)_2$) or hypochlorous acid (HClO). However, these reactions require careful control of pH and solubility problems arise frequently; for example, in basic bleach, VX has solubility problems. Also, large quantities of liquids have to be used for complete neutralization and hence aqueous phase methods are cumbersome. Dry powders have numerous advantages: (1) they are non-toxic, (2) easy to handle and store, (3) waterless and hence have low logistical burden and easy to transport, and finally (4) there is no liquid waste stream. Nanosize MgO, CaO, and Al_2O_3 have been used in room temperature reactions with chemical warfare agents such as VX, GD, and HD [80–82]. Reaction with nerve agents VX and GD and metal oxides results in the nerve agents being hydrolyzed. There are two important differences between their solution behavior and their destructive adsorption on nanoscale metal oxides. The first difference is that the non-toxic phosphonate products reside as surface-bound complexes. The second important difference is that toxic EA-2192, which is known to form under basic hydrolysis in aqueous phase, is not observed on the surface of either MgO or CaO.

Commercial Products

A comprehensive list of consumer products based on nanotechnology is available in the Internet [1]. As of early 2011, there are 1,015 products produced by 484 companies located in 24 countries. United States continues to be the leader in the commercialization with over 500 products. The inventory was first created in 2006 with a list containing initially 215 products. Of the 1,015 products, health and fitness accounts for over 60% of the products with 605 listed. In this category, the sub-category of personal care and clothing contains the largest number of products. When the products are examined in terms of the chemical constituent responsible for the product being listed in this inventory, silver nanoparticles account for over 250 products. The other two important classes of materials are carbon and titanium dioxide. Silver nanoparticles have been incorporated into a wide variety of products that include socks, wound dressings, shirts, toothpastes, air filters and purifiers, refrigerators, washing machines, and vacuum cleaners. The second widely used material, carbon is found in tennis rackets, bicycles, and tires to name a few products. Titanium dioxide nanomaterial is a popular choice of sunscreen lotions and creams because it has the ability to absorb harmful UV rays.

Conclusions

It is quite clear from the various applications listed above that consumer products based on nanotechnology have made inroads into our daily lives. As the technology becomes more mature and more products based on the principles of nanotechnology appear in the market, societal and environmental implications have also to be considered. Without a doubt, the economic potential of nanotechnology is tremendous; however, it is best to balance the benefits with potential risks and identify strategies to mitigate these. As discussed in this chapter, the reactivity of nanoparticles is significantly higher compared with bulk materials. Although the enhanced reactivity is useful for most applications, environmental effects are not known at this moment. Several properties such as solubility, permeability, and adsorption need to be studied in greater detail and their interaction with aquatic and ecological ecosystems needs to be monitored closely when they are released into the environment. For example, Ag nanoparticles have been detected in several wastewater treatments plants and it has been documented that at high concentrations, the growth of nitrifying bacteria is inhibited. This has prompted the EPA to take action to issue guidelines and policies that protect against unreasonable risk to human health and environment. It is worth concluding this chapter by quoting the Nobel laureate Richard Smalley, "*Just wait—the next century is going to be incredible. We are about to be able to build things that work on the smallest possible length scales, atom by atom. These little nanothings will revolutionize our industries and lives*" [83].

Nanostructured Materials: Industrial Applications

Kristin Clement, Angela Iseli, Dennis Karote, Jessica Cremer, and Shyamala Rajagopalan

Introduction

Nanoscience and nanotechnology are transforming materials science in a broad way, in a manner similar to polymer chemistry's transformation of materials science over the preceding century. The continuous development of novel nanostructured materials and the extensive study of physico-chemical phenomena at the nanoscale are creating new approaches to innovative technologies that are constantly resulting in products with a wide range of applications [1–5].

Nanoscience is generally defined as the study of phenomena and manipulation of materials at slightly above atomic or molecular scale, where properties of matter differ significantly from those at the macro scale. The term nanotechnology generally refers to techniques capable of designing and synthesizing nanomaterials that offer advanced material properties for novel applications. The US National Nanotechnology Initiative (NNI) defines a technology as nanotechnology only if it involves all of the following [6]:

- Research and technology development involving structures with at least one dimension in approximately the 1–100 nm range, frequently with atomic/molecular precision.
- Creating and using structures, devices, and systems that have novel properties and functions because of their nanometer scale dimensions.
- Ability to control or manipulate on the atomic scale.

History of Nanomaterials

It should be pointed out that nanomaterials are not entirely new. Carbon black, a material discovered in the early 1900s, is a nanomaterial that is used to increase the life of car tires and to provide the black color. Fumed silica, a component of silicone rubber, adhesives, coatings, and sealants, is a nanomaterial that has been in the market since the 1940s. Several chemicals and chemical processes possess nanoscale features—for example, large polymer molecules made up of tiny nanoscalar subunits. The first nanotechnologists were the Roman glass workers who invented dichroic glass. Other early nanotechnologists were the medieval glass workers who were responsible for providing the nanomaterials that gave stained glass and glazes their bright and vibrant colors. Similarly, nanotechnology has been used to create the tiny features on computer chips for the past several years. Over the last 20 years, the understanding of some preparations of metals, oxides, and other substances as nanomaterials has emerged through a vast body of research and development efforts. Additionally, with the development of more advanced analytical techniques, new nanomaterials are being developed in a systematic manner and with a greater understanding.

The origin of modern nanotechnology is mainly attributed to Professor Richard Feynman's speech "There's Plenty of Room at the Bottom," which was delivered in 1959 at the annual meeting of the American Physical Society at Caltech [7]. At the time, Professor Feynman's predictions were based on theoretical speculation that the principles of physics should allow the possibility of manipulating things atom by atom. He described such atomic scale fabrication as a bottom-up approach, as opposed to the top-down approach that is generally employed in manufacturing. However, developments such as the invention of the Scanning Tunneling Microscope in 1981 have since made nanoscale science a reality. Nanotechnology is now a rapidly growing field of research and development that is cutting across many traditional scientific boundaries.

Nanomaterials: What and Why

In typical nanomaterials, a large fraction of the atoms are located on the surface of the particles, whereas in conventional materials, they are located in the bulk. As a result, many of the intrinsic properties of nanomaterials are different from conventional materials, since many of the atoms are in a different environment. Two key factors cause the properties of nanomaterials to differ significantly from other materials: increased surface area and quantum effects. Nanomaterials have much greater surface area per unit mass compared to conventional materials. As chemical reactions occur at surfaces, this means that a given mass of nanomaterials will be more accessible than the same mass of material made up of larger particles. In addition, higher surface energies and the presence of many corners, edges, and surface defects cause additional intrinsic reactivity. Quantum effects also begin to dictate the properties of matter as size is reduced to the nanoscale, which in turn affects the optical, electrical, and magnetic behavior of materials.

Since industrial sectors such as aerospace, biotech, energy, healthcare, and transportation depend on materials and devices made of atoms and molecules, they can all be improved by application of nanomaterials. Indeed, this rapidly advancing field of science has afforded a variety of commercially available products including catalysts, cosmetics, electronics, paints, self-cleaning windows, suntan lotions, and stain-resistant clothing [8]. Of all the materials, the most commonly mentioned materials are carbon based on fullerenes and nanotubes, followed by silver, silica, titanium dioxide, zinc oxide, and cerium oxide. Iron nanoparticles appear to have potential for environmental applications, particularly for groundwater remediation [9, 10]. Nanoparticles of titanium dioxide and zinc oxide are included in personal care products such as toothpaste, beauty products, sunscreens, and textiles [11, 12]. Silver nanoparticles are used as antimicrobials in textiles such as socks and underwear and are recommended for use in food packaging and in detergents [8]. Areas producing the greatest revenue for nanoparticles reportedly are chemical–mechanical polishing, magnetic recording tapes, sunscreens, automotive catalyst supports, biolabeling, electroconductive coatings, and optical fibers. The number of consumer products on the market containing nanomaterials (as particles or fibers) now exceeds 1,000 and is growing quickly. This count includes nanomaterials containing carbon, cerium oxide, silver, silica, titanium dioxide, magnesium oxide, and zinc oxide. The remarkable advances in current nanotechnology are mirrored in our capability to design and control the chemical composition, size, shape, and assembly structure for various applications.

The advantages of nanotechnology are spreading to numerous industries and applications. The ability of nanoparticles to make products lighter, stronger, and less expensive will infiltrate nearly every part of our lives from transportation to what we wear to treatments of the human body. Products using nanotechnology are already on the market and include stronger tennis racquets and golf clubs, cleaning products with powerful bactericidal and odor removing capabilities, and fabrics treated with nanoparticles to provide odor, stain, or liquid-resistant clothing. Cosmetic companies are also finding nanomaterials to be increasingly effective in anti-wrinkle creams and sunscreens, along with many other applications that will be discussed later in the chapter.

Governments and global corporations are investing billions of dollars to grow nanotech research and development for many other applications that will be greener and more sustainable than current technologies. This investment will fuel the $1.6 trillion of nanomaterials that are expected to be incorporated into manufactured goods in 2013 [13].

Quite recently, the President's Council of Advisors on Science and Technology (PCAST) released their review of the US NNI. Among the major recommendations is enhanced support of commercialization efforts including nanomanufacturing along with continued support of science and engineering, better coordination between US agencies, and increased efforts in nanoscience education and in clearly understanding the societal impacts of nanotechnology. Most importantly, a forward-looking view of environmental health and safety for nanomaterials is promoted [14].

Worldwide Initiatives on Nanoscience and Nanotechnology

As mentioned earlier, the existence of nanosized materials has been known for centuries, but only recently has characterization and manipulation of nanoscale systems opened a new era of nanoscience. Worldwide initiatives in nanoscience have gained great momentum from public and private investors due to economic benefits. In the present global market, a market dominated by tough competition, and a taste for superior products and services, experts believe nanotechnology advancements promise a stronger economy, greater return on investments, and soaring job creation. Countries have realized the importance of nanotechnology for future economic development and its potential impact on various industries. Nanotechnology is expected to revolutionize the existing major industries to create new, enhanced products and processes. Energy, medicine, military, communication, electronics, transportation, and material sciences are just a few segments that would be improved by nanotechnology. Experts believe that all areas will be impacted by nanotechnology, which could lead to exponential economic growth and possibly be the next great accelerant for growth similar to the information technology boom.

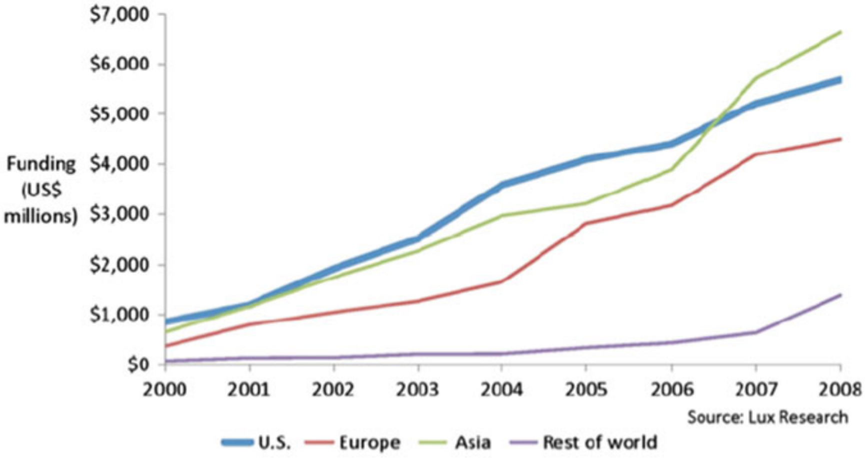

Fig. 9.1 Nanotechnology funding from 2000 to 2008 (includes public and private investments)

According to Lux Research, public and private investments totaled 18.2 billion USD globally in 2008. For the first time in 2007, private funding for nanotechnology worldwide surpassed public funding, indicating that basic research has led to commercialization and return on investments. The sales of nanotechnology related products grew 41% from 2007 to 2009, to a total of 224 billion USD [14].

Initiative and investment by governments in developed and emergent countries in this technology are an unambiguous indication of the relevance of nanotechnology. A market research firm, Cientifica, reports that in 2004, 85% of worldwide R&D spending was dominated by the European Union (27 EU member states), Japan, and the United States. In 2009, this dropped to 58% reflecting the emergence of additional countries contributing to nanotechnology [15]. Although the EU, Japan, and the US have increased their investments through 2009, other developing countries are catching up. Countries have varied approaches towards nanotechnology advancements. Some countries establish specific agencies to monitor progress, fund research, and transfer research to commercialization, while others utilize existing science technology for their advancements. According to an Organisation for Economic Co-Operation and Development (OECD) report, 17 of the 24 countries surveyed had specific governmental agencies focused on nanoscience, while six of the 24 countries invested in nanotechnology through the existing science and technology (S&T) agencies [16]. As countries continue the race to exploit nanotechnology for socioeconomic benefits, the scale of nanotechnology advancements can be measured by the number of nanotechnology centers and initiatives, public and private funding, number of active companies, number of scientific publications, patents, and number of Ph.D. graduates. The United States invests the most in the field of nanotechnology, but is losing ground against other foreign competitors (Fig. 9.1). Progress in basic and advanced research can be gauged by grouping the number of nanotechnology publications by country in the science citation index. Figure 9.2 illustrates publications reported in various geographical areas. The EU, which acts as the policy maker and funding agency, as well as one voice for Europe, has the most nanotechnology publications. China (including Taiwan) surpassed the US in 2007 for the number of nanotechnology publications [14].

Figure 9.3 shows China's dominance in patents compared to other countries. Currently, China has a larger number of patent applications than patents issued; nonetheless, China's progression in nanotechnology is impressive.

The US produces the majority of Ph.D. students in the field of science and engineering, but most of these students are foreign nationals. More than one third of these students leave the US, resulting in technology drain [14].

Governmental involvement in promoting nanoscience is the major driver for the current progress in the area of nanoscience. In the next section, various governmental initiatives introduced to promote nanotechnology growth are discussed. We will focus on key players in regions that have played a major role to date. These regions include North and South America, Europe, Eurasia (Russia), Asia, and Australia.

North and South America

United States of America

The US government, in hopes of maintaining its leadership in the field of nanotechnology, has founded the NNI to promote nanoscale science, engineering, technology research, and development programs. The NNI is a sub-branch of the National Science and Technology Council (NSTC), the cabinet level council by which the President coordinates science, space, and technology policies across the Federal Government. The program was established in 2001, and to date the cumulative investment is 12 billion USD. The proposed NNI budget for fiscal year 2010 is 1.64

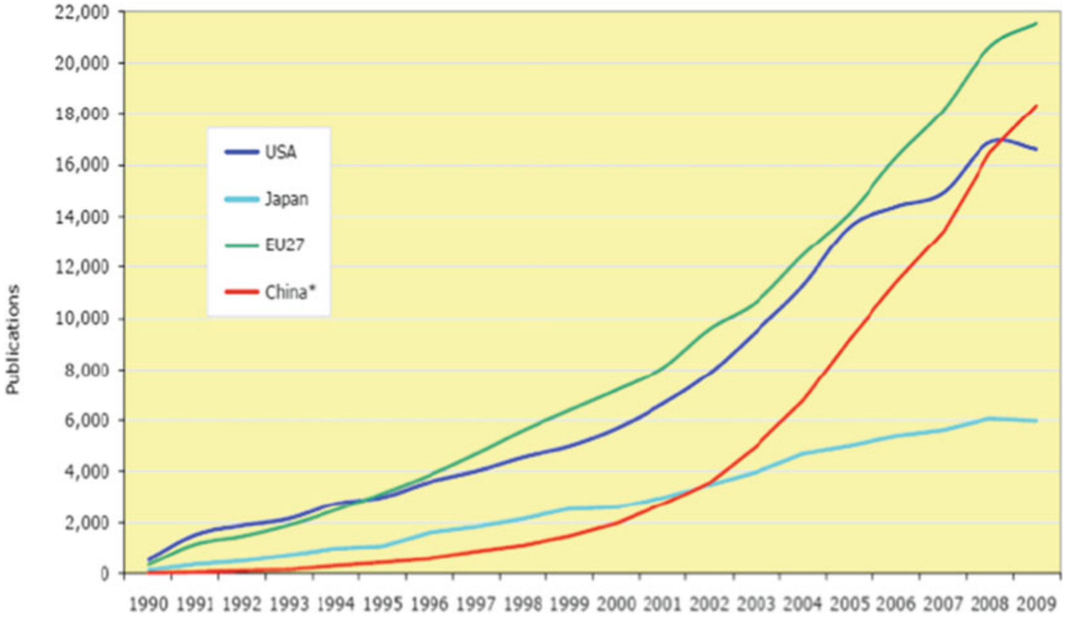

Fig. 9.2 Nanotechnology publications in science citation index by year. *Source*: Chen HC, Dang M, Roco MC. "Updated nanotechnology indicators, January 2010." Addendum to Chen H, Roco MC (eds). Mapping nanotechnology innovations and knowledge: global, longitudinal patent and literature analysis. New York: Springer, 2008

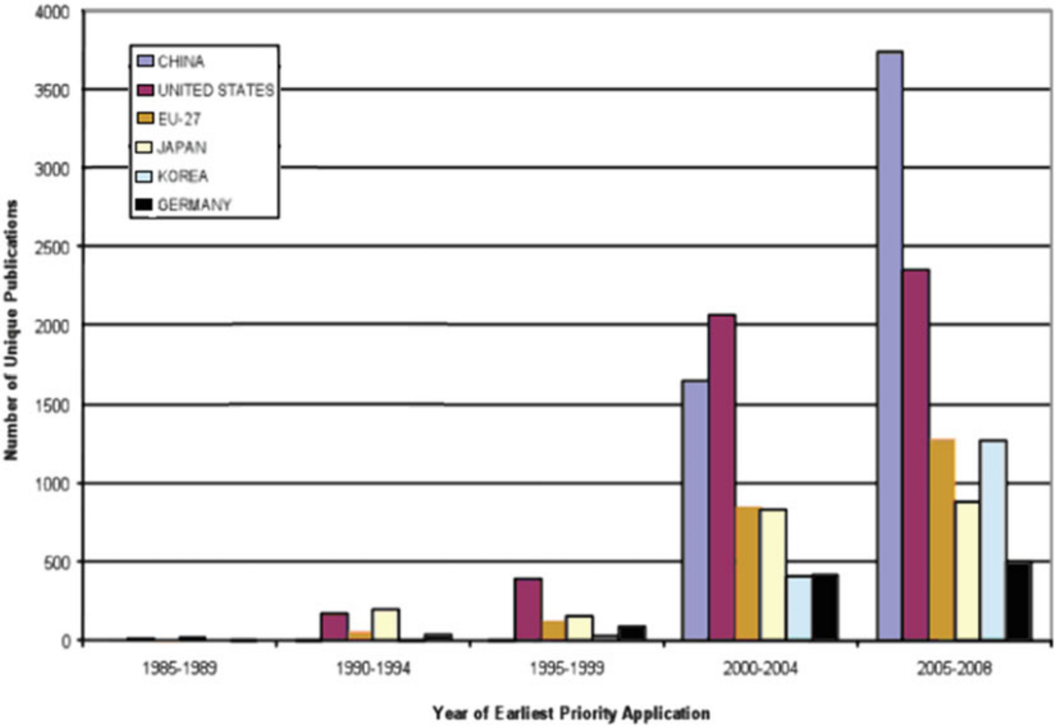

Fig. 9.3 Nanotechnology related patent applications. *Source*: Kisliuk B, USTPO, unpublished on comparative patent filings, January 2010

billion USD, with a growth of 8.5% over fiscal year 2009. Currently, the NNI involves 25 federal agencies, 13 of which had budgets for nanotechnology R&D in 2010. Table 9.1 displays NNI budgets (2008–2010) for the 13 budgeted federal agencies.

Of the total investment in the 2010 NNI proposed budget, 96% of the total is focused on five federal agencies, which are the National Science Foundation (NSF), the Department of Defense (DOD), the Department of Energy (DOE), the National Institutes of Health (NIH), and the National Institute

Table 9.1 National nanotechnology initiative (NNI) budget 2008–2010 (millions in USD)

Federal agencies	2008 Actual	2009 Estimate[a]	2010 Proposed
NSF	409	397	423
DOD	460	464	379
DOE	245	337	351
DHHS (NIH)	305	311	326
DOC (NIST)	86	87	91
EPA	12	16	18
NASA	17	17	17
DHHS (NIOSH)	7	7	12
DHS	3	9	12′
USDA (FS)	5	5	5
USDA (CSREES)	6	3	3
DOT (FHWA)	1	3	3
DOJ	0	0	0
Total	1,554	1,657	1,640

[a] 2009 Additional funds were allocated as a part of American Recovery and Reinvestment Act of 2009

of Standard and Technology (NIST). The NSF focuses on research across all disciplines of science and engineering; the DOD focuses on science and engineering research advancing defense; the DOE focuses on new and improved energy technologies; the NIH focuses on biomedical research at the intersection of life science and physical science; and the NIST focuses on fundamental research and development of measurement and fabrication tools, analytical methodologies, and metrology for nanotechnology [17].

Canada

Canada contributed 4.5% of the total global investment in 2008. The nanotechnology initiative by the Canadian government includes nine institutes of the National Research Council (NRC) distributed in several provinces. These provinces have spearheaded technological advancements in Canadian nanotechnology. Alberta, British Colombia, Ontario, and Quebec are some of the provinces central to innovation and competiveness in Canada. Currently, there are approximately 50–200 Canadian companies involved in the field of nanotechnology [18].

Brazil

Brazil, the leader of nanotechnology advancements in South America, commenced its governmental initiative in 2001. The National Council of Scientific and Technological Development (CNPq), the agency under the Ministry of Science and Technology (MCT), is dedicated to the promotion of scientific and technological research, human resources, and funding and is involved in the nanotechnological advancement in the country. In Brazil, funds for nanotechnology projects are distributed across various regions for the accepted proposals in hopes of stimulating the regional economy. In 2008, the responsible agency awarded 50% of its budget to the South-East, 15% to the South, and 35% of the budget to the North, North-East, and Center-West regions [19–21].

Europe

United Kingdom

Nanotechnology efforts in the United Kingdom were first initiated in 1986 by the National Initiative on Nanotechnology, led by the National Physical Laboratory. The initiative was jump-started with the Taylor report published in 2002, which highlighted the significance of nanotechnology. Currently, the Technology Strategy Board (TSB) is a governmental agency with a vision to be the global leader for innovation and attract inventive business. The Biotechnology and Biological Science Research Council (BBSRC), Engineering and Physical Science Research Council (EPSRC), and Natural Environment and Research Council (NERC) are the three research councils that drive nanotechnology advancement in the UK [22, 23].

Germany

The Federal Ministry of Education and Research (BMBF) has been funding nanotechnology activities since the late 1980s. The German government initiated a strategy to integrate seven ministries for the advancement of Nanotechnology in its "Nano Initiative-Action Plan 2010." The goal of the strategy can be summarized in five action priorities:

- Developing future fields and introducing new industries.
- Creating favorable framework conditions for science and economy.
- Recognizing risks and providing guidelines for responsible handling.
- Informing and integrating the public.
- Identifying research demands of tomorrow.

The seven federal ministries include the Federal Ministries for Labor and Social Affairs (BMAS), Environment, Nature Conservation and Nuclear Safety (BMU), Food, Agriculture and Consumer Protection (BMELV), Defense (BMVg), Health (BMG), Commerce and Technology (BMWi), and BMBF [24, 25].

Eurasia

Russia

The Russian government nanotechnology initiative includes the Russian Corporation of Nanotechnology (RUSNANO) with a five billon USD budget, specialized federal R&D program financing (2008–2011) for four billion USD, and Nanoindustry Infrastructure Development in the Russian

Federation for a period of 2008–2010 for one billion USD. The primary corporation, RUSNANO, was established in 2007 to advance the field of nanotechnology financed projects which include manufacturing projects to expand nanotechnological products; infrastructure projects to advance innovation, technology centers, technoparks, and information databases; and educational programs to train and educate the workforce for nano industries. The mission of RUSNANO is to make Russia the leading player in nanotechnology [26, 27].

Asia

Japan

Japan, one of the earliest players in the field of nanotechnology, leads the governmental effort through the agency MEXT (Ministry of Education, Culture, Sports, Science and Technology). MEXT is responsible for basic research and spearheads the nanotechnology advancement. The Ministry of Economy, Trade, and Industry (METI) leads the industrial development and commercialization efforts [28].

China

In 2001, an aggressive plan titled “Compendium of National Nanotechnology Development (2001–2010)” was issued to jump-start the Chinese initiative in Nanotechnology. The Chinese government spent 600 million USD in 2007 to promote nanotechnology with approximately 70 institutions engaging in nanotechnology research. The government backed funding agencies include the Chinese Academy of Science (CAS), National Science Foundation of China (NSFC), Ministry of Education (MOE), and Ministry of Science and Technology (MOST) [29, 30].

South Korea

South Korea’s aggressive plan to become one of the top three in the world by 2015 in nanotechnology competitiveness has led to the allocation of 16 billion USD for the period 2001–2010. The purpose of the Science and Technology framework law of 2001, launched by MOST, is to advance the nanotechnology effort in South Korea. MOST focuses on basic research and funds the knowledge base. The Ministry of Commerce, Industry, and Energy (MOCIE) and the Ministry of Information and Communication (MOIC) also promote nanotechnology growth in South Korea. The MOCIE focuses on commercialization efforts, whereas the MOIC funds projects that connect information technology with nanotechnology [31].

India

In 2001, India joined the race by launching the Nano Science and Technology Initiative (NSTI) under the Department of Science and Technology (DST), with a 20 million USD budget that financed infrastructure and 100 projects over 5 years. NSTI was superseded by the aggressive program Nano Mission within the DST with a budget of 254 million USD for 5 years. The objective of the Mission includes: Basic Research Promotion, Infrastructure Development for Nano Science & Technology Research, Nano Application and Technology Development Programs, Human Resource Development and International Collaborations. Other agencies involved in nanotechnology development include the Council of Scientific and Industrial Research (CSIR), the Department of Biotechnology (DBT), agencies under the Ministry of Information and Communication Technology, the Ministry of Family and Health and Welfare, the Ministry of Defense, and the Ministry of New and Renewable Energy [32–34].

Australia

Australia has made nanotechnology a national priority since 2004. A study conducted in 2004 by Australia Research Council (ARC) highlighted the shortcomings of Australia’s position in the global race. Numerous initiatives by the government were introduced to improve Australia’s status on the world stage. According to the Nanotechnology Australian Capability report, 75 nanotechnology research organizations, along with 80 nanotechnology companies, lead the nanotechnology effort. The government channels funding for nanotechnology through main agencies like the ARC, the Commonwealth Scientific and Industrial Research Organization (CSIRO), and the National Health and Medical Research Council (NHMRC). According to the Australian Office of Nanotechnology (AON), 21 of Australia’s 41 universities participate in nanotechnology advancements. For the period of 2008–2009, 107.7 million USD were allocated to nanotechnological advancement by participating governmental agencies [35, 36].

Nanotechnology Companies

Companies focusing primarily on nanotechnology products, as well as established companies with a nanotechnology subbranch, are on the rise. The drivers for private entities include return on profit, superior product/services, and monopoly. According to Nanovip International Nanotechnology Business Directory, in November 2008 there were 1,608 companies with nanotechnology products and services; however, this is only an estimate due to various standards as qualifiers in different countries. Currently, the US dominates the race for the number of companies compared to other nations [37].

Nanostructured Materials as Destructive Adsorbents

Nanostructured materials based on diatomaceous earth, carbon, zeolites, lime, and clays have been in use as adsorbents for many years to physically remove contaminants from surfaces [38]. Many of these materials were not initially recognized as being “nanostructured.” Nanostructured materials can exist as atomic, molecular, or crystallite clusters. They may form different shapes including, but not limited to, cages, sheets, tubes, spheres, and rods. In the process of forming these unique shapes, voids and defects are also formed which increase the nanostructured materials’ surface area and porosity through pits, holes, tunnels, and edges. These defects allow the nanostructured material to absorb liquids and trap gaseous molecules. The contaminants in the area are then removed by containment within the nanostructured materials’ overall structure.

Destructive adsorbents based on high surface area inorganic metal oxides act upon contacted contaminants in two ways: they contain the contaminant by trapping the liquid or gas into their structure, and they alter the original structure (destructive adsorption) such that the contaminants are immobilized. Typically immobilization is done through interaction with reactive sites on the adsorbent. The nanostructures’ inherent molecular structure discontinuity gives additional reactive sites such as terminal hydroxyls or coordination sites for anions and cations. Bonding of the adsorbate to the adsorbent through van der Waals forces usually begins the destructive process and instigates the reaction with the surface structures of the adsorbent.

Materials that combine these characteristics can be used in several ways, with the primary usages focused on air purification and destruction and immobilization of bulk quantities of hazardous chemicals [39]. Specifically, the high surface areas, increased porosity, large concentrations of surface defects, and unusual stabilized exposed planes are credited for these useful applications [40–42]. Several mechanisms can be facilitated by these surface structures including oxidation, hydrolysis, and elimination of appropriate functional groups from the adsorbed contaminant (Fig. 9.4).

Nanomaterials Based on Metal Oxides

Some of the materials that have garnered the most attention are based on metal oxides and zeolites. Each of these materials can be further modified with doping agents and functional groups to tailor the material to its intended use. Literature evidence for proving destructive adsorption is heavily directed towards high surface area metal oxides; therefore, metal oxides are the focus of this section. High temperature desorption by thermo gravimetric analysis (TGA) in combination with Fourier transform infrared (FTIR) or GC-MS show what heat releasable by-products are observable or key changes are seen in the reacted sorbent’s NMR peaks or FTIR spectral bands. Most available analyses rely on observed reduction in the challenge agent either through sorbent extraction or measurement of a gas stream before and after entry into the sorbent bed (flowthrough or breakthrough). In general, the best characteristics for a destructive adsorbent to have are high surface area, pore size, and volume in a mesoporous range for increased contact of adsorbate and a high number of surface hydroxyls to allow for a variety of species to interact with the surface groups [43].

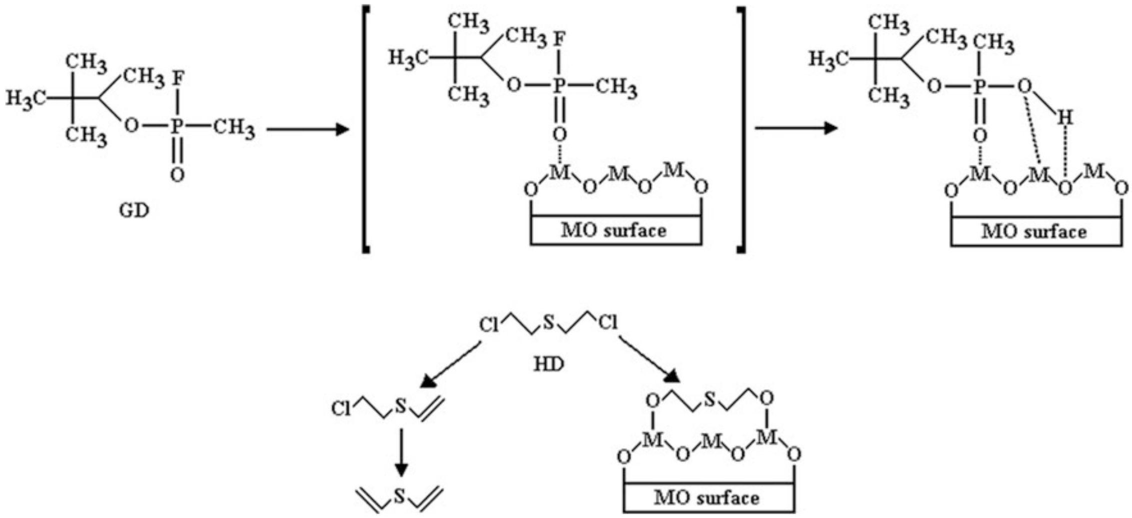

Fig. 9.4 Reaction schemes depicting destructive adsorption of GD and HD on nanocrystalline metal oxide surfaces

Nanocrystalline high surface area titanium oxide (TiO_2) has been extensively studied by several groups for its reaction with dimethyl methylphosphonate (DMMP), a common chemical warfare agent simulant for VX and G agents. Trubitsyn and Vorontsov examined ambient reactions of the anatase form by FTIR, comparing successive and simultaneous reaction processes of reactive adsorption, hydrolysis, and photocatalysis at both high and low DMMP concentrations, with and without humidity [44]. The rate of exposure to DMMP and relative humidity play a role in product formation and the degree of product binding to the surface of TiO_2 during adsorption and hydrolysis. The photocatalytic process is also affected by deactivation of sites by non-volatile products. Humidity aids in both hydrolysis and the release of converted volatiles. Interestingly, when all processes occur simultaneously, the destruction of DMMP is complete within 30 min.

Panayotov and Morris observed two paths that DMMP takes toward decomposition: molecular adsorption through hydrogen bonding at the hydroxyl groups and reactive adsorption through the Lewis acid active oxygen sites [45, 46]. They found that at low temperatures (295–400 K), nucleophilic attack from the neighboring surface hydroxyls form the Ti–CH_3 and P–O_x surface groups, while at higher temperatures (400–600 K) the lattice oxygens oxidize the Ti–CH_3. However, as the lattice oxygens are slowly poisoned and the non-volatiles accumulate, the isolated hydroxyls can be regenerated through thermal treatment in oxygen. Similar results were found during a molecular dynamics computer generated simulation performed by Quenneville et al. with varied surface hydroxylation of amorphous silica (SiO_2) and DMMP [47].

Li et al. have thoroughly investigated adsorption and decomposition of organophosphorus compounds with magnesium oxide (MgO) using an in situ pulse reactor GC-MS technique [39]. Comparison of two different MgO sorbent beds of varied surface areas (130 and 390 m^2/g), after exposure to various gaseous organophosphorus compounds, revealed several important facts related to decomposition temperature, product distribution, and capacity for destructive adsorption. Overall, MgO reduces the decomposition temperatures for these compounds via dealkylation reactions, proton abstractions, and nucleophilic displacements; the capacity for the reaction is dependent on surface area; and presence or absence of water affects product distribution.

Photocatalytic studies with high surface area TiO_2 and SiO_2-TiO_2 using the HD simulant, 2-chloroethyl ethyl sulfide (2-CEES), by FTIR show both partial and full oxidation products in addition to aldehydic, carboxylate, and carbonate products that are surface bound [48, 49]. Multiple reactive sites are used by TiO_2, while Si–OH sites hydrogen bond to 2-CEES through the sulfur and chlorine moieties. Similar studies with diethyl sulfide (DES) found other specific roles for the chlorine.

Studies with nano MgO and 2-CEES also found that liquid phase reactions are greatly affected by the solvent used. The most rapid results were observed from use of inert organic solvents with some addition of water to enhance the surface hydroxyl group numbers [50]. Nanomaterials that are prepared such that they are intimately intermingled with two or more nanomaterials can show synergistic performance compared to those prepared singularly. Studies with 2-CEES and mixed metal oxides found that the surface hydroxyls and the Lewis acid sites were responsible for conversion to the surface bound alkoxy species and vinyl products and swift reaction time [51, 52].

Carnes et al. explored the destructive adsorption reaction with an aluminum oxide (Al_2O_3) and MgO mixture for performance against diethyl 4-nitrophenyl phosphate (paraoxon) [53]. UV–vis and FTIR studies showed that very little paraoxon is released back to the environment after washing with solvent. Similarly, nano zinc oxide (ZnO), copper oxide (CuO), and nickel oxide (NiO) have been found to have increased reactivity and capacity towards paraoxon over commercially available forms [54, 55].

In a series of studies, Wagner et al. have explored the room temperature reaction of nanocrystalline MgO, calcium oxide (CaO), Al_2O_3, and nanotubular TiO_2 with real agents (VX, GD, and HD) by ^{1}H, ^{31}P, ^{27}Al, and ^{13}C NMR [42, 56–58]. All of these nanomaterials hydrolyze VX and GD to surface bound non-toxic compounds. With HD, both hydrolysis and elimination were observed by destructive adsorption modes. The many layers of nanotubular TiO_2 and the surfaces and pores of MgO, CaO, and Al_2O_3 trap water allowing for rapid hydrolysis, whereas the presence of water on CaO with HD creates a $CaCl_2$ coated surface, catalyzing fast elimination of HCl after an initial induction period. Rates of some of these reactions were found to approach the speed of liquid decontamination solutions.

Koper et al. have also studied the destruction of various chlorinated hydrocarbons over high surface area CaO (conventionally prepared—CP and aerogel prepared—AP) and compared to commercially available non-nano or micro material (CM) in a bed at different temperatures with and without water [59, 60]. Comparison of these materials of differing surface areas (CM ~10 m^2/g; CP ~100 m^2/g; AP ~120 m^2/g) led to several key conclusions. The material preparation method is critical, as it affects the surface area. Higher surface area generally results in faster reaction time, lower reaction temperature, and higher reaction capacity; however, this is highly compound dependent. While CP performs better with certain compounds, the reactions are slower with a higher capacity when compared to their AP prepared counterparts. Temperatures must be fine tuned for high efficiency and no graphite poisoning of the bed.

Nanocrystalline zinc oxide (ZnO), copper oxide (CuO), and nickel oxide (NiO) have also been found to have increased reactivity and capacity towards carbon tetrachloride (CCl_4) over the corresponding non-nano metal oxides [54, 55].

High surface area MgO and TiO_2 reactions with the halocarbons CF_2Cl_2 and $CFCl_3$ were found to have increased efficiency at lower reaction temperatures compared to their non-nano commercial forms. Interestingly carbon coating of these high surface area metal oxides also appear to improve the reactivity of the nano forms [61]. Addition of Fe_2O_3 or other transition metal oxides to high surface area nanocrystalline CaO was found to improve destructive adsorption activity against CCl_4 and C_2Cl_4 to near stoichiometric quantities at elevated temperatures [62]. Several polar organic compounds are also destructively adsorbed by nanocrystalline MgO with transition metal oxide shells such as vanadium oxide; however, powder forms perform better than pelletized forms [63].

Decker et al. and Khaleel et al. explored this application with Al_2O_3/MgO and other coated formulations against SO_2 (an acid industrial gas) [62, 63]. This intermingling of metal oxides shows that acid gas adsorption is also improved over its singularly prepared individual components. Vacuum desorption and FTIR studies show well bound monodentate SO_2 species on the surface of the powder. Similarly, nano ZnO, CuO, and NiO were found to have increased reactivity and capacity towards SO_2 over the corresponding non-nano forms [54, 55].

Room temperature FTIR studies of nanocrystalline MgO, CaO, and Al_2O_3 with volatile organics, such as aldehydes, ketones, amines, and alcohols, found high capacity adsorption of these materials through a multi-layer dissociative process at functional groups [64]. Similarly, acetaldehyde is adsorbed by nano TiO_2 and as temperature is slowly raised surface intermediates are observed by aldol condensation [65].

Reactions of H_2S with sol- or aero-gel prepared CaO, ZnO, Al_2O_3, strontium oxide (SrO_2), and MgO proceed with increased capacity over their non-nano formulations due to their higher surface areas as well as higher inherent reactivities. Nano ZnO and CaO work with high efficiency and the observed efficacy is attributed to nanocrystallites and unique morphology of the materials allowing for deeper reaction into the material [66]. High surface area SrO_2 was found to be a unique material which had greatly enhanced efficiency (stoichiometric) at RT, while at elevated temperatures exhibited reduced efficiency due to temperature induced crystal growth [67].

Studies of nanocrystalline MgO, CaO, Al_2O_3, TiO_2, and cerium oxide (CeO_2) with and without halogen (Cl_2, Br_2, and I_2) or interhalogen (ICl, IBr, and ICl_3) treatment have been carried out against *Escherichia coli*, *Bacillus cereus*, *Bacillus globibii*, aflatoxins, and MS2 bacteriophage [68, 69]. Vegetative cell studies found appreciable reduction of *E. coli* and *B. cereus* with halogenated MgO and CaO within minutes. Spore studies show some reduction of *B. cereus* by both halogenated and non-halogenated nano MgO and CaO within several hours. Colorimetric studies with aflatoxin show a neutralizing effect and MS2 studies found no plaque forming units after 5 min with some halogenated formulations. Atomic force microscopy (AFM) and TEM imagery illustrate significant changes in the cells or spores [70]. These biocidal properties are thought to be promoted by the abrasiveness, basic character, electrostatic attraction, and oxidation power of the wet slurries or dry powders of nanomaterials [71]. Other known antimicrobial materials may be incorporated into these metal oxides to provide additional biocidal properties. Photocatalytic and biological testing of nanostructured novel Ag–C–S–TiO_2 formulations shows both photodegradation of acetaldehyde and inactivation of *E. coli* and *Bacillus subtilis* spores without light activation compared to P25–TiO_2 [72].

Commercial Uses

The commercialization of nanotechnology using destructive adsorption has, so far, been limited to studies developed by one company, which has been particularly successful with this technology. NanoScale Corporation, located in Manhattan, KS, has been using nanocrystalline metal oxides for neutralizing toxins since 1995 for customers worldwide. The technology was originally developed at Kansas State University under Dr. Kenneth J. Klabunde. After years of continuous progress, FAST-ACT® (First Applied Sorbent Against Chemical Threats) was developed for the US Army for chemical warfare decontamination. FAST-ACT can be used on a variety of chemical releases to adsorb and eliminate chemical threats. The same technology was adapted to fit industrial and institutional needs for chemical hazards in the ChemKlenz® line of products. NanoScale offers products based on destructive adsorption of odors as well [73].

Destructive adsorption provides a superior technology to many alternatives since it does not release or mask contaminants. Guild Associates also uses adsorption technology in their material provided to the US Army [74]. Guild provides chemical and biological decontamination in various products. They have developed several types of mats and blankets, a protective barrier used for transport, wipes, laundry systems, and masks, among others.

Nanostructured Materials in Catalysis

Nanotechnology in the field of catalysis is ahead of other nanotechnology segments and is referred as “the engine that powers the world at the nanometer length scale” [75]. The exceptional morphology of nanostructured materials is

Table 9.2 Estimated impact of nanocatalysts [80]

Industry	Cost saving ($billion/year)	Energy savings (trillion BTU/year)

responsible for their enhanced catalytic properties [76]. Catalysts, by definition, accelerate chemical reactions by transforming reactants to products without being consumed during the process [77]. In the presence of an ideal catalyst, the preferred reaction can proceed at a faster rate, resulting in desired products and improved yields. The speed of the reaction is guided by catalytic activity, while the preferred reaction is a reflection of catalytic selectivity [78]. Catalysts at the same phase as reactants are known as homogenous and contribute to 10–15% of the catalyst market, whereas catalysts in a different phase are referred to as heterogeneous catalysts. In this topic we will focus on heterogeneous catalysts due to their extensive applications. Approximately 90% of newly developed chemical processes utilize catalysts, and improving catalyst efficiency via nanotechnology would have a significant impact on resources and the environment [79]. More specifically, improved process efficiency through use of enhanced nanocatalysts will allow for greener chemistry. Breakthroughs in energy and environmental applications with nanoscale catalysts have established great commercial success. For example, petroleum processing and the catalytic converter for automobiles utilize catalysts at nanoscale and are considered to be significant contributors [14]. Table 9.2 indicates cost and energy saving in the US per annum from exploiting nanoscale catalysts [80].

Refinery Industry

The refinery industry has successfully applied nanotechnology to improve the previously inefficient refining process by exploiting catalysis. Naphtha reforming and cracking are examples of unit processes where nanocatalysts have made major contributions [81]. Naphtha is used as a feedstock for the production of high octane gasoline by reforming and restructuring the hydrocarbons of low octane. Currently, bimetallic nanocatalysts based on Pt-Re/Pt-Sn on an acidic alumina substrate are commercially in use in the reforming units. Pt-Re on acidic alumina allows for longer catalytic activity with improved stability and Pt-Sn on acidic alumina has enhanced selectivity at low pressure. Metal moieties are the catalytic sites where dehydrogenation reactions occur, while acidic sites are required for isomerization, cyclization, and hydrocracking reactions [82, 83]. The improvements over the Pt-alumina monometallic catalyst introduced in 1950 have led to higher octane levels and lower usage of the precious metals. Additionally, previously used octane enhancers like lead and benzene are being phased out. Techniques to produce oil at a lower cost by minimizing the amount of catalyst by reducing the particles to nano-size have been widely successful in the petroleum industry. Over the last six decades, advancement in technology has resulted in the particle size decreasing from 100 nm to less than 2 nm. Materials with improved catalysis efficiency are obtained by synthesizing materials with uniform active sites, size, and shapes [84].

In the petroleum refinery, cracking is the largest volume process where crude oil of high molecular weight (high boiling point) is cracked to low molecular weight hydrocarbons like gasoline, diesel, or olefinic gases by the process of fluid catalytic cracking (FCC) [85]. Currently, nano-size catalysts based on zeolites are commonly used for catalytic cracking. Zeolite structures can be manipulated to 1 nm and provide an adjustable cage-like structure that allows specific molecular interactions for enhanced selectivity. AkzoNobel, ChevronTexaco, Engelhard, Exxon Mobil, and CRI International are major producers of zeolite catalysts [84].

Environmental Related

Air Purification

Nanocatalysts play a crucial role in air filtration applications related for odor removal and chemical remediation. Combustion engines, coal burning facilities, and chemical plants are all sources of toxic nitrogen, sulfur, and other volatile organic compounds (VOC) [86]. Nanocatalysts are designed for the specific polluting source for VOC removal. Metal oxides based on heterogeneous photocatalytic oxidation (HPO) in the presence of sunlight have been proven to degrade toxic organic pollutants to less toxic by-products by semiconductor photocatalysts in the presence of an energetic radiation source and an oxidizing agent [87–89]. For example, heterogeneous photocatalysts based on TiO_2 and ZnO are useful for capturing toxic VOCs by UV activation, similar to the water purification described in the next section. The energy of solar electromagnetic radiation should be larger than the band gap of the nanomaterials in order to activate the photocatalytic reaction. One such photocatalyst that can be activated by electromagnetic radiation from the sun is crystalline phase anatase TiO_2 which has a band gap of 3.2 eV at wavelength shorter than 387 nm [90, 91]. However, only 2.7% of the solar energy is at this region. To harvest more of the electromagnetic radiation from the sun, photocatalysts exploiting the visible light region are being explored [92]. Doping

with transition metal ions such as V, Mn, Cr, and Fe, or with nonmetals such as N, C, F, and P, semiconductor coupling with WO_3, CdS, or In_2O_3, and dye incorporated photocatalysts are a few methods to utilize a broader range of electromagnetic radiation from the sun [93–97]. For example, Lee et al. [92] reported carbon-doped titania with a pore size of 5–17 nm had a narrow band gap and was able to be activated at a wavelength of less than 550 nm. Similarly, Sathish et al. [98] reported a nano-photocatalyst of N-doped TiO_2 with activity in the visible region of the electromagnetic spectrum. These nanophotocatalysts are incorporated in curtains, blinds, or glass, where natural available UV sources are used to activate and purify air, as well as destroy pathogenic microorganisms [96, 99, 100].

Nanocatalysts in the catalytic converter and exhaust system of a chemical or coal burning facility have a different approach to neutralizing the exhaust air. These exhaust air streams are rich in NO_x, CO, and unburned hydrocarbons (UHC), which are greenhouse gases and are regulated by environmental agencies. A conventional catalytic converter utilizes precious metals such as Pt, Rh, and Pd to purify the exhaust stream. These metals tend to agglomerate into larger clumps upon exposure to hot exhaust gases, reducing the catalytic activity due to decreased surface area and thus requiring more of the expensive metal particles. Mazda Motor Corporation and Nissan Motor Company have successfully utilized metal nanoparticles in their catalytic converter systems for purifying exhaust emissions. Although their techniques are proprietary, the Mazda improved catalytic converter requires 70% less of the precious metal nanoparticles. Their nanosized particles are embedded in the substrate preventing agglomeration and enabling improved oxygen absorption and release rates for enhanced emission cleaning [101].

Chemical Industry

Nanocatalysts in the chemical industry are credited for maximizing synthesis efficiency, minimizing by-product formation, and saving energy by improving selectivity and activity. This is achieved by manipulating and controlling the size, shape, spatial distribution, surface composition, electronic structures, and stability of the catalyst materials. The detailed synthesis and mechanism of various nanocatalysts used in the chemical industry is beyond the scope of this report; however, economic benefits due to the use of nanocatalysts is briefly discussed. According to catalyst experts in Los Alamos National Laboratory, a $4 billion per year cost saving in production cost is possible with nanocatalysts. Table 9.2 depicts savings in production cost and energy savings utilizing catalysts at nanoscale in a common chemical manufacturing process. The data reported in Table 9.3 is based on the REMI model widely used in nonprofit institutions, universities, and US state governments [80].

Catalysts are widely used in all industries; however, the value of improved catalysts such as nanoscale catalyst is in exponential increase as the high energy demand, stringent pollution regulations, high process efficiencies, reduced supply of material, and low carbon footprint requirement are drivers for superior catalysts.

Commercialization

According to Global Industry Analysts, Inc., the global nanocatalyst market is estimated to reach six billion USD by 2015. A large part (about 743 million USD) is contributed to the refinery industry, but the environmental applications will be the fastest growing. Concerns about air pollution and depleted energy sources are drivers for the environmental applications. Other major markets include the food processing industry and the chemical industry, where catalysts at the nano size offer unique and valuable benefits [102].

Green Millennium, Inc., Corona, CA, is using nanotechnology in their photocatalytic air purifying technology. Their TiO_2, when exposed to light and water vapor, produces hydroxyl radicals and a superoxide anion which allow the oxidation of airborne VOCs and toxic organic matter into carbon dioxide and water. This reaction provides deodorization, air and water purification, and sterilization providing a cheap and low energy consumption technology for air purification. With this technology, windows and walls can become self-cleaning and anti-soiling. Green Millennium offers three TiO_2 coatings for use across industries such as transportation, environmental, medical, food, construction, manufacturing, and more [103].

NanoStellar, Inc., Redwood City, CA, develops materials containing precious metals for the power industry. They have created more efficient nano-engineered catalyst materials that reduce exhaust and increase catalyst effectiveness of precious metals by 25–30%. They stress the use of computation materials science, novel synthesis, and chemical engineering for their success in development.

NanoStellar's answer to the increasingly ambitious goals of countries to reduce emissions and pollutants are three products. NanoStellar promoted Platinum is available for low CO oxidation light-off temperatures and tunable NO oxidation characteristic applications. NanoStellar Pt:Pd 2:1 offers 25–30% better performance over traditional platinum only materials and can be used for light duty diesel vehicles. NanoStellar Gold™ improves hydrocarbon oxidation by 20% over Nanostellar Pt:Pd and is suitable for heavy-duty trucks and high efficiency diesel engines. NanoStellar products offer improved thermal stability, greater resistance to poisoning, and better light-off temperature [104].

Altimate Envirocare, Singapore, has created a PhotoCatatSmart Coating known as EnviroCare TiO_2 Photo-Compound Range. This is a spray coating that binds to many surfaces to provide a protective coating. Their TiO_2 Photo-Compounds, in reaction with light, produces "Super-Oxides" to destroy micro-organic substances through vaporization. This provides buildings, vehicles, textiles, and other surfaces with continuously clean surfaces. EnviroCare TiO_2 can be utilized in medical facilities to destroy infectious diseases like MRSA, *E. coli,* and others [105].

Nanostructured Materials in Environmental Remediation

Environmental pollution is a global concern. In the United States alone, there are approximately 1,244 US EPA Superfund sites—sites where the soil, air, and/or water are so polluted as to be an imminent health threat to anyone in the vicinity [106]. Environmental pollution may arise from innumerable sources and processes, both natural and anthropogenic. Wildfires and volcanoes pollute the air, as do many forms of transportation and industrial processes. Torrential rainfall washes topsoil and agricultural chemicals into watersheds. Seasonal winds blow pollutants far from their source into forests and grasslands. As pollution does not tend to stay confined to one area because of the natural patterns of air and water movement, pollutants released in one region may have dramatic impacts on another. Research by both the Commonwealth Scientific and Industrial Research Organization Marine and Atmospheric Research in Australia (CMAR) and the National Aeronautics and Space Administration (NASA) in the US has confirmed a link between air pollution and severe drought; a link which became more obvious after wildfires in the western US led to a drought in sub-Saharan Africa [107, 108]. More recently, there has been a great deal of debate about the process of "fracking," where high pressure fluids are injected into hydrocarbon-containing bedrock in order to liberate stores of oil and natural gas. In April 2010, the Cabot Oil and Gas Corporation was banned from further oil production in the state of Pennsylvania after an investigation showed that its operation in Dimock Township had contaminated the drinking water wells of 14 homes there [109]. April 2010 also saw the BP oil disaster, where 4.9 million barrels of oil were released into the Gulf of Mexico when the Deepwater Horizon drilling rig exploded [110]. Contaminants from such assorted sources as chemical spills, pharmaceuticals, fertilizer and pesticide runoff, abandoned mining and industrial sites, and airborne gaseous and particulate matter from various exhausts pollute the environment we live in and demand our attention for an efficient prevention strategy. Sustaining and enhancing air, soil, and water quality represent some of the most difficult challenges facing the global society in the twenty-first century.

Arsenic contamination of water is found worldwide, with incidents occurring in Thailand, mainland China, Taiwan, Bangladesh, India, Nepal, Argentina, Chile, and many sections of the U.S [111]. Arsenic is a toxic element that occurs naturally in soils, rocks, and groundwater. It enters drinking water supplies from natural deposits in the earth or from agricultural and industrial practices. Long-term drinking water exposure can cause serious health problems such as skin, lung, bladder, and kidney cancer. Many different nanostructured materials have been used to remediate As(III) contamination, including Fe-based materials (particularly nanoscale zero valent iron, or NZVI), high surface area alumina [112], and photocatalytic reactions with nanocrystalline TiO_2 [113].

Because of these diverse sources, causes, and types of pollution, there is a constant need for environmental remediation. Effective remediation strategies can render polluted air breathable, enable polluted water to support aquatic life

Fig. 9.5 Surface waters with heavy metal contamination. *Left*: uranium contamination; *right*: acid mine drainage and lead contamination (Images courtesy of the Center for Hazardous Substance Research, Kansas State University)

once more, and restore polluted soils to a more pristine state. Nanostructured materials are expected to play a role in these strategies, and some successes have already been reported in the literature. Because of their high surface area to volume ratio, nanostructured materials can be significantly more chemically reactive than their bulk counterparts. Tunable nanostructured materials designed to target specific pollutants in a specific setting (water, air, or soils) are also a possibility.

Water Remediation

Water pollution is a very common environmental problem. While surface water pollution is more prevalent, groundwater pollution is also widespread. A number of different nanostructured materials, many of them based on Fe(0) nanoparticles, have been shown to be effective against common water pollutants including halogenated organic compounds (HOCs) and heavy metals. Previously, it has been shown that granular iron can degrade many chlorinated compounds, including chlorinated aliphatics, chlorinated aromatics, and polychlorinated biphenyls (PCBs), as well as nitroaromatic compounds. Early studies by Gillham and O'Hannesin examined the utility of zero valent iron [Fe(0)] in the degradation of 14 chlorinated aliphatic hydrocarbons [114]. Fe(0) nanoparticles have been shown to actively degrade PCBs and trichloroethene [115]. Additionally, bimetallic nanoparticles of Pd/Fe, Pd/Ag, Ni/Fe, and Pd/Zn have been shown to destructively dechlorinate hexachlorobenzene [116–118].

Nanostructured Fe-based materials have also shown some capacity for removing inorganic metal contaminants, such as Cr(VI) [119], As(III) [120], and Pb(II) [121–123], from polluted water. Chromium contamination is a common result of the tanning industry and lead contamination results from activities such as mining and wildfowl hunting, while arsenic contamination is usually natural in origin. As ingestion of these metals may cause both acute and long-term chronic health issues, the ability to remove them from the water supply is sorely needed. Unfortunately, the removal of Cr (VI) proceeds poorly in the presence of bicarbonate, magnesium, or calcium ions. One study showed a 55–77% drop in removal capacity when these ions were present [124]. The removal of As(III) has also been shown to be impacted by the presence of certain ionic species [125, 126]. Figure 9.5 shows the typical appearance of surface waters with heavy metal contamination.

Probably the most common cause of water pollution is microbial contamination. A multitude of microorganisms commonly reside in water, both in surface water and in groundwater. While the water supply in developed countries is highly regulated and protected from sources of contamination, this is not the case in developing countries where people commonly obtain water from communal wells or surface bodies of water. In these cases microbial contamination from human and animal waste, as well as soil bacteria, is widespread. Contaminated water can spread cholera, polio, typhus, amoebic dysentery, hookworms, elephantiasis, and many other diseases. Fortunately, nanostructured materials have been shown to have some activity against many common waterborne diseases.

It has been reported that single or mixed metal oxide nanoparticles such as zinc oxide, copper oxide, aluminum oxide, or titanium oxide, incorporated into a filtration media containing a binder matrix, can destroy bacteria [127, 128]. These approaches are believed to offer advantages over the current process of drinking water purification, which relies upon the addition of disinfectants and sanitizers to kill microbes plus flocculants to settle out larger particles. In one study, the metal oxide nanocrystals were included in amounts ranging from approximately 0.1% up to about 10%

by weight, based on the entire filtration media. In another series of studies, it was shown that MgO nanoparticles are very effective biocides against Gram-positive and Gram-negative bacteria (*Escherichia coli* and *Bacillus megaterium*) and bacterial spores (*B. subtilis*) [70]. Other studies have shown that Ag-based materials are effective against viruses in drinking water [129].

Soil Remediation

Soil is essentially an agglomeration of mineral and organic matter, with pore spaces containing air, water, and nutrient solutions [130]. Specific soils develop under the influence of five different factors: Parent material, climate, living organisms, topography, and time [131]. The mineral portion may include both clays and mineral crystallites, while the organic portion consists of plant and animal residues and secondary products formed by bacterial action on the organic residues. Soil pollution, like water pollution, is relatively widespread and may be the result of both natural and anthropogenic practices.

Common soil contaminants include heavy metals such as arsenic and mercury; halogenated compounds such as PCBs; anthropogenic compounds such as estrones; and radioactive materials such as thorium [132]. The elemental contaminants, such as the radioactive materials and the heavy metals, may originate either from mining and manufacturing or may occur naturally as the result of weathering or leaching of minerals rich in those materials. For example, the minerals orpiment, lorandite, and smithite are rich in arsenic, and their weathering may release arsenic into the soil and water [133]. Historically, many metal-containing minerals have been valued by humans. Mining these minerals exposes even more of the naturally occurring mineral deposit to weathering and leaching thus accelerating soil contamination. The area of the Almadén del Azoque, Ciudad Real, Spain, where cinnabar has been mined since ancient times, is still heavily contaminated by mercury [134–136].

Non-elemental contaminants originate almost exclusively from human activity. Estrones, steroid hormones which are endocrine disrupting chemicals (EDCs), find their way into the environment as metabolites from birth control pills and fertility medications. They have a strong affinity for humic acid which leads them to bind to dissolved organic matter and be deposited when the matter drops out of solution [137]. PCBs were widely used as coolants and lubricants in capacitors, transformers, and other electrical equipment because of their nonflammable and insulating properties. While PCBs are no longer manufactured in the US, they are still present in old transformers and capacitors and are pollutants in soils and sludge in more than 400 US sites [138].

Many of the same nanostructured materials which are useful for water remediation also have some utility for soil remediation. Free iron and iron-based nanoparticles have been demonstrated to be highly effective at removing heavy metals, chlorinated organic solvents, polyaromatic hydrocarbons, and PCBs; however, they tend to aggregate rapidly and demonstrate poor mobility in porous media [139, 140]. Stabilized Fe(0) nanoparticles, which can be produced by a variety of methods including by surfactant modification or in colloidal solution with activated carbon or colloidal poly(acrylic acid) remain unagglomerated in solution for extended periods of time, which increases their mobility in contaminated soils, and are as reactive as free nanoparticles [141, 142]. There have also been efforts to incorporate these materials into membranes which can be placed in the path of contaminant plumes [143]. One study of removal of As(III) by NZVI found that the reaction resulted in the rapid formation of the minerals magnetite and lepidocrocite, which arose from corrosion products of the NZVI and adsorbed As(III). At pH values ranging from 4 to 10, between 88.6 and 99.9% of the aqueous As(III) was removed from solution. The presence of NO_3^-, SO_4^-, or HCO_3^- negatively affected the ability of the NZVI to adsorb As(III), as did the presence of H_4SiO_4 and $H_2PO_4^{2-}$[125, 126].

Pd(0) nanoparticles are also used for soil remediation as both free nanoparticles and as supported nanoparticles, where the supporting substrate may be various solid foams. Free Pd(0) nanoparticles produced by the bacteria *Shewanella oneidensis* were shown to reductively dechlorinate PCBs in solution, and supported Pd-Fe nanoparticles have been shown to assist in reductively dechlorinating 1,2,4-trichlorobenzene. In one such experiment, PCB 21 (2,3,4-chloro biphenyl) solubilized in M9 microbiological media at a concentration of 1 mg/L was reduced to undetectable levels within 1 h when 500 mg/L of palladized *S. oneidensis* (bioPd) was added to the mixture and incubated at 28°C. For the most part, Pd(0) nanoparticles appear to resist the agglomeration and oxidation problems which plague Fe (0) nanoparticles [144].

Nanostructured TiO_2 may be used to remove radioactive Th from soils. Experiments conducted in soils in the presence or absence of soil humic acid and fulvic acid demonstrated that both the fulvic and humic acids increased the sorption of Th(IV) to TiO_2 nanoparticles at acidic pH. Bare TiO_2 nanoparticles by themselves were able to form surface complexes with 94% of the available Th(IV); this percentage increased to 97–98% in the presence of fulvic or humic acids and remained stable with increasing pH [145].

Air Purification

Many VOCs, nitrogen oxides (NO_x), and sulfur oxides (SO_x) in air contribute to smog and high ozone levels, which harm human health [146]. Some of these, such as SO_x, may be produced both naturally and anthropogenically, while others are primarily the result of human activity.

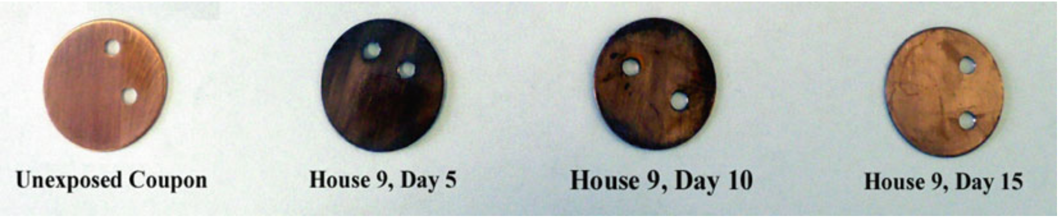

Fig. 9.6 Copper coupon corrosion (unexposed coupon = negative control, day 5 = baseline prior to treatment, day 10 = after first 5-day treatment, day 15 = after second 5-day treatment)

Nanostructured materials which are being used to purify the air include catalysts, which are currently in use and constantly being improved upon [147, 148], and nanostructured membranes, which are under development [149, 150].

Historically, carbon-based adsorbents or destructive oxidation have been used for air purification and particularly for VOC removal. More recently, nanoparticles of metal oxides (MgO and CaO) and core/shell binary oxides (Fe_2O_3/MgO or V_2O_3/MgO) have been tested against typical air pollutants such as acetaldehyde, propionaldehyde, perfluoropropene, and a number of other polar organic compounds [63]. MgO or CaO having a monolayer coating of Fe_2O_3 show enhanced reactivity for the destruction of chlorocarbons, organophosphates, and acid gases [152]. This destructive adsorption, where toxic gases are broken down into non-toxic or less-toxic products, is more desirable than the simple adsorption capability offered by carbon filters.

TiO_2 is widely used for photocatalysis of pollutants, as it generates hydroxyl radicals under UV radiation and the generated hydroxyl radicals then oxidize pollutants on the catalyst surface to form less harmful products. For example, oxidation of NO_x forms NO_3^- on the catalyst surface [153], meaning that TiO_2 has the potential for removing NO_x from polluted air [154]. In another study, it was found that mesoporous γ-MnO_2 displayed a good performance in the removal of NO_x (72 mg/g) and SO_x (700 mg/g) [155]. Nanocrystalline CaO was shown to react with SO_2 at a relatively low temperature to generate a mixture of calcium sulfite, calcium sulfate, and calcium sulfide [40]. The presence of a small amount of Fe_2O_3 on the surface of CaO enhances the ability of the CaO to act as a destructive adsorbent for SO_2.

Commercial Uses

According to a Bharat Book report, environmental remediation accounted for the largest end-user market, capturing 56% in 2007. The projection, however, is that environmental applications will decline through 2013 [156]. However, some technologies have already entered industry use.

To date, a number of businesses have begun utilizing nanotechnology for environmental remediation. Golder Associates, founded in Toronto, Canada, has been in the remediation industry for almost 30 years. They utilize NZVI to treat organic contaminants. The large surface area and high reactivity provide a cost efficient solution for remediating deeply contaminated sites. By injecting the NZVI into the subsurface, the chlorinated organics can be broken down. Other potential applications include treating sludge from various industries and polluted soils in situ instead of excavating them [157].

NanoH_2O, Inc., Los Angeles, CA, uses nanotechnology to desalinate and reuse water. Its Thin Film Nanocomposite membrane has specific characteristics including the membrane roughness, hydrophilicity, and surface charge. This inhibits the adhesion of bacterial cells leading to less biofilm coverage. The minimization of biofilm formation decreases the energy consumption and chemicals used making the reverse osmosis process more productive [158].

NanoStellar, Inc. is helping automakers bring diesel emissions levels down by using a unique nanotechnology. NanoStellar uses the surface chemistry of nanomaterials to engineer precious metals such as platinum, palladium, and gold on a nano-scale level in order to make more effective catalysts for the chemical reactions in emissions control. It is also a key supplier in the diesel industry and is expecting a growth in business due to the worldwide need for reduced diesel emissions [104].

NanoScale Corporation produces and markets nanomaterial-containing filters for improving indoor air quality in houses affected by contaminated drywall (which emits corrosive hydrogen sulfide and other air pollutants). Use of the filters has been shown to dramatically reduce copper corrosion and odor issues in affected houses. Figure 9.6 shows the copper corrosion in affected houses before, during, and after treatment.

Finally, the Dow Chemical Company offers a water treatment media called ADSORBSIA. This treatment media is used by many municipalities to remove dangerous levels of arsenic from water. It offers a number of advantages over conventional water treatment media including handling and disposal advantages [159].

Environmental Concerns Related to Nanomaterial Usage

While nanomaterials offer a great deal of promise in environmental remediation, their usage also comes with some environmental concerns. The impact of nanomaterials on the microbial populations of bodies of water, including surface water and groundwater, is not well studied. The impact of nanomaterials on the microbial populations of different soils has also not yet been thoroughly explored. Finally, questions have arisen about the potential health effects of nanomaterial exposure on wildlife and plants. Preliminary studies indicate that the microbial populations of aquifers change rapidly in response to nanomaterial exposure, but revert to baseline shortly thereafter [160]. NZVI particles also do not appear to have adverse effects on the germination and survival of certain plant species [161]. However, they do appear to have adverse effects on fish, particularly on the gills and intestines [162]. Their effect on larger animals and environmentally sensitive animals, such as frogs and salamanders, is currently unknown.

In conclusion, the environmental remediation possibilities offered by nanomaterials are extensive. However, as nanomaterials themselves may cause environmental damage in certain situations, it is imperative that the decision to use nanomaterials in the environment be made responsibly and with consideration to potential harmful effects. Companies such as NanoScale Corporation, located in Manhattan KS, have undertaken toxicology testing in response to these conditions; however, many nanomaterial producers have yet to follow suit.

Nanostructured Materials in Textiles

Nanotechnology in textiles is a powerful combination; integrating materials manipulated at atomic to molecular levels results in textiles with superior properties. Previously, the functions of textiles were traditionally limited mainly to clothing, comfort, decoration, and protection from temperature extremes. Advancement in nanotechnology, particularly in the field of textiles, led to novel functions and superiority over former materials. These novel functions include anti-static, water repellency, wrinkle resistance, UV protection, self-cleaning, protection against toxic chemical, biological and other pollutants, impact resistance, and protection against fire [163]. Textiles using nanotechnology have also advanced to provide superior protection against extreme weather and improved comfort in terms of weight, moisture transport and permeability, plus superior tear and puncture resistance [164]. The market for nanotechnology in textiles will reach $115 billion in 2012 [165]. In the following sections, highly specialized applications of nanotechnology in textiles are presented.

Chemical Protection

A chemical and biological (CB) protective suit is a necessary safety requirement for individuals who may come in contact with toxic chemicals and bioactive agents. Farmers, chemical plant employees, firefighters, soldiers, and all individuals who will likely come in contact with toxic chemicals or biological agents require a safety barrier. In the contemporary world, no market driver is as important as human life or safety. Exposure to hazardous chemicals and bioactive agents often leads to grave expenses, fines, and negative public relations. The unfortunate outcome of the 2001 anthrax attack in the US, the 1995 sarin gas attack on the Tokyo subway, the Bhopal disaster in 1984 due to the methyl isocyanate (MIC) gas leak, and 1980s Iran–Iraq chemical warfare are some of the more recent ill-fated events that have cost human life and suffering [166, 167]. Currently, two main categories of CB protective suits are available: impermeable polymer ensemble and permeable sorbent-based gear. Although impermeable polymer provides the most protection against CB threats, they cause a great amount of physiological strain. Productive time for the wearer is limited during strenuous activity due to heat stress [168]. The lack of moisture exchange can be detrimental to health causing various illnesses and in some cases death [169]. In sorbent-based technology, sorbent is sandwiched between the textile layers to create a composite laminate. This shields the wearer from the ill effects of toxic contaminants. Figure 9.7 shows a schematic of the concept behind sorbent-based CB protective clothing.

Activated carbon spheres have been the traditional sorbent incorporated between the textile layers to provide chemical protection. The carbon-based technology predominantly involves physical entrapment of toxins or chemical pollutants [170]. The toxin's proximity to the wearer, the potential of preferential adsorption of water by carbons, and a change in temperature resulting in off-gassing of adsorbed toxins are the major disadvantages of carbon-based chemical protective clothing (CPC). In sharp contrast, highly reactive nanocrystalline metal oxide sorbents integrated with textile matrices are expected to offer significant improvement in terms of true protection [171]. These high surface area sorbents with neutralizing capability decontaminate the toxic chemicals to non-toxic by-products.

NanoScale Corporation, as a commercial supplier of nanocrystalline metal oxides, markets its products under the NanoActive® brand name. Their nanocrystalline metal oxides are fine powders, with particles in the 1–10 μm range, similar to ordinary metal oxides, such as talcum powder. However, closer examination shows that they consist of very small crystals (usually 2–10 nm in size) that form large clusters. Figure 9.8 shows a photomicrograph of NanoActive TiO_2.

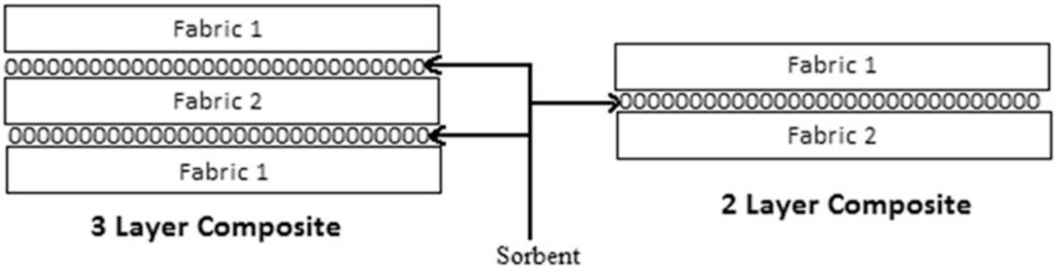

Fig. 9.7 Schematic of CB protective clothing liner

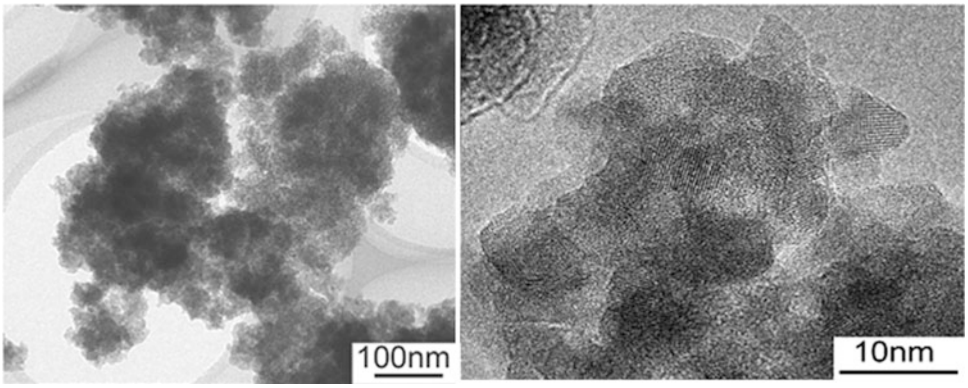

Fig. 9.8 Photomicrographs of NanoActive TiO_2. High-resolution photo (*right*) shows amorphous and nanocrystalline regions

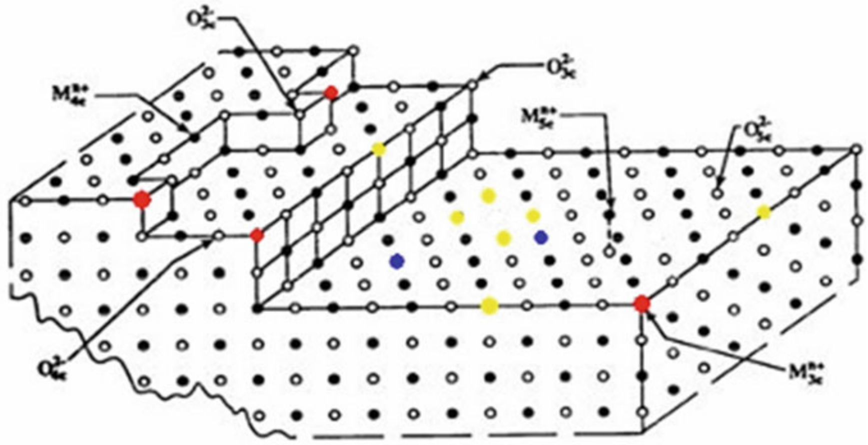

Fig. 9.9 Conceptual sketch, showing coordinatively unsaturated sites, as well as a vacancy defect site

NanoActive metal oxides are highly porous, with high surface areas (for example, NanoActive TiO_2 typically has a surface area exceeding 500 m^2/g). However, for reactivity, even more important than particle size and surface area is the presence of edges and corners, in which ions have a reduced coordination number, as conceptually illustrated in Fig. 9.9 (blue dots are examples of pentavalent surface ions, yellow dots are tetravalent edge ions, and red dots are trivalent corner ions). Such unusual morphology results in enhanced chemical reactivity and suggests a two-step decomposition mechanism on nanocrystalline metal oxides (the first step being adsorption of toxic agent on the surface by means of physisorption, followed by a second step, chemical decomposition).

The fate of chemical warfare agent simulants 2-CEES and DMMP was studied after permeation testing of nanomaterial incorporated textile swatches by ASTM F739. The performance of prototype reactive liners incorporated with nanocrystalline metal oxides was compared against carbon laminate. After the permeation testing, fabric laminates were extracted with ethyl ether and analyzed by gas chromatography-flame photometric detector (GC-FPD). Table 9.4 shows the outcome of permeation testing of 2-CEES exposed liners. As seen from the data, production of 2-hydroxyethyl ethyl sulfide (HEES) confirms destructive adsorption by nanocrystalline sorbent incorporated reactive liners.

Table 9.4 Gas chromatography-flame photometric detector (GC-FPD) analysis of textile swatches after permeation testing with 2-CEES

	% Extracted			2-CEES, (% permeated)
Sample	2-CEES	EVS	HEES	
Carbon laminate	92	0	0	23
NanoScale laminate 1	1.4	<1	18	2.8

Table 9.5 GC-FPD analysis of textile swatches from permeation testing of dimethyl methylphosphonate (DMMP)

Sample	DMMP (% extracted)	MPA	DMMP (% permeated)
Carbon laminate	85	Absent	6.2
NanoScale laminate	24	Present	0.60

Multiple analyses were performed to determine the fate of DMMP from the reactive liners. Solvent extraction of the liners retrieved from the permeation testing yielded unreacted DMMP. As seen from the data in Table 9.5, there was less extractable DMMP from the NanoScale prototype liner compared to the carbon control. The evidence for destructive adsorption of DMMP was acquired by TGA of sorbent material after permeation testing, which confirmed the presence of methyl phosphonic acid (MPA).

Figure 9.10 displays the TGA coupled with a 3D FTIR spectrum for DMMP adsorbed on nanocrystalline metal oxide. The band at 3039–2985 cm^{-1} due to off-gassing at 483–600°C is assigned to CH$_3$-P asymmetric stretch, a characteristic band for MPA seen with NanoScale sorbent, but not with carbon-based sorbent (Fig. 9.11). This band was confirmed by analyzing the neat MPA TGA profile (Fig. 9.12). From the comparison of Fig. 9.10 against Fig. 9.12, it is clear that the DMMP challenged nanocrystalline formulation generates MPA.

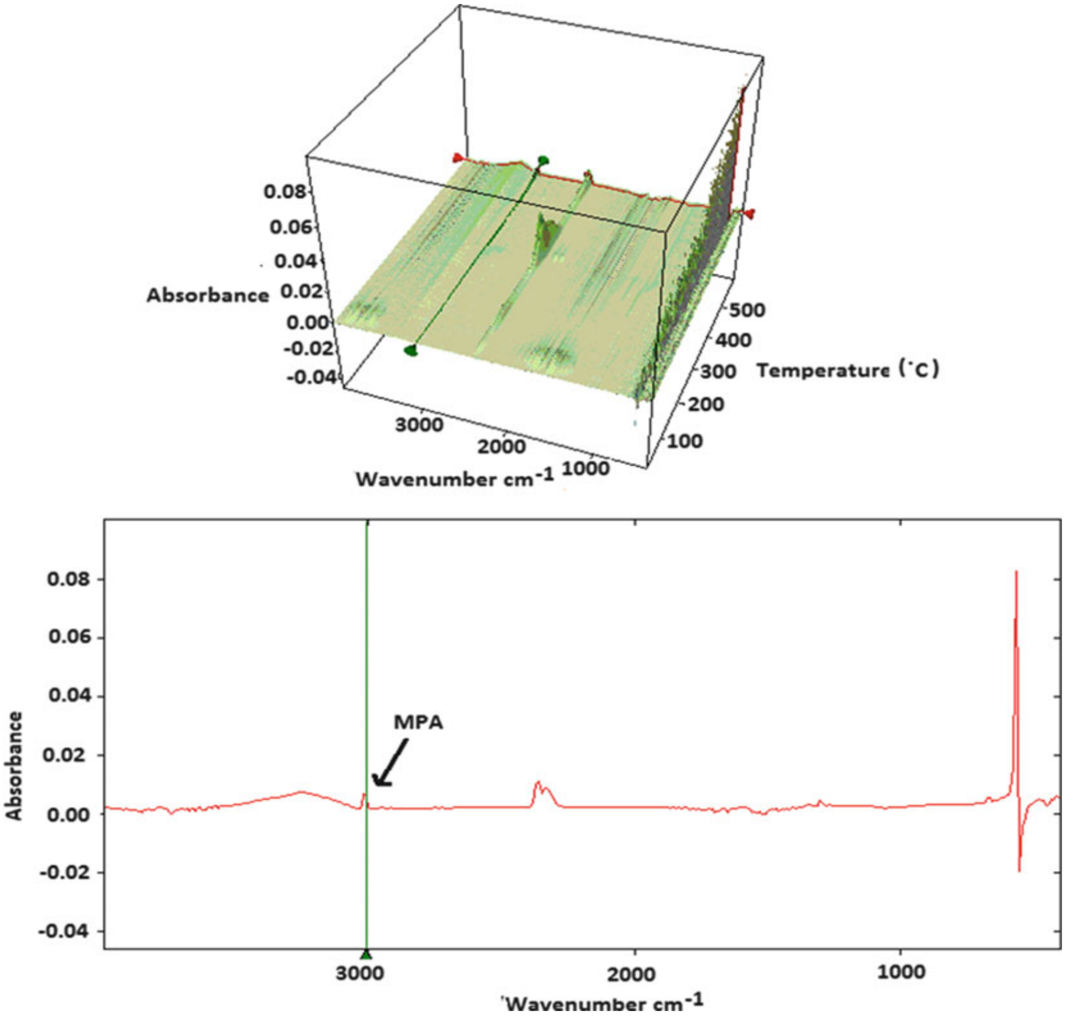

Fig. 9.10 Thermo gravimetric analysis (TGA) of dimethyl methylphosphonate (DMMP) adsorbed on nanoscale sorbent

Biological Protection

Nanocrystalline metal oxides have also shown activity against biological agents. Table 9.4 displays the biological activity of modified nanocrystalline metal oxides against *B. subtilis* spores and vegetative cells of *Burkholderia gladiolii*. Sporicidal testing was conducted according to ASTM 2414-05 "Standard test method for quantitative sporicidal three-step method (TSM) to determine sporicidal efficacy of liquids, liquids sprays, and vapor or gases on contaminated carrier surfaces." Biocidal activity was determined as per ASTM E 2149-01 "Standard test method for determining the antimicrobial activity of immobilized antimicrobial agents under dynamic contact conditions" [172].

Textile industries in the field of medicine have made significant progress by incorporating nanotechnology in the area of antibacterial textiles, antimicrobial wound dressing, and anti-adhesive wound dressings [173]. Antibacterial textiles have broad applications in the medical field; patient's clothing, hospital bedding, facial masks, and hospital furniture are a few examples. Wound dressings exploiting nanotechnology have also become commonplace. Commercial wound dressings with incorporated nanocrystalline silver release ionized silver, facilitating wound healing. They have been clinically tested on burn wounds [174], ulcers, and other wounds [175]. Acticoat®, marketed by Smith & Nephew, Hull, UK, is an example of this class of wound dressings. Wound dressings based on a silica nanosol derived from long chain alkyltrialkoxysilane function as anti-adhesive bandages with improved moisture permeability. These cover the wound without causing further irritation, unlike the traditional wound dressing, which adheres to the wound. The anti-adhesive dressings accelerate the healing process and provide additional comfort.

Self-Cleaning Fabrics

Self-cleaning fabric, a property made possible by exploiting nanotechnology, is useful for consumers ranging from

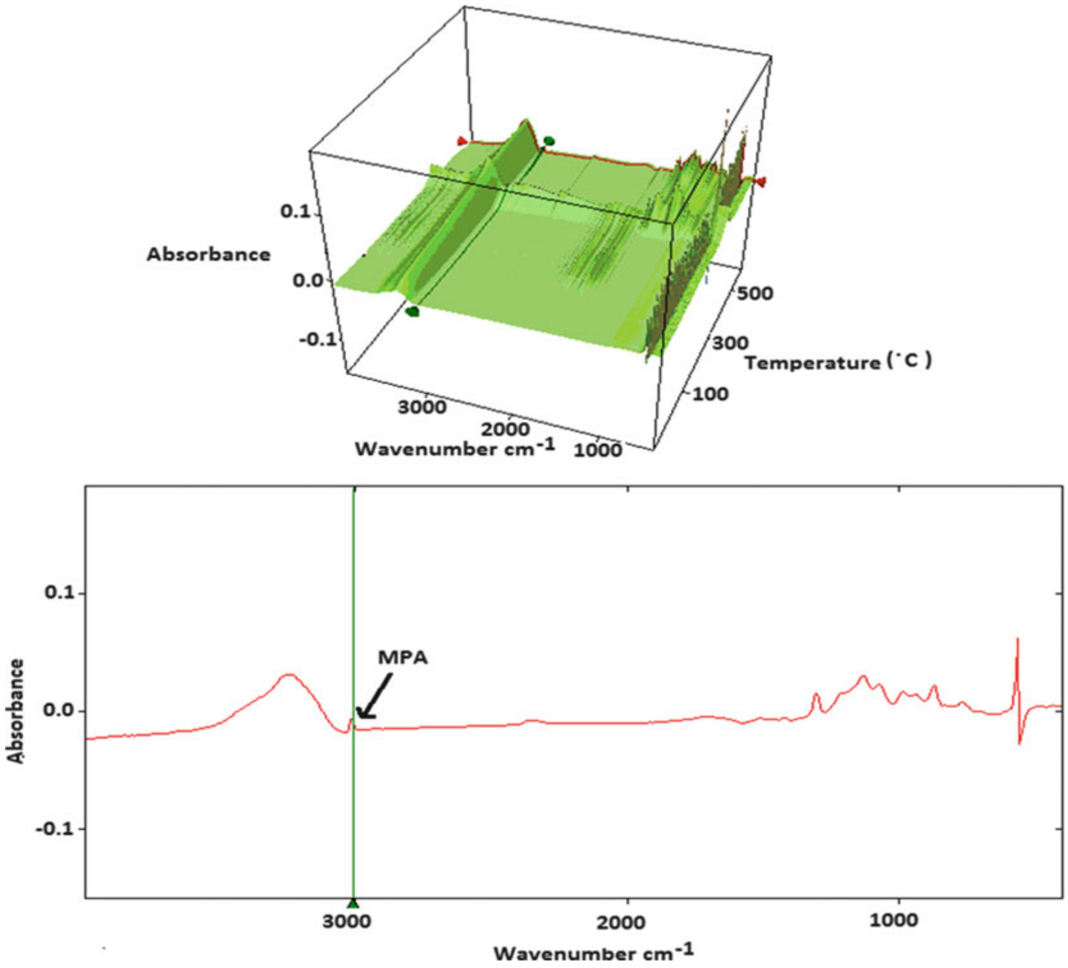

Fig. 9.12 TGA analysis of neat methyl phosphonic acid (MPA)

soldiers in the battlefield to toddlers at home. In the US, approximately two billion kg of surfactant are used annually. The laundry process requires significant energy, water, and detergent, causing greater energy usages and contamination of water streams from the use of detergent [176]. Nanotechnology is expected to make a promising contribution to this area, in the production of self-cleaning fabric via green chemistry. These fabrics are an improvement not only because they have a positive impact on the environment, but also because their usage saves time and effort. Self-cleaning fabrics can be further classified into those which act via photocatalytic activity and those which act via the Lotus effect.

The photoactivity of nanomaterials, in particular metal oxides with high surface area, is useful in decontaminating toxins and neutralizing odors. In the presence of sunlight or UV, electrons jump from their valance band (lower energy state) to their conduction band (higher energy state), leaving a strong oxidizing site in the valance band and creating a reduction site in the conduction band. These sites are reactive to adsorbed species. These reactive metal oxides, in particular TiO_2 coated on fabric, exist as Ti(IV) with an oxygen atom. When charged with UV radiation, the Ti(IV) cation is converted to Ti(III) by electron transfer and simultaneously reacts with the adsorbed species using the oxygen. This electron hole weakens the titania and oxygen bond, resulting in detachment of oxygen containing the adsorbed species. This site is further hydroxylated, and later oxidized back to Ti(IV) in a slow process in the absence of UV radiation. Thus, the fiber coated with TiO_2 acts as a catalyst [177].

The lotus effect is a phenomenon utilized by the Lotus plant (*Nelumbo nucifera*) to self-clean its leaves by exploiting the property of contact angle and sliding angle. The contact angle of a lotus leaf can reach 160 °, which is classified as a superhydrophobic surface. Lotus leaves have a rough surface due to structures called micropapillae which are 5–9 μm, and nanostructures within the micropapillae. When a water droplet contacts the leaf surfaces, it sits on the nanostructure as the air bubbles occupy the crevices in between nanostructures, thus minimizing drag for the droplet allowing the droplet to roll off the leaf [178].

Table 9.6 Biological activity of modified nanocrystalline metal oxides[a]

Modified nanocrystalline metal oxide formulations	Spore log reduction	Bacterial log reduction
[Ag]NA–TiO_2	3.8	8.3
[Ag]NA–TiO_2+ [Ag]NA–CaO	3.3	4.2
[Ag]FS–TiO_2+ NA–CaO+ NA–TiO_2	>3.0	2.6

NA nanoactive; *FS* fisher scientific
[a]NanoScale Corporation, internal research

This droplet removes dirt or particulate matter on the surface during the roll off making the surface clean. Mimicking this natural phenomenon, advancements in the area of superhydrophobic fabrics with high surface roughness have been made by using coatings with nanoparticles [179]. Carbon nanotubes on cotton fabric [180], fluorinated carbon [181], zinc oxide nanorod film [182], titiania [183], and silica [184] on polymeric substrates are a few examples of materials utilized to enhance superhydrophobicity.

Smart Textiles

Sensors using nanoscale systems have gained momentum in recent years. Smart textiles with sensors have become a complex tool monitoring the environment, health of the wearer, and gauging the life of the fabric. The unique characteristics of nanoscale materials are ideal for sensing physical, chemical, and biological signals. Sensors are widely used in present technology, and advanced sensors based on nanostructured metal oxides enable sensing of much lower signals at room temperature [185, 186]. Electrical conductivity, catalytic activity, high crystallinity, and high surface area of these metal oxides are properties required for sensing toxic gases in low levels [187]. Examples of metal oxides include: SnO_2, ZnO, TiO_2, WO_3, In_2O_3, Fe_2O_3, CuO, NiO, Ga_2O_3, and V_2O_5. SnO_2 is sensitive to all gaseous species, which makes it an excellent substrate for surface doping. This functionalized material enhances gas selection and sensitivity. Sensors based on nanostructured metal oxides are thermally activated; however, textile incorporation requires sensors operating at room temperature which limits the selection of metal oxides. SnO_2-based sensors for sensing NO_2, H_2, and CO function at room temperature. Similarly, ZnO-based sensors are reactive to H_2, H_2S, and NH_3 at room temperature [188]. Lim et al. outlines the mechanism of hydrogen gas sensors based on ZnO nanorods [189]. Oxygen molecules adsorb to the surface of ZnO nanorods and withdraw electrons from the conduction band to form the electron rich oxygen species O_2^-, O^-, and O^{2-}, which chemisorb at room temperature. This results in an electron poor space at the ZnO nanorod surface and creates resistance; however, when exposed to hydrogen gas, adsorbed oxygens are reduced to release electrons. This results in an electron rich space at the surface allowing decreased resistance. The sensitivity of this ZnO nanorod sensor can be improved greatly by doping with Pt or Pd metal which enhances the catalytic dissociation of H_2 to atomic hydrogen and eases the reduction of chemisorbed oxygen. These nanostructured metal oxides, when incorporated into textile matrices, are excellent indicators for exposure to toxic gases. Physical sensors based on nanoscale systems integrated into textiles which convert mechanical strain to electricity have multiple functions [190]. For example, CNT-based fabric sensors monitor respiration signals by measuring electrical resistance from the strain caused by respiration movements. Similarly, piezoelectric materials based on CNT-based fabric sensors generate electrical energy by sensing strain caused by movement [191]. Carboxylic acid and lactate oxidase functionalized single carbon nanotube (SCNT) are used to detect pathological disorders by sensing the pH and lactate present in excreted sweat. These biological sensors are excellent diagnostic tools [192]. Although incorporation of these physical, chemical, and biological sensors are at the initial stage of development, these smart textile-based nanoscale sensors are bound to change textile industry in the near future.

Textiles exploiting nanotechnology have long strides to make before their full introduction to the market place; these improvements include the durability to be washed and worn repeatedly without compromising functionality, large scale development needs, cost, and safety concerns. However, many textile products utilizing nanotechnology are commercially available and a few examples are listed below [193].

Commercial Uses

Nano-Tex®, based in Oakland, CA, uses nanotechnology to transform the molecular structures of fibers to produce fabrics that resist stains, moisture, odors, and static. According to Nano-Tex, more than 80 textile mills worldwide use Nano-Tex treatments in products sold by more than 100 leading apparel and commercial interior brands. Nano-Tex claims their treatment is permanently attached to fibers to improve the function of the garment without limiting the life [194].

NanoHorizons Inc., in Bellefonte, PA, uses technology based on silver nanoparticles less than 15 nm in size, incorporated into fabrics. A patented technology uses the antimicrobial properties of silver and their nanotechnology capabilities to combat microbial growth. NanoHorizons is able to permanently chemically bind molecules to fiber, foam, plastic, or coatings. NanoHorizons markets their technology under the brand SmartSilver® [195].

Although great advancements are being made in the textile industry, some of the most promising technology is still being developed. There is a substantial benefit to not having smelly, wrinkled clothing, but nanotechnology can do so much more. Sensatex Inc., Bethesda, MD, is developing what they have called the "SmartShirt."™ The SmartShirt has nanoscale wires interwoven into the fabric to track vital signs and control temperature and can communicate results through a PDA to a base station where they can be monitored [196]. Garments like these can be used on soldiers and law enforcement to promote safe missions and provide immediate notice if care is needed.

Nanostructured Materials in Electronics

When one thinks of nanostructured materials in electronics, several topics come to mind: batteries, devices, and components. In reality these three topics could be broken down to numerous subtopics. We use some form of nanostructured materials everyday in our cars, homes, schools, hospitals, and our personal belongings. However, a closer look reveals that two basic formats exist for preparing these materials, top-down and bottom-up production. Historically, the top-down approach has been used to make smaller, faster, improved devices and components, starting from bulk materials and carving or etching away unwanted material to create nanosystems, devices, and materials [197]. Much electronic circuitry is prepared in this manner. The bottom-up approach is where a desired object is built up from smaller building blocks such as atoms or molecules. Both methods have promise to improve current electronics, but much of the research focused on improving bottom-up methods is more closely related to traditional nanomaterials synthesis.

Nanostructures are of great interest in electronics due to the shape, size, and observed composition properties, as compared to their larger scale counterparts. With these smaller dimensions, electron relaxation rates and interfacial crossing rates of electrons and holes in composite structure become more favorable [198]. Controlling these parameters during growth can be done by template synthesis (colloidal synthesis using various ratios of precursor and capping material) and surface impurities. Similarly, Wei and Zamborini have produced a synthetic vessel which allows real time monitoring of nanostructure growth through AFM [199].

Several materials have found use as lithium-ion batteries. It is thought that these materials can potentially be the answer for high power and energy demands of small mobile electronics and electric cars; however, cost, safety concerns, and various deficiencies must be overcome. Cathode materials from $LiNi_xMn_yCo_{1-x-y}O_2$, $LiMn_2O_4$, and $LiFePO_4$ are considered the most desirable while the most used anode material is still graphite. The lithium materials are prepared through many methods including solid-state, hydrothermal, and sol–gel processes. The small particles of the base cathode material are a good fit for high power applications due to the large surface area, internal structure, short diffusion length, and faster kinetics. Nanoparticles are also more accommodating to volume changes with less risk of cracking and minimal diffusion path lengths. However, the large surface area allows for side reactions on the electrode, coating the material and reducing the life-cycle of the cell, affecting the capacity retention [200, 201].

Several devices use nanomaterials for their electronic components. These include carbon nanotubes used in flat panel color displays, silicon nanowires for electrical conduits in electric and optical devices (photovoltaics and LEDs), and other materials for chemical and biological sensors [202, 203]. Caminade and Majoral have investigated the implementation of phosphorous-based dendrimer macromolecules as a method of coating and modifying surfaces, imparting nanostructures to various components [204].

Woehrle et al. has found a method to organize gold nanoparticles (1.5 nm) into linear chains through biomolecular nanolithography. These gold chains of DNA templates result in angstrom-level precision for controlled interparticle spacing which is a key requirement for electrical and optical applications [205].

Hannon et al. have continued the search for methods to selectively place and orient carbon nanotubes for use in circuitry by micro contact printing and conventional lithography of alkylphosphonic acids onto metal oxide surfaces. This method could improve large-scale integration of superior performance of the carbon nanotube field-effect transistor over the conventional silicon device [206].

Low resistive and good corrosion-resistant noble metal, transition metal, or silicon thin films have been used as contacts and conductors in electronics. Two deposition methods are typically used: vapor-phase or liquid-based growth. Díaz et al. used a different method for thin film deposition, namely, pyrolysis of metallophosphazene in air at 800°C [207]. The resulting thin film's morphology is dependent on the polymeric or oligomeric nature of the precursor, preparation method used, and the surface to be coated. This could create a cheaper more controlled method for clean array formation with versatile film application compared to currently restrictive gold films through chemical methods.

Commercialization

In 2005, the National Center for Manufacturing Sciences (NCMS) surveyed 600 manufacturing companies to scope the future of nanotechnology. These companies included automotive, semiconductor, aerospace, energy, utility, and information technology sectors. The response? Sixty percent expected to include nanotechnology in their products by 2009, just a few years later [208].

Last year the NNI created a multi-agency collaboration, led by NSF, to promote nanoelectronics. “Nanoelectronics for 2020 and Beyond” pushes NSF, DOD, NIST, DOE, and IC to promote five areas of research and development.

- Exploring new or alternative “state variables” for computing
- Merging nanophotonics with nanoelectronics
- Exploring carbon-based nanoelectronics
- Exploiting nanoscale processes and phenomena for quantum information science
- Creating a National Nanoelectronics Research and Manufacturing Infrastructure Network

The goal of this research is to reduce power consumption and heat production in small electronics through carbon-based solutions, gain significant growth over other nations’ electronic capabilities, create high quality jobs, and lastly, create a foundation to foster other nanoelectronic successes [209].

NanoMarkets predicted the nanoelectronics market to reach $82.5 billion this year. The leading push on this market is expected to come from the demand of high-performance, non-volatile memories. Nanosensors are expected to capture a significant portion of the market in medical, homeland security, and aerospace applications [210].

Nanostructured Materials in Medicine

One of the most exciting potential uses of nanostructured materials is in medicine. Research into the mechanisms underlying different medical pathologies, particularly cancers, has led to a better understanding of the causes, progression, outcomes, and potential treatments for these conditions. Unfortunately, a greater understanding of a medical condition does not necessarily lead to an immediate advance in the therapy for the condition. The human body is an extremely complicated and very intricate structure, with the result that a therapy must be carefully designed to provide the maximum benefit with a minimum of associated side effects or toxicity. Nanostructured materials, with their unique capacity to be directed to specific individual cells, will provide safer and more effective treatments for a large number of medical conditions.

Nanomaterials and Cancer Therapies

One area where nanostructured materials are being investigated is in the diagnosis and treatment of cancer. Cancer is one of the most feared medical diagnoses, even though cancerous conditions are relatively common and most cancers are well understood. According to the CDC, the most common cancers are prostate, breast, lung, colon, uterine, urinary bladder, non-Hodgkin’s lymphoma, melanoma, kidney, and ovarian [211]. Cancer incidence is strongly associated with age, and its incidence increases dramatically after age 40 [212]. In the 6-year period from 1999 to 2005, more than nine million people in the US were diagnosed with cancer, which works out to approximately 1.5 million people in the US who are diagnosed annually, or approximately 1 in 200 [213].

Why is this relatively common and well-understood type of disease so feared? One reason for the anxiety surrounding this disease is the way it is currently treated. Most cancers are treated with a combination of surgery (to remove as much of the tumor as possible), radiation (to destroy any cancerous cells which could not be removed by surgery), and chemotherapy (to destroy any invasive or metastatic cancerous cells). Most cancer patients find the course of radiation and chemotherapy to be extremely unpleasant, which is to be expected when the side effects include fatigue, skin problems, loss of appetite, hair loss, and lowered blood count (from radiation therapy) [214] and nausea, muscle and nerve problems, fatigue, anemia, and difficulty breathing (from chemotherapy) [215]. Worse yet, more than one round of treatment may be required to eliminate all the cancerous cells from the body. Cancers which have evaded detection until they have progressed to advanced stages may be incurable, and the patient may undergo treatment only to prolong life.

Nanostructured materials are expected to provide substantial improvements in the diagnosis and treatment of cancer. Most types of cancer are very treatable in the early stages, with good chances of cure or lasting remission. However, many cancer types are difficult to detect in these early, highly treatable stages. Soft tissue cancers, such as ovarian, esophageal, and pancreatic cancer, are especially difficult to detect. These cancers commonly cause vague, poorly defined symptoms such as fatigue and digestive disturbances. As a consequence, these cancers are often not diagnosed until they are very advanced. The median survival time after a diagnosis of pancreatic cancer is currently—3–6 months, with fewer than 4% of those diagnosed still alive 5 years post-diagnosis [216].

Fortunately, improved diagnostic tools for these cancers are in development. In one experiment, functionalized semiconductor quantum rods were used to optically image pancreatic cancer in mice [217]. Other nanomaterials, including gold nanorods [218] and CdSe quantum dots, [219] offer enhancement of existing imaging techniques by acting as contrast agents. Improved imaging capabilities can mean substantial improvements in patient quality of life and treatment outcomes via improved staging of cancers and improved ability to gauge tumor invasiveness. In situ imaging, which discloses the exact location and size of the tumor, is particularly useful. However, nanomaterial-based assays which demonstrate improved detection sensitivity are also desirable.

One such assay, in which a nanoparticle immunoassay measured the degree of protein aggregation of known cancer biomarkers, found that the level of protein aggregation or complexation was a positive indicator of certain cancer types [220]. Another research group designed a detection system capable of detecting as few as 25 target cancer biomarker protein complexes. This system is based on fluorescent-conjugated polymers on Ag/Au nanorods [221].

Many developmental nanomaterials have shown promise as potential treatments for cancer. Iron-based nanoparticles, including iron oxide nanoparticles, are being widely investigated for both their imaging properties and their potential use in anti-tumor therapies. These nanomaterials may be used for drug delivery [222, 223] or may be used for imaging and hyperthermia treatments [224, 225]. Other nanomaterials which show potential as therapies include carbon nanotubes [226–228], copper sulfide nanoparticles [229], and silica-based nanomaterials [230, 231].

Drug Targeting

In addition to providing improved detection and treatment of cancer, nanostructured materials may be designed to enhance existing treatments. The drug Cisplatin is widely used to treat solid malignancies, both alone and in combination with other chemotherapy medications. Unfortunately, the drug also has a wide array of dangerous side effects, including fatigue, nausea, vomiting, diarrhea, nerve damage, immune system suppression, kidney damage, hearing loss, and even the formation of secondary cancers resulting from treatment. The kidney damage resulting from administration of this drug can be severe, so much so that it is often dose-limiting [232].

In an effort to improve the drug by reducing its nephrotoxicity, a team from the Department of Medicine at Brigham and Women's Hospital in Cambridge, MA, engineered a nanostructured version of this drug. Their nanostructured version consists of a polymer which self-assembles in the presence of the appropriate amount of platinum to produce a nanoparticle. This nanoparticle releases Cisplatin in a pH-dependent manner and is rapidly targeted into the lysosomes of cancer cells, where it releases the drug and kills the cells. Compared to the free Cisplatin, the nanoparticle demonstrated a reduced distribution in the system as a whole, which led to reduced toxicity [233].

A number of medicines have now been prepared by coprecipitating drugs and polymers to produce polymeric nanoparticles, including Cyclosporine A [234], Tamoxifen [235], and Daunorubicin [236]. In general, this approach is reported to result in improved tumor targeting, greater efficacy, and reduced toxicity.

The improved tissue targeting capability of nanoparticulate preparations of drugs is not limited to anti-cancer agents. Other areas of the body, most notably the central nervous system (CNS), are difficult to reach for most medications. In one study, poly(DL-lactic-co-glycolic acid) (PLGA) nanoparticles with modified surfaces (chitosan or Polysorbate 80) were found to be capable of passing the blood–brain barrier [237]. Other therapeutic nanomaterial preparations have been designed to deliver to the eye [238], across the mucosa [239], through the dermis [240], and to bone [241].

In contrast, organs involved in detoxification and excretion, such as the liver and kidneys, are frequent recipients of medications whether or not the medication is supposed to reach them [242]. This leads to toxicity and side effects from the medication, which can limit the dosage or usage. However, medical nanomaterials have been shown to greatly improve the targeting of these drugs to the tissue in need of treatment and away from the liver and kidneys [233]. This improved targeting not only allows the drugs to be more effective therapeutically, but also lessens any toxicity caused by detoxification and excretion.

Treatments for Lifestyle Illnesses

Medical nanomaterials also show promise in the treatment of "lifestyle illnesses" such as obesity, heart disease, and type 2 diabetes. As the population in the industrialized world grows fatter, more and more people will suffer the effects of being overweight. As a result, the demand for improved medical therapies for these conditions is growing. Patients want less invasive therapies for diabetes (no needle sticks for insulin administration or blood glucose analysis), heart disease (no shunts or coronary by-passes), and obesity (no gastric surgery and the ability to eat what they want, when they want). While it is improbable that medicine will advance to the point where patients can "have their cake and eat it too," any advances in treatment will be welcomed.

Diabetes currently affects 7.8% of the total US population. Of those 60 and older, the prevalence rises to 23.5% [243]. The CDC predicts that by 2050 this incidence will double or triple [244]. Clearly, the need for less invasive treatments will continue to increase for the foreseeable future.

The current method of insulin delivery by injection has disadvantages including the potential for infection and the stress associated with self-injection. Nanoencapsulation of insulin in zirconium phosphate for oral delivery has been explored in vitro and is reported to result in the stable release of insulin from the nanocapsules [245]. Supercritical antisolvent (SAS) micronization of insulin has also been investigated for transdermal insulin delivery [246], and solid lipid nanoparticles have been investigated as carriers of insulin for pulmonary delivery [247]. If one or more of these insulin delivery methods proves to be as safe and effective as insulin injections, daily injections will soon be a thing of the past.

Fewer nanomaterial options are available for the treatment of obesity. Currently, one of the few efforts reported in the literature is the production of nanosized particles of orlistat, a gastrointestinal lipase inhibitor [248]. This allows the drug to be handled and administered more easily, plus the nanosized particles are better absorbed than their conventional counterparts. Another is the development of PEGylated all-trans retinoic acid nanoparticles, which have been shown in vitro to prevent adipocyte development and differentiation [249]. As the incidence of obesity increases, obesity research involving nanomaterials is likely to become more urgent.

The options for treatment of cardiovascular disease are more varied. Approaches currently under study include the use of nanomaterials to produce synthetic High-Density Lipoproteins (HDL) [250], injection of peptide nanofibers to enhance stem cell therapy [251], the use of nanoparticles to prevent atherosclerosis [252], and making nanoformulations of growth factors for therapeutic angiogenesis [253]. These approaches encompass both the prevention of cardiovascular disease via the prevention of atherosclerosis and treatment of diagnosed disease via cell therapy to re-grow the damaged tissues and improve organ function.

Other Medical Nanomaterial Uses

Nanomaterials also have potential usages in gene therapy. The use of nanomaterials has been shown to enhance the transfection of different target cells, including cancer cells [254] and skeletal muscle cells [255]. Transfecting regulatory genes into cancer cells encourages the cells to down-regulate their growth, up-regulate their differentiation, and can cause them to recognize their abnormal condition and trigger their self-destruction pathway. The ability to transfect skeletal muscle cells will, it is hoped, provide a cure for several inherited degenerative muscle diseases which are currently fatal. Nanomaterials also offer a great deal of hope for various opthalmic conditions which are currently difficult to treat or for which there is no treatment, such as retinal degenerative disease [256]. Because of the unique structure, composition, and function of the eye, many conditions are currently difficult or impossible to treat. However, current research in medical nanomaterials may eventually change this.

Finally, nanomaterials may provide an improved way to prevent infection. Some potential uses for nanomaterials in this area include oral biofilm prevention [257], control of airborne indoor bacteria [258], and the production of titanium alloys which discourage infection [259].

Commercial Uses

The impact of nanotechnology on healthcare is likely to be the largest among nanotech applications. North America has the largest market, worth $4.75 billion in 2009 with Europe following at $3.65 billion. The drug delivery market alone is expected to grow to $16 billion by 2014. Other markets such as biocompatible implants and coatings and diagnostics are expected to grow 42 and 21.8%, respectively, from 2009 to 2014 [260].

Elan Drug Technologies, headquartered in Dublin, Ireland, has found a solution to a problem that could lower the dosage of the medicines you take. Their NanoCrystal® technology reduces the size of drug particles to less than 2,000 nm, exposing a larger surface area. Many drugs exhibit poor solubility and the NanoCrystal technology is a commercially available answer. This technology has produced five products and brought in $1.8+ billion annually in market sales [261].

NanoBio Corporation, Ann Arbor, MI, has technologies in development for topical anti-infective treatments and mucosal vaccines. This technology, NanoStat™, uses emulsions manufactured at the range of 150–400 nm. NanoStat treatments are toxic to microbes but non-irritating to skin and mucous membranes. This technology has shown effectiveness against certain bacteria, viruses, fungi, and spores. Since the mechanism involves a physical and not a chemical process, the potential for the development of drug resistance is substantially lowered. Vaccines for influenza and Hepatitis B are in current development [262].

There are numerous companies working on the delivery of drugs, typically in cancer applications. For example, the nanoscale development of gold-based drug compounds can be used to target tumors, limiting the impact on surrounding organs and tissues. Current issues with drug delivery are in the efficiency of loading and controlling the drug [263]. Future successes in nanotech drug delivery will depend greatly on the ability to scale up the technology, meaning a close scientist–engineer relationship to create an efficient, effective product.

In conclusion, the medical uses for nanomaterials are numerous and varied. Nanomaterials may eventually be used to provide routine treatments for conditions which are currently untreatable, such as muscular dystrophy and retinal degeneration, in addition to providing improved therapies for conditions such as cancer, cardiovascular disease, and diabetes.

Nanostructured Materials in Coatings

Another potential usage of nanomaterials is in coatings technology. There are innumerable different types of coatings, all designed for improving the characteristics of the coated material. A short list of coating types includes fabric coatings for improved stain resistance [264], antimicrobial coatings for infection prevention [265] and product preservation [266], conductive coatings for solar cells and other electronic applications [267], scratch-resistant coatings for optics [268], and antifouling coatings for marine applications [269]. Nanomaterials offer the opportunity for improvements in nearly all coating fields and applications.

Edible Nanomaterial Coatings

A number of different industries are currently using or are expected to use nanomaterial coatings. The food processing industry has been researching nanocellulose-based edible coatings for improved shelf life of fresh fruits, vegetables, and meat products [270, 271]. The medical industry uses nanosilver coatings on catheter surfaces and textiles [272], and marine equipment manufacturers use antifouling nanomaterial coatings [273]. Multiple applications for nanomaterial coatings exist in the electronics industry [274], most notably for applications such as solar cells [275].

Food safety is a significant public health concern. The CDC estimates that 48 million Americans are sickened annually by foodborne illnesses [276]. Because many food products are now mass produced, contaminated foodstuffs may easily produce nationwide outbreaks of foodborne illness. Additionally, fresh foodstuffs, such as produce, are highly perishable and have short shelf lives even under ideal conditions. Spoiled food represents a loss to everyone involved in food production and consumption: the consumer, who sees higher prices and lower availability thanks to spoilage; the grocer, who must pay to dispose of the spoiled food; and the producers and distributors, who don’t get paid for producing and transporting the food.

One high-tech solution which has been proposed to lower the incidence of contamination and prevent spoilage is the use of edible coatings. These coatings, which would predominantly be used on fresh or raw foods, could be designed with antioxidant capabilities (to prevent spoilage) as well as antimicrobial capabilities (to prevent contamination). Most commonly, the coatings consist of macro materials such as chitosan [277] or alginate [278]. However, a small number of researchers have reported that nanomaterials such as cellulose nanofibers [279] may be used to enhance the properties of these coatings. While only a few instances of edible nanomaterial coatings are currently known, the use of such coatings can be expected to increase as their safety is established and their organoleptic properties (their taste and smell) are improved.

Medical Nanomaterial Coatings

As was mentioned in depth in the Sect. 8, nanomaterials have a large number of uses in the medical field. However, here we will focus solely on nanomaterial coatings with medical uses.

One use for medical nanomaterial coatings is for infection prevention. The use of catheters and ports leaves patients more vulnerable to infection, as these indwelling medical devices lack the anti-infective properties of natural body orifices and are readily colonized by infectious organisms [280]. The most common antimicrobial nanomaterial coating currently in use is nanosilver, which is commonly encountered on medical instruments [281], in catheters [282], and in wound dressings [272]. The antimicrobial activity of nanosilver, when incorporated into these materials, offers the patient some protection against nosocomial infection and microbial colonization. These products are widely commercially available from a variety of suppliers and are widely used in hospitals and clinics.

Other medical uses of nanomaterial coatings include drug delivery [283, 284] and tissue scaffolding to enhance medical implant integration, particularly into bone [285, 286]. Naturally, prosthetic implants such as dental and joint implants are more successful if the patient’s healing process will integrate the implant into the existing bone, thereby securing it and allowing for more natural functioning. Hydroxyapatite nanoparticles (which can be incorporated by the body into bone structures) are especially useful when combined with the silica-polymerizing enzyme silicatein α (which encourages the process). Hydroxyapaptite nanoparticles are commercially available from suppliers such as Sigma Aldrich for use as a bone injectable substrate and for bone grafting.

Additionally, researchers are working on a nanomaterial coating that can safely eradicate *Staphylococcus aureus* (MRSA). A coating of this nature would be applied to a variety of surfaces including medical instruments and surgical masks. The research uses a naturally occurring enzyme which kills the target bacteria, attached to a carbon nanotube for increased mobility [287].

Industrial Nanomaterial Coatings

In addition to applications in food processing and medicine, nanomaterial coatings also have a great many industrial uses. Antifouling coatings are highly useful for the shipping industry, as smooth hulls and propellers create much less drag, which makes fuel usage more efficient [288]. Likewise, bioreactors and oil pipelines are expected to benefit from this technology [289], as are heat exchangers involved in food [290] or energy production [291]. The use of anti-adhesive or antifouling coatings on heat exchangers in power plants is expected to dramatically increase efficiency, as a 1 mm thick biofilm accumulation on the wall of a low carbon steel heat exchanger results in a resistance to heat transfer equivalent to an 80 mm increase in tube wall thickness [292]. There are environmental and safety concerns with some of this technology, as biocide-releasing coatings can adversely affect marine organisms or can lead to the presence of biocides in foodstuffs.

Other types of nanomaterial coatings, including self-cleaning coatings [293], are also expected to be extremely useful. Self-cleaning coatings on items such as solar cells could decrease maintenance costs and increase energy output. Currently, solar cell output can be severely affected by the presence of dust, with even tiny amounts such as 1/7th of an ounce per square yard decreasing power conversion by 40% [294]. Since the best locations for solar cells are in areas which receive large amounts of sunshine (and conversely, very little precipitation), dust is a serious problem. Self-cleaning coatings would go a long way towards remedying the effects of dust. Additionally, many optical instruments have parts which are difficult or time-consuming to clean, so self-cleaning coatings would decrease maintenance needs in these cases as well. Other less obvious uses for self-cleaning coatings include exterior coatings for building materials such as wood and stucco, which soil easily and can be colonized by algae and other microorganisms [295].

Scratch-resistant nanomaterial coatings have some obvious uses, such as in abrasion-resistant coatings for automobiles, industrial parts, furniture, and flooring [296]. Less obvious uses include abrasion-resistant coatings for use on teeth and bones [297]. Alumina nanoparticles are most commonly used for these coatings, although silica nanoparticles may also be used [298].

Finally, conductive nanomaterial coatings offer improved performance characteristics over currently used conductive coatings like indium tin oxide. Indium tin oxide coatings, while widely used, are brittle, expensive, and chemically unstable. Nanomaterials such as single-walled carbon nanotubes [299], conductive polyamide fibers [300], and single-walled carbon nanotubes with silver nanowire films [301] all offer advantages such as flexibility and improved chemical stability. Additionally, some of these coatings can be applied to inexpensive substrates to produce inexpensive energy storage devices.

Commercial Uses

Nanomaterial coatings are already a large portion of the commercial nanotechnology industry, as a whole. In 2008, commercial nanomaterial coatings generated revenues exceeding 600 million USD. Targets of these technologies include construction, healthcare, transportation, and defense markets. The commercial nanomaterial coatings market is expected to reach over five billion USD in revenues in 2013, according to a Research and Markets report [302].

Companies like Xurex, Inc., a manufacturer of nanomaterial coatings located in Albuquerque, NM, could make significant contributions to conserving building materials and lowering costs across many fields. Xurex offers coatings to combat the corrosion and degradation of pipes, roads, bridges, ships, etc., which could potentially save millions of dollars [303]. Other applications in technology include self-cleaning surfaces and more durable materials, such as concrete. These energy efficient improvements could reduce the 41% of all energy use that is lost to commercial and residential buildings [304].

There is a real commercial need for alternative coatings in relation to the aerospace and defense industries. Coatings for thermal barrier, anti-ice, and surface protection are a necessity. Funding from governments is pushing these applications as nanocoatings can typically offer additional properties, including heat resistance, as well as offering an environmentally friendly alternative to standard coatings [305].

Environment, Health, Safety Issues Related to Nanostructured Materials

Nanostructured materials have come into play in the consumer market after a relatively short development period. As they are part of such a new science, relatively little is known about them except for those that have been studied as desirable characteristics for developing products with distinct performance advantages. The greatest concern surrounding the use of nanotechnology is the possibility of toxicity or other damaging interactions with living organisms. Naturally, while toxic interactions with pathogens are desirable for some classes of nanomaterials, toxic interactions with organisms in general are not. The situation is further complicated by the fact that chemically identical nanomaterials with different sizes and shapes can and will show different toxicological profiles [306], different tissues and organisms used to assess toxicity will exhibit greater or lesser sensitivities, and approved, standardized methods for evaluating nanomaterial toxicity are scarce. Worse, the use of in vitro assays as a means of assessing toxicity may lead to erroneous conclusions regarding the toxicity of the nanomaterial in whole organisms.

For example, it is known that some mammalian organs and organ systems are more sensitive to nanomaterial toxicity than are others. The lungs, in particular, are known to be highly sensitive to nanomaterials [307]. However, toxicity assays which are conducted on lung tissues in vitro and in vivo can show very different outcomes. A study conducted on the toxicity of both nanoscale and fine zinc oxide particles in rat lungs found several confounding factors, including the failure of commercial samples to match the manufacturer's specifications and the development of “metal fume fever” in animals exposed to levels of zinc oxide which caused no demonstrable cytotoxicity in vitro [308]. Indeed, at exposure levels which were pathological to the animal, the in vitro assays failed to show evidence of any inflammatory responses including increased chemokine production. And what are we to make of another study, which found that the toxicity of zinc oxide nanoparticles could be lessened by doping them with iron [309], although iron oxide nanoparticles have themselves been found to be toxic? [310].

Some nanoparticles have demonstrated similar toxicity towards plants and bacteria. Phytotoxicity is usually measured by assessing seed germination and root elongation in seeds and seedlings exposed to the test material. One study which measured the effects of multiwalled carbon nanotubes and nanoparticulate forms of metallic copper, metallic silver, zinc oxide, or silicon on zucchini plants found that while exposure to these materials did not reduce germination, root elongation and plant biomass production was negatively affected [311]. Biomass in particular was greatly affected, with exposed plants showing biomass reductions of up to 75% of controls. As has been found in other studies, the negative effects were significantly more pronounced after exposure to nanoparticulate forms as compared to bulk forms. Nanomaterials have also been shown to be toxic to cyanobacteria and microalgae [312] and to microbial soil communities collected from California grassland [313]. In the case of the soil bacteria, nanomaterial exposure reduced the overall biomass of the community and altered the composition and diversity of the community. The effect of these changes on the chemical processes which occur in the soil, and on other denizens of the grassland, is not known.

How are analysts to proceed when confronted by these types of toxicological results? Conducting subsequent experiments to better understand the underlying mechanisms is one obvious answer, but various interested parties must still determine how to reasonably proceed safely in the meantime. The approach to nanomaterial safety currently taken by the US government is to make a coordinated effort to (1) monitor both expected and unexpected consequences of nanotechnology and (2) identify and prioritize nanomaterial health and safety research needs [314]. These actions were taken as part of the NNI, which was established in 2000. The findings from research undertaken by this group will be used to guide public policies at regulatory agencies such as the EPA and FDA. Currently, the EPA can’t ask a chemical producer to provide data regarding the risk assessment of a chemical, unless the EPA already has data showing that the chemical presents an “unreasonable risk” to human health or the environment [315]. Regulatory policies are greatly needed, as nanomaterial production and usage becomes more widespread. As a group of Swiss analysts found, many companies in industrial sectors other than those specifically identified as “nanotechnology” are already using nanomaterials [316].

Another approach, taken by members of the insurance industry, was to perform a relative risk assessment based on the nanomaterial manufacturing process. This risk assessment took into account the normal operations risk, incident risk, and latent contamination risk [317]. At the conclusion of the assessment, the risks of fabricating five different nanomaterial types (single-walled carbon nanotubes, buckyballs, zinc selenide quantum dots, alumoxane nanoparticles, and titanium dioxide nanoparticles) were determined to be comparatively low in relation to other manufacturing processes such as battery production.

There also is a movement towards understanding what safety steps other industrial nanomaterial producers are taking. Surveys of health and safety measures taken by industrial producers have found that most producers have given the issue some thought, with many specifying the use of PPE and engineering exposure controls [318]. Undertaking exposure and hazard assessment procedures are common in industry [319].

Waste management is another area impacted by nanotechnology. The introduction of nanomaterial containing products has instigated use of various assessment tools (i.e., life-cycle assessment, LCA) to establish the impact of products on global warming/climate change, stratospheric ozone depletion, human toxicity, ecotoxicity, and others. Nanocomponents are assessed for aspects that include material selection, manufacturing, application, and disposal/recycle. Physical properties must be well documented and investigated because they influence the toxicological impact through transport and interaction of the materials when released to the environment. Many products are currently using nanocomponents containing titanium, carbon, silver, iron oxide, zinc, gold, and/or silicon/silica. These include appliances, automotives, electronics and computers, food and beverage, children’s goods, health, personal care, sporting goods, and home and garden products. Most products are assessed for toxicity by producers on a cradle-to-gate basis, vs. cradle-to-grave, leaving the onus for safe disposal on the consumer and the public waste facilities [320].

Walser et al. performed a LCA for nanosilver t-shirts and compared the data to both triclosan biocidal t-shirts and non-biocidal t-shirts. The cradle-to-gate study found the flame spray pyrolysis method of producing nanoparticles had a climate footprint of 2.7 kg of CO_2-equivalents; the plasma polymerization with silver co-sputtering had 7.67–166 kg of CO_2-equivalents (depending on maturity). In contrast, regular and triclosan t-shirts had 2.55 kg of CO_2-equivalents. Based on this study, it is clear that the consumers’ wash cycle habits and eventual disposal of garments have minor effects on climate footprint. On the other hand, mining operations for raw materials have a greater effect due to toxic silver emissions [321].

One of the beneficial uses of TiO_2 is as a sunscreen due to its effective UV reflection and adsorption capacities. The nano-TiO_2 has higher transparency and efficiency making it even more desirable. Sunscreens undergo extensive testing in direct exposure to the skin scenarios but not further in its life-cycle. Botta et al. have investigated environmental release of these nano-TiO_2 containing sunscreens to water (fresh and salt) after artificial aging of the solutions. Their results found that in salt water, a major part of the nano-TiO_2 containing residue will aggregate and sediment, further affecting bottom dwelling sea life. In contrast, the fresh water released portion will remain stable and accessible to the entire water column [322].

Another application in use is nanoparticle CeO_2 as a diesel fuel additive. This additive has been designed to increase mileage by performing as a combustion efficiency aid. However, some CeO_2 <100 nm has been found in the expelled particulate matter. This is then released into the environment in relatively low concentrations. Several studies have been performed to determine toxicity of these particles, but no testing has been done on the diesel additive exhaust system emitted particles, or on low concentrations of ceria nanoparticles [323].

Currently, limited studies are available for nanomaterials that enter waste facilities. A newly emerging term, "nanowaste," is defined as any waste stream(s) that contain nanomaterials or synthetic by-products of nanoscale dimensions, generated either during production, storage, and distribution, or waste stream(s) resulting from the end of lifespan of formerly nanotechnology-enabled materials and products, or items contaminated by nanomaterials such as pipes, PPE, etc. Additionally, BSI British Standards Guide PD 6699-2 defines nanowastes in four forms: pure nanomaterials at point of production, materials and surfaces that have been contaminated with nanomaterials (containers, PPE, etc.), liquid suspensions containing nanomaterials, and solid matrices containing nanomaterials. Concerns that have been raised dealing with these nanowastes include increased uncontrolled releases of nanomaterials to the environment, the technological and legislative challenges nanowastes pose to waste management systems, establishing a nanowaste classification system, and ways to enhance current and ongoing management of nanowastes. The very nanostructures that are prized for their applications are now a concern due to their potential ability to aid faster bonding with pollutants, facilitating faster transfer and greater transport of hazardous materials through air, soil, and water. Traditional wastewater treatment by-products (biosolids from settling tanks) can become too concentrated with pollutants such as Ag to be reused as compost or fertilizer, flocculation methods can be thwarted by surface coatings or other functionalities present on the nanomaterial, or nanomaterials can just simply pass though without any interaction at all [324].

Some concerns with nanoparticulate materials are their capability for dispersion into air and water, then further into the environment. Drugs, personal care products, quantum dots, and environmental remediation projects all have high potential for uncontrolled environmental release and their incidence is expected to dramatically increase. Nanostructure characteristics that are a determining factor include particle size, surface area, chemical nature, and charge, while reactive oxygen species at the surface may have an effect. As human data is rather limited, animal studies have been performed. Major hazards include inhalation of particles <100 nm as they deposit in the pulmonary region causing inflammation of the lungs. Nanoparticulate to ultra fine particles (including PTFE, carbon [general, fullerenes, and nanotubes], and TiO_2) have been found to impair lung function, increase respiratory syncytial virus infection, impair phagocytosis, encourage tissue thickening or fibrosis, increase coughing and sputum production, give rise to higher risk of chronic bronchitis, encourage tumors, and cause lung cancer. Nanoparticles may penetrate lung tissue to enter the blood stream (and on to the heart, liver, and brain). Studies have found that SiO_2, TiO_2, ZnO, and Al_2O_3 can penetrate skin layers. Ingested TiO_2 particles (200 nm) are immunologically active and can further penetrate the intestinal barrier (onto the lymphatic and blood systems) [325].

NIOSH has partnered with several organizations throughout the world in government, academia, and business, creating the Nanotechnology Research Center (NTRC) to assess safe nanotechnology in the workplace. They have been investigating critical topic areas; namely, toxicity and internal dose, measurement methods, exposure assessment, epidemiology and surveillance, risk assessment, engineering controls and PPE, fire and explosion safety, recommendations and guidance, communication and information, and applications. NIOSH NTRC is collaborating with NNI to pursue these mutual goals [326, 327]. The investigations have been instrumental in providing guidance for those who produce and work with nanomaterials and nanomaterial-enhanced products. As work is continuing in each of these critical areas, information has been found to make the nanomaterial workplace a safer one. General guidelines have been determined for working with nanomaterials. These include minimizing worker exposure through engineering controls to reduce aerosol exposure, even up to source enclosure and isolation. Implementation of a risk management program should include: (1) evaluation of hazard posed by nanomaterials based on its available physical and chemical property data, toxicology, or health effects; (2) worker task exposure assessment; (3) good work practice education and training; (4) establishing criteria and procedures for installing and evaluating engineering controls at exposure locations; (5) procedures for determination of need and selection of PPE; and (6) systematic evaluation of exposures to ensure control measures are working properly and workers are being provided appropriate PPE. Filtration studies to date have indicated that high-efficiency particulate air (HEPA) filter applications (exhaust ventilation and vacuum pickup) should effectively remove nanomaterials from the air. When engineering controls are not enough, preliminary data suggests that a NIOSH-certified respirator will be useful; however, no guidelines have been set for airborne engineered nanoparticles [328]. Several tools have been developed for guidance in the form of documents for medical screening and hazard surveillance (DNNH NIOSH Publication No. 2009-116), managing health and safety concerns (DNNH NIOSH Publication No. 2008-112), and a searchable on-line library for nanoparticles, etc. [329].

From these results, it is obvious that more research into the environmental effects and fate of nanomaterials, and their known and potential effects on human health and the environment, is needed. Additionally, it is clear that an improved regulatory framework is also needed, in order to facilitate the collection, interpretation, and dissemination of the experimental findings.

Nanostructured Materials in Other Consumer Products

Nanotechnology has been finding its way into more and more consumer products over the past decade. As the realization of potential applications for nanotechnology grows, the knowledge will continue to spread. The bottom line for nanotechnology in consumer products will be “Is there a demand?” The consumer has the final say. Skeptics and scientists alike will be susceptible to the consumer’s last word, or rather, last dollar. The final say in 2009 was a resounding 1.545 billion USD spent on golf clubs, electronics, skin cream, and a plethora of other products that utilize nanotechnology. The skeptics lose out to the optimistic forecasts of Research & Markets report “The World Market for Nanotechnology and Nanomaterials in Consumer Products, 2010–2015,” which expects that number to triple by 2015. In 2015, 5.335 billion USD will be spent on innovative products that stand out from the rest because of something 100,000 times smaller than a human hair [330].

Tracking Commercial Nanomaterial Products

In April 2005, the Project on Emerging Nanotechnologies (PEN) was initiated. PEN contains the largest online inventory of commercial products with nanotechnology along with other nanotech learning resources. New products are added as often as they are found, which in 2008, was at a rate of 3–4 per week. PEN is a joint effort between the PEW Charitable Trusts and Woodrow Wilson International Center for Scholars. As of August 2009, the list of commercially available products contained over 1,000 products. The list realized a 379% growth since March 2006 [331].

Many groups worldwide, like PEN, are trying to identify the number of products available that use nanotechnology. Challenges exist which prevent a complete list from being formed. Currently, there are no requirements for nanotechnology products that would identify or separate them from their non-nano competition. Some products which claim to contain nanomaterials do not, and some products that do contain nanomaterials do not outwardly claim this. Nanotech products do not have special regulations, as of yet. Debates are raging on this topic and governments are being pressured to look further into the proposed risks. Until a decision is reached and the technology is tracked, nano products may be sold under the label of the manufacturers’ choosing.

Commercial Uses

Amid all of the debates and controversies, innovative and earth friendly products are being developed by companies large and small. What most people do not know is that some of the most widely known products, like the iPhone by Apple®, are products of nanotechnology. The iPhone features a memory chip which is a result of nanotechnology [332]. Additionally, many everyday products are being improved through the use of nano-sized materials. According to “The Nanotechnology Consumer Products Inventory,” the most common material mentioned in the product description was silver (259 products) [333]. Carbon was the second most referenced (82 products including fullerenes and nanotubes), followed by titanium dioxide (31), zinc oxide (24), silica (15), and cerium oxide (1). Among potential environmental applications of nano materials, remediation of contaminated ground water with nanoscale iron is one of the most important examples [10]. Nanoparticles of titanium dioxide and zinc oxide are included in personal care products such as beauty products, sun screens, toothpaste [334], and textiles [335]. Silver nanoparticles are increasingly used as antimicrobial components in detergents, food packaging, and textiles such as socks and underwear [333]. Other potential uses for silver nanomaterials include portable filters for water purification which could be used in remote or underdeveloped areas lacking water treatment infrastructure [336].

In addition to the use of nanotechnology to improve these classic consumer products, entirely new uses which take advantage of the novel physics of nanomaterials are being developed. Nano-emulsions, a variation on the “oil and water” mixture used for salad dressings and cosmetics, also hold great promise for applications as different as future food technology, pharmaceutical development, disinfection, and pesticide application [337].

Large companies, like Samsung and IBM, are in the midst of nanotechnology use and development and have products on the market. Samsung makes nanopowders and has prototype field emission displays (FED) [338]. IBM has a science department devoted to nanoscale research in carbon nanotubes and nanometer-scale local oxidation [339].

In addition to the large companies making the technology known through their products and research, smaller companies are also working to get their name and products on the market. The odor elimination products marketed as OdorKlenz® by NanoScale Corporation use destructive adsorption to neutralize odors. This technology stems from NanoScale’s flagship product, FAST-ACT®. The OdorKlenz product line includes a laundry additive, a surface treatment, a skunk treatment for pets, and a vomit absorbent. OdorKlenz also features an air filtration cartridge available to the disaster restoration market for odors after fires, floods, or other disasters. The OdorKlenz branded products were introduced to the market in 2007 [73].

Regulation

Decisions made in the near future may alter the currently optimistic outlook of nanotechnology. Governments have difficult decisions to make on the risk of nanotechnology in products from skin creams to foods to socks. One author, a member of the European Commission, stated “Further research is needed on the toxicological and ecotoxicological properties of nanoparticles, their uptake in the body, accumulation in the tissues and organs, transport characteristics, exposure and dose–response data, and their distribution and persistence in the environment” [340]. This uncertainty about regulatory issues has a discouraging effect on the commercial development of nanomaterials, as manufacturers are reluctant to develop products without a suitable regulatory framework and guidance on safety requirements. However, at the present time the promise of nanotechnology appears to outweigh any potential risks, and thus R&D efforts continue. There is no doubt that, one way or another; nanotechnology will become an integral part of our daily lives.

Concluding Remarks and Future Outlook

Previous chapter sections have reviewed a large number of different nanotechnology applications in various areas, including medicine, textiles, catalysis, electronics, and others. Nanomaterials are already in commercial use in many of these areas, with new technologies in development, as well. Consequently, nanomaterials are now widely encountered in daily life, although many consumers remain unaware of their presence in the products they use.

Despite the enormous promise offered by nanomaterials, there are still multiple barriers to their development and use. One substantial consideration for those seeking to commercialize a nanotechnology or include it in their commercial product is the regulatory framework which exists for nanotechnology. Consumers demand safe products, so product manufacturers and distributors put a great deal of time and effort (and money) into ensuring that their products comply with the appropriate regulations—and this is the primary hurdle to nanomaterial usage. Presently, many regulatory agencies such as the US EPA have few guidelines on how to regulate nanomaterials [341]. Without a suitable regulatory framework, manufacturers and distributors have difficulty assuring themselves and their buyers of the safety of their product.

How did this situation come about? The same unique qualities that enable nanomaterials to have their capabilities also make them difficult to regulate. Bulk materials, such as carbon, have set physical properties and capabilities. However, carbon nanomaterials have an entirely different set of physical properties and capabilities. Worse (from a regulatory standpoint), these physical properties and capabilities change with the size, shape, and structure of the carbon nanomaterial. Whereas bulk carbon does not conduct electricity very well, carbon nanotubes do [342]. Bulk carbon has few detrimental effects on aquatic life, but carbon nanotubes are known to be toxic [343], and a slightly different form, fullerenes, may accentuate the toxicity of other chemicals [344]. The quantum mechanics which regulate nanomaterials’ interactions with other substances also make their toxicological behavior difficult to predict.

A number of organizations, including federal bureaus such as the EPA and testing standards developers such as ASTM, have begun developing methods to assess nanomaterial properties. ASTM currently has seven standards related to nanotechnology: One defining the standard terminology [345], two defining methods for determining some of the physical characteristics of nanomaterials [346, 347], and four standards relating to health and safety [348–351]. Once sufficient research has been performed, trends in the toxicology of different nanomaterial types should become apparent, and a regulatory framework with standard assay methods can be established.

Previous chapter sections have given multiple estimates on the future size of different nanomaterial markets. If nanomaterials are not found to have serious adverse health or environmental effects, then the optimistic predictions of their worth will likely not fall short of the mark. However, if nanomaterials are found to have serious environmental effects or detrimental effects on human health, their commercial future is considerably less rosy.

In conclusion, much more research is needed into the properties and capabilities of nanomaterials. Nanomaterials offer great improvements in many different areas and may have very positive impacts on human health and the environment, but they may also have negative impacts which are not yet understood. As research and development efforts progress, both the promise of and the problems with nanomaterials will become apparent. Only after both of these aspects are recognized can the full potential of nanomaterial technologies be realized.

Questions

1. Why do nanomaterials behave differently from their macro counterparts?
   Answer: Because of the small size of nanomaterials, a large fraction of atoms are located close to the surface of the material instead of in the bulk, which increases their reactivity. Additionally, at such a small scale, quantum effects become increasingly important in governing the behavior of the material.
2. What are the advantages and disadvantages of a government guided research initiative like that of Germany as opposed to more independent research other countries use?
   Answer: The main advantage of government guided research is that a more focused approach will be implemented. With more researchers looking into the same set of problems, an outcome could be more likely. The disadvantage would be the limitations that are set on exploring new discoveries.
3. Should companies manufacturing nanotechnology containing products be mandated to add this information to their product labels?
   Answer: Yes, companies should be mandated to add the phrase “nanotechnology containing products” to their product labels should safety concerns arise later. All products should be labeled to include this information.—OR—No, the manufacturer should maintain the right to market/label as they see necessary unless risks become known. Restricting labels may inhibit the advancements of the nanotech industry.
4. What are some benefits of nanomaterials for use in cancer treatments?
   Answer: The benefits of using nanomaterials in cancer treatments include more accurate dosing, reduced side effects, reduced toxicity, accurate and non-invasive diagnostics.
5. Describe the significance of Richard Feynman’s speech and his approach to nanotechnology.
   Answer: Richard Feynman’s speech in 1959 opened discussion of the bottom-up approach as opposed to the top-down approach to nanotechnology and revolutionized the idea of nanotechnology.
6. What benefits do nanostructured materials bring to environmental remediation?
   Answer: Increased surface area means increased reactivity and adsorption capacity, therefore nanomaterials are more efficient than their non-nano counterparts in environmental remediation. For example, Fe(0) nanoparticles do not have mobility issues as larger Fe(0) particles.
7. Why is there so much regulatory uncertainty surrounding nanomaterials?
   Answer: One of the reasons there is so much regulatory uncertainty surrounding nanomaterials is because the properties of nanomaterials are dramatically different from those of bulk materials. Furthermore, because of quantum effects, the physical configuration (shape, structure) of a given nanomaterial can cause it to behave differently than another chemically identical nanomaterial with a slightly different physical structure. For example, carbon nanotubes will behave differently from carbon nanospheres, even though they may be chemically identical, even to the extent of containing the same number of carbon atoms.
8. Describe the two mechanisms of action of nanocrystalline high surface area TiO_2 on the chemical warfare agent simulant DMMP.
   Answer: Nanocrystalline high surface area TiO_2 can adsorb DMMP via hydrogen bonding to exposed hydroxyl groups (molecular adsorption) and via its titanium sites (reactive adsorption).
9. Why is the protection offered by textiles containing nanomaterials potentially preferable to that offered by textiles containing activated carbon spheres?
   Answer: Activated carbon spheres entrap chemical pollutants or toxins, but do not destroy them as nanomaterials do. Additionally, activated carbon spheres can off-gas the absorbed chemical during temperature changes and preferentially absorb humidity in the air rather than the toxin or pollutant.
10. You are a graduate student supported on an EPA fellowship research grant whose focus is removing Cr(VI)

contamination from groundwater in a limestone (calcium carbonate) aquifer. One of your research committee members has suggested Fe-based nanomaterials. Is this approach likely to work?

Answer: No, using Fe-based nanomaterials for removing Cr(VI) contamination from groundwater in a limestone (calcium carbonate) aquifer is not likely to work. Research has shown that, while Fe-based nanomaterials can remove Cr(VI) from contaminated waters, removal capacity drops to 55–77% in the presence of magnesium, calcium, or carbonate ions. As limestone is composed of calcium carbonate, the groundwater would almost certainly contain calcium and bicarbonate ions.

11. Which country has the largest number of nanotechnology companies?

    Answer: The United States of America has the largest number of nanotechnology companies.
12. How will self-cleaning and conductive coatings promote greener energy production?

    Answer: Both self-cleaning and conductive coatings are expected to improve the performance of solar cells promoting greener energy production. Self-cleaning surfaces will prevent dust build-up, while conductive coatings can provide both more efficient energy capture and potentially cheaper production of the cells and energy storage devices.

Acknowledgment The authors would like to thank Ms. Krista Hill-Combs for her assistance in preparing this manuscript.

Synthetic Organic Chemicals

10

Scott D. Barnicki

Introduction

Chapter Background

Synthetic organic chemicals are produced by the transformation of carbonaceous feedstocks into functionalized molecules through one or more chemical reactions. Such transformations are accomplished at vast industrial scales and the resulting products permeate every aspect of modern society. The molecules produced find use largely as monomers for polymer synthesis of ubiquitous plastics, or as task-specific ingredients for a myriad of applications as divergent as paint leveling agents to food preservatives. Advances in technology, significant increases in energy efficiency, as well as the utilization of fossil-fuel derived starting materials has resulted in unprecedented economy of scale and relatively stable product costs in spite of large relative increases in the price of oil and natural gas. The section entitled “Chemical Raw Materials and Feedstocks” covers the most important carbonaceous feedstocks currently utilized in the chemical processing industries; all derived from fossil-fuel based raw materials.

The volume of synthetic organic chemicals produced worldwide grew from less than 5 million metric tons in 1950 to more than 400 million metric tons in 2009, with an average annualized growth rate above 7% [1]. The value of all chemicals produced worldwide reached over $3.7 trillion dollars in 2008, before dropping somewhat to $3.4 trillion dollars during the 2009 recession as shown in Fig. 10.1. The average annualized worldwide growth rate in value of chemicals produced for the decade of 1999–2009 was 7.7% [2].

The United States has been the country with the largest chemical industry by volume and value for many years, due to inexpensive natural gas and very large consumer markets. However, this leadership position has deteriorated rapidly over the last decade with the dramatic growth in production of chemicals in China [2]. The value of all chemicals produced between 1999 and 2009 is shown in Fig. 10.2 for the traditional major chemical producing countries of the United States, Japan, and Germany in comparison to China. Average annualized growth rates in the value of chemicals produced over the decade for these countries are summarized in Table 10.1. The growth rate in value of chemicals produced in China far outpaces that in the United States. As a result, the US share of global chemical production value has dropped from 26% in 1999, to 20% in 2009, while that of China has rocketed from 5 to 19% in the same timeframe (Figs. 10.3 and 10.4).

The cost of a raw material can dramatically alter production patterns over a short period of time. Figure 10.5 shows chemical raw material usage of natural gas and annualized cost for natural gas for the years 1998, 2002, 2006 in the United States. After many decades near $2.00/million BTU, natural gas price in the United States began to rise and spiked dramatically in 2006 at above $9.50/MM BTU, leading to the shuttering of many older, small-scale marginal US facilities for the production of the ultra-commodities of ammonia-based fertilizers and methanol. As of 2007 only one US methanol facility based on coal, Eastman Chemical Company’s Kingsport plant, remained operational. Most of the US production moved overseas to the Middle East, Trinidad, and other regions with lower cost natural gas. Natural gas price since has dropped significantly in the US with the advent of substantial shale gas production.

Chapter Organization

The traditional approach to discussion of synthetic organic chemicals in most survey literature is to concentrate on families of derivatives from each specific chemical feedstock. Although many different chemicals can be made from each of the

feedstocks, only a limited number of different types of chemistry have found particular favor in large-scale commercial production of synthetic organic chemicals. These include: (1) oxidation, (2) carbonylation, (3) hydroformylation, (4) chlorination, (5) condensation, (6) hydration/hydrolysis, (7) esterification, (8) hydrogenation, (9) dehydrogenation, (10) sulfonation, and (11) ammonation/ammoxidation. The first nine of these are covered in this chapter. Discussion of the last two is found in other chapters of this book, in Chaps. 14, 22, and 36. Cross references within Chapter 10 are noted by subsection titles in quotation marks.

Organizing our discussion of the significant commercial processes by these chemistry themes allows one to see the commonality between many seemingly diverse production processes with very different raw materials and end products. In some cases a chemical is made commercially by very different chemistries, but the processes begin with the same feedstock. Examples include: (1) the production of alcohols by the direct or indirect hydration of olefins, (2) the various propylene-based routes to propylene oxide, and (3) the production of methyl methacrylate from ethylene by either carbonylation/esterification/condensation or hydroformylation/oxidation/esterification steps. In other cases, the feedstock may be entirely different, but end at the same product, such as the acetylene, propylene, and butane/butene-based processes for the production of 1,4-butanediol. More often, and to the point of the chapter organization, the chemistry is similar in spite of significant feedstock differences, such as hydroformylation of C_2-C_5 olefins, oxidation of aldehydes to carboxylic acids, or aldol condensations of a wide variety of carbonyls.

Often one basic chemistry route has become commercially dominant, for example ethylene oxide production via silver catalyzed oxidation of ethylene, terephthalic acid (TPA) by Co/Mn/Br catalyzed oxidation of *p*-xylene, or methanol by hydrogenation of carbon monoxide/carbon dioxide. In these cases, the key differences between commercial processes are more subtle and may amount to alternative catalysts, reactor conditions and designs, or separation sequences. A portion of these differences are highlighted in the discussion below where pertinent, but the roles of reaction engineering and separation process synthesis/design cannot be adequately covered in the space allotted. Many books and articles have been written on these process design subjects, with a few recommended texts given below [3–14].

The capacity, production, and consumption figures presented throughout the section, "Chemical Raw Materials and Feedstocks", for individual feedstocks and derivatives were derived from data gathered from a variety of literature sources, spanning the years 2006–2010 [15, 16]. Thus, some numbers reflect reduced production and consumption due to the 2008–2010 recession; some do not. The resulting variation in production/consumption numbers is estimated to be 5–10%.

The simplified flowsheets were drawn specifically for this chapter and are based on a compilation of open literature data (referenced in each subsection). The major processing steps of each flowsheet are named in italics and numbered. These designations appear as bolded numerals in parentheses in the corresponding process description in the text. Each process description includes a summary of temperature, pressure, yields, and selectivity, but open literature references can vary widely on the values.

Chemical Raw Materials and Feedstocks

Background

The formation of new a carbon–carbon bond is one of the more difficult chemical transformations to make. So the foundations of the modern chemical industry is very much a story of learning to exploit a small number of reactive skeletal carbon structures which can be derived from natural sources in relatively simple and efficient manner. In the early twentieth century the nascent chemical industry was based on utilization of coal tar liquids (a by-product of metallurgical coke production) and the fermentation of biologically derived feedstocks such as molasses, sugars, and whey. Coal tar liquids now provide a minor fraction of chemical feedstocks. Early fermentation routes, such as the ABE (acetone-butanol-ethanol) process, have all but disappeared due to poor economics. In spite of massive research efforts, newer bio-based processes have yet to compete favorably except in a few niche applications.

Rather, the substantial growth of the global chemical industry over the past 70 years would not have been possible without the concomitant rise in the fossil fuel energy infrastructure encompassing petroleum refining, natural gas production, and to a growing extent coal mining (primarily due to Chinese gasification projects). This close coupling of the chemical industry with the energy infrastructure is exemplified in the United States for the primary chemical raw materials of natural gas, petroleum products, and liquefied petroleum gases/natural gas liquids (LPG/NGL, C_2-C_4 hydrocarbons derived from crude natural gas and refinery gases). Figures 10.6, 10.7, and 10.8 show the relative magnitude of the total US energy consumption of these three key categories vs. their use as raw materials and energy sources for chemical production during the years 1998, 2002, and 2006. All quantities are expressed in trillions of BTUs of energy equivalent for easy comparison. Only LPG/NGL is used largely as a chemical raw material. Chemical raw material usages of natural gas and petroleum products represent just 1.6% and 4.5% of much larger power/heating and motor fuels markets respectively in the

Fig. 10.6 U.S. natural gas usage, 1998, 2002, and 2006

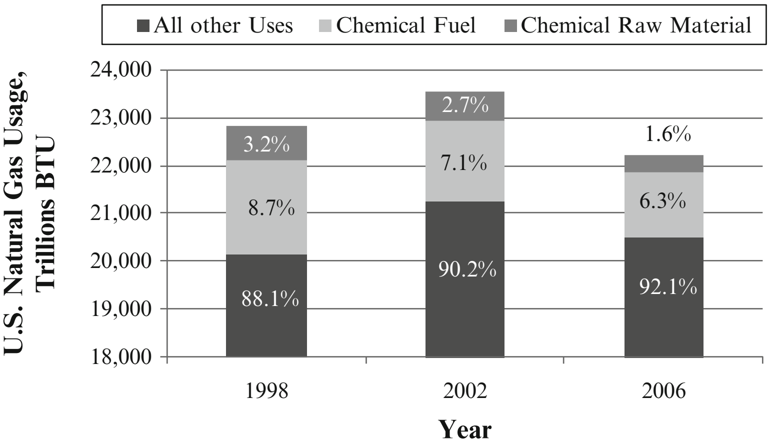

Fig. 10.7 U.S. LPG/NGL usage, 1998, 2002, and 2006

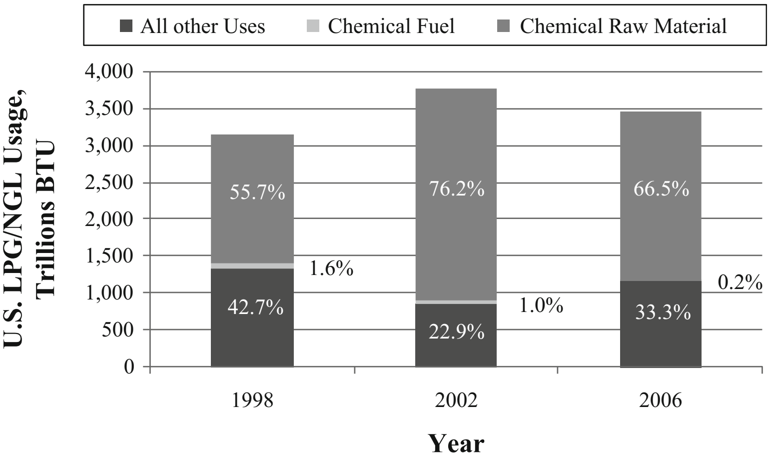

Fig. 10.8 U.S. usage of refined petroleum materials, 1998, 2002, and 2006

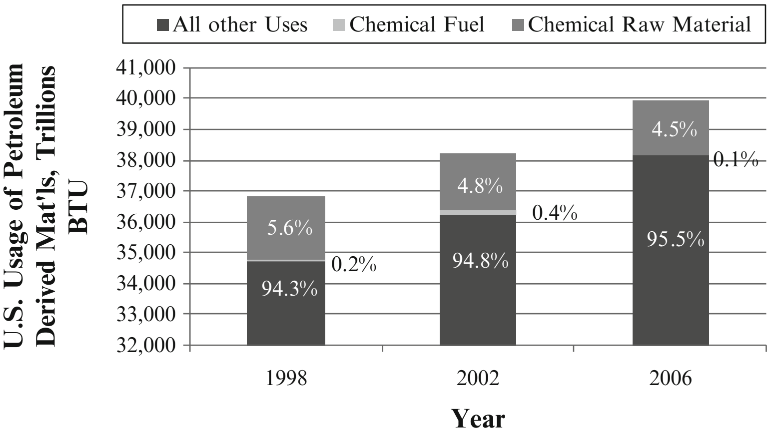

United States [17–19]. The situation is similar worldwide. Total global fossil fuel demand in 2007 was 282,000 trillion BTU's. About 9%, 25,500 trillion BTUs, was used as chemical raw materials, with 78.9% from petroleum, 16.9% from LPG/NGL, 3.9% from natural gas, and 0.3% from coal [20].

An overwhelming majority of the synthetic organic chemicals produced at commercial scale today begin with one of five major types of feedstocks:

1. Light olefins—ethylene and propylene
2. Aromatics—benzene, toluene, xylenes, or BTX

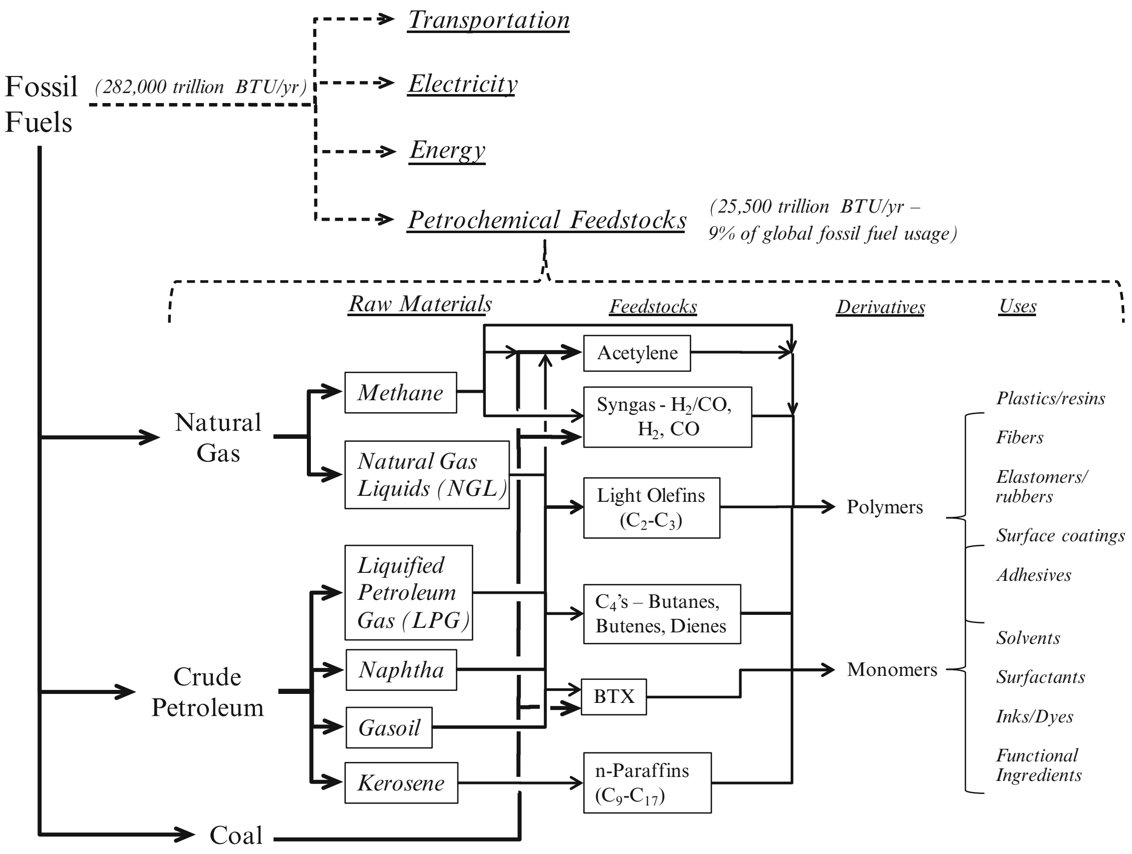

Fig. 10.9 Chemical raw material-feedstock-derivatives overview

3. C_4 hydrocarbons—butanes, butenes, butadiene
4. Kerosene derived C_9-C_{17} paraffins
5. Synthesis gas—a mixture of carbon monoxide and hydrogen

Figure 10.9 shows a simplified overview of the raw materials, feedstocks, and derivatives of the synthetic organic chemical industry. Major chemical feedstock capacity, production, and consumption for the world, United States, and China are summarized in Table 10.2.

As will become apparent below, the production of chemical feedstocks from fossil fuel raw materials typically involve highly endothermic processes. A large amount of energy must be expended for both driving endothermic reactions as well as for separation and purification. The resulting high energy, reactive feedstocks allow subsequent chemistry to proceeds favorably downhill to lower energy products, with mostly exothermic reactions and relatively high yields.

C_2-C_3 Light Olefins [21–25]

Ethylene and propylene are by far the most important building blocks of the petrochemical industry. The primary derivatives produced from ethylene and propylene feedstocks, the capacity/production/consumption of those primary derivatives, and their major applications are summarized in Tables 10.3, 10.4, 10.5, 10.6, 10.7, and 10.8. The family of derivatives produced from ethylene and propylene are presented in Figs. 10.10 and 10.11, respectively. Light olefins can be produced from a variety of raw materials and methods:

1. Steam cracking (thermal pyrolysis) of hydrocarbon raw materials ranging from LPG/NGL to naphthas and gas oils
2. Methanol to olefins
3. Recovery from refinery gases and FCC (fluid catalytic cracking) gases
4. Interconversion of butenes, ethylene, and propylene
5. Dehydrogenation of propane (propylene only)
6. Dehydration of bio-derived ethanol (ethylene only)

Steam cracking accounts for almost all of the ethylene and about 60% of the propylene produced worldwide. A simplified diagram of a naphtha-based cracker is shown in Fig. 10.12. In a thermal cracking unit, steam and the hydrocarbon raw material are heated in a short residence time tubular reactor/furnace (**1**) to 775–950°C, 0.17–0.24 MPa pressure, to initiate free radical cision, decomposition, isomerization, and aromatization reactions. The reactions are highly endothermic, requiring +1,600 to +2,800 kJ/kg of

hydrocarbon fed, or roughly +55 to +219 kJ/gmole of ethylene/propylene produced. The yield of ethylene vs. propylene is highly dependent on the hydrocarbon raw material used as well as the severity of conditions. Ethylene production is favored by use of light hydrocarbons and higher temperature conditions. Typical yields for several common hydrocarbon feeds are given in Table 10.9. Major by-products are methane, hydrogen, butanes/butenes/butadiene, pyrolysis gasoline (benzene, toluene, C_8 aromatics), and heavy oils. Steam feed helps mitigate coking, with increasing amounts of water required for heavier feedstocks, typically 0.3/1 to 0.75/1 kg water/kg hydrocarbon.

The cracked gases are rapidly quenched to halt further reaction, first by indirect cooling against water, then by direct contact cooling with recycled heavy ends (**2**). The effluent is fractionated to separate the light gases (containing ethylene, propylene, C_4−C_5+ fractions) from pyrolysis gasoline, heavy oil fractions, and to remove water (**3**). The light gas is compressed to about 3.5 MPa, caustic washed to remove acid gases (CO_2, H_2S, COS,

mercaptans), further cooled, and partially liquefied (**4**). The demethanizer (**5**) removes methane and hydrogen overhead, followed by the distillation of ethane/ethylene/(acetylenes) in the deethanizer (**7**). If desired, methane and hydrogen are separated by Joule–Thomson expansion/cooling to give about 85–90% hydrogen (**6**). The ethylene-rich fraction from the deethanizer is first hydrogenated over Pd or Ni fixed bed catalysts (**8**) to convert alkynes to alkenes to prevent fouling. Propane/propylene are taken overhead in the depropanizer (**10**), and C_4 components split from

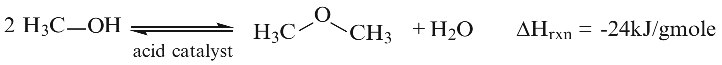
Epichlorohydrin	83% epoxy resins; 2% synthetic glycerine

remaining heavy materials in the debutanizer (**11**). A rather complex ethylene/propylene cycle is used to provide refrigeration needs in the plant.

Ethane/ethylene are split in a column comprising over 100 stages (**9**), with ethane underflow recycled to cracking. The propane/propylene separation requires several 100 stages to achieve polymer-grade purity (**12**). Propane underflow is also recycled to cracking. The distillative separation of ethane/ethylene (relative volatility ≈ 1.4) and propane/propylene (relative volatility ≈ 1.2) to produce polymer grade ethylene and propylene (typically 99.5% or greater purity) requires significant staging and reflux. The production of ethylene and propylene are the largest single users of energy in the chemical industries, equating to (not an insignificant) 1% of total energy demand globally.

About a third of propylene is recovered from refinery operations, such as FCC of heavy oils. FCC produces primarily motor gasoline components, but also 5–9% propylene, which can be recovered by fractionation [26]. See Chap. 18. Less than 10% of propylene currently comes from on-purpose propane dehydrogenation, ethylene–butene disproportionation/metathesis, and other sources [27]. During the next decade in the United States in particular, the significant increase in availability of NGL from shale gas is expected to move to higher usage of light feedstocks for cracking. This will exacerbate the relative shortage of propylene and may lead to more serious investment in metathesis and dehydrogenation processes.

It has been known for many years that methanol could be reacted over acidic zeolites at high temperatures to produce primarily an aromatic-heavy gasoline as well as some C_2-C_4 olefins. This type of process was commercialized briefly in New Zealand in the 1980s for gasoline production and later shut down due to poor economics [28]. The catalyst was the ubiquitous ZSM-5 zeolite. In all process variations, methanol is first converted into dimethyl ether with release of water. DME then further generates a "pool" of CH_2 equivalents on the catalyst surface.



$$2\ H_3C{-}OH \underset{\text{acid catalyst}}{\rightleftharpoons} H_3C{-}O{-}CH_3 + H_2O \qquad \Delta H_{rxn} = \text{-24kJ/gmole}$$

Total	100	100	100	100	100

These CH_2 equivalents then participate in the formation of larger molecules of many possible types, such as *n*-olefins, aromatics, naphthenes, relatively small amounts of *n*-paraffins, CO_2, hydrogen, methane, and trace amounts of lower carboxylic acids [29–31]. The product distribution is heavily dependent on process conditions as well as zeolite geometry. High temperatures favor aromatic formation, while the pore size of the zeolite, if properly chosen, can significantly reduce or virtually eliminate aromatic formation. For example, SAPO-34, a template-based silica aluminophosphate molecular sieve zeolite with a pore opening of 3.8 Å, controls the size of the olefin produced to mostly C_2-C_3, as well as minimizing aromatics formation. ZSM-5 and MFI zeolites, with pore openings of 5.1–5.6 Å, lead to much higher aromatics production.

Modern methanol-to-olefins processes capable of producing relatively high yields of ethylene and propylene, are just beginning to be commercialized, in particular in China, where the methanol is largely derived from coal [32–34]. In the UOP/Hydro Methanol-to-Olefins (MTO) process methanol is reacted at 350–550°C, 0.2–0.4 MPa, over SAPO-34 zeolite to produce predominantly ethylene and propylene. Approximately 80% of the input carbon is converted into ethylene and propylene, and as high as about 90% with recycle of the butanes fraction. The ethylene/propylene product mass ratio can be varied between 0.75 and 1.05, dependent on process conditions. For 100 kg of methanol input, typical mass yields are 17 kg ethylene, 17 kg propylene, 5 kg mixed C_4's, 1.9 kg C_5+, 1.7 kg fuel gases, 57 kg water, 1 kg and minor materials (CO_2, coke, carboxylic acids). This process uses a fluid bed reactor with a separate regenerator vessel (using air), much like an FCC unit. The reactor effluent is separated from the water by-product and unreacted DME is recovered. The hydrocarbon fraction is washed with caustic to remove acids, dried, and compressed. Recovery of pure ethylene and propylene occurs in a distillation train very similar to that used in steam cracking for olefin production.

In the Lurgi MTP® process, methanol is converted to DME over γ-alumina in a separate reactor, followed by zeolite-based conversion to hydrocarbons in a six-stage adiabatic reactor system. Propylene yield is about 70% on input carbon, with relatively minor amounts of ethylene. A gasoline fraction of relatively modest octane is the major by-product.

As of 2011, at least one plant has been built in Brazil for dehydration of sugarcane-derived ethanol to ethylene (200 KMTA of ethylene, <0.2% of world capacity), and additional facilities are planned in Brazil and India [35–37].

C_6-C_8 Aromatics: BTX [38–42]

In the early twentieth century, the primary source of the C_6-C_8 aromatics (benzene, toluene, *o*-, *m*-, *p*-xylenes, BTX) was coal tar liquids (the aromatics-rich fraction is also called benzole) from the carbonization of coal to produce metallurgical coke. The rise of the petroleum refining industry has significantly diminished the contribution of this source of aromatics, less than 2% of aromatics are still derived from coal tars. Globally BTX is produced primarily by catalytic reformer operations (55–60%), and by recovery from pyrolysis gasoline (40–45%). Because of the large gasoline demand (as well as the tradtional use of LPG/NGL for steam cracking), about 70–75% of aromatics produced in the United States comes from reformates. The situation is reversed in Europe, Japan, and China. The predominance of naphtha steam cracking in these locations leads to larger amounts of aromatics from pyrolysis gasoline.

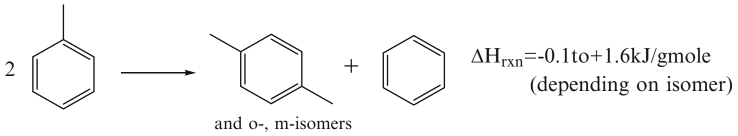
In catalytic reformers, dehydroisomerization and cyclization/dehydrogenation reactions convert cycloparaffins and alkylcyclopentanes (naphthenes), along with paraffins into predominately aromatic liquid products at high temperature over platinum-based catalysts (with H_2 and lighter hydrocarbon as by-products). Reforming significantly improves the octane, or gasoline blending quality of the stream. A typical reformate contains 50–60% aromatics, mostly toluene and xylenes. In the United States about 90% of this reformate is used for gasoline production, the other 10% becomes chemical feedstocks.

The amount and composition of the BTX fraction recovered from pyrolysis gasoline is highly dependent on the steam cracking feedstock and severity of conditions (see Table 10.9). Due to its high content of polymerizable components (not good for internal combustion engines), virtually all of the pyrolysis gasoline is used for chemical feedstock production rather than gasoline production.

The most important aromatics for chemical production are benzene and *p*-xylene. Reformer and pyrolysis gasoline (pygas) aromatic fractions as produced typically do not meet the demand patterns for these aromatics. Four families of processes are widely used to adjust the natural distribution between benzene, toluene, xylene isomers, and lesser amounts of polyalkylbenzenes and ethylbenzene [43–47]. See also the discussion of alkylation in Section 10.3 below.

1. *Hydrodealkylation* involves the thermal or catalytic reaction of alkylated aromatics (normally methyl aromatics) with hydrogen to produce light alkanes (normally methane) and benzene.

   Toluene is the most common feed substrate, but higher alkylated benzenes (e.g., xylenes and trimethyl benzene) are also used. In the catalytic process, temperatures stay below 500°C to prevent metal sintering, with pressures from 2.5 to 7.0 MPa. Common catalysts are Group VIII metals and metal oxides, e.g., chromium oxides, Pt, Pt oxide, on alumina. Thermal dealkylation requires a temperature of 600–660°C, pressures of 3.5–7.0 MPa. The heat of reaction is controlled by recycling cold hydrogen at high (6:1 to 8:1) molar ratio to substrate. Because of the formation of the highly stable by-product of methane, the reaction goes very far to completion. Selectivity to benzene approaches 99% in the thermal process and 98–99% in the catalytic processes. Many versions of hydrodealkylation have been commercialized and are available for license.
2. *Transalkylation/disporportionation* involves the migration of methyl groups among aromatic rings in the presence of hydrogen. For example two toluene molecules produce a mixture of xylene isomers.



The reaction proceeds over aluminosilicate or silicoaluminophosphate zeolites (often containing noble metal (Pt) or rare earths) at 400–470°C, pressures of 1.4–3 MPa, with a hydrogen:aromatic molar ratio of 5:1 to 12:1. Yield is well above 90%. Under normal reaction conditions the xylene isomer composition approaches the equilibrium value. At 400°C the distribution is about 21.6% *ortho*-, 24.4% *para*-, and 54% *meta*-xylene. Thus, if *p*-xylene is the desired product (usually), conversion to *para*-xylene is low per pass. Separation and recycle are critical (and expensive).

A fairly recent innovation has been the use of shape selective zeolite catalysts that allow toluene into the zeolite cage, but only allow *para*-xylene, with its narrow cross sectional area, to leave. *Ortho*- and *meta*-isomers are trapped and isomerized until *para*-xylene is formed. Significantly greater than equilibrium levels of *para*-xylene can be produced with much less separation and recycle requirements.

The other significant C_8 isomer, ethylbenzene (EB), can be present in appreciable amounts, depending on the origin of the stream. Difficult to separate cleanly (requiring superfractionation with over 200 stages), it can be converted via several reaction pathways: (1) de-ethylation to benzene (similar to HDA); (2) exhaustive hydrogenation to ethylcyclohexane, rearrangement to dimethylcyclohexanes, and dehydrogenation to xylene isomers; (3) disproportionation with xylenes to give benzene and ethyl xylenes. All three are operational on most transalkylation and disproportionation catalysts, typically giving at least 30% up to almost 100% EB conversion per pass.

3. *Isomerization* is a related process using much the same catalysts and reaction conditions as transalkylation. Some versions do not require hydrogen co-feed and can operate at 200–260°C. Shape selective catalysts that enhance *para*-xylene formation are also employed for isomerization.
4. *Toluene methanation* is a fourth process to convert toluene to xylenes that has been commercialized in the last decade to a limited extent. Methanol is reacted with excess toluene at high temperature over acidic or zeolite catalysts to produce xylene isomers and water.

   Toluene is distilled and recycled, while the product mixture of xylene isomers must be separated and isomerized to maximize *p*-xylene. Shape selective, *para*-enhancing zeolites are also used here. Note that this reaction cannot be accomplished with methane as the alkylating agent.

Recovery and purification of individual BTX components are challenging separations problems. Separation of paraffins and olefins from aromatics is typically done by some combination of simple distillation, extraction, and extractive distillation. Benzene and toluene (normal boiling points of 80.1°C and 110.6°C respectively) can be separated from C_8 and higher aromatics by simple distillation. However, the C_8 isomers all boil within about 8°C of each other (ethylbenzene at 136.2°C, *p*-xylene at 138.3°C, *m*-xylene at 139.1°C, and *o*-xylene at 144.4°C), rendering simple distillation impractical. Crystallization and shape-selective molecular sieve adsorption have become standard techniques for xylene isomer purification. A rich literature on these separations is readily available [48–53]. An aromatics complex often has many of these reaction and separation processes working in concert. Further information on aromatics production is given in Chap. 18.

The primary derivatives produced from BTX feedstocks, the capacity/production/consumption of those primary derivatives, and their major applications are summarized in Tables 10.10, 10.11, and 10.12. The family of derivatives produced from BTX is presented in Fig. 10.13.

C_4 Hydrocarbons: Butanes, Butenes, Butadiene [54–58]

The two saturated C_4 hydrocarbons, *n*-butane and isobutane (2-methylpropane), are obtained directly as components of NGL or from a variety of petroleum refining operations. Crude natural gas typically contains 1–2 mole% butanes, with a normal to iso ratio between 1:2 and 2:1. Much of these butanes become raw material for stream cracking to light olefins. Refinery processes giving appreciable amounts of butanes include crude distillation, catalytic cracking, catalytic reforming, delayed coking, fluid coking, visbreaking, and hydrocracking. Further information on these processes is given in Chap. 18. In the United States, refinery operations account for close to 80% of the butanes produced. A significant portion of the refinery butanes is used for fuel, gasoline blending, and other gasoline-producing operations. Only about 10% is diverted as a raw material for chemical synthesis.

Butenes comprise C_4 mono-olefin isomers, 1-butene, cis-2-butene, trans-2-butene, and isobutylene. These isomers are co-produced with butanes in refinery and steam cracking operations. Typical yields of butanes, butenes, and butadiene for several processes are given in Table 10.13. These C_4 fractions cannot be separated economically into pure components by simple distillation due to close boiling points. Rather, separation and reaction methods that exploit property differences due to molecular structure or between functional groups are employed, such as shape-selective adsorption, extraction, extractive distillation, isomerization, and dehydrogenation. Separation sequences typically begin with removal of 1,3-butadiene via extraction or extractive distillation (see below). The remaining butanes/butenes can be treated by a variety of methods including adsorption (to separate branched and normal species); reactions that exploit the reactivity of the olefins, especially isobutylene, over paraffins; extraction or extractive distillation (to separate butenes from butanes), or isomerization (to convert *n*-butenes to isobutylene or visa versa, *n*-butane to isobutane or visa versa, or 2-butene to 1-butene). A large body of information on these technologies is available in the open

Table 10.12 Major uses of BTX primary derivatives

	BTX derivative	Major uses
Benzene	Ethylbenzene	≈100% styrene
	Cumene	≈100% phenol/acetone
	Cyclohexane	>95% KO oil (cyclohexanol-cyclohexanone)—mostly for nylon intermediates
	Nitrobenzene	97% aniline, 3% pharma, dyes, intermediates
	Alkylbenzenes	≈100% linear alkylbenzene sulfonate surfactants
	Monochlorobenzene	79% nitrochlorobenzene production; 7% sulfone polumers; 3% phenyl compounds
	Ortho-dichlorobenzene	87% dichloroaniline; 12% solvent
	p-Dichlorobenzene	57% polyphenylene sulfide polymer; 16% moth control; 14% air deodorants
	Higher chorobenzenes	Solvents and intermediates
Toluene	Toluene diisocynate	90% flexible polyurethane foams; rigid foams, adhesives, paints, concrete sealers, cross-linker [321]
	Benzoic acid	43% benzoate salts; 22% benzoate plasticizers; 11% alkyd resins; 8% feed additives, 4% benzoyl chloride
Xylenes	Terephthalic acid/DMT (TPA equivalents)	60% PET Fibers; 31% Bottles/Packaging; 5% Films; 2% PBT
	Phthalic acid/phthalic anhydride	53% plasticizers; 21% alkyd resins; 16% unsaturated polyester resins
	Isophthalic acid	33% unsat polyesters; 39% co-polyesters; 19% surface coating resins

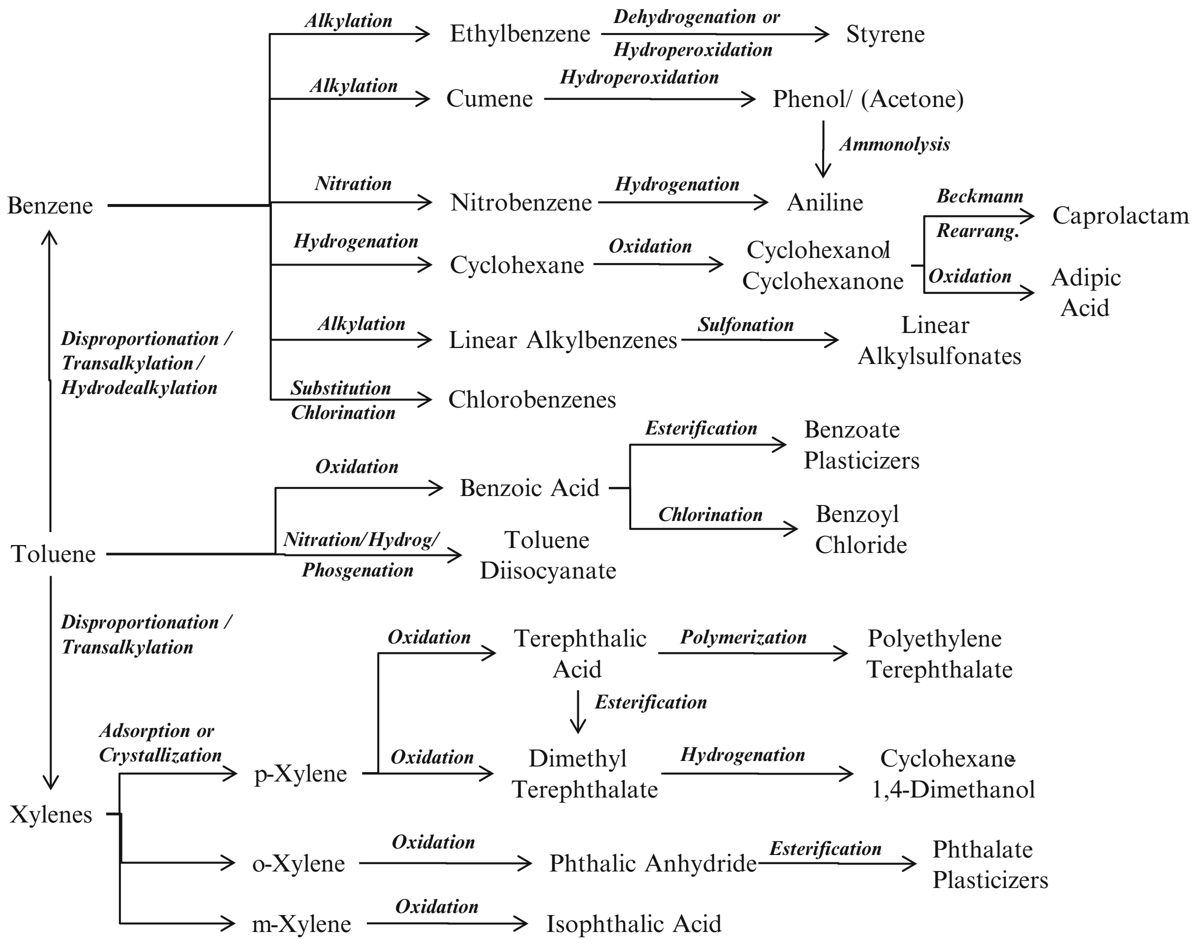

Fig. 10.13 BTX derivative tree

literature [55, 58–60]. Dehydrogenation of C_4 species is covered briefly in the section, “Butenes and 1,3-Butadiene.”

During the 1990s in the United States, a significant fraction of the butenes pool was used for production of ether oxygenates, such as MTBE (methyl tert-butyl ether) for gasoline blending to meet specifications for reformulated gasoline. MTBE use in gasoline was later discontinued and replaced with corn-based ethanol. A large portion of the butenes is now used for alkylation (isobutane reacted with propylene and/or butenes) and for the production of higher octane butene dimer blending components. Further information on these processes is given in Chap. 18.

Over 95% of the 1,3-butadiene (1,3-BD) produced globally is recovered as a by-product of light olefins production from steam cracking. A number of extractive distillation processes, such as the *n*-methylpyrrolidone (NMP)-based process illustrated in Fig. 10.14, have been commercialized for recovery of 1,3-BD from such mixed C_4 streams [61–64]. The mixed C_4 stream, containing *n*/*i*-butanes, *n*/-*i*-butenes, 1,3-BD, 1,2-butadiene, and alkynes, is fed to a predistillation column (**1**), where propyne, propadiene, and other lights are removed overhead. The underflow of this column is fed to the bottom of the stripping section of the extractive distillation column using NMP as the extractive distillation solvent (**2**). The distillate is a butadiene-free butanes/butenes mixture (commonly referred to as raffinate-1). The bottom butadiene-rich stream is sent to the rectifying section of the extractive distillation, a divided wall column (**3**), where butenes are stripped out of the column feed mixture in one compartment (**3a**), with the stripped materials returned to the extractive stripping column. In the second compartment (**3b**), the more soluble C_4 alkynes are removed from the crude 1,3-BD by extraction into NMP. The bottoms of the rectifying section are distilled in the stripping column (**4**) to remove light hydrocarbons from the recycle solvent. Acetylenes banding in this column are removed as a sidedraw, scrubbed of NMP (**6**), and added to the raffinate-1 stream if desired. The stipped hydrocarbons are recompressed (**5**) and recycled to the rectifying section of extractive column. The overhead from the rectifying section (**3b**) is distilled in the final butadiene column (**7**), with water removed overhead, 1,3-BD taken as a liquid sidedraw product, and C_4-C_5 hydrocarbons underflowed. Recovery of 1,3-BD is above 98%.

Table 10.13 Typical C_4 fractions from some cracking operations

	Catalytic cracking of gas oil (%)	Delayed coking (%)	Naphtha steam cracking (%)
C_4 product as % of feed	3–10	1.5–2.0	2–12
n-Butane	7–13	47	2–5
i-Butane	28–52	12	0.5–1.5
1-Butene	7–8	13	14–16
Cis-2-butene	20–30	5	5–6
Trans-2-butene	20–30	7	6–7
Isobutylene	26–28	16	22–27
1,3-Butadiene	0.1–0.5	0.5	37–45
1,2-Butadiene, C_3-C_4 acetylenes	1–2	<3	3–8

A number of older processes for on-purpose synthesis of 1,3-BD, such aldol condensation of acetaldehyde, followed by hydrogenation/dehydration, ethanol to acetaldehyde to butadiene(via aldol), or acetylene plus formaldehyde [65], are largely obsolete. A small amount of butadiene is produced by dehydrogenation or oxidative dehydrogenation of butane/butenes, as discussed in section, "Butenes and 1,3-Butadiene."

The primary derivatives produced from C_4 hydrocarbon feedstocks, the capacity/production/consumption of those primary derivatives, and their major applications are summarized in Tables 10.14, 10.15, and 10.16. The family of derivatives produced from C_4 hydrocarbon feedstocks is presented in Fig. 10.15.

C_9-C_{17} Paraffins [66–68]

Higher C_9-C_{17} alkanes derived from petroleum, find limited but important uses as raw materials for the production of higher C_9-C_{17} *n*-olefins. These higher *n*-olefins are intermediates in the manufacture of detergents and anionic surfactants. Because of their wide availability and generally low cost, heavy naphthas (boiling range of 150–200°C) and

kerosene (boiling range of 190–250°C) are the raw materials for production these olefins. The naphtha and kerosene fractions typically contain 20% or more *n*-paraffin content. After hydrotreating to remove sulfur which poisons downstream catalysts, the naphtha and kerosene cuts are separated by shape-selective adsorption that takes advantage of the larger cross-sectional area of the branched isomers. The *n*-alkanes are preferentially adsorbed, while the branched materials largely pass through. The *n*-alkanes are desorbed by a light hydrocarbon, and distilled to recover the desorbent. Both vapor and liquid phase adsorption processes are practiced. The high *n*-alkane product is then dehydrogenated to give most internal olefins. Further details on the dehydrogenation process are given in the section, "Internal Olefins from Higher *n*-Alkanes." The primary derivatives produced from C_9-C_{17} hydrocarbon feedstocks, the capacity/production/consumption of those primary derivatives, and their major applications are summarized in Tables 10.17, 10.18, and 10.19. The family of derivatives produced from C_9-C_{17} hydrocarbon feedstocks is presented in Fig. 10.16.

Synthesis Gas [69–77]

Synthesis gas, or "syngas," is a mixture of hydrogen and carbon monoxide produced by the partial oxidation of carbonaceous feedstocks. The ratio of hydrogen to carbon monoxide in the crude syngas (as well as carbon dioxide content and impurities) is highly dependent on the carbonaceous raw material as well as the process used to generate the syngas. Natural gas is the most important raw material for syngas generation worldwide, with limited coal-based production in

Chemical	Major uses
Linear alkylbenzenes	≈100% surfactants
Detergent alcohols	42% alcohol ethoxylates; 27% alcohol ether sulfates; 13% alcohol sulfates
Chloroparaffins	Intermediate for linear alkylbenzenes, solvents

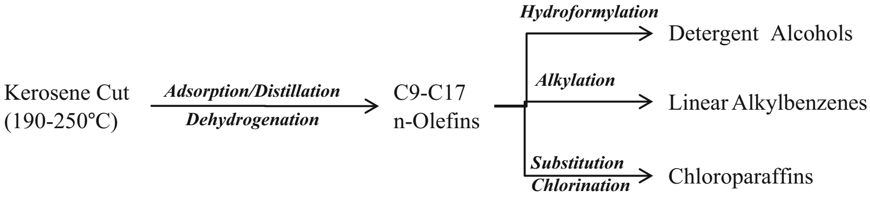

Fig. 10.16 C_9-C_{17} normal paraffins derivative tree

the United States, South Africa, India, and significantly growing production in China. Liquid hydrocarbons (naphtha, heavy fuel oils, and vacuum resid) are also used to some extent.

Syngas production involves the breaking of C–C and C–H bonds of the raw material molecules at high temperature via reaction with water (steam reforming), oxygen (partial oxidation), or carbon dioxide (carbon dioxide reforming), or combinations therein (autothermal reforming or gasification). The primary reactions in steam methane reforming (SMR), stream hydrocarbon reforming (SHR), and carbon dioxide reforming (CMR—not yet commercial) are endothermic, with only the water-gas shift reaction providing heat. Heat must be added externally, normally by superheating steam and raw materials in a fired furnace.

$$CH_4 + H_2O \leftrightarrow CO + 3H_2$$
$$\Delta H_r = +206 \text{ kJ/gmole(methane steam reforming)}$$

$$C_nH_m + nH_2O \rightarrow nCO + (n + 1/2m)H_2$$
$$\Delta H_r \approx +170 \text{ kJ/gmole - } CH_2 - \text{(hydrocarbon reform)}$$

$$CH_4 + CO_2 \leftrightarrow 2CO + 2H_2 \quad \Delta H_r = +247 \text{ kJ/gmole}$$
$$\text{(methane } CO_2 \text{ reforming)}$$

$$CO + H_2O \leftrightarrow CO_2 + H_2$$
$$\Delta H_r = -41 \text{ kJ/gmole(water - gas shift)}$$

Syngas can also be produced by partial oxidation, typically with high purity oxygen (to avoid dilution with large quantities of hard to separate nitrogen). In partial oxidation, a fraction of the raw material is simultaneously combusted to completion to provide in situ heat input. Roughly 70–85% of the energy in the raw material is preserved in the syngas produced. For methane, pertinent reactions are given below, with reforming and water-gas shift reactions also occurring to some extent.

$$CH_4 + \frac{1}{2}O_2 \rightarrow CO + 2H_2$$
$$\Delta H_r = -36 \text{ kJ/gmole(partial oxidation)}$$

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$$
$$\Delta H_r = -803 \text{ kJ/gmole(combustion)}$$

$$C_nH_m + (n/2)O_2 \rightarrow nCO + (m/2)H_2$$
$$\Delta H_r \approx -80 \text{ kJ/gmole - } CH_2 - \text{(hydrocarbon part. ox.)}$$

$$C_nH_m + (n + m/4)O_2 \rightarrow nCO_2 + (m/2)H_2O$$
$$\Delta H_r = -650 \text{ kJ/gmole(combustion)}$$

$$CO + \frac{1}{2}O_2 \rightarrow CO_2 \quad \Delta H_r = -283 \text{ kJ/gmole(combustion)}$$

$$H_2 + \frac{1}{2}O_2 \rightarrow H_2O \quad \Delta H_r = -242 \text{ kJ/gmole(combustion)}$$

Table 10.20 H_2/CO ratios of syngas processes

Syngas Production Method	Feedstock	Feedstock C/H wt ratio	Product H_2/CO molar ratio	Stoicheometric number
Syngas production method	Natural gas	3.2	2.8–4.7 (avg 4.3)	2.1 avg
	Naphtha	8.4	2.1–4.4	2.0 avg
Autothermal reforming	Natural gas	3.2	1.8–3.8	2.0 avg
	Naphtha	8.4	1.1–3.4	2.0 avg
POX	Natural gas	3.2	1.75	1.6
	Naphtha	8.4	1.1	1.0
	Heavy fuel oil	5.2	0.95	0.8
Gasification—carbonaceous solids				
Entrained flow—O_2 blown, water slurry (general electric)	Coal—Pittsburgh #8	7.3	0.89	0.34
	Coal—Illinois #6	7.7	0.86	0.30
	Petcoke	11.6	0.62	0.24
Entrained flow—O_2 blown, dry feed (shell)	Coal—appalachian	8.1	0.47	0.45
	Coal—Illinois #6	6.4	0.47	0.42
	Lignite	6.2	0.49	0.38
Biomass gasifier (silva gas—POX)	Wood	8.6	0.55	0.17

Underground gasification	Coal—Illinois #6	7.4	2.02	0.26
	Coal—powder river basin	6.9	2.53	−0.15

Gasification of solid carbonaceous raw materials adds additional endothermic reactions of solid carbon with steam and exothermic reactions with oxygen. Methanation may also occur under appropriate conditions.

$$C + CO_2 \leftrightarrow 2CO$$
$$\Delta H_r = +172\ \text{kJ/gmole(Boudouard reaction)}$$

$$C + H_2O \leftrightarrow CO + H_2$$
$$\Delta H_r = +131\ \text{kJ/gmole(water gas reaction)}$$

$$C + \frac{1}{2}O_2 \rightarrow CO$$
$$\Delta H_r = -111\ \text{kJ/gmole(partial oxidation)}$$

$$C + 2H_2 \leftrightarrow CH_4$$
$$\Delta H_r = -75\ \text{kJ/gmole(methanation)}$$

Typical H_2/CO ratios for the most important syngas-generating processes are summarized in Table 10.20. Further information on syngas production from natural gas and via coal gasification is given in Chaps. 19, 20, and 22.

It is not much of an exaggeration to say that coal contains every element on the periodic table, many of which end up in the crude syngas, such as mercury, arsenic, and sulfur as H_2S and COS. To a lesser extent natural gas often contains H_2S, COS, as well as mercaptans. Many of the downstream catalysts used in syngas derivative processes are particularly susceptible to poisoning by these trace elements. A wide variety of techniques, mostly involving absorption and adsorption, have been developed and implemented for removal of such trace elements.

Most syngas derivatives are produced optimally at a specific H_2/CO ratio, with a limited acceptable CO_2 content [78]. See Fig. 10.17 for the syngas family of derivatives produced from different H_2/CO ratios. If not produced directly from the syngas generator, a number of reaction and separation techniques are used to adjust the composition of the gas.

1. The water-gas shift reaction is the primary mechanism for reactive adjustments of the H_2/CO ratio. Both sweet (very low amounts of H_2S and other sulfur moieties present) and sour (high sulfur levels) shifts are practiced. The feed gas enters the shift reactor at 200°C or higher.

$$CO + H_2O \leftrightarrow CO_2 + H_2$$
$$\Delta H_r = -42\ \text{kJ/gmole(water gas reaction)}$$

   The reaction is normally run adiabatically with a significant temperature, often of 200°C or more. As temperature is increased, the equilibrium shifts more toward the left. Multiple stages, with heat interstage steam generation for cooling, is required for high levels of conversion, i.e., for hydrogen production.
2. Carbon dioxide is removed by absorption with either physical or chemical absorbents, the choice depending on gas pressure, CO_2 concentrations, and desired level of removal.
3. Small adjustments of H_2/CO may be accomplished by membrane permeation (hydrogen permeates primarily), decreasing the H_2/CO ratio of the retentate. Membrane permeation is particularly common for production of 1/1 H_2/CO syngas for hydroformylation.

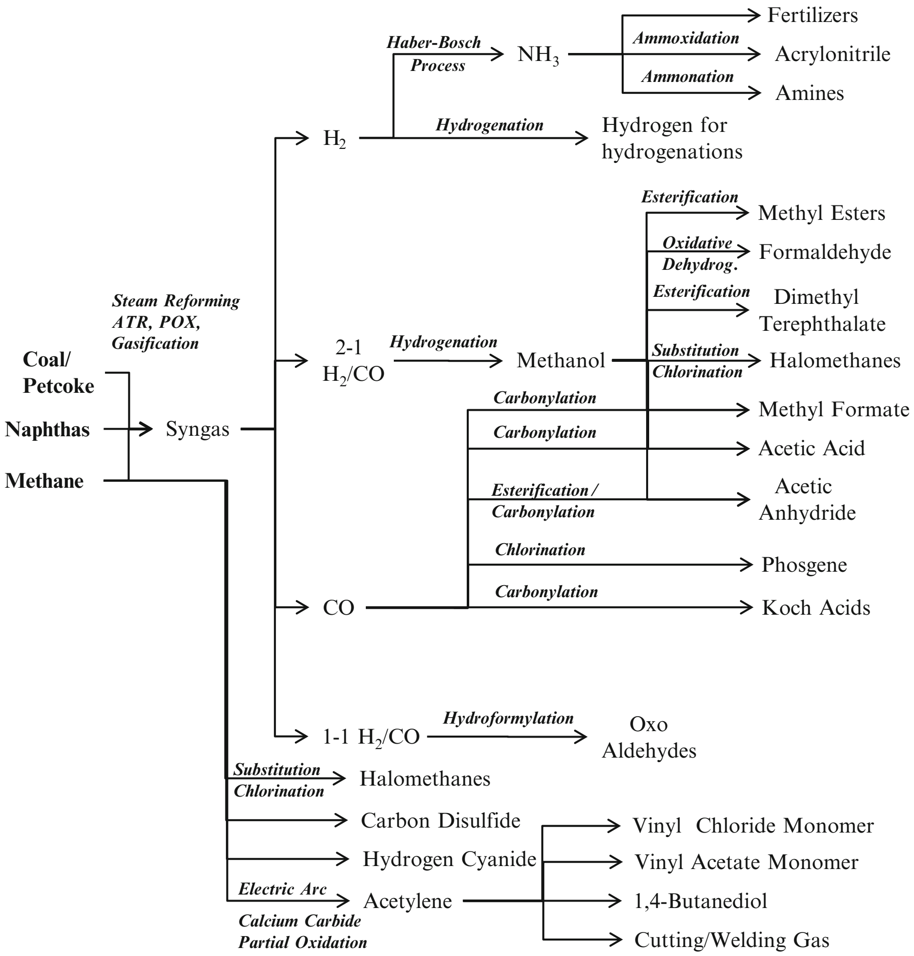

Fig. 10.17 Syngas and methane derivative tree

Table 10.21 Breakdown of syngas types (see also Chaps. 19, 20, and 22)

Type of syngas	Estimated % of worldwide production
Ammonia syngas	65
Hydrogen	11
2-1 H_2/CO (methanol syngas)[a]	21
1-1 H_2/CO (oxo syngas)	2
Carbon monoxide	2

[a] Does not include 2-1 H_2/CO syngas used for Fischer-Tropsch synthesis of fuels

4. High purity hydrogen is produced by water-gas shift, followed by CO_2 absorption, and pressure swing adsorption.
5. CO may be produced at up to about 95% purity by membrane permeation (more extreme case of 3). High purity CO (>99.9%) is made by cryogenic distillation of syngas, or less commonly by chemical absorption processes (CO absorbed).

Estimated global production of syngas, at common H_2/CO ratios, is given in Table 10.21. The capacity/production/consumption of primary derivatives produced from syngas feedstocks and their major applications are summarized in Tables 10.22 and 10.23.

Minor Feedstocks: Methane and Acetylene

Methane itself is relatively unreactive. Much effort has been expended to synthesize functionalized chemicals from methane directly. Examples of large-scale industrial syntheses are carbon disulfide, hydrogen cyanide, and to some extent chloromethanes. However, most other direct methane processes have been ultimately uneconomical and have fallen by the wayside or never been commercialized.

Until the rise of the massive global petrochemical infrastructure in the late 1940s and 1950s, acetylene was one of the most important feedstocks for the production synthetic organic chemicals. Although highly reactive, high conversion and generally very good selectivities can be achieved in acetylene-based chemistries, Such routes thus were favored for many years. Acetylene was once a major feedstock for the production of vinyl chloride monomer (VCM), acrylic acid, acrylonitrile, and many chlorinated solvents. Olefin-based processes have largely supplanted those starting with acetylene. Between 1965 (near its peak demand) and 2007, acetylene usage for

chemical synthesis has dropped at least 70% in all areas of the world except China. Acetylene demand, especially for VCM, has enjoyed somewhat of a renaissance in China, with capacity growth above 15% per year over the last decade. The fact that acetylene can be made from a wide variety of feedstocks, including coal, is a particular advantage in oil-poor China. Currently about 75% of global acetylene feedstock usage occurs in China. Capacity/consumption statistics for acetylene are given in Table 10.24 for the year 2007. Remaining large scale applications of acetylene are summarized in Table 10.25.

Acetylene can be produced by a wide variety of processes [79, 80]. These include:

1. *Calcium carbide processes*, in which calcium oxide and coke are electrothermally reacted at 2,250°C to produce calcium carbide. The reaction is highly endothermic at +465 kJ/gmole. Calcium carbide is reacted with water in an exothermic reaction acetylene and calcium hydroxide. Yield of acetylene is about 76% on calcium carbide.
2. *Electric arc processes*, in which a carbonaceous raw material is cracked at very high temperatures up to 20,000°C in an electric arc-generated plasma with very short residence times of 0.001–0.01 s. Rapid quenching to 200–300°C freezes the composition and prevents decomposition of acetylene to thermodynamically favorable soot and hydrogen. Typical yields are around 45 wt% of feed carbon to acetylene and 25% to ethylene.
3. *Autothermal partial oxidation processes*, in which light hydrocarbons (predominantly methane in practice) are reacted with oxygen in a controlled fashion. In one version methane and oxygen at a 2:1 M ratio are preheated separately to 500–600°C, mixed, and reacted in proprietary burner configurations at 1,500°C, millisecond residence times to produce syngas and acetylene. The endothermic acetylene formation reaction is coupled with the highly exothermic partial combustion of methane to provide in situ heat integration:

$$CaC_2 + 2H_2O \longrightarrow HC{\equiv}CH + Ca(OH)_2 \qquad \Delta H_{rxn} = -130 kJ/gmole$$

Table 10.26 Raw materials and chemistries of downstream derivatives

Chemical	Raw materials	Chemistry
Vinyl chloride monomer	Ethylene dichloride	Pyrolysis
Ethyl acetate	Ethanol, acetic acid	Esterification; Tishchenko
Ethylene glycol	Ethylene oxide; ethylene carbonate	Hydration; hydration
Ethylene oxide glcyol ethers	Ethylene oxide, alcohols	Alcoholysis
Chloroethanes	EDC, Cl_2	Substitution chlorination
Phenol	Cumene, air	Hydroperoxidation
Acetone	Cumene, air; isopropanol	Hydroperoxidation; dehydrogenation
Hydroquinone	Diisopropylbenzene, air	Hydroperoxidation
MIBK	Acetone, H_2	Aldol, hydrogenation
2-Ethylhexanol	*n*-Butyraldehyde, H_2	Aldol, hydrogenation
Propylene glycol	Propylene oxide	Hydration
Propylene oxide glycol ethers	Propylene oxide, alcohols	Alcoholysis
n-Butanol	*n*-Butyraldehyde, H_2	Hydrogenation
Isobutanol	*i*-Butyraldehyde, H_2	Hydrogenation
Bisphenol A	Phenol, acetone	Condensation
Styrene	Ethylbenzene; propylene, ethylbenzene	Dehydrogenation; hydroperoxid.
Cyclohexanone-cyclohexanol	Cyclohexane	Oxidation
Formaldehyde	Methanol, air	Oxidation
Neopentyl polyols—NPG, PE,TMP, TME	Formaldehyde, C_2-C_4 aldehydes	Aldol, hydrogenation
Ketene	Acetic acid	Thermal dehydration
Ketene derivatives, diketene	Ketene, many others	Many
Methyl chloride	Methanol/HCl; methane/Cl_2	Hydrochlorination; chlorination
Methylene chloride	Methyl chloride	Substitution chlorination
Chloroform	Methylene chloride	Substitution chlorination
Carbon tetrachloride	Chloroform; higher polychlorinated species	Substitution chlorination; perchlorination
Acetate esters (methyl, ethyl, *i*/*n*-propyl, *i*/*n*-butyl)	Acetic acid; C_1-C_4 alkanols	Esterification
1,4-Butanediol	Formaldehyde/acetylene/H_2; maleic anhydride/H_2	Condensation/hydrog; hydrog

$$2\,CH_4 \xrightarrow[1500°C]{\Delta} HC\equiv CH + 3H_2 \qquad \Delta H_{rxn}=+377\,kJ/gmole$$

$$CH_4 + 1.5\,O_2 \longrightarrow CO + 2\,H_2O \qquad \Delta H_{rxn}=-520\,kJ/gmole$$

The reaction gases are rapidly quenched with water or oil to prevent decomposition to soot and hydrogen. The cooled gas, comprising 8% acetylene, 57% H_2, and 26% CO, is contacted with *N*-methylpyrrolidone (NMP) in a countercurrent absorber to recover acetylene (see the section, “C_4 Hydrocarbons: Butanes, Butenes, Butadiene,” for a similar use of NMP). About 25–30% of the carbon in the raw material is converted into acetylene, with about 3–5% going to coke. Most of the rest ends up as CO.

Downstream Derivatives

Many of the primary derivatives of the major petrochemical feedstocks are intermediates for the synthesis of additional downstream derivatives The raw materials and chemistries of these downstream derivatives are summarized in Table 10.26. Capacity/production/consumption figures and major uses of the downstream derivatives are presented in Tables 10.27 and 10.28, respectively.

Manipulation of Hydrocarbons: Oligomerization, Metathesis, Alkylation

Oligomerization

Linear α-Olefins [81–84]

Linear α-olefins can be produced from higher *n*-paraffins by dehydrogenation, as described in the section, “Internal Olefins from Higher *n*-Alkanes.” Linear terminal olefins with an even number of carbon atoms can be produced by a family of related processes based on oligomerization/metathesis of ethylene using trialkyl aluminum or titanium (Ziegler) catalysts or liganded Ni catalysts. The reaction takes place in two steps:

Table 10.27 Capacity/production/consumption of downstream derivatives

	Capacity, in kilo metric tons			Production, in kilo metric tons			Consumption, in KMT[a]	
Chemical	World	USA	China	World	USA	China	USA	China
Vinyl chloride monomer	45,000	9,200	14,000	33,000	6,800	8,300	6,100	9,100

[a] Gray shading indicates net importer

1. In the oligomerization, or chain growth step, ethylene is inserted progressively into the carbon-catalyst metal bond, leading to a longer linear alkyl chain.
2. To terminate the chain growth, ethylene displaces the longer chain alkyl unit from the C-metal bond, releasing a longer chain α-olefin, and starting the oligomerization cycle over again.

The product composition follows the Shulz–Flory distribution of chain lengths, with substantial amounts of undesirable high and low molecular weight tails. Both one-reactor and two-reactor processes are practiced commercially. The one-reactor process leads to a somewhat broader distribution of molecular weights, with typical conditions of 170–290°C, 14–28 MPa. For a two-reactor process with a Ziegler catalyst, typical conditions are 100–120°C, 7–20 MPa for oligomerization and termination at 260–300°C, 2–5 MPa. With a nickel catalyst, more mild oligomerization conditions are possible, 80–120°C, 7–14 MPa. A typical product distribution is 5–14 wt% C_4, 25–50 wt% C_6-C_{10}, 15–20 wt% C_{12}-C_{14}, 11–15 wt% C_{16}-C_{18}, and 3–15 wt% C_{20+} One process can produce a very narrow distribution of closer to 75% C_6-C_{10} olefins. Depending on the process conditions, catalyst, and molecular weight of the olefin in question, the product comprises 88–98% linear α-olefins. Distillation is used to separate the crude olefin product into molecular weight ranges required for various applications (e.g., oxo for detergent alcohols, LAB production).

Two methods are commonly used for narrowing the molecular weight range of the ultimate product. Low molecular weight olefins may be recycled to participate in further oligomerization (see above). Secondly, light and heavy fractions may be metathesized to produce two smaller olefinic molecules (see section "Metathesis", directly below).

Metathesis [85]

An intriguing reaction in which the carbon–carbon double bonds of two olefins are broken and remade, resulting in the switching of their alkylidene groups, is referred to as olefin metathesis.

Table 10.28 Major uses of downstream derivatives

Chemical	Major uses
Vinyl chloride monomer	≈100% polyvinyl chloride
Ethyl acetate	50% surface coatings; inks, solvent applications
Ethylene glycol	85% polyethylene terphthalate; 10% antifreeze
Ethylene oxide glycol ethers	Solvents, paints, inks, cleaning fluids
Chloroethanes	Flurocarbon intermediates
Phenol	44% BPA; 27% phenol/formaldehyde resins; 7% caprolactam; 3% alkylphenols
Acetone	29% methyl methacrylate; 29% solvent applications; 22% bisphenol A; 10% aldol chemicals
Hydroquinone	41% antioxidant; 21% polymerization inhibitor; 14% photographic processing
MIBK	67% solvent applications; 22% rubber antiozonants
2-Ethylhexanol	70% plasticizer esters; acrylate esters; solvent applications
Propylene glycol	30% unsaturated polyester resins; functional fluids; personal care; P type glycol ethers
Propylene oxide glycol ethers	Solvents, paints, inks, cleaning fluids
n-Butanol	33% acrylate esters; 15% acetate esters; 15% glycol ethers; solvent applications
Isobutanol	Acetate esters; glycol ethers; other esters; solvent applications
Bisphenol A	69% polycarbonate; 27% epoxy resins
Styrene	59% polystyrene; 16% ABS/SAN resins
Cyclohexanone-cyclohexanol	62% caprolactam; 34% adipic acid; solvent applications
Formaldehyde	Resins: 46% urea/formald, 11% phenol/formald, 8% polyacetal, 6% melamine'/formald; 5% pentaerthyritol; 4% 1,4-BDO
Neopentyl polyols—NPG, PE,TMP, TME	70% coatings resins; 10% lube esters; 7% unsaturated polyester resins; 3% acrylates/methacrylates
Ketene	70% acetic anhydride; 14% diketene; 5% sorbic acid
Ketene derivatives, diketene	Acetoacetate esters; arylides
Methyl chloride	Intermediate for production of silicones; methyl cellulose solvent, butyl rubber solvent
Methylene chloride	Adhesives, paint removal; solvent for chemical/pharma processes; aerosols; metal cleaning
Chloroform	Intermediate for production of HCFC-22 (R-22); raw material for substitution fluorination for fluorpolymers, e.g., Teflon
Carbon tetrachloride	Intermediate for production of HFC-245fa and HFC-365mfc fluorocarbons
Acetate esters (methyl, ethyl, *i*/*n*-propyl, *i*/*n*-butyl)	Solvents
1,4-Butanediol	50% THF/spandex; 24% polybutylene terephthalate; 14% gamma-butyrolactone; 9% polyurethanes

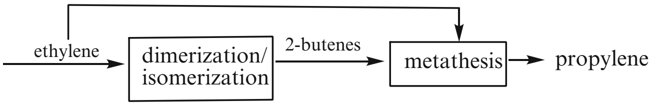
$$\mathrm{RHC{=}CHR + R'HC{=}CHR' \rightleftharpoons 2\ RHC{=}CHR'}$$

The analogous reaction for carbon–carbon triple bonds, alkyne metathesis, was also discovered at about the same time, in the early 1960s.

$$\mathrm{RC{\equiv}CR + R'C{\equiv}CR' \rightleftharpoons 2\ RC{\equiv}CR'}$$

One of the earliest applications of olefin metathesis was developed at Phillips Petroleum and is known as the Triolefin Process [86]. It illustrates the simplest case of olefin metathesis in which propylene is converted to ethylene and both cis and trans isomers of 2-butene.

The process was practiced as described (propylene-to-ethylene/butene) by Shawinigan Chemical from 1964 to 1972 but the demand for propylene vs. ethylene shifted. Now processes have been developed by ARCO (now Lummus OCT: olefin conversion technology) and Axen (Meta-4) to execute variations of the opposite in which C_4 streams, derived from hydrocarbon cracking, are reacted with ethylene to produce propylene. This technology thus provides the opportunity to enrich the ethylene/propylene product ratio of a cracker to favor propylene. In OCT, ethylene is dimerized to butenes and then cracked with additional ethylene ("ethenolysis") to yield propylene, allowing total conversion of such a stream to propylene. Several different metal oxides, such as $CoO\text{-}MoO_3/Al_2O_3$ oxide (120–210°C), WO_3/SiO_2 (450–500°C) and Re_2O_7/Al_2O_3 (450–500°C), are employed as catalysts.



Another example of ethenolysis to produce valuable products is the cracking of unsaturated fatty acid esters for production of fuels from renewable materials [87].

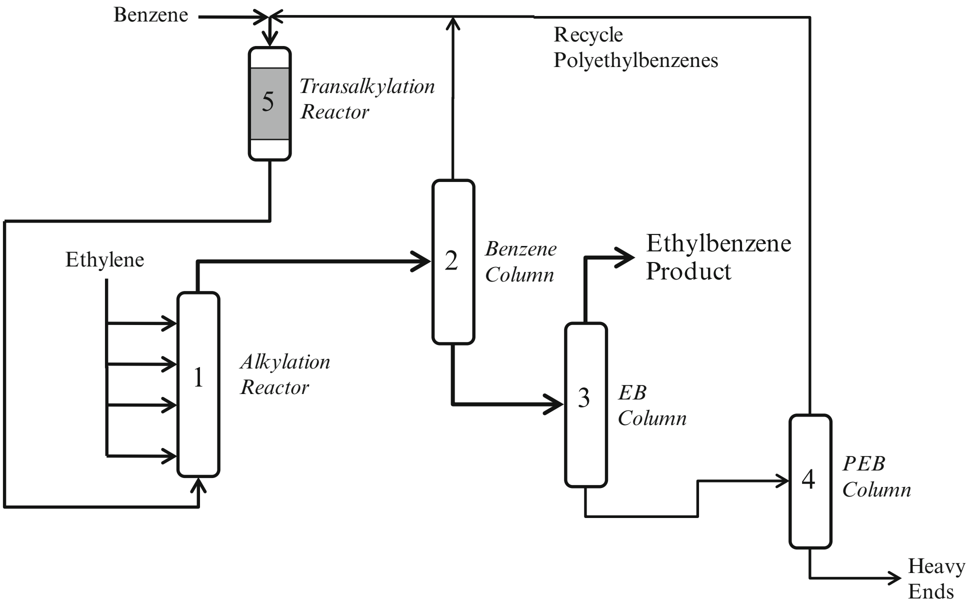


Fig. 10.18 Flowsheet alkylation of benzene to ethylbenzene

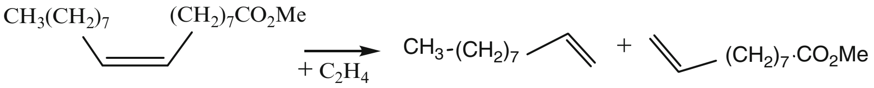
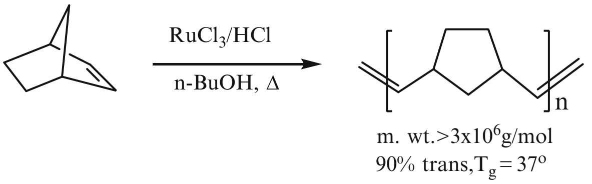
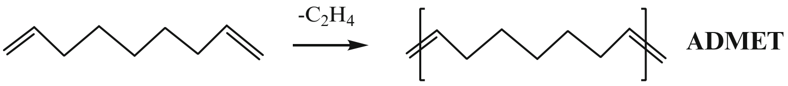
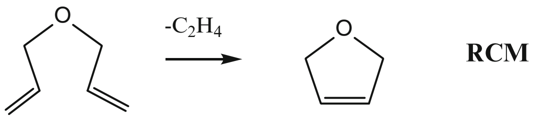


Olefin metathesis is an equilibrium controlled reaction, and the equilibria of a related set of olefins are typically close to a statistical mixture, thus limiting the conversion of reactants. However, if one olefin of the equilibrating mixture can be selectively removed then a metathesis reaction can be driven to high conversion. A simple strategy which exploits this concept is the reactions of a-olefins which produce low boiling ethylene (the oppositie of ethenolysis). As the volatile alkene escapes from solution the reaction proceeds to completion. This approach is exploited in polymer synthesis by reacting various α-, ω-dienes to generate ethylene and a growing polymer chain (referred to as "Acyclic Diene Metathesis" ADMET, polymerization). Likewise, dienes which can produce a favored ring size yield "Ring Closing Metathesis." (RCM).

A second strategy for driving a metathesis reaction toward complete conversion is demonstrated by polymerization of cyclic monomers, such as norbornene, which release enough energy upon ring-opening to drive the polymerization. This method is known as ring-opening metathesis polymerization (ROMP) [88].







The reaction above gives an early example of the homogeneous catalysis of metathesis reactions by metals such as ruthenium or iridium [89, 90]. The development of single-component metal-carbene metathesis catalysts, in particular those of ruthenium, and their applications in organic synthesis have been the subject of an enormous body of research in the last 20 years and the 2005 Nobel prize in chemistry was awarded to three of the pioneers in this area: Yves Chauvin, Robert Grubbs and Richard Schrock. ROMP is one of the most promising techniques to emerge in this work with ready applications in polymer and material science. The structures of some of the most widely utilized catalysts are given in Fig. 10.18.

In 1977, Shell commercialized a process known as the SHOP Process (Shell Higher Olefin Process) for the production of detergent alcohols at their plant in Geismar, LA. The 2010 capacity of this plant for olefin production is over 900,000 M-tons/year. Detergent alcohols are produced in four steps from ethylene. First, the ethylene is oligomerzed using a homogeneous nickel-based catalyst with a chelating P-O ligand ([Ni] ~50 ppm). Oligomerization is carried out at 80–140°C and 7–14 MPa in a polar organic solvent (1,4-butanediol) which phase separates from C_4-C_{30} α-olefin products [91]. The nickel catalyst solution phase is separated in a high-pressure separator and the C_4-C_{20} α-olefins are distilled from the mixture and are purified and sold as Shell's Neodene linear α-olefins.

In the next step the mixture of α-olefins are isomerized in the liquid phase using a heterogeneous catalyst such as MgO granules. This produces all possible isomers of the even-numbered linear olefins. Then, in the third step, olefin metathesis of this mixture over a molybdenum/alumina catalyst (100–125°C, 10 MPa) further complicates this mixture by doubling the number of olefins within the range to include not only the even (C_4, C_6, C_8, etc.) but also all of the odd-numbered (C_4, C_5, C_6, C_7, etc.) olefins in a thermodynamically controlled equilibrium. The yield of desired C_{11}-C_{14} olefins is 10–15% per pass. These olefins are treated in the final step with syngas ($CO:H_2 = 1:2$) using a phosphine-modified cobalt catalyst (170°C, 10 MPa). In this process internal double bonds are isomerized rapidly, resulting in a highly linear alcohol product (75–90% linear).

Alkylation [92, 93]

Chemistry

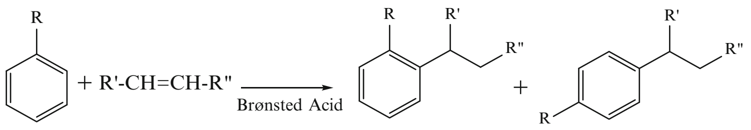
Catalytic alkylation of aromatics is a substitution reaction in which a hydrogen atom on the ring or side chain of the aromatic is replaced by an alkyl group derived from an alkylating agent. Alkylation may occur on both unsubstituted as well as substituted aromatics. The reaction is shown below for ring substitution with an olefinic alkylating agent:

Acid-catalyzed electrophilic substitution (by way of a carbonium ion) gives replacement on the ring. If the alkylation is to occur on the side chain, then nucleophilic (base-catalyzed), or free radical reactions are involved. Most large-scale commercial alkylations are electrophilic in nature, e.g., cumene, ethylbenzene, and linear alkylbenzenes (LAB's) syntheses, but a few are nucleophilic, e.g., isobutylbenzene, dimethylnaphthalene syntheses.

Alkylating agents can be olefins, alkynes, dienes, alcohols, and ethers. For electrophilic substitution, any substrate capable of forming a carbonium ion may be used, although the use of olefins predominates for all applications except introduction of a methyl group. Methanol is a common methylating agent as it can give a carbonium ion equivalent, whereas methane itself is unreactive.

Acid catalysts useful for aromatic alkylations are Brønsted acids containing acidic protons. Examples include protonic acids such as sulfuric, HF, phosphoric, solid phosphoric acid (SPA), polysulfonate cation-exchange resins; acidic aluminas, silicas, alumina-silicas, zeolites (aluminosilicates and silicoaluminophosphates); and acidic halides, such as $AlCl_3$ and BF_3. The latter are relatively inactive in their pure states, but become catalytically active when coupled with trace concentrations of water, alcohols, or hydrogen halides (giving the needed Brønsted acidity). These Lewis acids were the original highly effective Friedel-Crafts catalysts, with high activity at low temperature (<100°C), but have largely been replaced commercially with more selective, less corrosive, and environmentally friendly zeolites.

With strong Brønsted acid catalysis, the olefin is protonated to form an activated electrophile (carbonium ion), which attacks the electron-rich π-complex of the aromatic ring. A new C–C-bond is formed, followed by regeneration of an acidic proton. Acid-catalyzed skeletonal rearrangement of the alkylating agent leads to formation of the most substituted and stable ion (tert > iso > normal). Relative rates of alkylation of the ring and isomerization of the alkylating agent dictate the product distribution. Typically for small alkylating agents like butenes, (especially isobutene) rearrangement is fast, giving almost exclusively tert-butyl aromatics. Thus synthesis of isopropylbenzene (cumene) and diisopropylbenzene from propylene and benzene is highly selective while isobutylbenzene formation must be base catalyzed. Alklyation rate also roughly follows carbonium ion stability, with isopropylation roughly 1,500 times faster than ethylation and 20,000 times faster than methylation.



ΔH_{rxn} = -80 to -115kJ/gmole
(depending on alkylating agent)

R, R', R" = H, methyl, ethyl, propyl, etc.

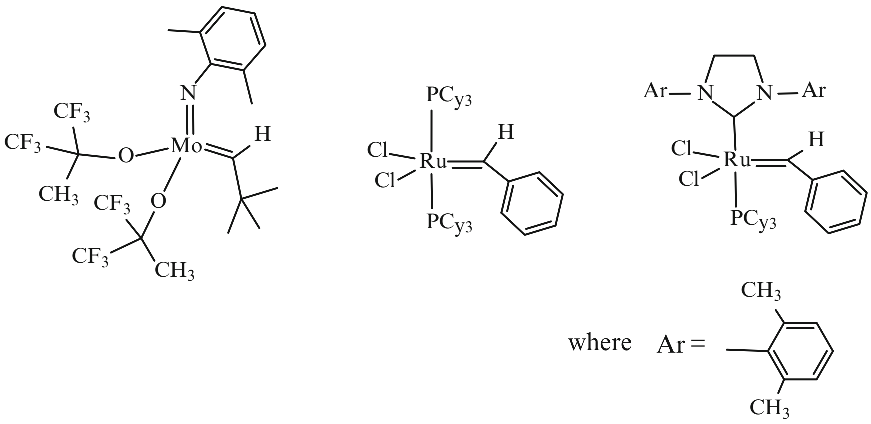


Fig. 10.19 Single-component olefin metathesis catalysts

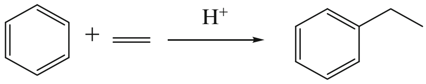
The rate of alkylation of benzene is slower than alkylation of alkylaromatics, so polyalkylation is kinetically favored. However, many of the most important alkylation products (e.g., cumene and ethylbenzene) are monosubstituted. The traditional method of limiting polyalkylation is to use high ratios of aromatic to alkylating agent, leading to low per pass aromatics conversion, and high separation/recycle costs. One of the most intriguing breakthroughs in alkylation technology in the last two decades has been the commercialization of shape-selective zeolite catalysts, which can largely eliminate polyalkylation, as well as allow much higher than equilibrium production of *para*-isomers (see the section, "C_6-C_8 Aromatics: BTX," above).

Ethylbenzene [94–98]

Well over 90% of the ethylbenzene consumed worldwide is formed by the alkylation of benzene with ethylene.



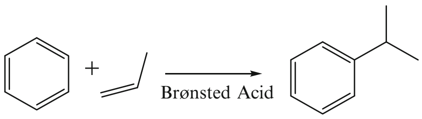
ΔH_{rxn} = -113 kJ/gmole

Early processes employed $AlCl_3$ in liquid phase processes operating below 130°C. Significant polyalklyation occurred, but was controlled by high benzene to ethylene feed ratios and recycle of polyethylbenzene (PEB) materials for equilibration in the alkylation reactor. High temperature (>300°C) vapor phase zeolite (ZSM-5) processes made significant inroads starting in the 1970s, but reactors coked quickly and required frequent regenerations.

Greenfield plants predominantly rely on next generation large pore zeolite catalysts to allow liquid-phase operation at 170–240°C (more than 100°C lower than the older vapor phase processes), at 3.5 MPa, with a much smaller excess of benzene to ethylene required. Low temperature operation decreases formation of by-product xylenes, polyaromatics, and PEB. In a typical commercial process (Fig. 10.19), benzene at less than 7:1 B:E molar ratio is fed to zeolite-filled alkylation beds in series (**1**), with cooled ethylene added between stages. Older vapor phase processes required a B:E of 18:1. Interstage cooling provides additional temperature control. Purification is accomplished in a three column distillation sequence. Unreacted benzene (for recycle) is taken overhead in the benzene column (**2**), EB overhead in the product column (**3**), and PEB for recycle in the third column (**4**), with polyaromatics and other heavies as underflow. PEB are converted to EB by reaction with benzene in a separate transalkylation unit (**5**). Ethylene and benzene consumption are respectively 0.265 and 0.738 kg/kg EB. Ethylene containing up to about 30% ethane can be used with the addition of a column for recovery of ethylene from off-gas ethane by absorption into benzene feedstock.

Cumene and Diisopropylbenzene [99–103]

Cumene production via alkylation of benzene with propylene, began in World War II as a high octane aviation fuel component. This early vapor phase process operated at 200–250°C, 1.5–3.5 MPa, over a silicophosphoric acid (SPA), with a 7:1 benzene:propylene ratio, with benzene-based yields above 95%.

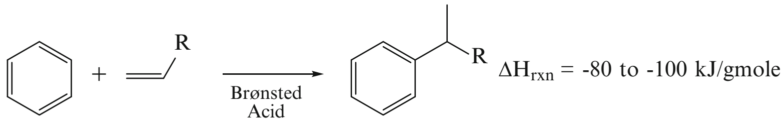


ΔH_{rxn} = -106 kJ/gmole

The SPA process was widely used for decades with little change, competing well against even zeolite based processes. Although successful for ethylbenzene synthesis, similar early generation zeolites were found to be unsuitable for cumene production. These narrow pore zeolites promote excessive *n*-propylbenzene formation due to (unwanted) shape selectivity, as well as propylene oligomerization (propylene is more reactive to oligomerization than ethylene). In the mid-1990s, a proprietary zeolite was invented with unique crystal structure that largely eliminated these former disadvantages, even at benzene:propylene ratios less than 2:1. Commercialized liquid phase processes using this zeolite are capable of greater than 99.7% yield of cumene, at 99.97% purity. The process flowsheet for cumene production looks very similar to that of ethylbenzene, with a mult-stage series alkylation system, a separate transalkylation step, and a three-stage distillation sequence for purification. Benzene, cumene, polyisopropylbenzene are taken overhead in successive columns, and heavies as underflow in the final column. Para-DIPB can be made in essentially an identical process, but with a higher propylene to benzene feed ratio.

Higher Alkylbenzenes [104–107]

Linear alkylbenzenes (LAB's) with a C_{10}-C_{14} side chain are important intermediates for the production of alkylbenzenesulfonate anionic detergents (see Chap. 36). The name is somewhat of a misnomer, as the alkylation reaction produces predominately branched 2-phenylalkane derivatives, rather than true linear 1-phenylalkanes.



Alkylation with the propylene tetramer has largely become obsolete, as the resulting branched alkylbenzene sulfonates are not readily biodegradable. The higher alkylbenzenes are synthesized by the liquid-phase reaction of C_{10}-C_{14} α-olefins and internal olefins with benzene, using typical Friedel-Crafts catalysts such as HF, $AlCl_3$, or zeolites. The higher chain olefins are sourced from either: (1) catalytic dehydration of the *n*-paraffin fraction recovered from the kerosene crude distillation cut to give largely internal olefins (see the section, "Internal Olefins from Higher *n*-Alkanes"), or (2) ethylene oligomerization processes (see above, the section, "Oligomerization"), which give largely α-olefins. Newer zeolite catalysts favor the more desirable 2-phenylalkane isomers with both internal and α-olefin feedstocks. Most greenfield LAB plants are now zeolite-based, with their clear advantage in safety, catalyst and capital cost, with elimination of catalyst neutralization stepsand corrosion concerns.

Oxidation

Chemistry [108–115]

Roughly two-thirds of high value synthetic organic chemicals are oxygenated. These include aldehydes, ketones, alcohols, organic acids, anhydrides, esters, and epoxides. Many of these functional groups ultimately are derived from some form of selective oxidation. In its broadest sense, oxidation is the process whereby the oxidation state of a substrate (typically carbon in this chapter) is increased. Although conceptually simple the controlled addition of oxygen to a hydrocarbon feedstock, i.e., partial oxidation, is a tricky feat to master. The principle technical challenges in partial oxidation of organic substrates are (1) finding a catalyst or conditions that give high selectivity toward the desired oxidation state and low selectivity for over or complete oxidation; and (2) carefully controlling reaction conditions, especially temperature and composition, to prevent loss of selectivity, runaway exothermicity, or explosive conditions.

Selective oxidations can be classified into two broad categories:

1. *Electrophilic oxidations* involve activation of dioxygen into electron-seeking forms such as O_2^- or O^- and formation of free radical intermediates.
2. *Nucleophilic oxidations* involve activation of the organic substrate followed by stepwise nucleophilic addition of O_2^- and hydrogen abstraction.

In order of increasing severity, electrophilic oxidations include; (1) addition of atomic oxygen to a high electron density double bond to form an epoxide, (2) formation of an alkyl hydroperoxide via hemolytic cleavage of a C–H bond by an oxygen radical to form an alkyl radical followed by reaction with dioxygen, (3) fission of C–C bonds to form two aldehydic groups, (4) rapid stepwise fission of C–H and C–C bonds to form CO_2 and water—i.e., total combustion. Nucleophilic oxidations in increasing severity include; (1) abstraction of hydrogen from an aldehyde followed by nucleophilic addition of oxygen to form an acid, (2) abstraction of hydrogen from an alcohol substrate to form an aldehyde or ketone, (3) abstraction of hydrogen from a substrate to form olefins, diolefins, aromatics from hydrocarbons, (4) abstraction of hydrogen from an olefin followed by successive nucleophilic additions of heteroatoms such as O, Cl, S, and N.

Electrophilic oxidations alter the carbon skeleton and π electron systems, while nucleophilic oxidations do not. Nucleophilic oxidations often involve a redox mechanism, in which oxygen is supplied indirectly to the substrate from the oxide lattice of the catalyst, and the catalyst lattice is then reoxidized by dissolved or gaseous dioxygen. Important industrial oxidation reactions described in this chapter are classified and summarized in Table 10.29.

The design and operation of reactors for oxidation service are demanding tasks. The desired products of selective partial oxidation are invariably not the thermodynamically

Table 10.29 Summary of oxidation reactions

Product	Substrate	Oxidant	Oxidation type[a]	Catalyst	Catalyst form	Phase	Conversion per pass	Selectivity
Ethylene oxide	Ethylene	>99% O_2	E-1	Ag (K, Cl) on α-Al_2O_3	Heterogeneous	Vapor	7–15%	Up to ~90%
Propylene oxide/styrene	Propylene/ ethylbenzene	Air	E-2	Mo complex or Si-supported TiO_2	Homog or hetero	Liquid	13% EB, ~100% propylene	~90%
Propylene oxide/t-butanol	Propylene/ isobutene	Air	E-2	Mo complex	Homogeneous	Liquid	~30% i-C_4 ~9% propylene	>90%
Phenol/acetone	Cumene	Air	E-2	Co/Mn salts	Homogeneous	Liquid	>99% of cumene	>95%
Hydroquinone/ acetone	Disopropylbenzene	Air	E-2	Co/Mn salts	Homogeneous	Liquid	>90%	>90%
Maleic anhydride	Benzene	Air	E-3, N-1	V-Mo oxides	Heterogeneous	Vapor	96%	73%
Adipic acid	Cyclohexanone/ cyclohexanol	HNO_3	E-3, N-2	Co salts, V-Cu salts	Heterogeneous	Liquid	>95%	92–96%
Acrylic acid	Acrolein	Air	N-1	V/Mo/W oxides	Heterogeneous	Vapor	~100%	90–95%
Methacrylic acid	Methacrolein	Air	N-1	V/Mo/W oxides	Heterogeneous	Vapor	90%	80–90%
C_2-C_8 carboxylic acids	C_2-C_8 saturated aldehydes	Air	N-1	None or Co,Mn, Cu salts	Homogeneous	Liquid	80–95%	>90–95%
Formaldehyde	Methanol	Air	N-2	Ag	Heterogeneous	Vapor	70–80% or >99%	89–92%
Formaldehyde	Methanol	Air	N-2	Fe-Mo oxides	Heterogeneous	Vapor	70–80% or >99%	93–96%
Maleic anhydride	Butane or butenes	Air	N-3,4	V-P oxide	Heterogeneous	Vapor	80%	70%
Acetaldehyde	Ethylene	Air	N-4	Pd/CuCl	Homogeneous	Liquid	>99%	92–94%
Acrolein	Propylene	Air	N-4	Bi/Mo/Fe/Co/K oxides	Heterogeneous	Vapor	>95%	80% acrol. 10% acry acid
Methacrolein	Isobutylene	Air	N-4	Bi/Mo/Fe/Co/K oxides	Heterogeneous	Vapor	>95%	~75–85%
Terephthalic acid	*p*-Xylene	Air	N-4	Co/Mn/Br	Homogeneous	Liquid	>99%	>98%
Phthalic anhydride	*o*-Xylene	Air	N-4	Ti-V oxides	Heterogeneous	Liquid	92–96%	75–85%
Benzoic acid	Toluene	Air	N-4	Co salts	Homogeneous	Liquid	>50%	90%
Cyclohexanone/ cyclohexanol	Cyclohexane	Air	N-4	Co/Cr salts	Homogeneous	Liquid	5–7%	75–80%
VAM	Ethylene/acetic acid	Air	N-4	Pd/Ag/K on α-Al_2O_3 or silica	Heterogeneous	Vapor	8–15% ethylene, 15–35% Acetic acid	94–96% on ethylene, >98% on acetic
VCM	1,2-Dichloroethane		N-4	Cu(II)Cl2 on γ-Al_2O_3	Heterogeneous	Vapor	93–97%	91–96%
1,3-Butadiene	Butanes/butenes	Air	N-3	Ferrite/Zn, ferrite/Mn	Heterogeneous	Vapor	>60%	90–93%

[a] *E* electrophilic; *N* nucleophilic; see text for number designation

stable products. Thus kinetic controls must be exploited to avoid overoxidation or complete combustion. Moreover, complete combustion releases typically four to ten times the energy of selective partial oxidations. Heat management is of paramount importance as non-selective reactions often have higher activation energies than the selective pathways, and are thus accelerated disproportionally by poor heat control. A large body of literature has been built up on heat and mass transfer, as well as reactor design. Some representative references are given below [116–118].

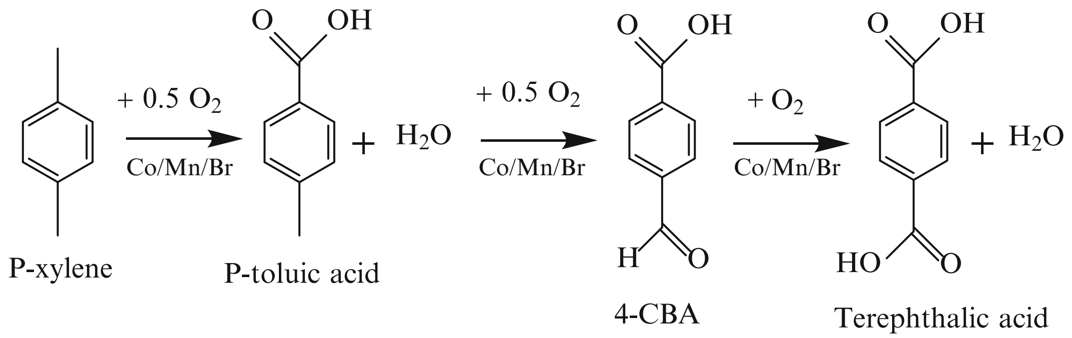
Responsible industrial implementation of oxidation chemistry requires understanding the implications of generating potentially flammable or explosive mixtures. The literature on safety issues, data and discussions of explosive limits is quite extensive. A few key references are cited here [119–123].

Homogeneous Aromatic Oxidations

Terephthalic, Isophthalic, Trimellitic Acids [124–126]

A number of aromatic carboxylic acids such as TPA, isophthalic acid (IPA), and trimellitic anhydride (TMA), are produced by the liquid phase air oxidation of the parent aromatic (*p*-xylene, *m*-xylene, and 1,2,4-trimethyl benzene respectively) with a homogenous catalyst comprising cobalt, manganese, and bromine salts. The key breakthrough in the development of this family of processes was the addition of the bromine promoter which resulted in a remarkably higher reaction rate and selectivity than with Co/Mn alone [127]. TPA is by far the largest volume product of this group and is produced via the stepwise oxidation of *p*-xylene:

The oxidation sequence begins by with hydrogen abstraction from one of the methyl groups of *p*-xylene by a bromine radical to form a benzyl radical. Dioxygen reacts with this species to form a hydroperoxide intermediate that passes through tolualdehyde on the way to toluic acid. Toluic acid is somewhat deactivated toward oxidation compared to *p*-xylene, but conversion of the second methyl group proceeds via a similar pathway, albeit at a slower rate.



ΔH_{rxn} = -1363 kJ/gmole

A simplified flowsheet for one commercial process is given in Fig. 10.20. Air is compressed (**1**) and fed along with *p*-xylene, acetic acid solvent, and catalyst salts into a bubble column reactor or CSTR (**2**). The reaction occurs in the liquid phase at 175–230°C, 1.5–3.0 MPa. The exothermic heat of reaction is removed by evaporation of the reaction mixture. These vapors are carried into the water column (**3**), where the water of reaction is removed overhead, and off-gases are vented to a scrubber to prevent emission of bromine species. The underflow of the water column, comprising acetic acid is returned to the process. Conversion of *p*-xylene is typically above 99%, with greater than 98% selectivity to TPA. Small amounts of acetic acid (about 36 kg/metric ton of TPA) and *p*-xylene are lost by complete oxidation to carbon dioxide and water. The inlet air rate is controlled so that the off-gases contain less than the minimum oxygen composition needed to form explosive mixtures.

TPA is highly insoluble at reaction conditions and largely precipitates as it forms. Efficient absorption and dispersion of oxygen is critical for the reduction of partially oxidized intermediates which can cause purity problems in the final TPA. 4-Carboxybenzaldehyde (4-CBA), generated at up 5,000 ppm in the oxidizer, tends to occlude in the TPA crystals and must be removed to give high quality TPA monomer. A class of compounds generated in ppm levels, known as florenones, are highly colored and result in yellowed polymer if not removed or destroyed in the TPA purification process.

Upon exiting the oxidizer, the crude TPA slurry is centrifuged and washed with acetic acid (**4**). Recycle of the Co/Mn/Br catalyst and purging of by-products in the filtrate and wash streams typically involve proprietary processes (**5**) that are extremely important for good economics. In order to reduce 4-CBA and toluic acid to acceptable levels, the crude TPA is subjected to a series of long residence time post oxidations (**6**) with air at high temperature and pressure. Although still a slurry in the post oxidizer, the crystals continually remelt and recrystallize in a steady state fashion, allowing occluded impurities to be further oxidized in solution. The TPA slurry effluent from the post oxidizers is fed to the flash crystallizer (**7**) for concentration and to build crystal size. Further solvent is removed in the vacuum flash drum (**8**). Crystals are collected on the rotary

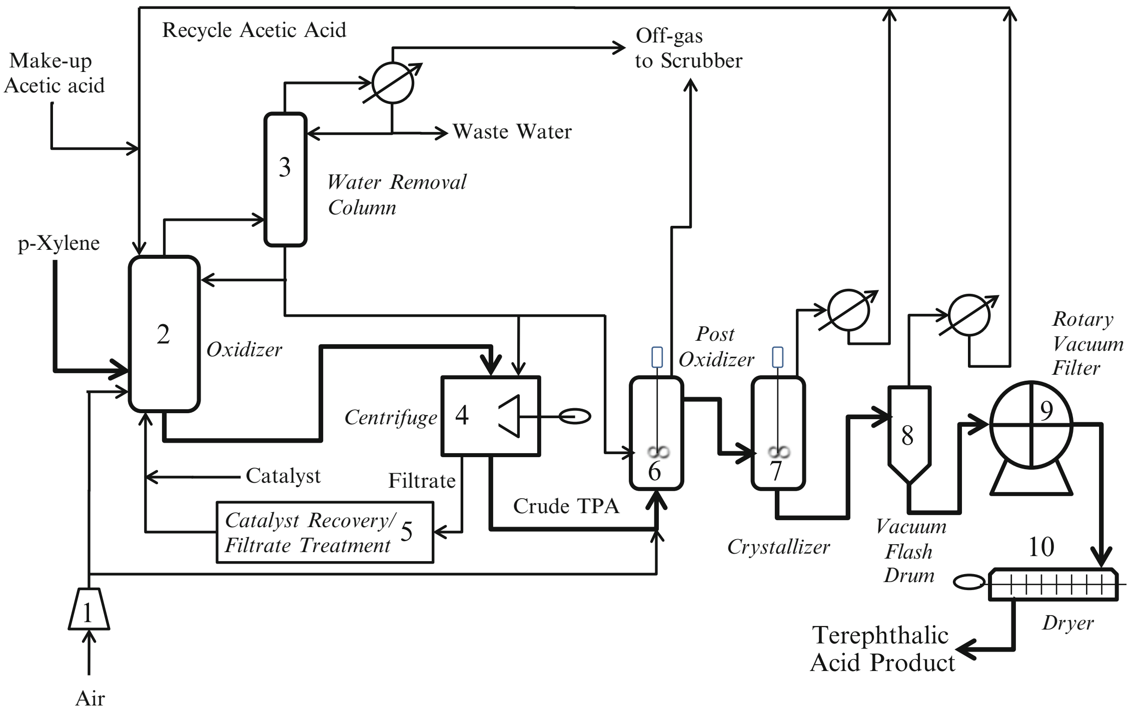


Fig. 10.20 Flowsheet for oxidation of *p*-xylene to terephthalic acid

vacuum filter (**9**) and the dryer (**10**) produces the final polymer grade TPA product with less than 200 ppm CBA and less than 10 ppm toluic acid. The high corrosivity of process streams necessitates the use of expensive titanium reactors and hastelloy in most other locations.

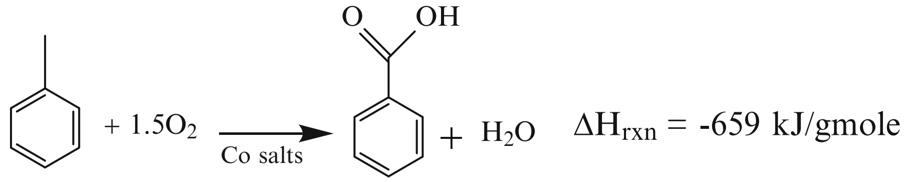
In another widely practiced process, the crude TPA from the centrifuge is dissolved in water at around 260°C. The aqueous TPA solution is hydrogenated over a Pd/carbon catalyst at high temperature and pressure to convert the 4-CBA to *p*-toluic acid and for color body destruction. The hydrogenated effluent is cooled, crystallized, centrifuged, washed, and dried to produce polymer grade TPA.

For many years the best method for purifying TPA to remove color bodies and monofunctional by-products was via esterification with methanol to produce dimethyl terephthalate (DMT), with subsequent distillative purification of DMT. However, the hydrogenation and post oxidation steps have demonstrated superior economics, although giving not quite as pure a product as the DMT route. DMT still finds use in a number of niche applications.

The production of IPA is very similar to TPA. However, IPA is 8–12 times more soluble (depending on temperature) in the reaction media than TPA, does not precipitate as readily, and has less issues with 3-CBA occlusion. On the negative side, IPA's higher solubility requires more stringent crystallization and purging protocols for high recovery.

Benzoic Acid [128, 129]

In a common industrial process, benzoic acid is produced via the liquid-phase air oxidation of toluene with a homogenous cobalt catalyst at 130–170°C, 0.3–1.0 MPa.

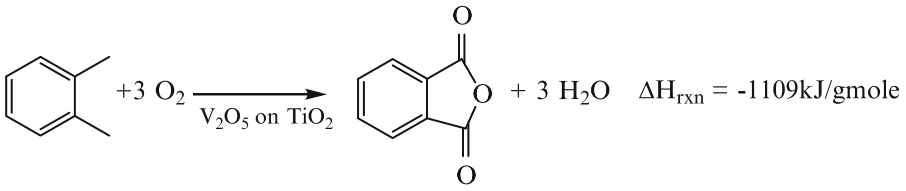


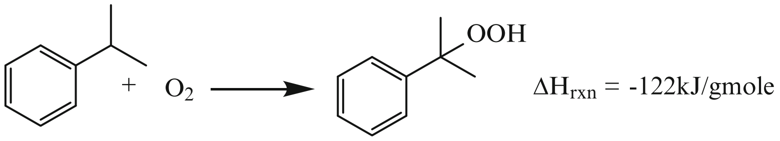
The reaction is carried out normally in a bubble column or CSTR. The exothermic heat of reaction is removed by evaporation of the reaction mixture, or via a circulating cooler. Partial conversion of toluene is typical, with selectivity on toluene of about 90% to benzoic acid, 7–9% to benzaldehyde, and the remainder a mix of benzyl alcohol, benzyl formate, methyl biphenylsm and other minor by-products. Unreacted toluene is flashed off and benzoic acid is purified by distillation. The heavy ends are extracted to recover cobalt. High purity benzoic acid may also be produced by recrystallization from water. As with TPA, the reaction proceeds through a free-radical chain process, with a hydroperoxide intermediate. Cobalt shortens the induction period, and retards by-product formation. Oxygen in the off-gas is kept below the critical explosive concentration to ensure safe operation.

Benzoic acid may be produced with the same catalyst system (Co/Mn/Br) at similar conditions to TPA and IPA, with essentially complete conversion and high yield. However, the use of Br requires expensive titanium and hastelloy metallurgy, whereas the cobalt system can be practiced in cheaper stainless steels.

Phthalic Anhydride [130–133]

In the early 1960s naphthalene from coke oven gases was the predominant raw material for phthalic anhydride production. Since the mid-1990s, over 90% of phthalic anhydride has been made from *o*-xylene over TiO_2-supported V_2O_5 catalsysts with promoters such as K, Cs, P, Sb, or Nb. The formation of phthalic anhydride from *o*-xylene is highly exothermic, with a heat of reaction of $-1{,}109$ kJ/gmole. Nonselective complete combustion is about four times more energetic per mole of xylene than the desired reaction. The reaction takes place at 360–390°C, less than 0.1 MPa.





Conversion of *o*-xylene is 92–96% per pass, with the molar yield on *o*-xylene is around 75–85%. Major by-products are CO_2, benzoic acid, phthalide, *o*-toualdehyde, and maleic anhydride. Formation of potentially explosive feed and product mixtures dictates a very low *o*-xylene to air mass ratio of 1/60 to 1/120 (or about 1.2 mole% in air) [134].

A simplified flow sheet for the high temperature partial oxidation of *ortho*-xylene in air is given in Fig. 10.21. The *o*-xylene feed is vaporized into air and fed into the fixed bed tubular reactor (**1**) where the heat of reaction is controlled by shell-side generation of high pressure steam or exchange against molten salt. The reactor effluent, containing around 1% phthalic anhydride and other by-products, is cooled by steam generation (**2**), and desublimated in a device called a switch condenser (**3**) (a cyclically operated finned heat exchanger in which the anhydride is solidified and periodically melted). The crude anhydride is thermally treated (**4**) at 230–300°C to decompose or polymerize some of the by-products, followed by distillation. The first column removes light ends such as benzoic acid and maleic anhydride (**5**), and the product column (**6**) takes phthalic anhydride overhead from heavies. Off-gases are scrubbed with water (**7**), to recover maleic and fumaric acids.

Peroxidations of Secondary or Tert-Alkyl Benzene Derivatives

Phenol/Acetone or MEK and Hydroquinone/Acetone [135–140]

Greater than 90% of phenol and acetone are produced worldwide by the air oxidation of cumene via a free radical chain mechanism in which cumene hydroperoxide (CHP) is the chain initiator. [1] The reaction is autocatalytic and reasonably exothermic. As shown in Fig. 10.22, cumene and air are reacted in two to four bubble columns in series (**1**) at 85–110°C, 0.5–0.8 MPa, to produce CHP at 25–30 wt% concentration in excess cumene.

---

[1] Most of the remainder of world acetone production is derived from dehydrogenation of isopropanol. See the section, "Dehydrogenation."

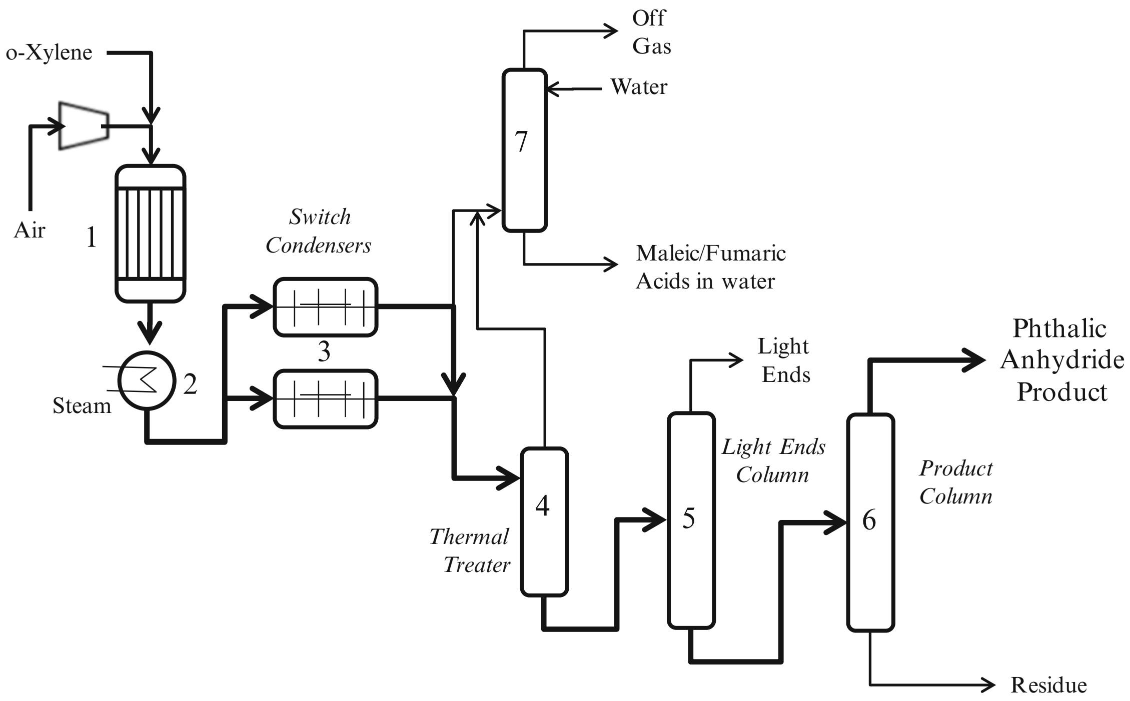


Fig. 10.21 Flowsheet for oxidation of *o*-xylene to phthalic anhydride

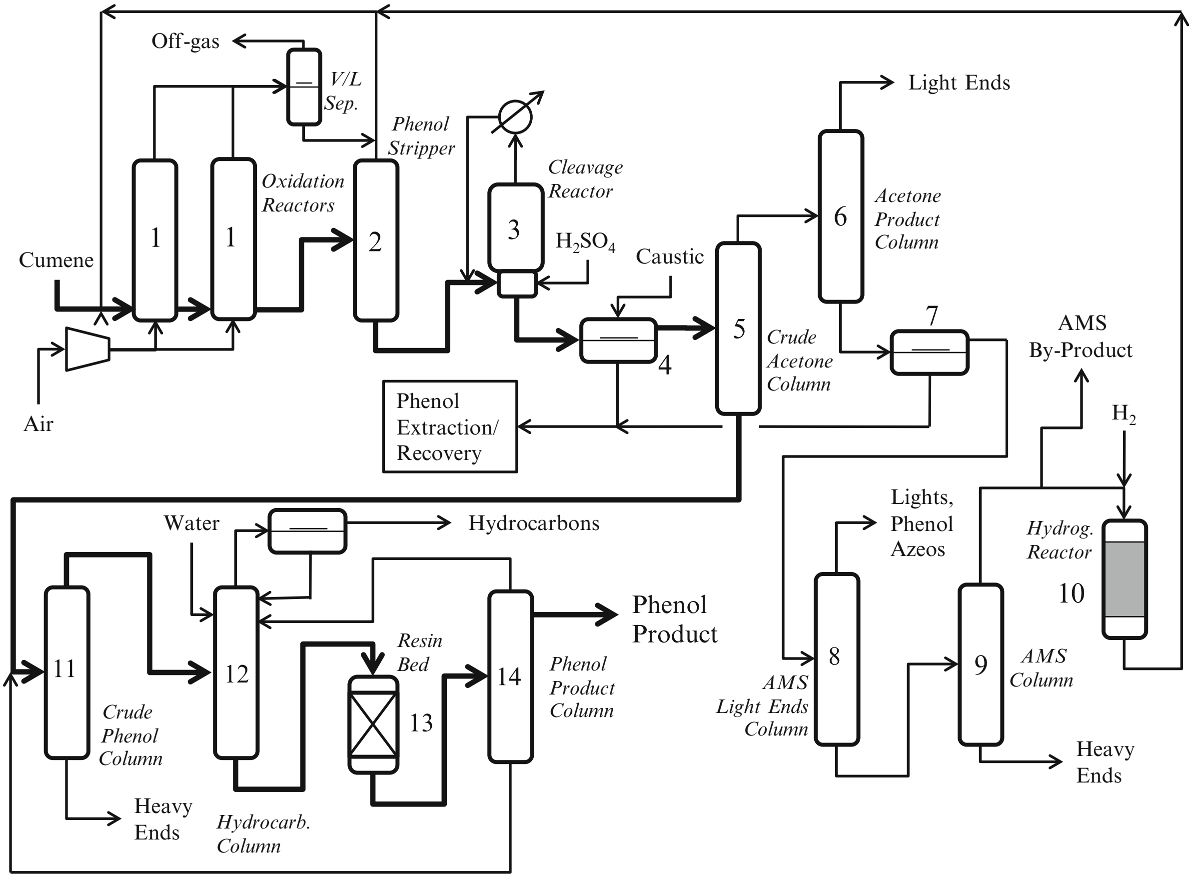

Fig. 10.22 Flowsheet for cumene hydroperoxidation to phenol/acetone

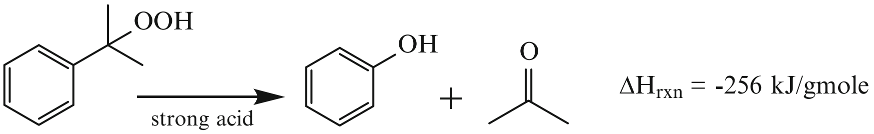
Temperature is controlled by evaporation of cumene and water as well as by cooling in external heat exchangers. Conversion of cumene is essentially complete with a selectivity of greater than 95% to CHP. Phenol is an inhibitor to oxidation, so cleavage to phenol is undesirable at this point. In some processes a small amount of sodium carbonate or sodium hydroxide is added to maintain a neutral solution and prevent the acid-catalyzed decomposition of CHP. Thermal decomposition of CHP (rapid above 130°C) leads to the by-products α,α-dimethylphenyl methanol (DMPM), acetophenone, methanol, formic acid, and acetic acid. Alkaline earth bismuthates, stannates, antimonates, and metal phthalocyanines are known to catalyze the reaction, but are not used industrially as they tend to also catalyze the decomposition of CHP to by-products. As both cumene and CHP are potentially explosive, the oxygen in the reactor off-gas is maintained at 1–6 volume %, below its critical concentration of 8.5–9.5% under reaction conditions.

The crude CHP from the bubble columns is vacuum-distilled (**2**) to remove cumene and concentrated to 65–85 wt% CHP. The concentrated solution is cleaved at 70–90°C in the presence of a strong acid catalyst such as sulfuric acid, to produce phenol and acetone in an exothermic reaction.



Temperature is controlled by boiling of acetone. Under these conditions DMPM dehydrates to α-methylstyrene (AMS), while diacetone alcohol and mesityl oxide form via aldol/dehydration of acetone. The cleavage mixture is neutralized with caustic or sodium phenolate, phase separated (**4**) and the organic layer is refined in a series of distillations. Many distillation sequences are possible and are practiced. One variation is shown in Fig. 10.22. The neutralized organic layer is fed to the crude acetone column (**5**) to distill acetone, mesityl oxide, water, lights, cumene, and AMS overhead from crude phenol and heavies. This distillate is further fractionated under vacuum in the acetone product column (**6**) to remove lights (aldehydes) overhead, acetone as a sidedraw near the top, and heavy water/hydrocarbon azeotropes out the bottom. Traces of caustic are sometimes added to this column to catalyze aldol condensations of aldehyde impurities into higher boiling, easily separable materials. The bottoms stream separates into two liquid phases (**7**). The organic phase is distilled to remove low-boiling AMS-cumene-phenol azeotropes overhead (**8**). After removal of heavies in the AMS column underflow (**9**), the AMS is subjected to hydrogenation (**10**) over Ni, Cu, or Pd catalysts and converted back into cumene for recycle.

In the crude phenol column (**11**), the bulk of the phenol is removed overhead with light organics. The crude phenol bottoms further distilled (**12**) for additional phenol recovery, with the residue used as fuel. Hydrocarbons are azeotroped out of the distilled phenol (**13**) with water and the bottoms phenol product is passed through a resin bed (**14**) to convert any carbonyls present to heavy ends. This treated material is subjected to a final distillation (**15**), with trace hydrocarbon/water removal overhead, and phenol product recovered as a sidedraw.

Decanter water streams are acidified, if needed, to convert the sodium phenolate contained therein back into phenol. Phenol is then recovered by extraction into cumene or other suitable solvents, distilled, and recycled. Overall selectivity on cumene is about 97.5%. Many other process variations are practiced.

Hydroperoxide Co-product Processes for Propylene Oxide

Although differing from ethylene oxide by only one extra carbon in the backbone, propylene oxide (PO) has not been made successfully at commercial scale by the direct oxidation of propylene. The presence of allylic hydrogens dramatically and adversely affects the efficacy of silver-based catalysts for the selective oxidation of propylene to PO with oxygen [141]. In spite of significant research over the last several decades, no catalysts have been found that show commercially viable yields or rates. Instead, all world scale PO plants rely on indirect oxidation of propylene by either the chlorohydrin route (50% of total, see the section, “Propylene Oxide via Propylene Chlorohydrin”) or co-product hydroperoxide routes (50% of total, described herein).

Styrene/Propylene Oxide Co-production [142]

About 15% of commercial styrene is produced by the rather complex air oxidation of ethylbenzene with coproduction of propylene oxide. The remaining 85% is produced via dehydrogenation of ethylbenzene (see the section, “Styrene from Ethylbenzene”). The process consists of four steps:

1. Ethylbenzene is oxidized directly by air to produce ethylbenzene hydroperoxide at around 130°C, 0.2 MPa, and 13% conversion per pass. Yields are about 90% to the

hydroperoxide, 5–7% to acetophenone and α-methylbenzyl alcohol.

2. The hydroperoxide is reacted with propylene (molybdenum or titanium catalysts) at about 110°C, 4.0 MPa, with essentially complete peroxide conversion to give α-methylbenzyl alcohol and propylene oxide. Propylene oxide and ethylbenzene for recycle are separated by distillation from the acetophenone and α-methylbenzyl alcohol.
3. α-Methylbenzyl alcohol is dehydrated in the vapor phase at about 250°C and low pressure over an acidic oxide such as alumina, to produce styrene. Styrene is purified by distillation.
4. Recovered acetophenone is hydrogenated in the liquid phase (Zn-Cu oxide catalyst) at 90–150°C, 8.0 MPa, to give α-methylbenzyl alcohol at 92% selectivity.

This route offers a pathway to propylene oxide without chlorohydrin production, but produces a weight ratio of styrene to propylene oxide of 2.5 to 1, which does not match the relative market demands of the two products and is quite capital intensive.

Tert-Butanol/Propylene Oxide Co-production [143]

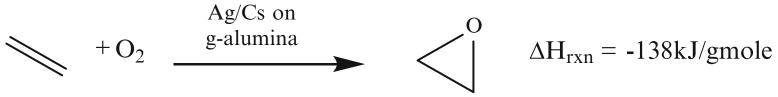
This route is similar to the styrene co-product process:

1. Isobutene is oxidized in the liquid phase with pure oxygen to produce tert-butyl hydroperoxide at around 130°C, 2.5–3.5 MPa, and 15–40% conversion per pass. Yields are about 50% to the hydroperoxide, 46% to tert-butanol, and a minor amount of aldehydes and ketones.
2. The hydroperoxide is reacted with propylene at a 1:10 M ratio (molybdenum catalyst in toluene) in a two-stage process. The first stage is held at about 110°C, 4.0 MPa, with the second stage elevated to 120°C to ensure essentially complete peroxide conversion. Propylene conversion is about 9% per pass at greater than 90% selectivity. Propylene and other lights are removed overhead by distillation for recycle, followed recovery of crude propylene oxide overhead and tert-butanol, catalyst, and other higher boiling by-products as underflow.
3. Production of high purity PO requires further distillation to remove lights such as ethylene oxide, and extractive distillation with a heavy hydrocarbon to remove close-boiling or azeotrope-forming hydrocarbons or carbonyls.

This route also offers a pathway to propylene oxide without chlorohydrin production, but produces a weight ratio of tert-butanol to propylene oxide of about 3 to 1. Economic utilization of the tert-butanol relies on demand for methyl-tert-butyl ether, or other secondary isobutylene markets.

Ethylene Oxide [144–149]

Ethylene oxide (EO) is one of the most versatile and reactive chemicals produced commercially at large scale. Formerly, EO was produced via the chlorohydrin of ethylene, similar to propylene oxide (see below). This route has been abandoned commercially in favor of the direct oxidation of ethylene. The use of high purity oxygen (>99%) instead of air as the source of the oxidant has become standard. A simplified flowsheet of a typical oxygen-based EO plant is shown in Fig. 10.23. Ethylene is reacted with compressed (**1**) oxygen over a silver-based catalyst in a multi-tubular fixed bed reactor (**2**), with a hot spot temperature of 250–275°C, 1–2.2 MPa pressure.



The complete combustion of ethylene to CO_2 and water releases −1,688 kJ/gmole. Commercial selectivities range from 80 to 90% on ethylene over the lifetime of the catalyst, resulting in a net heat load of 230–450 kJ/gmole. Ethylene conversion is 7–15% per pass. The off-gas from the reactor typically comprises 1–2 vol% EO, 5–6 vol% CO_2, 5–9 vol% O_2, 15–40 vol% ethylene, 5–15% inerts (Ar, N_2, ethane), and 1–60 vol% methane. The methane ballast gas acts as a heat sink and keeps the recycle gas above the upper explosive limit at the oxygen-recycle gas mix point.

The reactor effluent is cooled and EO is absorbed into water (**3**), or in some specialized plants into ethylene carbonate. The EO is recovered by distillation (**4**, **5**, **6**) from the water, if desired in pure form. Alternatively, the EO is reacted with water to produce a mixture of mono-, di-, and tri-ethylene glycols directly, or with CO_2, then water, to produce higher purity monoethylene glycol (see Section 10.8 below). The safe handling of concentrated EO requires an appreciation of its volatility (normal boiling point of 10.8°C), and ability to form explosive mixtures without an additional oxidant (the upper explosive limit goes up to 100% EO) [150, 151].

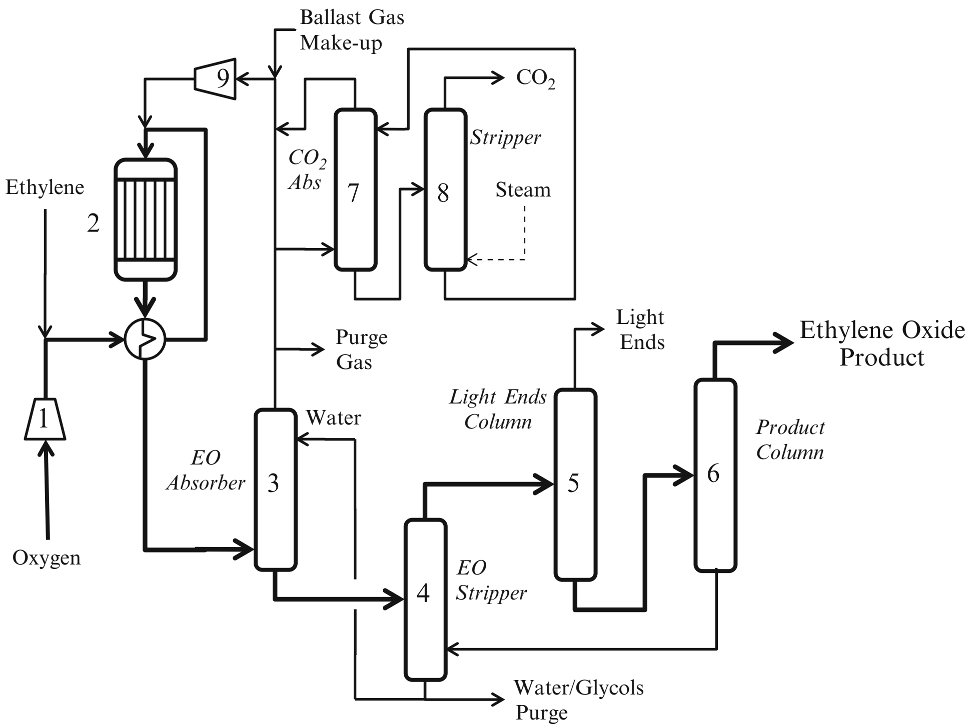


Fig. 10.23 Flowsheet for oxidation of ethylene to ethylene oxide

Carbon dioxide is a modest reversible retardant to the epoxidation reaction; a slipstream of EO-free recycle gas is treated with hot potassium carbonate to absorb out the CO_2 (**7**). The CO_2-rich absorbent is regenerated by vacuum steam stripping (**8**) [152]. A small purge is also removed to prevent the build-up of inerts from the ethylene and oxygen feeds, before recompression and recycle (**9**).

The only effective catalyst discovered thus far for this epoxidation reaction comprises silver on ultrapure γ-alumina, typically with a cesium promoter. Catalyst selectivity has dramatically improved over the past 40 years, from about 65% in 1966 to a maximum of about 90% today. A small continuous feed of a chlorinated hydrocarbon (1–10 ppmv), such as 1,2-dichloroethane, vinyl chloride, or ethyl chloride helps to suppress the combustion of ethylene, significantly improving yield and controllability. The beneficial effect of the chlorinated hydrocarbon was found serendipitously in the early days of commercial silver-catalyzed ethylene oxidation. The air intake for an EO plant was located near the off-gas outlet of a vinyl chloride plant. Unexpected improved performance of the EO reactor was eventually traced back to small quantities of chlorinated hydrocarbons present in the inlet air.

By adjustment of the Cs/Ag ratio on the catalyst, the analogous epoxide of butadiene, 1,2-epoxybutene, can be made by a similar vapor phase oxidation process [153].

Wacker Oxidation: Acetaldehyde [154–158]

Acetaldehyde, a very reactive and versatile molecule, historically was an important intermediate for the production of a wide variety of chemicals. Large volume applications included:

(a) *n-Butanol*, via aldol condensation to crotonaldehyde, followed by hydrogenation—now supplanted by hydroformylation of propylene (see section "Hydroformylation, Lower C_2-C_5 Olefins").

(b) *Terephthalic acid*, added as a peroxidant rate accelerator for the oxidation of *p*-xylene to TPA—now supplanted by more effective Co/Mn/Br catalyst systems.

(c) *Vinyl acetate*, via reaction with acetic anhydride or ketene to form ethylidene diacetate (EDA), with subsequent cracking to VAM—now supplanted by oxidative esterification of ethylene with acetic acid (see section "Esters via Oxidative Acetylation of Olefins, VAM").

(d) *Acetic acid*, via oxidation (see section "Oxidation of Aldehydes to Acids")—largely supplanted by carbonylation of methanol (see "Acetic Acid").

(e) *Ethyl acetate*, via Tishchenko reaction (see section "Tishchenko Reactions: Ethyl Acetate and 2,2,4-Trimethyl-1,3-Pentanediol Derivatives")—still practiced, competes against acetic acid-ethanol esterification (see section "Low-Boiling Esters").

(f) *Pyridine derivatives*, via reaction of paraldehyde (acetaldehyde cyclic trimer) with aqueous ammonia and formaldehyde [159]—still a significant outlet for acetaldehyde. Current applications are dominated by the latter three, while the first three, once the biggest uses, are essentially gone.

Acetaldehyde has been made by dehydrogenation of ethanol over Ag (similar to formaldehyde, See section, "Formaldehyde"). However, much of the remaining world capacity is based on the homogeneous $PdCl_2/CuCl_2$-catalyzed

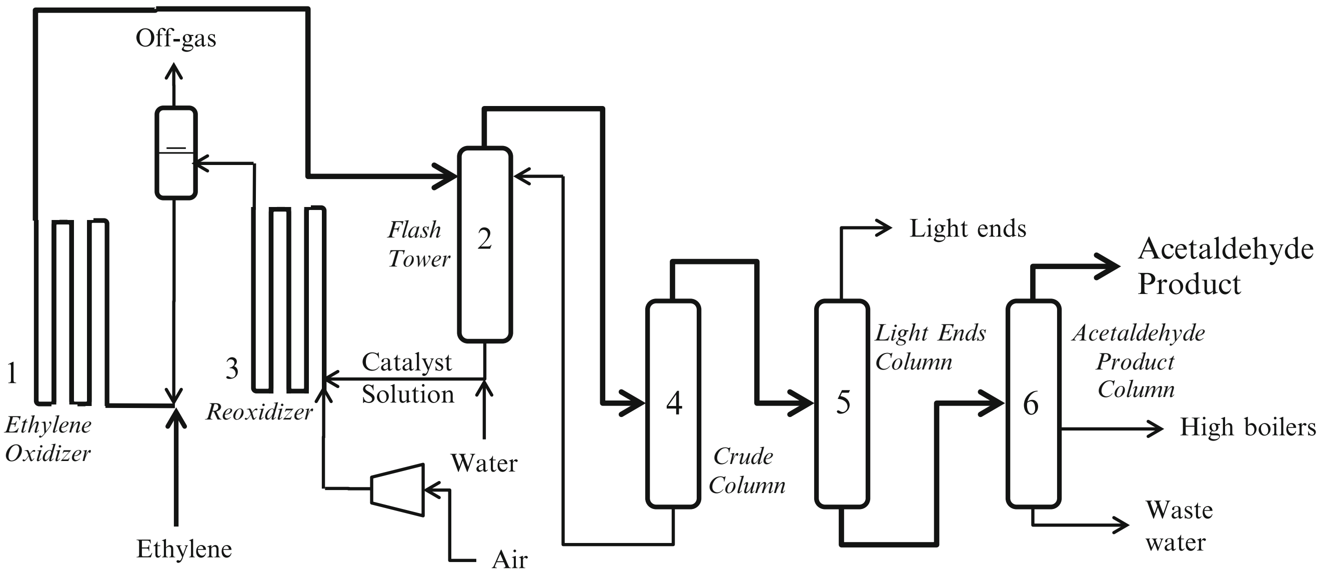

Fig. 10.24 Flowsheet for Wacker oxidation of ethylene to acetaldehyde

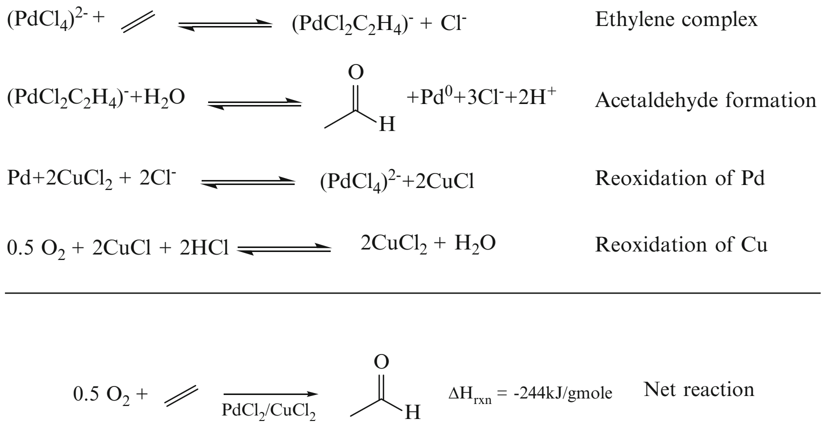
direct oxidation of ethylene with air developed in the late 1950s. The catalytic cycle begins with the complexation of Pd with ethylene. Water addition leads to hydride transfer and reductive elimination to produce acetaldehyde, reduced Pd, and hydrochloric acid. Cupric chloride reoxidizes the reduced Pd, regenerating the active Pd species. Finally, cuprous chloride is re-oxidized by oxygen back to Cu(II). The net reaction is the addition of 0.5 moles of oxygen to ethylene.



The palladium catalyzed oxidation of an olefin is highly efficient and only a small concentration of expensive Pd is required for commercially viable rates if sufficient (and comparatively inexpensive) reoxidant is present.

Both one-stage (ethylene reaction and entire redox cycle occur in one vessel) and two-stage (ethylene reaction and reoxidation of cuprous chloride with air in separate vessels) processes have been commercialized, although the two-step process was and is more prevalent. In a typical commercial two-step process, as illustrated in Fig. 10.24, ethylene gas is mixed with freshly reoxidized aqueous catalyst solution and passed through a tubular serpentine reactor (**1**) at 105–110°C, 0.9–1.0 MPa, where acetaldehyde is formed with close to 100% conversion of ethylene. The catalyst solution contains a substantially higher molar concentration of Cu(II) than Pd (typically 150 to 200 to 1), allowing multiple Pd turnovers per reactor pass. The reactor effluent is then flashed (**2**) to remove most of the acetaldehyde as vapor, along with water, and by-products, prior to the lean reduced catalyst solution entering the second tubular reactor (**3**). Air is compressed to about 1.0 MPa and allowed to react with Cu(I) ions at about 100–110°C, to regenerate Cu (II). Recycled and make-up water is added to maintain the catalyst concentration before reentering the ethylene reactor. Conversion of ethylene is close to 99%, with a selectivity of greater than 94%. By-products include chloroacetaldehydes (1–2 mole%), ethyl chloride, chloromethane (0.5–1.0%), carbon dioxide (~0.8%), and acetic acid (2–4%) resulting from over-oxidation of acetaldehyde.

The crude acetaldehyde is purified by a series of distillations. Acetaldehyde is concentrated in the crude column (**4**), with underflow returned as reflux to the flash tower. In the light ends column (**5**), low-boiling substances (chloromethanes, chloroethane, carbon dioxide) are removed overhead. Aqueous acetaldehyde and high boilers are distilled further in the product column (**6**), with high purity acetaldehyde collected as distillate, water/acetic acid as underflow. A fraction of the underflow is purged to prevent buildup of acetic acid, the rest recycled. Mid-boiling chloroaldehydes are removed as azeotropes with water in a sidedraw. This stream may be further concentrated if desired in a sidedraw stripper. The catalyst solution contains appreciable free hydrochloric acid and is quite corrosive. Significant parts of the plant must be constructed of corrosion-resistant materials such as titanium. Small amounts of chloride are lost in the chlorinated by-products. A constant makeup of chloride is fed as hydrochloric acid.

This process may also be adapted for higher olefins, with production of the corresponding internal carbonyl (i.e., ketone) predominating. Thus, propylene gives acetone and 1-/2-butenes give methyl ethyl ketone (MEK), typically 88–92% yield on the olefin. Acetone was produced commercially in Japan for a number of years via the Wacker oxidation of propylene, but the plant has subsequently shut down.

Considerable literature has been published in the past two decades on the use of vanadium-molybdenum-phosphorus homogeneous heteropolyacids (HPA) as replacements for the copper-based reoxidant. The required $PdCl_2$ concentration is considerably reduced, HCl concentration is essentially zero, and formation of chlororinated by-product species is claimed to be virtually eliminated [160, 161]. No commercialized applications of HPA systems are known.

Acrolein/Acrylic Acid and Methacrolein/ Methacrylic Acid [162–165]

Acrylic and methacrylic acids are produced commercially by similar two-step oxidations of propylene and isobutene/isobutene. Propylene oxidation is now the dominant route for acrylic acid, while several methacrylic acid processes are competitive including acetone cyanohydrin (see Chaps. 14 and 22), propionaldehyde/formaldehyde aldol/oxidation (see section “Mannich Base Condensation: Methacrolein”), ethylene carbonylation, and isobutene oxidation. For acrylic acid, propylene/air/steam at a ratio of 1:8:4 (plus recycled gas) is fed over a bismuth molybdate oxide catalyst in a multi-tubular fixed bed reactor at 300–400°C, 0.15–0.25 MPa.

Conversion of propylene is greater than 95% per pass, with a yield of 80% acrolein, 5–10% acrylic acid. By-products are CO, CO_2, acetic acid, acetaldehyde, and polyacrolein. The reactor is cooled by molten salt circulation and steam generation. A world scale reactor with 40,000 tubes in a single shell can produce 100,000 metric tons/year, with a catalyst lifetime up to 10 years.

Pure acrolein can be obtained by water washing of the reactor gases to knock out acids, followed by quench absorption in water. The crude, wet acrolein is distilled overhead, with additional steps for light/heavy ends removal. Acrolein is prone to oligomerization; hydroquinone or a derivative is added as a stabilizer.

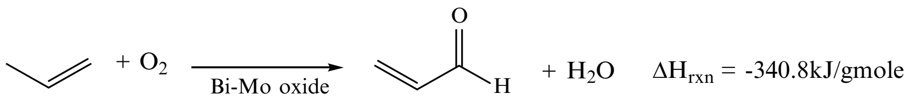
More commonly acrylic acid is the desired end product. The crude acrolein gaseous effluent is sent directly to a second salt/steam cooled multi-tubular fixed bed reactor operating at around 260°C to complete the oxidation to acrylic acid.

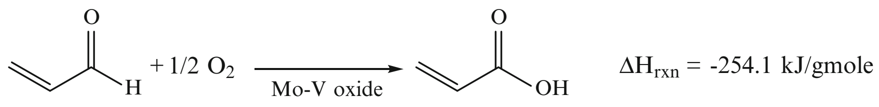
Conversion of acrolein is essentially 100% at greater than 90% yield. Modern catalysts comprise Molybdenum– vanadium oxides with copper, tungsten, or cerium promoters. The reactor effluent is cooled further by steam generation.

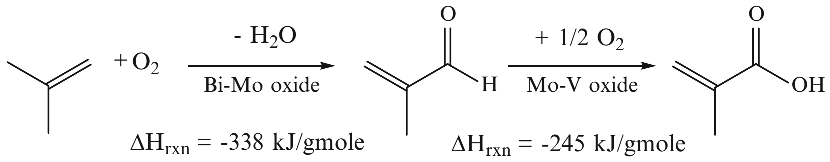
Many different approaches are practiced for the recovery and purification of the acrylic acid. In one variation, the crude acrylic acid is quenched and absorbed into water to produce a 20–70 wt% solution in water. The acrylic acid is concentrated by extraction into an organic solvent (examples are ethyl acetate, MEK, butyl acetate, ethyl acrylate), followed by azeotropic distillation of the extract phase. Water is removed overhead as the solvent-water azeotrope, and the dry acrylic acid bottoms product is distilled overhead in a second column, with oligomers, dimers, and polymers taken as underflow. Additional acrylic acid is recovered from the heavy ends by decomposition of acrylate dimers in an evaporator.

In a second recovery scheme, the cooled acrylic acid reactor effluent is absorbed into a high boiling ester rather than water. This eliminates the extractor, but azeotropic distillation is required for drying, and the acrylic must be distilled from the ester. In both processes, an inhibitor (phenothiazone, hydroquinone, or hydroquinone monomethyl ether) is added to prevent polymerization of the acrylic acid.

In an analogous process for methacrylic acid, isobutene/air/steam at a ratio of 1:11.5:7.5 (plus recycled gas) is fed over a bismuth molybdate oxide catalyst at about 350°C, followed by second stage oxidation over Mo–V oxides at about 280°C







The multi-tubular fixed bed reactors are cooled by molten salt circulation and steam generation. Conversion of methacrolein is around 90% per pass to keep selectivity to 80–90% methacrylic acid. Product recovery by distillation is similar.

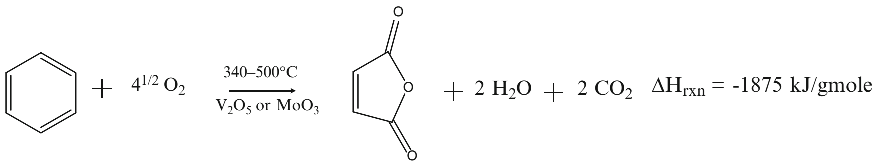
KA Oil: Cyclohexanone/Cyclohexanol [166–168]

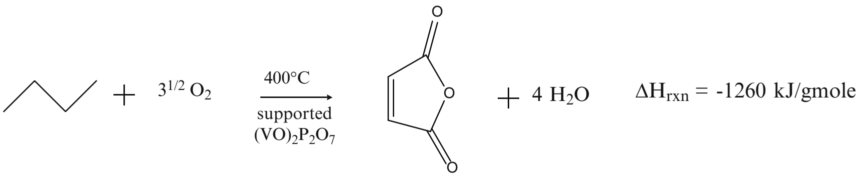
A mixture of cyclohexanone and cyclohexanol known as KA (Ketone-Alcohol) oil is made predominately by the liquid phase cobalt-catalyzed air oxidation of cyclohexane at 140–160°C, 0.8–2.0 MPa. A typical catalyst is the soluble Co(II) naphthenate, which gives a ketone to alcohol ratio of 1:1 to 1:3.5. Conversion must be kept low (about 5–7% per pass) in order to achieve selectivities as high 75–77%. The addition of chromium increases the ketone to alcohol ratio close to 2:1, while promotion with boron compounds such as boric anhydride (B_2O_3), boric acid (H_3BO_3), or metaboric acid (HBO_2) results in a ketone to alcohol ratio as low as 1:10 and increased selectivity to 85–90%. Stoicheometric amounts of slurried borate are required and must be recycled. In an alternative approach, the cyclohexyl hydroperoxide intermediate is formed in an initial uncatalyzed air oxidation step, followed by decomposition in the presence of cobalt or other transition metal catalyst. Yields as high as 84% are achievable with the high hydroperoxide route. In all process variations, the crude KA oil is purified by water extraction for removal of dibasic acids such as adipic, glutaric, and succinic, as well as C_4-C_6 carboxylic and hydroxycarboxylate acids, followed by distillation.

KA oil is an important intermediate for the production of both adipic acid and caprolactam for nylon-6,6 production (see Chap. 22). Purified cyclohexanol and cyclohexanone both find limited uses as solvents.

Maleic Anhydride [169–172]

Prior to 1975, benzene was the predominant raw material for the production of maleic anhydride. Currently worldwide, over 80% of maleic anhydride is made from butane or butane/butene mixtures of high alkane content. About 2% is recovered as a by-product of phthalic anhydride production, and the remainder is derived from benzene. The formation of maleic anhydride from either benzene or butane is highly exothermic.





Nonselective complete combustion of benzene (−3,136 kJ/gmole) and butane (−2,655 kJ/gmole) are much more energetic than the desired reaction.

Benzene is oxidized in air over V_2O_5 or MoO_3 catalysts in a multi-tubular fixed bed reactor at 340–500°C, 0.15–0.25 MPa, with molten salt-steam generation for heat control. The benzene content is kept below the lower explosive limit (LEL). Typically more steam is generated than is needed in the process. Selectivity to maleic anhydride is around 73 mole% at 96% conversion per pass.

Typical conditions for the air oxidation of *n*-butane are a temperature of about 400°C, pressure of 0.15–0.25 MPa, with 80% conversion per pass, at about 70% selectivity to maleic anhydride. Vanadyl pyrophosphate, $(VO)_2P_2O_7$, often bound with TiO_2, SiO_2, or Al_2O_3, (with the latter two supports used for abrasive service in fluid beds) is the only material found thus far with high enough selectivity to be used commercially for butane oxidation. Multi-tubular fixed bed, fluid bed, and transport reactors have all been used for this service. The inlet gas to a multi-tubular reactor is kept below the LEL, about 1.8% butane, while the excellent heat control and thermal mass of the circulating catalyst in the fluid bed design allows for operation in the explosive regime at close to the stoichiometric O_2 to butane ratio (about 5.5% butane). As a result, fluid bed processes have much smaller equipment in the reactor loop, and are favored for new installations.

Two alternative recovery and purification are practiced commercially. The reactor effluent is further cooled by generating lower pressure steam, and then is absorbed into either an organic solvent or water. If water is chosen as the absorbent, a substantial amount of the maleic anhydride may be hydrolyzed to maleic acid. The maleic acid/anhydride mixture must then be converted back. A common method for water removal is heterogeneous azeotropic distillation with an entrainer such as xylene. Maleic acid is prone to thermal isomerization to fumaric acid, a high melting (286°C) by-product. Thus, residence time at the high temperatures in the dehydrating column base must be kept to a minimum. The resulting concentrated maleic anhydride solution is then distilled to remove lights and traces of solvent, and then taken overhead to remove heavies.

When a high-boiling, water-immiscible solvent, such as dibutyl hexahydrophthalate, is used for absorption, much less maleic anhydride is converted into the acid. No separate dehydration step is required, resulting in much lower energy requirements. Maleic anhydride is stripped overhead from the rich solvent stream from the absorber. This crude anhydride is distilled to separate light and heavy impurities. A slipstream of lean recycle solvent is treated to eliminate any heavy by-product that may build up.

The transport process, commercialized in 1996, was revolutionary in its use of separate butane oxidation and catalyst reoxidation zones. The butane was oxidized by the oxygen lattice of the catalyst, which was then regenerated with air in a separate vessel. Air and butane were never mixed. However, an unexpectedly high make rate of fumaric acid in the transport reactor system caused severe operational difficulties and poor plant availability. These problems led to the permanent shut down and dismantling of the one and only commercialized transport reactor process in 2004 [173].

Formaldehyde [174–179]

The production of formaldehyde from methanol illustrates that many different process alternatives, such as choice of catalyst, conversion per pass, separation selection, and safety considerations, can lead to a commercially practiced, economically viable process. With the mixed metal oxide catalyst (Fe/Mo, often with Cr promoter), formaldehyde is produced via the endothermic oxidative dehydrogenation of methanol:

$$CH_3OH + 1/2\ O_2 \longrightarrow H_2C{=}O + H_2O \quad \Delta H_{rxn} = -157 kJ/gmole$$

The additional pathway of equilibrium-limited, endothermic dehydrogenation occurs simultaneously in a ratio of 40% dehydrogenation, 60% oxidative dehydrogenation on silver catalysts:

$$CH_3OH \rightleftharpoons H_2C{=}O + H_2 \qquad \Delta H_{rxn} = +85\ kJ/gmole$$

In a typical silver catalyst process, a mixture of air–steam–methanol is reacted adiabatically over a thin layer (2.5–3.0 cm thick) of silver gauze or crystals at slightly above atmospheric pressure and high temperature. The formaldehyde-rich effluent is cooled initially by steam generation, and formaldehyde is recovered from the gas in a water-fed circulating quench absorber. The hydrogen-rich absorber tail gas is burned for steam generation. Both complete and partial methanol conversion processes are practiced commercially. In the complete conversion process, the feed gas comprises sufficient methanol to be above the upper explosive limit (25–27 mole% methanol), along with 46–54 mole% air, and 20–30 mole% steam. Conversion is greater than 99% at reaction temperature of 600–720°C, at a selectivity of 89–91%. A product of 40–55 wt% formaldehyde with <1 wt% methanol can be produced without further distillation. In the partial conversion process a mixture of 40–45% methanol, 20–25% air, and 20–35% steam is adiabatically converted to formaldehyde at 550–650°C. Methanol conversion is 70–80%, with a selectivity of 90–92%. Distillation is required to concentrate the product formaldehyde and remove unreacted methanol for recycle. Some vendors offer as high as 68 wt% formaldehyde with less than 1 wt% methanol.

The mixed metal oxide process operates below the LEL with 9 mole% methanol in air diluted with recycled off-gas and steam. The methanol is converted in a non-isothermal, multi-tubular fixed bed reactor at 350–390°C, where the heat of reaction is controlled by shell-side generation of high pressure steam. Formaldehyde is recovered by absorption into sufficient water to produce a solution of 50 wt% formaldehyde, with less than 1 wt% methanol without further distillation. Conversion is greater than 99%, at a selectivity of 93–96%. Purged gas does not contain sufficient combustibles and must be incinerated or catalytically oxidized with supplemental fuel. Formaldehyde is susceptible to oligomerization in the liquid phase and must be kept warm if concentrated, and is often stabilized with the addition of a small amount of methanol [180, 181].

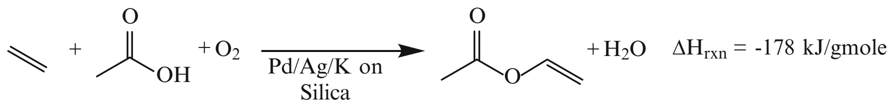
Esters via Oxidative Acetylation of Olefins, VAM [182–186]

Many routes for the production of the important monomer vinyl acetate (VAM), the unsaturated two-carbon ester of acetic, have been developed. These include:

1. Addition of acetic acid to acetylene form VAM directly (once a significant commercial process)
2. Reaction of acetic anhydride with acetaldehyde to form EDA, with subsequent cleavage to VAM and acetic acid (also once a significant commercial approach)
3. Carbonylation of methyl acetate with CO and H_2 to form EDA, with subsequent cleavage (never commercialized fully)
4. A vapor or liquid phase reaction of acetic acid, ethylene, and oxygen to form VAM and water

The latter route, as a gas phase reaction dominates commercial practice. In the typical industrial process acetic acid is vaporized and mixed with a fresh and recycle stream of ethylene. The combined gas is then mixed with high purity oxygen in a highly reinforced and shielded mixing unit. The feed gas to the reactor typically comprises 10–20 mol% acetic acid, 10–30 mol% CO_2, 10 mol% N_2, Ar or other inerts, 50 mol% ethylene, and less than 8 mol% oxygen. This composition is above the upper explosive limit.

The exothermic reaction occurs in a multitubular fixed bed reactor over a silica supported Pd/Ag/K catalyst at 140–180°C, 0.5–1.2 MPa. Steam is generated on the reactor shell side for heat removal and control of the hot spot temperature. By-products are water, carbon dioxide, and small amounts of EDA, ethyl acetate, acetaldehyde, methyl acetate, and glycol acetates.

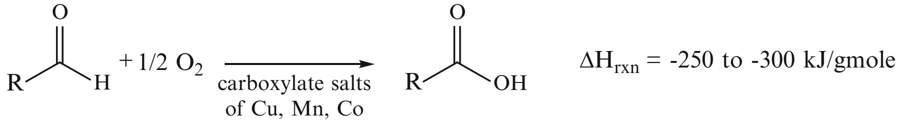


The reactor effluent is interchanged with the incoming feed gases and fed to a predehydration column, where about 50% of the water contained therein is removed by azeotropic distillation using the hot incoming gases for boil-up. The water/VAM azeotrope is taken overhead, decanted and VAM refluxed to the column. The crude VAM in the bottoms stream (20–40% VAM, 6–10 wt% water, the rest acetic acid and by-products) is dehydrated further by a similar water/VAM heterogeneous azeotropic distillation, with the VAM phase refluxed. The aqueous phase is further steam stripped to recover VAM for recycle to the first column and wastewater discharged as underflow. Final purification occurs in a third column, with the product VAM taken overhead, ethyl acetate as a sidedraw, and acetic acid and heavies (EDA, glycol acetates) as the bottoms. The acetic acid is recycled, with a heavy purge taken from the sludge of the acetic acid evaporator.

The ethylene-rich off-gas from the predehydrator is largely recycled, but a fraction is purged to prevent build-up of argon and nitrogen, and another portion is scrubbed with water to remove acetic acid prior to contacting with hot potassium carbonate system for carbon dioxide removal. Per pass conversion of ethylene, acetic acid, and oxygen range from 8–15%, 15–35%, and up to 90%, respectively. Selectivities of 94–96% on ethylene and greater than 98% on acetic acid are achievable.

Oxidation of Aldehydes to Acids [187]

The principle industrial route to C_3-C_{10} carboxylic acids is by the homogeneous liquid phase oxidation of the corresponding aldehyde, due to their wide availability from hydroformylation.



Examples of acids produced at large scale by aldehyde oxidation are propionic, *n*-butyric, isobutyric, *n*-valeric, isovaleric, and 2-ethylhexanoic acid. This chemistry typically is not sufficiently selective for use with unsaturated aldehydes (e.g., acrolein, methacrolein). Other methods are used for these substrates (see above, this section).

The oxidation may be carried out with oxygen or more typically with air, usually without an additional solvent, and with or without a catalyst present. Oxidation of a branched-chain aldehyde, exemplified by 2-ethylhexanal, is extremely sluggish and non-selective without a catalyst, while straight chain moieties can be oxidized successfully without a catalyst. The most effective catalysts are primarily transition metal ions that can transfer only one electron, and have two valence states of equal stability to allow efficient oxidation/reduction, such as Cu^{I}/Cu^{II}, Co^{II}/Co^{III}, and Mn^{II}/Mn^{III}. The metal is most conveniently introduced into the reaction system as the carboxylic acid salt of either acetic acid (commonly available) or as the salt of the acid to be produced. Although these oxidations typically give greater than 90–95% selectivity, common types of by-products include formate esters, ketones, and $n-1$ hydrocarbons and alcohols.

A transition metal-catalyzed oxidation reaction proceeds through a number of identifiable steps: (1) a hydrogen atom is abstracted from an aldehyde molecule by a metal ion to form a carbonyl radical, with reduction of the oxidation state of the metal; (2) dioxygen adds to the carbonyl radical to form a percarbonyl radical; (3) the percarbonyl reacts with another aldehyde molecule to form a peracid and regenerates a carbonyl radical (chain propagation); (4) the peracid reacts with another aldehyde molecule to form two acid molecules; (5) the metal is returned to its original oxidation state via reaction with a peracid, with formation of an acid molecule. The catalyst acts as an initiator for rapid generation of a high flux of carbonyl radicals, but also can inhibit the reaction if at too high a concentration (too many radicals, not enough free aldehyde to accomplish step 3). Typically there is an optimal catalyst concentration that balances radical chain formation and decomposition. Without a catalyst, there is often a lengthy induction period, before sufficient radials are generated to kick off the chain mechanism.

In a generic industrial process illustrated in Fig. 10.25, air, the aldehyde substrate, and the catalyst are fed to a bubble column reactor or CSTR (**1**) at 50–150°C, close to atmospheric pressure. Conversion of aldehyde is 80–95%, depending on the substrate. The off-gas from the reactor is cooled to remove condensable species, separated into vapor and liquid phases (**2**), and off-gases are scrubbed to remove traces of organics before emission to the atmosphere. Temperature, air, and aldehyde flow are adjusted to ensure that the exit gas is outside of the explosive region.

Liquid product from the reactor, containing unreacted aldehyde, product acid, catalyst, and a range of high, medium, and low boiling by-products is distilled (**3**), with materials boiling lighter than the product acid taken overhead and acid, catalyst, heavies as bottoms product. Depending on the by-product slate (some oxidations produce formate esters and ketones boiling closely to the aldehyde), the distillate of the crude column may be further treated in one or two columns to remove lights (**4**), medium boilers (**5**), and to recycle unreacted aldehyde. The crude acid is taken overhead in the product column (**6**), with concentrated catalyst underflow for recycle, less a purge for heavy ends.

Carbonylation

Chemistry

Carbonylation is a catalytic reaction between carbon monoxide (CO) and an organic substrate to form a new carbon–carbon bond with the introduction of an oxygen-containing functional group into the product. Technically any reaction involving CO alone or in tandem with another molecule, e.g., H_2 or H_2O is a carbonylation. However, historically reactions involving the insertion of CO and H_2 commonly have been known as hydroformylation or oxo reactions. This important class of carbonylations is treated separately in the section, “Hydroformylation.” In this section, the types of carbonylation reactions highlighted are:

1. Liquid phase reaction of CO with methanol or methyl acetate catalyzed by homogeneous Rh or Ir complexes to form acetic acid or anhydride
2. Liquid phase reaction of CO with methanol catalyzed by a strong base to form methyl formate
3. Liquid phase reaction of CO and ethylene with methanol over a strong base catalyst to form methyl propionate
4. Liquid phase reaction of CO, water, and olefins catalyzed by a strong acid to form neo acids, also known as Koch carbonylation or hydrocarboxylation

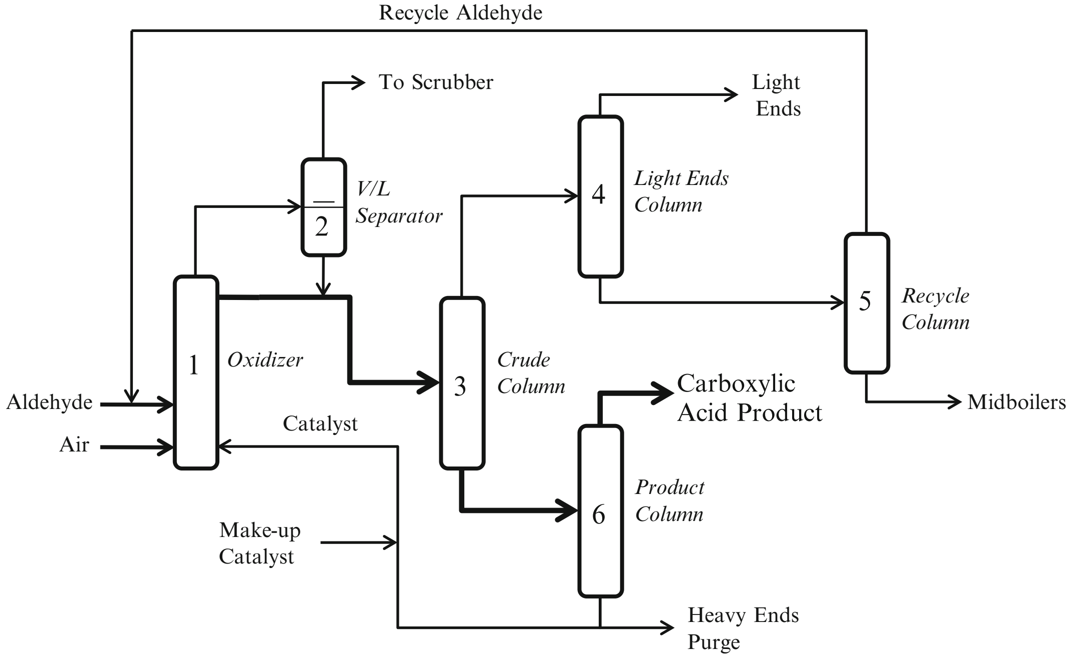


Fig. 10.25 Flowsheet for oxidation of aldehydes to carboxylic acids

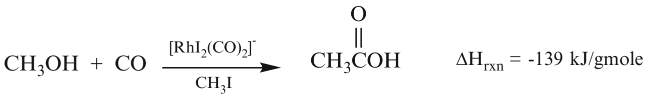
Acetic Acid [188–193]

The carbonylation of methanol has largely displaced earlier synthetic routes to acetic acid such as partial oxidation of hydrocarbons, fermentation of carbohydrates, and oxidation of acetaldehyde derived from ethylene. Methanol carbonylation, a net insertion of carbon monoxide into methanol, has been known since 1913 and practiced commercially since the 1950s, initially as a high temperature, high pressure process (250°C, 70 MPa) using cobalt iodide as a catalyst. The breakthrough for methanol carbonylation occurred in the late 1960s with the discovery of rhodium catalysts promoted with methyl iodide, allowing operation at much lower temperatures and pressures and much higher productivity and yield than the original cobalt systems.



$$CH_3OH + CO \xrightarrow[CH_3I]{[RhI_2(CO)_2]^-} CH_3\overset{\overset{\displaystyle O}{\|}}{C}OH \qquad \Delta H_{rxn} = -139\ \text{kJ/gmole}$$

Under reaction conditions, the active catalyst is the $[RhI_2(CO)_2]^-$ anion. Oxidative addition of methyl iodide (formed from HI and methanol) $[RhI_2(CO)_2]^-$ followed by insertion of CO into the Rh-CH_3 bond and coordination of CO yields $[CH_3C(O)RhI_3(CO)_2]^-$. Reductive elimination of acetyl iodide (CH_3COI) liberates the original $[RhI_2(CO)_2]^-$ complex, and rapid hydration of acetyl iodide produces acetic acid and regenerates HI. The reaction is zero order in methanol and CO and first order in methyl iodide and rhodium. The concentration of methyl iodide in the reactor is substantial, around 20–25 wt%. With the original Rh—methyl iodide system, high water concentration (14–15 wt%) is required for high activity and for Rh stability. This high water level also promotes the water-gas shift reaction, resulting in byproduct CO_2 and H_2. Propionic acid is the major heavy byproduct, formed primarily via carbonylation of ethanol resulting from small quantities of acetaldehyde formed by acetic acid reduction or homologation of methanol.

Table 10.30 Commercial methanol carbonylation systems

Active catalyst species	Promoters	Reactor water content (wt%)
$[RhI_2(CO)_2]^-$ complex	CH_3I	14–15
$[RhI_2(CO)_2]^-$ complex	CH_3I, LiI	4–5
$[RhI_2(CO)_2]^-$ complex, bound to polyvinyl pyridine resin	CH_3I	3–7
$[IrI_2(CO)_2]^-$ complex	CH_3I, Ru or Re salts	<8

Many catalytic advances have been made since the 1970s, enhancing selectivity, productivity, and reducing energy usage. The four basic catalytic systems used in practice today are summarized in Table 10.30. The latter three allow high selectivity and productivity at much lower water content in the reactor loop than the original Rh-methyl iodide system. The water-rich end of acetic acid–water vapor–liquid equilibrium is fairly pinched, the heat of vaporization of water is high, and all the water present in the reactor loop must be distilled overhead, so low water content translates into substantial energy and capital savings.

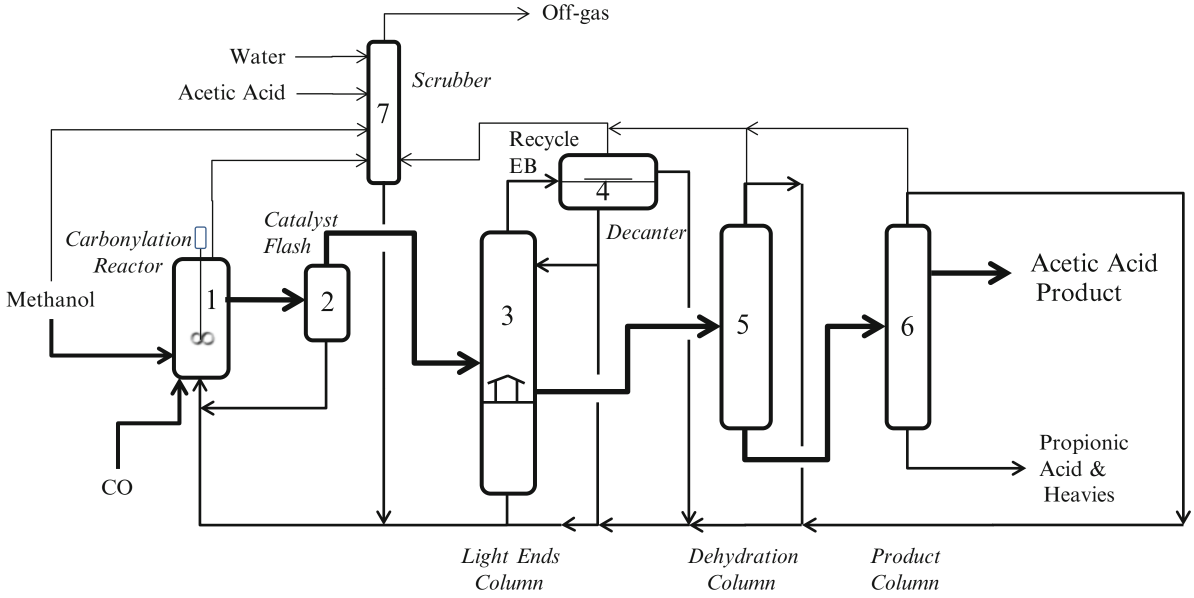


Fig. 10.26 Flowsheet for carbonylation of methanol to acetic acid

The addition of LiI greatly enhances rates by assisting in formation of methyl iodide from methanol and stabilizes the rhodium complex under low water conditions. Use of a heterogeneous rhodium catalyst, addresses many of the drawbacks of the original homogeneous Rh system. The rhodium is immobilized in a highly stable state on a polyvinyl pyridine resin. The bound, catalytically active $[RhI_2(CO)_2]^-$ remains stable at low water levels, and without LiI addition. The reaction is accomplished in a three phase gas lift reactor. By-product propionic acid, CO_2 and H_2 production are reduced.

Iridium-based carbonylation has been commercialized fairly recently by BP (the Cativa process), and is yet a third method to reduce water content. The rate of methyl iodide addition to the active $[IrI_2(CO)_2]^-$ complex is about 150 times faster than to $[RhI_2(CO)_2]^-$. Insertion of CO to form the iridium acetyl species is the slow step, but is accelerated by addition of Re or Ru promoters. Substantial Ir concentrations are required for good rates, but low water operation is possible with lower methyl iodide concentrations and without LiI addition. With Ir, production of propionic acid, CO_2 and H_2 is reduced, but methane formation is higher.

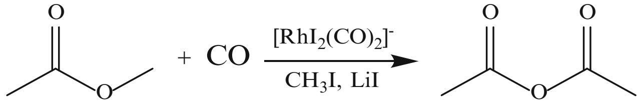
A flow sheet for a typical modern acetic acid plant is shown in Fig. 10.26. High purity carbon monoxide, methanol, catalyst, and promoters (methyl iodide and others), are introduced into a CSTR or gas lift (thermosyphon) reactor system (**1**) operated at (150–200°C, 2–4 MPa). The exothermic heat of reaction is controlled by flashing of the reactor effluent to produce a crude acetic acid vapor product and a catalyst residue for recycle to the reactor (**2**). Noncondensable byproducts, (methane, hydrogen, carbon dioxide) are vented from the reactor loop to control the CO partial pressure. These off-gases must be thoroughly scrubbed, typically by a staged absorption system of methanol, acetic acid, water to ensure that no iodine containing species are released (**7**).

The crude acetic acid from the flash unit is sent to the light ends column (**3**) where methyl iodide, water, and methyl acetate are taken overhead as a two phase mixture (**4**) for recycle to the reactor. Bottoms from this column are recycled to the reactor and wet acetic acid is taken as a vapor side draw above the feed. The wet acid is dehydrated in another column (**5**), with dry acid as underflow, and water/acetic acid distillate for recycle. The product column (**6**) produces glacial acetic acid as a sidedraw high in the column. Overhead material is recycled and by-product propionic acid and heavies are purged as underflow. Overall selectivity on methanol is typically 99% and greater than 90% on carbon monoxide.

Although highly selective and productive, Rh and Ir are very expensive, requiring millions of dollars for catalyst inventory. Moreover, the processes require high metallurgy (many parts Hastelloy) and appropriate systems to handle volatile iodide species.

Acetic Anhydride [194–196]

Acetic anhydride is an important acetylating agent for the production of such materials as cellulose acetate esters, ibuprofen and other pharmaceuticals, and hard-to-esterify esters. The predominant route to acetic anhydride involves the thermal cracking of acetic acid to ketene and water, followed by the reactive absorption of ketene into acetic acid (see the section, “Ketene”). However since 1983, a significant fraction of acetic anhydride (about 20% worldwide, over 50% in the USA) is produced via the carbonylation of methyl acetate:



ΔH$_{rxn}$ = -95 kJ/gmole

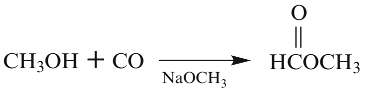
The carbonylation of methyl acetate is similar in many respects to the carbonylation of methanol described above, but differs in some key aspects:

1. Methanol carbonylation is done in an aqueous medium. Anhydride production necessitates anhydrous conditions, with significantly reduced Rh stability/solubility at reaction conditions.
2. Hydrogen addition is required to generate and maintain the active catalyst form. Unlike in the aqueous methanol system, no water is available for in situ hydrogen generation via water-gas shift.
3. LiI promoter is absolutely required to generate the active Rh catalyst species and to activate the alkyl methyl group of methyl acetate under anhydrous conditions.
4. Methyl acetate carbonylation is equilibrium-limited, with conversion of methyl acetate between 50 and 75% vs. essentially 100% in methanol carbonylation.
5. The by-product slate is different. EDA, "tars," acetone, and CO_2 are the primary by-products. Propionic acid is not formed to any extent, nor is methane.
6. Production of "tars," primarily derived from by-product EDA, is significantly higher under methyl acetate carbonylation conditions. These tars must be purged and tend to bind Rh more effectively than acetic acid residue. A much more complex tar purge/Rh recovery system is required.

In the anhydride production process, methyl acetate, recycle methyl iodide, catalyst, CO, a small amount of H_2, and LiI promoter are fed to a back-mixed reactor system at 160–190°C, 2–5 MPa to produce crude anhydride. Unreacted CO and other purge gases are scrubbed after leaving the reactor to recover acetyl and iodide moieties. The liquid draw off from the reactor is expanded and flash distilled under low CO/H_2 pressure to prevent catalyst decomposition. The flash bottoms are largely recycled, but a purge is taken for tar removal and Rhodium recovery. The crude anhydride flash distillate is purified in a three column sequence. In the first, methyl iodide and methyl acetate are distilled for recycle to the reactor. In the second, acetic acid id distilled overhead for recycle to the methyl acetate production process. The methyl acetate feedstock can be produced via reactive distillation, as shown in the section, "Methyl Acetate." The final column produces 99% acetic anhydride product as a distillate, with tars and heavies as the bottoms stream.

Methyl Formate [197]

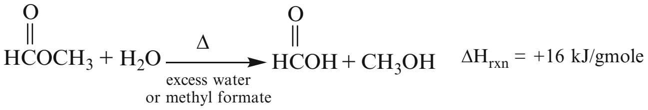
The equilibrium for the direct synthesis of formic acid by the addition of water to carbon monoxide is quite unfavorable and has not been exploited to produce commercial quantities of formic acid. Instead, formic acid is produced by acidification of formate salts (30% of global production) or hydrolysis of methyl formate (70% of global production). The acidification route involves reacting sodium or calcium formate (largely generated as a by-product of aldol/cannizzaro reactions, see the section, "Neopentyl Polyhydric Alcohols") with a strong acid, usually sulfuric acid, to yield dilute free formic acid and sodium or calcium sulfate. The second route begins with carbonylation of methanol to give methyl formate in a liquid phase reaction using a dilute strong base catalyst (e.g., sodium methoxide) at a temperature around 80°C and pressure of 4–5 MPa:



$$CH_3OH + CO \xrightarrow[NaOCH_3]{} H\overset{O}{\overset{\|}{C}}OCH_3 \qquad \Delta H_{rxn} = -29\text{kJ/gmole}$$

This carbonylation is equilibrium-limited, resulting in 30–50% methanol and 95% CO conversion per pass. Sodium methoxide can react with methyl formate to give sodium sulfate and dimethyl ether. Dry conditions are required to limit hydrolysis of methyl formate to sodium formate and methanol, and to prevent leveling of the strong alkoxide base to the catalytically ineffective weaker hydroxide ion. The crude methyl formate is flashed to atmospheric pressure and distilled. The low-boiling methyl formate/methanol azeotrope is taken overhead for hydrolysis and the underflow is recycled to the carbonylation step, with purge for removal of sodium formate by crystallization.

The equilibrium-limited hydrolysis of methyl formate is accomplished in both two-stage (1-1 water-methyl formate molar ratio, followed by addition of excess methyl formate—30% conversion/pass) and one-stage processes (5-1 water-methyl formate molar ratio, 60% conversion/pass):

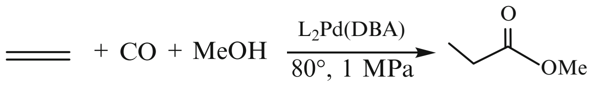


$$H\overset{\overset{O}{\|}}{C}OCH_3 + H_2O \xrightarrow[\text{excess water or methyl formate}]{\Delta} H\overset{\overset{O}{\|}}{C}OH + CH_3OH \qquad \Delta H_{rxn} = +16 \text{ kJ/gmole}$$

Unreacted methyl formate and methanol are distilled from the crude hydrolysis product, leaving a dilute water-formic acid mixture as underflow. Production of concentrated formic acid from this underflow product presents particular problems due to the high-boiling water/formic acid azeotrope. A number of separation schemes are practiced commercially; the most common approach is pressure-swing distillation. Excess water is distilled overhead in a first higher pressure column to produce azeotropic formic acid/water as a bottoms product. This azeotrope composition is distilled in a second vacuum column to produce concentrated formic acid (90–98% purity) as distillate, and the low pressure azeotrope composition is recycled to the first column [198]. Energy usage is improved with the one-stage hydrolysis process if excess water is removed by extraction (with a secondary amide or other solvents), prior to pressure-swing distillation.

Methyl Propionate [199–201]

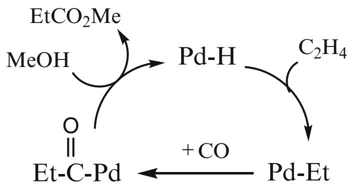
When ethylene and carbon monoxide are reacted in methanol, in the presence of a palladium diphosphine catalyst, either polyketone or methyl propionate may result depending on the identity of the diphosphine ligand. Lucite, formerly a subsidiary of ICI, has developed this carbomethoxylation as a step of their "Alpha Process" for the production of methyl methacrylate. In the Alpha Process, methyl propionate is reacted with formaldehyde to ultimately produce MMA. The rate and selectivity of this carbonylation catalysis are extraordinarily high under relatively mild conditions.



L_2=1,2-bis(di-t-butylphosphinomethyl)benzene
DBA=dibenzylidene acetone

selectivity = 99.8%
TON = 50,000/h

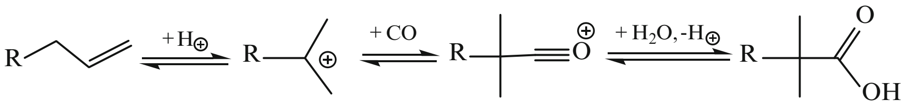
Mechanistic studies have established the catalytic cycle depicted below with the key intermediates being a palladium hydride, which reacts with ethylene to produce a palladium ethyl species that rapidly inserts a carbon monoxide yielding the palladium propionyl complex. This complex is methanolyzed to produce methyl propionate product and regenerate the palladium hydride intermediate.



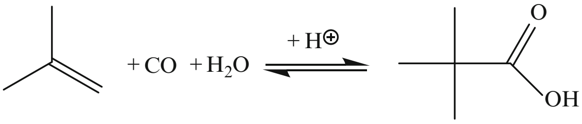
Shell developed very similar catalysis for the production of their Carilon polyketone in which the diphosphine ligand in bis(diphenylphosphino)propane rather than the 1,2-bis(di-t-butylphosphinomethyl)benzene employed by Lucite, illustrating the exquisite sensitivity of this catalysis to the structural details of the palladium diphosphine catalyst. A commercial scale MMA plant (Jurong Island, Singapore) based on the Alpha process has operated at design capacity since 2008.

Koch Acids

Koch carbonylation (also called hydrocarboxylation or the Koch-Haaf reaction) is the synthesis of predominantly tertiary (neo) carboxylic acids from olefins, CO, and water using a strong acid catalyst, typically H_3PO_4/BF_3 or an acidic zeolite. In the initial step of the reaction, the olefin is protonated, generally with isomerization and rearrangement, to form the most stable (i.e., tertiary) carbonium ion. Carbon monoxide then adds to the carbonium ion to form an acylium cation. Further reaction with water and regeneration of the proton results in the formation of the tertiary carboxylic acid.



An example of this chemistry is conversion of mixed butenes, especially isobutylene to pivalic (neopentanoic) acid.

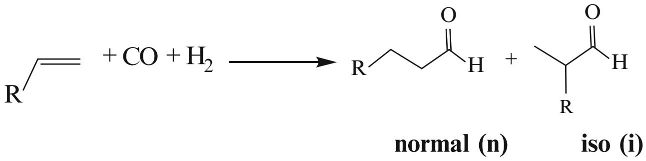


In the typical industrial process, CO is contacted with the olefin and H_3PO_4/BF_3 catalyst in a CSTR at 20–80°C, 2–10 MPa. Conversion of the olefin is generally very high with 80–100% selectivity to the neo acid. Main by-products are neo acids of the oligomerized feedstock olefins. Product neo-acids are washed with water and decanted for removal of the catalyst acids. C_5 to C_{11} neo acids are made industrially form the corresponding C_4-C_{10} olefins. The higher olefinic feedstocks are typically derived from ethylene oligomerization or dehydration of paraffinic fractions.

Hydroformylation [202–207]

Chemistry

Hydroformylation, commonly known as oxo synthesis, is a C–C bond-forming reaction of an olefin with syngas (~1:1 M ratio of CO:H_2) to produce aldehydes. When the olefin is a terminal, or α-olefin, two products may be formed and are referred to as the normal (straight chain) and iso (branched chain) products.



The reaction is employed in practice with C_2 to C_{14} olefins, but hydroformylation of propylene is the primary application. The oxo aldehydes are valuable and reactive intermediates for a number of secondary transformations, including hydrogenation to alcohols, oxidation to acids, and aldol condensation to higher aldehydes and ketones, with subsequent further transformations of these products to esters, anhydrides, ketenes, glycol ethers, and sulfonates to name a few.

Process conditions vary significantly with olefin substrate and catalyst employed, but typically fall in the range of 1–20 MPa and 40–200°C. All current commercial catalysts are based on either Co or Rh transition metal complexes. The first commercial catalyst, $HCo(CO)_4$, discovered by Otto Roelen in Germany in 1938, required high pressures (20–35 MPa) for acceptable operation. Subsequent work demonstrated that phosphine ligands could, allowed practical operation at much lower pressures 1–10 MPa and could further hydrogenate the product aldehydes to alcohols (Shell process). Another quantum leap in productivity and selectivity occurred with the introduction of Rh-based catalyst complexes in the early-1970s, with operating pressures as low as 1–2 MPa. Although Rh is roughly 1,000 times more expensive than Co, it is also several orders of magnitude more active than Co, for a substantial net benefit. Low pressure Rh operation reduces syngas compression energy over fivefold and significantly lowers capital costs over that of the original cobalt hydrido carbonyl catalyst system. The formation of an aldehyde via Rh-catalyzed oxo synthesis involves the following catalytic steps:

1. An olefin coordinates to a coordinatively unsaturated metal hydrido carbonyl complex, exemplified by $HCo(CO)_3$ and $HRh(CO)(PPh_3)_2$, followed by insertion of the olefin into the metal hydride bond to give an alkyl complex.
2. A second migratory insertion of CO converts the alkyl into an acyl group.
3. Oxidative addition of H_2 yielding a metal dihydride.
4. Reductive elimination of the aldehyde product regenerates the coordinatively unsaturated metal hydrido carbonyl complex (back to step 1).

A simplified expression for the rate of aldehyde formation illustrates some of the kinetic tradeoffs: [208, 209]

$$\text{Rate of aldehyde formation} = k\frac{[\text{olefin}][\text{metal (Co or Rh)}]p_{H_2}}{p_{co}}$$

For lower olefins, especially ethylene and propylene, the concentration of the olefin in the liquid reaction phase is proportional to pressure, higher pressure gives higher solubility. Likewise, high hydrogen partial pressures favor aldehyde formation, as does increasing catalyst concentration (for Rh, this approach is expensive). At some point hydrogenation of the olefin to paraffin or loss of selectivity by hydrogenation of the product aldehyde may also occur. However, reducing CO partial pressure enhances the rate, but a minimum CO pressure is needed to maintain stability of the metal catalyst complexes, as well as for product formation. In practice, a complex tradeoff of these effects is required, with low pressure, low catalyst concentration, and about 1:1 H_2/CO molar ratio tending toward optimal.

A key consideration in hydroformylation of α-olefins is the n:i ratio of products for C_3 and higher olefin substrates. For example, with propylene, the C–C bond may form to give a linear (n), or a branched product (i):

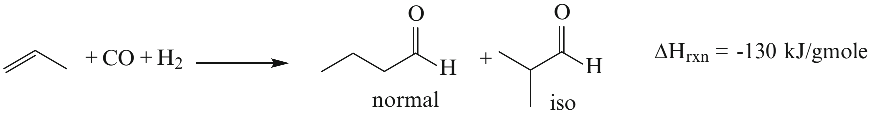


Table 10.31 Hydroformylation systems

Descriptor	Unmodified cobalt	Cobalt ligand	Rh, no ligand	Rh, classic low P	Water soluble	High normal	Higher Iso
Catalyst metal	CO	CO	Rh	Rh	Rh	Rh	Rh
Ligand	No ligand	Triphenyl phosphine	No ligand	Triphenyl phosphine	Triphenylphosphine sodium sulfonate	Bisphosphite	Halophosphite

Metal cost	Low	Low	High	High	High	High	High
Ligand cost	None	Low	None	Low	High	High	Medium
Practitioner/licenser	No active licensers, but still used	Shell	Johnson Matthey/Davy	Dow/Davy	Ruhrchemie/Rhône-Poulenc	Dow/Davy	Eastman Chemical Co.

Linear aldehydes are more valuable intermediates for production of plasticizers and detergents (linear molecules are more biodegradable). Significant research effort has been expended over the last 80 years developing high n:i ratio catalysts. Formation of straight chain olefins is favored by bulky, electron-rich ligands. The vast majority of companies practicing oxo synthesis use catalyst systems that preferentially produce normal as opposed to iso aldehyde products. A company uses proprietary rhodium—halophosphite catalysts that produce an unusually low n:i product mix.

The chain-length of the feedstock olefin and desired n:i ratio of the aldehyde product largely dictate which metal–ligand catalyst combination is more desirable. Table 10.31 summarizes operating conditions and results for a number of commercial systems, with highlights about each given below. Corresponding catalyst structures are presented in Fig. 10.27.

Catalyst I. $HCo(CO)_4$: The first generation cobalt carbonyl/hydrocarbonyl catalyst, originally developed in the 1930s, required a high pressure, 20–35 MPa, for good activity. It is not used commercially for lower olefins any longer, but finds some applications with higher olefins.

Catalyst II. Cobalt, phospine ligand: The second-generation phosphine-modified cobalt catalyst, developed in the 1960s, significantly reduced the required operating pressure, improved the n:i ratio to between 6:1 to 9:1, and gives mostly terminal hydroformylation, even when fed internal olefins (by promoting double bond migration). This process is used mostly for production of detergent range alcohols, where the greater propensity of cobalt to hydrogenate the oxo aldehyde is not a disadvantage. Trialkyl phosphines are preferred and derivatives of the phobanes depicted in Fig. 10.27 are used commercially by Shell.

Catalyst III. HRh(CO)4: A rhodium carbonyl hydride catalyst without a phosphine or phosphite is currently used for hydroformylation of C_6 to C_{14} linear and branched olefins. Without expensive ligands to recover, a unique adsorption/ion exchange method is used for efficient catalyst recovery. Isononanol and isodecanol are important products.

Catalyst IV. Rhodium, triphenyl phosphine ligand: The phosphine-modified rhodium catalyst was developed in the 1970s and has been successfully employed since, largely for propylene and butene hydroformylation. This system dramatically reduced required operating pressures, while giving several orders of magnitude rate improvement and higher n:i ratios. Several variations are practiced; (1) vapor stripped reactor for product removal and catalyst separation (product taken as vapor directly from reactor, (2) liquid take-off with flash separation of aldehyde and catalyst.

Catalyst V. Rhodium, water soluble phosphine: The phosphine-modified rhodium catalyst was made water-soluble by adding sulfonate groups to the phenyl rings. In this way a simple separation of catalyst for recycle is facilitated by decantation of the catalyst-bearing aqueous phase from the product-laden organic phase. This low pressure process is used commercially for hydroformylation of propylene to high-normal butyraldehyde n;i ratio of about 10:1 to 20:1.

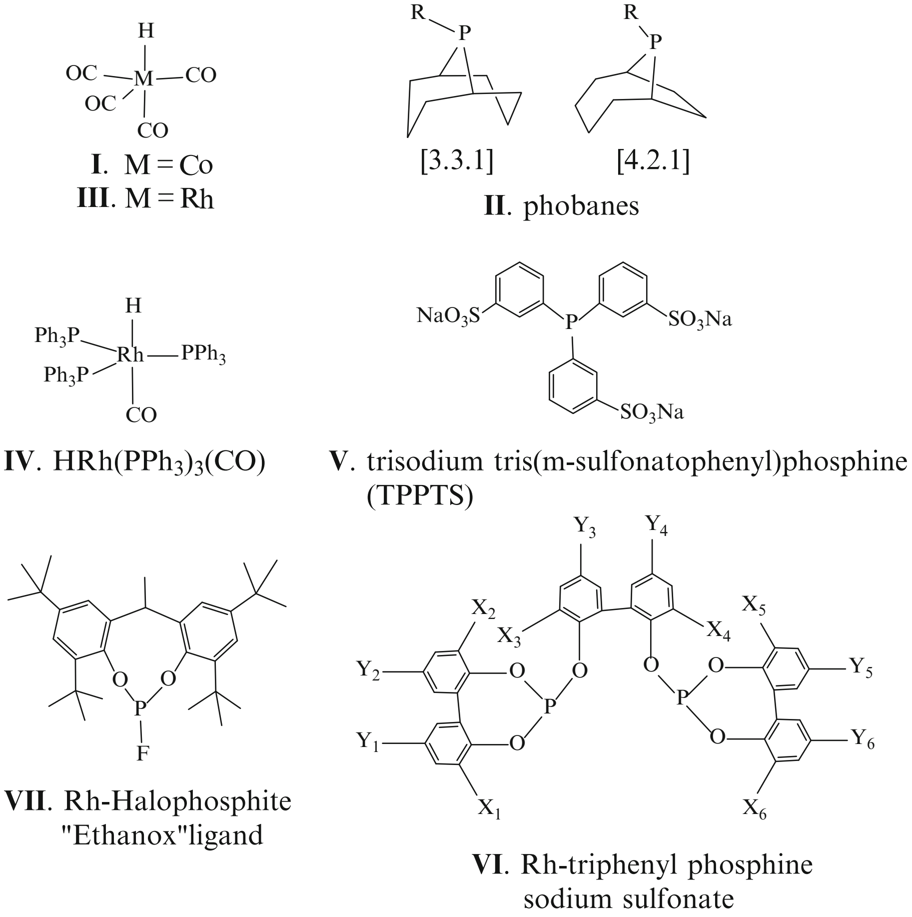

Fig. 10.27 Hydroformylation catalyst structures

I. M = Co
III. M = Rh

[3.3.1] [4.2.1]
II. phobanes

IV. HRh(PPh$_3$)$_3$(CO)

V. trisodium tris(m-sulfonatophenyl)phosphine (TPPTS)

VII. Rh-Halophosphite "Ethanox"ligand

VI. Rh-triphenyl phosphine sodium sulfonate

Catalyst VI. Rhodium, *bisphosphite ligand*: The family of bisphosphite ligands dramatically increases the n:i ratio to about 30:1, the highest level yet achievable. Both propylene and butene feedstocks are usable.

Catalyst VII. Rhodium, *tridentate halophosphite ligands*: Unlike the other six catalyst systems, tridentate halophosphite ligands produce the lowest commercialized n/i ratio, typically less than 3:1. Ethylene and propylene are common feedstocks. With these halophosphite ligand, the n:i butyraldehyde ratio dependson the ligand to rhodium molar ratios, the reaction temperature, and the carbon monoxide partial pressure [210].

More detailed descriptions of typical oxo processes for short and long chain olefins are given below.

Lower C$_2$-C$_5$ Olefins

In a typical commercial process for catalyst types V, VI, and VII, a mixture of 1:1 syngas and lower olefins (can be a mixture) are fed to a stirred tank or bubble column reactor along with fresh and recycle homogeneous catalyst solution, where hydroformylation takes place. Temperature and pressure conditions depend on the metal-ligand catalyst chosen, as well as the chain length of the olefin. Heat is removed by the reactor jacket, an external cooling loop, or alternatively, boiling of the product aldehyde. If a vapor-stripped reactor system is used, the vaporous effluent and unreacted gases from the reactor are cooled, allowed to condense, and separated into gas and liquid streams. If conversion of olefin is low, the off-gases are compressed and recycled, with some amount purged to prevent buildup of inerts (i.e., alkanes in the olefin feed). If the aldehyde is the final end product, the crude aldehyde is distilled to remove water and high boilers (usually alcohols and esters), and possibly further fractionated to separate iso and normal isomers. The phosphine or phosphite ligands tend to degrade at a low, but finite rate, so it is necessary to purge some amount of the catalyst solution. Subsequent recovery of Rh, typically involves distillation, evaporation, decantation, or extraction. Decantation is used, for example, with the water soluble ligand system described in Table 10.31.

Higher Oxo: Detergent Alcohols [211]

In one commercial process, linear and branched C$_6$-C$_{14}$ olefins derived from light olefin oligomerization or paraffin dehydrogenation, are reacted in the liquid phase with 1:1 syngas at 95–180°C, about 25 MPa, using a homogenous rhodium carbonyl catalyst (without additional ligands) to form isomeric oxo aldehydes. Depending on the reactivity of the olefin feedstock (branched < internal olefin < α-olefin), conversion can reach 95%, but is typically limited to 80% for a first pass. The less reactive olefins are removed and sent to a second pass with more severe conditions and higher catalyst loading, with 75% second pass conversion (95% overall conversion for two pass). Mild conditions favor linear, terminal olefin synthesis, while more forcing conditions tend to lead to isomerization of double bonds, yielding higher levels of internal olefins and thus branched aldehydes products.

The pressure of the reactor effluent is let down to remove dissolved CO and hydrogen. This off-gas is recycled, with a purge to prevent build-up of inerts. Since there is no expensive ligand to recover, Rh ions are adsorbed from the degassed olefin/aldehyde liquid product by passing through a series of ion exchange resin beds. The ion exchange bed is periodically incinerated, converting the Rh metal to Rh oxide, which is readily recycled to the Rh salt catalyst precursor. The crude catalyst-free aldehyde is typically sent directly to hydrogenation for conversion into alcohols before distillation. See the section, "Aldehydes and Ketones to Alcohols," for information on the hydrogenation of the higher aldehydes to alcohols.

Chlorination [212, 213]

Chemistry

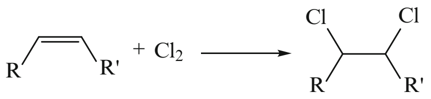
As the name implies, chlorination is a family of reactions in which one or more chlorine atoms are incorporated into a molecule. For large scale commercial synthesis the most common chlorine sources are Cl_2, HCl, and HOCl (hypochlorous acid). Chlorinated molecules are extremely important to many industries, including construction, automotive, toys (vinyl chloride, PVC), silicon products (methyl chloride), dry cleaning and solvent applications, and air conditioning (HFC's). Some rank among the largest volume chemicals produced. Several basic types of chlorination reactions are employed industrially:

1. *Substitution* is the abstraction and replacement of a hydrogen atom by a chlorine atom (from Cl_2 gas), with HCl as the co-product. The reaction involves a free radical chain mechanism initiated by thermal dissociation of Cl_2, with a chloride radical as the chain carrier. Selectivity is generally poor, as all hydrogen atoms on a molecule are more or less available for substitution in the order tertiary > secondary > primary, saturate > unsaturated > aromatic. Further information on relative reactivity of various substrates is available in standard texts [214]. The substitution reaction can be extremely fast and exothermic, with a heat of reaction on the order of −90 to −135 kJ/gmole of Cl added. Less reactive substrates require either high temperature or a Lewis acid catalyst. Alkane and aromatic substrates are used:

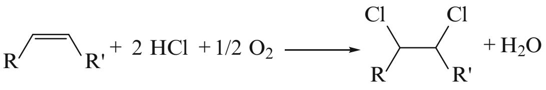
$$C_nH_{2n+2}+mCl_2 \longrightarrow C_nH_{2n+2-m}Cl_m+m\ HCl \qquad 1\leq m\leq 2n+2$$

$$ArH+Cl_2 \longrightarrow ArCl + HCl$$

2. *Addition* involves the insertion of Cl_2 across an unsaturated (double or triple) bond in a hydrocarbon molecule. Mild temperatures, 70–120°C, are required. The addition is highly specific; chlorine atoms are symmetrically distributed, and selectivities above 90% are common. The substitution reaction is exothermic, with a heat of reaction on the order of −180 to −230 kJ/gmole of Cl_2 added. Lewic acids such as $FeCl_3$, $ZnCl_2$, and PCl_3 are common catalysts.



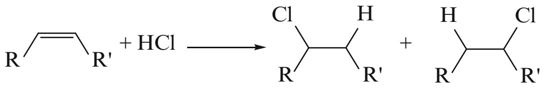
3. *Oxychlorination* is the reaction of HCl and oxygen with a substrate to produce a chlorinated species and water. Reaction temperature can range from 80 to over 200°C, depending on substrate. The reaction is generally selective (>90%). The heat of reaction is very high, around −250 to −300 kJ/gmole. Common catalysts are $CuCl_2$ and $ZnCl_2$.



4. *Hydrochlorination* is the reaction of HCl with a substrate to produce a mono-chlorinated species. If the substrate is an alcohol, then the by-product is water:

$$R\text{-}OH + HCl \longrightarrow R\text{-}Cl + H_2O$$

The reaction with an alcohol is generally very selective (>90%), with the diether as the major by-product. The heat of reaction, around −30 to −50 kJ/gmole, is relatively low compared to other types of chlorinations. HCl may also be added across a double bond:

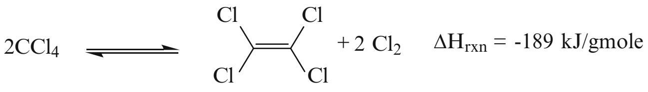


5. *Perchlorination* (sometimes called chlorinolysis) is the high temperature (400–700°C) exhaustive chlorination of a multi-carbon substrate with concomitant breaking of at

least one C–C bond to form smaller fully chlorinated fragments. Both hydrocarbon and partially substituted chlorohydrocarbons are potential feedstocks. At full conversion and complete fragmentation to C_1 pieces, the reaction stoichiometry is:

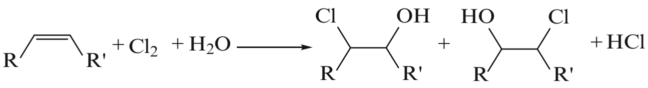
$$C_nH_{2n}Cl_2 + (3n\text{-}1)\ Cl_2 \longrightarrow n\ CCl_4 + 2nHCl \qquad n > 1$$

At high temperature (>600°C), an additional equilibrium exists between carbon tetrachloride and perchloroethylene.



Large excesses of Cl_2 or high pressure are needed to drive to mostly single carbon fragments. Perchlorination is an important component of an integrated chlorination facility, taking in low value chlorinated by-products from other processes, to produce exhaustively chlorinated, lower carbon number materials. Any aliphatic, aromatic, or oxygenated hydrocarbon may be reacted via perchlorination. Oxygenates produce phosgene as a by-product.

6. *Chlorohydrination* is the reaction of an olefin with Cl_2 and water to form a vicinal hydroxy chloride moiety (chlorohydrin), with HCl as a co-product.



A large excess of water and low olefin concentration is required to prevent by-product formation by addition and substitution reactions. When $R \neq R'$, isomers differing in the position of the hydroxyl and Cl may be formed. Chlorohydrins are important intermediates in the synthesis of epoxides, especially propylene oxide.

Hydrochlorination and oxychlorination reactions are often more economical uses of HCl generated by substitution and addition reactions than disposal of excess HCl as a gaseous or dilute aqueous co-product. Examples of some industrially important chlorination reactions are summarized in Table 10.32. The types of reactions discussed above may also be applied to other common halogens, with reactivity in the order F > Cl > Br > I. Fluorine is so reactive and exothermic that fluorinations are not normally done directly, but by indirect methods exemplified by halogen substitution [215].

Chloromethanes [216–218]

The chloromethanes (one-carbon molecules containing one to four chlorines), are primarily used as intermediates for other chemistries: methyl chloride for silicones production; methylene chloride for solvents; chloroform for hydrochlorofluorocarbon production; and carbon tetrachloride for chlorofluorocarbons. The more substituted chloromethanes are made predominately by successive substitutions of methyl chloride or perchlorination of C_1-C_3 chlorinated streams. The use of carbon disulfide as a feedstock for methyl chloride synthesis is essentially obsolete, and thermal substitution of methane is falling out of favor. The flowsheet for a typical integrated chloromethanes process is shown in Fig. 10.28. Methyl chloride is now largely produced via gas phase hydrochlorination of methanol with excess HCl at 280–350°C, 0.3–0.6 MPa, in a multitubular steam-generating fixed bed reactor filled with γ-alumina catalyst (**1**).

$$CH_3\text{-}OH + HCl \xrightarrow[\gamma\text{-alumina}]{} CH_3\text{-}Cl + H_2O \qquad \Delta H_{rxn} = -33\ \text{kJ/gmole}$$

An older process using 70% aqueous zinc chloride/HCl at 130–150°C is not used much anymore. The reactor effluent is cooled by direct contact quench with recycle ~30 wt% aqueous HCl (**2**). Diluted ~20 wt% aqueous HCl exits as underflow from the quench tower, and gaseous crude methyl chloride is scrubbed further with caustic (**3**), and then concentrated (96 wt%) H_2SO_4 to remove dimethyl ether (which reacts to form methyl sulfate) and water (**4**). The diluted H_2SO_4 (~80 wt%) is a by-product. Dry methyl chloride is compressed (**5**) to around 2 MPa, condensed, and distilled overhead as a pure product, or used along with the higher chlorinated by-products as feedstock for further substitution chlorination.

In order to produce a slate of chloromethanes, methyl chloride and by-products from the hydrochlorination step are further thermally substituted with gaseous chlorine at 350–400°C, 0.8–1.5 MPa, in an adiabatic reactor (**6**), usually without catalyst. If the reaction mixture is allowed to reach about 450°C or above, rapid pyrolysis may occur, with the very undesirable formation of carbon soot. The reactor effluent is quenched (**7**), separated from co-product HCl by multistage condensation (**8**), stripped of residual HCl (**9**), and distilled to take mono-, di-, tri- and tetra-chloromethanes overhead in successive columns (**10**), (**11**), (**12**), (**13**) respectively. Depending on the desired product distribution, any partially substituted product may be recycled to the substitution reactor for further chlorination. Overall yield on methanol is at least 95% and greater than 98% on chlorine.

The heavy chlorinated residue from the last column and other chlorination by-products (e.g., 1,2-dichloropropane from propylene oxide production, vinyl chloride residues) may be fed to a perchlorination unit for production of smaller chain fully substituted materials. A typical high pressure tubular perchlorination unit operates adiabatically at up to about 620°C, 10–20 MPa, with a Cl_2/substrate

Table 10.32 Chlorination products

Product	Common industrial method[a]	Feed substrate	Chlorine source	Co-product	Heat of reaction, kJ/gmole
Methyl chloride	H	Methanol	HCl	Water	−33.0
Methyl chloride	S (less common)	Methane	Cl_2	HCl	−103.5
Methylene chloride	S	Methyl chloride	Cl_2	HCl	−102.5
Chloroform	S	Methylene chloride	Cl_2	HCl	−99.2
Carbon tetrachloride	S or P	Chloroform	Cl_2	HCl	−94.8
Carbon tetrachloride	P	Chlorinated C_1-C_3 species	Cl_2	HCl	Exothermic, depends on feed substrate
Chlorobenzene	S	Benzene	Cl_2	HCl	−131.5

Propylene chlorohydrin	C	Propylene	Cl_2/H_2O	HCl	

[a] *S* substitution; *A* addition; *O* oxychlorination; *H* hydrochlorination; *P* perchlorination; *C* chlorohydrination; *Cr* cracking

ratio dependent on the desired perchloroethylene/carbon tetrachloride product mix. The effluent, comprising carbon tetrachloride, HCl, Cl_2, perchloroethylene, and small amounts of hexachlorobenzene (recyclable to extinction), is quenched with cold carbon tetrachloride, flashed to remove Cl_2 and HCl, and distilled to produce carbon tetrachloride and perchloroethylene as pure streams. The reactor must be Ni clad to prevent corrosion. With the decline in applications for carbon tetrachloride, the production of most perchlorination units are slated heavily to perchloroethylene by a ratio of roughly 3-1.

Chloroaromatics [219–221]

A wide variety of chlorinated aromatics, with and without additional functional groups on the aromatic ring, may be produced by substitution chlorination, with co-production of HCl. These include mono- and di-chlorobenzenes, chlorotoluene, benzyl chloride. The product mix ultimately obtained is highly dependent on Cl_2/aromatic molar ratio, temperature, catalyst composition, co-catalyst (if any), location of other groups already on the benzene ring, and contacting mode. High temperature and high Cl_2/aromatic ratio favor multiple chlorinations. Backmixed (CSTR) operation leads to increased levels of multi-chlorinated products; batch or reactive distillation approaches tend to increase monochloride content. The heats of reaction for mono- and dichlorobenzenes are summarized in Table 10.32. A typical continuous process for mono and di-chlorination of benzene operates at 20–80°C, with dissolved ferric chloride catalyst/organic sulfide co-catalyst, and with very low water content (25–35 ppm) to prevent catalyst deactivation. The resulting effluent is neutralized with caustic, or in more modern plants distilled directly to separate HCl and Cl_2 from aromatics. Unreacted benzene is recovered overhead first, with monochlorobenzene taken overhead in a second column. Dichlorobenzenes are close boiling and generally must be separated by crystallization to obtain high purity single isomers. Product distribution between mono- and dichlorobenzenes is highly dependent on the ratio of benzene to chlorine fed to the reactor.

1,2-Dichloroethane (Ethylene Dichloride) and Vinyl Chloride Monomer (VCM) [222–225]

Ethylene dichloride (EDC), and its primary end product vinyl chloride monomer (VCM), are produced at truly immense scale, constituting about 8% of global output of chemicals. EDC and VCM were once produced primarily by chlorination of acetylene. Limited application for the by-product HCl posed a major restriction to the growth of EDC and VCM. However, major producers now use a combination of direct chlorination and oxychlorination of ethylene to produce EDC and VCM without significant coproduction of HCl. Figure 10.29 shows such an integrated

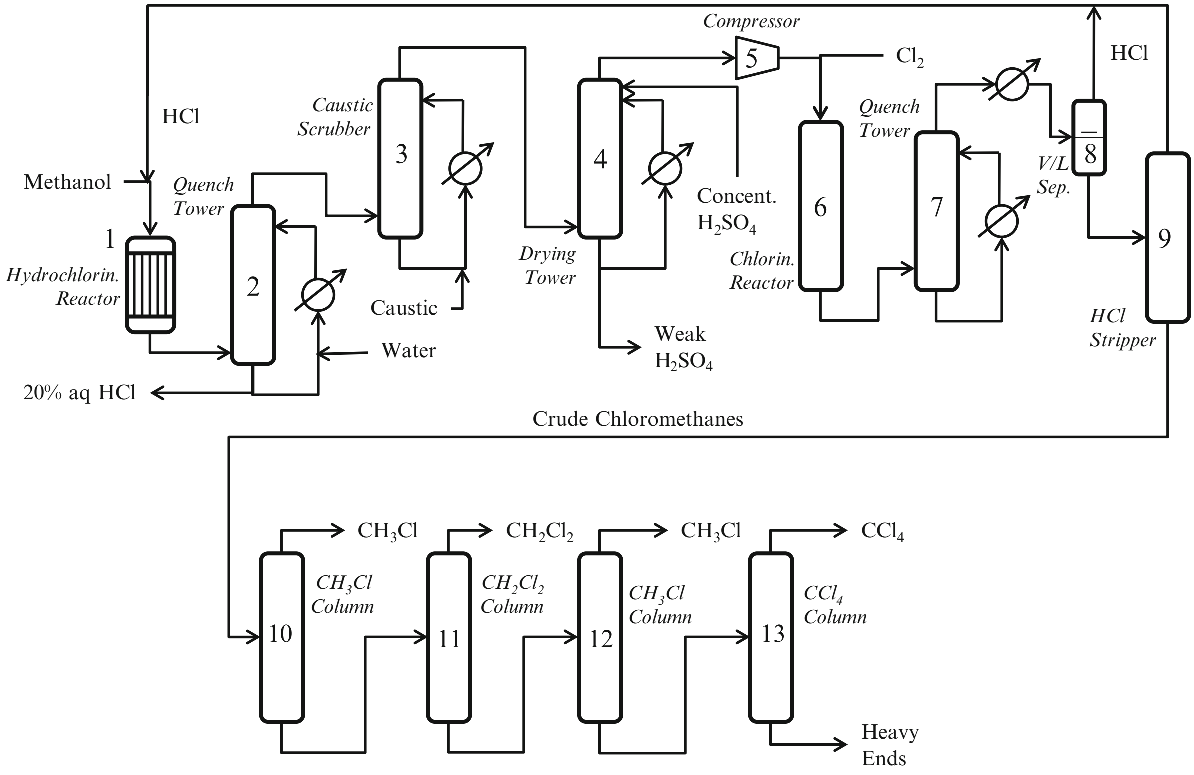

Fig. 10.28 Flowsheet for production of chloromethanes

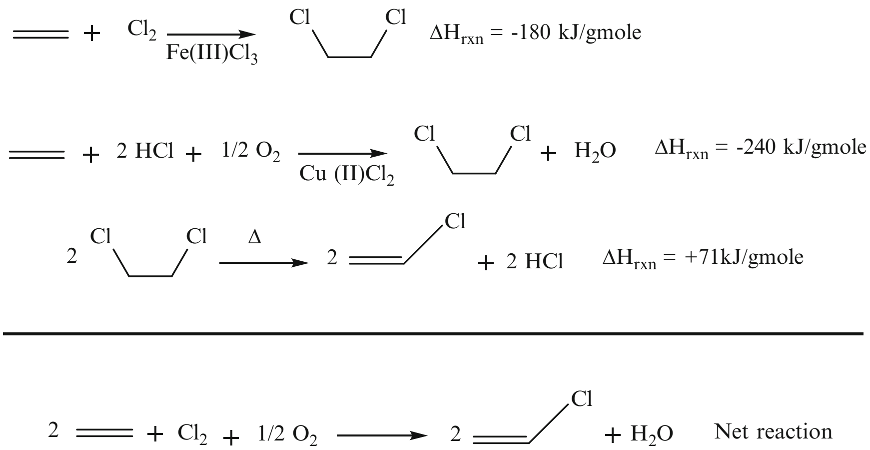
plant for producing EDC and vinyl chloride from ethylene, chlorine, and air. The chemical reactions are as follows:



The oxychlorination step (**1**), catalyzed by Cu(II)Cl_2-impregnated alumina at 200°C and 0.2–0.5 MPa pressure, uses recycled HCl from the EDC pyrolysis step, with oxygen and ethylene to produce EDC and water. This reaction is even more exothermic (−290 kJ/gmole) than direct chlorination. Both multi-tubular fixed bed and fluidized bed reactor designs with steam generation are used commercially to control the heat release. The fluid bed design, although suffering from lower selectivity than a PFR due to back mixing, can be run advantageously in the explosive region. Conversion is typically 93–97% per pass, with a selectivity on ethylene around 95%. Major by products are heavy trichlorinated species, trichloroacetaldehyde, and oxygenated lights such as CO, carbon dioxide, formic acid.

The addition chlorination of ethylene is done usually in a liquid-phase reactor (**3**), catalyzed by the Lewis acid, iron(III)

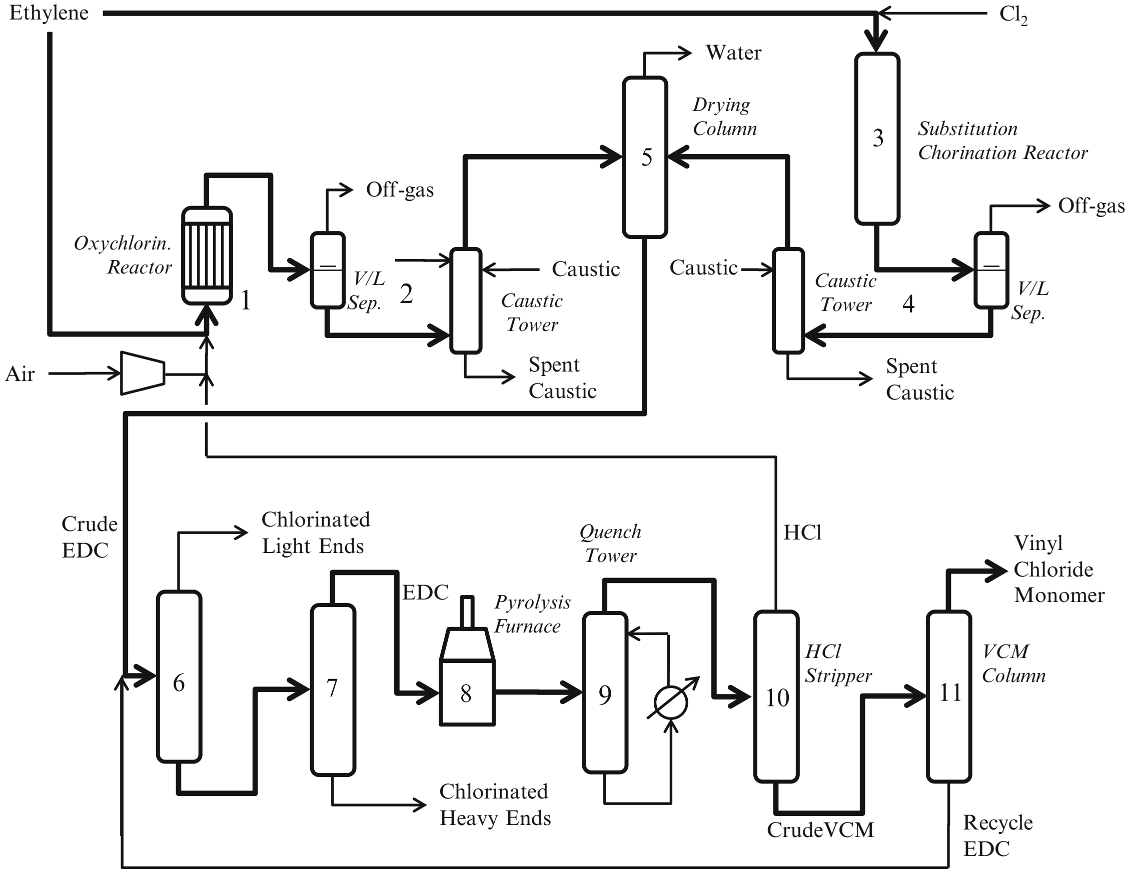


Fig. 10.29 Flowsheet for production of vinyl chloride monomer

chloride at 40–100°C, 0.4–0.5 MPa. Ethylene absorption is the rate limiting step. The heat of reaction (−180 kJ/gmole) can be removed either by heat exchange in the reactor, or more economically by running the reaction above 100°C and using the generated heat to distill the EDC. High-purity ethylene, with low propylene content, is preferred to avoid formation of chlorinated C_3 by-products. Ethylene conversion approaches 100%, with a selectivity of 98% on ethylene and 99% on chlorine.

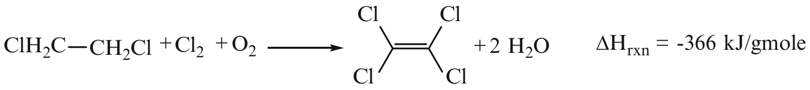
The effluents from reactors (**1**) and (**3**) are disengaged from vapors and scrubbed with caustic for additional removal of HCl (**2**),(**4**). The crude EDC is azeotropically distilled to remove residual water (**5**), and subjected to distillation to separate light (**6**) and heavy (**7**) chlorinated by products. These chlorinated species may be used in chlorinolysis or production of other halogenated species.

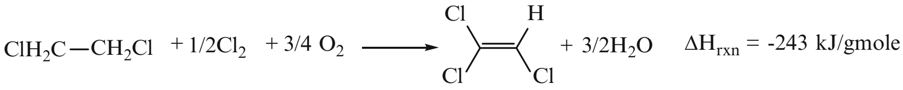
The cracking (pyrolysis) of EDC to VCM typically is carried out at temperatures of 500–550°C without a catalyst (**8**). Selectivity to VCM is greater than 98%. The hot gases are quenched (**9**) and distilled to strip out HCl (**10**) and then VCM (**11**). The unconverted EDC is returned to the EDC purification train.

About 35% of the chlorine produced globally goes to the manufacture of VCM. More than 95% of all VCM is used to produce polyvinyl chloride (PVC), an important polymer for the housing and automotive industries (See Chap. 15). The rest of the VCM goes into the production of chlorinated solvents and ethylenediamine.

Chloroethanes [226–228]

The commercial importance of the chlorinated ethane derivatives, perchloroethylene, 1,1,1-trichloroethane, and trichloroethylene, has declined significantly since the 1980s due to t the declining use of chlorofluorocarbons. Major uses of all three are as precursors for fluorocarbon production, dry cleaning agents, and solvents. With declining use of carbon tetrachloride, perchlorination (see Section 10.7.1) is becoming a more significant route to perchloroethylene. 1,1,1-trichloroethane is produced predominantly by a two-step process starting with vinyl chloride monomer (VCM): (1) hydrochlorination of VCM with HCl produce predominantly 1,1-dichloroethane; (2) thermal or photochemical (more selective) substitution chlorination of 1,1-dichloroethane to 1,1,1-trichloroethane. Perchloroethylene and trichloroethylene are also made by the oxychlorination of 1,2-dichloroethane (VCM intermediate, see above):

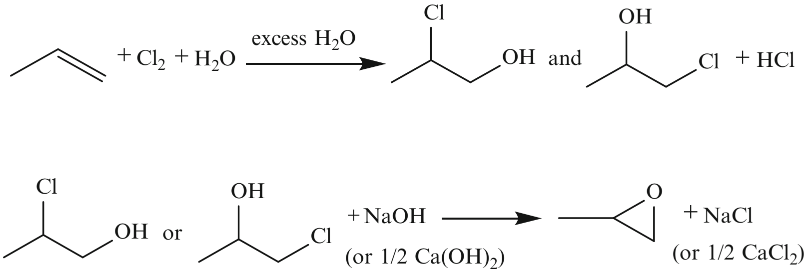




Propylene Oxide via Propylene Chlorohydrin [229, 230]

Although differing from ethylene oxide by only one extra carbon in the backbone, propylene oxide (PO) has not been made successfully at commercial scale by the direct oxidation of propylene. The presence of allylic hydrogens dramatically and adversely affects the efficacy of silver-based catalysts for the selective oxidation of propylene to PO with oxygen [231]. Instead all world scale PO plants are based either on indirect oxidation of propylene by either the co-product hydroperoxide routes (50% of total, see the section, "Hydroperoxide Co-product Processes for Propylene Oxide") or the chlorohydrin route described herein.

The chlorohydrin route entails two main steps: (1) synthesis of propylene chlorohydrins (PCH) by the reaction of propylene, chlorine, and water (chlorohydrination) and (2) synthesis of PO via the reaction of PCH with an alkali or alkaline earth hydroxide (dehydrochlorination).



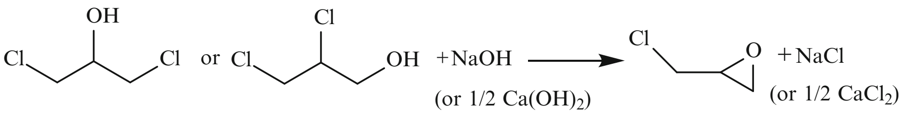
In the first step chemical or polymer grade propylene, gaseous chlorine reacts in equimolar amounts in the presence of excess water at 45–90°C, 0.11–0.19 MPa in bubble column or CSTR, to produce a solution of about 4 wt% PCH isomers, roughly a mole of HCl per mole of PCH, and other chlorinated by-products. Excess water (around a 50:1 mole ratio of water to propylene) is critical to suppress undesired substitution and addition reactions, but 1,2-dichloropropane (DCP), 1,3-dichloropropan-2-ol or 2,3-dichloropropan-1-ol (DCH), 2,2′-dichlorodiisopropyl ether (DICPE) are major by-products. Yields are typically 88–96% PCH isomers, 3–10% DCP, 0.3–1.2% DCH, 0.2–0.8% DCIPE, and 1% of others including allyl chloride. The PCH solution is disengaged from the vent gases (subsequently scrubbed with caustic and thermally oxidized), and conveyed to the dehydrochlorination reactor.

The PCH solution is reacted with slightly more than two equivalents of base (either NaOH or $Ca(OH)_2$) to neutralize the HCl produced in the first step and to saponify PCH to propylene oxide and salt. The reactions are rapid and exothermic. The crude PO is distilled in a two column sequence, with lights taken overhead in the first column and PO distilled overhead in the second column. DCP, DCIPE, and epichlorohydrin are underflowed in the second column. Almost all streams in the chlorhydrin process are extremely corrosive, requiring expensive materials of construction such as Teflon coatings, fiber reinforced plastics, graphite, rubber, brick-linings, Inconel, Hastelloy, or Monel alloys.

This process produces roughly 2 kg of either NaCl or $CaCl_2$ per kg of PO. Economics dictate that the PO unit be associated with a world-scale chloralkali, mercury, or membrane chlorine processes for regeneration of the chlorine and base. 1,2-Butylene oxide (and 1,2-butanediol upon hydrolysis) is made from 1-butene at a substantially smaller scale by a similar chlorohydration/dehydrochlorination route.

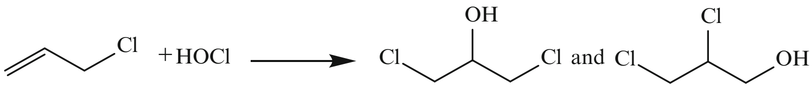
Epichlorohydrin [232, 233]

Epichlorhydrin, an important intermediate for coatings and urethane applications, is produced in 90% yield via dehydrochlorination of 1,3-dichloropropan-2-ol or 2,3-dichloropropan-1-ol (DCH).



The DCH may be a by-product of propylene oxide production (see above), or formed on purpose in a two-step process from propylene. In 1936, it was discovered that when propylene is reacted with chlorine at high temperature (500–510°C in practice), free radical substitution of an allyl hydrogen predominates over double bond addition, giving allyl chloride in 80–85% yield.

Excess propylene (4:1 M ratio) is required to ensure essentially complete conversion of chlorine, and for good selectivity. In the second step, allyl chloride is reacted with aqueous hypochlorous acid at 50–60°C to yield a mixture of DCH isomers.



Condensation

In its broadest sense, a condensation reaction involves the combination of two molecules or functional groups of the same molecule to form a new species, typically with the elimination of a small molecule such as water or an alcohol. In the present context, condensation reactions are limited to the coupling of two molecules via the formation of a new carbon–carbon bond, with elimination of water. The discussion to follow covers aldol condensations and the acid-catalyzed condensation of phenols and ketones, as exemplified by the synthesis of bisphenol A (BPA).

Aldol Condensation [234–236]

Chemistry

The aldol reaction is one of the most important industrial means of forming carbon–carbon bonds to directly synthesize complex functionalized molecules. A large number of commercially significant molecules are produced via aldol chemistry as shown in Table 10.33. Many of these compounds are intermediates for further transformations such as hydrogenation or oxidation.

In the aldol addition reaction, an enolizable ketone or aldehyde, i.e., one that has at least one acidic proton alpha to the carbonyl, reacts with another aldehyde or ketone to form a β-hydroxycarbonyl compound. The enolizable carbonyl acts as a nucleophile and other carbonyl as an accepting electrophile. The reaction is called a crossed aldol addition when the nucleophile and electrophile are different and a self aldol dimerization when they are the same.

Aldol reactions are catalyzed most commonly by bases such as alkali earth and alkaline earth hydroxides (e.g., NaOH or $Ca(OH)_2$), and amines (e.g., triethylamine, dimethylamine). Acid catalysis also occurs (and is often a source of by-product formation in acid catalyzed reaction where ketones or aldehydes are present), although is less effective for on-purpose production. The aldol addition reaction may proceed via two fundamentally different mechanisms, depending on whether an acid or base catalyst is used.

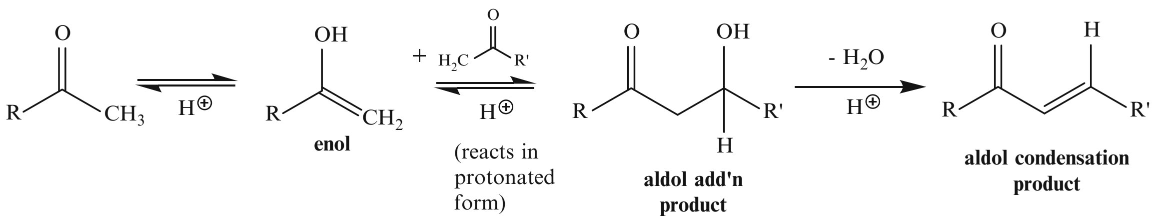
With an acid catalyst, the initial step in the reaction mechanism involves acid-catalyzed tautomerization of the carbonyl compound to the enol. The acid also serves to

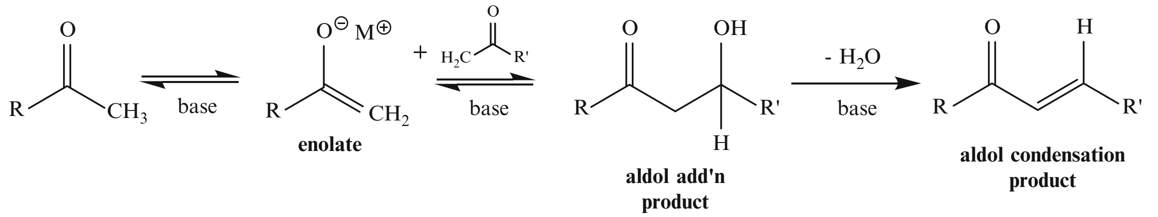
Table 10.33 Aldol reaction products

Enolate-forming carbonyl	Acceptor carbonyl	Chemistry	Product
n-Butyraldehyde	*n*-Butyraldehyde	SA, D, DH	2-Ethylhexaldehyde
n-Butyraldehyde	*n*-Butyraldehyde	SA, D, DH, CH	2-Ethylhexanol
Acetone	Acetone	SA	Diacetone alcohol
Acetone	Acetone	SA, D	Mesityl oxide
Acetone	Acetone	SA, D, DH	4-Methyl-2-pentanone
Acetaldehyde	Formaldehyde	CA, CH or CA, CZ	Pentaerythritol
Propionaldehyde	Formaldehyde	M	Methacrolein
Propionaldehyde	Formaldehyde	CA, CH or CA, CZ	Trimethylolethane (TME)
n-Butyraldehyde	Formaldehyde	CA, CH or CA, CZ	Trimethylolpropane (TMP)
i-Butyraldehyde	Formaldehyde	CA,CH or CA, CZ	Neopentyl glycol (NPG)
Acetaldehyde	Acetaldehyde	SA, D	Crotonaldehyde
Acetaldehyde	Acetaldehyde	SA, D, DH	*n*-Butyraldehyde
Acetaldehyde	Acetaldehyde	SA, D, DH, CH	*n*-Butanol
Acetaldehyde	Acetaldehyde	SA, CH	1,3-Butanediol
Acetaldehyde	Acetaldehyde	T	Ethyl acetate
i-Butyraldehyde	*i*-Butyraldehyde	T	2,2,4-Trimethyl-1,3-pentanediol (TMPD), isobutylisobutyrate, mono-/di-isobutyrate esters of TMPD
n-Valeraldehyde	*n*-Valeraldehyde	SA,D,DH,CH	2-Propylheptanol

SA self-aldol condensation; *CA* crossed-aldol condensation; *D* dehydration; *DH* double bond hydrogenation; *CH* carbonyl hydrogenation; *CZ* Canizzaro reaction; *T* Tishchenko reaction; *M* Mannich base condensation

activate the carbonyl group of another molecule by protonation, rendering it highly electrophilic. The enol is nucleophilic at the α-carbon, allowing it to attack the protonated carbonyl compound, leading to the aldol after deprotonation. The secondary or tertiary hydroxyl thus formed is highly favored to dehydrate to give the α,β-unsaturated carbonyl compound under acidic conditions. The combination of the aldol addition and dehydration steps is sometimes called an aldol condensation reaction.





Base-catalyzed aldol reactions begin as acid–base reactions and are thus extremely fast. An α-proton next to a carbonyl group is weakly acidic (pKa of 12–14). In the presence of a strong base, the α-carbon is deprotonated to a small extent to form an enolate ion. The coupling reaction occurs via nucleophilic attack by the resonance-stabilized enolate on the electrophilic carbonyl group of another molecule, which form a β-hydroxy carbonyl derivative (the aldol product) upon regeneration of the base catalyst. The aldol product may then undergo based-catalyzed dehydration to give the α,β-unsaturated carbonyl compound.

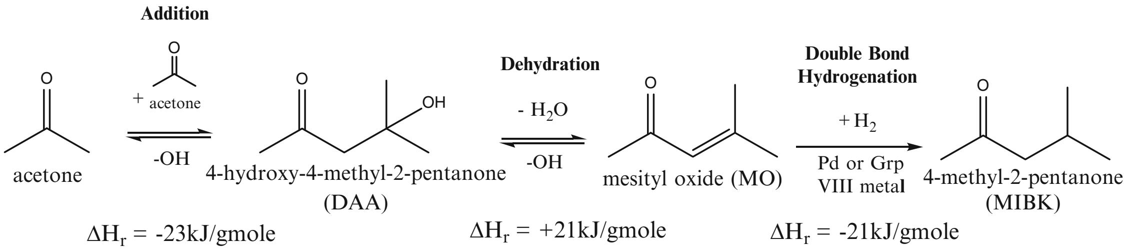
Ketones generally have a slightly lower pKa than aldehydes. Thus in a mixed ketone-aldehyde system, the ketone is favored to form the enolate and the aldehyde to act as the acceptor. Both steps are equilibrium limited, but the extent of the formation of addition and aldol dehydration products dictated by the structure of the reactants. For the following nucleophile-electrophile pairs the order of greatest shift to aldol products is:

$$\text{Aldehyde-Aldehyde} > \text{Ketone-Aldehyde} > \text{Ketone-Ketone}$$

Reactivity also diminishes with steric hindrance and with reduced solubility in the catalyst-containing phase (if the reaction is performed with a separate caustic-rich phase). A selection of industrially significant aldol-based processes is described in more detail below.

MIBK, Diacetone Alcohol (DAA), and Mesityl Oxide (MO) [237–239]

MIBK (4-methyl-2-pentanone), related intermediates, and its derivatives are the third largest end use for acetone behind methyl methacrylate and BPA. The synthesis of MIBK is a classic example of an aldol-based reaction pathway comprising self-aldol addition, dehydration, and hydrogenation:



This chemistry is practiced in both three-step and one-step process implementations. In the three-step process, acetone, dilute caustic is fed to a CSTR controlled at 10–20°C to enhance the equilibrium amount of DAA, but acetone conversion is typically only 8–10%. The reactor effluent is neutralized with phosphoric acid and stripped of unreacted acetone. Additional phosphoric acid is added to acidify the mixture to catalyze dehydration of DAA during distillation. Back-reacted acetone and the Mesityl oxide/water heterogeneous azeotrope are taken overhead and by-product salty water is underflowed. The organic layer from the overhead decanter is dehydrated and stripped of residual acetone in the next column. The dry underflow mesityl oxide (98–99 wt%) is hydrogenated over a Pd or Group VIII metal (e.g., Ni, Cu, Cr) in either a liquid phase reactor or in a low pressure hydrogenation/distillation column. One advantage of this process is that it allows for isolation of intermediates DAA and mesityl oxide.

The one-step process is much less capital intensive and generally allows for 30–50% per pass conversion of acetone. Acetone and hydrogen are fed to a packed bed reactor, slurry reactor, or catalytic distillation, typically at 130–140°C, 3–6 MPa, with an appropriate dual function catalyst combination to perform the aldol addition, dehydration, and hydrogenation reactions simultaneously. Many catalyst combinations have been reported in the open literature, including cation exchange resin impregnated with Pd, physically mixed exchange resin and supported Pd, zirconium phosphate-Pd, and niobium-Pd catalysts. Acetone, MIBK, and many of the reaction intermediates are present and active for further aldol and hydrogenation reactions, resulting in a very large reaction network. Typical yields of MIBK are 90–96% on acetone.

Neopentyl Polyhydric Alcohols [240, 241]

An important family of polyhydric alcohols with a neopentyl structure are pentaerythritol, trimethylolethane (TME), trimethylolpropane (TMP), and neopentyl glycol (NPG). These compounds are formed by the successive aldol addition reactions of formaldehyde with C_2 to C_4 aldehydes followed by reduction of the resulting hydroxy-aldehyde intermediate, as shown in Table 10.34. The aldol addition reactions are rapid, cannot be readily stopped at a lower number of formaldehyde additions, and do not lead to dehydration.

The typical process for pentaerythritol has not changed significantly for several decades. Aqueous formaldehyde, acetaldehyde, and aqueous $Ca(OH)_2$ or NaOH are fed to a CSTR maintained at 15–45°C. Three successive aldol additions of formaldehyde to acetaldehyde is followed by a Cannizzaro reaction (reduction of trimethylol acetlaldehyde by formaldehyde with formation of formic acid as a co-product) to form pentaerythritol. Overall the aldol-Cannizzarro sequence releases about 92 kJ/gmole of heat, necessitating effective reactor cooling. Although stoichiometry dictates the use of 4 moles of formaldehyde per mole of aldehyde, up to 16 moles per mole is added to limit formation of other acetaldehyde aldol and dipentaerythritol by-products.

Following neutralization of excess base with formic acid, unreacted formaldehyde is recovered by pressure distillation. The product polyol is recovered by stepwise vacuum concentration and fractional crystallization. If caustic is used as the base, an additional recrystallization from water is required to produce pentaerythritol free of sodium formate. On the other hand, calcium formate has very low solubility

Table 10.34 Neopentyl polyols

Name	Aldehyde feedstock	Feedstock structure	No. of α-hydrogens	Product structure
Pentaerythritol	Acetaldehyde		3	Trimethylolethane (TME)	Propionaldehyde		2	Trimethylolpropane (TMP)	*n*-Butyraldehyde		2	Neopentyl glycol (NPG)	*i*-Butyraldehyde		1	
in water and can be precipitated prior to pentaerythritol concentration/crystallization. No effective methods for direct hydrogenation of trimethylol acetaldehyde to pentaerythritol have been commercialized. Yields are typically about 90% on acetaldehyde. Finding industrial uses for the formate salts limits the application of this chemistry.

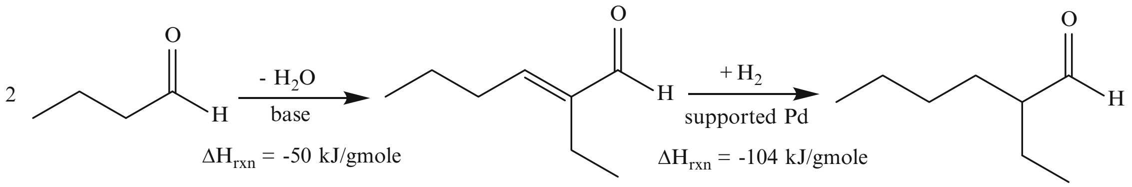
TME and TMP are produced commercially by very similar aldol-Cannazzaro processes, with the exception that the polyol often is extracted from the reaction mixture with a solvent, such as acetate esters, alcohols, or cyclohexanol, then purified by distillation. Yields are similar to pentaerythritol, reaching about 90%.

A significant portion of the neopentyl glycol produced commercially is synthesized by aldol addition with either sodium hydroxide or calcium hydroxide catalyst. The intermediate, hydroxypivaldehyde, can be finished via a Cannizzaro reaction, or more commonly by direct catalytic hydrogenation with Cu, Cu/Cr,Co, or Ni catalysts at 80–200°C, greater than 3.5 MPa pressure. Because the self-aldol of isobutyraldehyde requires a base stronger than hydroxide ion to occur to a significant extent (see section "Tischenko Reactions: Ethyl Acetate and 2,2,4-Trimethyl-1,3-Propanediol Derivatives" below), a relatively small excess of formaldehyde is sufficient for high conversion and a selectivity greater than 90%. Major by-products are 2,2,4-trimethyl-1,3-propanediol, neopentyl glycol isobutyrate, formic acid, formate salts, and NPG-hydroxypivalic acid esters. Purification involves extraction of the hydroxypivaldehyde intermediate with a solvent, followed by a series of distillations.

State-of-the-art NPG plants now use a tertiary amine catalyst in place of hydroxide catalysts. Complete conversion of formaldehyde occurs with a slight excess of isobutyraldehyde. The excess aldehyde is distilled with the amine and the two are recycled together. The reaction is quite selective and the most of acidic by-products produced by formaldehyde reduction are absent. The synthesis is finished with a similar catalytic hydrogenation. In both processes, hydroxypivaldehyde may be isolated and oxidized to the product hydroxypivalic acid.

2-Ethylhexanal [242, 243]

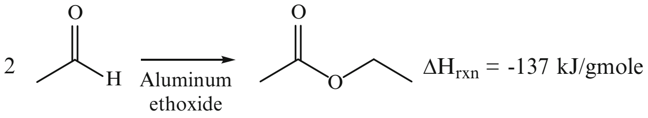
2-ethylhexanal is an extremely important intermediate for solvent and plasticizer applications. It is manufactured from *n*-butyraldehyde (see section "Hydroformylation") by aldol condensation in an alkaline medium or with a basic ion exchange resin at 80–130°C, 0.3–1.0 MPa. This is followed by catalytic hydrogenation of the double bond of the α,β-unsaturated aldehyde under mild conditions, 50–100°C, 0.2–2 MPa, to give 2-ethylhexanal. Supported Pd is a typical catalyst.



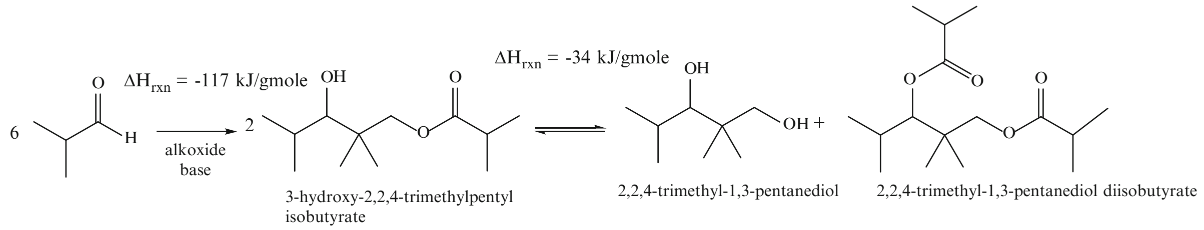
Conversion of *n*-butyraldehyde is high. The yield to 2-ethyhexanal are well above 90%, with major by-products of 2-ethylhexanol, and higher aldolized species. Under more severe conditions the α,β-unsaturated aldehyde intermediate can be converted directly to 2-ethylhexanol (see the section, "Hydrogenation"). Purification of 2-ethylhexanal occurs by distillation.

Tishchenko Reactions: Ethyl Acetate and 2,2,4-Trimethyl-1,3-Pentanediol Derivatives [244–246]

A closely related cousin of the aldol addition is the Tishchenko reaction occurring with aldehydes. In the presence of a base such as an aluminum alkoxide, one aldehyde molecule is reduced and the other is oxidized, with the direct formation of an ester. The largest industrial use of this reaction is in the formation of ethyl acetate from acetaldehyde:



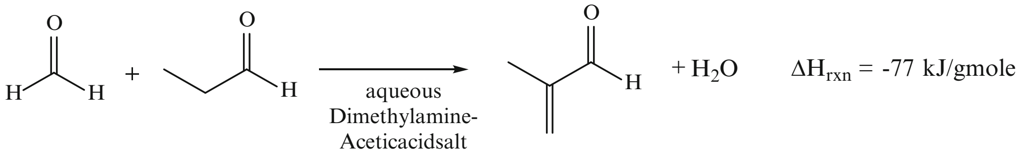
With a stronger alkali metal alkoxide base (e.g., sodium alkoxide), aldol addition is a competitive parallel reaction. An important application of the tandem Aldol-Tishchenko pathway is in the synthesis of 3-hydroxy-2,2,4-trimethylpentyl isobutyrate from isobutyraldehyde in the liquid phase using an alkali metal alkoxide salt as the catalyst.



A parallel Tishchenko reaction pathway produces isobutyl isobutyrate while equilibrium-limited transesterifications lead to 2,2,4-trimethyl-1,3-pentanediol and 2,2,4-trimethyl-1,3-pentanediol isobutyrate co-products. The products are separated by distillation.

Mannich Base Condensation: Methacrolein [247, 248]

The industrial use of a Mannich base (carboxylic or inorganic acid salt of a secondary amine) for aldol-type condensations is illustrated by the synthesis of methacrolein, the initial step in an alternate synthesis of methylacrylic acid. Propionaldehyde is condensed with aqueous formaldehyde in the liquid-phase in the presence of the Mannich base to form methacrolein and water:

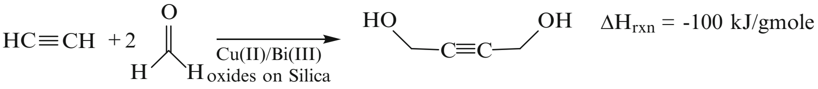


The best-performing base has been found to be a 40% aqueous solution of the dimethylamine-acetic acid salt. The synthesis methacrolein is remarkably selective (greater than 95%) and conversion of both formaldehyde and aldehyde are very high. Methacrolein is recovered by distillation from the reactor effluent as the methacrolein/water heterogeneous azeotrope, and further purified by distillation. The dimethylamine-acetic acid base is recycled to the reactor. The methacrolein thus produced can be oxidized in the same fashion as described in the section, "Acrolein/Acrylic Acid and Methacrolein/Methacrylic Acid."

Condensation of Formaldehyde with Acetylene: 1,4-Butanediol [249, 250]

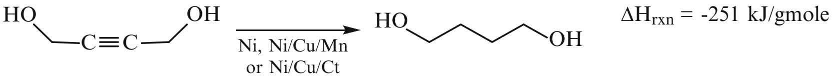
One of the major remaining applications of acetylene as a feedstock is in the synthesis of 2-butyne-1,4-diol, a precursor of 1,4-butanediol. This route still commands about 40% of the capacity for 1,4-butanediol. Acetylene is first reacted with 30–55 wt% formaldehyde in a series of three to five trickle bed columns at 80–110°C, 0.2–2.0 MPa over a silica supported Cu acetylide/Bi-promoted catalyst to produce

2-butyne-1,4-diol. Selectivity is about 90% on acetylene and greater than 90% on formaldehyde.



The CuO is converted to an acetylide under acetylene partial pressure. The reaction is first order in formaldehyde and zero order in acetylene. Back-mixed reactors helps to keep the unconverted formaldehyde level low in order to prevent catalyst inhibition and formation of formals. Conversion of formaldehyde is typically 97–99%. Dilute alkali is added to keep the pH in the 5–8 range. The Bi_2O_3 inhibits the formation of water-insoluble Cu-acetylene oligomers. The oligomers are quite shock sensitive, especially when dry. Deposition of these complexes in the reactor head spaces may lead to the formation of potentially explosive conditions and are to be avoided. Major by-products are propagyl alcohol, and sodium formate, along with unreacted formaldehyde. The butyne-diol is purified by vacuum distillation of the reactor effluent. Propagyl alcohol is removed as an azeotrope.

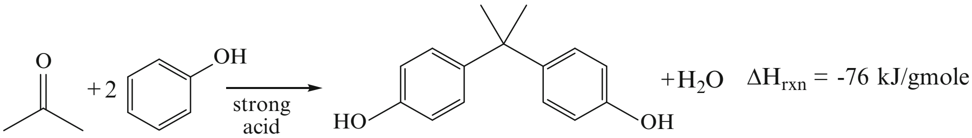
In the second step, the butyne is hydrogenated to 1,4-butanediol in the liquid phase at 70–170°C, 14–30 MPa, if Raney Ni is used, or 180–200°C, 20 MPa with Ni/Cu/Cr catalysts.



Both one- and two-stage fixed bed hydrogenation processes are used. Major by-products are methanol, *n*-propanol, *n*-butanol, hydroxyl-buyraldehyde, 2-methyl-1,4-butanediol, and formals Selectivity to butanediol is about 95%. The product is purified by distillation.

Bis-Hydroxyaryl Alkanes: Bisphenol A [251–253]

The bis-hydroxyaryl alkane structure, comprising two phenol molecules linked by a hydrocarbon chain, is synthesized by the acid-catalyzed liquid phase condensation of phenol with an aldehyde or ketone. Cyclohexanone, formaldehyde, and acetone adducts are produced commercially by similar processes. The acetone adduct, known as BPA, is by far the most important. BPA is produced from acetone and phenol in a fixed liquid-circulating bed or CSTR at 50–90°C, 0.11–0.40 MPa:



A high molar ratio of phenol to acetone, up to 15:1, helps suppress aldol reactions of acetone and multiple acetone/phenol condensations. The new carbon–carbon bonds occur almost exclusively in the 4-position of the phenol molecules. Acetone conversion is essentially complete, with yields greater than 90%. Sulfonated acid ion exchange resins are favored in newer installations over mineral acids, such as HCl or H_2SO_4, due to lower corrosion and ease of separation from the crude BPA.

Many flowsheet variations are practiced, but in one licensed process the reactor effluent is distilled to remove water and any unreacted acetone overhead. The bottoms of this column is distilled further to remove phenol for recycle and to produce a concentrated BPA bottoms stream. Solvent is added (alkane or aromatic) and the 1-1 phenol:BPA adduct is crystallized from the concentrate. Distilled to recover solvent, the remaining mother liquor is recycled to the reactor. A purge of the recycle, along with phenol-laden process water, is treated for removal of heavies and recovery of phenol. The adduct is melted and separated by distillation. Phenol is taken overhead, and the molten BPA underflow is prilled in a final processing step.

Hydration/Hydrolysis/Dehydration/Alcoholysis

Hydration of Olefins: Ethanol, Isopropanol, sec-Butanol, tert-Butanol [254–258]

Strong acid catalyzed hydration of olefins is an important industrial method for the production of alcohols. Ethanol, isopropanol, sec-butanol, and tert-butanol are produced in this fashion from ethylene, propylene, 1-butene, and isobutylene respectively. Both indirect and direct methods continue to be used. For unsymmetical olefins (anything greater than C_2), the addition of water follows Markovnikov's rule. Initial protonation of the olefin occurs so as to give the more stable, most substituted carbocation [259].

In the indirect method the olefin is absorbed into concentrated (about 60 wt%) sulfuric acid resulting in protonation of the olefin and formation of a carbocation. The HSO_4^- ion then adds to the carbocation to form mono- and di-alkyl sulfate intermediates. The alkyl sulfates are hydrolyzed to the corresponding alcohol by sparging with steam, which also serves to azeotropically distill the alcohol overhead and reconcentrate the sulfuric acid solution for recycle. Reactor conditions of 75–80°C, 0.6–3.0 MPa are typical, with selectivities of greater than 90%. The concentrated sulfuric acid solutions employed in the indirect process require the use of expensive corrosion-resistant materials of construction.

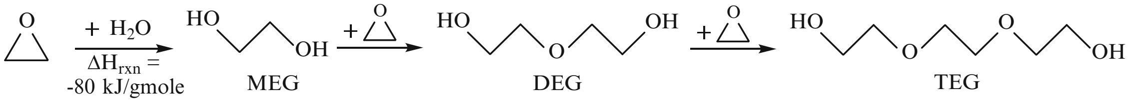
In direct processes, the carbocation intermediate is formed by a heterogeneous strong acid catalyst, such as a sulfonated polystyrene ion exchange resin, tungsten oxide, or supported phosphoric acid catalyst. Water then adds to form the corresponding alcohol in one step. Direct hydrolysis is an equilibrium-limited reaction, favored by low temperature, high pressure, and high water to olefin molar ratios. Both high (260–300°C, 7–20 MPa) and low (130–160°C, 8–10 MPa) temperature fixed bed processes are employed, with 20–75% conversion of the olefin per pass and selectivities of greater than 94%. Due to more mild conditions and lower corrosivity, direct hydrolysis has become the favored method.

In both direct and indirect methods, higher alcohols resulting from olefin oligomerization/hydrolysis, as well as the corresponding dialkyl ether of the product alcohol are typical by-products. All of the C_2-C_4 alkanols form low-boiling azeotropes with water. Thus, the recovery of an anhydrous product cannot be accomplished in a simple single-feed distillation step. Rather, dehydration of the alcohol is accomplished by a two or three column azeotropic distillation/decantation sequence. If dilute in the reactor effluent, the crude alcohol is first concentrated to close to its azeotropic concentration with water. An entrainer is added that forms an appropriate low-boiling heterogeneous azeotrope with water. Water is removed overhead as the heterogeneous water-entrainer azeotrope in a second distillation. This overhead mixture is decanted, with the water phase steam stripped to recover the entrainer and any alcohol, and the organic phase refluxed to the column. Anhydrous alcohol is recovered as the bottoms of the azeo column.

A convenient entrainer for isopropanol is diisopropylether made as a by-product in the hydration reaction. No additional entrainer is required for sec-butanol, nor for tert-butanol dehydration, as these form heterogeneous azeotropes with water. Diethyl ether can be used for ethanol, as well as other compounds such as *n*-hexane. A hybrid distillation/adsorption process, utilizing small pore molecular sieves for final removal of water is becoming more common, especially for dehydration of ethanol.

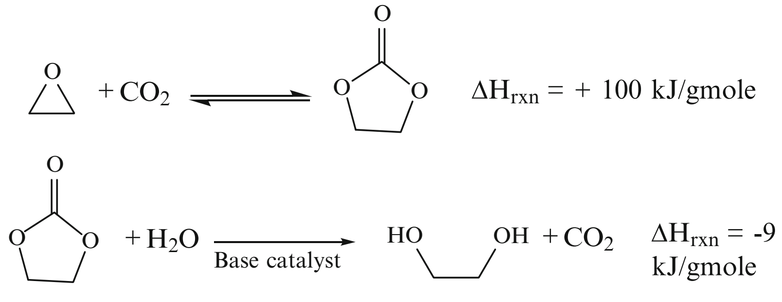
Hydrolysis of Epoxides and Carbonates: Ethylene Glycol, Propylene Glycol, and Higher Analogues [260, 261]

The ring opening of epoxide rings by addition of water is an extremely important industrial reaction, resulting in the formation of glycols and oligomeric ether glycols. Hydrolysis of ethylene oxide is the major industrial route to the production of ethylene glycol. In the typical industrial process, ethylene oxide is reacted thermally at 200°C with a high excess of water (20-1 mole ratio) to produce mono-, di-, and tri-ethylene glycols at a molar selectivity of 90-9-1 respectively.



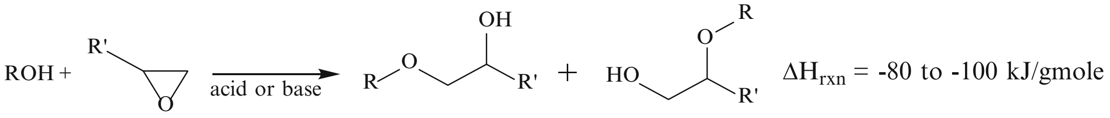
The hydrolyzed mixture is purified in a series of distillation columns with increasing vacuum level, to successively remove excess water, monethylene glycol, diethylene glycol, triethylene glycol overhead, and higher glycol oligomers as the bottoms of the final column. The purification train is quite energy intensive.

A recently commercialized process involves the hydrolysis of ethylene carbonate, with very high selectivity (>98%) to monoethylene glycol. In this process, ethylene oxide is reacted with carbon dioxide to form ethylene carbonate. Base-catalyzed hydrolysis of ethylene carbonate lead to predominantly monoethylene glycol.



Alcoholysis of Epoxides: Glymes and Ether Alcohols [262–266]

Another important use of epoxides is the formation of glycol ethers by alcoholysis:



When R´ is not hydrogen, such as with propylene oxide, two isomers may be formed. One isomer has a primary hydroxyl group and secondary ether group, the other has the opposite.

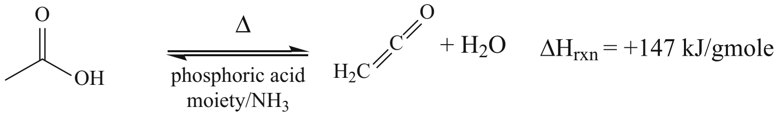
The reaction may be catalyzed by both acids and bases, exhibiting a catalyst-dependent product isomer mixture. The epoxide ring may open at either the primary or secondary C–O bond. With anionic (basic) catalysts, the epoxide ring opens preferentially at the least sterically hindered position, typically resulting in 95% or more secondary alcohol product (i.e., 1-alkoxy-2-alkanol). Acid catalysis affords a mixture of the 1-alkoxy-2-alkanol and 2-alkoxy-1-alkanol, with the relative ratio affected by the particular acid catalyst chosen and steric effects related to the size and structure of the reactant alcohol.

Large quantities of glycol ethers derived from C_1-C_4, C_6, and C_8 alcohols and ethylene oxide or propylene oxide are produced worldwide, mostly for solvent applications. In order to minimize the further reaction of the formed glycol ether with additional epoxide, a large excess of alcohol is used, at least 5:1 moles of alcohol per mole of epoxide. Alcoholysis of an epoxide is exothermic, with an average heat of reaction of about -80 to -100 kJ/gmole. Reaction conditions depend on the alcohol and epoxide, but are typically 170–220°C, 1.0–1.5 MPa. Conversion of the epoxide is essentially complete, with 80–90% molar selectivity to the mono glycol ether. The product is distilled to recover unreacted alcohol overhead for recycle, and the product glycol ether is distilled under vacuum in a second column, with higher glycol ethers as underflow. If markets dictate, diglycol and higher ethers may be recovered by further distillation of the bottoms.

The reaction of ethylene and propylene oxides with C_{10}-C_{14} detergent range alcohols affords ethoxylates and propoxylates, which are commonly employed as nonionic surfactants. The solubility of the product alkoxylate can be varied according to the number and type of epoxide molecules incorporated in to the molecule, as well as the chain length of the fatty alcohol. Longer chain groups reduce the solubility in water. Alcohols may be derived from natural fatty acids or higher oxo alcohols (either via ethylene oligomers or kerosene-based olefins).

Dehydration of Acetic Acid: Ketene [267–271]

Ketene, a highly reactive and useful intermediate, has been produced commercially since the 1920s by the high temperature, low pressure, equilibrium-limited, thermal decomposition of acetic acid, with concomitant generation of water (700–750°C, 0.005–0.02 MPa):



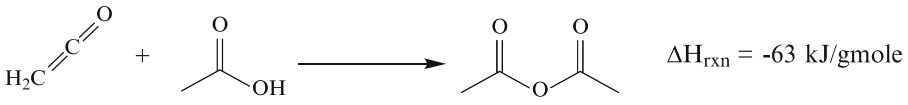
The equilibrium is shifted toward ketene production as the temperature is increased. The reaction occurs without a catalyst, but the higher temperatures needed to achieve reasonable rates and high equilibrium conversion without a catalyst lead to excessive decomposition to methane, CO, and CO_2. Commercial processes universally are catalyzed, typically with a derivative of phosphoric acid. Phosphoric acid itself, trialkyl phosphates, especially triethyl phosphate, and many other similar compounds are reported in the literature. Heterogeneous catalysis has been extensively studied, but has not been successfully commercialized [272].

In order to efficiently provide the large endothermic heat of reaction, the synthesis is carried out in a plug flow tubular reactor inside a fired furnace. Residence time is a matter of seconds, with achievable conversion of acetic acid of 70–80% per pass at the exit of the tubes. The temperature must be reduced quickly, with effective and rapid separation of liquid water and acetic acid from ketene vapor to prevent extensive back reaction of ketene with water. This quenching is usually accomplished by a series of low residence time, low pressure drop condensers. Overall conversion ends up at 40–70% per pass, depending on condenser design. Ammonia is added, either to the feed or to the furnace effluent to neutralize the phosphoric moieties and help prevent catalysis of the back reaction.

The condensed liquids, with concentration of 30–45% acetic acid in water, are processed, typically by extraction and/or azeotropic distillation to recycle low-water acetic acid to the furnace feed. The ketene thus produced is an efficient acylating agent, and is employed in a variety of downstream processes, such as direct production of esters via reaction with alcohols, synthesis of diketene, and predominantly for the formation of acetic anhydride. In the 1950s and early 1960s the major route to acrylic acid involved the pyrolysis of β-propriolactone, formed by the reaction of formaldehyde with ketene. This route has been completely supplanted by propylene oxidation.

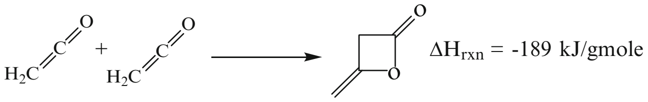
Ketene may also be produced by thermal decomposition of acetone above about 550–600°C (ketene + methane), or from acetic anhydride above about 600–650°C (ketene + acetic acid). The anhydride route is used to some extent to make ketene derivatives in India.

For acetic anhydride production, crude ketene effluent from the condensing train is scrubbed from the vapor phase by acetic acid in an absorber at 45–55°C. Rapid reaction with acetic acid produces acetic anhydride at essentially complete conversion and greater than 95% selectivity.



Heat is removed by a cooled circulation loop at the bottom of the absorber. The crude acetic anhydride, typically 80–90% purity, containing acetic acid and high boiling tars, is distilled in a two column sequence. Acetic acid and lights are recovered as the first distillate and largely recycled to the furnace, while acetic anhydride is recovered overhead in the second column, with tars removed as underflow.

Diketene is produced in a similar fashion by absorption of ketene into crude diketene in an absorber. The [2+2] cycloaddition product of ketene with itself is the four-member lactone, diketene:



Diketene is an extremely reactive and energetic molecule, but can be purified by distillation at reduced pressure and temperature. Diketene is used to produce a variety of specialty acetoacetates and arylides.

Esterification and Related Reactions [273–277]

Chemistry

Esterification is the reaction of a carboxylic acid with an alcohol to produce the corresponding ester and water:

In general, esterifications follow an $A_{Ac}2$ reaction pathway. A strong acid catalyst normally is necessary to achieve industrially viable rates. Typical catalysts are sulfuric acid, sulfonic acids, such as toluene sulfonic and methanesulfonic acids, or sulfonated polystyrene ion exchange resins in the hydrogen form. Although less expensive than sulfonic acids, sulfuric acid tends to promote dehydration of the alcohols to ethers and olefins more so than sulfonic acids. This is especially true for secondary and tertiary alcohols, which also suffer from significantly lower rates of reaction and equilibrium amounts of ester than primary alcohols.

The equilibrium constant for esterification, K_{eq}, can be expressed in terms of liquid concentrations or mole fractions and activity coefficients,

$$K_{eq} = \frac{[C_{ester}][C_{water}]}{[C_{acid}][C_{alcohol}]} = K_x K_\gamma = \frac{[x_{ester}][x_{water}]}{[x_{acid}][xC_{alcohol}]} \frac{[\gamma_{ester}][\gamma_{water}]}{[\gamma_{acid}][\gamma_{alcohol}]}$$

The equilibrium constant is usually on the order of magnitude of unity and the heat of reaction is close to neutral, as shown in Table 10.35 for a selection of esters. Thus, high conversion would require large excesses of alcohol or acid and corresponding large recycles of unreacted materials. To overcome these limitations, a common commercial approach

Table 10.35 Equilibrium constants and heat of reactions for acetate esters [277, 322, 323]

Carboxylic acid	Alcohol	K_{eq}	Standard heat of reaction, ΔH_r, kJ/gmole[a] [324]	Alcohol/acid molar ratio required for 50% conversion	Alcohol/acid molar ratio required for 90% conversion	Alcohol/acid molar ratio required for 99% conversion
Formic acid	Methanol	7.1	−16.0	0.57	2.0	14.8
Acetic acid	Methanol	5.2	−8.0	0.60	2.5	19.8

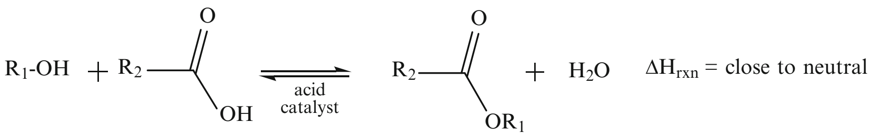
[a] If $\Delta H_r > 0$, then endothermic, if $\Delta H_r < 0$, then exothermic



is to use reactive distillation with the aid of azeotropes and two-phase liquid-liquid formation to allow for high conversion at or near stoichiometric feeds. Ester formation is an excellent illustration of LeChatlier's principle; an equilibrium reaction can be driven to completion by removal of one or more products of the reaction. Several flowsheets are possible, depending on the relative boiling points and azeotropes formed by the acid-water-ester-alcohol system.

Low Boiling Esters

When the ester forms a heterogeneous binary low-boiling azeotrope with water or a heterogeneous tertiary water-ester-alcohol azeotrope, the continuous flow sheet illustrated in Fig. 10.30 can be used. Large volume esters made by this process include ethyl acetate, *n*-propyl acetate, isopropyl acetate, and *n*-butyl acetate. In this process, the acid and alcohol are continuously fed to the reboiler-reactor (**1**) of the esterification column (**2**), along with a homogeneous strong acid catalyst, such as sulfuric acid, methanesulfonic acid, or toluene sulfonic acid. The low-boiling water-laden azeotrope is taken as the distillate product, which decants into two phases (**3**). The water layer is steam-stripped (**4**), with organic distillates returned to the ester column and underflow water discarded. If the water content of the ester-water azeotrope is more than the amount of water created in the esterification reaction, then some of this water may be recycled to the ester column. A portion of the organic layer from the esterification column decanter is refluxed to the ester column, and the rest is distilled in a low boiler column (**5**). The low boiler column distillate, containing alcohol, water, and ester are returned to the reactor. The dry, alcohol-free ester underflow from the low boiler column is fed to a refining column (**6**) for final purification from heavies. Heavies, sludge, and spent catalyst is removed as the bottoms of the esterification column and discarded. Sometimes extra water is added near the top of the esterification column to aid in azeotroping the ester overhead.

High Boiling Esters

With high boiling esters that cannot be conveniently taken overhead, or those that boil too closely or form azeotropes

Fig. 10.30 Flowsheet for production of low-boiling esters

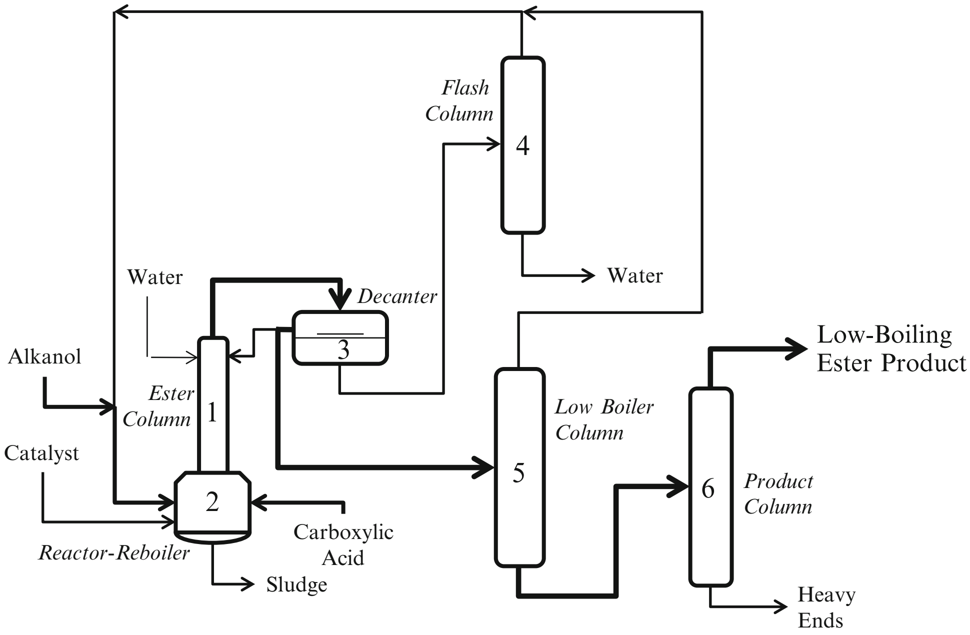


Fig. 10.31 Flowsheet for production of high-boiling esters

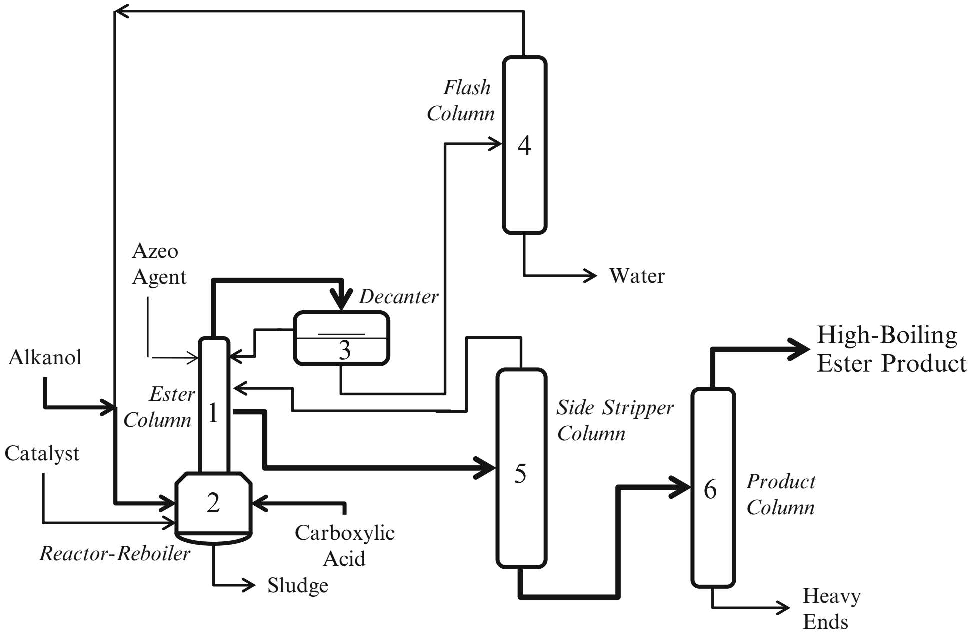

with their raw material acids and alcohols to allow for easy separation, the reaction still can be driven to completion by using an azeotropic distillation-sidedraw scheme as shown in Fig. 10.31. The acid and alcohol are continuously fed to the reboiler-reactor (**1**) of the esterification column (**2**), along with a homogeneous strong acid catalyst, such as sulfuric acid, methanesulfonic acid, or toluene sulfonic acid. Water is removed overhead by azeotroping out as any convenient heterogenous acid-water-ester-alcohol azeotrope or by adding an inert species such as cyclohexane or toluene that forms a low-boiling heterogeneous azeotrope with water. The azeotrope is decanted (**3**), with the organic layer refluxed to the ester column. The water layer is steam-stripped (**4**), with organic distillates returned to the ester column and underflow water discarded. The crude product ester is removed low down in the ester column as a sidedraw product with further purification by a sidedraw stripper (**5**). The ester is taken overhead in the product column (**6**), with heavy residue as underflow. Many glycol ether esters and higher boiling esters such as butyl butyrate can be made with such a flow sheet.

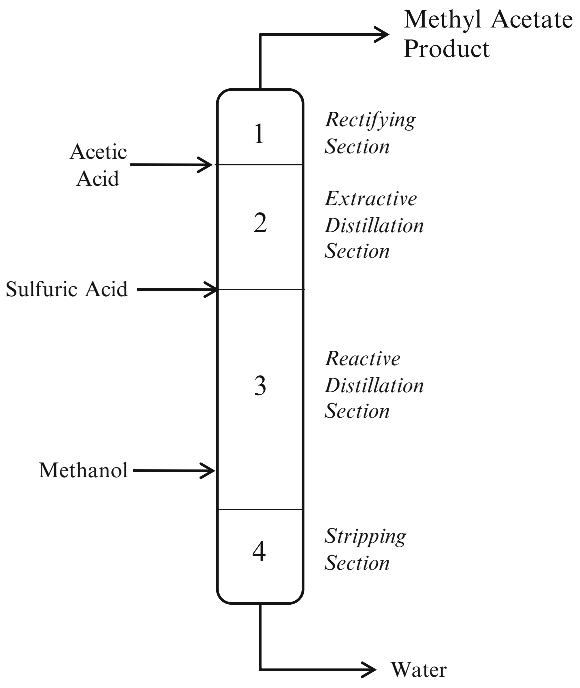

Fig. 10.32 Flowsheet for production of methyl acetate by reactive distillation

Methyl Acetate [278]

Methyl acetate cannot be produced in high purity using the simple esterification schemes outlined above due to unfavorable vapor–liquid and liquid-liquid equilibrium behavior:

1. The methyl acetate-methanol–water system does not form a ternary azeotrope.
2. The methyl acetate-methanol azeotrope is lower boiling than the water-methyl acetate azeotrope.
3. There is a distillation boundary between the two azeotropes.
4. The liquid-liquid region does not include either the methyl acetate-water or the methyl acetate-methanol azeotrope, nor does it cross the distillation boundary.

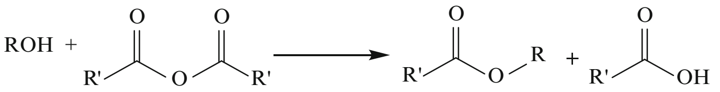
Consequently the water generated by esterification cannot be removed effectively, nor can the methyl acetate azeotropes be broken readily. The reactive distillation process (see Fig. 10.32) overcomes both unfavorable reaction and poor phase equilibriums to produce high purity methyl acetate and water in one column from near stoichiometric acetic acid-methanol feed ratios. Conceptually this column can be thought of as four heat-integrated distillation columns and a reactor stacked on top of each other. Reaction occurs below the sulfuric acid feed in a series of countercurrent high hold-up trays. This countercurrent separation, along with the low feed point of methanol results in high local excesses of at each end of the reactive section (**3**) in spite of the overall stoichiometric feed. The acetic acid feed acts as an extractive distillation agent above the reaction zone (**2**) to break the methyl acetate-methanol azeotrope. The upper rectification section (**1**) knocks back any acetic acid from the methyl acetate product, and the lowermost stripping section (**4**) removes methanol from the water bottoms. High purity methyl acetate is the distillate product, and clean water underflows.

Plasticizer Esters

One of the primary uses of higher boiling and low volatility esters is as plasticizers. A plasticizer increases the flexibility and ductility of a brittle thermoplastic polymer by reducing the glass transition of the polymer. PVC is the most commonly plasticized polymer. A large number of plasticizers based on phthalic anhydride, TPA, adipic acid, TMA, benzoic acid with 2-ethylhexanol, or C_9 and C_{10} iso-alcohols are made commercially, by anhydride reactions with alcohols (e.g., di-2-ethylhexylphthalate) or high boiling acid-alcohol reactions driven to completion by introduction of excess alcohol and removal of water generated [279].

Esterifications with Anhydrides

For hindered, unreactive alcohols, those susceptible to dehydration, and those producing very high boiling esters, it is often more favorable to produce the ester via reaction with an anhydride. The basic reaction of a symmetric anhydride with an alcohol is given by:



ΔH_{rxn} = -60 to - 70 kJ/gmole

The equilibrium is quite favorable and lies essentially completely toward the ester. Since the reaction is first order in both alcohol and anhydride, a small excess (less than 5 mole%) of either the alcohol or anhydride is added in practice to ensure complete conversion in reasonable reaction times. Typically a catalyst is not necessary, but strong acids or pyridine derivatives can be used to accelerate the rate.

Many carboxylic acid anhydrides can be made via reactive distillation in which a low boiling anhydride is reacted with a higher boiling carboxylic acid. This reaction, occurring stepwise, is equilibrium-limited and can be driven to complete formation of the symmetric anhydride of the high boiling acid by distillative removal of the generated low-boiling acid. The most common low boiling anhydride used in such a process is acetic anhydride.

Hydrogenation [280–283]

Chemistry

Hydrogenation involves the addition of molecular hydrogen (H_2) to a functional group to reduce its oxidation state. Typical substrates and products of hydrogenation reactions include: alkynes, alkenes, and aromatic rings to alkanes, aldehydes to primary alcohols, ketones to secondary alcohols, esters and carboxylic acid to alcohols, nitriles to imines and amines, and amides to amines. A closely related type of reaction, hydrogenolysis, involves hydrogen addition with concomitant breaking of other carbon–carbon or carbon-heteroatom (oxygen, nitrogen or halogen) bonds. Hydrogenation differs from protonation or hydride addition; in a hydrogenation the products have the same charge as the reactants. The ease of hydrogenation of various functional groups generally follows the decreasing order: [284]

$$\text{alkynes} > \text{alkenes} > \text{nitriles, nitros} > \text{aldehydes} > \text{ketones} \\ > \text{aromatic rings} > \text{anhydrides} > \text{esters} > \text{carboxylic acids}$$

Steric factors and substitution patterns further dictate the ease of hydrogenation, decreasing in order of straight chain > branched far from the functional group to be hydrogenated > branched adjacent to the functional group to be hydrogenated. Bulky substituents also tend decrease reactivity. Selective hydrogenation of one functional group in the presence of another functional group (e.g., hydrogenation of the double bond of an α β-unsaturated ketone, while preserving the ketone group) is a fairly common issue, often solved by judicious selection of catalyst metal as well as reaction conditions.

A hydrogenation reactor must be designed for effective heat and mass transfer. Most hydrogenation reactions are highly exothermic, with heats of reaction at least above −50 kJ/gmole and high adiabatic temperature rises. Typical heats of reaction for various functional group hydrogenations are given in Table 10.36. Moreover, hydrogen gas must get to the surface of the catalyst through vapor or liquid films. Common reactor formats include CSTR's with internal cooling coils or external exchanger loops, Buss loop reactors, and trickle beds with cooling loops. These formats provide good mixing for mass and heat transfer, but as backmixed systems require large reactor volumes for high, i.e., greater than 95%, conversion. Often a small plug flow polishing fixed bed is included after the main reactor to get the conversion up to above 99%. See for example, the hydrogenation of benzene to cyclohexane. Examples of commercially significant hydrogenation reactions are given in the subsections which follow.

Table 10.36 Typical heats of reaction for hydrogenation of various functional groups

Functional group transformation	Heat of reaction, kJ/gmole
Saturation of double bond	−90 to −130
Saturation of triple bond	−300
Aromatic ring saturation	−200 to −215
Carbonyl to alcohol	−60 to −65
Ester to alcohols	−25 to −100
Acid to alcohol	−25 to −75
Nitro to amine	−550

Methanol [285–289]

Methanol is produced by the hydrogenation of carbon monoxide and carbon dioxide. The first industrial production of methanol from CO, CO_2, and H_2, i.e., synthesis gas, was carried out over a zinc oxide/chromium oxide catalyst at high pressure (25–35 MPa) and temperature (300–450°C). Developments during the late 1960s and early 1970s resulted in the first modern Cu/ZnO/catalysts capable of operation at much lower temperatures (200–310°C) and pressures (4–10 MPa). The low pressure process results in lower investment and production costs, higher yields, improved reliability, and much larger potential plant size. Plant capacity has increased dramatically from less than 1,000 metric tons per day for old plants, to more typically greater than 2,500 tons per day, with single train capacities of 5,000 metric tons per day or more now in operation.

The synthesis of methanol can be thought of as the hydrogenation of carbon monoxide and carbon dioxide. A typical feed gas contains somewhat higher than a 2–1 M ratio of H_2 to CO, and 2–12 mole% CO_2. The feed gas composition often is characterized by the stoichiometric number, SN, defined as:

$$\mathrm{SN} = \frac{(\mathrm{H_2} - \mathrm{CO_2})}{(\mathrm{CO} + \mathrm{CO_2})}$$

The value of SN should be about 2.05 for optimal performance. Syngas for methanol production can (and does) originate from a variety of sources and processes

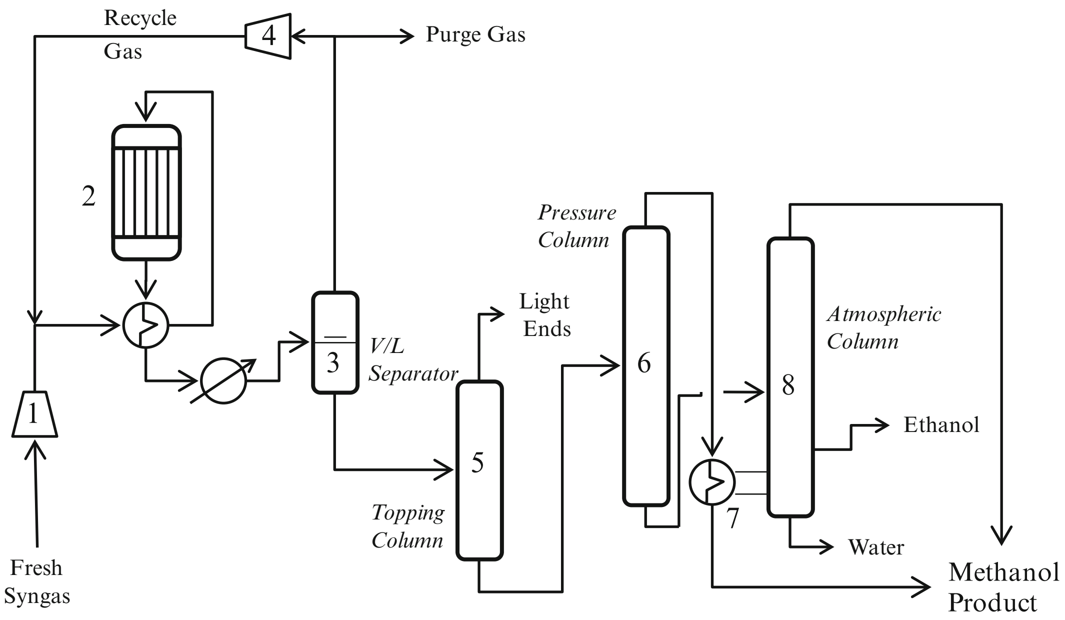


Fig. 10.33 Flowsheet for production of methanol

including natural gas via SMR, partial oxidation (POX), or autothermal reforming (ATR), as well as gasification of coal. ATR generally produces the appropriate SN for methanol directly. SMR needs CO_2 addition; coal gasification and POX require additional water-gas shift and subsequent CO_2 separation to enhance hydrogen sufficiently to give the desired SN of 2.05. See Section "Synthesis Gas", and Chaps. 19, 20, and 22 for further details on syngas production.

The net stoichiometry of the reaction is:

$$CO + 2H_2 \xrightleftharpoons{Cu/ZnO/Al_2O_3} CH_3OH \qquad \Delta H_{rxn} = -91\ \text{kJ/gmole}$$

In reality, the main source of the carbon incorporated into the methanol molecule is actually derived from carbon dioxide via reaction with hydrogen:

$$CO_2 + 3H_2 \rightleftharpoons CH_3OH + H_2O \qquad \Delta H_{rxn} = -49\ \text{kJ/gmole}$$

As the carbon dioxide in the feed is consumed, the reverse water-gas shift reaction kicks in to supply more:

$$CO_2 + H_2 \rightleftharpoons CO + H_2O \qquad \Delta H_{rxn} = +42\ \text{kJ/gmole}$$

The overall methanol synthesis network is equilibrium-limited, exothermic, and results in a reduction of volume upon reaction. Low temperatures and high reaction pressures favor conversion to methanol.

The modern low pressure methanol process is relatively simple as shown in Fig. 10.33. A syngas with SN = 2.05, less than 0.05 ppm sulfur (as H_2S), is compressed (**1**), if needed, to the reactor loop pressure of 4–10 MPa,[2] interchanged with the reactor effluent, combined with recycle gas, and fed to the fixed bead reactor containing the $Cu/ZnO/Al_2O_3$ catalyst (**2**). Both multistage intercooled adiabatic, and multi-tubular steam cooled reactors are used commercially. Some commercial processes use reactors in series at different conditions for higher per pass conversion. The reactor temperature is usually maintained below 260°C. Conversion of CO is about 50% per pass. Major by-products are ethanol (150–200 ppm); higher alcohols (300–400 ppm); acetone, MEK, and other ketones (less than 10 ppm); and depending on the generation of catalyst, 20–100 ppm dimethyl ether. Yield from CO is quite high, usually more than 99%.

The methanol–rich reactor effluent is cooled, and crude methanol is separated from non-condensables before further purification (**3**). A small purge is taken from the separator off-gas to prevent build-up of inerts such as argon, nitrogen, methane entering with the inlet syngas. The remainder of the gas (typically at a SN of 3 to about 10) is boosted to loop pressure and recycled (**4**).

The crude methanol is typically purified in a two or three column distillation sequence. The first column (**5**) removes light ends overhead (dissolved gases and other species). The product methanol is then distilled overhead, with water taken as underflow, and intermediate boiling-impurities

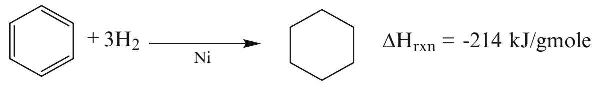
---

[2] Coal gasification-derived gas is usually high enough pressure, SMR, ATR, POX gas needs compression.

(ethanol, higher alcohols, ketones) as a sidedraw, if high purity is needed. The product distillation is often done as a dual-column pressure swing setup to reduce energy consumption. In this scheme, steam is fed only to the reboiler of first high pressure methanol product column (**6**). A portion of the methanol is distilled overhead, with methanol–water as bottoms. The vaporous product methanol from the first column is not condensed, but used to drive the reboiler (**7**) of the second lower pressure column (**8**). The remainder of the methanol is distilled in the second column, with water taken as bottoms product, and impurities as a sidedraw if needed.

Aromatic Ring Saturation: Cyclohexane [290–292]

Cyclohexane, via the hydrogenation of benzene, is an important intermediate in the production of adipic acid and caprolactam, monomers for nylon 6,6.



Both vapor and liquid phase processes are practiced commercially. In one common liquid phase process, benzene is hydrogenated isothermally over a fine slurry of suspended Raney nickel at 180–200°C, 5 MPa. Soluble catalysts are also used. The heat of reaction is removed by a combination of an external steam generating heat exchanger and by vaporization of part of the reactor contents. Vapors from the first stage reactor are passed to a fixed-bed polishing reactor for final conversion. Conversion is about 95% in the first stage, with essentially complete conversion in the polishing bed. The vapor effluent is flashed, condensed and separated from hydrogen and light gases for recycle and purging. If the hydrogen purity is low, then the cyclohexane is fed to a small stabilizer column to remove light ends. Low temperature operation significantly reduces the equilibrium isomerization of cyclohexane to methylcyclopentane. Selectivity is greater than 99.8% to benzene with less than 100 ppm methylcyclopentane.

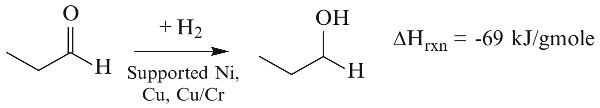
α,β-Unsaturated Carbonyls to Saturated Ketones and Aldehydes [293, 294]

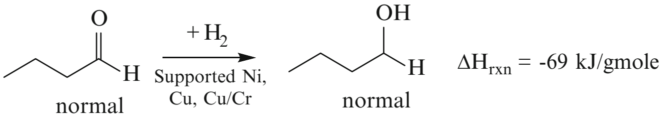
An important aspect of the production of ketones and aldehydes via aldolization (see section "Aldol Condensation") is the selective hydrogenation of the double bond of the α,β-unsaturated carbonyl intermediate without formation of alcohols. Pd on alumina, silica, titania, or carbon have been found to be very effective catalysts for this transformation, with 100/1. Ni, Cu, Cu/Cr, and Pt catalysts normally are not selective for double bond hydrogenation without excessive alcohol formation.

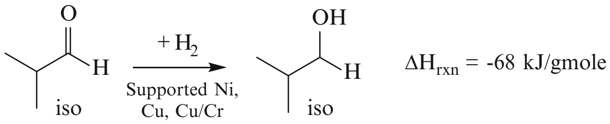
Much research effort has been expended on developing selective catalysts for reduction of the α,β-unsaturated carbonyl to an alcohol, while retaining the double bond functionality.

Aldehydes and Ketones to Alcohols [295, 296]

Aldehydes are readily hydrogenated to their corresponding alcohols under relatively mild conditions. Three alcohols of significant volume produced by the hydrogenation of Oxo-derived aldehydes are *n*-propanol, *n*-butanol, and *i*-butanol:

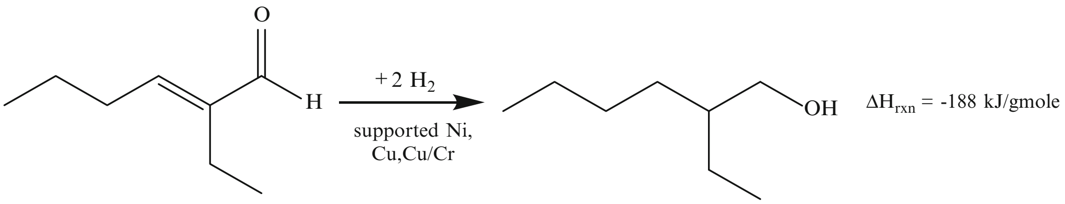






The hydrogenation may be conducted in either the gas or liquid phase with supported Ni, Cu, or Cu/Cr, or Cu/Zn catalysts at about 115–160°C, 0.2–8 MPa. Yields are typically above 98%. By-products consist of minor amounts of acetals, ethers, and higher boiling condensation products. Detergent range alcohols are also produced in this fashion from higher Oxo aldehydes.

The important plasticizer alcohol, 2-ethyl-hexanol, may be synthesized by a similar hydrogenation of 2-ethylhexaldehyde, or alternatively directly from the aldol-derived α β-unsaturated aldehyde by the simultaneous hydrogenation of the double bond and carbonyl.



Both vapor and liquid phase processes are utilized with supported Ni, Ni/Cu, Cu, or Cu/Cr catalysts. Vapor phase processes are commonly run in two stages, with about 90% conversion in the first stage. The first stage is operated at 100–170 or 200–250°C, 0.5–5.0 MPa. The final polishing stage is operated at 200–250°C, 0.5–5.0 MPa.

Carbinols, the common name for ketone-derived secondary alcohols, can be produced in very similar vapor or liquid hydrogenation processes under slightly more forcing temperature and pressure conditions than aldehyde conversion. The conversion of more hindered ketones, such as MIBK (4-methyl-2-pentanone) to methyl isobutyl carbinol (MIBC) require somewhat longer residence times, temperature, and/or hydrogen pressure, but yields are essentially quantitative. The equilibrium for formation of ketols from ketones and product alcohols is much less favorable than for aldehyde-alcohol acetal formation.

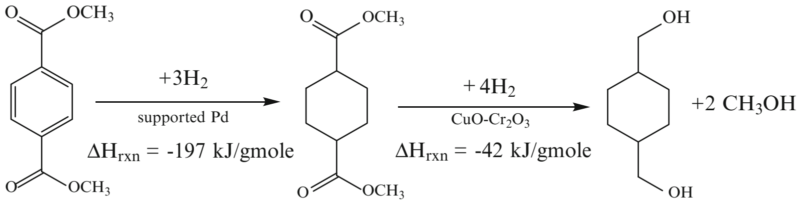
Supported heterogeneous Pt and Ru catalysts are successfully employed for the reduction of highly hindered or sensitive carbonyls, as exemplified by the conversion of the ring-strained 2,2,4,4-tetramethyl-1,3-cyclobutadione to 2,2,4,4-tetramethyl-1,3-cyclobutadiol [297], but are not normally used for more commodity applications.

Esters to Alcohols: Dimethyl Maleate to γ-Butyrolactone, THF, and 1,4-Butanediol [298–301]

In one commercial process, maleic anhydride is esterified with methanol in a reactive distillation column to form the intermediate dimethyl maleate. The reaction is driven to completion by removal of water and methanol from the top of the column. Methanol and water are separated by distillation, with the methanol recycled. The maleate ester underflow from the first column is vaporized in excess hydrogen and is hydrogenated in a fixed bed adiabatic reactor. The reactor effluent is cooled, condensed, and the crude BDO product is separated from hydrogen (which is recompressed and recycled). The crude BDO is separated in a three-column distillation sequence. THF and other lights are removed overhead in the first column. Methanol is distilled overhead in second column for recycle, and high purity product BDO is the distillate of the third column. Unreacted maleate ester and γ–butyrolactone by-product in the underflow of the column are recycled for further conversion. The molar yield of BDO from maleic anhydride is about 97%. Conditions can be modified to produce all THF or to recover GBL. In another commercial process maleic anhydride is hydrogenated directly without first making the diester.

Esters to Alcohols: Dimethyl Terephthalate to 1,4-Cyclohexanedimethanol [302]

An example of the large-scale hydrogenation of an ester to alcohols is the production of 1.4-cyclohexanedimethanol (CHDM) from DMT. DMT in a mixture of methanol and CHDM is hydrogenated in the liquid phase over a supported Pd catalyst at 110–180°C, 30–40 MPa to give a mixture of cis/trans-cyclohexane-1,4-dicarboxylic acid dimethyl ester. Further hydrogenation over copper chromite at more severe conditions yields CHDM.



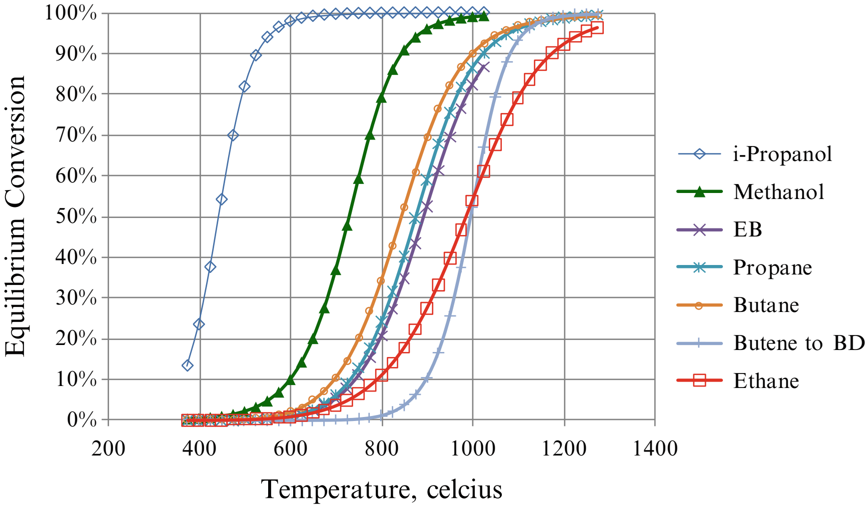
Co-polyesters of TPA, ethylene glycol, and CHDM have enhanced toughness, better injection molding and sheet extrusion properties than simple polyethyleneterephthalate polymers.

Dehydrogenation [303–305]

Chemistry

Conceptually, direct dehydrogenation, a reaction producing hydrogen as a by-product, is simply the reverse of hydrogenation. Direct dehydrogenation reactions find commercial use primarily in the conversion of saturated alkanes and alkyl aromatics into olefinic and diolefinic compounds (butanes to butenes, butenes to butadiene, ethylbenzene to styrene, long chain *n*-paraffins to olefins), as well as the conversion of secondary alcohols into ketones (isopropanol to acetone, sec-butanol to 2-butanone, methanol to formaldehyde). Oxidative dehydrogenation, wherein the hydrogen is converted in situ to water, is also practiced for accomplishing the same ends as direct dehydrogenation. See for example the discussion on formaldehyde earlier in this chapter.

Fig. 10.34 Effect of temperature on equilibrium conversion for several dehydrogenation reactions, pressure of 0.1 MPa



Dehydrogenation reactions are endothermic and generally severely equilibrium-limited. Reasonable rates and conversion are favored by high temperature and low pressure, as the number of moles increases with generation of hydrogen. Figure 10.34 presents the effect of temperature on equilibrium conversion for several important dehydrogenation systems (at 0.1 MPa total pressure, with no diluents added). Note that very high temperatures are required with most hydrocarbon systems for a reasonable conversion of 50%. This graph illustrates at least one reason ethane to ethylene dehydrogenation has not been commercialized. To get conversions of ethane comparable to steam cracking, one has to operate at temperatures where thermal cracking is significant anyway. High temperature operation leads to other collateral problems:

1. Significant high temperature (i.e., expensive) energy is needed for heating feeds and reaction mixtures.
2. The thermal cracking of molecules has a high activation energy and tends to compete with dehydrogenation above about 650°C.
3. Consecutive dehydrogenations of the same molecule (often energetically favorable) tend to lead to rapid coke formation and catalyst fouling, with frequent regenerations required.
4. Metal sintering and permanent deactivation is accelerated at high temperatures.

Reactor designs reflect these factors. Common designs include, (a) direct-fired furnace feed heaters with adiabatic fixed beds in series (often with hot shots of feed between beds), (b) isothermal fixed beds (reactor in a furnace), (c) moving beds to allow for regeneration, and (d) fluid beds for heat control, with separate continuous regenerators (much like FCC units).

Manipulation of the partial pressure of products generated is another approach to allow lower temperature operation. Common methods include:

1. Operation at subatmospheric pressure.
2. Addition of steam or other inerts to lower hydrogen and product partial pressures.
3. React away hydrogen as it is formed or form water instead (i.e., oxidative dehydrogenation).

The effect of the magnitude of the equilibrium constant, inert addition, feed hydrogen, and total system pressure on equilibrium conversion can be calculated readily by the relationship given below [306]:

$$K_{\mathrm{p}} = \frac{XP(H+X)}{(1-X)(1+I+H+X)}$$

where

K_{p} = temperature-dependent equilibrium constant
X = molar conversion of reactant
H = moles of H_2 in feed to moles of reactant
P = total system pressure
I = moles of inerts in feed to moles of reactant

The process designer has many degrees of freedom, with tradeoff on temperature, partial pressure, and diluents addition, as well as reactor format. Thus, many flowsheet alternatives can accomplish the same end result, and many versions of dehydrogenation processes, particularly for alkanes to olefins, have been successfully commercialized.

Catalysts used for hydrogenations, such as precious metals and Group VIII transition metals, generally also are useful for dehydrogenation reactions. Supported Pt—Sn and Cr-based catalysts are the most common used commercially. Although inactive itself for dehydrogenation, the addition of Sn to Pt catalysts acts to suppress hydrogenolysis, moderates coking rate (promotes migration of coke from the active catalyst metal to the support), and reduces sintering. Table 10.37 summarizes commercial conditions and

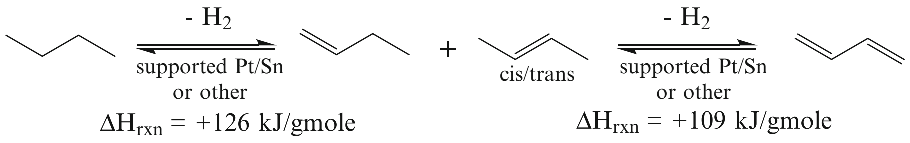
Table 10.37 Important dehydrogenation reactions

Reactant	Product	Catalyst	Conditions	Heat of reaction, kJ/gmole
C_3-C_4 alkanes [325]	C_3-C_4 mono-olefins	Pt/Sn on γ-Al_2O_3, zirconia, or Zn/Ca-aluminate; chromia on γ-Al_2O_3	530–650 °C; 0.03–0.5 MPa; some processes steam co-feed	+126 to +137
C_{10}-C_{16} alkanes	C_{10}-C_{16} internal alkenes	Promoted Pt/Sn on γ-Al_2O_3	300–550 °C; 0.1–0.3 MPa; H_2/alkane (5–9)/1	+120 to +135
Butenes [307]	1,3-Butadiene	Chromia on γ-Al_2O_3; cromium oxide-Ca-Ni-phosphate; iron oxide	575–700 °C; 0.014–0.03 MPa; some with steam co-feed; some processes use oxydehydrogenation	+109
Ethylbenzene	Styrene	K_2O/Fe oxide	600–720 °C; 0.1 MPa; steam co-feed, (1–2)/1 wt ratio	+125
sec-Butanol	Methyl ethyl ketone	Cu oxide, Cu chromite, Cu/K/SiO_2, ZnO, Pt/Al_2O_3	240–420 °C; 0.1–0.6 MPa	+59
Isopropanol	Acetone	Cu oxide, Cu chromite, Cu/Na/SiO_2, ZnO	220–400 °C; 0.1–0.3 MPa	+67
Methanol	Formaldehyde	Silver gauze or crystals	600–720 °C; 0.1 MPa; air co-feed	+85

catalysts for a number of important industrial dehydrogenation reactions. More detailed discussions of a few key processes are given below.

Butenes and 1,3-Butadiene [307–309]

A large number of similar commercial processes have been developed for the dehydrogenation of butanes to butenes and butanes/butenes to 1,3-butadiene, using heterogeneous catalysts (e.g., Pt/Sn on γ-Al_2O_3; zirconia, or Zn/Ca-aluminate; Chromia on γ-Al_2O_3; Cromium oxide-Ca-Ni-phosphate; iron oxide) at 530–700°C, 0.03–0.5 MPa.



Butadiene is particularly susceptible to polymerization and coking, so high steam to feed ratios are often used to reduce coke formation and to lower the partial pressure of hydrogen to shift the equilibrium toward butadiene. Even with these steps, coking occurs rapidly. Multiple reactors are used to allow regeneration/operation to occur in cycles lasting on the order of an hour or less.

In an alternative approach, oxidative dehydrogenation methods have also been employed to overcome the unfavorable equilibrium. In one version, butanes and/or butenes, steam, and air are fed to a fixed bed reactor at a relatively low inlet temperature of about 370°C, where combustion of produced hydrogen supplies the necessary heat of reaction for the dehydrogenation. The outlet temperature rises to about 480–600°C due this combustion. Conversion over the ferrite/Zn or ferrite/Mn catalyst is greater than 60%, at up to about 90–93% selectivity.

Internal Olefins from Higher *n*-Alkanes [310, 311]

The dehydrogenation of C_{10}-C_{14} *n*-paraffinic materials derived from kerosene fuels is an important source of internal olefins for linear alkylbenzene production (see Section 10.3 above). In a typical commercial process, a narrow-boiling kerosene cut is first treated by shape-selective adsorption to recover a stream high in *n*-paraffins. This material is dehydrogenated in the vapor phase over Pt/Sn on alumina (often with In and Li promoters) at 300–550°C, 0.1–0.3 MPa, with H:C ratio of (5–9):1. The higher alkanes are particularly susceptible to thermal cracking reactions, and the hydrogen helps prevent this decomposition pathway. Conversion is 10–15% per pass at selectivities of 90–94%. Unreacted *n*-paraffins for recycle are separated from olefins by adsorption. This is another example of a separation exploiting functional group differences to effect the separation in a single step, whereas separation by volatility differences (distillation) would be prohibitively complicated.

Styrene from Ethylbenzene [312–315]

Direct dehydrogenation of ethylbenzene to styrene accounts for about 85% of commercial production. The remaining styrene is produced via coproduction with propylene oxide (see section 1 of this chapter). The major reaction is the endothermic (+125 kJ/gmole), high temperature, vapor phase conversion of ethylbenzene to styrene and hydrogen.

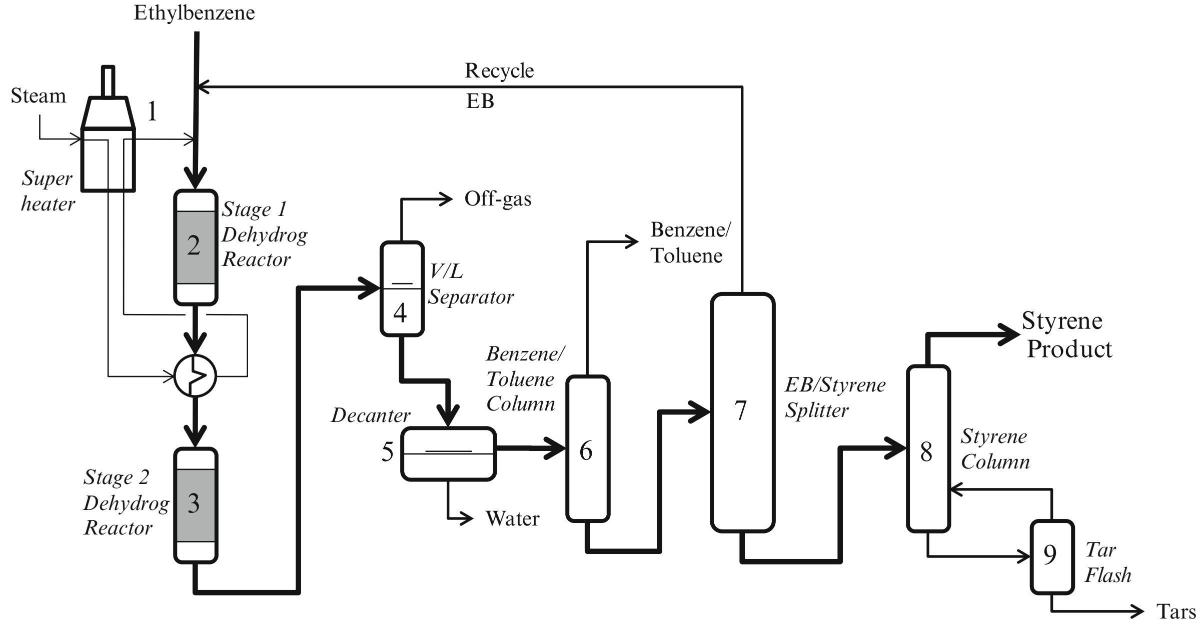


Fig. 10.35 Flowsheet for dehydration of ethylbenzene to styrene

Side reactions include the thermal degradation of ethylbenzene to benzene and ethylene, and catalyzed formation of toluene and methane from styrene and hydrogen.

In a typical commercial process as shown in Fig. 10.35, superheated steam (**1**) and ethylbenzene (1:1 weight ratio, 6:1 M ratio) are fed at about 620°C over potassium promoted iron oxide catalyst in a series of adiabatic fixed bed reactors (**2**), (**3**), under vacuum (around 0.06 MPa). The effluent from each stage must be reheated by superheated steam injection or indirect fired heating to keep equilibrium conversion and rates sufficiently high. Overall conversion is typically 60–70% per pass at up to 97% selectivity to styrene. Steam plays an important role in the process. It:

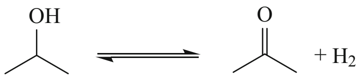
1. Brings in heat to get the reaction mixture up to temperature
2. Reduces the partial pressures of products allowing a tradeoff between temperature and conversion
3. Removes coke by steam–carbon reaction (catalyzed by potassium)
4. Minimizes EB cracking
5. Keeps the iron catalyst in the correct oxidation state (H_2 will reduce iron to its catalytically inactive elemental state)
6. Redistributes potassium on the working catalyst, enhancing lifetime

The reactor effluent is cooled, separated from off-gases (**4**) and allowed to phase separate to remove the bulk of the water (**5**). Purification is accomplished by a straight-forward series of distillations, but time at high temperatures must be limited to minimize losses to styrene polymerization. Toluene and benzene are distilled overhead first (6), followed by distillation of ethylbenzene for recycle (**7**), and finally the styrene product is taken overhead from heavies (**8**). Additional styrene is recovered from the tar stream in a flash step (**9**). Styrene purities range from 99.85 to 99.95%. Ethylbenzene and styrene are close boiling, with a relative volatility of about 1.3. Thus, 70–100 fractionation stages are required, depending on purity requirements. Most modern plants use high efficiency packing to reduce pressure drop, increase stage efficiency for the same height, and to increase throughput for a given column diameter. Styrene is quite prone to polymerization.

An oxidative reheat process is also commercially practiced, typically for retrofits to increase capacity of bottlenecked plants. Air is introduced between the dehydrogenation stages to convert some of the hydrogen into water to overcome the equilibrium limitations and to generate heat. Advantages include increasing the ethylbenzene conversion to about 75% per pass, unloading the costly ethylbenzene/styrene fractionation column, reducing interstage heating requirements, and lowering superheated steam consumption.

Dehydrogenation of Alcohols: MEK, Acetone, and Formaldehyde [316–320]

Aldehydes and ketones can be made by the dehydrogenation of alcohols, liberating hydrogen as a by-product, as illustrated for acetone and MEK:



$\Delta H_{rxn} = +67$ kJ/gmole

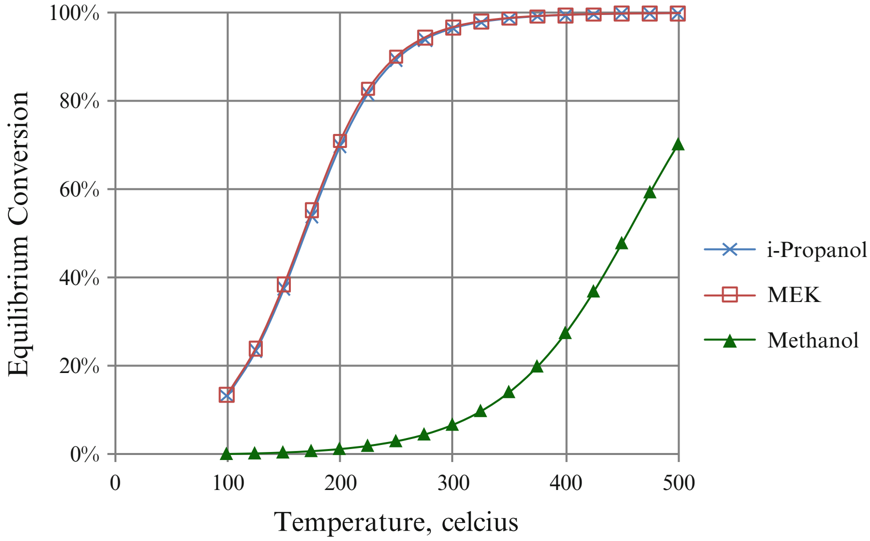


Fig. 10.36 Effect of temperature on equilibrium conversion for alcohol dehydrogenations

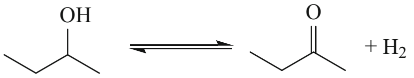

$\Delta H_{rxn} = +59$ kJ/gmole

These reactions are equilibrium-limited, modestly endothermic, and are favored by low pressure and high temperatures. Required temperatures are considerably lower than for alkane dehydrogenation. Compare Figs. 10.34 and 10.36. Both 2-butanone (MEK) and acetone are produced commercially by similar high temperature vapor phase catalytic dehydrogenations, from sec-butanol and isopropanol respectively. Typical conditions are 220–450°C, 0.1–0.6 MPa. A multitubular fixed bed reactor with hot oil circulation provides the endothermic heat of reaction. Copper catalysts are highly active for these dehydrogenation reactions and give high selectivities, typically greater than 90%. The main side products are the alkene (butenes or propylene) formed by dehydration of the parent alcohol, as well as small amounts of aldol condensation products. The high temperatures and the formation of unsaturated by-products lead to relatively rapid coking and deactivation. The catalyst must be burned off roughly every 3–6 months for optimal productivity.

Low temperature (150°C) liquid phase processes using Raney nickel or copper chromite are also practiced for the production of MEK, especially in Europe. Selectivity is somewhat better than the vapor phase process. Dehydrogenation of isopropanol to acetone is currently a relatively minor contributor to acetone production worldwide, with most acetone is derived as a by-product of phenol production (see section "Phenol/Acetone or MEK and Hydroquinone/Acetone" for a discussion of the phenol/acetone process).

A similar direct dehydrogenation of methanol to formaldehyde occurs to a limited extent with commercial silver catalysts for the conversion of methanol to formaldehyde, but is combined with oxidative dehydrogenation for more efficient operation (see the section, "Formaldehyde," for further details).

Acknowledgements The author would like to thank Robert T. Hembre and Steven L. Perri, both of Eastman Chemical Co., Kingsport, for taking their time to read and edit the chapter. The author would also like to acknowledge Robert Hembre's helpful revisions to the sections, "Carbonylation" and "Hydroformylation," in particular, as well as his addition of the section, "Metathesis."

Chemistry in the Pharmaceutical Industry

11

John F. Kadow, Nicholas A. Meanwell, Kyle J. Eastman,
Kap-Sun Yeung, and Joseph Payack

Introduction

This chapter discusses the role of chemistry within the pharmaceutical industry [1–3]. Although the focus is upon the industry within the United States, much of the discussion is equally relevant to pharmaceutical companies based in other first-world nations such as Japan and those in Europe. The primary objective of the pharmaceutical industry is the discovery, development, and marketing of safe and efficacious drugs for the treatment of human disease. However, drug companies do not exist as altruistic, charitable organizations. As with other shareholder-owned corporations within a capitalistic society, drug companies must earn profits in order to remain viable. Profits from the enterprise finance the essential research and development that leads to new drugs designed to address unmet medical needs. Thus, there exists a tension between the dual goals of enhancing the quality and duration of human life and that of increasing stockholder equity. Much has been written and spoken in the lay media about the high prices of prescription drugs and the hardships these place upon the elderly and others of limited income. Consequently, some consumer advocate groups support governmental imposition of price controls on ethical pharmaceuticals in the United States, such as those that exist in a number of other countries. However the out-of-pocket dollars spent by patients on prescription drugs must be weighed against the more costly and inherently risky alternatives of surgery and hospitalization, which can often be obviated by drug therapy. Consideration must also be given to the enormous expense associated with the development of new drugs. It typically takes 10 or more years from the inception of a drug in the laboratory to registrational approval and marketing at an overall cost which is now estimated to be in excess of $800 million and increasing, a figure that includes the opportunity costs of failed development campaigns. Only 1 out of 10,000–20,000 compounds prepared as potential drug candidates ever reach clinical testing in humans and the attrition rate of those that do is >80%, a success rate that has been stubbornly difficult to change despite advances in improving candidate quality and significant increases in investment in research and development. The expense of developing a promising drug grows steadily the further through the pipeline it progresses; clinical trials can be several orders of magnitude more costly than the preclinical development of a compound. While the sales of drugs that complete clinical trials and reach the shelves of pharmacies can eventually recoup their developmental expenses many times over if successful, many fail to do so and the cost of the drugs that fail is never recovered.

To a large extent, the difficulties associated with bringing a drug to market have arisen from the increasingly stringent but appropriate criteria that have been imposed by the Food and Drug Administration (FDA) in the United States and analogous regulatory agencies in other countries. In the current regulatory environment, it is unlikely that an occurrence similar to that associated with thalidomide, a disaster that resulted in terrible birth defects several decades ago, would recur. Moreover, the era of pursuing "me-too" drugs that offer little advantage over a marketed agent is largely obsolete. It is now necessary for a sponsor to demonstrate that a drug for which a New Drug Application (NDA) is submitted to the FDA offers significant benefits in terms of efficacy and/or safety relative to the existing drug therapy. The approvability bar may be lowered for agents designed to treat life-threatening maladies such as cancer and AIDS or for diseases of the nature of Alzheimer's disease for which no effective therapy currently exists. However, even in these cases it is incumbent upon the sponsoring company to provide compelling evidence that their drug is safe and effective. The restrictions imposed by Health Maintenance

Organizations (HMOs) and other payers may also have a significant impact on the sales of any given drug. Most HMOs list only a select few drugs for which they will reimburse costs within any given category, particularly antidepressants and anti-hypertensive or cholesterol-lowering agents.

A major consequence of the financial and logistical impediments to the successful introduction of new drugs has been the high incidence of mergers and acquisitions among US-based pharmaceutical companies in the recent years. These events have not occurred because bigger is necessarily better but because the critical mass of internal resources required to bring a drug from the test tube to the pharmacy continues to grow. In contrast to this trend among the major drug companies (often dubbed "big pharma"), there has been a proliferation of start-up companies often founded by entrepreneurial scientists with "big pharma" or academic experience and financed by venture capital investment. While many such start-ups are tightly focused on the application of biotechnology to develop protein- and nucleic acid-based drugs, others function as mini-drug companies, staffed by both medicinal chemists and biologists. Unlike their much larger brethren, small companies cannot address a wide range of drug research opportunity, leading to a focus upon a particular therapeutic area and, perhaps, even a specific disease. Their mission is to discover drug candidates which a large company may be interested in licensing and developing. The "big pharma" companies do not rely exclusively upon filling their developmental pipelines with drug candidates that have been discovered in-house but often enter into collaborations and licensing agreements to acquire the rights to promising agents from the laboratories of smaller companies or academic researchers in addition to other members of "big pharma."

Medicinal Chemistry

Chemistry has long been an integral part of the pharmaceutical industry and remains an important capability, relying on both purely synthetic molecules and natural products as a source of lead compounds. Many currently marketed drugs, such as the antineoplastic agent paclitaxel and the antibiotic vancomycin, are natural products. The extracts of plants and marine organisms and the products of soil bacteria fermentation continue to be investigated as potential sources of powerful new drug substances. In this arena of drug discovery, chemists conduct the painstaking isolation, purification, and structural characterization of pharmacologically active components which most often are present in minute amounts in the natural source and which typically have extremely complex chemical structures. More recently, the enormous advances in molecular biology have resulted in the successful development of bio-engineered injectable, protein-based therapeutic agents that are encompassed under the general term biologics and which are described in greater detail later in this chapter. It is anticipated that by 2014, biologic drugs will represent the majority of the top ten selling prescription medicines; however, the impact of this development on the role of medicinal chemists is unclear.

The majority of existing drugs are small organic molecules of molecular weight approximately 200–600 that have been designed and synthesized by medicinal chemists. It is thus important to define what is meant by "medicinal chemist" and what role is played by the practitioners of this sub-discipline in the pharmaceutical industry [4]. A traditional and, perhaps, somewhat narrow definition of a medicinal chemist is that of a researcher engaged in the design and synthesis of bioactive molecules. As part of their academic training, many medicinal chemists performed doctoral and postdoctoral work that involved the total synthesis of natural products and/or the development of synthetic methodology. They are hired by pharmaceutical companies based on their ability and skill in planning and conducting the synthesis of organic compounds. While such skills can remain important throughout the chemists' careers, they alone are insufficient for the challenging task of drug discovery. In contrast to an academic environment where the synthesis of target molecules is frequently the objective, the enterprising young chemical researcher who enters the pharmaceutical industry must be able and willing to undergo an evolution from that of a pure synthetic chemist to that of the medicinal chemist who also has insights into drug design principles and an excellent understanding of the biochemistry underlying therapeutic targets.

Several aspects of drug design and function are important components of the medicinal chemists' knowledge. The essential structural elements that comprise a drug molecule and enable it to interact on the molecular level with a biological macromolecule such as a receptor or enzyme and thus impart a pharmacological effect are defined as pharmacophores, which can be of varying complexity. The medicinal chemist must become skilled at analyzing structure activity relationships (SAR) that pertain to a series of compounds under study. These relate the activity of analogs within an active series tested in a biological assay with changes in structure that depend on the introduction of substituents of various size, polarity, and lipophilicity at various domains of the parent drug molecule. Elucidation of the SAR within a series of active compounds is the key to optimizing the potency and other desirable biological properties in order to identify a new chemical entity (NCE) as a *bona fide* drug candidate. Quantitative structure activity relationships (QSAR) are often employed in this effort; analyses that employ linear free-energy relationships, linear regression, and other techniques that can be utilized to correlate biological activity with the electronic, steric, polarizability, and other physical/chemical parameters of the substituent groups of structurally related compounds. There is also a rising appreciation of the benefits of optimizing compounds based on ligand efficiency, which relates potency to the number of heavy atoms in a molecule, and lipophilic ligand efficiency which assesses the relationship between biological activity and compound lipophilicity. The objective of these analyses is to minimize molecular size and hydrophobicity while maximizing potency and selectivity.

The synthesis and isolation of pure enantiomers has become increasingly important. In the past, chiral drugs were frequently marketed as racemic mixtures since it was not deemed cost-effective to provide them in enantiomerically pure form. However, in many cases one or the other enantiomers of an optically active drug may have a significantly greater level of the desired biological activity and/or lower side effect liability than its antipode. Regulatory agencies such as the FDA now routinely require that each enantiomer of a chiral drug be isolated and evaluated in tests of efficacy, side effects, and toxicity. If one of the enantiomers is shown to be clearly superior, then it is likely that it is the form that will be developed as the drug candidate. Thus, enantioselective chemical reactions which can afford a high enantiomeric excess (ee) of one or the other of a pair of enantiomers are valuable components of the medicinal chemist's synthetic toolkit. Enzymes also play a prominent role in drug development since isolated enzymes or microorganisms can often achieve an enantiospecific chemical transformation much more efficiently and economically than conventional synthetic methods. Many "big pharma" companies now have dedicated groups that exclusively study and develop enzymatic reactions.

Research Strategies

The discovery of a new drug may occur in a serendipitous fashion or as a result of a unique insight. However, pharmaceutical companies cannot depend on chance occurrences as a research strategy. The aforementioned "me-too" approach has not been completely abandoned and it is likely that the clinical evaluation of a novel drug will be followed by a number of competitors' agents but with the caveat that the latter offer some therapeutic advantage over the prototype.

The most scientifically sound approach is that of rational drug design, which is based on an understanding of the biochemical mechanisms underlying a particular disease. If, for example, over activity or under activity of a certain neurotransmitter system is believed to be responsible for a central nervous system (CNS) disorder such as depression, then medicinal chemists can endeavor to design agents capable of normalizing neurotransmission by their action upon the receptor proteins through which interneuronal communication is mediated. The cloning and expression of human genes to afford functional receptors and enzymes that can be studied in cell culture has been a tremendous advance in the ability to evaluate drug action at the molecular level. Similarly, advances in molecular biology have afforded access to quantities of pure macromolecules that are essential to the life cycle of pathogens such as bacteria and viruses, thus enabling novel mechanistic strategies for the treatment of infectious disease. In many cases, X-ray crystallography has provided a detailed 3D structure of a macromolecule such as an enzyme with or without a bound substrate. Researchers with expertise in computer-assisted drug design (CADD) can depict the determined structure on graphics terminals and, in collaboration with medicinal chemists, propose drug molecules designed to effectively complement an active site. This kind of detailed analysis of protein structure was instrumental in the design of a number of drugs that inhibit human immunodeficiency virus (HIV) protease, an enzyme essential to the replication of the virus that causes AIDS.

There have been approximately 1,000 human proteins identified as potential targets for drug intervention in various diseases and it has been estimated that the determination of the human genome would increase that number by at least tenfold. Therefore, it seems safe to predict that the rational approach to drug discovery will grow accordingly and with it the role of synthetic/medicinal chemistry. There will be intense competition within the pharmaceutical industry to determine the functional relevance of this multitude of new targets in the absence and presence of disease, a critical validation exercise imperative if compound attrition in the clinic is to be reduced. A close nexus to this quest will be the search for compounds that can impart selective pharmacological effects upon target proteins. It is unlikely that these goals will be met by employing only the classical iterative approach which entails the synthesis of one compound at a time and low volume testing. Instead, the challenges of this new era of research must be met by methodologies that can synthesize and test large numbers of compounds in a short period of time—that is, combinatorial chemistry and high-throughput screening (HTS). In the context of its application within pharmaceutical research, combinatorial chemistry should not be regarded as a separate discipline but as a technologically specialized part of medicinal chemistry. This topic will be discussed in detail in a later section of the chapter.

Another important interface occurs between discovery medicinal chemists and chemists in process research and development. Medicinal chemists are not overly concerned with the cost, toxicity, or environmental impact of the starting materials, reagents, and solvents they employ to synthesize target compounds since they are dealing with relatively small quantities of compound. Similarly, reaction conditions that employ very low or elevated temperatures and pressures are not problematic on the discovery scale and synthetic sequences are typically designed to maximize access to diverse target structures. However, these and other pragmatic considerations must be taken into account for the bulk-scale preparation of experimental drugs. Process chemists invariably modify the synthetic procedures implemented by medicinal chemists and, in many cases, devise an entirely new synthetic pathway. Process chemistry will also be discussed in an ensuing section.

Pharmacodynamics

Medicinal chemists must be knowledgeable about pharmacodynamics, that is, the effect of drugs upon biological systems. In addition to being aware of the state-of-the-art understanding of the biological mechanisms that underlie the particular diseases for which they are endeavoring to discover drug therapy, they need to understand the basis of the various in vitro and in vivo tests that biologists employ to evaluate both the potential efficacy and side-effect liability of synthesized compounds. Because drug research covers a plethora of human diseases, each with its own unique combination of etiology and biochemical mechanisms, the number and diversity of biological tests are far too great to discuss in this chapter. Suffice it to say that in a general sense, the primary and often even the secondary biological tests of drugs for a particular disease target are in vitro tests that can be run quickly, inexpensively, and using small amounts of compound. For example, these can be receptor-binding assays for CNS drugs, enzyme assays for antihypertensive agents, inhibition of bacterial colony growth by antibiotics, and the killing of cultured cancer cells by oncolytic drugs. Encouraging results from in vitro evaluation lead to in vivo testing in an appropriate animal model. In vivo tests are more laborious and costly, but are necessary to establish that a drug is effective in an intact living organism; they can range from complex behavioral paradigms for CNS drugs to enhancement of survival time of tumor-implanted mice by experimental cancer drugs. An evaluation of the propensity of a drug candidate to cause side effects is as important as efficacy testing. Even if a compound shows an encouraging level of the desired activity, a lack of selectivity can cause it to induce a number of undesirable pharmacological effects thus precluding its further development. The medicinal chemist must be able to interpret the results of tests run on lead compounds and use this information as a guide to further synthetic work.

Table 11.1 Lipinski's rules for drug absorption

Absorption of a drug following oral administration is favored by:
Molecular weight of <500
The drug molecule has <5 hydrogen bond donors
The drug molecule has <10 hydrogen bond acceptors
The octanol/water distribution coefficient, log P, is <5

Source: Lipinski et al. [5]

Pharmacokinetics and Toxicity

It is also necessary that chemists understand the principles of pharmacokinetics (PK), that is, the effects of biological systems upon drugs. The key PK parameters, absorption, distribution, metabolism, and excretion (ADME), are as critical as biological activity in determining whether an NCE is a viable drug candidate. A compound may exhibit high affinity for a biological receptor or potent inhibition of an enzyme in an in vitro assay but if it is poorly absorbed or rapidly metabolized to an inactive species then it will be ineffective as a drug. For example, the empirically based Lipinski's rule of five (Table 11.1) broadly defines the optimal physical/chemical properties, including molecular weight, lipophilicity, and hydrogen-bond forming moieties, that promote oral absorption of drug candidates [5]. A compound with potent intrinsic activity can be rendered ineffective in vivo by its rapid conversion to inactive metabolites. The susceptibility of compounds to metabolic conversion can be assessed by incubating them with liver microsomal homogenates from various species including rodent, dog, monkey, and human or with cloned, expressed human hepatic metabolizing enzymes. Analysis of the incubated drugs by liquid chromatography/mass spectometry (LC/MS) can quantify the extent of metabolism and even identify some specific metabolites. In vivo administration of a drug candidate to one or several animal species is required to determine its oral bioavailability, half-life, and other PK properties such as distribution and elimination. If an unsatisfactory PK profile threatens the demise of an otherwise promising drug candidate, it falls upon the medicinal chemist to make structural permutations designed to correct the problem. If poor absorption is the problem, this may entail modifying the lipophilicity of the drug molecule to render it more membrane permeable. A metabolic liability might be rectified by blocking the site of biotransformation with a metabolically inert atom or group.

Toxic effects of a compound on blood or organs or the potential to cause gene aberrations will eliminate a compound from further consideration even if biological activity and PK properties are excellent. Promising lead compounds are screened using in vitro tests in bacteria and mammalian cells to determine whether they cause damage to DNA or induce genetic mutations. If they pass this hurdle, compounds are dosed on a daily basis for periods ranging from several weeks to several months to both a rodent and non-rodent (usually dog or monkey) species with the animals observed closely for any adverse effects. At the completion of the study period, test animals are necropsied to ascertain whether any organ or tissue damage occurred at the microscopic level. Unacceptable toxicological findings will invariably lead to the termination of a drug candidate, with responsibility once again falling to the medicinal chemist to devise and implement structural modifications designed to eliminate the toxicity. This may be a more daunting task than overcoming a side effect or metabolic issue, since the underlying cause of toxicity is frequently not defined or the toxicity may be related to the mechanism of action of the compound.

Drug Delivery

Drugs can be administered to patients in many ways. The most common and preferred route is oral administration and oral drugs are generally formulated as tablets or capsules in which a specific dose of the drug substance is homogeneously mixed with an inert filler or excipient designed to modulate drug dissolution. Some oral medications, such as antibiotics for use in the pediatric population, are formulated as solutions, as are injectable drugs. Obviously this requires satisfactory solubilization of the drug, preferably in aqueous medium, and compounds bearing an ionizable group such as a basic amine or an acidic functionality can usually be converted into water-soluble salts. However, neutral molecules present greater difficulties. In some cases, the results of clinical trials have indicated that an experimental injectable drug showed promising efficacy but failed to elicit a robust response because poor intrinsic solubility limited the amount that can be administered, resulting in low plasma levels of the drug. Inadequate membrane permeability can restrict the absorption and, hence, the bioavailability of an orally administered drug. Medicinal chemists can respond to such findings by investigating the feasibility of preparing a suitable prodrug [6]. A prodrug is a derivative in which a cleavable solubilizing or permeabilizing group is covalently appended to the parent drug molecule, most often via a hetero atom such as oxygen or nitrogen. An effective prodrug is the one which has much higher solubility or permeability than the parent drug but which is rapidly cleaved in vivo following administration to achieve a therapeutically beneficial plasma concentration of the biologically active parent drug.

Patents

The granting of patent protection on both approved and experimental drugs is of critical importance to the pharmaceutical industry. Issued patents provide a company with exclusivity for the manufacture, use, and sale of drug products and it is highly unlikely that a company would undertake the risks and costs of developing an agent for which it had no patent protection. There are several types of patents of which the “composition of matter” (COM) or “product” patent may be deemed to have the greatest value. An approved COM patent covers specifically claimed compounds of a defined structural chemotype and provides tangible evidence that the claimed compounds have been prepared, characterized, and found to have utility, the latter a critical aspect of an invention. In order to be patentable, the compounds must have structural novelty and cannot have been publicly disclosed either in the scientific or patent literature or by oral presentation. However, structural novelty alone is an insufficient basis for a patent to be granted since it must be demonstrated that the compounds have utility in the treatment of a disease. The basis of such utility is activity in appropriate and relevant biological tests. Clinical data may also be used in support of a patent application although in the great majority of cases the applications are filed well before any compound within the application reaches clinical trials. Medicinal chemists are closely affiliated with the patent process and are most commonly named as inventors listed on COM patents covering drug substances. The chemists and other researchers with whom they collaborate must provide the chemical and biological data that is included in a patent application and the chemists will also provide input that defines the scope and claims of the invention. Since patents are legal documents that provide the assignee exclusive proprietary rights to the claimed subject matter for 20 years from the date issuance, it is essential that all supportive data be accurate and instructive. If a patent is challenged by another party and is found to contain erroneous information, it may be invalidated. Moreover, in the United States, patents are granted on a “first-to-invent” basis. Thus, if two or more parties submit applications to the US Patent Office claiming identical subject matter, then the patent will be awarded to the party that can prove that it had the earliest conception and reduction to practice of the subject matter. Therefore, it is imperative that chemists maintain accurate records of all experimental work in approved notebooks and that such records are dated, signed, and witnessed in a timely fashion. In March of 2013, the United States will change from "First to Invent" to "First to File" in order to harmonize with the rest of the world.

Other types of drug-related patents include process, use, and formulation patents. Chemists are responsible for process patents, which describe an improved method of preparation of some drug substance, but are typically minimally involved with the others. Use patents are based on the discovery of some non-obvious utility of a compound that is either part of the public domain or covered by an existing patent; such discoveries are most likely to be made by biologists. Formulation patents disclose a preferred means of drug delivery of a known drug substance.

Clinical Trials

Even though there is no involvement of chemistry in the clinical evaluation of drugs, any discussion of the pharmaceutical industry must include clinical trials since the results determine whether an experimental drug has the combination of efficacy, safety, and tolerability that will allow it to achieve registrational approval and reach the market. If a drug candidate survives the hurdles of preclinical pharmacological, pharmacokinetic, and toxicological testing, the next customary step in the United States is the sponsoring firm's filing of an Investigational New Drug (IND) application with the FDA. This is a formal request to initiate clinical investigation in humans that describes the preclinical profile of a molecule and is accompanied by a detailed description of the planned studies and clinical protocols. Upon approval of the IND, Phase I clinical studies are initiated.

Phase I studies are conducted in healthy volunteers in order to establish the drug's safety and to determine appropriate dosage levels. If the drug is found to have an acceptable human pharmacokinetic profile and to be free of untoward side effect liabilities, it is advanced into Phase II trials, which are typically carried out in as many as several hundred patients and may last from 6 months to 2 years. Phase II trials are designed to ascertain the appropriate dosing regimen for a drug and whether it is effective in treating the targeted disease. Only about one-third of drugs pass Phase II trials, most failing because of a lack of efficacy or unacceptable side effects. Those that pass are advanced into Phase III trials which may involve from several hundred to several thousand patients and which can last from 1 to more than 3 years, depending on the type of drug and disease under study and the complexities of the study design. Phase III trials provide the ultimate test of an experimental drug since they are designed to verify the drug's effectiveness against the target disease and define its long-term safety profile. For agents that are intended for chronic use, studies also monitor adverse reactions that may develop only after long-term use and the development of tolerance. Clinical studies of many drug classes will commonly employ several patient groups of approximately equal size with one group receiving the experimental drug, another placebo (nondrug), and/or another a positive control; that is, a marketed drug used to treat the same disease for which the experimental agent is being evaluated. In order to minimize the possibility of bias in favor of the test drug, such studies are most often run in a double-blinded manner with neither patients nor clinical investigators knowing which group is receiving treatment until the conclusion of the trial.

If a drug candidate is among the 20–25% that successfully negotiates Phases I–III and if statistical analysis of the clinical data supports its efficacy, then the sponsor will assemble the voluminous data generated into a NDA which is submitted to the FDA. The standard period for review of the NDA is 10 months but a priority review can be requested based on unmet medical need which reduces the time to 6 months. Actual approval can take longer, as long as 1–2 years if the FDA requests that additional information be provided or even that some additional studies be conducted. When approval is granted, the company is free to market the drug. The most typical current practice is for NDAs to be filed globally with regulatory agencies around the world essentially simultaneously with the submission in the United States. This is a resource-intensive practice which reflects the importance of non-US markets. The results of clinical evaluation of an experimental drug can feed back into medicinal chemistry. For example, if a drug is found to fail because of poor bioavailability in humans, medicinal chemists will endeavor to design and prepare an analog with improved pharmacokinetic properties.

Summary

The preceding sections, by necessity, present a succinct and somewhat superficial overview of the very extensive and complex role of a medicinal chemist in the pharmaceutical industry and the interface with other disciplines. An acquired understanding of relevant biology, pharmacology, toxicity, and its application to drug design is not simply of heuristic value but is essential for the chemist to engage in meaningful dialogue with colleagues who work in these specialties. Successful drug discovery and development cannot be performed by individuals working in isolation but requires the interactive collaboration of a multitude of researchers representing multiple scientific disciplines, as depicted in Fig. 11.1. It can be argued that medicinal chemists are the most versatile generalists among these researchers since they must command a primary expertise in chemistry along with an extensive knowledge of the other disciplines that contribute to drug discovery and development. The following section presents examples of marketed drugs in a number of different therapeutic categories.

Cardiovascular Agents

Hypertension

A variety of agents of several mechanistic types are currently available for the treatment of hypertension (elevated blood pressure). The dihydropyridine derivative amlodipine (Norvasc®) is a receptor-operated, calcium channel blocker that prevents Ca^{2+} entry into vascular smooth muscle cells that is also useful for the treatment of

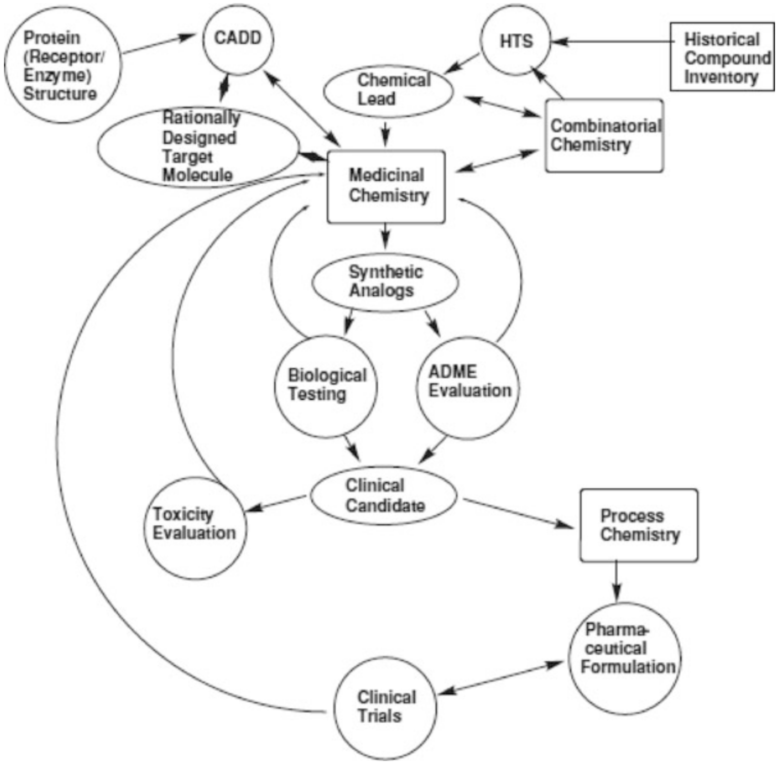

Fig. 11.1 Drug discovery and development is a complicated process that involves the interaction of researchers in a range of disciplines. Medicinal chemists may synthesize analogs based on chemical leads arising from the high-throughput screening of combinatorial libraries or historical compound inventories. Alternatively, analog synthesis can be based on a collaboration between medicinal chemistry and computer-assisted drug design scientists to rationally design small molecules capable of interacting with a macromolecular biological target (receptor or enzyme). Subsequent biological, pharmacokinetic, and toxicological evaluations lead to the identification of a drug candidate that, following development of a suitable bulk scale synthesis by process chemistry and pharmaceutical formulation, is advanced into clinical trials. Feedback to medicinal chemistry from any of these developmental steps can give rise to further optimization of structure by synthetic modifications and refinement

angina. Losartan (Cozaar®) is an angiotensin receptor antagonist that inhibits the action of the peptide angiotensin II on the AT1 receptor and is often prescribed in combination with the diuretic hydrochlorothiazide (Hyzaar®). Metoprolol (Toprol®) is a cardioselective, β1-adrenergic receptor blocking agent that is also useful in the treatment of angina.

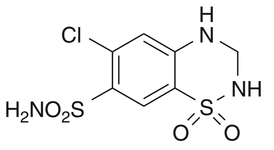
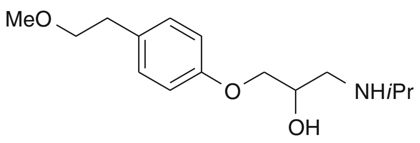
losartan



hydrochlorothiazide



metoprolol

Congestive Heart Failure, Migraine, and Antithrombotic Agents

Enalapril (Vasotek®) and lisinopril (Zestril® and Prinvil®) are angiotensin-converting enzyme (ACE) inhibitors, useful in the treatment of congestive heart failure and hypertension by suppression of the renin–angiotensin–aldosterone system. Enalapril is an ethyl ester prodrug that is hydrolyzed in the liver to the active carboxylic acid enalaprilat. Aliskiren (Tekturna®) is the first direct-acting renin inhibitor to be marketed for the treatment of hypertension.

Sumatriptan is a selective agonist at serotonin (5-hydroxytryptamine) type-1 receptors (most likely the 5-HT1$_B$ and 5-HT1$_D$ subtypes) in the vasculature. It is thought to exert its beneficial effects on migraine headaches by selectively constricting certain large cranial blood vessels and/or possibly through suppression of neurogenic inflammatory processes in the CNS. Clopidogrel (Plavix®) is the prodrug of an inhibitor of ADP-induced platelet aggregation that is useful in the prevention of thrombotic events such as stroke and myocardial infarction in patients with symptomatic atherosclerosis and acute coronary syndrome without ST-segment elevation. Rivaroxaban (Xarelto®) is the first direct-acting inhibitor of the coagulation enzyme factor Xa to be approved in Europe for the prevention of venous thromboembolism in adults undergoing total hip replacement or total knee replacement surgery. Dabigatran etexilate (Pradaxa®) is a double prodrug of the first direct-acting thrombin inhibitor to be approved for the prevention of stroke and systemic embolism in patients with atrial fibrillation. Rivaroxaban and dabigatran are the first members of a new class of anti-coagulants designed to replace warfarin.

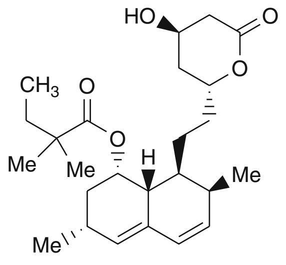
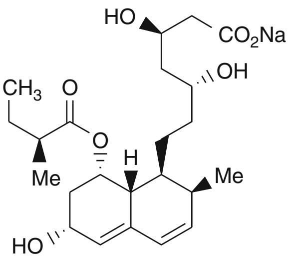
Metabolic Agents

Hyperlipidemia

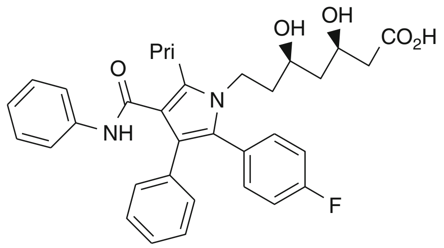
Simvastatin (Zocor®), pravastatin sodium (Pravachol®), atorvastatin (Lipitor®/Pfizer), and rosuvastatin (Crestor®) are hydroxymethylglutaryl-CoA (HMG-CoA) reductase inhibitors (statins) that lower serum lipid levels by inhibiting cholesterol biosynthesis. Simvastatin and pravastatin sodium are semi-synthetic, mevalonic acid-derived antilhyperipidemic agents whereas atorvastatin is a wholly synthetic, pentasubstituted pyrrolo heptanoic acid. Unlike pravastatin, simvastatin is a lactone prodrug which must be converted to the corresponding, ring-opened δ-hydroxy acid in vivo. Ezetimibe (Zetia®) is a newer antihyperipidemic agent with a novel mechanism of action. Ezetimibe does not inhibit cholesterol biosynthesis in the liver as do the statins but rather inhibits cholesterol absorption in the intestine. This novel action is complementary to the HMG-CoA reductase mechanism displayed by the statins. An innovative new product for the treatment of hyperlipidemia is Vytorin® which consists of a mixture of simvastatin and ezetimibe in one pill.



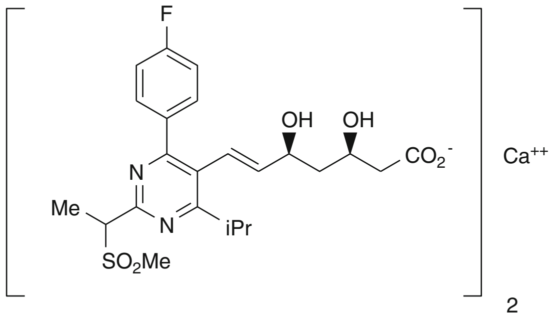
simvastatin



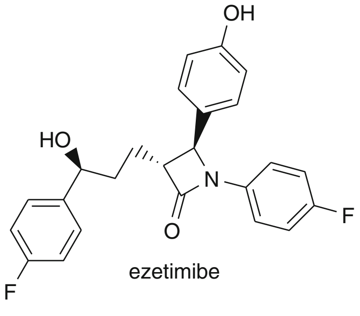
pravastatin sodium



atorvastatin



rosuvastatin



ezetimibe

Diabetes

A variety of mechanistic agents are currently available for the treatment of type 2 (non-insulin dependent) diabetes mellitus (NIDDM). Rosiglitazone (Avandia®) and pioglitazone (Actos®) are thiazolidinedione antidiabetic agents and agonists at the peroxisome proliferator-activated receptor-gamma (PPARgamma). Activation of this receptor enhances insulin sensitivity in target tissues by increasing insulin-responsive gene transcription. Concern about adverse effects has reduced the use of Avandia® and made its manufacturer the target of many lawsuits despite its sustained effects on glycemic control. Some reviewers of available data have concluded that Avandia® caused more deaths than Actos® but an FDA panel disagreed and it remains on the market in the US, subject to significant restrictions. Metformin (Glucophage®) is an antihyperglycemic agent that improves glucose tolerance in patients with type 2 diabetes. The compound acts by decreasing both hepatic glucose production and intestinal absorption of glucose, and improves insulin sensitivity by increasing peripheral glucose uptake and utilization. Glimepiride (Amaryl®) is a member of the sulfonylurea class of antidiabetic agents that is thought to lower blood glucose concentration by stimulating insulin secretion in pancreatic beta cells. Saxagliptin (Onglyza®), sitagliptin (Januvia®), and vildagliptin (Galvus®) are newer drugs for the treatment of type 2 diabetes mellitus. These agents inhibit the proteolytic activity of the serine protease dipeptidylpeptidase-4, thereby potentiating the glucose regulatory action of the endogenous incretin peptides. Therapy that combines these DPP4 inhibitors with metformin has demonstrated beneficial effects in improving glycemic control compared to monotherapy with either type of agent alone.

Obesity

Orlistat (Xenical®) is a reversible gastric and pancreatic lipase inhibitor. The compound has no effect on appetite suppression but rather acts by inhibiting dietary fat absorption from the GI tract. Obesity is an area that remains one of compelling and urgent significant medical need but it has been very difficult to identify effective and safe anti-obesity agents with alternative mechanisms of action. Sibutramine (Meridia®) and its major active metabolites are re-uptake inhibitors of norepinephrine, serotonin, and dopamine and exert their beneficial effect through appetite suppression but marketing of the compound in the United States was discontinued in October of 2010 due to elevated risk of cardiovascular side effects identified in post-marketing studies. The cannabinoid-1 receptor blocker, rimonabant (Acomplia®), decreases the activity of the endocannabinoid system, which is essential in regulating body weight and energy balance in addition to glucose and lipid metabolism. However, rimonabant has recently been suspended from the European market due to concerns over psychiatric adverse events and has not been approved for use in the United States.

Gastrointestinal and Genitourinary Agents

Antisecretory

Ranitidine (Zantac®) is a histamine H_2-receptor antagonist that inhibits the release of gastric acid and is useful in the treatment of a variety of hypersecretory conditions (dyspepsia, heartburn, duodenal and gastric ulcers, and gastroesophageal reflux (GERD)). Lansoprazole (Prevacid®), omeprazole (Prilosec®), and esomeprazole (Nexium®) are benzimidazole gastric antisecretory agents and are unrelated both chemically and pharmacologically to the H_2-receptor antagonists. These agents are known as proton pump inhibitors due to their ability to inhibit the H^+K^+-ATPase (the proton pump) in gastric parietal cells thereby blocking the secretion of hydrochloric acid. Esomeprazole is the (*S*)-enantiomer of omeprazole which is racemic and is thus a mixture of both its (*R*)- and (*S*)-enantiomers. Lansoprazole and omeprazole are also useful in the management of duodenal and gastric ulcers, and GERD.

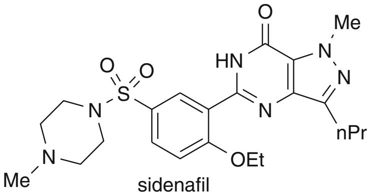
Benign Prostatic Hyperplasia and Urinary Urge Incontinence

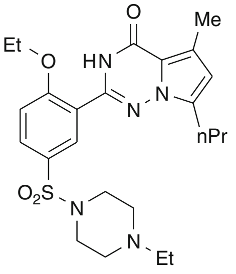
Doxazosin (Cardura®), tamsulosin (Flomax®), and alfuzosin (Uroxatral®) are used in the management of benign prostatic hyperplasia (BPH). These compounds are postsynaptic, α_1-adrenergic blocking agents that relax prostatic tissue and increase urinary outflow in men. Because tamsulosin demonstrates selectivity for the α_{1a}-adrenergic receptor subtype located in prostate over that of α_{1b}-subtype located in vascular tissue, there is a reduced incidence of cardiovascular side effects (hypotension, dizziness, and syncope). Because doxazosin is not selective for the α_{1a}-subtype, it is also useful in the treatment of hypertension. Finasteride (Proscar®) and dutasteride (Avodart®) are 5α-reductase inhibitors that block the conversion of testosterone to 5α-dihydrotestosterone (DHT). Because DHT is an androgen responsible for prostatic growth, inhibition of the 5α-reductase enzyme is beneficial in reducing prostatic enlargement.

Erectile Dysfunction

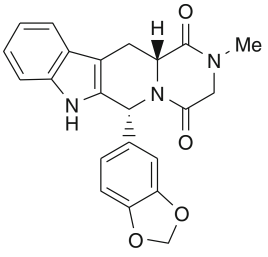
The pyrazolopyrimidinone derivative sildenafil (Viagra®), the indolopyrazinone derivative tadalafil (Cialis®), and the imidazotrizinone derivative vardenafil (Levitra®) are selective inhibitors of the phosphodiesterase (PDE) type 5 enzyme marketed for the treatment of erectile dysfunction. Selective blockade of the PDE type 5 isoenzyme enhances cGMP levels, causing vasodilation in corpus cavernosal tissue which increases penile blood flow and, in turn, penile tumescence and rigidity.



sidenafil



vardenafil



tadalafil

Pulmonary Agents

Asthma and Allergic Rhinitis

The butyrophenone derivative fexofenadine (Allegra®) is an antihistamine and used in the treatment of seasonal allergic rhinitis. Because fexofenadine does not readily cross the blood–brain barrier, it is considered to be a "non-sedating" antihistamine. Loratadine (commonly known as Claritin®) and cetirizine (Zyrtec®) are other non-sedating antihistamines that have been converted from prescription-only to over-the-counter status.

Fluticasone propionate (Flovent®) is a synthetic corticosteroid derivative that is a selective agonist at the human glucocorticoid receptor and useful in the treatment of asthma. Although the precise mechanism of fluticasone action in asthma is unknown, it is believed that its anti-inflammatory property contributes to the observed beneficial effects. Combination of an inhaled corticosteroid with a long-acting β_2-adrenergic agonist is a major therapeutic regimen for treating asthma and chronic obstructive pulmonary disorder (COPD). Fluticasone/salmeterol (Advair®) and budesonide/formoterol (Symbicort®), taken by oral inhalation, are examples of this class. More recently, the quaternary ammonium tricyle tiotropium bromide (Spiriva®) has been introduced. It is a long-acting bronchodilator useful in the treatment of asthma and COPD, and exerts its pharmacological effect through inhibition of the muscarinic M3 receptor. Montelukast (Singulair®) is a leukotriene receptor antagonist indicated for the treatment of asthma, as well as seasonal and perennial allergic rhinitis, that acts through the inhibition of the leukotriene-mediated inflammatory processes.

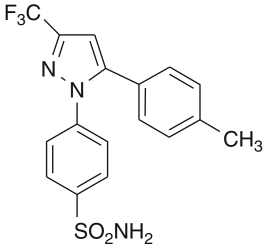
Inflammation and Osteoporosis

Arthritis

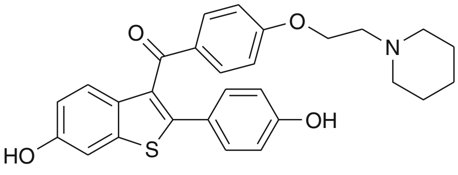
The diaryl pyrazole derivative celecoxib (Celebrex®) is a selective cyclooxygenase type-2 (COX-2) inhibitor useful in the treatment of arthritis. The compound exerts its pharmacological effect by selectively blocking the COX-2 enzyme to produce an anti-inflammatory effect without the adverse gastrointestinal side effects that accompany COX-1 inhibition. In addition, celecoxib also displays analgesic and antipyretic activities in animal models.



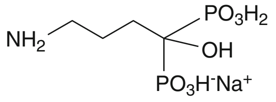
celecoxib

Osteoporosis

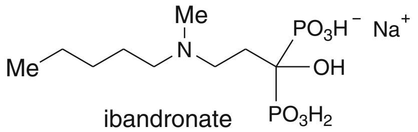
The benzothiophene derivative raloxifene (Evista®) is a selective estrogen receptor modulator (SERM). Raloxifene produces its biological actions via modulation (both activation and blockade) of estrogen receptors that ultimately results in decreased resorption of bone. The bisphosphonate derivative alendronate (Fosamax®), an inhibitor of osteoclast-mediated bone resorption, is also useful in the treatment of osteoporosis. Ibandronate sodium (Boniva®) that can be taken once monthly is another bisphosphonate derivative which, like alendronate and raloxifene, is useful in the treatment of osteoporosis in postmenopausal women.



raloxifene



alendronate

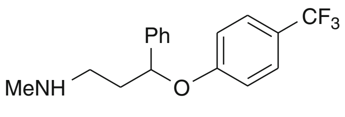


ibandronate

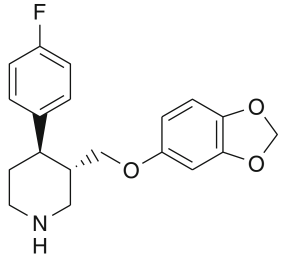
Central Nervous System Agents

Antidepressants

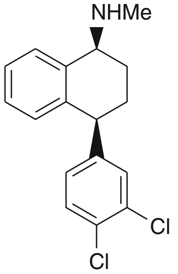
Fluoxetine (Prozac®), paroxetine (Paxil®), and sertraline (Zoloft®) are selective serotonin reuptake inhibitors (SSRIs) that are useful for the treatment of depression. These agents potentiate the pharmacological actions of the neurotransmitter serotonin by preventing its reuptake at presynaptic neuronal membranes. In addition to its SSRI properties, venlafaxine (Effexor®) also appears to be a potent inhibitor of neuronal norepinephrine reuptake and a weak inhibitor of dopamine reuptake, thereby concomitantly enhancing the actions of these neurotransmitters. Venlafaxine is indicated for use in the treatment of anxiety and depression.



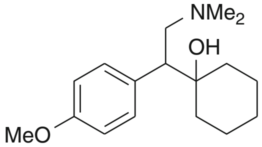
fluoxetine



paroxetine



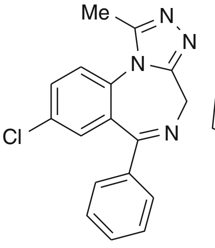
sertraline



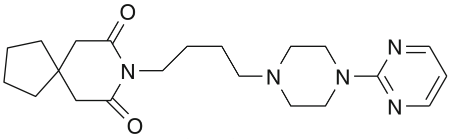
venlafaxine

Anxiolytics

Alprazolam (Xanax®), a benzodiazepine derivative, is used for the treatment of both anxiety and panic disorder while buspirone (Buspar®) is indicated for the treatment of anxiety. The mechanism of action of buspirone is distinct from that of the benzodiazepines and is believed to be mediated mainly through modulation of serotonergic neurotransmission via its interaction with the 5-HT$_{1A}$ serotonin receptor subtype.



alprazolam



buspirone

Bipolar Disorders, Schizophrenia, and Epilepsy

The thienobenzodiazepine derivative olanzapine (Zyprexa®), the benzisoxazole risperidone (Risperidal®), and the thiazepine quetiapine (Seroquel®) are atypical antipsychotic agents. Olanzapine is used in the treatment of bipolar disorder and risperidone is useful in the management of schizophrenia. It is believed that both compounds exert their beneficial effects through antagonism of serotonergic and dopaminergic receptors. Quetiapine is approved in the US for use as monotherapy in both bipolar mania and depression, offering potential compliance advantages. The precise mechanism of action is unknown, although its antidepressant activity may be linked to its higher affinity for serotonergic than dopaminergic receptors. A newer agent for the treatment of schizophrenia is aripiprazole (Abilify®). It is believed the pharmacological effects of aripiprazole are mediated through a combination of partial agonist activity at the dopamine D_2 and serotonin 5-HT$_{1a}$ receptors and antagonism at the serotinergic 5-HT$_2$ receptor. The γ-aminobutyric acid derivative (GABA) gabapentin (Neurontin®) is useful in the treatment of epilepsy. Although gabapentin is structurally related to GABA, it has no GABA-ergic activity and the mechanism of its anticonvulsive actions is currently unknown.

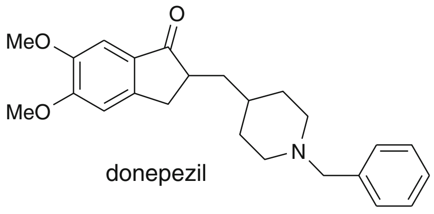
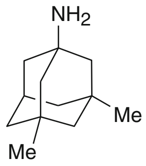
Alzheimer's Disease

The indanone derivative donepezil (Aricept®) is an acetycholinesterase inhibitor and is structurally unrelated to other cholinesterase inhibitors. Because it increases the concentration of the neurotransmitter acetycholine at cholinergic sites, it is used in the treatment of Alzheimer's disease (dementia) and appears to provide modest benefits in cognition and behavior. Another agent useful in the treatment of Alzheimer's disease is the adamantylamine derivative, memantine (Namenda®). Memantine is an *N*-methyl-D-aspartate (NMDA) receptor antagonist that is thought to exert its pharmacological effect by blocking the excitatory action of the amino acid glutamate at this receptor. However, memantine has shown no evidence of preventing or slowing the neurodegeneration associated with Alzheimer's disease.



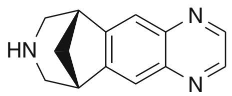
donepezil



memantine

Smoking Cessation

The pyrazino-benzaepine derivative varenicline (Chantix®) is a partial agonist of the $\alpha_4\beta_2$ subtype of the nicotinic acetylcholine receptor that activates the receptor without creating the full effect on the release of dopamine that is associated with nicotine. Varenicline is indicated as a treatment for smoking cessation.



varenicline

Infectious Diseases

Antibacterial Agents

The primary driver for research in the antibacterial area over the past decade has been the emergence of organisms resistant to the existing antibiotics. Important members of the armamentarium of antibacterials include azithromycin (Zithromax®), linezolid (Zyvox®), amoxicillin/potassium clavulanate (Augmentin®), levofloxacin (Levaquin®), ciprofloxacin (Cipro®), and daptomycin (Cubicin®). Azithromycin is a semisynthetic 9α-azalide analog of erythromycin possessing improved resistance to acid-mediated degradation, increased activity against gram-negative organisms, and improved pharmacokinetics. Its indications include the treatment of mild to moderate upper and lower respiratory tract infections and otitis media in pediatric patients. Interestingly, azithromycin tends to concentrate in lung tissue which is the site of many bacterial infections. Linezolid is a completely synthetic oxazolidinone derivative which has a unique mechanism of action, resulting in a low potential for cross resistance to other antibacterial agents. Linezolid is indicated for the treatment of community-acquired pneumonia, MRSA, and VRE infections and has the distinctive characteristic of being nearly 100% orally bioavailable. Amoxicillin/clavulanate is one of the few approved drug mixtures and is a drug of choice for the treatment of acute otitis media. Amoxicilin is a beta lactam antibiotic that works by inhibiting bacterial cell wall synthesis. However, bacteria have developed enzymes called beta lactamases that inactivate amoxicillin. Clavulanate has no antibacterial activity of its own but inactivates beta lactamases thus augmenting the efficacy of the amoxicillin. Amoxicillin/clavulanate is also an alternative treatment for anthrax exposure in pediatrics. Levofloxacin is a totally synthetic fluoroquinolone antibiotic indicated for the treatment of pneumonia; chronic bronchitis; and sinus, urinary tract, kidney, prostate, and skin infections. It is administered by injection and the balance of superior efficacy coupled with reduced side effects positions levofloxacin for administration after other antibiotics have failed. Ciprofloxacin is another synthetic fluoroquinolone antibacterial that acts as a DNA gyrase inhibitor. It is active against a broad range of pathogens, including both gram-positive and gram-negative aerobic bacteria and is effective against urinary tract and lower respiratory tract infections. Daptomycin, a naturally occurring cyclic lipopeptide of molecular formula $C_{72}H_{101}N_{17}O_{26}$ is a cidal antibacterial agent used for the treatment of infections caused by gram-positive bacteria, including those that are resistant to standard antibacterial regimens. It is a large molecule with a complex structure, so it is not depicted in the scheme.

Antifungal Agents

The increasing immunocompromised patient population has exacerbated the need for effective antifungal agents to combat the opportunistic fungal infections that arise in these patients. Current therapy for localized or systemic fungal infections comprises several groups including azoles, polyenes, allylamines, flucytosine, and griseofulvin. Many of these antimycotic agents target the production and integrity of the fungal cell wall, ergosterol biosynthesis and membrane function, nucleic acid biosynthesis, and mitosis [7]. In particular, fluconazole (Trican®), an achiral triazole derivative, inhibits the fungal cytochrome P450 enzyme 14α-demethylase, effectively preventing the conversion of lanosterol to ergosterol, an essential component of the fungal cytoplasmic membrane. Fluconazole is indicated for the treatment of systemic candidiasis as well as meningitis caused by *Cryptococcus neoformans*. Amphotericin B is a naturally occurring polyene antimycotic used topically for localized fungal infections or intravenously for systemic fungal infections. Amphotericin B irreversibly binds to ergosterol forming a transmembrane channel that results in monovalent cation leakage, which is thought to contribute to cell death. Similar to other allylamines, terbinafine (Lamisil®) inhibits ergosterol synthesis by binding to squalene epoxidase, an enzyme that is part of the fungal cell membrane biosynthesis pathway. This is thought to change cell membrane permeability, causing fungal cell lysis. Terbinafine's highly lipophilic nature results in its accumulation in skin, nails, and fatty tissues. It can be administered either systemically or topically and is a treatment of choice for dermatophytosis. Flucytosine (Ancobon®) effectively inhibits fungal protein synthesis by the action of multiple metabolites on fungal RNA and DNA. However, due to documented primary and secondary resistance, flucytosine is not an optimal monotherapy. Instead, flucytosine is often co-administered with amphotericin B. Indications include treatment of serious infections caused by susceptible strains of *Candida* or *Cryptococcus neoformans*. It can also be used for the treatment of chronomycosis (chromoblastomycosis), if susceptible strains cause the infection. Finally, griseofulvin exerts its activity against dermatophytes via binding to tubulin, thus interfering with microtubule function and, consequently, inhibiting mitosis. Its primary indication is for the treatment of mycoses of the hair, nail, and skin. In addition to continued research efforts directed at targeting historical mycotic vulnerabilities, there are signs of an emerging paradigm targeting virulence as a potential treatment for fungal diseases.

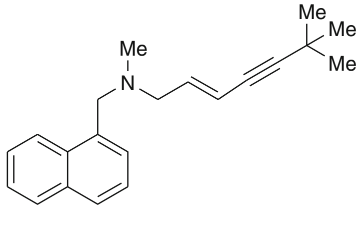
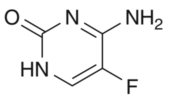
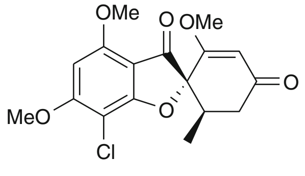
fluconazole



terbinafine



flucytosine



griseofulvin

Antiviral Agents

Antiviral research has become a major focus in the pharmaceutical industry over the past decade as evidenced by the marketing of a plethora of antiviral agents active against HIV/AIDS, hepatitis B and C, influenza, and respiratory syncytial virus (RSV). Tenofovir combined with emtricitabine (Truvada®), efavirenz combined with tenofovir and emtricitabine (Atripla®), valaciclovir (Valtrex®), and pegylated interferon alfa-2a (Pegasys®/ pegylated interferon alfa-2b (Peg-Intron®) represent the top four selling antiviral agents worldwide. The combination of nucleoside analog transcriptase inhibitors tenofovir and emtricitabine into a single pill (truvada) provides a well-tolerated and effective dosage form that increases compliance by the patient due to the reduced pill burden. In addition to its efficacy as a treatment for HIV, Truvada® has also been shown to have potential as a preventative measure if administered regularly prior to exposure. The most convenient triple therapy, Atripla®, provides the combination of efavirenz, a non-nucleoside reverse transcriptase inhibitor, with tenofovir and emtricitabine in the first effective single pill cocktail for once a day HIV treatment. Atazanavir sulfate (Reyataz®) or Lopinavir (sold as Kaletra® which is a coformulation with ritonavir) are members of a group of HIV protease inhibitors that are used in conjunction with other anti-retroviral chemotherapeutic agents for the treatment of HIV in adults and adolescents. Atazanivir is a Phe-Pro scissile bond peptidomimetic that clinical data suggests may have a more favorable hypertriglyceridemia profile as compared to other protease inhibitors. Darunavir (Prezista®) is the most recently marketed HIV protease inhibitor. Valaciclovir is an antiviral compound used in the treatment of herpes simplex and herpes zoster that has been marketed generically since late 2009. The valine moiety of this prodrug, which facilitates oral absorption by active transport, is cleaved in vivo converting it to acyclovir. Pegylated interferon α-2a or α-2b bolsters the immune system and weekly injections combined with twice daily dosing of ribavirin, a synthetic nucleoside analog, was the current optimal therapy for the treatment of hepatitis C virus. The serious side effects associated with this treatment and the modest efficacy (40–50%) have stimulated a substantial effort toward developing improved HCV treatments and several compounds are in late stage clinical trials, the NS3 protease inhibitors telaprevir or Boceprevir have now been approved for use in combination with pegylated interferon and ribavirin. Oseltamivir phosphate (Tamiflu®) is an orally active anti-influenza drug that inhibits neuraminidase and is being stockpiled for use in future outbreaks of influenza.

oseltamivir

Antineoplastic Agents

Paclitaxel (Taxol®) and irinotecan (Camptosar®) were discovered as a result of natural product extract screening. Paclitaxel is a naturally occurring diterpene that exerts its antineoplastic effect via stabilization of the mitotic spindle during cell replication. It is used for the treatment of non-small cell lung, breast, ovarian, and esophageal carcinomas as well as Kaposi's sarcoma. The semi-synthetic taxane analog docetaxel (Taxotere®), the epothilone analog ixabepilone (Ixempra®), and eribulin mesylate (Halaven®) have a similar mechanism of action in that they also target the microtubules used to form the mitotic spindle. Halaven® received FDA approval in November 2010 and is a synthetic analog of a marine natural product isolated from the sea sponge *Halichondria okadai*. Irinotecan is a prodrug that upon release of the piperidinylpiperidine carbamate moiety reveals the pharmacologically active parent SN-38 which is a derivative of the naturally occurring camptothecin. Irinotecan exerts its antineoplastic activity via the inhibition of Type I DNA topoisomerase and stabilization of the transiently formed topoisomerase I/DNA-cleavable complex. Tamoxifen (Nolvadex®), a nonsteroidal antiestrogen chemotherapeutic possessing both agonistic and antagonistic properties, is used for the treatment and prevention of breast cancer. Imatinib (Gleevec®), an inhibitor of the Bcr-Abl tyrosine kinase, is used for the treatment of chronic myelogenous leukemia. Dasatinib (Sprycel®) inhibits Bcr-abl, Src family kinases and others and has recently been approved for first-line treatment of the same indication. Bortezomib (Velcade®), a ubiquitin proteosome inhibitor administered parenterally, is used for the treatment of multiple myeloma in patients who have been refractory to other chemotherapeutic regimens. Erbitux (Cetuximab®), a human-murine chimeric monoclonal antibody that blocks the epidermal growth factor receptor (EGFR), was developed for the treatment of irinotecan-refractory colorectal cancer. This agent is also used in patients who are intolerant of irinotecan-based therapy. A number of small molecule kinase inhibitors have been approved for oncology applications including the small molecule EGFR tyrosine kinase inhibitor gefitinib (Iressa®) used to treat non-small cell lung cancer. Several additional important oncology drugs are described in the section on biologics.

Miscellaneous Agents

Glaucoma and Nausea

Latanoprost (Xalatan®) is a topical, ocular hypotensive agent used to treat glaucoma. The compound is a synthetic analog of the naturally occurring prostaglandin PGF2α and is thought to reduce intraocular pressure by increasing outflow of the aqueous humor. Odansetron (Zofran®) is a selective serotonergic 5-HT_3 receptor antagonist that is used to ameliorate the nausea and vomiting frequently associated with chemotherapy.

Biologics

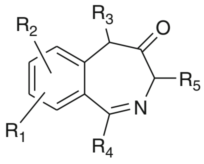
A key question that will affect the future of medicinal chemists in the pharmaceutical industry is what will be the balance of research funding and efforts between discovering and developing traditional small molecule drugs and biologics. Biologics are defined as a preparation, such as a drug, a vaccine, or an antitoxin, that is synthesized from living organisms or their products and used as a diagnostic, preventive, or therapeutic agent, Biologics are typically large macromolecules that, to date, have been limited to injectable administration methods and not been suitable for oral dosing. In 2006, none of the top 20 brand name drugs by retail sale dollars was a biologic but in 2009 that number rose to 8 out of 20. These include the tumor necrosis factor inhibitor etanercept, marketed as Enbrel® for the treatment of rheumatoid arthritis; the immunosuppresive agent infixamade (Remikade®); the specific antirheumatic agent adalimumab (Humira®); the antitneoplastics bevacizumab (Avastin®), a VEGF kianase inhibitor; rituximab (Mabthera®); the monoclonal antibody trastuzumab, marketed as Herceptin® for the treatment of breast cancer; the heparin enoxeparin (Lovenox®) for anticoagulative indications; and human insulin analogs of which Lantus® is representative. The role that medicinal chemists may play in the future design and development of biologics continues to be defined.

Small Molecule High Throughput Synthesis

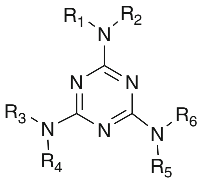
The field of non-oligomeric, small molecule, high throughput synthesis came into existence in 1992 and has developed into an important strategy for both lead identification and lead optimization [8, 9]. Synthetic libraries have been categorized as follows: (1) discovery libraries: opportunistic libraries synthesized with no preconceived notion about which molecular target it may be active against. These libraries tend to be large in size, typically >5,000 compounds; (2) targeted libraries: these libraries are biased in their design and contain a pharmacophore known to interact with a specific target, or a family of targets; (3) optimization libraries: libraries are constructed around an existing lead with the intent to improve potency, selectivity, and pharmacokinetic profile. These libraries tend to be smaller in size, usually ranging from tens up to a few hundred compounds.

Discovery Libraries

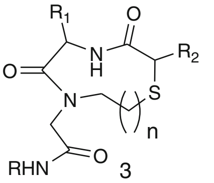
Researchers have employed several different strategies to create populations of molecules that are used for broad-based screening. One strategy is to synthesize libraries based on "privileged pharmacophores," heterocyclic scaffolds such as benzodiazepines (**1**) or triazines (**2**) that have been shown to possess biological activity in multiple settings. A second strategy is to design scaffolds or templates for library synthesis that are based on important molecular recognition recognitions elements including, for example, peptide β-turn mimetics (**3**). The discovery of chemical encoding technologies and radio-frequency (Rf)-encoded synthesis has had a major impact on the synthesis of lead discovery libraries. Both technologies utilize resin-based split-pool synthesis to prepare large arrays of compounds with libraries of >50,000 members typically prepared using chemically encoded beads. Chemical encryption, in the form of unique chemical markers (tags), is associated with synthetic identity of the library member tethered to the resin bead. However, the restricted amounts typically prepared (200–300 μg), the lack of analytical characterization of library members, and the requirement of a specialized screening format for chemically encoded libraries have limited the utility of this technology. Radio frequency encoded synthesis overcomes some of these limitations while retaining the efficiency of split-pool synthesis. Libraries of 10,000–15,000 members can be prepared, with individual members quantified and characterized by LC/MS. Most pharmaceutical companies have utilized Rf-encoded synthesis in their lead identification efforts.



1



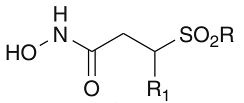
2



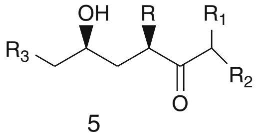
3

Targeted Libraries

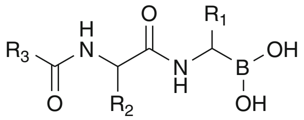
Libraries targeted towards proteolytic enzymes, non-proteolytic enzymes, G-protein coupled receptors (GPCRs), and ion channels have been very successful in lead identification. Libraries of hydroxamates (**4**), hydroxy ethylenes (**5**), boronic acids (**6**), and β-keto sulfonamides (**7**) have been prepared as inhibitors of metallo-, aspartyl, serine, and cysteine proteases, respectively, using either solid phase or solution phase synthesis.



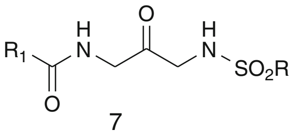
4



5

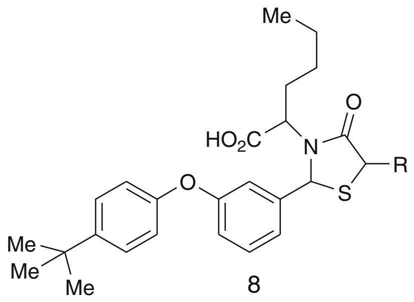


6



7

Structure-based design has been effectively utilized in the synthesis of inhibitors of nonproteolytic enzymes. Inhibitors of MurB, an essential bacterial enzyme required for the biosynthesis of peptidoglycan, were identified using the X-ray structure of the enzyme as a tool for library design. Thiazolidinone inhibitors (**8**) thus identified are the first examples of small molecule inhibitors of MurB.

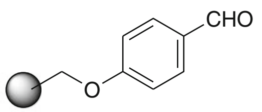


8

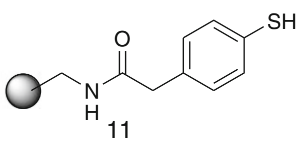
Substituted indoles ($5HT_{2a}$; D_4 and α_{2a} receptor antagonists) and piperazines (opioid antagonists) are representative chemotypes targeted towards GPCRs.

Advances made in solid-phase extraction (SPE) and in the development of resin-based scavengers have increased the versatility of chemistries implemented for the synthesis of targeted libraries. A combination of cation exchange (SCX) and anion exchange (SAX) resin was effectively utilized to prepare libraries of highly substituted amides. Scavenger resins and polymer-bound reagents are routinely used to prepare medium-sized (500–1,000 members) libraries. Polymer-bound isocyanates (**9**) and aldehydes (**10**) are used to remove amines from reaction mixtures, while polymer-bound thiols (**11**) are used to scavenge halides.

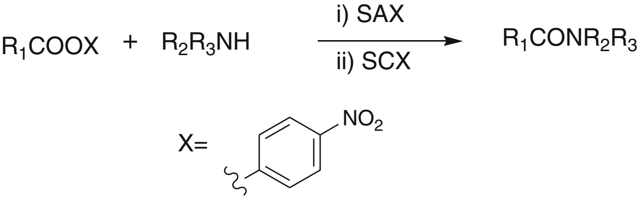
9



10

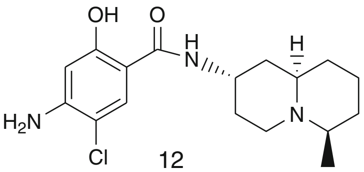


11

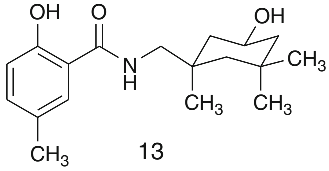


Optimization Libraries

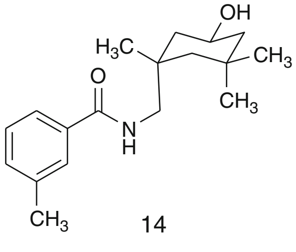
Starting with a lead structure, researchers have demonstrated that parallel synthesis can be effectively utilized to optimize biological activity while reducing timelines for the iterative process. A parallel synthesis strategy was implemented to identify structurally simpler and more potent analogs of the influenza hemagglutinin inhibitor **12**, $EC_{50} = 4$ μg/mL. SPE was used to automate the preparation of >400 analogs, resulting in the identification of **13**, $EC_{50} = 20$ ng/mL, and **14**, $EC_{50} = 20$ ng/mL as simpler and more potent influenza inhibitors.



12

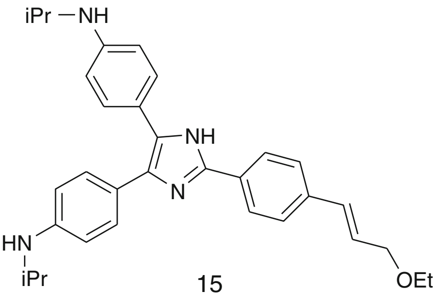


13

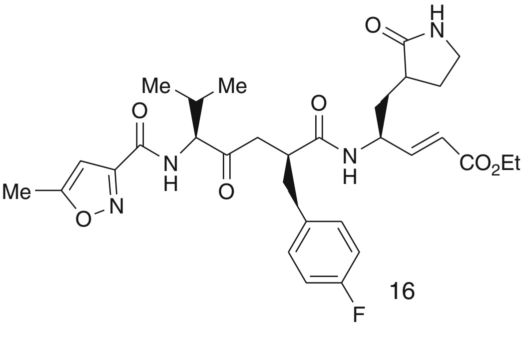


14

During the past 10 years, the pharmaceutical industry has expended significant resources in developing and assimilating technologies to increase synthesis throughput and decrease preclinical time lines. There are numerous examples in the literature demonstrating the effective use of high-throughput synthesis for lead discovery and optimization. There are two publicly known examples of clinical candidates that have emerged directly from optimization libraries. OC144-093 (**15**) is a P-glycoprotein modulator, $IC_{50} = 50$ nM, while AG-7088, (**16**) a potent rhinovirus 3C protease inhibitor, k_{obs}/1,470,000 m/s, advanced into clinical trials for the treatment of the common cold.



15



16

Chemical Process R&D in the Pharmaceutical Industry

Most of the active pharmaceutical ingredients (APIs) of commercially available pharmaceuticals are manufactured either by chemical syntheses or by microbial fermentations. However, some of the active ingredients are directly obtained from natural sources. This section addresses the development and manufacture of APIs [10]. Drug candidates in development are becoming increasing complicated, with multiple chiral centers and/or difficult to assemble heterocyclic systems. Incessant demand to shorten the timelines for the discovery, development, and launch of NCEs coupled with environmental concerns has necessitated the development of higher yielding, more robust, and environmentally friendly processes in shorter times. The success of a pharmaceutical company greatly depends not only on discovering important NCEs that fulfill unmet medical need but also on its ability to design, optimize, and scale up a chemical process to commercial manufacturing with increasing rapidity. The chemical manufacturing process must be a robust procedure capable of operating routinely in a manufacturing environment. The recent trend towards outsourcing the preparation of key intermediates (or even the entire API) during the early phases of a program has added additional time constraints on the development of robust processes. Often the early preclinical and phase 1 supplies are made via "fit for purpose" strategies, and the process chemist is handed the program well into development, with shortened timelines before process lock.

Considerable attention has to be given to various parameters in developing a manufacturing process for an API including, for example, efficiency of the synthesis, availability and cost of starting materials, toxicity of the reagents, stability and toxicity profiles of intermediates, formation of by-products, and safe disposal of waste materials. Data from various aspects of chemical process development, including process structure and flowsheet, operational guidelines, optimization, process management, process control, fault diagnostics, and equipment management need to be in place in order to support a smooth transition from the laboratory to the manufacturing plant. Safety is another critical factor requiring consideration for large-scale manufacture. All reactions should undergo a process hazard analysis for incident-free and successful plant implementation before scale up. The use of automation in accelerating the design of cost-effective and well-understood synthetic processes is growing very rapidly [12]. Automation concepts and tools such as statistical design of experiments (DOE) and parallel experimentation using in-house built reactor blocks or commercially available robots play an ever expanding role in increasing the productivity of process R&D with respect to speed and economics, as well as obtaining process knowledge. Production and logistical processes are becoming more complex due to an increasing number of products and smaller batch sizes. To manage this, supply chain optimization and production planning activities need to be addressed. Production simulation can be used for performance measurements and capacity assessments of manufacturing as well as material and information flow processes. Some applications of production simulation include bottleneck analysis, examination of process alternatives, and assessment of investment decisions.

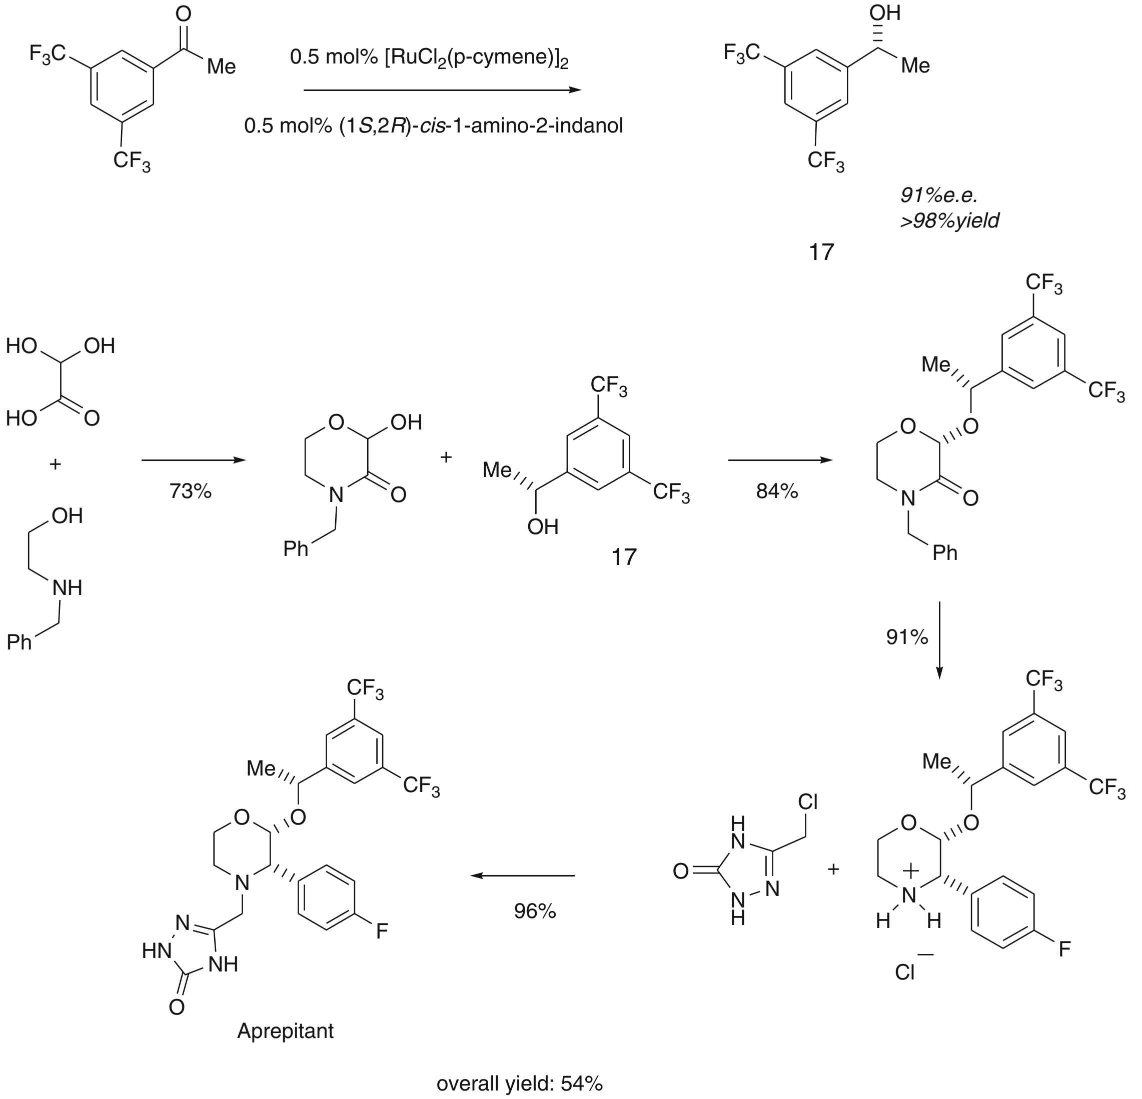
Batch process development is a fairly complex series of engineering tasks. In the pharmaceutical industry, the production of a majority of APIs is based on a batch concept. This concept offers many advantages with respect to quality assurance as an individual batch can be accepted or rejected. However, the scale up of the batch size without proper controls may lead to problems. As a new product approaches commercialization, a database of appropriate controls and processing parameters is developed for each late-stage step. This leads to a 'design space' of acceptable processing parameters, ensuring that the desired yield and quality is obtained. The FDA has encouraged manufacturers to adopt quality by design (QbD) principles which are described in a document *ICH Q8R1* that was authored by pharmaceutical industry experts from the United States, Europe, and Japan with the goal of standardizing development parameters so that they will be applicable worldwide. Examples of topics covered include quality management, personnel qualifications and hygiene, process equipment cleaning and calibration, documentation and records, material management, production and in-process controls, packaging and labeling, and many others. In QbD, a design space is developed, either by traditional one-variable experimentation or, more commonly, by multivariate DOE. By thoroughly defining the design space, product quality can be assured by maintaining processing parameters within the acceptable ranges. In-line testing (also known as process analytical techniques) has become a mainstay of modern manufacturing, lessening the need for traditional off-line testing.

Quality standards for pharmaceutical products have always been (understandably) more rigorous than for other commercial chemicals. The QbD paradigm is a step towards limiting batch release testing; however, the goal of eliminating analytical release may prove elusive. Even a well-defined process operating within its quality design space will require that the raw materials used meet established specifications. This may push analytical testing earlier in the synthesis, perhaps even onto the suppliers, but will not eliminate it.

Potential genotoxic impurities in both marketed and experimental medicines have become a large regulatory and quality issue. Indeed, nearly an entire issue of the respected journal *Organic Process Research & Development* was devoted to the subject [11]. Potential genotoxic impurities are required to be below the default threshold of toxicological concern limit (TTC) of 1.5 μg/day. The genotoxic potential of intermediates, impurities, and reagents in a process to make API must all be assessed. An initial in silico evaluation using programs such as DEREK, TOPKAT, and MCASE provide "alerting structures" that then require further investigation, usually via Ames testing. Compounds testing Ames positive are considered putative mutagens and must be controlled at the TTC limit of 1.5 μg/day. The level of detection required for high-dose compounds can be <1 ppm, demanding ever more sensitive analytical techniques. Indeed, satisfactory routes to a given API may be discarded because of potential genotoxic impurities if those impurities cannot be removed or adequately controlled.

Crystallization, filtration, drying, and milling (if required) are other important factors that need to be defined well before a process to manufacture solid APIs is finalized. Physicochemical properties of APIs play a vital role in providing the pharmaceutical drug products with desired bioavailability, manufacturing properties, and good final product quality. Particle size, density, flowability, polymorphism, hygroscopicity, and stability are critical properties for solid APIs in the development of formulations. Polymorphism is very important in determining the physical properties of various crystal forms of a drug for optimal chemical and formulation processing, as well as for satisfying regulatory and patent issues for producing consistent solid forms of a drug.

Asymmetric enantioselective syntheses have begun to supplant traditional resolution methods for chiral intermediates leading to APIs [13]. The most elegant of these asymmetric approaches involves the use of chiral catalysts. The following flow diagrams highlight the use of enantioselective chiral catalysts in preparation of APIs of some widely used pharmaceutical drugs in today's market. Scheme 11.1 shows the preparation of aprepitant, the active ingredient of the anti-

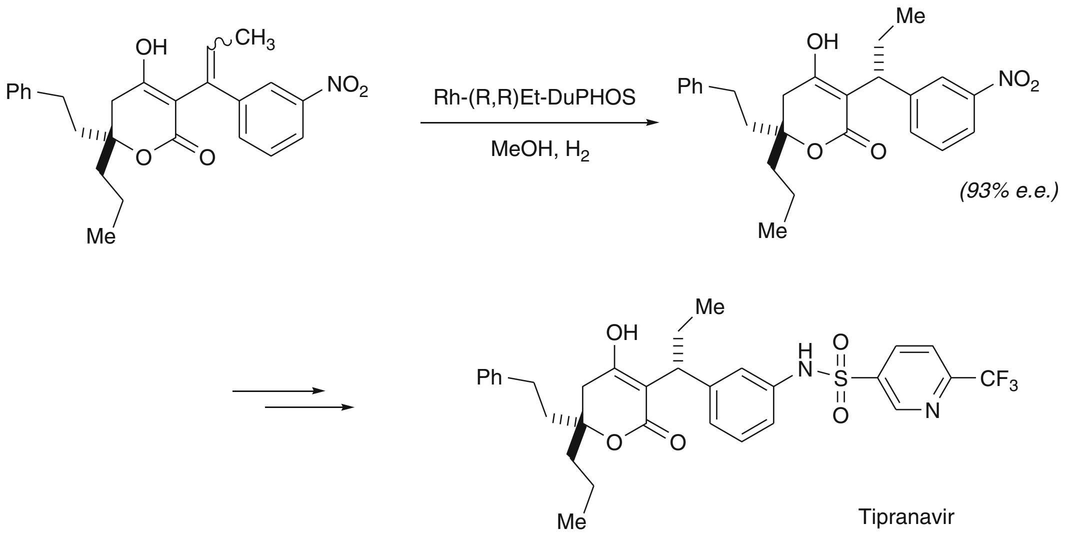


overall yield: 54%

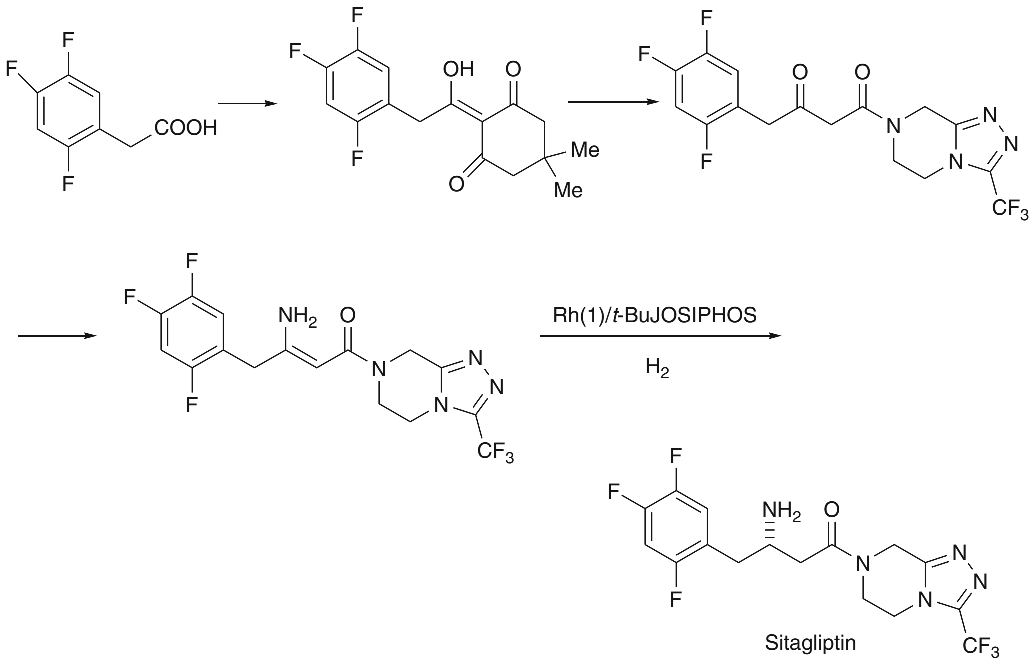
Scheme 11.1 Preparation of aprepitant emetic Emend®. A chiral reduction to form alcohol **17** proceeds in high yield and good ee. Recrystallization increased chiral purity to over 99%. All three chiral centers in the API are derived from the initial chiral reduction [14].

The key step toward the synthesis of the HIV protease inhibitor tipranavir is shown in Scheme 11.2. A rather unique alkene hydrogenation is used for the late-stage installation of a chiral center [15].

An elegant and efficient route to sitagliptin was developed that utilizes a previously undocumented asymmetric hydrogenation of an enamine in the final step [16] (Scheme 11.3).



Scheme 11.2 Key step in the preparation of tipranavir



Scheme 11.3 Preparation of sitagliptin

Conclusion

The discovery and development of novel therapeutic agents by the pharmaceutical industry has afforded physicians an extensive armamentarium to fight a wide range of human diseases. Undoubtedly, there remains the opportunity for even more effective drugs with greater benefit-to-risk ratios than those currently available. The elucidation of the human genome may eventually lead to the identification of many new macromolecular targets for drug intervention and the application of new technologies has, to date, been modestly beneficial to the overall success of drug discovery. The considerable challenges faced by pharmaceutical research will undoubtedly best be addressed by creative and observant scientists operating cohesively and openly in multidisciplinary teams. Medicinal chemists have been and will likely continue to play integral roles in these groups, operating at the forefront of pharmaceutical research to identify innovative drugs that the future demands.

Manufactured Textile Fibers*

12

Bhupender S. Gupta

Textile Background

The first conversion of naturally occurring fibers into threads strong enough to be looped into snares, knit to form nets, or woven into fabrics is lost in prehistory. Unlike stone weapons, such threads, cords, and fabrics—being organic in nature—have in most part disappeared, although in some dry caves traces remain. There is ample evidence to indicate that spindles used to assist in the twisting of fibers together had been developed long before the dawn of recorded history. In that spinning process, fibers such as wool were drawn out of a loose mass, perhaps held in a distaff, and made parallel by human fingers. (A maidservant so spins in Giotto's *The Annunciation to Anne*, ca. AD 1306, Arena Chapel, Padua, Italy [1].) A rod (spindle), hooked to the lengthening thread, was rotated so that the fibers while so held were twisted together to form additional thread. The finished length then was wound by hand around the spindle, which, in becoming the core on which the finished product was accumulated, served the dual role of twisting and storing and, in so doing, established a principle still in use today. (Even now, a "spindle" is 14,400 yards of coarse linen thread). Thus, the formation of any threadlike structure became known as spinning, and it followed that a spider spins a web, a silkworm spins a cocoon, and manufactured fibers are spun by extrusion, although no rotation is involved.

It is not surprising that words from this ancient craft still carry specialized meanings within the textile industry and have entered everyday parlance, quite often with very different meanings. Explanations are in order for some of the words used in the following pages. For example, as already indicated, "spinning" describes either the twisting of a bundle of essentially parallel short pieces of wool, cotton, or precut manufactured fibers into thread or the extrusion of continuous long lengths of manufactured fibers. In the former case, the short lengths are known as "staple" fibers, and the resulting product is a "spun yarn," whereas the long lengths are called "continuous-filament yarn" or merely "filament yarn." Neither is called a "thread," for in the textile industry that term is reserved for sewing thread and rubber or metallic threads. Although to the layperson "yarn" connotes a material used in hand knitting, the term will be used in the textile sense hereinafter.

Before manufactured fibers are discussed, it is necessary to define some terms.[1] The "denier" of a fiber or a yarn defines its linear density, that is, the mass in grams of a 9,000 m length of the material at standard conditions of 70°F and 65% relative humidity. Although denier is actually a measure of linear density, in the textile industry, the word connotes the size of the filament or yarn. Fibers usually range from 1 to 15 denier and yarns from 15 to 1,650. Single fibers, usually 15 denier or larger, used singly, are termed "monofils." The cross-sectional area of fibers of identical deniers will be inversely related to their densities, which range from 0.92 g/cc for polypropylene to 2.54 g/cc for glass. The approximate densities of some of the other commonly used fibers are given in Table 12.1. Because by definition denier is measured at standard conditions, it describes the amount of "bone-dry" material plus the moisture regain, which ranges from zero for glass and polypropylene to 14% for rayon. It should be mentioned that some years ago, scientific organizations throughout the world accepted the word "tex," this being the mass (g) of 1 km of

Synthetic				
Acrylic	26	25	1.5	1.18
Modacrylic	28	32	1.5	1.32
Nylon	50	25	4	1.14
Polyester	50	15	0.4	1.38
Polypropylene	53	17	0	0.92

the material, as a more useful term than denier. “Tex” is an accepted adjunct to the SI or International System of Units, but it has received only limited acceptance in commerce, whereas the SI units are being employed increasingly in scientific organizations. Furthermore, the sizes of cotton, wool, and worsted yarns, and yarns containing manufactured fibers but produced by the traditional cotton, wool, or worsted systems, still are expressed in the inverse-count system that has been used for centuries.

The “breaking tenacity” or more commonly, “tenacity,” is the breaking strength of a fiber or a yarn expressed in force per unit denier, that is, in grams per denier, calculated from the denier of the original unstretched specimen. “Breaking length” expresses the theoretical length of yarn that would break under its own weight and is used mostly in Europe. “Elongation” means “breaking elongation” and is expressed in units of increase in length to break calculated as a percentage of the original specimen length.

Typical force–elongation curves of some manufactured and natural staple fibers and textile-type manufactured filaments are shown in Figs. 12.1 and 12.2. Table 12.1 gives the values of some of the physical and tensile properties of textile fibers.

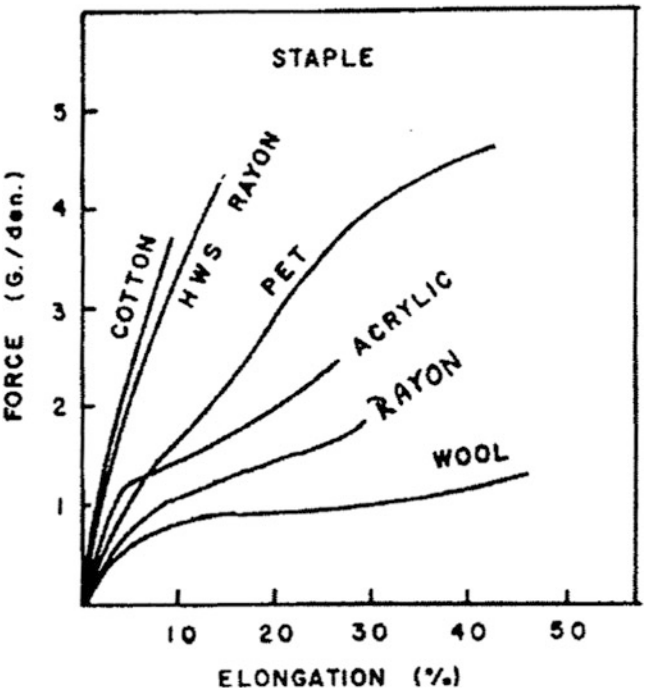

Fig. 12.1 Force–elongation curves of natural and manufactured staple fibers at standard conditions of 70°F and 65% humidity

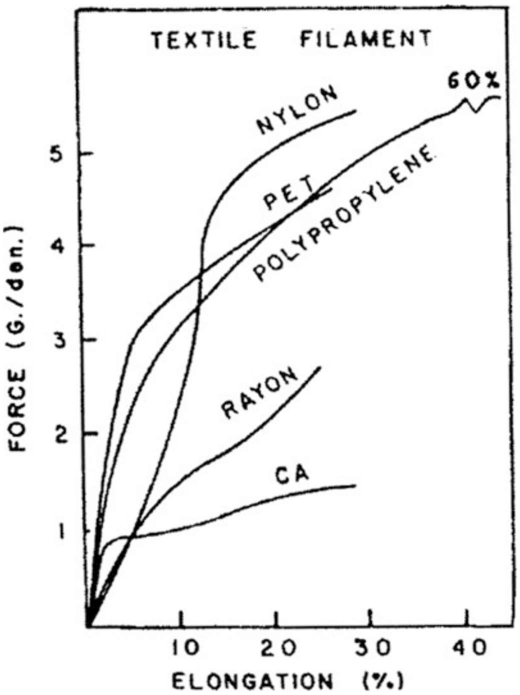

Fig. 12.2 Force–elongation curves of manufactured textile continuous-filament yarns at standard conditions of 70°F and 65% relative humidity

History

Early humans, over time, became aware of the presence and usefulness of fibrous materials available from such sources as seeds, leaves, stems, animal coverings, and cocoons. They learned to spin, weave, knit, felt, or braid these fibers to protect their bodies and improve their lifestyle. A few hundred years ago, it has been suggested, someone took a clue from a busy worm and thought that it should be possible for humans to make a silklike fiber that would be of commercial value. Curiosity combined with simple experiments strengthened that premise and much later led to the development of viscose rayon, only partially a manufactured fiber, in the nineteenth century. Further curiosity, wartime need, and superior commitment by modern researchers led to the synthesis of a totally synthetic fiber in the 1930s. The knowledge gained and the spark thus ignited resulted in the development of other fibers to such an extent that manufactured fibers now dominate the market in the industrialized nations in all major categories of apparel, home furnishing, and industrial end uses.

The story of the development of manufactured fibers is of great historical interest, beginning in 1664 when Robert Hooke, an Englishman, suggested that it should be possible to make a fiber much like silk that could be of value in the marketplace. Audemars, a Swiss chemist, received the first patent for making silklike fiber in 1855. He drew fibers by dipping a needle and pulling it out from a solution of cellulose nitrate containing some rubber.

The credit for using a spinnerette and forcing a solution through it for producing a fiber, however, goes to the English scientist Sir Joseph W. Swan, in the early 1880s. The first person to put the idea into commercial practice was the French chemist Count Hilaire de Chardonnet, who built the first plant to commercially produce a fiber based on regenerated cellulose, called “artificial silk,” at Besançon, France, in 1891. During the last years of the nineteenth century and the beginning of the twentieth century, progress was so rapid that the production of this fiber increased from several thousand pounds in 1891 to over two million in 1910. Commercial production of the fiber in the United States began in 1910 with the opening of the first plant. In 1924, the industry gave the “artificial silk” fiber a new name, rayon.

By the year, 1910, the brothers Camille and Henry Dreyfus had discovered a practical method for producing cellulose acetate polymer and were making plastic film and toilet articles in Basel, Switzerland. During World War I, they built a plant in England to produce acetate dope for painting airplane wings to render them air impervious. The success of the product led the U.S. government to invite the Dreyfus brothers to build a plant in the United States, which started commercial production in 1924.

The successful manufacture of these two fibers, although based on fibrous materials available in nature, marked the beginning of the development of manufactured fibers in the 1930s. This effort, initiated by a technological breakthrough, was marked by the work of W. H. Carothers, aimed at learning how and why certain molecules joined to form large molecules or polymers [2]. Fibers were described as being composed of high-molecular-weight linear polymers, and the first one to be manufactured, nylon 66, was synthesized and produced on a commercial scale in 1939. It was quickly followed by nylon 6, the second most widely used nylon, and modacrylic (1949), olefin (1949), acrylic (1950), polyester (1953), and triacetate (1954). Glass had joined this group of large-production items earlier in 1936.

Several other fibrous materials have been produced, but they are regarded as fibers with special performance characteristics, used either in limited textile or in specialized industrial applications. Some of these, worth noting, are spandex (1959), aramid (1961), polybenzimidazole (PBI) (1983), and sulfar (1983).

Thus, the period from the 1930s to the 1960s can be considered as a time of discoveries and innovations for manufactured fibers, when the majority of the basic fibers were developed. The years since then may be thought of as a period of modification of performance characteristics. The basic generic materials have been manipulated both chemically and physically to produce a wide variety of different fibers, tailored to secure the desired characteristics for specific end-use products. Thus, fibers can be extruded in different shapes and sizes for special purposes. They can be modified to offer greater comfort, flame resistance, or static-free behavior in apparel; they can offer soil release and other desirable characteristics for carpets; they can be developed with unique surface characteristics, easier dyeability, or better blending qualities. The industry has begun to discover many possibilities for modifying the behavior of a given fibrous material. It has learned how to produce new fibers with greater strength, greater thermal resistance, or other special qualities. In particular worth mentioning are the biodegradable polymers, and the fibers based on them, that had controlled absorbability and entered the market later in the twentieth century. These materials, limited to specialized applications and therefore produced in low volume, were developed primarily for use in medical textile products.

Essentially, then, no new, large-volume, highly profitable fibers have been developed since the mid-1950s. Instead, the existing ones have become commodities with all the economic impact thereby implied. No major chemical engineering processes have been added, although the previously described ones have been modified to allow for spinning of liquid crystalline polymers or the formation of gel-spun fibers. Research activity has been reduced and centered essentially on modifications of fiber size, shape, and properties, and many variants now are successfully marketed. Production volumes have increased enormously for nylon, polyester, and polyolefin.

Fiber Consumption

Figure 12.3 compares population growth with the production of manufactured fibers and the mill consumption of natural fibers in the United States. Per capita consumption of all fibers, starting at a level in the 1920s of about 30 lb, rose to approximately 40 lb following World War II and reached a level at or about 50 lb in the 1970s. It topped 60 lb in 1973, dropped below 45 lb in 1982, and in 1991 was at 55 lb. But clearly overshadowing the increases resulting from population growth and a higher standard of living are the volumes produced of, first, the cellulosic manufactured fibers and, second, the

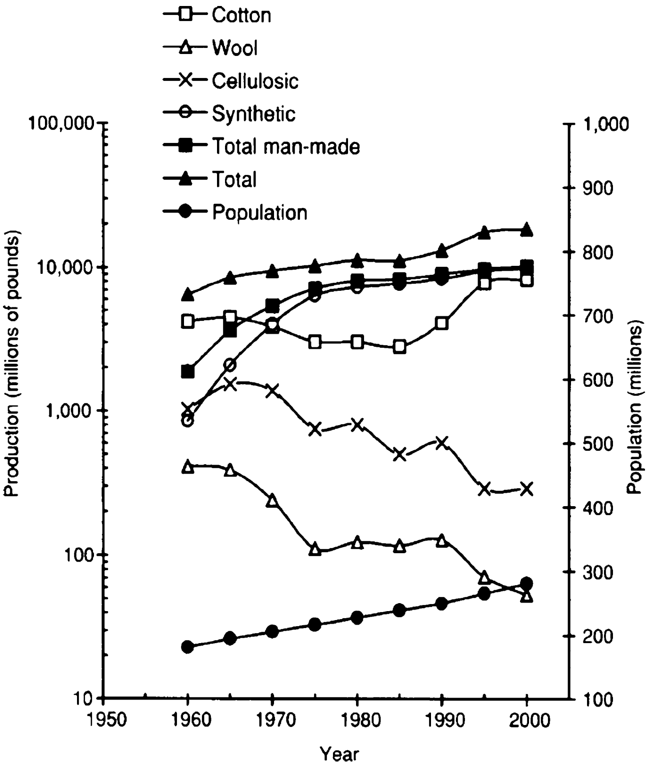

Fig. 12.3 Comparative growth of population and fiber consumption in the United States, 1960–2000

noncellulosic or completely synthetic fibers. The consumption of manufactured fibers increased from about two billion lb in 1960 to nearly nine billion lb in 1990. During the 1980s, the increase was about 11%, made up of a decrease in cellulosics of about 200 million lb (25%) and an increase in synthetics of about 1.2 billion lb (17%). Of the 13.2 billion lb of fibers used in the United States in 1990, 4.6% was the manufactured cellulosics, 63.3% was the synthetics (67.9% manufactured), 31.1% was cotton, and less than 1% was wool. A significant increase was noted in the use of cotton during the 1980s, from 3.0 billion lb in 1980 to 4.1 billion lb in 1990, believed to be in large measure due to advances in chemical finishes that made caring for the natural fibers easier than it was with the older technology. To some extent, this increase also may have occurred because people were willing to accept a more wrinkled look in order to gain the comfort of hydrophilic fibers. Still, the general figures represent quite a reversal in the consumption of fiber types seen three or more decades ago. For example, in 1960, of the 6.5 billion lb of fibers used, manufactured fibers accounted for only 29% of the total, with cotton 65% and wool 6%.

Major applications of fibers lie in apparel, home furnishing, and industrial products. In each of these, manufactured fibers have made large inroads, and currently, their usage dominates. As an illustration, consider the changes that have taken place in the use of the materials required in the manufacture of tire cords. Originally made from cotton, rayon took a commanding position during World War II. But as late as 1951, cotton comprised about 40% of the total output of tire cords of approximately half a billion lb, and nylon was at a negligible level of four million lb. By 1960, however, cotton had all but disappeared; nylon represented about 37% of the total (on a weight basis), even though only about 0.8 lb of nylon is needed to replace 1.0 lb of rayon. Whereas rayon for several years had dominated the so-called original-equipment tire market and nylon had held a corresponding position for replacement tires, more recently, glass and polyester have made heavy inroads into both—especially in belted constructions. The situation continued to change in favor of noncellulosic manufactured fiber usage in tires so that by 1972, rayon was down to 14%, nylon up to 42%, polyester up to 32%, glass up to 7%, and steel at 5%, all on a weight basis. By the late 1970s, tire markets were dominated wholly by manufactured fibers with polyester holding over 90% of the passenger car original-equipment market and nylon commanding over 90% of the truck original-equipment market. This division of markets is a direct result of the performance characteristics of the two fibers. Polyester-containing tires are free of "flat-spotting" or cold-morning thump and so are preferred in passenger cars for their smooth ride. On the other hand, nylon-containing tires are tougher and more durable and so are the choice for trucks and off-road vehicles.

The production of manufactured fibers throughout the world has developed in a manner that rather parallels the situation in the United States, as may be seen in Fig. 12.4. There are some expected differences, and obviously, the data for world usage are strongly influenced by the large components attributable to the United States, which currently account for about 23% of the manufactured fiber and about 15% of the total fiber consumption. The output of the world cellulosics has leveled off, but expansion of the noncellulosics has continued unabated. The use, or at least the recorded use, of the natural fibers, cotton and wool, rose rapidly in the 1950s, as the world economy rebounded at the conclusion of World War II. Since then (1960–1970), a modest increase has continued, essentially parallel to the growth of world population. But, in comparison with population trends, it appears that the great demand has been for manufactured textile fibers. Much of this increase has resulted from an improved standard of living and the absence of major wars.

A detailed economic examination of the processing of fibers and the changes that have taken place during the last half century would show two rather vivid occurrences. The first of these is a rapid decrease in the prices of the newer fibers as they became established, followed by a leveling out and stabilization. The second is the relative stability of prices of the manufactured fibers on short-term and even

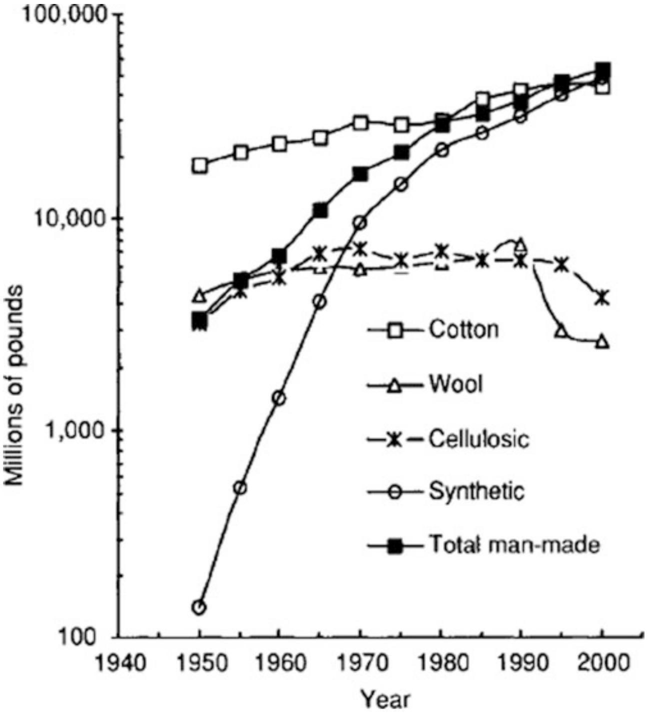

Fig. 12.4 Production of fibers in the world, 1950–2000

long-term bases, as compared with fluctuations in the prices for the natural fibers where governmentally imposed stability has not been in effect. Data are not presented about it in this text, but in the first half of the twentieth century, there was a saying in the textile industry that the person who made or lost money for the company was the one who was responsible for buying cotton and wool "futures." However, it should also be emphasized that list prices of manufactured fibers are ceiling prices and do not reflect the short-term discounts, allowances, and special arrangements that are given in a free marketplace when the demand for any manufactured fiber softens.

A presentation of complete information about the consumption of raw materials, chemical reactions, reagents and catalysts used, and efficiencies of operation in the production of manufactured fibers undoubtedly would contribute to a better understanding of the industrial chemistry involved. Several factors have prevented this, however. In the first half of the twentieth century, a historical belief in the efficacy of trade secrets still permeated the chemical industry. Even with the increased mobility of technical and scientific personnel during and following World War II, the idea still prevailed that if nothing other than patents was allowed to become public knowledge, so much the better. The situation has changed considerably since about 1960, as can be noted from the availability of information contained in the list of suggested readings that follows this chapter, yet, secrecy tends to be maintained despite the fact that key employees move from company to company, and the chemical engineering knowledge available in chemical companies that produce large volumes of fibers permits an almost complete appraisal of a competitor's activities.

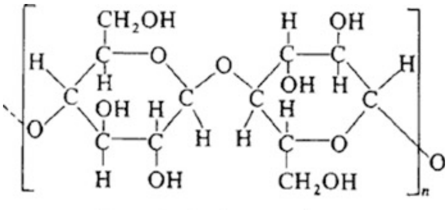
In general, in the early period of production of a fiber, the cost of the original raw material may have had very little bearing on the selling price of the final fiber. The most important factor is the action of the producer's competitors and the conditions of the market and the demand that can be developed. But the complexity of the processes involved in conversion determines the base cost of the fiber at the point of manufacture. As the process becomes older, research reduces this complexity; with simplification, there may be rapid drops in plant cost. If demand remains high, such reductions will not be expected to be reflected in selling prices; rather, profits are high. As more producers enter the field in order to share in those profits, output capacity surpasses demand, and in accordance with classical economic theory, major selling price reductions result. This was happening, in general, in the 1960s and for cellulose-based manufactured fibers in the 1970s. But beginning in 1973, the cost of petroleum-based products started to rise steeply and erratically. This rise was based not on economic considerations alone but on political considerations among the oil-producing and exporting countries (OPEC) as well. Further upward pressure on manufactured fiber prices has resulted from governmental limitations placed on chemical usage and exposure and on amounts of chemicals that can be discharged into the air and water. To meet these limitations, the manufactured fiber industry has had to supply large infusion of capital. In some instances, such expenditures could not be justified, and plant capacity was shut down permanently. This was particularly true in the case of filament rayon. In recent years, the factors of rapidly rising raw material/energy prices and the costs of meeting environmental regulations have not allowed the prices of manufactured fibers to fall as production experience has been gained and technological advances have been introduced. Instead, selling prices have been continually adjusted upward in an effort to pass along unavoidable cost increases so as to maintain profitability. In areas of application in which a manufactured fiber replaced a natural one because of lower prices and stable availability, swings in fashion and increases in imports sometimes have caused a reduction in fiber utilization. This scenario, combined with environmental concerns, is believed to have particularly applied to acrylic fiber, whose production has decreased recently in both Europe and the United States.

The great importance of manufactured fibers in the chemical industry and in the overall economy of the United States (and, in general, the developed countries) becomes apparent when the volume of production of these materials is considered and compared with the market value of even the least expensive of the raw materials used by them. The amounts of oil and natural gas consumed by the manufactured fiber industry represent around 1% of national annual usage. Of this amount, about one half is used to produce raw materials from petrochemicals, with the other half used for energy to convert trees to wood pulp for cellulose-based fibers and to convert the wood pulp and petrochemical-derived raw materials to fibers.

Rayon

Chemical Manufacture

Rayon, the first of the manufactured fibers produced in large volume, is based on the natural polymer cellulose, a repeat unit of which is shown below:



Two anhydroglucose units

Although in the early days the main source of this raw material was cotton linters, a combination of improved technologies for obtaining alpha cellulose from wood and the shortage of cotton linters used for the manufacture of cellulose nitrate during World War II resulted in a shift in raw material to wood pulp. Only certain trees constitute the most economical supply of dissolving pulp, as the final product is called; the process economics depend upon the cost of logs delivered at the pulping mill and the relative yield of alpha cellulose after the unusable lignin, and the other components of the wood are discarded.

A general flow diagram for the manufacture of rayon is given in Fig. 12.5. The dissolving pulp is received by the rayon manufacturer in sheet or roll form. In the manufacturing process, impurities are removed, with special attention being given to removal of traces of such metallic elements as manganese and iron, the former having an effect on the manufacturing process (as will be noted later) and the latter an effect on the color of the final product. The production of dissolving pulp involves drastic chemical action at elevated temperatures, which substantially reduces the originally very high molecular weight of the cellulose. The portion not soluble in 17–18% aqueous caustic, known as alpha cellulose, remains, and the lower-molecular-weight beta and gamma fractions are largely soluble and lost. The composition of the pulp is aimed at high alpha content. A typical economic trade-off is involved. The pulp producers can secure an alpha content of up to 98% by means of a cold caustic extraction, or, on the other hand, the rayon manufacturer can use a less expensive, lower alpha content pulp (90–96%) and expect to secure a lower yield. The sellers have numerous grades available to meet the specific process needs and end-product requirements of each of the buyers.

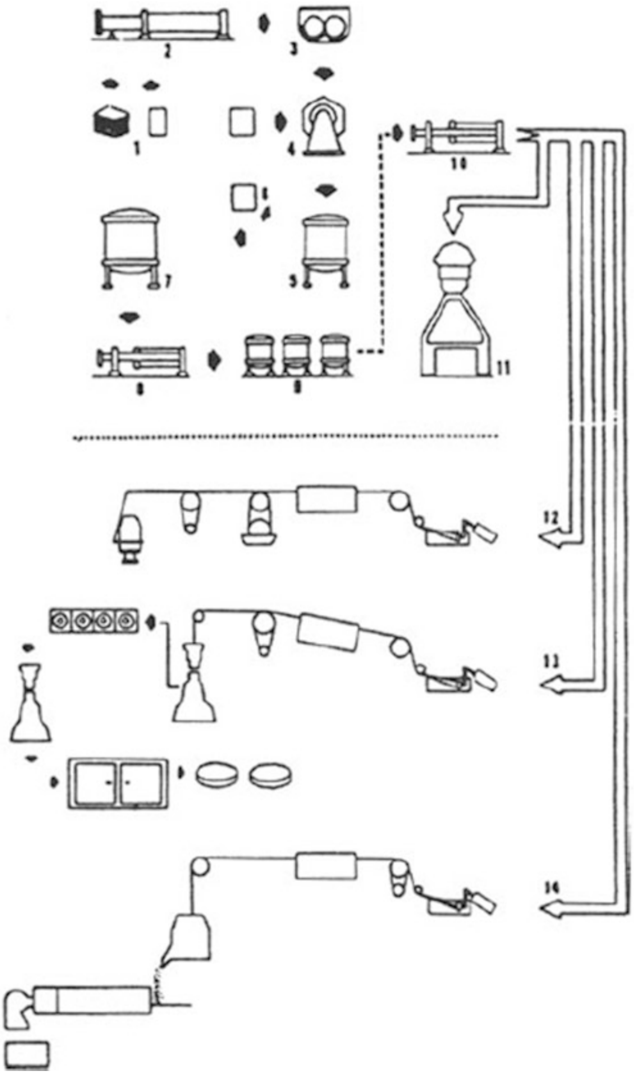


Fig. 12.5 Flow diagram for manufacture of viscose yarn: (1) cellulose sheets and caustic soda, (2) steeping press, (3) shredder, (4) xanthating churn, (5) dissolver, (6) caustic supply, (7) ripener, (8) filtration, (9) deaeration, (10) filtration, (11) continuous process, (12) tire cord, (13) pot spinning, (14) staple spinning

In the manufacture of rayon, it is the usual practice to begin "blending" at the first step, which involves steeping the pulp. Further blending proceeds throughout successive steps. The warehouse supply of pulp consists of numerous shipments, and in making up the batches for the conventional process, a few sheets are taken from each of several shipments. This serves two purposes. It prevents a slight variation in a single pulp lot from unduly affecting any

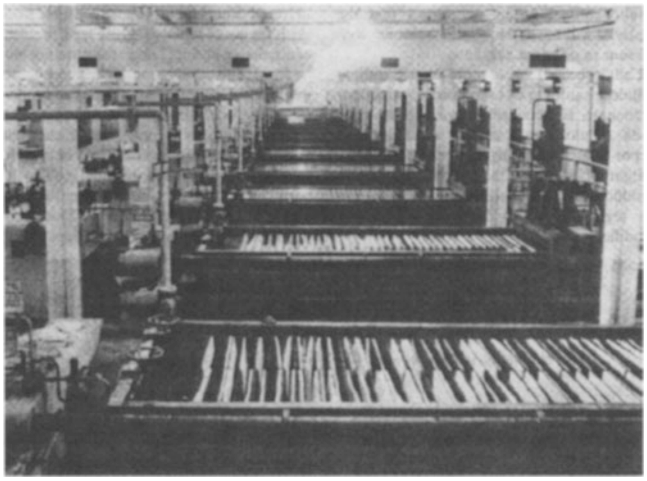

Fig. 12.6 Steeping of cellulose in the manufacture of viscose rayon (Courtesy of Avtex Fibers, Inc.)

given volume of production, and it provides a moving average so that changes with time are reduced to a minimum.

The cellulose sheets are loaded vertically, but loosely, into a combination steeping bath and press (Fig. 12.6), which is slowly filled with a solution of 17–19% caustic, where they remain for about 1 h. In the steeping, the alpha cellulose is converted into alkali or "soda" cellulose; at the same time, as already mentioned, the caustic solution removes most of the beta and gamma celluloses (also called hemicelluloses). The exact chemical composition of the soda cellulose is not known, but there is evidence that one molecule of NaOH is associated with two anhydroglucose units in the polymer chain:

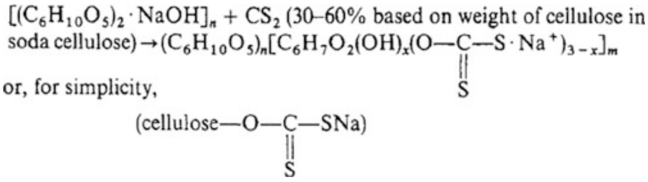
$$\begin{aligned}&(C_6H_{10}O_5)_n\ (\text{cellulose}) + 18\%\ \text{aqueous NaOH}\\&\quad\rightarrow [(C_6H_{10}O_5)_2 \bullet \text{NaOH}]_n\\&\quad\times (\text{swollen, insoluble, soda cellulose I})\\&\quad+ \text{soluble soda cellulose from } \beta \text{ and } \gamma \text{ celluloses}\end{aligned}$$

The excess caustic solution is drained off for reuse. Additional amounts are removed by forcing the sheets through a press. The sheets are still in a swollen state and retain from 2.7 to 3.0 parts of the alkali solution. The spent steeping solution squeezed out of the pulp is processed for recovering the caustic from the organic materials.

The sheets of soda cellulose are discharged into a shredder. If blending is desired, the charges from two or more steeping presses are mixed in a single shredder, where the already soft sheets are torn into crumbs; cooling is provided to prevent thermal degradation. Shredding is controlled to produce crumbs that are open and fluffy, and that will allow air to penetrate the mass readily; this is essential in aging.

Soda cellulose is aged by holding it at a constant temperature in perforated containers. The oxygen in the air produces uniform aging accompanied by a reduction in molecular weight and an increase in the number of carboxyl groups present. The target of aging is an average molecular weight high enough to produce satisfactory strength in the final fiber but low enough so that the viscosity of the solution will not be excessively high at the desired concentration for spinning. Each of the various rayon end products has its optimum degree of polymerization or chain length, ranging from about one fourth the original length for regular rayon to one half for certain high-performance fibers. As noted earlier, this optimum size is generally established by effecting a compromise between process economics and desired end-product properties. The aging proceeds for periods of up to 2 or 3 days, although the tendency is to speed up the operation by using higher temperatures and traces of metal ions, such as manganese or cobalt, to catalyze the reaction. A combination of experience and constant quality-control testing guarantees that the material will reach the correct point for conversion to cellulose xanthate.

Cellulose xanthate, or more exactly, sodium cellulose xanthate or sodium cellulose dithiocarbonate, is obtained by mixing the aged soda cellulose with carbon disulfide in a vapor-tight xanthating churn. Based upon weight of cellulose, the amount of carbon disulfide used will be in the range of 30% for regular rayon to 50–60% for modified varieties.



$$[(C_6H_{10}O_5)_2 \cdot \text{NaOH}]_n + CS_2\ (30\text{–}60\%\ \text{based on weight of cellulose in soda cellulose}) \rightarrow (C_6H_{10}O_5)_n[C_6H_7O_2(OH)_x(O\text{—}\underset{\underset{S}{\|}}{C}\text{—}S \cdot Na^+)_{3-x}]_m$$

or, for simplicity,

$$(\text{cellulose—O—}\underset{\underset{S}{\|}}{C}\text{—SNa})$$

The xanthate is soluble in a dilute solution of sodium hydroxide—a characteristic discovered by Cross and Bevan in 1892—and this property makes the spinning of rayon possible. It is a yellow solid; when dissolved in a dilute solution of alkali, it becomes a viscous, honey-colored liquid—hence the word "viscose." At this stage, the viscous solution may contain about 7.25% cellulose as xanthate in about a 6.5% solution of sodium hydroxide, although concentrations of both vary, depending on what end products are desired. The solution is ready for mixing with other batches to promote uniformity, to be followed by filtration, ripening, deaeration, and spinning. The filtration process usually involves several stages so that filters of decreasing pore size may be used to secure a balance of throughput and stepwise particle and gel removal.

Such an operation is a straightforward one for "bright" rayon, but only in the days of "artificial silk" did the shiny fiber alone satisfy the market. After a few years, a dull-appearing fiber also was demanded. At first, fine droplets of oil in the filaments were used to produce dullness until it was discovered that titanium dioxide pigment having a particle size smaller than 1 μm in diameter was even more satisfactory. The latter has since become the universal delustrant for all manufactured fibers. With the use of pigments of any type, problems of dispersion and agglomerate formation must be faced. The usual practice has been to add this pigment when mixing the cellulose xanthate into the dilute solution of caustic.

However, there are many other chemicals and additives that a producer may be required to add to the solution, including (1) a few parts per million of a tracer element for later identification of the product, (2) coloring pigments for “dope-dyed” rayon (“dope dyeing” will be discussed in greater detail under another heading); (3) chemicals for controlling the rate of precipitation and regeneration for obtaining rayon with so-called high performance), and (4) polymers and chemicals to impart specific properties to the fiber. From the standpoint of chemical processing, it is obvious that these additives may also be added when the sodium cellulose xanthate is dissolved in dilute caustic solution or may be injected into the solution before it enters the spinnerette prior to being extruded. To keep the operations as flexible as possible, the additives should be injected at the last possible moment so that when a changeover is desired, there will be a minimum amount of equipment to be cleaned. On the other hand, the farther along in the operation that additives are placed into the stream, the greater the problem of obtaining uniformity in an extremely viscous medium and the greater the difficulty in maintaining exact control of proportions before the viscous solution is passed forward and spun. Furthermore, all insoluble additives must be of extremely small particle size, and all injected slurries must be freed of agglomerates by prefiltration; if not, the viscous solution containing the additives must be filtered. Each manufacturer of viscose rayon develops the particular conditions for making additions, depending on a multitude of factors, not the least of which is the existing investment in equipment. All manufacturers must face the universal necessity of filtering the solution with or without pigments or other additives, so that all impurities and agglomerates that might block the tiny holes in the spinnerette are removed.

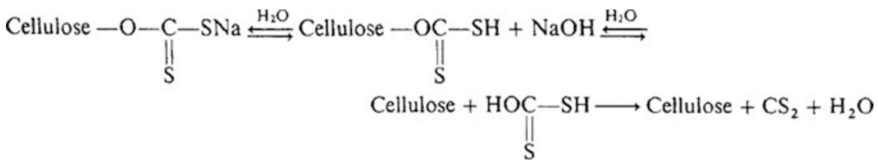
Although it was known in the years following the discovery by Cross and Bevan that a viscose type of solution could be used in the preparation of regenerated cellulose, the conversion of this solution into useful fibers was not possible until the discovery that the solution required aging until “ripe.” Ripening is the first part of the actual chemical decomposition of cellulose xanthate, which, if allowed to proceed unhampered, would result in gelation of the viscose solution.

Experience has taught the manufacturer the correct time and conditions for the aging operation, but the requirement of aging itself demands that the entire process be so planned that the viscose solution will arrive at the spinnerette possessing, as nearly as possible, the optimum degree of ripeness, to produce fibers having the desired characteristics. This degree of ripeness is determined by an empirical test made periodically, which is a measurement of the resistance of the solution to precipitation of the soda cellulose when a salt solution is titrated into it. Thus, it is known as the “salt index” or “Hottenroth number” after its originator. An additional step in the overall ripening operation involves the removal of dissolved and mechanically held air by the use of a vacuum on a moving thin film of the viscose solution.

It should be mentioned that so inevitable is decomposition of cellulose xanthate and consequent gelation of the contents of pipes and tanks that all viscose rayon plants must be prepared to pump in-process viscose solutions to other spinning machines or to a waste receiver, purging the entire system with dilute caustic solution, in the event of a long delay in spinning.

Wet Spinning

Spinning a viscose solution into rayon fibers (wet spinning) is the oldest of the three common ways of making manufactured fibers. In this method, the polymer is dissolved in an appropriate solvent, and this solution is forced through fine holes in the face of the spinnerette, which is submerged in a bath of such composition that the polymer precipitates. The pressure necessary for this extrusion is supplied by a gear pump, which also acts as a metering device; the solution is moved through a final or “candle” filter before it emerges from the holes of the spinnerette. There is immediate contact between these tiny streams and the liquid or “wet” bath. As the bath solution makes contact with the material extruded from the holes, chemical or physical changes take place. These changes, whether of lesser or greater complexity, convert the solution of high-molecular-weight linear polymer first to a gel structure and then to a fiber. As will be observed in what follows, it is an interesting fact that the spinning of viscose rayon, with all of the ramifications made possible by variations in the composition of the solution and the precipitating bath, as well as in the operating conditions, presents the chemist and the chemical engineer with both the oldest and the most complex wet-spinning process.

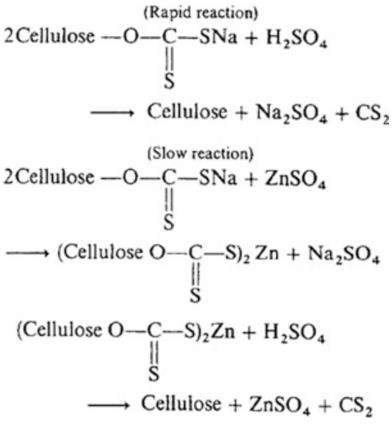


$$\text{Cellulose—O—}\underset{\underset{\displaystyle S}{\|}}{\text{C}}\text{—SNa} \overset{H_2O}{\rightleftharpoons} \text{Cellulose—O}\underset{\underset{\displaystyle S}{\|}}{\text{C}}\text{—SH} + \text{NaOH} \overset{H_2O}{\rightleftharpoons}$$

$$\text{Cellulose} + \text{HO}\underset{\underset{\displaystyle S}{\|}}{\text{C}}\text{—SH} \longrightarrow \text{Cellulose} + CS_2 + H_2O$$

The formation of rayon fibers from viscose solution is far from being simple, from either a physical or a chemical standpoint. The spinning bath usually contains 1–5% zinc sulfate and 7–10% sulfuric acid, as well as a surface-active agent, without which minute deposits will form around the holes in the spinnerette. Sodium sulfate (15–22%) is present, formed by the reactions, and as sulfuric acid is depleted and sodium sulfate concentration builds up, an appropriate replenishment of the acid is required. There is a coagulation of the organic material as the sulfuric acid in the spinning bath neutralizes the sodium hydroxide in the viscose solution; at the same time, chemical decomposition of the sodium cellulose xanthate takes place to regenerate the cellulose. If zinc ions are present, which is the usual situation in the production of the improved types of rayon, an interchange takes place so that the zinc cellulose xanthate becomes an intermediate. It reacts at a slower rate, causing slower decomposition to cellulose. This provides conditions for more effective stretching or drawing of the fiber. Chemical additives usually are present to repress hydrogen ion action. The gel-like structure, the first state through which the material passes, is not capable of supporting itself outside the spinning bath. As it travels through the bath, however, it quickly becomes transformed into a fiber that can be drawn from the spinning bath and that can support itself in subsequent operation (Fig. 12.7).

The reaction between the bath and the fiber that is forming is paramount in determining the characteristics of the final product; it is for this reason that additives (previously mentioned), as well as zinc ions, may be used to control both the rate of coagulation and regeneration. In this manner, the arrangement of the cellulose molecules may be controlled to produce the conformational structure desired. A practical application of this will be discussed later.



$$\text{(Rapid reaction)}$$
$$2\text{Cellulose}-\text{O}-\underset{\underset{\displaystyle \text{S}}{\|}}{\text{C}}-\text{SNa} + \text{H}_2\text{SO}_4 \longrightarrow \text{Cellulose} + \text{Na}_2\text{SO}_4 + \text{CS}_2$$
$$\text{(Slow reaction)}$$
$$2\text{Cellulose}-\text{O}-\underset{\underset{\displaystyle \text{S}}{\|}}{\text{C}}-\text{SNa} + \text{ZnSO}_4 \longrightarrow (\text{Cellulose O}-\underset{\underset{\displaystyle \text{S}}{\|}}{\text{C}}-\text{S})_2\,\text{Zn} + \text{Na}_2\text{SO}_4$$
$$(\text{Cellulose O}-\underset{\underset{\displaystyle \text{S}}{\|}}{\text{C}}-\text{S})_2\text{Zn} + \text{H}_2\text{SO}_4 \longrightarrow \text{Cellulose} + \text{ZnSO}_4 + \text{CS}_2$$

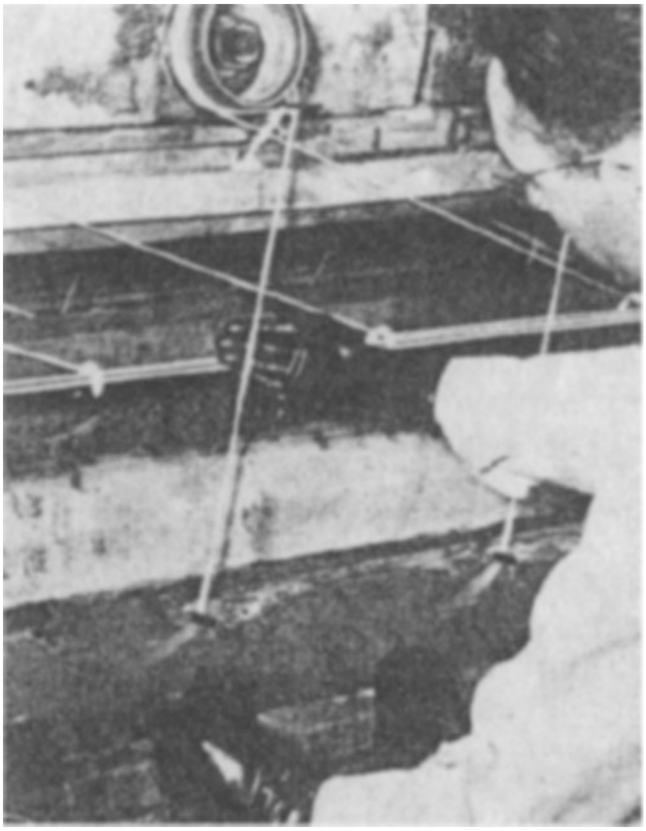


Fig. 12.7 Spinning of viscose rayon (Courtesy of Avtex Fibers, Inc.)

Because of hydraulic drag, stretching occurs in the bath and also in a separate step after the yarn leaves the bath. In both cases, the linear molecules of cellulose are oriented from random positions to positions more parallel to the fiber axis. If a rayon tire cord is to be the final product, the fibers must be severely stretched to produce a very high orientation of the molecule. This is the basis of the tire cord's high strength and ability to resist stretching, without which growth of the tire body would occur. For regular textile and nonwoven uses, such high strengths are not desired, and the spinning and stretching conditions are controlled to produce rayon of lower strength and greater stretchability under stress.

In order to stretch the yarn uniformly during the manufacturing process, two sets of paired rollers or "godets" are employed, each of the two sets operating at different rotational speeds. The yarn is passed around the first set of godets several times to prevent slippage and is supplied to the stretching area at a constant speed. A second set of godets moves it forward at a more rapid rate, also without slippage. Stretching may range from a few to 100 or more percent. Spinning speeds are of the order of 100 m/min but may vary with both the size of the yarn and the process used.

Spinning conditions, composition of the spinning bath, and additives to the viscose solution determine the physical characteristics of the rayon—its breaking strength and elongation, modulus, ability to resist swelling in water, and characteristics in the wet state as compared with those of the dry material. Not only must the chemical composition of the spinning bath be carefully controlled but the temperature must be regulated at a selected point, somewhere in the range of 35–60°C, to ensure those precipitation and regeneration conditions that are essential to the manufacture of any particular viscose rayon having the properties needed for a selected end use.

After precipitation and regeneration of cellulose have been completed and raw rayon fiber has been formed, the subsequent steps must be controlled so that differences in treatment are minimized; otherwise, such sensitive properties as “dye acceptance” will be affected, and the appearance of the final product will vary.

Minute traces of suspended sulfur resulting from the chemical decomposition of cellulose xanthate must be removed by washing with a solution of sodium sulfide. It is expedient to bleach the newly formed fibers with hypochlorite to improve their whiteness; an “antichlor” follows. The chemicals originally present and those used to purify the fibers must be removed by washing. As a final step, a small amount of lubricant is placed on the filaments to reduce friction and improve processibility in subsequent operations.

Several different processes are used for the steps involved in spinning and purifying continuous-filament rayon. One of the most common involves the formation of packages of yarn, each weighing several pounds, for separate treatment. After it has been passed upward out of the spinning bath and stretched to the desired degree, the yarn is fed downward vertically into a rapidly rotating can-like container called a spinning pot or “Topham” box (after the man who invented it in 1900). It is thrown outward to the wall of the pot by centrifugal force and gradually builds up like a cake, with excess water being removed by the same centrifugal force. This cake is firm, although it must be handled with care, and is sufficiently permeable to aqueous solution to permit purification.

In another method of package spinning, the yarn is wound onto a mandrel from the side at a uniform peripheral speed. With this process, the yarn may be purified and dried in the package thus formed. In any of these systems, the spinning and stretching, as well as subsequent steps, may involve separate baths.

The continuous process for spinning and purifying textile-grade rayon yarn merits particular mention from the standpoint of industrial chemistry, as it is rather an axiom that a continuous process is to be preferred over a batch or discontinuous operation. This method employs “advancing rolls” or godets that make it possible for the yarn to dwell for a sufficient length of time on each pair, thus allowing the several chemical operations to take place in a relatively small area. Their operation depends on the geometry existing when the shafts of a pair of adjacent cylindrical rolls are oriented slightly askew. Yarn led onto the end of one of these and then around the pair will progress toward the other end of the set with every pass, the rate of traversing, and therefore the number of wraps, being determined by the degree of skewness.

The production of rayon to be converted to staple fiber also is amenable to line operation. Here, the spinnerette has many thousands of holes, and a correspondingly large number of filaments are formed in the precipitation bath. The resulting tow then is stretched to the desired degree and immediately cut in the wet and unpurified condition. The mass of short lengths can be conveyed through the usual chemical treatments, after which it is washed and dried. It is fluffed to prevent matting and is packaged for shipment in large cases.

Cuprammonium, Nitrocellulose, and Cellulose Acetate Processes for Rayon

Cuprammonium Cellulose. Cellulose forms a soluble complex with copper salts and ammonia. Thus, when cellulose is added to an ammoniacal solution of copper sulfate that also contains sodium hydroxide, it dissolves to form a viscous blue solution, and in this form, it is known as cuprammonium cellulose. The principles on which the chemical and spinning steps of this process are based are the same as those for the viscose process. Cellulose is dissolved, in this case, in a solution containing ammonia, copper sulfate, and sodium hydroxide. Unlike the viscose solution, the cuprammonium solution need not be aged and will not precipitate spontaneously on standing except after long periods. It is, however, sensitive to light and oxygen. It is spun into water and given an acid wash to remove the last traces of ammonia and copper ions. Although this rayon was never manufactured in a volume even approaching that achieved by the viscose process, the smaller individual filaments inherent in it made it useful in certain specialty markets. It no longer is manufactured in the United States but continues to be made abroad.

Nitrocellulose and Cellulose Acetate. Although nitrocellulose and cellulose acetate intermediates have been made and regenerated to form cellulose fibers, neither of these historical processes associated with rayon manufacture are still in operation.

Textile Operations

After the filament rayon fiber has been spun and chemically purified, much of it passes through what are known as “textile operations” before it is ready to be knitted or woven. Because these steps of twisting and packaging or beaming are common to the manufacture of all manufactured fibers, it is advisable to review briefly the background and the processes.

Rayon, the first manufactured fiber, not only had to compete in an established field but also had to break into a conservative industry. Silk was the only continuous-filament yarn, and products made from it were expensive and possessed of high prestige so that they offered a tempting market for rayon. Thus, the new product entered as a competitor to silk and, as already noted, became known as "artificial silk." Under the circumstances, it was necessary for rayon to adapt itself to the then-existing silk-processing operations and technologies. It was customary to twist several silk filaments together to secure a yarn of the desired size, strength, and abrasion resistance. Because rayon was weaker than silk and its individual filaments were smaller, it required as much twisting as silk or even more.

This twisting could have been carried out in the same plant where the yarn was spun, but the existence of silk "throwsters" (from the Anglo-Saxon thrawan, to twist or revolve) made that unnecessary. However, as the rayon industry developed, the amount of yarn twisted in the producing plant or sent forward to throwsters decreased. Over the years, the trend has been to use less twist and to place, instead, several thousand parallel ends directly on a "beam" to form packages weighing as much as 300–400 lb, which are shipped directly to a weaving or knitting mill. The advent of stronger rayons, as well as other strong fibers, and a diminishing market for crepe fabrics which required highly twisted yarns accelerated the trend away from twisting.

In all twisting and packaging operations, the yarn makes contact with guide surfaces and tensioning devices, often at very high speeds. To reduce friction, it is necessary to add a lubricant as a protective coating for the filaments. This is generally true of all manufactured fibers, and it is customary to apply the lubricant or "spinning finish" or "spinning lubricant" as early in the manufacturing process as possible. For those materials that develop static charges in passing over surfaces, this lubricant also must provide antistatic characteristics.

It is difficult to overstate the importance of fiber lubricants to the successful utilization of manufactured fibers. Few problems can be more damaging to a fiber-handling operation than a lubricant upset. A separate chapter could be written on lubricant usage, but some of its more important aspects will be mentioned here. Obviously, lubricants must reduce friction between the fiber and various surfaces to allow movement without excessive damage to the fiber or the surface contacted, the latter being any one of a variety of metals or ceramics. Similarly, a fiber comes in contact with the surface of other fibers in staple fiber processing and in packaging. The lubricant composition must be stable under a variety of storage conditions, without decomposing or migrating within the package or being lost from the fiber surface by adsorption into the fiber, and must be nontoxic and nondermatitic. It also must be compatible with other materials added during textile processes, such as the protective size coat applied to warp yarns before weaving or the wax coat often applied to yarns before circular knitting. Possible metal corrosion must be evaluated for each lubricant composition. Finally, after having performed its function, the fiber finish or lubricant must be completely scoured from the fabric to permit uniform adsorption of dyes and fabric finishes. The application of sewing lubricants to fabric to be cut and sewn is yet another area requiring attention.

Spun Yarn. After rayon became established in the textile industry, where it could be used as a silklike fiber, and its selling price was greatly reduced, other markets for it were developed. The cotton, wool, worsted, and linen systems of converting short discontinuous fibers to yarns were well established, and their products were universally accepted. Here again, it was necessary to make rayon fit the requirements of existing equipment and historically acceptable operations. The first of these was that it be cut into the same lengths as those found in cotton and wool. Fortunately, the viscose rayon process was and is eminently suited to the production of tows containing thousands of filaments. The pressure required to force the solution through the holes is so low that neither thick metal sections nor reinforcement of the surface is necessary to prevent bulging, and large spinnerettes containing several thousand holes can be used. Furthermore, the spinning bath succeeds in making contact with all the filaments uniformly. As a result, the spinning of viscose rayon tow is very similar in principle to the production of the smaller continuous-filament yarns.

Because both cotton and wool possess distortions from a straight rodlike structure, machinery for their processing was designed to operate best with such crimped fibers. Thus, it was necessary for rayon staple to possess similar lengths and crimpiness in order to be adapted to existing equipment. The crimp, that is, several distortions from a straight path per inch, is produced in rayon "chemically" by modification of the structure. The precipitation-stretching step in spinning is carried out so that the skin and the core of the individual filaments are radially nonuniform and constantly changing over very short lengths along the filaments. Because the skin and the core differ in sensitivity to moisture, the two components shrink differentially, leading to the development of permanent distortions of the filaments. The latent chemical crimp may be enhanced by a thermomechanical step. In this, the tow is fed between two wheels, which in turn force it into a chamber, called a "stuffer box," heated with steam, in which it is forced against the compacted material ahead of it, causing the straight filaments to collapse immediately. As the mass of material is pressed forward, it becomes tightly compacted, and it tends to remain axially distorted after it escapes through a pressure-loaded door at the opposite end of the chamber.

Modified Viscose Rayon Fibers

The variations of chemical ingredients, their concentrations, and the temperature of the spinning bath determine the rates of coagulation and regeneration and thus the relative amounts of "skin" and "core" in the cross section of the fiber. The skin is known to possess a higher degree of order and better mechanical properties than the core, so an increase in its proportion is desired in higher-performance fibers. The degree of orientation is determined by the stretch imparted. Inherent in-process variations such as these are what may be called the "art" of viscose rayon manufacturing, whereby great diversity in rayon properties can be obtained. The cross-sectional morphologies of some rayons are illustrated in Fig. 12.8.

High-Wet-Modulus Rayon. One of the important innovations in the rayon industry has been the development of high-wet-modulus (HWM) rayon. For its manufacture, the cellulose molecules require a higher degree of polymerization (DP) than regular rayon, so aging and ripening times are decreased, and the processing temperature is lowered. As the viscose solution flows through the spinnerette into the bath, coagulation takes place to form the needed skin. However, in order for an increase in tenacity to occur, regeneration should proceed slowly; this is aided by using a lower concentration of acid in the spin bath. Also, zinc is added because zinc ions in the bath slow down regeneration by forming zinc cellulose xanthate, which is more resistant to acid decomposition than is sodium xanthate. Because of the slow generation process, what is actually formed is nearly an "all-skin" rayon with a round cross section. Because the structure also is stretched before it crystallizes, a higher stretch is possible; this gives a higher orientation. The fiber thus has significantly higher strength than regular rayon. This higher tenacity exists not only when the material is dry but also when it is wet, hence the name HWM rayon. Because of its high structural orientation and greater order, the fibers have fewer physically accessible sites for water molecules; thus, it is less susceptible to swelling and to the adverse effects of basic cleaning solutions so that the fiber's launderability is improved. The HWM rayons are used extensively for blending with cotton, wool, silk, and all other manufactured fibers.

High Absorbency Rayons. Over the past years, disposable products have become commonplace, especially in the United States and Europe. Cellulosic fibers, particularly rayons, have served the needs of the disposables industry because of their absorbent qualities. The most useful fibers for disposable/absorbent applications are the rayons with crenulations, crimp, and hollow regions, all of which add to the absorbency of the fiber. These characteristics are achieved in varying degrees by physical and chemical alterations in the spinning process. Crenulations or random irregularities in the shape of the cross section, typical for most rayon fibers, are caused by the rapid formation of skin before the dehydration is complete. As the fiber interior loses solvent, it collapses in certain areas and produces the crenulated shape. Furthermore, fabricators have learned how to control the cross-sectional shape of filaments by using spinnerettes containing other than round holes. One example is fibers having Y or trilobal-shaped cross sections, which have been found to be capable of picking up more water and at a faster rate than possible with fibers of round cross sections [4].

Hollow viscose fibers contain gas pockets produced by adding "blowing" agents, such as sodium carbonate, to the viscose. When carbon dioxide is released during regeneration, the fibers inflate, leading to the formation of hollow filaments. The added free volume and decrease in molecular order increase the ability of the fibers to pick up water.

Other New Developments

A number of other developments are taking place in the rayon industry, the target of one being the manufacture of lint—free rayon for use in products such as circuit boards. In another, graphite particles are blended in with the viscose to reduce static buildup. Production of flame-retardant rayon has received increased attention, in one case being achieved by the addition of phosphorus compounds to the spinning dope. The advanced technology now can produce flame-resistant fibers that, when exposed to high temperatures, will not shrink or emit toxic gases. Other developments are in the area of finding better and environmentally safer solvents for the cellulosic raw material. Searches are under way for solvents that may lead to lyotropic liquid crystalline polymer solutions from which ultrahigh-strength and high-modulus fibers can be spun.

Environmentally Friendly High-Wet-Strength Rayon: Lyocell

Low wet strength of rayon in general has restricted the application of the fiber to disposable and semidurable materials. Additionally, the environmental concerns associated with its manufacture have resulted in significant curtailment in production of the fiber during the recent past. Search for ways and means to produce a high-wet-strength fiber using

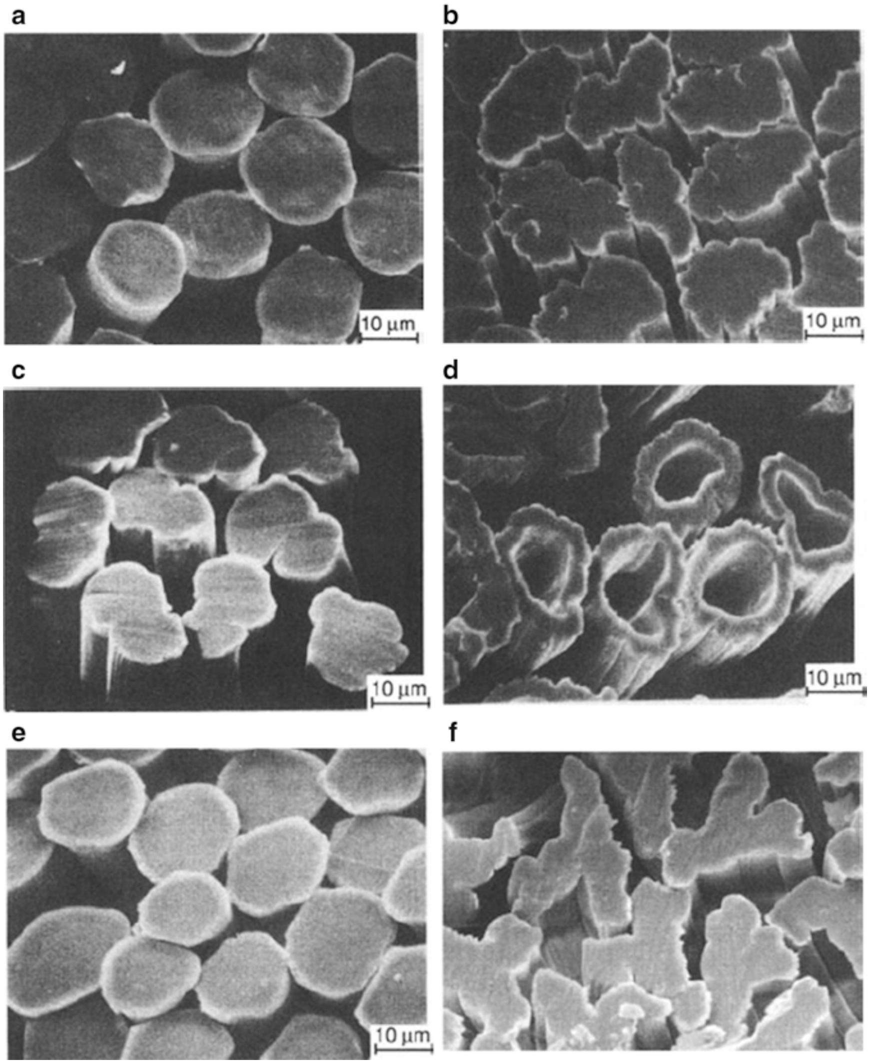

Fig. 12.8 Cross-sectional morphologies of some of the rayon fibers. (**a**) High-wet modulus, (**b**) regular rayon, (**c**) crimped HWM, (**d**) hollow, (**e**) cuprammonium, (**f**) trilobal (*Sources*: All except trilobal: Turbak [3], copyright John Wiley & Sons, Inc., New York, 1985 and used with permission of the copyright owner; trilobal photo: Gupta and Hong [4])

an environmentally acceptable process has occupied much of the research effort during the past two decades. One of the latest additions to the family of rayon fibers is lyocell. The fiber has wet strength comparable to that of the natural cellulosic fibers and is manufactured with a solvent that is essentially totally recovered and recycled [5]. The solvent used is *N*-methyl morphine oxide, $O(C_4H_8)$ $NOCH_3$, popularly known as amine oxide. The manufacturing process involves the dissolving of pulp in hot amine oxide, filtration of the solution, and then spinning into a bath containing a dilute solution of the solvent. The bath removes the amine oxide from the fibers, which are washed and dried, and the removed solvent is almost totally reclaimed for further use. The final fiber is said to have a different molecular structure from that of normal rayon and a smooth surface and a round cross section. The fiber is noted to be stronger than cotton and normal rayon in both the dry and the wet states [6].

Cellulose Acetate

Historical

Cellulose acetate was known as a chemical compound long before its potential use as a plastic or fiber-forming material was recognized. The presence of hydroxyl groups had made it possible to prepare cellulose esters from various organic acids, as cellulose consists of a long molecular chain of beta-anhydroglucose units, each of which carries three hydroxyl groups—one primary, the other two secondary. The formula for cellulose (already noted) is $[C_6H_7O_2(OH)_3]_n$; when this is fully esterified, a triester results. It was learned quite early that although cellulose triacetate is soluble only in chlorinated solvents, a product obtained by partial hydrolysis of the triester to a "secondary" ester (having about 2.35–2.40 acetyl groups per anhydroglucose unit) was easily soluble in acetone obtaining a small amount of water. Many

other cellulose esters have been prepared, but only the acetate has been commercialized successfully as a manufactured fiber. Propionates and butyrates, and mixed esters of one or both the acetates, have applications as plastics. The first acetate fibers were produced in 1921 in Europe and in 1924 in the United States.

Manufacture of Cellulose Secondary Acetate

Cellulose acetate originally was made from purified cotton linters, but this raw material has been entirely replaced by wood pulp. The other raw materials used are acetic acid and acetic anhydride.

Cellulose acetate is manufactured by a batch process (see Fig. 12.9). There has been mention in the patent literature of a continuous system, but its utilization as a production process has not been announced. The "charge" of cellulose, purified, bleached, and shredded, is of the order of 800–1,500 lb. It is pretreated with about one third its weight of acetic acid and a very necessary amount of water, about 6% of its weight. If it is too dry at the time of use, more H_2O must be added to the acetic acid. A small amount of sulfuric acid may be used to assist in swelling the cellulose and to make it "accessible" to the esterifying mixture.

Although there has been much discussion of the chemistry of cellulose acetylation, it is now generally agreed that the sulfuric acid is not a "catalyst" in the normal sense of the word but rather that it reacts with the cellulose to form a sulfoester. The acetic anhydride is the reactant that provides the acetate groups for esterification. The acetylation mixture consists of the output from the acetic anhydride recovery unit, being about 60% acetic acid and 40% acetic anhydride, in an amount 5–10% above the stoichiometric requirement, to which has been added 10–14% sulfuric acid based on the weight of cellulose used. The reaction is exothermic and requires that the heat be dissipated.

In preparing for acetylation, the liquid reactants are cooled to a point (0°C) where the acetic acid crystallizes, the heat of crystallization being removed by an appropriate cooling system. The slush of acetic acid crystals in the acetic anhydride–sulfuric acid mixture is pumped to the acetylizer, a brine-cooled mixer of heavy construction (see Fig. 12.10).

The pretreated cellulose is dropped in from the pretreating unit located above. The reaction is highly exothermic, and at the start, large amounts of heat are produced. As the temperature of the reaction mixture rises to the melting point of the acetic acid (16.6°C), its large heat of fusion (45.91 cal/g) prevents a dangerous rise in temperature that would degrade the molecular weight of the cellulose chain.

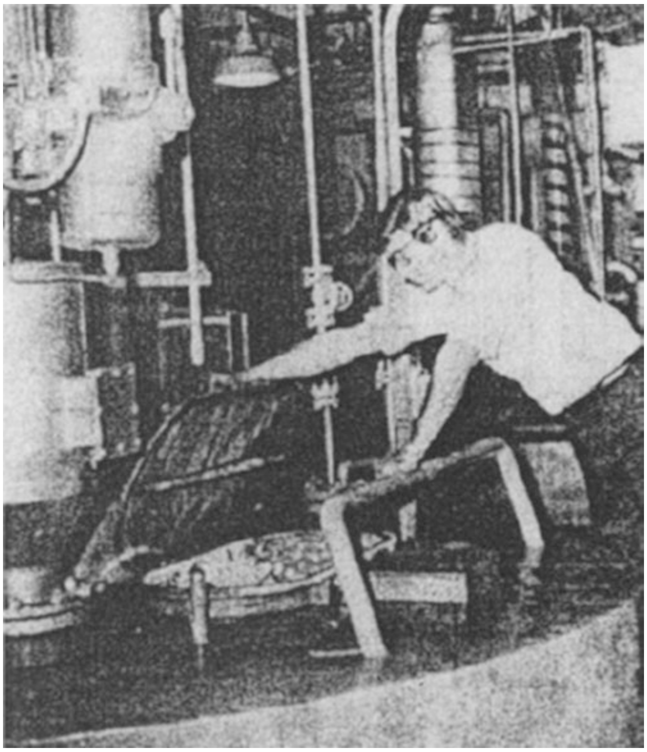

Fig. 12.10 Process vessel for acetylation of cellulose (Courtesy of Celanese Fibers Co.)

As the reaction proceeds, brine in the jacket of the acetylizer provides additional cooling:

$$\begin{aligned}&\text{Cellulose} + (CH_3CO)_2O + H_2SO_4(10-15\%\\ &\text{based on weight of cellulose}) \xrightarrow[\text{[Anhydrous]}]{CH_3COOH}\\ &[C_6H_7O_2(OSO_3H)_{0.2}(CH_3COO)_{2.8}]_n\end{aligned}$$

The reaction product is soluble in the acetylation mixture; as it is formed and dissolved, new surfaces of the cellulose are presented to the reagents. One variation of this procedure uses methylene chloride, rather than an excess of acetic acid in the reaction mixture. This chemical is used both to dissipate the heat by refluxing (boiling point, 41.2°C) and to dissolve the cellulose ester as it is formed. As the reaction proceeds, the temperature is allowed to rise. Because cellulose is a natural product obtained from many sources, it varies slightly in composition, and at the end of the reaction, it's dissolvability cannot be predicted exactly; the disappearance of fibers as determined by microscopic examination thus is the usual means of following its progress.

During the acetylation operation, a certain amount of chain fission is allowed to take place in the cellulose molecule. This is to ensure that the viscosity of the cellulose acetate spinning solution will be low enough for ease of handling but high enough to produce fibers with the required strength. The temperature of the reaction controls the rates of both acetylation and degradation of molecular weight.

The next step in the manufacture is "ripening," whose object is to convert the triester, the "primary" cellulose acetate, to a "secondary" acetate having an average of about 2.35–2.40 acetyl and no sulfo groups (if any sulfuric acid is used in pretreatment) per anhydroglucose unit. While the cellulose sulfoacetate is still in the acetylizer, sufficient water is added to react with the excess anhydride and start the hydrolysis of the ester. Usually, the water is used as a solution of sodium or magnesium acetate, which increases the pH and promotes hydrolysis. The temperature is raised to about 70–80°C by direct injection of steam to speed up the reaction. Hydrolysis is continued until the desired acetyl content is obtained. When this value is reached, an aqueous solution of magnesium or sodium acetate is added to cool the batch and stop the hydrolysis. It is then ready for precipitation. For example,

$$\begin{aligned}&[C_6H_7O_2(OSO_3H)_{0.2}(CH_3COO)_{2.8}]_n\\ &\quad + (CH_3COO)_2Mg \xrightarrow{\text{Aqueous conc. } CH_3COOH}\\ &\quad [C_6H_7O_2(OH)_{0.65}(CH_3COO)_{2.35}]_n + MgSO_4\end{aligned}$$

The solution is carried to the verge of precipitation by adding dilute acetic acid. Then it is flooded with more dilute acetic acid and mixed vigorously, so that the cellulose acetate comes out as a "flake" rather than a gelatinous mass or fine powder. The flake then is washed by standard countercurrent methods to remove the last traces of acid and is dried in a suitable dryer.

Manufacture of Cellulose Triacetate

To obtain completely acetylated cellulose, the reaction requires the use of perchloric acid rather than sulfuric acid as the catalyst. In the presence of 1% perchloric acid, a mixture of acetic acid and acetic anhydride converts a previously "pretreated" cellulose to triacetate without changing the morphology of the fibers. If methylene chloride rather than an excess of acetic acid is present in the acetylation mixture, a solution is obtained. However, usually a degree of substitution between 92% and 100% is acceptable. For obtaining such a triester, it is possible to use about 1% sulfuric acid instead of perchloric acid. When the sulfoacetate obtained from such a reaction is hydrolyzed with the objective of removing only the sulfoester groups, the resulting product has about 2.94 acetyl groups per anhydroglucose unit. The preparation, hydrolysis, precipitation, and washing of "triacetate" are in all other respects similar to the corresponding steps in the manufacture of the more common secondary acetate. Cellulose triacetate,

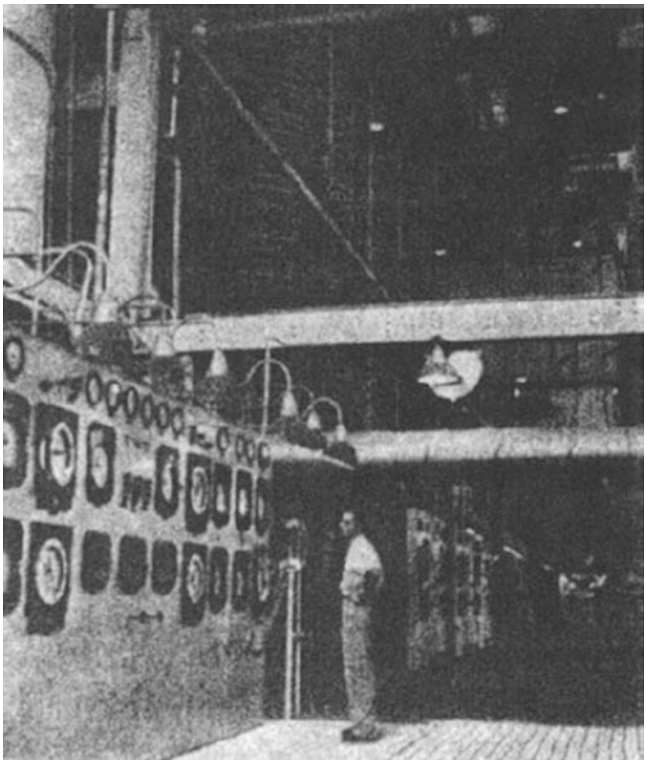

Fig. 12.11 Recovery of acetic acid (Courtesy of Celanese Fibers Co.)

formerly produced under the trade name Arnel® by Celanese Corporation, is no longer in production in the United States.

Acid Recovery. In the manufacture of every pound of cellulose acetate, about 4 lb of acetic acid is produced in 30–35% aqueous solution. The accumulated acid contains a small amount of suspended fibers and some dissolved cellulose esters. To remove the suspended material, the acid is passed slowly through settling tanks. Then it is mixed with organic solvents, so that the acid becomes concentrated in an organic layer, which is decanted. Distillation separates the acid from the organic solvent.

To produce the acetic anhydride, the acid is dehydrated to ketene and reacted with acetic acid using a phosphate catalyst at 500°C or higher in a tubular furnace:

$$CH_3COOH \xrightarrow[\text{Catalyst}]{\text{Heat}} H_2O + CH_2 = C = O$$

$$CH_2 = C = O + CH_3COOH \rightarrow (CH_3CO)_2O$$

The mixture of unreacted acid, water, and anhydride is fed to a still, which yields dilute acetic acid overhead and an anhydride–acetic acid mixture at the bottom (see Fig. 12.11). Conditions are controlled in such a way that the raffinate is about 40% anhydride and 60% acetic acid. As already mentioned, this is the desired ratio for the reaction mixture used for acetylation of cellulose.

Blending of Flake. As in the manufacture of viscose, the products of batch operations are blended to promote uniformity in the manufacture of cellulose acetate. Although a blend of different celluloses is selected in the beginning, the pretreatment, acetylation, and ripening are batch operations with little or no mixing. Before precipitation, a holding tank provides an opportunity for mixing; then precipitation, washing, and drying—all continuous—promote uniformity. The dried cellulose acetate flake moves to holding bins for analysis—the moisture content, acetyl value, and viscosity being especially important. The results of the analyses determine how much further blending is necessary. After blending and mixing of portions of selected batches, the lot is air-conveyed to large storage bins or "silos," which are filled from the center of the top and emptied from the center of the bottom, thus bringing about further mixing.

Spinning Cellulose Acetate

Acetone is metered into a vertical tank equipped with a stirrer, and the cellulose acetate flake and filter aid are weighed in an automatic hopper; all operations are controlled by proportioning methods common to the chemical industry. The ratio of materials is about 25% cellulose acetate, 4% water, less than 1% ground wood pulp as a filter aid, and the remainder acetone. The mixture moves forward through two or three stages at the rate at which it is used, the hold time being determined by experience. After dissolution is completed, filtration is carried out in batteries of plate and frame filter presses in three or even four stages, the passage of the "dope" being through presses of decreasing porosity.

Much of the cellulose acetate is delustered by the addition of titanium dioxide pigment, as with viscose rayon. Between filtrations (and after the last filtration), the dope goes to storage tanks that serve to remove bubbles; in this case, a vacuum is not necessary. From the final storage tank, it is pumped into a header located at the top of each spinning machine; then it is directed to a series of metering gear pumps, one for each spinnerette. Because the holes in the cellulose acetate spinning spinnerette are smaller (0.03–0.05 mm) than those in the corresponding viscose devices, great care must be taken with the final filtration. An additional filter for the removal of any small particles that may have passed through the large filters is placed in the fixture, sometimes called the "candle," to which the spinnerette assembly is fastened. A final filter is placed in the spinnerette-assembly unit over the top of the spinnerette itself.

The method used for spinning cellulose acetate is "dry" spinning. The dope is heated (in some cases above the boiling point of acetone, 56.5°C) to lower its viscosity and thus reduce the pressure required to extrude it and to supply

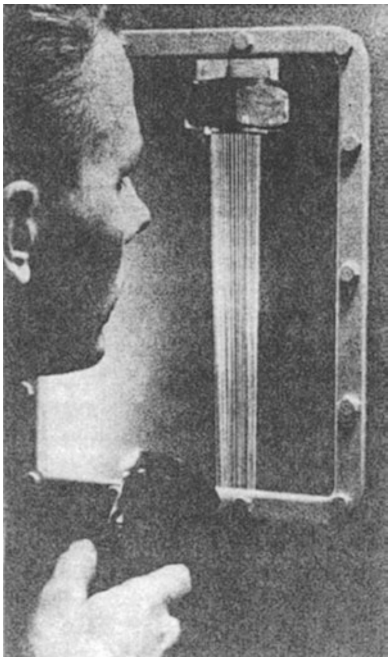

Fig. 12.12 Dry spinning of cellulose acetate (Courtesy of Tennessee Eastman Co.)

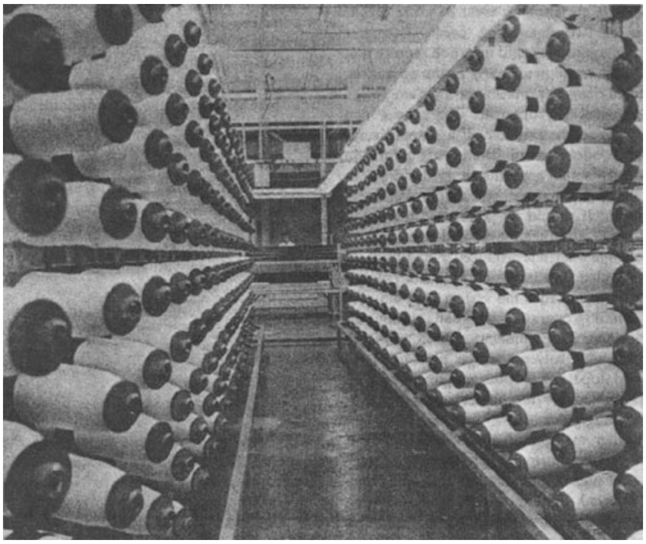

Fig. 12.13 Beaming cellulose acetate yarn from a reel holding about 800 packages of yarn (Courtesy of Tennessee Eastman Co.)

some of the heat needed for evaporating the acetone solvent (see Fig. 12.12).

The spinnerette is stainless steel, and because the filaments must be heated and prevented from sticking together and because space must be allowed for the escape of acetone vapor, the holes must be kept farther apart than those of the spinnerettes used for wet spinning. As the hot solution of cellulose acetate in acetone emerges downward into the spinning cabinet, an instantaneous loss of acetone takes place from the surface of the filaments, which tend to form a solid skin over the still liquid or plastic interior. A current of air, either in the direction the filaments are moving or countercurrent, heats the filaments, and as the acetone is diffused from the center through the more solid skin, each filament collapses to form the indented cross-sectional shape typical of cellulose acetate. The heated air removes the vaporized acetone. Each manufacturer uses a preferred updraft, downdraft, or mixed-draft operation, as needs dictate.

The cabinet through which the yarn passes vertically downward must be long enough to allow sufficient acetone to diffuse outward and evaporate from the surfaces of the filaments so that the latter will not stick to the first surface contacted or fuse to each other. The temperature of the air in the cabinet, the rate of flow, the length of the cabinet, the size and number of filaments, and the rate of travel are all interrelated in the spinning process. Because it is desirable to increase spinning speeds to the limit of the equipment, the tendency has been to construct longer spinning cabinets as each new plant is built. Present spinning speeds are of the order of 600 or more meters per minute, measured as the yarn emerges from the cabinet.

Other dry-spinning operations have followed essentially the same pattern. For example, the dry spinning of cellulose triacetate was identical to that for secondary acetate except that the acetone solvent had been replaced by a chlorinated hydrocarbon such as methylene chloride, the solubility of which was improved by the addition of a small amount of methanol (5–15%).

The acetate yarn emerging from the cabinet makes contact with an applicator that provides the lubricant required to reduce both friction and static formation in subsequent operations. With its surface lubricated, the yarn passes around a “feed” roll that determines the rate of withdrawal from the spinning cabinet and then to any of several desired packaging devices.

Unlike the packaging of rayon yarn, cellulose acetates are either “ring”-spun or wound into a package called a “disc,” “zero twist,” or “cam wound.” In the ring-spun package, the yarn carries a slight twist of less than one turn per inch, but it requires a relatively expensive bobbin. Since the trend is toward less twisting, such acetate yarn is “beamed” in the producer’s plant after little or no twisting, the heavy beams being shipped directly to knitters or weavers (see Fig. 12.13).

Filament yarns are twisted for two reasons. One is to supply certain esthetic characteristics such as touch, drapability, and elasticity. The other more fundamental reason is to provide physical integrity to the filament bundle so that it can be warped, woven, and knitted without excessive breakage or fraying of individual filaments.

The yarn just mentioned as having no twist imparted before beaming may have been subjected to intermingling just prior to windup after extrusion. In the intermingling process, yarn with no twist, and usually under low tension, is passed through a zone where it is impinged upon by a jet stream of compressed air. This causes the filaments to interlace or intermingle with each other, and they can become metastable in this configuration when tension is reapplied. In this condition, the yarn has the integrity of twisted yarn and will pass through several textile processing steps without difficulty, but with each handling, some of the intermingling is worked out.

Solvent Recovery. The air containing the acetone vapor is drawn out of the spinning cabinet and passed through beds of activated carbon that sorb the organic solvent. The acetone is recovered by steaming and then by separating it from the water by distillation. The efficiency of recovery is about 95%.

Dope Dying. As with viscose rayon, colored pigments or dyestuffs may be added to the spinning solution so that the yarn will be colored as it is produced, thus eliminating the need for dyeing the final fabric. As mentioned earlier, even in using titanium dioxide, a compromise must be made on the basis of two competing needs. Complete mixing, uniformity, and filtration require that the addition be made early in the operation; minimal cleaning problems during changeovers require just the opposite. There exist two solutions to the problem. If a manufacturer must produce a multitude of colors in relatively small amounts, it is desirable to premix individual batches of spinning dope. Each batch should be pretested on a small scale to ensure that the desired color will be acceptable when it is produced. Facilities must be provided to allow each batch of colored dope to be cut into the system very close to the spinning operation in order to minimize pipe cleaning. Permanent piping must be flushed with solvent or the new batch of colored dope; some of the equipment may be disassembled for mechanical cleaning after each change of color.

Another method of producing spun-dyed yarn involves using a group of "master" dopes of such color versatility that when they are injected by appropriate proportioning pumps into a mixer located near the spinning operation, they will produce the final desired color. The advantages of such an operation are obvious; the disadvantage lies in the public demand for an infinite number of colors. No small group of known pigments will produce final colors of every desired shade.

Protein Fibers

As previously mentioned, the use of naturally existing polymers to produce fibers has had a long history. In the case of cellulose, the results were fabulous. An initial investment of $930,000 produced net profits of $354,000,000 in 24 years for one rayon company [7]. On the other hand, efforts to use another family of natural polymers—proteins—have thus far resulted in failure or at best very limited production.

These regenerated proteins are obtained from milk (casein), soya beans, corn, and peanuts. More or less complex chemical separation and purification processes are required to isolate them from the parent materials. They may be dissolved in aqueous solutions of caustic, and wet-spun to form fibers, which usually require further chemical treatment as, for example, with formaldehyde. This reduces the tendency to swell or dissolve in subsequent wet-processing operations or final end uses. These fibers are characterized by a woollike feel, low strength, and ease of dyeing. Nevertheless, for economic and other reasons, they have not been able to compete successfully with either wool (after which they were modeled) or with other manufactured fibers.

Nylon

Historical

Nylon was the first direct product of the technological breakthrough achieved by W. H. Carothers of E. I. du Pont de Nemours and Co. Until he began his classic research on high polymers, the production of manufactured fibers was based almost completely on natural linear polymers. Such materials included rayon, cellulose acetate, and the proteins. His research showed that chemicals of low molecular weight could be reacted to form polymers of high molecular weight. By selecting reactants that produce linear molecules having great length in comparison with their cross section, fiber-forming polymers are obtained. With this discovery, the manufactured fiber industry entered a new and dramatic era.

Manufacture

Nylon 66. The word "nylon" was established as a generic name for polyamides, one class of the new high-molecular-weight linear polymers. The first of these, and the one still produced in the largest volume, was nylon 66 or polyhexamethylene adipamide. Numbers are used following the word "nylon" to indicate the number of carbon atoms contributed by the diamine and dicarboxylic acid constituents, in this case hexamethylenediamine and adipic acid, respectively.

To emphasize the fact that it does not depend on a naturally occurring polymer as a source of raw material, nylon often has been called a "truly synthetic fiber." To start the synthesis, benzene may be hydrogenated to cyclohexane

$$C_6H_6 + 3H_2 \xrightarrow{\text{Catalyst}} C_6H_{12}$$

or the cyclohexane may be obtained by fractionation of petroleum. The next step is oxidation to a cyclohexanol–cyclohexanone mixture by means of air:

$$xC_6H_{12} + O_2(\text{air}) \xrightarrow{\text{Catalyst}} yC_6H_{11}OH + zC_6H_{10}O$$

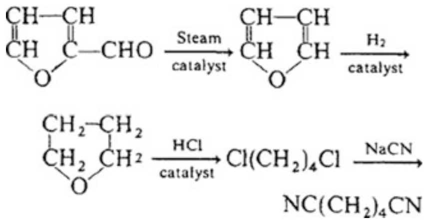
In turn, this mixture is oxidized by nitric acid to adipic acid:

$$C_6H_{11}OH + C_6H_{10}O + HNO_3 \xrightarrow{\text{Catalyst}} (CH_2)_4(COOH)_2$$

Adipic acid so obtained is both a reactant for the production of nylon and the raw material source for hexamethylenediamine, the other reactant. The adipic acid first is converted to adiponitrile by ammonolysis and then to hexamethylenediamine by hydrogenation:

$$(CH_2)_4(COOH)_2 + 2NH_3 \xrightarrow{\text{Catalyst}} (CH_2)_4(CN)_2 + 4H_2O$$
$$(CH_2)_4(CN)_2 + 4H_2 \xrightarrow{\text{Catalyst}} (CH_2)_6(NH_2)_2$$

Another approach is through the series of compounds furfural, furane, cyclotetramethylene oxide, 1,4-dichlorobutane, and adiponitrile, as illustrated below. The furfural is obtained from oat hulls and corn cobs.



Or 1,4-butadiene obtained from petroleum may be used as a starting raw material to make the adiponitrile via 1, 4-dichloro-2-butene and 1,4-dicyano-2-butene:

$$CH_2{=}CHCH{=}CH_2 \rightarrow ClCH_2CH{=}CHCH_2Cl$$
$$\xrightarrow[\text{Catalyst}]{HCN} NCCH_2CH{=}CHCH_2CN$$
$$\xrightarrow[\text{Catalyst}]{H_2} NC(CH_2)_4CN$$

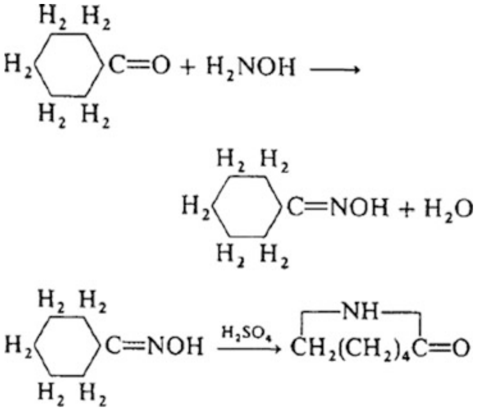
When hexamethylenediamine and adipic acid are mixed in solution in a one-to-one molar ratio, the "nylon salt" hexamethylenediammoniumadipate, the direct progenitor of the polymer, is precipitated. After purification, this nylon salt is polymerized to obtain a material of the desired molecular weight. It is heated to about 280°C under vacuum while being stirred in an autoclave for 2–3 h; a shorter holding period follows; and the process is finished off at 300°C. The molecular weight must be raised to a level high enough to provide a fiber-forming material, yet no higher. If it is too high, the corresponding viscosity in the subsequent spinning operation will require extremely high temperatures and pressure to make it flow. Accordingly, a small amount of acetic acid is added to terminate the growth of the long-chain molecules by reaction with the end amino groups.

The polymerized product is an extremely insoluble material and must be melt-spun, as discussed later. Therefore, should a delustered or precolored fiber be desired, it is necessary to add the titanium dioxide or colored pigment to the polymerization batch prior to solidification. For ease of handling, the batch of nylon polymer may be extruded from the autoclave to form a thin ribbon, which is easily broken down into chips after rapid cooling. But, whenever possible, the liquid polymer is pumped directly to the fiber melt-spinning operation (see Fig. 12.14).

Nylon 6. Nylon 6 is made from caprolactam and is known as Perlon® in Germany, where it was originally developed by Dr. Paul Schlack [8]. Its production has reached a very large volume in the United States in recent years.

Like nylon 66, nylon 6 uses benzene as raw material, which is converted through previously mentioned steps to cyclohexanone.

This compound is in turn converted to the corresponding oxime by reaction with hydroxylamine, and cyclohexanone oxime is made into caprolactam by the Beckmann rearrangement.



After purification, the lactam is polymerized by heating at elevated temperatures in an inert atmosphere. During self-condensation, the ring structure of the lactam is opened so that the monomer acts as an epsilon aminocaproic acid radical. Unlike that of nylon 66, the polymerization of caprolactam is reversible; the polymer remains in equilibrium

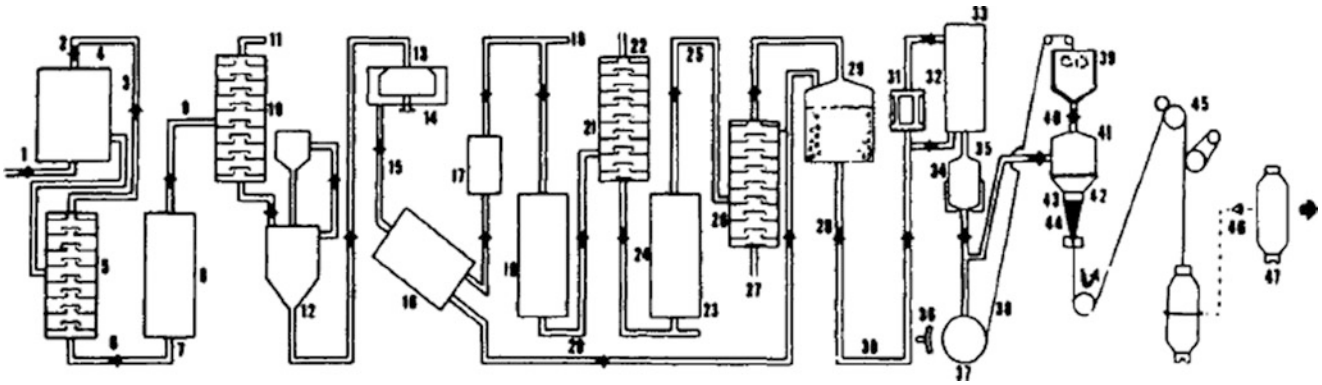


Fig. 12.14 Flow diagram for the manufacture of nylon 66 yarn: (1) air, (2) cyclohexane from petroleum, (3) reactor, (4) recycle cyclohexane, (5) still, (6) cyclohexanol–cyclohexanone, (7) nitric acid, (8) converter, (9) adipic acid solution, (10) still, (11) impurities, (12) crystallizer, (13) centrifuge, (14) impurities, (15) adipic acid crystals, (16) dryer, (17) vaporizer, (18) ammonia, (19) converter, (20) crude adiponitrile, (21) still, (22) impurities, (23) hydrogen, (24) converter, (25) crude diamine, (26) still, (27) impurities, (28) nylon salt solution, (29) reactor, (30) stabilizer, (31) calandria, (32) evaporator, (33) excess water, (34) autoclave, (35) delustrant, (36) water sprays, (37) casting wheel, (38) polymer ribbon, (39) grinder, (40) polymer flake, (41) spinning machine, (42) heating cells, (43) spinnerette, (44) air, (45) draw twisting, (46) inspection, (47) nylon bobbin (*Note*: Whenever the demand for liquid polymer at a spinnerette is large, as, for example, in the spinning of tire yarn, it is pumped directly from the autoclave)

with a small amount of monomer. As with nylon 66, nylon 6 is extruded in thin strands, quenched, and cut into chips for subsequent spinning, or the molten polymer is pumped directly to the spinning equipment.

Melt Spinning

Because of its extremely low solubility in low-boiling and inexpensive organic solvents, nylon 66 required a new technique for converting the solid polymer into fibers, hence the development of "melt" spinning, the third basic method for producing manufactured fibers. The following description refers essentially to nylon 66 because it was the first to use the method, but the process applies, in general, to all melt-spun manufactured fibers.

In the original production of nylon fiber by melt spinning, the chips of predried polymer were fed from a chamber onto a melting grid whose holes were so small that only passage of molten polymer was possible. Both solid and liquid were prevented from contacting oxygen by maintaining an inert nitrogen atmosphere over the polymer supply. The polymer melted in contact with the hot grid and dripped into a pool where it became the supply for the spinning itself. This melting operation has been entirely replaced by delivery of the molten polymer pumped directly from the polymerization stage or by "screw" melting. In the latter process, the solid polymer in chip form is fed into an extrusion-type screw contained in a heated tube. The depth and the helix angle of the grooves are engineered in such a way that melting takes place in the rear section, and the molten polymer is moved forward under increasing pressure to a uniformly heated chamber preceding the metering pump.

Whatever means is used to secure the molten polymer, it is moved forward to a gear-type pump that provides both high pressure and a constant rate of flow to the final filter and spinnerette. The filter consists of either sintered metal candle filters, several metal screens of increasing fineness, or graded sand arranged in such a way that the finest sand is at the bottom. After being filtered, the molten polymer at a pressure of several thousand pounds per square inch is extruded through the small capillaries in the heavily constructed spinnerette. It is necessary to maintain the temperature of the pool, pump, filter, spinnerette assembly, and spinnerette at about 20–30°C above the melting point of the nylon, which is about 264°C for nylon 66 and 220°C for nylon 6. Fibers having desired cross-sectional shapes can be produced by selecting spinnerettes containing holes of appropriate configuration. An example of a trilobal spinnerette capillary and the shape of the resulting trilobal fiber is given in Fig. 12.15.

The nylon production process requires that the extruded fibers emerge from the spinnerette face into a quench chamber where a crosscurrent of relatively cool quench air is provided to promote rapid solidification. The solid filaments then travel down a chimney to cool further, and a lubricant is applied before they make contact with the windup rolls in order to prevent static formation and to reduce friction in subsequent textile operations. The freshly spun yarn from the spinning chamber is taken up by a traversing winder onto a yarn package and "drawn" in a separate operation. In modern high-speed processes, drawing still is required, but in many cases, this is combined with spinning in a single operation, as will be described in what follows.

Drawing

It was learned early that the "as-spun" fibers made from nylon 66 could be extended to about four times their original length with very little effort, but that thereafter a marked resistance to extension took place. It was discovered that during this high extension, the entire length of fiber under stress did not extend uniformly. Rather, a "necking down" occurred at one or more points, and when the entire length under tension had passed through this phenomenon, a high-strength fiber was obtained. It also was found that when more than one necking down was allowed to take place in a given length of fiber, a discontinuity occurred at the point where the two came together. Accordingly, the drawing operation was aimed at forcing the drawing to occur at a single point as the yarn advanced from the supply to the take-up package.

Where still used, cold drawing consists essentially of removing the yarn from the package prepared in the melt-spinning operation and feeding it forward at a uniformly controlled rate under low tension. It is passed around a godet or roller that determines the supply rate and prevents slippage; for nylon 66, it then is wrapped several times around a stationary snubbing pin. From there, it goes to a second roller that rotates faster than the supply roller to produce the desired amount of stretch, usually about 400%. The necking down occurs at the pin. In the case of nylon 6, drawing may be effected satisfactorily without passing the yarn around such a snubbing pin.

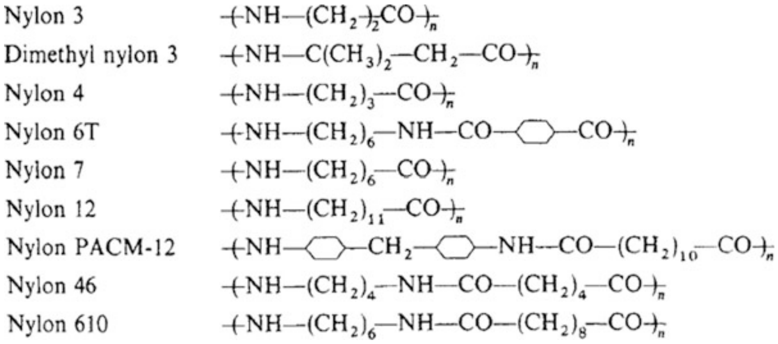
The long molecules of the nylon 66 or 6 polymer, which are randomly positioned in the molten polymer, when extruded from the spinnerette tend to form "crystalline" areas of molecular dimensions as the polymers solidify in the form of freshly spun fibers. In the drawing operation, both these more ordered portions and the amorphous areas tend to become oriented so that the lengthwise dimensions of the molecules become parallel to the long axis of the fiber, and additional intermolecular hydrogen bonding is facilitated. It is this orientation that converts the fiber having low resistance to stress into one of high strength.

By controlling the amount of drawing as well as the conditions under which this operation takes place, it is possible to vary the amount of orientation and the degree of crystallization. A minimal amount is preferable in the manufacture of yarns intended for textile applications wherein elongation of considerable magnitude and low modulus or stiffness are required rather than high strength. On the other hand, high strength and modulus are at a premium when fibers are to be used in tire cords and other industrial applications. High resistance to elongation is imperative if the tire is not to grow under conditions of use. In this connection, it should be noted that nylon tire cord that has been produced by twisting the original tire yarn and plying the ends of these twisted yarns together is hot stretched just before use at the tire plant to increase strength and reduce even further the tendency to elongate under tension.

The separate operations of spinning and drawing nylon presented a challenge whose object was combination of the two operations into a single continuous step. But the problem was obvious, for the operating speeds of the two separate steps already had been pushed as high as was thought to be possible. How then would it be possible to combine them into a continuous spin draw, wherein a stretching of about 400% could take place? The answer lay in the manner in which the cooling air was used and in the development of improved high-speed winding devices. By first cooling the emerging fibers by a concurrent flow of air and then cooling them further by a countercurrent flow, the vertical length of the cooling columns can be kept within reason. In-line drawing may occur in one or two stages, and relaxation may be induced if needed. The final yarn is said to be packaged at speeds of 6,000 m/min.

Other Nylons, Modifications, and New Developments

Although nylon 66 and 6 account for most of the polyamide fibers produced, a great many others have been experimentally synthesized and have been developed and manufactured in commercial amounts. Of these, some have been made into fibers, some with limited economic success. These nylons are identified by either the same numbering system used for nylon 66 or 6 or by a combination of numbers and letters, as follows:



Dimethyl nylon 3 is solution-spun because it tends to decompose during melt spinning. Nylon 4 has a moisture regain (mass water per unit mass of dry fiber, under standard atmospheric conditions of 20°C and 65% RH) of 6–9% and therefore is superior to other nylons for textile usages, being comparable to cotton [9]. Nylon 11 was developed in France and has been trademarked as Rilsan®. It has a moisture regain of 1.8% and density of 1.04 g/cc as compared with 4% and 1.14 g/cc, respectively, for nylon 66. Nylon 7 is made in the former Soviet Union and marketed under the name Enant. The fiber has better stability to heat and ultraviolet light than nylon 66 and 6. Nylon 6T, an aromatic polymer, has a much higher melting point (370°C), a higher density (1.21 g/cc), and slightly higher moisture regain (4.5%) than nylon 66. It also has superior resistance than nylon 66 against heat. This fiber has served as a precursor to the development of aramid fibers. Nylon PACM-12, formerly produced under the trade name Qiana® in the United States, is no longer in production.

A *chemical and engineering news* report [10] suggested that the most serious competition to nylon 66 and 6 will be provided by a new, still experimental fiber, nylon 46, which was being developed by DSM in the Netherlands, trade-named Stanyl®; this fiber results from the interaction of 1,4-diaminobutane and adipic acid. Better order in the structure in the fiber leads to greater crystallinity and, thus, to greater density (1.18 g/cc). The fiber has a melting point of about 300°C, a breaking stress or tenacity of 9.5 g force/denier (~1 GPa), modulus at 120°C of 20 g force/denier (2.1 GPa), and shrinkage in gas at 160°C of 3%.

Some of the outstanding characteristics of nylon that are responsible for its many uses in apparel, home furnishing, and industrial products are its high strength and toughness, elastic recovery, resilience, abrasion resistance, and low density. Among many applications of the fiber are such products as intimate apparel and foundation garments, sportswear, carpets, parachutes, tents, sleeping bags, and tire cords.

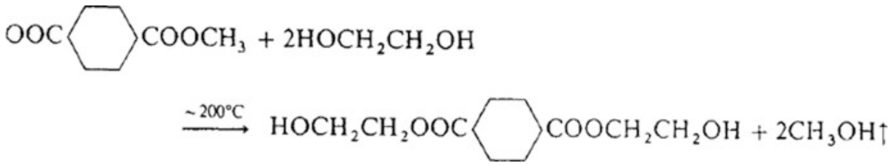
The world production of nylon has doubled in recent years, increasing from 3.8 billion lb in 1970 to about 7.5 billion lb in 1990. The fiber accounts for about 24% of the synthetic fibers produced worldwide. In the United States, the production of the fiber also doubled in two decades, increasing from 1.2 billion lb in 1970 to about 2.4 billion lb in 1990.

The newest activity connected with nylon is the effort at developing a more highly oriented stronger nylon than possible by the current technology. Because of the formation of hydrogen bonds between the chains, the normal polymer is restricted in terms of the maximum draw ratio by which it can be oriented. In the new technique [11], nylon 66 is dissolved in an agent such as gallium trichloride, which effectively breaks the hydrogen bonds. The solution is spun by the dry jet–wet spinning method. The $GaCl_3$/nylon 66 complex so obtained can now be stretched to very high draw ratios, levels as high as 40× have been possible. Once drawn, the structure is soaked in water to remove gallium trichloride, which allows the hydrogen bonds to reestablish and link the chains. In preliminary work done thus far, the strength and the modulus obtained exceed the values usually found in nylon 66.

Polyesters

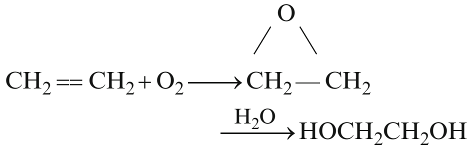
Historical

The stimulus for the development of polyester, as for nylon, was provided by the fundamental work of Carothers. Although his team's initial work was directed toward this material, because of greater promise shown by polyamides at the time, the developmental work on polyesters was temporarily set aside. The polymer, however, attracted interest in Great Britain, where J. T. Dickson and J. R. Whinfield experimented with it and developed a successful polyester fiber [7]. They found that a synthetic linear polymer could be produced by condensing ethylene glycol with terephthalic acid or by an ester exchange between the glycol and pure dimethyl terephthalate. The polymer thus obtained could be converted to fibers having valuable properties, including the absence of color. Like nylon, this material has been popularized under its generic name, polyester or just "poly." Those persons working with it commonly refer to it as polyethylene terephthalate (PET). It first appeared under the trade name Terylene® (Imperial Chemical Industries, Ltd.), in England, and was first commercialized in the United States in 1953 as Dacron® (E. I. du Pont de Nemours and Co.).



Manufacture

When the development of PET occurred, ethylene glycol already was being produced in large amounts from ethylene, a by-product of petroleum cracking, by the oxidation of ethylene to ethylene oxide and subsequent hydration to ethylene glycol, which, in a noncatalytic process, uses high pressure and temperature in the presence of excess water.



$$\mathrm{CH_2{=}CH_2 + O_2 \longrightarrow \overset{O}{CH_2{-}CH_2} \xrightarrow{H_2O} HOCH_2CH_2OH}$$

On the other hand, although *o*-phthalic acid, or rather its anhydride, had long been produced in enormous amounts for use in the manufacture of alkyd resins, the *para* derivative was less well known and not available on a large scale. The synthesis is a straightforward one, however, from *p*-xylene, which is oxidized to terephthalic acid, either by means of nitric acid in the older process or by air (catalyzed) in the newer one. In the early years, this compound then was converted to the easily purified dimethyl ester in order to obtain a colorless polymer adequate for the manufacture of commercially acceptable fibers.

Several other methods were developed for producing the desired dimethyl terephthalate. The Witten (Hercules) process goes from *p*-xylene to toluic acid by oxidation of one of the methyl groups on the ring, following which the carboxyl group is esterified with methanol. This process then is repeated with the second methyl group to secure the dimethyl ester of terephthalic acid.

Either phthalic anhydride or toluene, both in ample supply as raw materials, can be used in the Henkel processes. Use of phthalic anhydride depends only upon dry isomerization of the potassium salt of the *ortho* derivative to the *para* form at about 430°C and 20 atmospheric pressure, or toluene is oxidized to benzoic acid, whose potassium salt can be converted to benzene and the potassium salt of terephthalic acid by disproportionation.

The first step in the reaction of dimethyl terephthalate and ethylene glycol is *trans*esterification to form bis (*p*-hydroxyethyl) terephthalate (bis-HET) and eliminate methanol. This product then is polymerized in the presence of a catalyst to a low-molecular-weight compound, and the by-product glycol is eliminated. In a second stage, at a temperature of about 275°C and under a high vacuum, the molecular weight is raised to secure the melt viscosity desired for the particular material involved. Like nylon, this final material may be extruded, cooled, and cut into chips for storage and remelting, or it may be pumped directly to the spinning machines.
