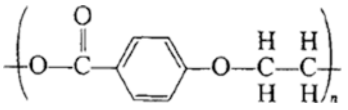
From the beginning, it was obvious that there would be considerable progress in industrial chemistry, to say nothing of cost reduction, if the process could be simplified by making it unnecessary to go through the dimethyl derivative to secure a product of adequate purity. This was accomplished in the early 1960s when methods of purifying the crude terephthalic acid were developed, and conditions and catalysts were found that made possible the continuous production of a color-free polymer. It is said that the selection of the catalyst is especially aimed at the prevention of ether linkages in the polymer chain due to intracondensation of the glycol end groups.

Two additional rather similar routes are known. Both depend upon the reaction between ethylene oxide, rather than ethylene glycol, and terephthalic acid to form the bis-HET monomer already mentioned. The difference between the two methods lies in the point where purification is done: in one case, it is the crude terephthalic acid; in the other, it is the bis-HET monomer. In both cases, this monomer is polymerized by known procedures to form a fiber-grade polyester. The titanium dioxide delustrant is added, as might be expected, early in the polymerizing process.

Another polyester that has reached long-term commercialization is now produced in limited volume as Kodel 200® by Tennessee Eastman Co. and is considered to be 1–4 cyclohexylene dimethylene terephthalate. The glycol that is used instead of ethylene glycol in this process exists in two isomeric forms, one melting at 43°C and the other at 67°C. This makes possible their separation by crystallization, to secure the desired ratio of the two forms for conversion to the polymer. This ratio determines the melting point of the polymer, a most important property for a material that is to be melt-spun. The polymer from the 100% *cis* form melts at 275°C and that from the 100% *trans* form at 318°C. Indications are that the commercial product is about 30/70 *cis–trans*.

In 1973, the Federal Trade Commission modified the generic definition of polyester to include in the polyester category materials that previously were polyester ethers or benzoate polyesters. As a result, the fiber known as poly (ethylene oxybenzoate) or PEB and manufactured under the trade name A-Tell in Japan came to be known as polyester. This material is made by reacting parahydroxybenzoic acid and ethylene oxide to give paraoxyethylenebenzoic acid, which is then polymerized to obtain PEB:



The fiber softens at about 200°C and melts at 225°C. It is said to have a silklike hand and appearance and other properties comparable to those of other polyesters.

Polyesters are melt-spun in equipment essentially the same as that used for nylon, already described. Wherever the volume is large and the stability of demand is adequate, the molten polymer is pumped directly from the final polymerization stage to the melt-spinning machine. The molten polymer is both metered and moved forward at high pressure by the use of an extruder coupled with a gear-type pump, through filters to the spinnerette, which contains capillaries of about 9 mil (230 μm) in diameter. Great care is taken to eliminate moisture and oxygen from the chips, if they are used, and from the spinning chamber. When the polyester fibers are destined to become staple, the emerging filaments from a number of spinnerettes are combined to form a tow, which can be further processed as a unit. Continuous-filament yarn is packaged for further processing such as drawing or texturing. Spin drawing, described later, has become commonplace today and represents major cost savings to the fiber manufacturer.

Drawing

Unlike nylon, which in the as-spun state contains a high amount of crystalline component, PET fibers are essentially amorphous as spun. In order to secure a usable textile yarn or staple fiber, this product must be drawn under conditions that will result in an increase in both molecular orientation and crystallinity. This is done by drawing at a temperature well above the glass transition point, T_g, which is about 80°C. Conditions of rate and temperature must be selected so that the amorphous areas are oriented, and crystallization will take place as the temperature of the drawn fibers drops to room temperature.

An appropriate contact-type hot plate or other device is used, and about 300–400% extension is effected [10]. Figure 12.16 shows a filament withdrawn and undrawn segments. As with nylon, the conditions of draw, especially the amount, determine the force–elongation properties of the

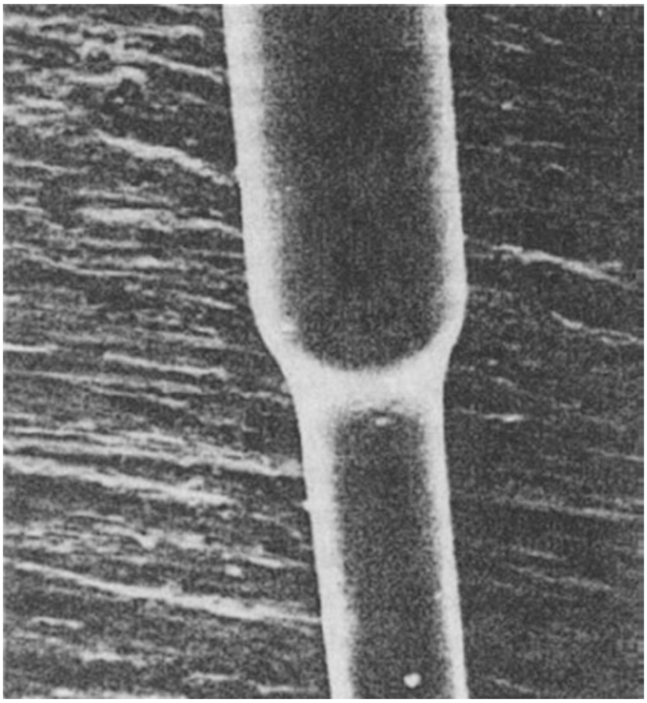


Fig. 12.16 Drawnecking in polyester single filament (Courtesy of E. I. du Pont de Nemours and Co.)

product. Industrial-type yarns, such as those intended to be used as tire cord, are more highly drawn than other yarns and have higher strength with less elongation. The fibers develop the much desired fibrillar morphology for such applications (Fig. 12.17).

Heat Setting

The ability of textile fibers to be "set" is not characteristic of manufactured fibers alone. Aided in many cases by the presence of starch, cotton fabrics can be ironed to a smooth and wrinkle-free condition; also, a sharp crease in wool trousers has been commonplace for generations. In other words, these fabrics were exposed to moisture at elevated temperatures while being held or pressed into desired geometrical configurations and then allowed to cool before being released from constraint. Such fabrics tend to remain unchanged while cool and dry, even though the fibers from which they are formed carry internal stresses, but reversion takes place upon washing or exposure to high relative humidity.

With the development of nylon, and especially polyesters, a durable kind of setting has become possible. When fabrics made from these fibers are shaped and then exposed to elevated temperatures either in the dry condition or, in the case of nylon particularly, in the presence of water vapor, thermoplastic relaxation of induced stresses in the fiber takes place and configurations at the molecular level adjust to a new and lower energy level. This depends on not only the temperature used but also the duration of the exposure. Thus a few seconds at 230°C will produce the same results as exposure for a considerably longer period at a temperature 50–75 ºC lower. The permanency of the setting, that is, the ability of a fabric or garment to return to its original configuration after temporary distortion even while exposed to moisture and raised temperatures, is a function of the severity of the heat setting. To impart true permanence, it is essential that the internal crystalline structure be annealed.

It is this property of polyamides and polyesters that has been the main factor contributing to "ease-of-care" and the "wash-and-wear" characteristics of garments made from these polymers. In turn, these garments have revolutionized both the textile and the apparel industries.

Textured Yarns

Fundamentally, the manufacture of "textured" yarns is closely related to the heat setting of fabrics, which must be composed of thermoplastic fibers such as nylon or polyester, the difference being that the individual filaments or bundle of filaments in textured yarns are distorted from an essentially straight rodlike form and then heat-set. In some instances, the fibers are distorted in a more or less random way; at other times, a regular pattern is introduced.

The first commercially successful textured yarn was produced by highly twisting nylon 66, heat-setting it as a full package of yarn, and then untwisting it through zero and a small amount of twist in the opposite direction. This process changed yarn from a close-packed structure to one that was voluminous because of mutual interference of distorted filaments. The technique of heat-setting the twisted yarn as a batch-unit operation now has been replaced by a continuous operation, using what is known as a "false-twisting" process. This is based upon the principle that if a length of yarn is prevented from rotating at both ends but is rotated on its axis at its center point, the resulting two sections will contain both "Z" and "S" twists in equal amounts. When this occurs with a moving yarn, any element in it will first receive a twist in one direction but, after passing the false-twisting point, must revert to zero twist. If it is then made to pass over a hot plate while in the twisted state and is heat-set in that configuration, even after returning to the untwisted condition, the individual filaments will tend to remain distorted when lengthwise stress is released. Because of the low mass and diameters of textile yarns or monofilaments, it is possible to false twist them at extremely high rotational speeds. Yarn forward speeds of about 1,000 m/min are currently obtainable by passing the yarn between, and in contact with, high-speed-friction twisting discs. (When attempts are made to secure higher rates, problems of twist control develop.) The same technique is now more commonly applied to unoriented (undrawn) or partially oriented yarn (POY) at the draw-texturing machine. The resulting yarn may be heat-set as part of the same continuous operation by passing it through a second heater under conditions of overfeed or little or no tension in order to secure both thermally stable geometric configurations in the individual distorted filaments that comprise the yarn and the degree of "stretchiness" and bulk desired in the final product.

Because these yarns are being made in one less step and also within the plants spinning the parent product, this latest development may be said to constitute another advance in the industrial chemical technology of manufactured textile products. This draw texturing appears to be especially applicable to polyester yarns intended for fabrics known as "double knits" and "textured wovens."

Yarn can be forced forward by means of "nip" rolls, although this may seem to be quite contrary to the old adage that one cannot push on an end of string. When this is done so that the yarn is jammed into a receiver (stuffer box) already full of the preceding materials, it collapses with sharp bends between very short lengths of straight sections. In this condition, heat is applied, usually in the form of superheated steam, to set it. In practice, the mass of such yarn is pushed through a heated tube until it escapes at the exit past a spring-loaded gate. During this passage, it is heat-set in a highly crimped configuration; then it is cooled before being straightened and wound onto a package. In another continuous process, the yarn or monofilament is pulled under tension over a hot sharp edge so that it is bent beyond its elastic limit and is heat-set in that condition. The process is known as "edge crimping," and the result is not unlike that produced by drawing a human hair over the thumbnail. The process is not used much today, but a yarn with similar crimp is produced by bicomponent spinning.

When such yarns are knitted or woven into fabric, the filaments tend to return to the configurations in which they were originally heat-set. Contraction takes place in the direction of the yarn axis, and this in turn converts the smooth flat fabric into a "stretch" fabric and gives the surface a textured appearance. These fabrics or the garments made from them, whatever the process used to produce the yarns, may be given additional heat treatment to secure stability in a desired geometric configuration. A degree of stretch may be retained, or a flat and stable textured surface may be produced. There are a number of variations of the texturing process, which, combined with the many possibilities of heat setting, impart considerable versatility to the final product (see Fig. 12.18).

The growth in the use of these products in the 1960s is well known. Carpeting also provides a significant market for them, as texture is one of the most important characteristics of soft floor coverings. Such products have been important to the successful use and expanded development of nylon and polyester yarns.

Staple Process

Unlike nylon, which is used mostly in the form of continuous-filament yarn, polyester is utilized both in staple and in continuous-filament form in large volumes. For producing staple fiber, the spinning machines consist of a series of packs, 10–30, each with 1,000–3,000 holes. The extrudates from different packs after solidification and application of finish are combined to form a subtow and collected in a can. Then several such cans are brought together in a creel area, and subtows from these cans are combined to feed a staple drawline. The latter may involve one or more stages of drawing and relaxation, one or more stuffer-box-type crimpers, a drying unit, and a cutter. A baling unit following the cutter collects and bales the cut fiber.

Continuous-Filament Yarn Process Variants

For producing continuous-filament yarn, several process routes are available [12], each of which involves the basic processes of polymer synthesis, extrusion, quenching,

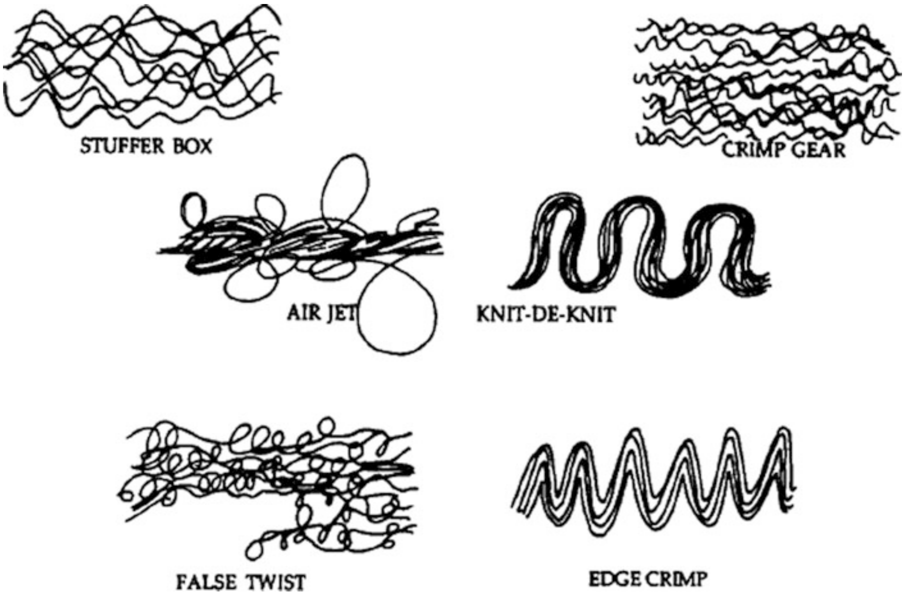

Fig. 12.18 Schematic comparison of the shapes of some textured yarns

stretching, and winding. In one process, specially meant for textile-type uses, spinnerettes with 20–100 holes typically are used. After solidification and finish application, the filaments may be split into smaller bundles, depending upon end-use applications, for downstream processing. The drawing can also be done in a single integrated process (spin draw) immediately after finish application to yield a fully oriented yarn (FOY), which, having no bulk or texture, is referred to as a flat yarn. Spinning speeds of the order of 1,000 m/min or more and winding speeds of about 4,000 m/min are used. Similar yarn may be produced on a separate drawing unit, but this process—called draw twisting because a certain amount of twist is also inserted prior to winding—is less commonly used today. It is more usual to see the separate drawing process done in conjunction with a texturing process—most commonly false twisting and called draw texturing—to give a textured yarn. The process leads to orientation and crystallization of the filament structure and bulking of the yarn. The feed yarn for such processes usually is produced at 3,000–4,000 m/min spinning speed as POY. The latter is designed to be run on draw-texturing machines at speeds ranging from 800 to 1,200 m/min.

For industrial applications, polyester filaments having high strength low shrinkage (HSLS), low creep properties, and high glass transition temperatures are targeted. To produce such a filament, more severe processing conditions and higher-molecular-weight polymer are generally used. The filament is spun at low speeds (500–1,000 m/min), sometimes with retarded quench, to obtain minimum orientation. The drawing can be achieved in the more common integrated, or spin draw, process or in a separate draw–twist operation. High strength is achieved by drawing the filament to several times its length over very high-temperature rolls and then heat-setting and relaxing the structure prior to winding. Low shrinkage properties are obtained with a relaxing step at high temperature.

Modifications and New Developments

As was the case with the nylon fibers, the potential the polyester fibers offered in apparel, home furnishing, and industrial applications was judged to be enormous. For this potential to be realized in practice, however, some characteristics had to be improved, and others had to be engineered for specific end uses. Thus, fibers of different cross-sectional shapes were developed in order to impart antisoiling, reflective, and resilient characteristics for rug and carpet applications. A difficulty associated with the early polyester fiber that restricted its applications was its lack of ability to take on dyes through one of many methods available for dyeing. This problem was overcome by introducing chemicals that added sulfonate groups to the molecule and by substituting in some cases isophthalic acid for a small portion of terephthalic acid. These changes allowed fibers to be dyed by cationic and disperse dyes, the dyes most frequently used for polyester. Another area of modification has been the development of inherently flame-resistant fiber. One process involves copolymerizing a derivative of phosphoric acid with PET. An exciting new development in polyester filament yarn for apparel uses is the production of microdenier fiber (denier per filament less than one), discussed later in a separate section. The introduction of finer denier yarns opened up a whole new field for developing fabrics with special esthetic and performance characteristics that were not possible earlier.

With the use of fibers in conveyor belts, tires, and composites, fibers of greater strength and modulus and lower extensibility have been needed. Much effort was directed in the 1970s and, later, to developing such fibers from polyester. The composition and the properties of wholly aromatic polyamides or aramids are discussed in a later section. When both the diacid and diamine components are *para*-substituted aromatic compounds, the resulting polymer is capable of forming lyotropic liquid–crystalline solutions. These solutions can be dry- or wet-spun into fibers with unusually high tensile strength and tensile modulus. When a similar strategy is tried to make polyester fiber from a homopolymer of a *para*-substituted aromatic diacid and a *para*-substituted aromatic diol, only infusible and intractable materials are obtained. A solution to this problem has been found in the development of polyester copolymers that give thermotropic liquid–crystalline melts over a useful temperature range and have viscosities suitable for melt extrusion into fibers or films having high levels of orientation. Spin-line stretch factors of the order of several hundred percent are used to achieve orientation, and physical properties are developed further by heat treatment at temperatures approaching melting conditions.

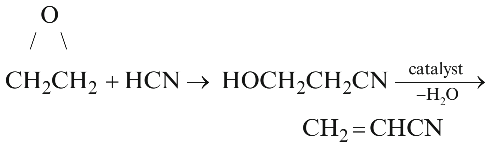
The first fibers from a thermotropic liquid–crystalline melt whose properties were reported were spun from a copolyester of *para*-hydroxybenzoic acid (PHB) and PET by workers at Tennessee Eastman Co. The preparation of the copolymer proceeds in two stages. First, *para*-acetoxybenzoic acid is reacted with PET in an acidolysis step to give a copolyester prepolymer, which in the second step is condensed further to a higher degree of polymerization suitable for fiber formation.

Among melt-spun fibers, those based on thermotropic liquid–crystalline melts have the highest strength and rigidity reported to date and appear comparable to polyamides spun from lyotropic liquid–crystalline solutions. This was a very active field of research in the 1970s, and later, and many comonomers have been reported. Obviously, these compositions must contain three components at a minimum, but many have four or five components. Some frequently used constituents, in addition to those mentioned above, are 2,6-naphthalenedicarboxylic acid, hydroquinone, 4,4′-biphenol, isophthalic acid, and 4,4′-dihydroxy-diphenyl ether.

Acrylics

Polymer Manufacture

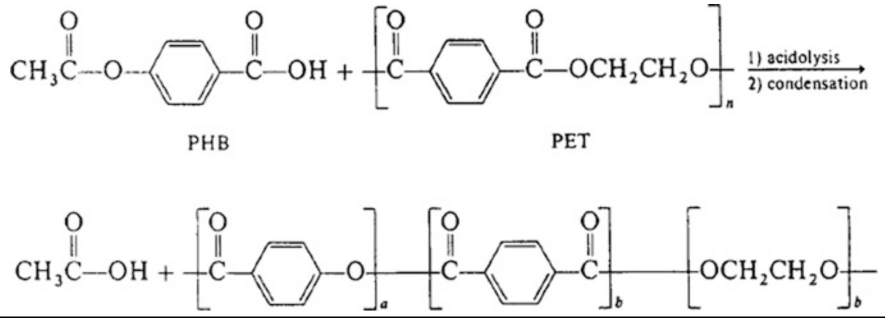
Acrylic fibers are spun from polymers that are made from monomers containing a minimum of 85% acrylonitrile. This compound may be made from hydrogen cyanide and ethylene oxide through the intermediate ethylene cyanohydrin.



$$\overset{\overset{\text{O}}{/\ \ \backslash}}{\text{CH}_2\text{CH}_2} + \text{HCN} \rightarrow \text{HOCH}_2\text{CH}_2\text{CN} \xrightarrow[-\text{H}_2\text{O}]{\text{catalyst}} \text{CH}_2{=}\text{CHCN}$$

It also may be made directly from acetylene and hydrogen cyanide:

$$\text{CH} \equiv \text{CH} + \text{HCN} \rightarrow \text{CH}_2 = \text{CHCN}$$



When the mol.% of PHB in the copolymer exceeds about 30–40%, a liquid–crystalline melt is obtained. Up to about 60 mol.%, order in the melt increases and melt viscosity decreases. Compositions containing about 60 mol.% PHB can be melt-spun into fibers using standard extrusion techniques. It is the unusual combination of properties that makes this class of materials valuable for the formation of high-strength fibers and plastics.

But the reaction that currently is preferred uses propylene, ammonia, and air:

$$\begin{aligned} &3\text{CH}_2 = \text{CHCH}_3 + 3\text{NH}_3 + 7\text{O}_2(\text{air}) \\ &\xrightarrow[<500\,^\circ\text{C}]{\text{Catalyst}} \text{CH}_2 = \text{CHCN} + 2\text{CO} + \text{CO}_2 \\ &\qquad + \text{CH}_3\text{CN} + \text{HCN} + 10\text{H}_2\text{O} \end{aligned}$$

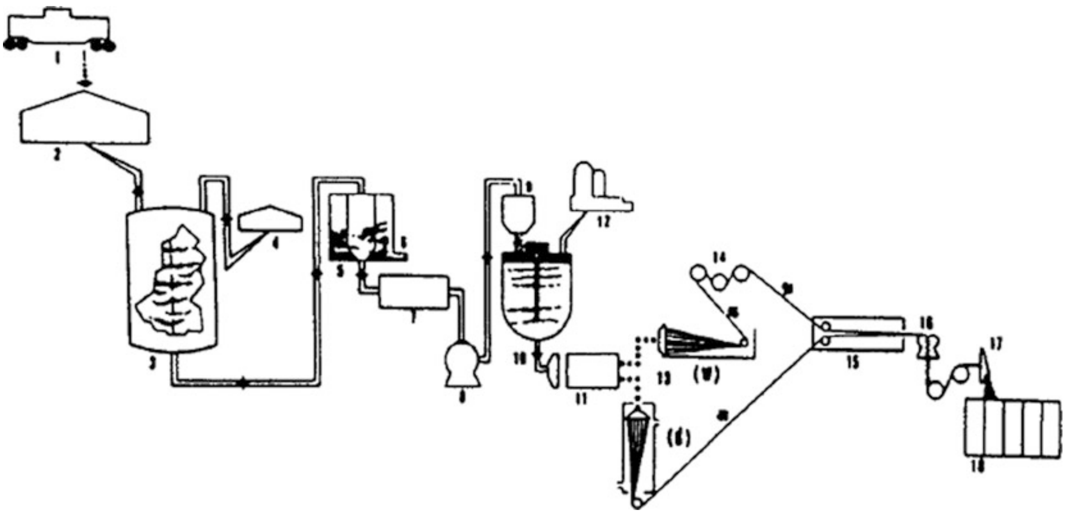


Fig. 12.19 Flow diagram for the manufacture of acrylic fiber: (1) acrylonitrile, (2) tank farm, (3) polymerizer, (4) comonomer and catalyst, (5) centrifuge, (6) waste liquid, (7) dried polymer, (8) grinding, (9) polymer storage, (10) dissolver, (11) filter, (12) solvent plant, (13) spinnerette, (13w) wet spinning, (13d) dry spinning, (14) roller dryer, (15) additional treatment, (16) crimper, (17) cutter, (18) acrylic fiber bale

Pure acrylonitrile may polymerize at room temperature to polyacrylonitrile (PAN), a compound that, unlike polyamides and polyesters, does not melt at elevated temperatures but only softens and finally discolors and decomposes. Nor is it soluble in inexpensive low-boiling organic solvents. Because fibers made from it resist the dyeing operations commonly used in the textile industry, the usual practice is to modify it by copolymerization with other monomers, for example, vinyl acetate, styrene, acrylic esters, acrylamide, or vinyl pyridine in amounts up to 15% of the total weight (beyond which the final product may not be termed an acrylic fiber). The choice of modifier depends on the characteristics that a given manufacturer considers important in a fiber, the availability and cost of the raw materials in the manufacturer's particular area of production, and the patent situation.

In copolymerizing acrylonitrile with another monomer, conditions must be controlled in such a way that the reaction produces a polymer having the desired chain structure and length. The reaction takes place in the presence of substances capable of producing free radicals. In addition, certain trace metals that have been found to increase reaction rates offer a means of controlling chain length. When polymerization is carried out in solution, after an induction period, the reaction is rapid and liberates a considerable amount of heat. Furthermore, because the polymer is not soluble in the monomer, a thick paste is formed. These facts limit the usefulness of such a process. Carrying out the polymerization in the presence of a large amount of water (water/monomer of 2/1 to 3/1) is a convenient method and the one most generally used. In this case, the polymer forms a slurry, and the water provides a means for removing the heat from the site of the reaction. Moreover, most of the common redox catalyst systems are water soluble. Polymerization may be carried out batchwise or by a continuous process.

In the batch method, the monomers and catalyst solutions are fed slowly into an agitated vessel containing a quantity of water. The heat of reaction is removed either by circulating cold water through the jacket surrounding the vessel or by operating the reaction mixture at reflux temperature and eliminating the heat through the condenser water. The monomer and catalyst feeds are stopped when the desired amounts have been added, and polymerization is allowed to continue until there is only a small amount of monomer remaining in the reaction mixture. Then the slurry is dumped from the reaction vessel, filtered, washed, and dried (see Fig. 12.19).

In the continuous overflow method, rather than stopping the monomer and catalyst feed when the reaction vessel is full, the slurry is simply allowed to overflow; the solids are removed by filtration, washed, and dried. The filtrate contains a certain amount of unreacted monomer, which is recovered by steam distillation after the trace metal present has been chelated to stop the redox reaction and thus further polymerization. The dried polymer is the raw material from which fibers are spun.

As mentioned, PAN polymer has two major weaknesses: (1) extremely poor dyeing characteristics due to highly ordered structure and (2) very low solubility in most of the solvents. To overcome these problems, comonomers are incorporated into the chains. Comonomers have been used to improve hydrophilicity, dyeability, flame retardancy, heat resistance, and so on. For obtaining hydrophilic acrylic fiber,

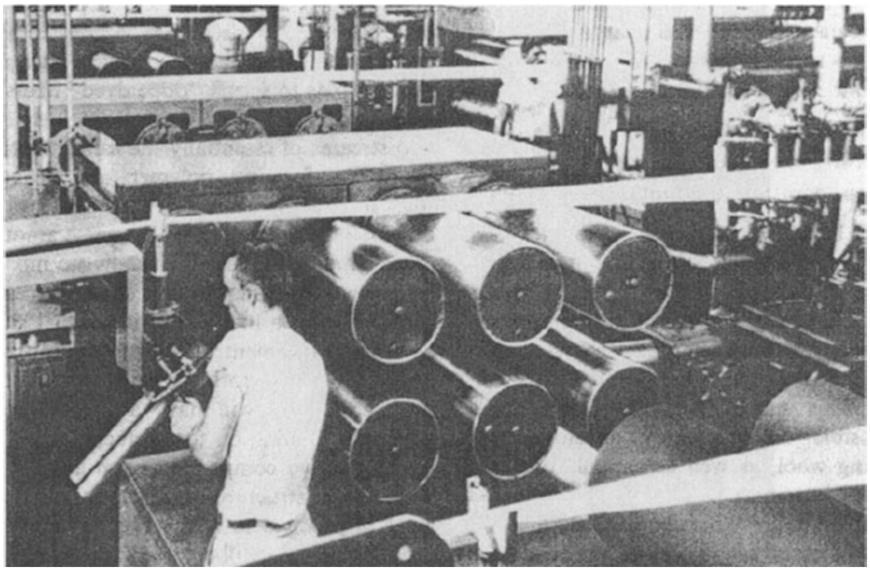

Fig. 12.20 Wet spinning of acrylic tow (Courtesy of Monsanto Co.)

comonomers containing hydrophilic functional groups such as hydroxyl, ester, carboxyl, amide, and substituted amide are used. To make the fiber base dyeable, comonomer containing carboxylic and sulfonic acid groups is introduced, and to obtain acid-dyeable fiber, comonomers containing pyridine, aliphatic amine, or quaternary ammonium salt are used. Antistatic acrylic fibers can be made by incorporating in the chain polyethylene oxide, polyalkylene derivatives, polyethylene glycol, acrylates, or methacrylates as the comonomers. For improved flame retardancy, halogen-containing vinyl comonomers are used.

Spinning

As already indicated, pure PAN softens at elevated temperatures, and thermal decomposition starts before the molten state is reached. The same is true of the copolymers commonly used to produce fibers. Accordingly, melt spinning is not possible; spinning must be done from a solution of the polymer. Both dry and wet spinning are carried out in current commercial operations.

The operations used to either wet- or dry-spin acrylics are essentially the same as those already described for rayon and acetate, respectively. The polymer must be completely dissolved in solvent and the solution filtered to remove any impurities that would cause spinnerette blockage. Because acrylic polymers are not soluble in common nonpolar solvents, polar substances such as dimethylformamide, dimethylacetamide, or aqueous solutions of inorganic salts such as zinc chloride or sodium thiocyanate are required. Only wet spinning is possible with the latter. Dimethyl formamide boils at 152.8°C and exerts a vapor pressure of 3.7 mm of Hg at 25°C compared with acetone (used in dry spinning of cellulose acetate), which has a vapor pressure of 228.2 mm of Hg at 25°C. It follows that, unlike acetone which requires an activated-carbon system for recovery, dimethylformamide may be condensed directly from the gas stream used to evaporate the solvent from the forming fiber.

In order to obtain the desired characteristics of modulus, rupture tenacity, and rupture elongation, acrylics, like rayon, require stretching which is usually carried out after the fiber has been spun, either as part of the fiber washing operation or after the fiber has been dried. These same properties are influenced by spinning speeds and the temperature of the drying air, if they are dry-spun, or the temperature and the composition of the bath, if wet-spun. The multitude of combinations made possible by the use of various comonomers and the flexibility of the fiber-forming operations furnish the different manufacturers with versatility and the users with a variety of acrylic fibers. Figure 12.20 shows a wet-spinning operation for acrylic tow.

Acrylic fibers possess a property that made it possible for them in the late 1950s and early 1960s to find immediate, even spectacular, acceptance in the knitted sweater field, until then dominated by wool. When acrylic fibers, normally in the form of a heavy tow, are hot stretched (e.g., by being drawn over a hot plate and then cooled under tension), they are converted to a labile state. Upon immersion in hot water, such fibers will contract considerably, but not to their prior unstretched length. In practice, this characteristic is used to produce a bulky yarn resembling the woolen yarns long accepted for use in sweaters. The process is described briefly below.

Using “stretch-break” equipment, the stretched labile fibers are further cold stretched to the breaking point so that the fiber breaks at different points leading to a distribution of fiber lengths, similar to the lengths found in wool. These are crimped and then mixed with thermally stable acrylic fibers that have been stretched and relaxed and have about the same length and degree of crimp. The blend is converted to a spun yarn by the same process used in making woolen yarns, and in turn, this yarn is knitted into sweaters and other similar products. When such garments are dyed in hot water, the labile fibers, intimately blended with stable ones, contract lengthwise individually. In the process, segments of the stable units tend to be carried along physically by entrapment and friction, but because such fibers do not change their overall length, the yarn as a whole decreases in length. Lateral displacement of the large volume of stable fibers results in the formation of a more voluminous structure known as “hi-bulk” yarn.

Bicomponent or Conjugate Spun Fibers

As will be shown, it should be theoretically possible to make any of the common manufactured fibers in bicomponent forms. However, acrylics have received the most attention for quite good reasons. Their general characteristics have tended to make them competitive with wool. This means that they should be processible on machinery developed for handling wool, as well as capable of being accepted into markets previously dominated by an animal hair fiber. It follows that because the natural fiber possesses crimp which produces the cohesion that determines its behavior in processing and in part its appearance and “hand” in usage, a similar crimp was desired for acrylics.

The principle that is the basis for bicomponent fibers usually is likened to that which underlies the bicomponent metal strips often used in temperature controllers. With the latter, differential thermal expansion of the two joined components results in a bending of the thermal element. With fibers, moisture usually is the agent that acts upon the two side-by-side portions. Differential swelling or shrinkage causes the fiber to be brought into a crimped, or preferably, a spirally distorted condition. As such, the side-by-side structure exists naturally in wool.

The combination of small size and large number of holes in a spinnerette might lead one to conclude that it would be almost impossible to design a spinnerette assembly that could bring two streams of polymer or polymer solutions together at each such hole and extrude them side by side to form a single filament. Such designs have, in fact, been made, but solutions of fiber-forming polymers fortunately possess properties that encourage laminar flow and thus make other approaches possible. This phenomenon was remarked upon earlier in connection with dope dyeing; when a suspension of a colored pigment is injected into a dope stream, a considerable problem must be overcome to achieve adequate mixing so as to secure “dope-dyed” fibers of a uniform color. Thus, it was known that when two streams of essentially the same solution of a fiber-forming polymer are brought together, side by side, and moved forward down a pipe or channel by the same amount of pressure behind each, virtually no mixing takes place. By bringing these streams to each spinnerette hole in such an individual side-by-side arrangement and using appropriate mechanical separators, the extruded filament from each hole will have a bicomponent structure. In addition to producing fibers in which the two components form a bilateral symmetrical structure, an ingenious arrangement of predividers of the two streams can produce from the full complement of holes in a single spinnerette a selected group of fibers wherein the amount and the position of each of the two components are randomly distributed throughout their cross sections. It follows that curls of uniform or random geometry may be produced to meet the required needs.

The worldwide production of acrylic fiber has declined significantly over the years because of the environmental concerns associated with the solution-spun process. In view of this, scientists have sought over the years a method that could render the high acrylics melt spinnable. Such a method would not only be economical and environmentally friendly but also allow for engineering the fiber with a wider range of morphologies and properties. In 1997, British Petroleum patented a polymerization process in which the two components usually used in developing spinnable acrylic copolymer were redistributed to allow the resulting material to be melt processable [13, 14]. Preliminary findings show that the polymer can be melt-spun into reasonable fine denier fibers with mechanical properties expected of the usual solution-spun material [15].

Vinyl and Modacrylic Fibers

Vinyls

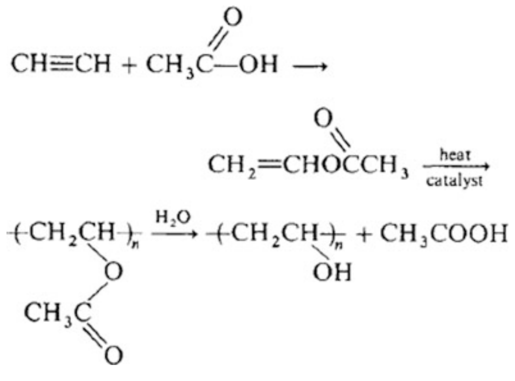
When nylon 66 was developed, it was described as being “synthetic” or “fully synthetic” in order to differentiate it from rayon and acetate. This was no small act of courage, as the word “synthetic,” in that period just following the repeal of Prohibition in the United States, was often associated in the public mind with the least palatable kind of alcoholic beverages. In due time, what is known in the advertising business as “puffing” led it to be known as the “first fully synthetic fiber,” which was an anachronism. It so happens that fibers based upon polyvinyl chloride (PVC) predated nylon by several years.

About 1931, the production of fibers from PVC was accomplished by dry spinning from a solution in cyclohexanone. But by chlorinating the polymer, it was possible to secure solubility in acetone, which has the advantage of possessing a boiling point about 100°C lower than that of cyclohexanone. Several million pounds per year of this fiber were produced in Germany during World War II to relieve the shortages of other materials. Unfortunately, PVC begins to soften at about 65°C, and in the fibrous state, it shrinks disastrously upon heating. Because of its low softening point, it cannot be dyed at the temperatures commonly used for this purpose, and, furthermore, it resists dyeing.

Modifications of PVC have been produced by copolymerization with other monomers. The first successful one consisted of 90% vinyl chloride copolymerized with 10% vinyl acetate. It was dry-spun from acetone and given the trade name Vinyon by its producer, Union Carbide Corporation. (In 1960, vinyon was accepted as a generic name for fibers containing not less than 85% vinyl chloride.) It has never been produced in large volume; it is used for heat-sealable compositions.

A copolymer of vinyl chloride with vinylidene chloride was used for a number of years to produce melt-spun, heavy monofilaments, which found use in heavy fabrics, where the chemical inertness of the polymer was needed, in outdoor furniture, and in upholstery for seats in public-transportation vehicles.

Another vinyl-based fiber, polyvinyl alcohol, or vinal, was developed in Japan but has not been produced or used in the United States. As such, it illustrates the importance of both relative availability of raw materials and differences in markets, in the success of a chemical product. Acetylene made from calcium carbide is converted to vinyl acetate, which, following polymerization, is saponified to polyvinyl alcohol.



The polyvinyl alcohol is soluble in hot water, and the solution is wet-spun into a coagulating bath consisting of a concentrated solution of sodium sulfate. The fibers are heat-treated to provide temporary stability so that they may be converted to the formal derivative by treatment with an aqueous solution of formaldehyde and sulfuric acid. This final product resists hydrolysis up to the boiling point of water. It seems reasonable to assume that it contains hemiacetal groups and some unreacted hydroxyls on the polymer chain, as well as cross-linking acetyl groups between the adjacent molecules.

Under the trade name Kuralon® (Kuraray Co., Ltd.), it achieved a production level of about 180 million lb in 1970, but production dropped to 16 million lb of continuous filament and 87 million lb of staple in 1980. The former has been mainly used in industrial rubber products, and the latter has been used mostly for uniforms, nonwoven and coated fabrics, and filters.

Modacrylics

In the United States, the modification of PVC has moved in the direction of copolymerizing vinyl chloride with acrylonitrile, or perhaps, it should be said that PAN has been modified by copolymerizing the acrylonitrile with chlorine-containing vinyl compounds. In any case, one modacrylic fiber is currently produced in the United States, a modacrylic being defined as containing at least 35% but not over 85% acrylonitrile.

The first two modacrylic fibers ever introduced in the United States were Dynel® (by Union Carbide) in 1949 and Verel® (by Tennessee Eastman Co.) in 1956. The former was a copolymer of 60% vinyl chloride and 40% acrylonitrile, and the latter was said to be a 50–50 copolymer of vinylidene chloride and acrylonitrile with perhaps a third component graft copolymerized onto the primary material to secure dyeability. SEF® and its version for wigs, Elura®, were introduced by Monsanto Fibers in 1972. A few foreign manufacturers are making modacrylic fibers, but the only modacrylic fiber currently in production in the United States is SEF®.

Modacrylic fibers, like acrylic, require after stretching and heat stabilization in order to develop the necessary properties. It is thought that the stretching is of the order of 900–1300% and that, in a separate operation, shrinkage of about 15–25% is allowed during the time that the fibers are heat stabilized.

The modacrylic fibers, like vinyon and unlike the acrylic fibers, have not become general-purpose fibers. They can be dyed satisfactorily and thus are acceptable in many normal textile products, but their nonflammability tends to place them in uses where that property is important, even vital. Blended with other fibers, they are used in carpets, but their largest market is in deep-pile products, such as “fake furs,” or in doll hair, where a fire hazard cannot be tolerated.

Elastomeric Fibers

The well-known elastic properties of natural rubber early led to processes for preparing it in forms that could be incorporated into fabrics for garments. One such process uses standard rubber technology. A raw rubber of high quality is compounded with sulfur and other necessary chemicals, calendered as a uniform thin sheet onto a large metal drum, and vulcanized under water. The resulting skin is spirally cut into strips that may be as narrow as they are thick, for example, 0.010 in. by 0.010 in. square in cross section. These strips are desulfurized, washed, dried, and packaged. Larger cross sections are easier to make. This product, coming out of the rubber rather than the textile industry, is known as a thread.

Another method produces a monofilament known as a latex thread. As the name would indicate, rubber latex is the raw material, and because extrusion through small holes is required, the purity of the material must be of a high order. With proper stabilization, the latex solution may be shipped from the rubber plantation to the plant, where it is compounded with sulfur and other chemicals needed for curing, as well as with pigments, antioxidants, and similar additives. This is followed by "precuring" to convert the latex to a form that will coagulate upon extrusion into a precipitating bath of dilute acetic acid and will form a filament having sufficient strength for subsequent operations. It passes out of the bath and is washed, dried, vulcanized in one or two stages, and packaged.

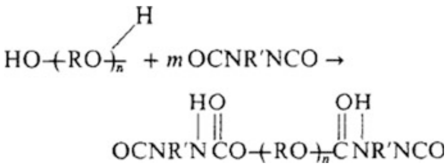
The rubber threads manufactured by either process can be used as such in combination with normal nonelastomeric yarns in fabrics made by weaving or knitting, but most of them, especially those made by a latex process, first are covered by a spiral winding of natural or manufactured yarns. Often, two layers are applied in opposite directions to minimize the effects of torque. Such coverings have two purposes. The first is to replace the less desirable "feel" of rubber on human skin by that of the more acceptable "hard" fiber. The second concerns the engineering of desired properties into the product to be woven or knitted into fabric. As an elastomeric material begins to recover from a state of high elongation, it supplies a high stress, but as it approaches its original unstretched condition, the stress drops to a very low order. When wound in an elongated state with a yarn having high initial modulus and strength, the elastomeric component cannot retract completely because its lateral expansion is limited, and jamming of the winding yarn occurs. Thus, the combination of such materials can be made to provide stretch and recovery characteristics needed for a broad spectrum of applications.

The traditional elastomeric threads have been subject to certain inherent limitations, however. The presence of unreacted double bonds makes them sensitive to oxidation, especially with exposure to the ultraviolet radiation of direct sunlight. They also have low resistance to laundry and household bleaches and dry-cleaning fluids.

During recent years, elastomeric yarns or threads have been used to impart comfort, fit, and shape retention to a variety of garments such as women's hosiery and swimwear. Such garments must be thin and highly effective per unit of weight. The materials of which they are composed must be compatible with these requirements. Thus, it was not unexpected that the producers of manufactured fibers, already eminently successful in meeting the needs of the marketplace, should look to the field of elastomeric fibers for new possibilities. Given the limitations of rubbers, both natural and synthetic, as well as the relationships between molecular structure and behavior of fiber-forming linear polymers, the scientists faced new challenges.

As an oversimplification, it can be said that within limits, a rubberlike material can be stretched relatively easily but reaches a state where crystallization tends to occur. The structure produced in this manner resists further extension, and the modulus rises sharply. In contrast to the conditions that occur when the manufactured fibers discussed earlier such as nylon or polyester are drawn to form fibers of stable geometry in the crystalline and oriented states, the crystalline state of the elastomeric fibers is labile unless the temperature is lowered materially. Thus, to improve on the chemical sensitivity of rubber, new approaches were necessary. The solution was found in developing linear block copolymers containing "soft" liquid-like sections that impart elasticity, connected with "hard" components that act as tie points to hold the structure together.

The soft, flexible, and low melting part is commonly an aliphatic polyether or a polyester with hydroxyl end groups and molecular weight in the range of 500–4,000. The hard portion is derived from an aromatic diisocyanate supplied in an amount that will react with both end groups of the polyether or polyester to form urethane groups. The product, an intermediate known as a prepolymer, is a thick liquid composed essentially of molecules carrying active isocyanate groups at each end. For example,



$$\mathrm{HO{+}RO{+}_{n}H} + m\,\mathrm{OCNR'NCO} \rightarrow \mathrm{OCNR'\overset{H}{\underset{}{N}}\overset{\overset{O}{\|}}{C}O{+}RO{+}_{n}\overset{\overset{O}{\|}}{C}\overset{H}{N}R'NCO}$$

where –(RO)– is an aliphatic polyether chain, R′ is one of several commonly available ring structures, *n* ~ 10–30, and *m* ~ 1.5–2.

The elastomeric polymer is obtained by "extending" the prepolymer through its reaction with short-chain diols such as butanediol or diamines such as ethylene diamine, thus completing the formation of hard groups between soft, flexible chains. When amines are used, the final step is typically done in a polar solvent such as dimethylacetamide. The conversion of these polymers into usable fibers may be accomplished by wet-, dry-, or melt-spinning operations, depending on the polymer. Additives to impart whiteness or improve resistance to ultraviolet radiation and oxidation may be incorporated in the spinning solutions or in the melts.

The development of elastomeric fibers has resulted in a variant of wet spinning called "reaction" or "chemical" spinning. In point of fact, rayon, the first wet-spun material, might properly be said to be produced by "reaction wet spinning" or "chemical wet spinning" because complex chemical reactions always have been involved in that operation. In any case, it has been found that the prepolymer of an elastomeric fiber may be extruded into a bath containing a highly reactive diamine so that the chemical conversion from liquid to solid occurs there.

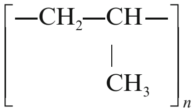
The elastomeric fibers produced in this fashion are based upon segmented polyurethanes and by definition are known generically as spandex yarns. Each manufacturer uses a trade name, for the usual commercial reasons. Perhaps the most noteworthy aspect from the standpoint of industrial chemistry is the multitude of options available to the manufacturer through the ingenious use of various chemicals for soft segments, hard units, chain extenders, and conditions of chemical reaction, followed by numerous possibilities for extrusion and aftertreatments. In the United States, there are two main producers of spandex fibers: DuPont (Lycra®) and Globe Rubber Co. (Cleerspan®, Glospan®). There are numerous worldwide producers, including Bayer, Germany (Dorlastan®); Asahi, Japan (Roica®); Nisshinbo, Japan (Mobilon®); and Taekwang, Korea (Acelan®).

Polyolefin Fibers

Polypropylene

Although polyethylene was considered a source of useful fibers at an early date, its low melting point (110–120°C) as well as other limitations precluded active development during the period when production of other fibers based upon the petrochemical industry expanded enormously. The higher melting point of high-density polyethylene (HDPE) gave some promise, but it was overshadowed by the introduction of polypropylene (PP) around 1958–1959. Great expectations were held for the latter as a quick competitor with the polyamides and the polyesters, already successful, as well as the acrylics, which then were entering the fiber field in volume. PP was thought to have several advantages. The raw material costs were low, only a few cents a pound; also, there was a high level of sophistication in the spinning and processing of fibers and a presumption that this would readily lead to the development of means for converting the polymer to fibers; and, finally, there was the belief that the American consumer would be ready to accept, and perhaps even demand, something new and different, which this polymer offered. However, the limitations of PP fibers, such as lack of dyeability, low melting temperature, low heat stability, and poor light stability, combined with the lower prices and the greater versatility of the already-established fibers, dashed the hopes for quick success. However, all of these deficiencies except the low melting temperature and lack of dyeability now have been overcome. The fiber has found an increasingly important place, and its properties have led to new techniques of manufacture and specialized uses

The structural formula of PP is as given below, where $100{,}000 < n < 600{,}000$ for chips or granules and $50{,}000 < n < 250{,}000$ for fibers:



$$\left[-CH_2-\underset{\displaystyle CH_3}{\underset{|}{CH}}- \right]_n$$

The steric configuration is extremely important in the polymer. Only isotactic polypropylene (iPP) has the properties necessary for forming fibers. The molecules are cross-linked only by van der Waals forces, so it is important that they pack as closely as possible. The isotactic molecules form a 3_1 helix, as shown in Fig. 12.21 [16], and exhibit a high crystallization rate.

The atactic molecules, shown in the figure, do not pack well, and although the syndiotactic molecules can pack better and crystallize, this configuration is not a normal product of commonly used catalyst systems. Some properties of isotactic, syndiotactic, and atactic PP are listed in Table 12.2 [17]. The insolubility of iPP in hydrocarbon solvents at room temperature often is used to separate iPP from atactic polypropylene (aPP). The insolubility of iPP in hydrocarbon solvents at room temperature often is used to separate iPP from aPP.

Early in the manufacture of PP, a concept was developed for dry spinning directly from the solution obtained in the polymerization operation. Had it been feasible, it would have been the realization of a chemical engineer's dream: the gaseous olefin fed into one end of the equipment and the packaged fiber, ready for shipment to a textile mill, coming out the other end. But it did not turn out that way, and today, melt spinning is the accepted technique for the production of staple fibers, monofilament, and multifilament yarns. To this usual method have been added the fibrillation and the "slit film" procedures for producing yarns.

The PP materials are completely resistant to bacterial attack, are chemically inert, and are unaffected by water.

Monofilaments can be produced that possess high strength, low elongation under stress, and dimensional stability at normal atmospheric temperatures.

PP monofilaments have found broad application in cordage and fishing nets (which float), and if highly stabilized, they are woven into fabrics used for outdoor furniture, tarpaulins, and similar applications. Large filament denier staple is used widely in "indoor–outdoor" carpets. Also, staple fibers have found major applications in tufted indoor carpets and nonwovens used for diaper, filtration, and civil engineering fabrics.

Synthesis. The early PP plants used a slurry process adopted from polyethylene technology. An inert liquid hydrocarbon diluent, such as hexane, was stirred in an autoclave at temperatures and pressures sufficient to keep 10–20% of the propylene monomer concentrated in the liquid phase. The traditional catalyst system was the crystalline, violet form of $TiCl_3$ and $AlCl(C_2H_5)_2$. Isotactic polymer particles that were formed remained in suspension and were removed as a 20–40% solid slurry while the atactic portion remained as a solution in the liquid hydrocarbon. The catalyst was deactivated and solubilized by adding HCl and alcohol. The iPP was removed by centrifugation, filtration, or aqueous extraction, and the atactic portion was recovered by evaporation of the solvent. The first plants were inefficient because of low catalyst productivity and low crystalline yields. With some modifications to the catalyst system, basically the same process is in use today.

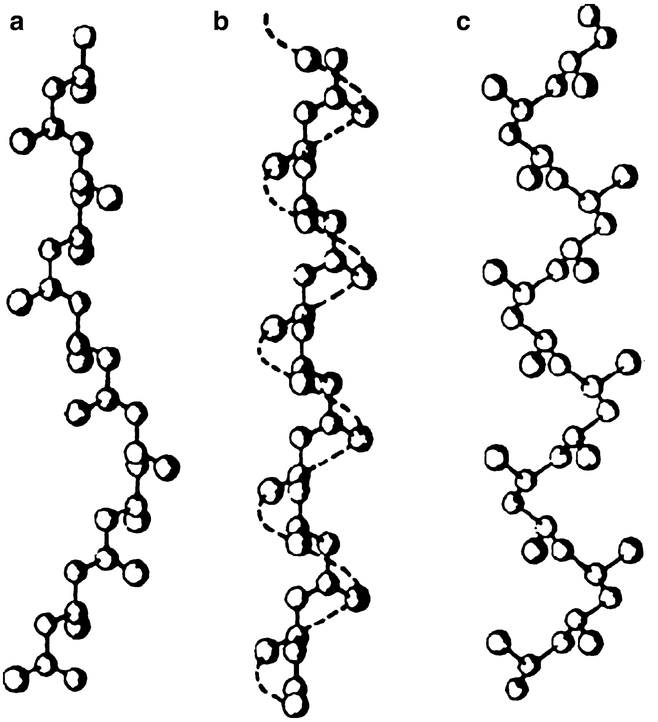


Fig. 12.21 Diagrams showing (**a**) irregular atactic, (**b**) stereoregular isotactic, and (**c**) stereoregular syndiotactic configurations in polypropylene polymer (*Source*: Ahmed [16]) (Copyright © M. Ahmed with permission)

In 1963, liquid polymerization was introduced in which liquid propylene, catalysts, and hydrogen were pumped continuously into the reactor, while polypropylene slurry was transferred to a cyclone separator. The unconverted monomer gas was removed, compressed, condensed, and recycled, and the polymer was treated to reduce the catalyst residue. This system also suffered from a poor catalyst yield, and the polymer produced lacked the required stereospecificity, so that it was necessary to remove the atactic portion of the polymer.

In the mid-1960s, a gas-phase process was introduced for production of the polymer. The monomer was pumped over adsorbing beds and entered the reactor with the catalyst system. These feed streams of monomer and catalyst, together with a mechanical stirrer, created a turbulent bed of powdered polymer. Periodically, the polymer powder was vented off in a carrier gas to extrusion storage hoppers. Meanwhile, the heat of polymerization was removed by condensing the unreacted monomer in a cooling loop and returning it to the reactor, where it immediately vaporized. This process eventually led to the production of highly crystalline products and was adopted by several companies in the United States.

Most processes in use today rely on a combination of these technologies. Montedison's introduction in 1975 of third-generation catalysts gave high yields and allowed polymerization to take place at 60–80°C and 2.5–3.5 MPa (362–507 psi). This was welcome news during the energy crisis, but the resulting polymer was not stereospecific enough to eliminate the need for removal of aPP. Real progress came with the discovery of superactive

Table 12.2 Properties of isotactic, syndiotactic, and atactic polypropylene

Property	Isotactic	Syndiotactic	Atactic
Density (g/cm^3)	0.92–0.94	0.89–0.91	0.85–0.90
Melting point (°C)	165	135	
Solubility in hydrocarbons at 20 °C	None	Medium	High
Yield strength	High	Medium	Very low

Production. Classical melt spinning, which was developed for the production of nylon filaments, is widely used to produce PP fibers today. It involves a high-speed process (2,000–3,000 m/min) that is particularly suitable for long production runs. The average molecular weight of polypropylene polymer, like that of other addition (olefin) polymers, is relatively high compared to that of other polymers. This results in a high melt viscosity, so, unlike the case of other polymers, its extrusion temperatures are 70–100°C above its melting point. Single-screw extruders are used for melting and homogenizing the polymer. The screw diameters are from 45 to 200 mm, and screw lengths are 24, 30, or 36 times the diameter. The polymer granules are fed into the extruder hopper, where they are melted and homogenized. Chips carrying pigments can be fed into and blended with the main charge of the extruder if colored fibers are desired. The molten polymer is forced through the spinnerette via a screen pack to eliminate any contaminant particles. The spinnerette hole determines the shape of the filaments, and the flow rate and the take-up speed determine the size. The polymer has high specific heat and low thermal conductivity, so the cooling zones must be longer than those for polyester and nylon. For filament yarn production, the filaments are drawn at high speed and wound on packages. For staple fiber production, the filaments are collected in the form of tow and then are drawn, crimped, and cut. The multifilament yarns are often textured to improve bulk and appearance. The false twist method is generally used to texture finer yarns, with the stuffer box used for coarser yarns.

The short spinning method used to produce staple fiber is considerably slower than high-speed spinning. The lower spinning speeds (30–150 m/min) would have a negative effect on productivity, but this is counteracted in industry by the use of spinnerettes with a large number of holes (up to 55,000). The required cooling zones are much shorter because of the lower speeds and the use of higher volumes of quench air, which gives this method its name. Because the drawing units can match these low speeds, the two can be fed directly and continuously from the spinning machine to the draw frame to the texturing chamber or the crimper to produce bulked continuous-filament (BCF) yarn or staple fiber, respectively. The short spinning method is used to produce high-tenacity fibers. Many PP yarns are produced using the slit film method. The film extruder is almost identical to a filament extruder. In it, the molten polymer is forced through a film die that converts the melt into film, where the thickness of the film can be controlled by adjusting one of the die lips. The takeoff unit is either a chill roll that removes the film uniformly and cools it below T_m or a water bath followed by nip rolls. The cooled film is slit into separate tapes using a slitter bar that contains a large number of special knives separated by spacers. The film tapes are heated and drawn to their final length.

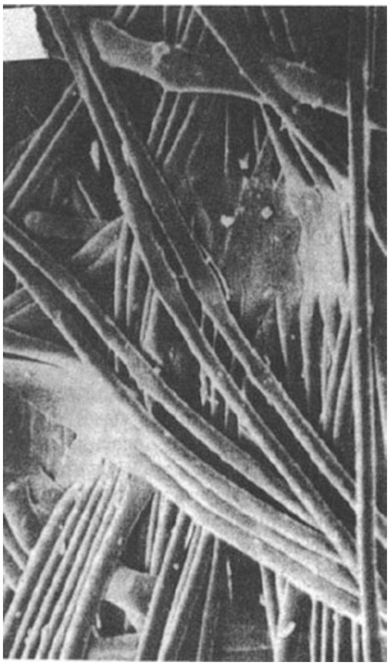

Fig. 12.22 Spunbonded polypropylene showing interfiber bonding, which binds the structure (Courtesy of E.I. du Pont de Nemours and Co.)

Several methods are used to produce fibrillated film. They are produced in much the same way as slit film, but these techniques take advantage of the tendency of PP to fibrillate. In one method, a profiled tape is extruded and hot-drawn. It is drawn again to achieve a 10:1 ratio, and the film splits into separate filaments. In another method, called roll embossing, the film is hot-drawn, and then embossed using profiled rollers. The profiled film is drawn again, and fibrillation results. In the pin-roller technique, the film is drawn and cut by knives or pins on a rotating cylinder. This method can produce individual fibers or a controlled web network.

PP nonwovens are created by forming a staple fiber web and then consolidating the latter. The fibers can be entangled by a needling machine, an air jet, an air jet, or a water jet. Another method uses a single-stage process in which melt-spun fibers are drawn through an air aspirator jet and deposited randomly on a conveyor. The fibers then are bonded by fusion under heat and pressure to give a "spunbonded" nonwoven fabric (see Fig. 12.22).

Yet another method, known as melt blowing, can be used in producing a nonwoven web having special characteristics. The melt-blown (MB) fibers are characterized as ultrafine fibers because of their size relative to other fibers. In the process, molten polymer is forced through a melt-blowing

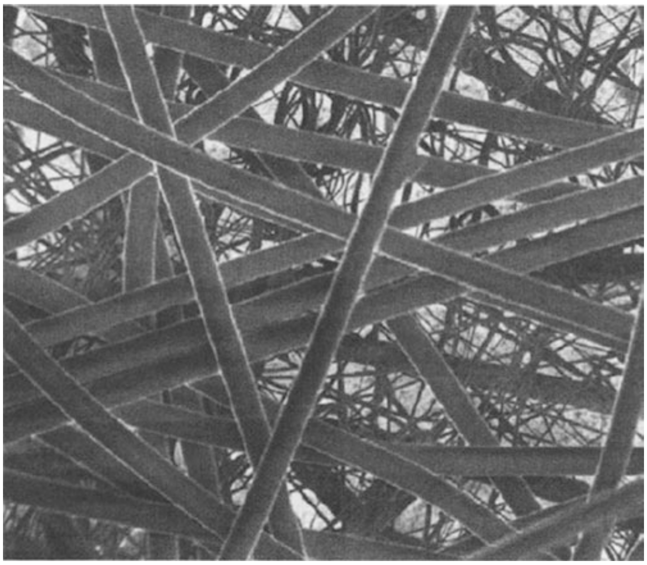

Fig. 12.23 Spunbond/melt-blown composite, SMMS, containing two layers of melt-blown microfibers sandwiched between two layers of spunbonded material and bonded by hot calendaring (*Source*: Madsen [20])

die and die-tip orifice that are finer than most orifices used to make manufactured fibers; it is attenuated by a jet of high-velocity hot air. This allows the polymer to stay in a molten state but attenuate until broken. The fibers then come in contact with cool quench air, which causes the former to solidify. The fibers deposit on a collector screen and form a MB web. These webs, composed of very fine-sized fibers, can be engineered for applications in areas where barrier (such as against bacteria), insulative, and absorptive (such as for oil) characteristics are important.

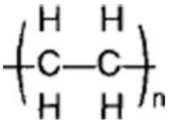
One of the most recent developments in the use of polyolefin fibers is in composites of spunbond (SB) and melt-blown systems. Some examples of structures being made are SB/MB, known as SM, SB/MB/SB, or SMS, and other combinations of SB and MB. The production and properties of these are particularly enhanced by the use of PP/polyethylene bicomponent fibers in the preparation of the MB layers. Such to composites are particularly suited for use as lightweight coversheets or facings for diapers and sanitary products. The spunbond layers on the top and bottom provide the needed high strength, whereas the layers of MB microfibers sandwiched between them provide the greatly enhanced visual uniformity and barrier properties [19]. Figure 12.23 illustrates a low-weight (15 g/m^2) SMMS fabric comprised of MB fibers accounting for less than 15% of the structure by weight [20].

The production figures of PP show impressive growth. The volume, which was less than 10 million lb in 1965, reached over 1.5 billion lb in 1990. This included approximately 17% filament yarn, 23% staple fiber, 18% spunbonded fabrics, and 38% split film products.

It is recognized that despite its many advantages compared with other synthetic fibers, the use of the fiber is restricted by the fact that most dyestuffs lack affinity for the material. This makes the fiber unsuitable for conventional exhaustion dyeing techniques using disperse or acid dyes. A number of attempts have been made in recent years to improve dyeability of the material [21]. In one of the most recent studies, an alloy fiber of polypropylene (PP) and nylon 6 (N6) has been produced by melt spinning. The fiber contained PP grafted with maleic anhydride (MAH) as the third component. The MAH units reacted with the amine end groups of N6 to form block or graft copolymers that acted as a compatibilizer for the blend. Addition of 10% N6 produced a fiber that could be dyed conventionally using disperse dyes [22].

High-Molecular-Weight Polyethylene

Polyethylene is probably the material one encounters most abundantly in daily life, such as in the form of grocery bags, shampoo bottles, and toys, but now, one also finds it as the material in such superhigh-performance products as bullet-proof vests. For such a versatile fibrous material, it has the simplest structure of all known polymers:



$$\left[\begin{array}{cc} \mathrm{H} & \mathrm{H} \\ | & | \\ \mathrm{C} - & \mathrm{C} \\ | & | \\ \mathrm{H} & \mathrm{H} \end{array} \right]_n$$

However, during the general addition polymerization process, some of the carbon atoms, instead of having hydrogen attached to them, have segments of polyethylene chains grown on them, leading to a branched or low-density polyethylene (LDPE). If branching is eliminated or greatly minimized, such as found with the use of the Ziegler–Natta polymerization process, utilizing special catalysts, one can get linear chains capable of greater packing. This provides an HDPE material suitable for fiber use. Molecular weights of the order of one million have been achieved resulting in ultrahigh-molecular-weight polymer (UHMWPE). Accordingly, a recent addition to the group of high-performance fibers is the ultrahigh-molecular-weight, extended-chain, linear polyethylene. Although fundamental work in the area of developing fully oriented and crystalline structures in polyethylene polymer had been going on since the mid-1960s, it was not until the late 1970s that the possibility of producing such materials on a commercial scale became evident. Presently, three companies worldwide are manufacturing extended-chain polyethylene fibers, which have very high-strength and high-modulus characteristics.

Routes to High Performance. The achievement of ultimate strength and high modulus in fibers has been a subject of great interest to material scientists and fiber producers. In an attempt to identify the preferred structures for high performance, many theoretical analyses have been conducted to calculate the limiting values. The basis of such calculations is the assumption that in a fiber in which all polymer chains of infinitely long dimensions are extended and oriented parallel to the axis, rupture will occur only when the stress exerted exceeds the intramolecular bond strength. Such calculations show that the limiting theoretical values for conventional fibers usually are several times higher than those obtained in actual practice. The reasons for this difference lie in one or more of the following explanations: (1) the molecular weights are not high enough, (2) the chains are not fully extended, and (3) the chains are not fully oriented. For a given polymer system and molecular weight, tensile strength and modulus can be enhanced by extending and orienting the chains. Practically, many modern techniques, including zone stretching, multiple-step stretching, and state-of-the-art high-speed extrusion methods, have been adopted to achieve such results.

Still, the results of studies on conventional fibers show that modifications in physical processing alone cannot lead to values that even approach the theoretical maximum to within an order of magnitude. Flexible chains, which characterize the bulk of the commercial polymers, tend to conform to a random coil or folded chain structure in an as-spun material, and are very difficult, to reorganize into an extended-chain structure by known methods. Accordingly, in order to achieve ultimate properties, either novel spinning methods are needed, which allow flexible chains to be fully extended, or the chains used must be so configured that they have high intrinsic stiffness and would remain extended in solution or melt. Both of these goals have been met and are exemplified in the production of (1) high-strength polyethylene fibers, discussed in this section, and (2) aramid fibers, discussed in the next section.

Extended-chain polyethylene fiber became available commercially in 1984 when DSM, a Dutch firm in the Netherlands, introduced Dyneema® and Mitsui Petrochemicals in Japan announced Tekmilon®. AlliedSignal of the United States entered the field in 1985 when it introduced Spectra® fibers. These materials are characterized by very high strength and modulus, which are achieved by the use of ultrahigh-molecular-weight polyethylene spun by the gel-spinning method into fibers having extended-chain structures and near-perfect orientation.

Gel Spinning. In general, the purpose for which the gel-spinning method is used is to produce an as-spun fiber that contains a loose network of chains with few entanglements, which then can be drawn out to ultrahigh levels to yield a highly oriented structure. The surface-growth method of Pennings [23], which uses a Couette-type apparatus, and the gel-spinning method of Smith–Lemstra [24], which uses a more conventional spinning apparatus, led to the achievement of this goal. In the former method, a polymer solution is stirred between two counterrotating cylinders that provides the elongational flow necessary for initial chain alignment. Essentially the same result is achieved by passing the polymer solution through a constriction prior to spinning in the latter method.

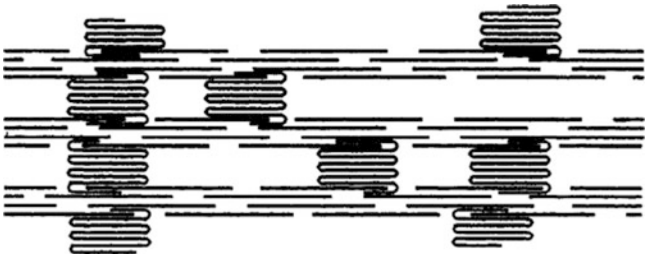


Fig. 12.24 "Shish-kebab" structure showing extended-chain crystals with lamellar overgrowths

In the surface-growth technique, polymer solution between the inner rotating cylinder and the outer stationary cylinder is maintained within a certain temperature range above the polymer crystallization temperature. A fiber seed is immersed through an opening in the outer cylinder, and its tip is made to attach to the polymer layers absorbed on the inner rotating cylinder. By pulling on the other end of the fiber and winding it onto a bobbin, while at the same time replenishing the solution in the gap between the cylinders, a fiber can be produced continuously. This process results in a fibrous precipitate with a "shish-kebab" morphology (Fig. 12.24).

One can conclude, then, that the flow field that is developed extends the chains, which then crystallize in a fibrillar form. Chains that are left unextended, those that are below a certain length for the speed, use the preformed clusters (shishes) as nuclei and crystallize as overgrowths in the form of chain-folded lamellae (kebabs). Fibers formed in this way showed remarkable mechanical properties with modulus in excess of 1,200 g force/denier (102 GPa) and tensile strength in the neighborhood of 30 g force/denier (2.6 GPa).

Production. Recognition that the shish-kebab fibers produced by the surface-growth procedure result from the deformation of a gel-like entangled network layer at the rotor surface led to the development of gel-spun polyethylene fibers. The fiber is made by the solution spinning method. The polymer is dissolved in a high-temperature solvent, such as decalin, at a low concentration, 10% or less, and extruded into cold water. Initially, the fiber is formed as a gel that still contains the spinning solvent.

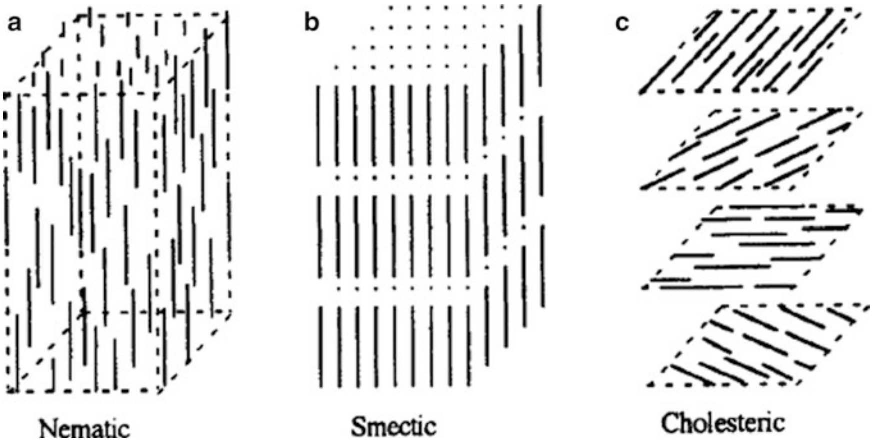

Fig. 12.25 Structure of liquid crystalline polymers showing (**a**) nematic, (**b**) smectic, and (**c**) cholesteric orders

It can be oriented by drawing at remarkably high draw ratios of 30 or greater, either before or after solvent removal. A method of spinning polyethylene fiber is described in the patent by Kavesh and Prevorsek [25]. The factors that govern the properties of fibers produced by this method are the polymer molecular weight, the concentration of polymer in the solvent, the type of solvent, the solution temperature, and the stage and the extent of drawing.

The high-performance behavior in these fibers is obtained from their having a very high molecular weight (1–5 million) combined with a very high degree of extended-chain crystal continuity. The fiber can approach a 100% crystalline structure with a theoretical maximum density (~0.97 g/cc). Their use, of course, is limited by the melting point of the polymer, which even in the extended form is only about 150°C. Although higher than that of ordinary polyethylene, it is still much lower (80°C or more) than those of commercial textile and other higher-performance industrial fibers. There also has been concern about the creep that occurs in these fibers, although significant improvement has been made in this regard since the introduction of the first fiber. In spite of the limitations mentioned, the unique combination of strength, stiffness and lightness properties have allowed these fibers to prove highly successful in a number of applications, such as sailcloth, body armor, medical implants, fishing net, and sports equipment.

Aramids

Introduction

As pointed out in the preceding section, a second route for developing fibers having properties approaching the ultimate values is the use of polymer chains that have high intrinsic stiffness and will remain extended in solution or melt. The development of aramid organic fibers based on aromatic polyamides met these requirements and added another chapter to the history of the development of synthetic fibers. Nomex® aramid, a thermally resistant fiber based on a *meta*-oriented structure, was commercialized by the DuPont company in 1962.

Following the technological breakthroughs which led to the discovery of (1) the liquid crystalline behavior of *para*-oriented aramids [26] and (2) a novel method for spinning anisotropic liquid crystalline polymer solutions [27], Kevlar® aramid fiber was produced and commercialized by the DuPont company in 1972. Other fibers based on aromatic polyamide compositions, which were produced and commercialized by other companies, were Technora® (Teijin, Japan), Teijinconex® (Teijin, Japan), and Twaron® (Akzo, The Netherlands). Additionally, SVM is a fiber produced in the former Soviet Union, and it was announced in 1990 that a new aramid fiber had been introduced by Hoechst, in Germany.

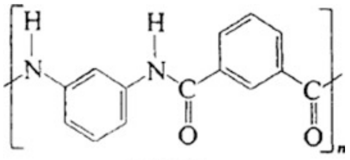
The rigid rod chains in *para*-aramids tend to form so-called liquid crystals when they are dissolved in polar solvents or heated to certain temperatures. The polymers showing liquid crystalline behavior in melts are called the thermotropic liquid crystalline polymers, and those showing similar properties in solution are called the lyotropic liquid crystalline polymers. These liquid crystals exist in three distinct phases according to their specific structures (Fig. 12.25).

A one-dimensional arrangement of rigid rods is called a nematic structure; a two-dimensional ordered arrangement represents a smectic structure; and the cholesteric structure is formed in terms of rotating oriented sheets so that rigid rods align parallel to each other in every layer, but the directional vectors in each layer are different. The preferential phase considered for fiber spinning is nematic. Nematic solutions or melts are easy to develop into oriented structures through shearing and elongational flow during extrusion because of the rigidity of the polymer chains.

Thus high orientation can be obtained in the as-spun fibers without much posttreatment.

Manufacture

In 1973, the Federal Trade Commission recognized aramid as a distinctly different generic material and defined it as "a long-chain synthetic polyamide in which at least 85% of the amide linkages are attached directly to two aromatic rings." This distinguishes aramids from nylon, which was redefined as a polyamide with less than 85% of the amide linkages attached to two aromatic rings. The first aramid fiber produced in the United States was Nomex®, the reactants being *m*-phenylene diamine and isophthaloyl chloride to give poly (*m*-phenylene-isophthalamide) (MPD-I).

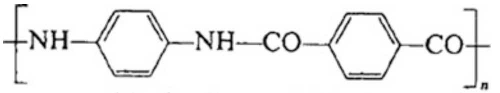


MPD-1

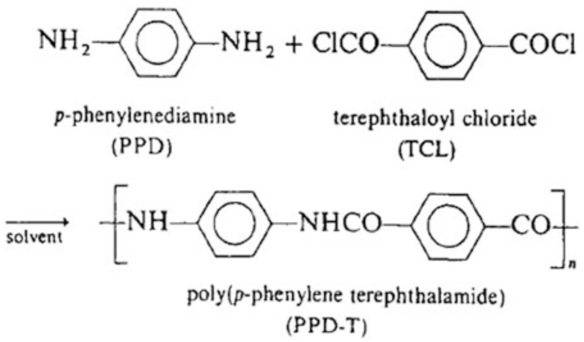
This polymer could not be melted without decomposition, so the preferred fiber formation route was solution spinning. Patent literature suggests that the fiber is spun from a solvent system composed of dimethylformamide and lithium chloride. The final properties are achieved by stretching in steam after washing to remove residual solvent.

The physical and chemical properties of this fiber are not remarkably different from those of other strong polyamides, but it does have excellent heat and flame resistance that makes it particularly suited for use in protective clothing and in specified industrial end uses. Military flight suits, firefighter uniforms, and hot gas filtration are a few of its many possible applications.

The other important fiber in this category, which also was first produced commercially in the United States, is Kevlar®, introduced in 1971 as fiber B and later coded as Kevlar® 29. It was produced from poly(*p*-phenylene terephthalamide) (PPD-T).



poly(*p*-phenylene terephthalamide)



Later, a higher modulus version, Kevlar® 49, believed to be made by heat annealing of Kevlar® 29, was introduced.

Poly(*p*-phenylene terephthalamide) PPD-T, also called *para*-aramid, can be polymerized to a fiber-forming molecular weight by polycondensation of terephthaloyl chloride and 1,4-phenylene diamine.

Poly(1,4-phenylene terephthalamide) (PPD-T) of high molecular weight can be prepared by low-temperature solution polymerization techniques. This polymer is less soluble in amide-type solvents than is poly(*p*-benzamide). The most successful conditions required hexamethylene phosphoramide (HMPA), the original solvent, alone or mixed with *N*-methyl-2-pyrrolidone (NMP), although other mixtures such as NMP containing $CaCl_2$ also could produce a fiber-forming polymer. During polymerization, the molecular weight increases rapidly within the first few seconds of the reaction. The critical molecular weight or viscosity is reached, and the stir opalescence typical of lyotropic solutions is observed. Although gelation of the reaction mixture occurs quickly, polymerization continues but at a greatly reduced rate. With the choice of a suitable solvent system, gelation can be delayed until the desired higher molecular weight is reached. Large-scale manufacture of a polymer requires continuous polymerization to minimize cost. In the case of PPD-T, special problems that had to be accommodated included the rapid gelation of the reaction solution with increasing molecular weight, the need to control the temperature of a vigorous exothermic reaction, and the handling of solvent HMPA, which is suspected to be a carcinogen.

Although melt spinning would be preferred from the standpoint of process simplicity and conversion cost, aramids must be spun from solutions, by wet, dry, or dry jet–wet methods because they decompose before or during melting, ruling out melt spinning. Dry spinning is used to produce Nomex® fiber, where a dope (20%) of the polymer in solvent is converted to yarn. In wet spinning, the

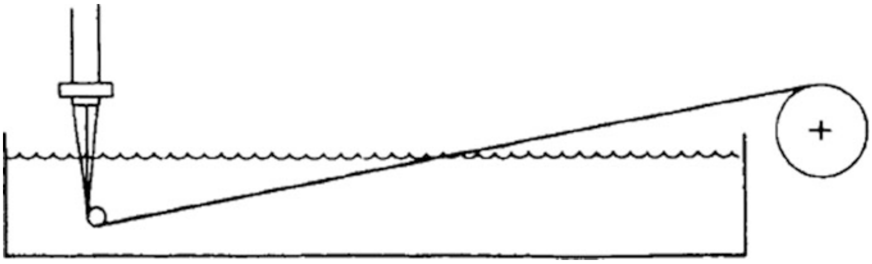


Fig. 12.26 Schematic of dry jet–wet spinning method

polymer dope is extruded into a nonsolvent where the fiber coagulates. The coagulated fiber then is washed and often drawn to develop desired fiber properties. In wet spinning, the spinnerette is in the coagulation bath, hence the dope temperature and the coagulation temperature are the same.

In dry jet–wet spinning (Fig. 12.26), as used for Kevlar®, on the other hand, the spinnerette is separated from the coagulation bath, allowing independent control of the dope extrusion and coagulation temperatures. The extrusion jet is placed a small distance above the coagulation bath, and the nascent fibers descend into the liquid, pass under a guide, and proceed in the bath while undergoing stretch; then they are withdrawn from the bath and wound up. A subsequent washing step may be required to remove residual acid solvent. In systems where the dope must be hot to lower viscosities to extrudable levels, and the bath cold for developing specific structures during coagulation, as is preferred with Kevlar®, dry jet–wet spinning is the option. For production of Kevlar® fibers, a PPD-T/concentrated sulfuric acid solution, containing approximately 20% polymer, is extruded at 90°C into a cold water bath (~1°C). Following extrusion, the fiber is washed, dried, and given posttreatment, depending upon the properties desired. Kevlar® is reported to have about twice the breaking strength (23–27 g force/denier or 2.9–3.4 GPa) of high-tenacity nylon and polyester, but its most outstanding physical property is its high stiffness (550–1,000 g force/denier or 70–127 GPa), which can range up to an order of magnitude greater than that of standard polyester. This property has led to high-volume usage of the fiber as reinforcement in composite materials such as belts in radial tires and aerospace structures. The world production figure (1999) of this fiber was estimated to be over 60 million lb.

High-Temperature-Resistant Fibers

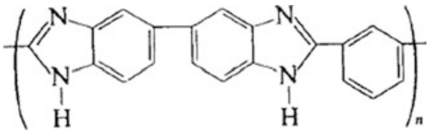
The need for high-temperature-resistant fibers has arisen from demands of a number of industrial applications, as well as applications in aerospace programs. In many of these applications, the usual characteristics of organic-based fibers are desired, but the high temperature resistance of inorganic fibers is required. Thus, the fibers are expected to retain their structural integrity at temperatures of 300°C and above for considerable periods of time, while their other physical and mechanical properties resemble those of the more common manufactured textile fibers. The two leading groups of fibers in this area are the *meta*-aramids and PBI.

Meta-Aramid

The major fibers in this group, based on sales volume, are the products made from poly(*m*-phenylene-isophthalamide), which were introduced by DuPont in 1962 as HT-1 nylon (later known as Nomex®) and by Teijin in 1972 as Conex®. General manufacture of the fiber was described earlier under the heading "Aramids." Other manufacturers now are entering the field with products of similar chemical structure. Although these products are made and spun by different processes, their chemical and physical properties are similar. The fiber is usually utilized in the form of cut staple, which is amenable to conversion on traditional spinning and weaving machinery. Its mechanical properties (tenacity 4–5 g force/denier, ultimate strain 25–30%, and initial modulus 90–100 g force/denier) compare favorably with those of other textile fibers. The main utility of the fiber lies in the resistance it offers to combustion: it has a limiting oxygen index (LOI) of about 0.29, a melting point above decomposition temperature, an ignition point above 600°C, and a flash point about 800°C [28]. The LOI gives a relative measure of flame resistance; the higher the number, the lower the flammability. The fiber Kermel® from Rhone Poulenc also is classified as an aramid. It is, chemically, a polyamide-imide fiber and has an LOI of about 0.31. A major application of these fibers is in protective clothing. In order to reduce their cost, they often are blended with other, less expensive, flame-retardant fibers such as those based on cotton, rayon, and wool.

PBI

Poly-2-2′-(*m*-phenylene)-5,5′-bibenzimidazole, commonly called PBI, was developed under the aegis of the U.S. Air Force Materials Laboratory in cooperation with the then-existing Celanese Corporation. The fiber went into commercial production in the United States in 1983. It is a condensation polymer obtained from the reaction of tetraaminobiphenyl and diphenylisophthalate in a nitrogen atmosphere at temperatures that may reach 400°C in the final stages [29]. The structure of a repeating unit is shown below:



The polymer is dissolved at a high temperature under nitrogen pressure in dimethylacetamide, to which a small amount of lithium chloride may be added to increase the stability of the solution. Then, it is dry-spun in an atmosphere of heated nitrogen (about 200°C), from which the solvent is recovered; next, it is stretched slightly in steam and washed. Drawing and relaxing are done in an inert atmosphere, as might be expected, because temperatures up to 250°C or higher are used. The fiber then is given a stabilization treatment in a sequence of steps and made into staple fibers using conventional crimping and cutting techniques. The stabilization treatment involves reaction with sulfuric acid and heating at high temperatures (~475°C) for short periods of time. The process, known as sulfonation, yields a product that has a significantly lower shrinkage than the unstabilized material.

The final yarn is golden yellow, and because this color appears to be an intrinsic property of the polymer, it may have some limitation as far as the civilian market is concerned. This material originally suffered from high shrinkage on exposure to flame; however, further developments including the sulfonation treatment have reduced the shrinkage to only about 5–10% at 600°C [30]. The fiber is capable of retaining about one half of its original strength (~3 g force/denier) upon exposure to air for 18 h at 350°C or 1 h at 425°C; it has an LOI of 0.41, which is well above that of the aramids; and it has high resistance to inorganic acids and bases and organic chemicals. Further, with tensile and moisture regain properties comparable to those of many textile fibers, the PBI fiber is well suited for blending with other fibers and conversion into final products using conventional spinning and weaving or nonwoven equipment. Applications include high-performance protective apparel, flight suits, and aircraft furnishings.

Polytetrafluoroethylene

Historical

Polytetrafluoroethylene (PTFE) was discovered in 1938 when Dr. Roy J. Plunkett and his assistants working on new nontoxic, nonflammable refrigerants at E. I. du Pont de Nemours and Co. found that one cylinder, which was supposed to contain tetrafluoroethylene (TFE), ceased to release the gaseous material. Upon opening the cylinder, they discovered that the inside was covered with a white powder. Polymerization of TFE had taken place. The result was PTFE or Teflon®, which is the trade name applied to that polymer by DuPont. The company tested the polymer and found that it was virtually inert to all known solvents, acids, and bases, a characteristic that was unique at that time. It also found that this material was resistant to high temperature and had the lowest coefficient of friction of any known solid. The research on PTFE was intensified during World War II because of military demands for improved materials for products such as gaskets, packing, and linings for containers for handling corrosive materials. When the war was over, the release of classified information caused a booming interest in the polymer. Since that time, PTFE has found itself in many different applications.

Manufacture

In one process, the manufacture of the monomer, TFE, involves the following reactions: hydrogen fluoride is made by reacting calcium fluoride with sulfuric acid:

$$CaF_2 + H_2SO_4 \rightarrow CaSO_4 + 2HF$$

Chloroform is reacted with hydrogen fluoride in the presence of antimony trifluoride as the catalyst:

$$CHCl_3 + 2HF \rightarrow CHClF_2 + 2HCl$$

TFE is obtained by the thermal decomposition of this monochlorodifluoromethane (known as Freon) in a continuous noncatalytic gas-phase reaction, carried out at or below atmospheric pressure at temperatures from 600 to 900°C:

$$2CHClF_2 \rightarrow C_2F_4 + 2HCl$$

Numerous side products are generated in this process. Many of them are present in trace amounts, but the highly toxic perfluoroisobutylene, $CF_2{=}C(CF_3)_2$, requires special precautions.

TFE also may be manufactured by the reaction of zinc and tetrafluorodichloroethane

$$ClF_2C - CF_2Cl + Zn \rightarrow C_2F_4 + ZnCl_2$$

or by the reaction of tetrafluoromethane molecules in an electric arc furnace

$$2CF_4 \rightarrow C_2F_4 + 2F_2$$

TFE is a colorless, tasteless, odorless, and nontoxic gas. To avoid any undesired reactions during storage, inhibitors must be added. The polymerization is carried out by an addition-type reaction in an aqueous emulsion medium and in the presence of initiators such as benzoyl peroxide, hydrogen peroxide, and persulfates. The monomer is fed into a cooled emulsion medium and then heated to a temperature of 70–80°C, at which the polymerization takes place:

$$CF_2 = CF_2 \rightarrow \left(CF_2 - CF_2 \right)_n$$

The pressure may range from 40 to 100 atmospheres. After removal of the unreacted material, the polymer is washed, pressed, and dried. The degree of polymerization can be quite high, of the order of 50,000. PTFE is manufactured in four different forms, granular, fine powder, aqueous dispersion, and micropowder, and in a variety of grades, each differing in properties. Fillers such as glass fibers, asbestos, graphite, or powdered metals may be added to the granules in order to modify properties.

Fiber Manufacture

Because Teflon® is not soluble, it cannot be wet- or dry-spun, and because it is thermally unstable at its melting point of about 400°C, this combination would seem to pose an impossible problem for the production of fibers. Research into the fundamental characteristics of the polymer, however, revealed that the submicroscopic particles precipitated from the polymerization reaction were about 100 times as long as they were thick.

In one manufacturing process, an aqueous dispersion of PTFE is mixed with a solution of ripened cellulose xanthate, from which a fiber is obtained by a wet-spinning process, after which the cellulose is completely decomposed by heating. The remaining PTFE is sintered into continuous fibers by transporting them over heated metal rolls, followed by stretching to achieve the desired diameters and physical structure. In a process known as “paste extrusion,” the powder is mixed with an organic plasticizer and compressed at 300–500 psi to make a preform or billet. The latter is extruded into filaments which are then dried to evaporate the lubricant. In another process, films are produced that are slit into strips of very small widths, which then are stretched and sintered. In yet another, tapes are extruded, which are converted to fibers by stretching while being twisted to a very small cross-sectional area.

Properties

The unique combination of properties, including chemical resistance, thermal oxidation resistance, high lubricity, electrical and thermal insulation, low flammability, and excellent weatherability, is derived primarily from two factors, namely, the molecular structure and the molecular weight of PTFE. The structure consists of a core chain of carbon atoms with a fluorine sheath, which essentially completely shields the core. The fluorine atoms are so tightly packed that steric interactions cause a slight rotation of the carbon chain from the normal planar zigzag to a helical conformation. This dense shield has a low surface energy and a very smooth surface with no side chains or imperfections. As a result, the interchain forces are low, and individual molecules are able to slide past each other with relative ease. Compared with other polymers, therefore, creep tends to be high.

The polymer chains pack themselves very closely and regularly to give cylindrical packing which consequently leads to very high crystallinity (~90%). The material has a high melting point which is about 330°C. The smooth surface when combined with low surface energy makes the surface so neutral that it resists sticking to any material. Accordingly, PTFE has the unique property of the lowest coefficient of friction (~0.007), with essentially no stick–slip character. The material has no affinity for water and, therefore, is totally hydrophobic.

The chemical inertness and the thermal stability of this polymer are so great that, in spite of its high price ($4–10/lb, depending on the resin type), it is used in chemical operations where drastic conditions exist and no other organic material is suitable. Its low friction allows it to be used as nonstick coating for metals, work surfaces, and cooking utensils. The polymer is regarded as biocompatible and tends to be well accepted by the body. This has allowed PTFE to be explored as a material for surgical implants.

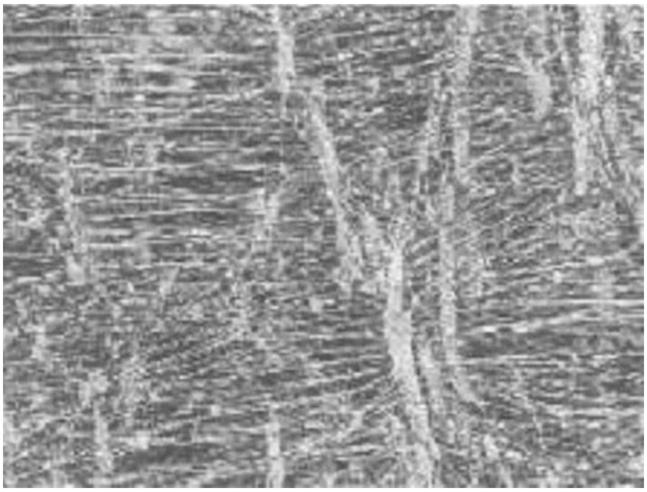


Fig. 12.27 Expanded PTFE micrograph (Microtex® Membrane at ×500) showing a porous structure containing nodes interconnected by fibrils (Courtesy of Menardi-MikroPul, LLC)

Expanded PTFE

In early 1970s, Dr. Robert W. Gore invented a process by which PTFE could be expanded and gave the trade name of Gore-Tex® to the product obtained. In this process, the specific gravity is reduced by the introduction of micropores, but much of the original properties of the polymer are retained. The new material is a hydrophobic but porous membrane of PTFE that is used as a protective layer in a number of applications.

In the process used, in general, a paste is formed of the PTFE polymer and a plasticizer and shaped into an article. It is then expanded by stretching in one or more directions, and while it is held in the stretched form, it is stabilized by heating to high temperature (~327°C) and cooling. The porosity that is produced by the process is retained in the final product [31]. The structure formed by the process consists of "nodes" and "fibrils." The nodes, that vary in size from 5 to 500 μm and are always found perpendicular to the direction of expansion, are interconnected by fibrils. This is seen in Fig. 12.27, which shows a micrograph of Mikrotex®, an expanded PTFE (ePTFE) product [32]. An ePTFE material may have as many as a billion or more randomly spaced pores per square centimeter. These pores are unique in size: they are three or more orders of magnitude smaller than the size of a water droplet but two or more orders of magnitude larger than a water vapor molecule. Thus, when used as a rain wear, the product allows the perspiration vapors to escape but blocks out the liquid water from penetrating. The product can likewise serve as a barrier against chemicals and microbes.

Glass and Carbon Fibers

Glass

Among the manufactured inorganic fibers, glass is produced in by far the largest volume. There has been a rapid increase in the use of glass fibers in both the textile and the industrial grades. Some of the key applications are in belts, air filters, thermal insulation (glass wool), and reinforced plastics.

Glass possesses obvious and well-known characteristics which have largely determined the methods used to form it into large objects. It flows readily when molten and can be drawn into filaments, whose extreme fineness appears to be limited only by the drawing speed. The method used in producing textile-grade glass fibers follows this principle (see Fig. 12.28).

In the commercial operation, the molten glass, produced either directly from raw materials or by remelting of marbles, is held at a uniform temperature in a vessel, whose bottom carries a bushing containing small uniform holes. The molten glass flows through these holes as tiny streams that are attenuated into filaments at speeds on the order of 3,000 m/min; these filaments are coated with a lubricant, gathered into groups to form yarns, and wound up. For a particular glass viscosity, the size of the individual filaments is determined by the combination of the hole size and the speed of attenuation. Because of the inherently high modulus of glass, very fine filaments are required in order to approach the required properties of textile materials. Thus, the diameter of glass filaments falls in the range of 3.8–7.6 μm, whereas the average diameter of the finest organic fibers is about twice as large. The fiber and yarn numbering system is based on nomenclature used in the glass industry and differs from the traditional systems accepted in the textile and organic fiber industries.

The method of manufacture of glass staple fibers differs from those used to produce the corresponding organic materials, all of which are based upon cutting the continuous-filament product. Air jets, directed in the same line of flow as the emerging streams of glass, attenuate the streams and break the solid glass into the lengths desired for further processing, which are gathered on an appropriate vacuum drum and delivered as slivers or a matte. To produce fibers that may be coarser and considerably less uniform in length, to be used for the production of filters, paper, or thermal insulation, large streams of molten glass are cross-blown by blasts of hot air, steam, or burning gas.

As might be expected from the nature of glass, the conversion of glass fibers into final products has required the development of new lubricants, finishes, and processing

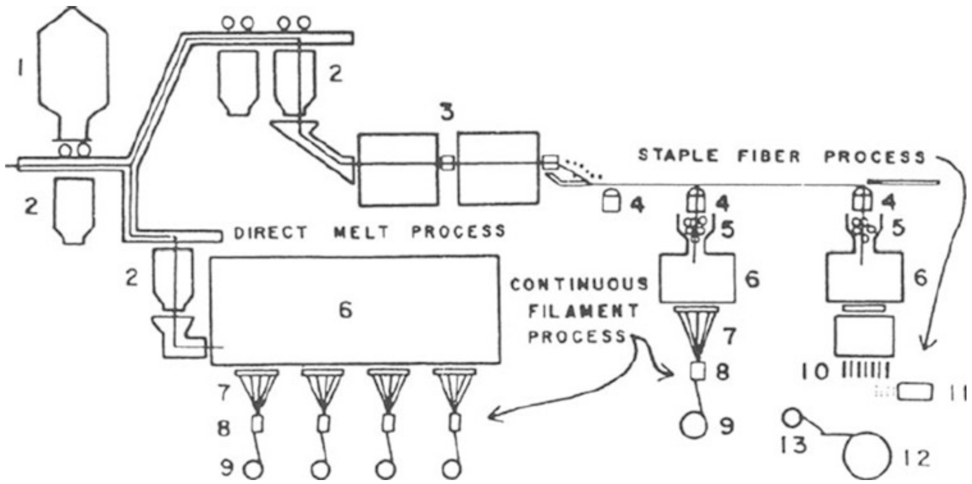

Fig. 12.28 Flow diagram for manufacture of textile glass fiber: (1) glass batch, (2) batch cans, (3) marble forming, (4) cullet cans, (5) marbles, (6) melting furnaces, (7) filament yarn formation, (8) gathering and sizing, (9) yarn packaging, (10) air jets, (11) lubricant spray, (12) collection for staple fibers, (13) staple fiber packaging (Courtesy of Owens Corning Fiberglass Corp.)

techniques. For example, because glass fabrics cannot be dyed directly or printed with the colors demanded for their acceptance as draperies, the colorant must be applied to a resin coating. But before applying the coating, it is necessary to remove the lubricant that was placed on the fibers to permit their conversion into a fabric, which is done by burning. The elevated temperature resulting from this operation also relaxes the internal strains developed in the glass fibers during the steps of the textile operations and sets the yarns in the required geometry. The fabric then is resin-treated, cured, and dyed or printed.

Another inherent property of glass is the tendency of unprotected fiber surfaces to abrade each other to destruction under the action of very little mechanical working. When it was first considered for rubber-reinforcing purposes, its poor adhesion to rubber and the inadequacy of the then-existing bonding agents frustrated attempts by manufacturers to take advantage of the very high tensile strength, completely elastic behavior, high modulus, and lack of moisture sensitivity of glass fibers. However, it has been possible to modify the fiber surfaces so that satisfactory adhesion is achievable, and the impregnant can be applied in such a way that fiber-to-fiber contact is prevented. With the adhesion problems solved, glass in cord form could effectively enter markets in belt-type tire construction and in all kinds of power-transmitting rubber belts. It is estimated that the total glass fiber production in the United States in 2000 was approximately 2.5 billion lb.

Carbon and Graphite Fibers

Following World War II, the development of jet aircraft and rockets created demands for fibers having thermal resistance, strength, and modulus far beyond what could be obtained in existing organic fibers. Much of this need was for reinforcing materials that could be embedded in matrices of one type or another. As a result, techniques have been developed for preparing fibers from a good many metals and refractory inorganic compounds. Although these materials are essential for certain uses, the volume of production still is low, and the prices are correspondingly high (as much as $1,000/lb).

Carbon and graphite fibers are made from rayon and acrylic precursors by driving off virtually all of the hydrogen and oxygen contained in them. The principle is essentially the same as that which brought about the formation of coal or, citing a more recently discovered and dramatic example, the conversion of the original wooden beams of buildings in Herculaneum, buried by a flow of mud from Vesuvius in AD 67, to what appears to be charcoal. In the present commercial process, the starting material is selected so as to produce a final product of the desired size and properties. Cotton, bamboo, and other natural fibers were the earliest materials used as precursors. In the 1950s, rayon was used for this purpose, but the first attempts led to fibers with poor strength. Union Carbide, in the mid-1960s, made the first strong carbon fiber from rayon and extended its work to using PAN as the precursor. The use of mesophase pitch as the starting material began in the 1970s. Carbon fibers may be divided into three types: (1) highly graphitized with a high modulus, (2) heat-treated at a lower temperature to produce fibers with lower modulus but high strength, and (3) randomly oriented crystallites with relatively low modulus, and low strength, but most importantly, low cost

The preparation of fibers generally consists of heat-treating the precursor at a low temperature (200–350°C), usually in air, which gives a stable fiber for higher temperature processing. During this step, extensive decomposition occurs, and a percentage of the initial weight is lost, which is related to the cleavage of the C–C and C=O bonds and expulsion of H_2O, CO, and CO_2 (additionally HCN in the case of PAN precursor) as gases. This step is followed by carbonization in an inert atmosphere at 1,000–2,000°C, which is said to collapse the cyclized structure into a stacked ring carbon fiber structure. Almost all noncarbon elements are removed as volatiles. This is followed by graphitization, which usually is carried out at temperatures above 2,500°C for short periods in argon or nitrogen. The process increases the purity, removes the defects, and further improves the order in the structure. Thus, the difference between the so-called carbon and graphite fibers lies in differences in the ranges of temperatures at which the last step is carried out, the degree of carbon content (97% for carbon and 99.6% for graphite), and the mechanical properties, which are superior in the graphite fibers. In usual discussions, the term "carbon fibers" covers both materials. The majority of carbon fibers produced today are made from a PAN precursor. PAN fibers are finer and have a higher degree of molecular order and a higher decomposition point than those from rayon. This precursor also leads to a greater carbon yield (45%, as opposed to 24% from rayon), but the fibers are more expensive to produce than those based on rayon. Recent commercial developments have allowed the production of carbon fibers from low-cost petroleum or coal-tar pitch, instead of synthetic fibers. These precursors lead to a higher yield (90%) of carbon, improved lubricity of fiber products, and higher production rates. However, the pitch-based fibers may be more brittle and harder to handle, have a higher specific gravity (2.0, as opposed to 1.8 for those from PAN and 1.66 from rayon) and lower compatibility with some matrix materials.

The fibers have a diversity of applications. One major application is in composites, where they are used for reinforcing resins and metals to provide structural materials with high strength, high modulus, and lightweight. The resulting composites are used in the aircraft and aerospace (the largest users), automotive, and sports industries. The fibers also find uses in protective garments, electrical devices, insulation, and filtration. The use of the fibers in the world was about 25 million lb in 2000. The prices dropped significantly during the past decades, but in 2000, the majority remained in the $15–70/lb range. The price of the ultra high modulus carbon fibers, however, can be as high as $1,500/lb or greater.

Sulfar

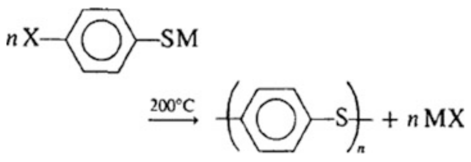
Historical

Sulfar fibers are extruded from poly(phenylene sulfide) or PPS by the melt-spinning process. The first PPS polymer was made in 1897 by the Friedel–Crafts reaction of sulfur and benzene. Researchers at Dow Chemical, in the early 1950s, succeeded in producing high-molecular-weight linear PPS by means of the Ullmann condensation of alkali metal salts of *p*-bromothiophenol.

In 1973, Phillips Petroleum Company introduced linear and branched products under the trade name Ryton® by reacting 1,4-dichlorobezene with sodium sulfide in a dipolar aprotic solvent. In 1983, the same company succeeded in stable melt spinning of PPS. In 1986, the Federal Trade Commission gave the fiber the generic name sulfar, defined as "a manufactured fiber in which the fiber forming substance is a long chain synthetic polysulfide in which at least 85% of the sulfide (–S–) linkages are attached directly to two aromatic rings."

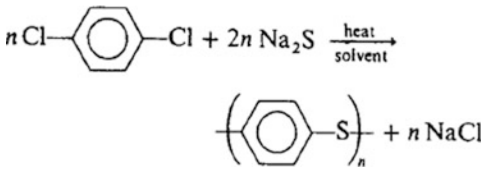
Manufacture

In one process, synthesis was carried out by self-condensation of a metal salt of a *p*-halothiophenol



where *X* is a halogen, preferably Br, and *M* is a metal (Na, Li, K, or Cu, preferably Cu). This reaction was carried out under nitrogen in the solid state or in the presence of materials such as pyridine as reaction media. Considerable difficulty was encountered in removing the by-product, copper bromide, from polymers made by this process. The current commercial synthesis of the polymer is carried out by reaction between *p*-dichlorobenzene and sodium sulfide in a polar solvent.

The process discovered by workers in the laboratories of Phillips Petroleum Co. marked a significant departure from prior processes and made it possible to prepare a variety of arylene sulfide polymers from the readily available starting materials [33].



Melt spinning of PPS involves problems such as plugging of the filter and the spinnerette. In order to prevent cross-linking and gel formation during the process of spinning, the company introduced cure retarders comprising group IIA or group IIB metal salts of fatty acids, which improved the heat stability of PPS:

$$(CH_3(CH_2)_nCOO-)_2M,$$

where M is a group IIA or IIB metal and n is an integer from 8 to 18. Representative compounds of the type described above include calcium stearate, calcium laurate, calcium caparate, and calcium palmitate. In general, the cure-retardant additives are employed in an amount within the range, of about 0.1–5, preferably about 0.5–2, weight percent based on the weight of the PPS.

Sulfar fibers, sold under the trade name Ryton® in the United States, are characterized by high heat resistance, inherent flame retardancy, excellent chemical resistance, low friction coefficient, good abrasion resistance, and good electrical properties [34]. Physical characteristics include medium tenacity (3.5 g force/denier or 423 MPa) and elongation (25–40%) and low shrinkage (<5% at 100°C). The fibers find application in a number of industrial products, including filter fabric for coal-fired boiler bag houses, paper maker's felts, materials for electrical insulation, high-performance composites, gaskets, and packings.

Several Japanese and European companies have begun the production of PPS, some with a U.S. partner. The new decade should see the introduction of a number of new fibers and fiber products based on the PPS polymer.

Microdenier Fibers

One of the more important developments in the field of fiber technology in recent years has been the production of fine denier fibers, with worldwide activity in developing new products and applications for them. Improvements in the quality of polymers, coupled with new technology for extrusion of fibers, have led to the production of fibers with sizes ranging from 1 to 0.1 denier or even lower. Fabrics produced from such fibers have novel and unique properties, and they are finding applications in a wide variety of apparel, and industrial products, including high-fashion fabrics with silk-like texture, synthetic suede, breathable porous but rainproof or bacteria-proof fabrics, wipes for oil and other spills, clean room materials, and cloths for cleaning camera, microscope, and spectacle lenses and compact discs.

Unfortunately, there is no universally accepted definition for microdenier, and companies have been free to use terms they choose. In general, there seems to be a consensus that the term "fine" may be used for a denier of 1 or less and "micro" for a denier less than 0.5. The production of such fibers is difficult and expensive because the throughput rate must be reduced in order to obtain fine denier filaments, and there is a limit to how fine in denier a regular process could be made to go. Generally, the technology of production of fine and microdenier filaments can be divided into five categories. First, conventional spinning technology can be used by using fine-size dies and adjusting the throughput rate and quenching and drawing parameters to obtain fine denier polyester filaments. This method has been used by most fiber manufacturers to produce such fibers in limited quantities. In another method, alkali reduction or surface etching is used to dissolve the surface layers, in an effort to reduce the cross-sectional size of filaments in a polyester fabric. A weight loss of as much as 25% has been achieved by this process. In the MB process, molten polymer is forced through a melt-blowing die and die-tip orifices, and the emerging stream is attenuated by a jet of high-velocity hot air until broken. Then the broken fiber is forced into a stream of cold air, where the fiber solidifies. The fiber is collected on a wire screen or apron with other fibers, and a homogeneous MB web is produced. This method is used extensively with PP materials, but other polymers such as nylon, polyester, and polyethylene also have been used. Fibers as fine as 0.5 μm and finer have been produced.

In another approach, filaments containing two polymers that do not adhere to each other are spun and then split. One may, for example, spin a bicomponent fiber of nylon that has several filaments of polyester embedded. After a fabric containing bicomponent filaments has been woven, it is treated to split the components, thus converting the original filament into several smaller filaments. Deniers of the order of 0.1 can be achieved by this ingenious method. In the last method, instead of splitting the two components as in the previous example, one component is dissolved away chemically, leaving bundles of very fine fibers in the fabric.

The majority of the technology for producing fine and microdenier fibers is new and thus expensive, so efforts in the future can be expected to be directed toward optimizing process parameters in existing methods and discovering faster and cheaper methods for manufacturing these esthetically attractive and functionally very promising fibers.

Nanofibers

An extreme example of the microdenier-size fibers discussed above is the nanofibers that are one or more orders of magnitude smaller in diameter. The fiber with diameter at submicron or nanometer level is spun by a process known as electrospinning, in which the fiber is spun in a field involving high electrostatic forces [35].

The electrospinning setup essentially consists of a capillary tube or a needle attached to a syringe filled with a polymer solution or melt, a grounded collector screen, and a high-voltage power supply (Fig. 12.29). The collector

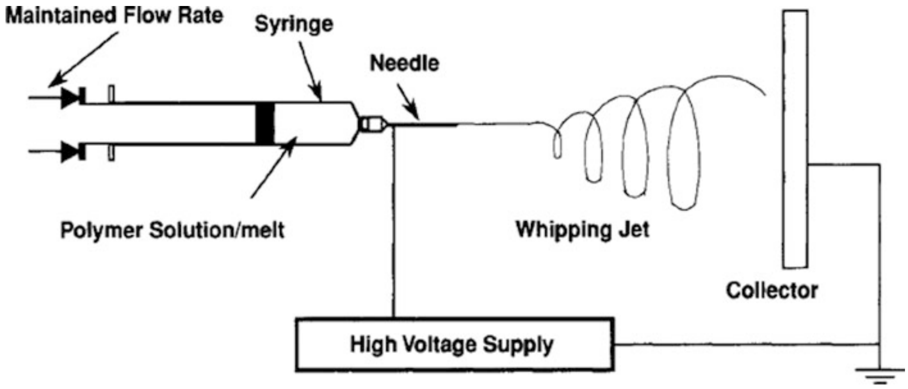


Fig. 12.29 Electrospinning setup in horizontal configuration

typically is a metal plate, an aluminum foil, or a metal grid. Other forms of the collector, such as a rotating drum, have been used. When the potential (1–30 kV) is applied, the pendant droplet at the end of the needle becomes charged, and two opposite forces, namely, the surface tension of the droplet itself and the electrostatic force due to applied field, act on it. As the potential is increased, at a certain point, electrostatic force overcomes the surface tension of the droplet, and a cone-like structure, commonly known as a "Taylor cone," is formed at the tip of the droplet, and a jet of polymer solution or melt emanates from it which is accelerated toward the collector [36]. In this process, the polymer jet gets drawn to submicron level while the solvent evaporates or the melt cools down to form the fibers that deposit on the collector and form a nonwoven web.

The electrospun nanofiber webs, with very high surface area to volume ratio and high porosity with interconnected pore networks, have been explored for applications in a number of highly specialized areas such as the scaffolding for tissue engineering, wound dressing, drug delivery, nanosensors, and nanoelectronics. More than 50 different polymers have been electrospun successfully in a solution or melt form that include synthetic nondegradable (polyesters, polyamides, polyurethanes, polycarbonates, etc.), natural (collagen, elastin, chitosan, silk, etc.), and synthetic biodegradable (polyglycolic acid, polycaprolactone, polylactic acid, polylactide-*co*-glycolide, etc.) polymers [37].

Fiber Variants

Introduction

In a previous section, data and plots were given showing the rapid rise in consumption and production of commonly used manufactured textile fibers at the expense of natural fibers. The principal reason for this has been the wide range of manufactured fiber variants that can be produced from a single fiber-forming polymer. The wide range of polymers available, each with its particular properties, adds yet another dimension. This is not to say that there is only one type of cotton, wool, silk, or asbestos fiber; there are many varieties of natural fibers, but their supply is limited by natural factors such as climate and genetics. The relative availabilities of manufactured fiber types can be altered by controlled chemical process changes, whereas the amount and the quality of a desired cotton type that can be grown is determined to a great extent by climatic conditions, which humans have not yet learned to control. Another factor that has aided the growth of manufactured fibers is their consistent quality and properties. Again, the grade and the quality of natural fibers are subject to the vagaries of nature.

For the purposes of this discussion, fiber variants will be divided into two types: chemical and physical. Chemical variants will be those involving a small but significant change in composition, whereas physical changes will be those involving a change in either the dimensions of the fiber or its stress/strain or stability features. The definitions of the two variants also could be based on modification of either esthetics or functionality.

Physical Variants

Most manufactured fibers are available as staple, tow, and filament. Natural fibers are available only in the characteristic forms in which they occur, with filament silk and cotton staple as examples. All manufactured fibers are formed initially as filament yarns. The German adjective *endlos* (literally translated "endless") is very descriptive, as filament yarns are continuous strands consisting of one or more members that for most practical purposes are infinite in length. Fine filament yarns (40–100 denier) are used in producing lightweight apparel fabrics, whereas coarse filament yarns (800–1,200 denier) are found as reinforcement in tires or conveyor belts. These examples are chosen as extremes to show the range or applicability of manufactured fibers and represent only a small fraction of the actual range of end uses.

When many filament yarns are collected into a bundle immediately after formation, the resulting structure is called a tow. Tows may range from 10,000 to over a million in total denier. In a next step, the tow may be crimped by the process previously described, which imparts what is usually a sawtooth appearance along the length of all the filaments. For some end uses, the crimped tow itself is provided by the fiber maker, as are, for example, the previously discussed acrylic tows, which are converted to staple as part of the spinning of yarns with a woollike character. Another example is the cellulose acetate tows used to form cigarette filters or the ink reservoirs for marker pens. In the latter case, the compact tow bundle first is treated to separate the individual filaments, giving a voluminous structure, which then is gathered into a continuous rod, wrapped in paper, and cut into appropriate lengths.

In the fiber-making plant, tow may be cut into short lengths of staple, ranging in length from $\frac{1}{16}$ to 6 in., depending upon the end use. For instance, the very short staples are used either in making flocked structures or in the production of papers containing blends of natural cellulose and manufactured fiber. The longest lengths are used in spinning heavy yarns for carpets or cordage. But most staple is $1\frac{1}{2} - - 3$ in. length and is used to form blends with cotton, rayon, or wool in the yarns employed in standard apparel fabrics. The staple length of the manufactured fiber is chosen to match that of the other blend component; otherwise, uneven yarn of poor quality results.

The size of a manufactured fiber can be altered by changing the size of the hole through which it is extruded and maintaining a constant take-up speed. Commercial fibers range from about 1.25 to 25 denier, corresponding to average diameters of about 5–50 μm. The very large ones would be used to make doll's hair or wigs, but the majority of manufactured fiber staples are made in the 1.5–6.0 denier range, corresponding to cotton-blending fiber at the low denier end and coarse-wool-blending fiber at the high end. Staple and filament yarns used in carpets are in the 12–16 denier range, whereas industrial filament yarns such as tire cord are about 6 denier per filament. The size of a fiber is a determinant of its stiffness, which in turn influences the draping, quality, and the surface feel (often called hand in the textile industry) of a fabric made from it.

Although fibers normally are extruded through circular jet holes, the use of noncircular holes in the jets has led to the availability of a wide variety of cross-sectional shapes. In the case of fibers dry- or wet-spun from solutions, most of the mass exiting from the jet hole is not the polymer. For example, cellulose acetate fiber is made from a 25% solution of cellulose acetate in acetone containing a small amount of water. After the fiber leaves the jet face, solvent begins to evaporate, and as a result, the area of the fiber cross section decreases. The final result is a fiber of roughly circular cross section, but with a serrated edge, and much smaller in area than the parent jet hole. When cellulose acetate is extruded through a triangular jet hole, the end result is a fiber of "Y" cross section due to shrinkage from the original triangular shape.

In the melt-spinning process, there is no solvent loss to influence final cross-sectional shape. In the case of a triangular jet hole in melt spinning, the molten fiber leaves the jet face with a triangular cross section but, being molten, immediately tends to return to a circular cross section due to surface tension forces. It is necessary, therefore, to quench or cool the fiber as soon as possible in order to maintain the desired cross-sectional definition. Some loss of this definition is unavoidable during the drawing step that normally follows extrusion in a melt-spinning process.

Fibers of noncircular cross section can modify and change both functional and esthetic properties in textile structures. The triangular cross section is typical in those respects; its shape leads to a stiffer fiber than circular fiber of the same cross-sectional area, and in a fabric, this results in less drapability and a crisper surface feel. Also, the flat surfaces reflect light in a different way than do curved surfaces and can create desirable lustrous effects. These optical effects are subject to many subtle influences having to do with the size of the reflecting surface and the amount of internal reflection that takes place. Triangular or "Y" cross-sectional fibers have greater specific surface areas per unit weight than their circular counterparts, which accounts for their use in aerosol filtration, where surface area is a major factor in efficiency. Yarns made with triangular cross section fibers are more voluminous than those from round cross section fibers. Thus, when the two types are made into fabrics of equal weight, the variant cross-sectional fabric will transmit less light and be less permeable to air than that made with round cross section fibers. In the spinning of blended staple yarns, maximum strength is obtained if the blend components have similar load/elongation characteristics. The stiffness of polyester staple fibers can be varied mainly by changing the draw ratio used to orient the fiber after extrusion and thus producing fibers suitable for blending with cotton, rayon, acrylic, or wool fibers, which possess markedly different properties. In many industrial applications, fibers and yarns are used under conditions where they bear a load while hot, as, for example, in tires and power transmission belts, where it is important that they do not grow or stretch significantly under these conditions. Accordingly, industrial yarns are drawn to a greater extent than other yarns to reduce as much as possible the stretch of the final products. Relatively, these yarns have high strengths, high stiffnesses, and low elongations at rupture.

Although in most instances it is desirable to have fibers that are dimensionally stable, in some structures, it is advantageous to use mixtures of fibers that are stable with fibers that do shrink upon exposure to heat or steam. High shrinkage potential usually is built into a fiber by stretching it and not giving it a stabilization treatment. The yarn bulking that occurs with blend yarns of high- and low-shrinkage acrylic staples has already been described in the section on that fiber. Using the same principle, feltlike structures can be made by heat treatment of nonwoven battings containing low- and high-shrink staple.

Chemical Variants

The use of titanium dioxide as an additive in the delustering or dulling of manufactured fibers was discussed in the section on viscose rayon. The addition of pigment particles influences the processing and performance of the fiber, along with changing its appearance. Because of the whiteness of the delustered fiber, it requires more dyestuff to reach a given shade than that needed in the case of a bright fiber. The sliding friction of a delustered fiber is lower because the pigment particles protruding from the fiber surface reduce the contact area between a fiber and the surface it slides against—a guide, for example. By the same token, some pigments can accelerate the wear of contacted surfaces. It has been suggested that the drawing and consequent orientation of delustered fibers proceeds more smoothly because the pigment particles act as nucleation sites where molecular motion is initiated. Unless specially treated, the surface of anatase—one of the crystalline forms of titanium dioxide—can accelerate the ultraviolet light degradation of acetate or nylon fibers. It is postulated that the crystal surface catalyzes the formation of peroxides from the water and oxygen under the influence of ultraviolet light, and that peroxides are the active species in the resulting polymer degradation. For this reason, rutile—the other common crystalline form of titanium dioxide—is used to deluster fibers when improved sunlight resistance is needed.

The degree of polymerization or the molecular weight of the polymers on which manufactured fibers are based can be controlled as part of one of the early steps in the process. The polymer molecular weight chosen for a fiber has a strong influence on process economics, ease of conversion to fiber, and end-use performance. Commercially acceptable fibers are based on the best balance of these factors. However, in fabrics that are open in texture and made from standard polyester staple spun yarns of low twist, a condition known as "pilling" will develop as a result of wearing. The pills are made up of fiber ends that have worked loose from the yarn bundles as a result of surface rubbing and have wrapped around themselves. In the case of fabrics from natural fibers, which are generally less wear resistant than manufactured fibers, these pills or fiber bundles will be lost by attrition with continuing wear. Because the wear resistance of a manufactured fiber is related to its molecular weight in a general way, the pilling tendency of a polyester staple can be reduced by lowering its degree of polymerization. This compromises the tensile characteristics of the fiber only to a small extent, and all the other desirable properties such as minimum care characteristics are essentially unaffected. When the molecular weight of a polyester or a nylon polymer is increased above the standard, the resultant fibers will have increased tensile properties and fatigue resistance. The filament polyester and the nylon yarns used in end products such as tires and conveyor belts are based on such polymers.

The technology for "dope dyeing" or mass coloration of fiber as part of the fiber manufacturing operation was described in the sections on viscose rayon and cellulose acetate. The use of this technology has decreased largely because of problems of profitably managing the required inventory of colors in rapidly changing fashion markets, and for this reason, it is used extensively only if the fiber cannot be dyed by any other means. PP fiber for use in outdoor carpets is a good example of such a situation. However, if one regards "white" as a color, one finds that a substantial portion of the polyester staple fiber produced for blending with cotton or rayon contains an optical brightener or a fluorescing agent. This is needed to overcome the yellowing tendency of polyester following the absorption of hydrophobic soils. The cotton or rayon fibers in a blend are continually rewhitened by the fluorescing agents added to laundry detergents for that purpose, but these agents are without effect on the polyester blend component. Because the polyester component usually is at least half of the blend, the spun-in optical brightener it contains is vital for the maintenance of overall whiteness.

In the cases of polyester, nylon, and acrylic fibers, their manufacturers have developed fiber variants with a wide range of dyeing behavior referred to as dye variant fibers. Polyester fibers usually are dyed with what are described as disperse dyes. These dyes are only slightly soluble in boiling water and are used in the form of dispersions. The dye in aqueous solution is assumed to be in monomolecular form and is absorbed from the dyebath into the polyester fiber by a process often called solid solutioning. As this occurs, more solid dye is dissolved to replenish that entering the fiber. The overall rate of dyeing is a very complex phenomenon but in part is determined by the molecular structure of the fiber through which the dye must diffuse. Generally, the more that the polymer molecules have been organized by drawing and annealing into more geometrically perfect domains or crystallites, the slower is the dyeing rate. The ability of the molecules to be thus organized into compact ordered structures can be reduced by polymerizing a small amount of a foreign dibasic acid or glycol into the polymer. Usually, 5–10 mol% is sufficient to prevent this regularity. Adipic acid, isophthalic acid, and polyethylene glycols are used to produce some of the comonomers for fast- or deep-dyeing polyesters. In this way, these fibers are made more economical to dye or print because special dyebath additives, high dyeing temperatures, and high-pressure steam-print fixation usually are not required.

Polyester fibers can be given an additional mechanism for dyeing if an ionic comonomer is added during polymerization. A common additive is an alkali metal salt of dimethyl-5-sulfo-isophthalate, which gives sulfonic (anionic) groups as part of the polymer structure. These groups allow the fiber to absorb basic (cationic) dyes by a specific ionic mechanism. The amount of cationic dye that can be absorbed by the fiber is stoichiometrically related to the number of anionic sites present in the fiber; this is quite distinct from the general solid solutioning that takes place with disperse dyes and polyester. A cationic dyeable polyester is useful for two main reasons in fabric coloration. First, cationic dyes give brighter, clearer shades than disperse dyes, and this can be important for both solid-dyed shades and prints during ever-changing fashion cycles. Second, fabrics containing arrangements of unmodified and cationic dyeable polyesters can be dyed in the piece to a variety of color/white combinations by selection of dyestuffs, as day-to-day changes in demand may require. This is more economical than dyeing yarns to different colors, holding them in inventory, and then weaving them into fabrics, if and when they are required.

Nylon 66 can be dyed either with disperse dyes or with acid (anionic) dyes, the former carried out by essentially the same steps as described above for polyester, except that nylon absorbs these dyes much more readily. The ability of nylon to absorb acid (anionic) dyes is the result of a significant number of accessible free amine (cationic) end groups being present in the polymer. The dyeing of nylon with acid dyes is analogous to the dyeing of wool or to the dyeing of modified polyester with basic dyes, except that the polarities of the interacting groups are reversed in the latter case.

For best fastness to light and washing, nylon 66 is dyed with acid dyes, and nylon dye variants thus are based on manipulation of the level of acid dye uptake. By adding a monobasic acid such as acetic acid to the reaction mix near the end of the polymerization process, the amino end groups are converted to amide groups which have no affinity for acid dyes under normal dyeing conditions. This technique creates light acid dyeing or acid reserve dye variants that can have some capacity to absorb basic dyes at the carboxyl end groups. Nylon dye variants with increased acid dye uptake can be made by using a slight excess of diamine in the polymerization. In this way, there are no free carboxylic acid end groups. Nylon dye variants have found the greatest acceptance in floor coverings where attractive patterns can be piece-dyed using controlled dyebath conditions and selected acid dyestuffs.

Acrylic fibers are dyed most frequently with basic dyes. This is made possible by copolymerizing acrylonitrile with an acidic monomer such as styrene-*para*-sulfonic acid. Acrylic fiber suitable for acid dyeing can be made by using a basic comonomer such as a vinyl pyridine or a vinyl pyrrolidone.

Fibers not having inherent flame resistance often can be given this property by incorporation of a suitable additive. This may be done by copolymerization of the additive into the polymer reaction of the additive with the polymer after polymerization or by applying a polymeric or monomeric noninflammable finish to the surface as a coating. These additives usually contain bromine, nitrogen, or phosphorus or a combination of these elements. Great care must be taken in choosing the additive and its level of addition in order to prevent loss of other desirable fiber properties and to avoid any harmful effects to processors or ultimate consumers.

A wide variety of special durable surface treatments have been used on manufactured fibers. These include treatments for imparting such characteristics as soil resistance, antistatic behavior, and wearer comfort through moisture wicking and transport. Fiber finishes also have been used successfully in promoting adhesion between two materials, as, for example, between polyester tire cord and rubber, and between glass fiber and polyester resin.

Polymers, Fibers, and Textiles in Medicine

Introduction

Over the past six decades, polymers, fibers, and fabrics have found numerous applications in medicine. Starting from their use as sutures over 4,000 years ago to their application as arterial, skin, hernia repair meshes, and other prostheses in the present century, fibrous materials continue to be selected and explored for new and novel products in the healthcare field. This trend has its basis in a fiber's ability to be modified chemically and physically and easily converted into a wide array of desired end products. Textiles are unique materials with unique properties. They are known to be lightweight and flexible, and, what is commonly not realized is that on a weight-to-weight basis, they are very strong, that is, usually two or more times stronger than steel. Since the majority of fibers are extruded products of synthetic or regenerated polymers, they can be manufactured in different cross-sectional shapes and sizes to meet the design needs of different applications. In addition, a given polymer can be alloyed with another material and/or chemically or physically modified to further vary its characteristics. Accordingly, because of the outstanding inherent properties of fibrous polymers, essentially unlimited potential one has for tailoring their behaviors, and those of several different types of assembly structures made from them, textiles have been sought for designing and used in manufacturing a wide range of medical products.

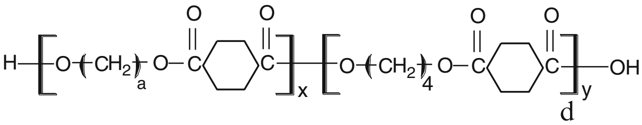
Examples of Medical Products and Fibers Used to Produce Them

Broadly, the medical products available include absorbent materials for blood and other fluids resulting from injury, surgery, or incontinence (cotton, rayon); protective gowns, masks, and covers for patients, nurses, and doctors (cotton, polyester, polyolefin); dressings and bandages for caring for and managing wounds (cotton, rayon, chitosan, alginate); fabrics for repair of fractures and rehabilitation of injured (fiber glass, polyester, polyolefin, cotton); and, most noteworthy, many different types of implants, which include sutures and ligatures for closing wounds and prostheses for replacing or bypassing injured or failing organs. Polymer-based fibers and textiles are particularly suited for making implants as body tissues are themselves polymers and have structures and properties that closely match those found in fibers. Among the implants, some relatively well known are surgical sutures (PET or polyester, polypropylene, ePTFE, nylon, polybutester, and the aliphatic or biodegradable polyesters, mentioned and discussed in the next section), arterial and stent grafts (polyester, ePTFE), hernia and prolapsed repair meshes (polypropylene, polyester), and tendon and ligament prostheses (polyester). The examples of products given are of textile-based structures that must be largely flexible and able to stretch, bend, and twist. Used as implants are also strictly polymer-based devices such as those used for correcting vision (ocular lenses), filtering blood (in kidney dialysis devices), and repairing or replacing joints and bones. Additionally, fibrous polymers have drawn interest for use as scaffolds for engineering tissues.

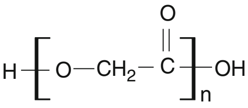
Special Fibers Developed Primarily for Use in Medicine

Clearly, many different types of fibers (natural and manufactured) have been used in medicine, some of these (manufactured) have already been covered in detail earlier in this chapter. There are several others that are more specific to medicine and were in fact largely developed for this application. These, along with their chemical structures, are listed below. Out of these, the first six are polyesters and the last two polysaccharides. Of these, the first, that is, polybutester, is an aromatic block copolymer, which is nonabsorbable and has properties that are a compromise between fibers and elastomers. The next five (polyglycolic acid, polylactic acid, polyglactin, polydiaxanone, and polycarbonate) are aliphatic and biodegradable. The intermolecular links being weak and the molecular weights being low, these materials break down by the hydrolytic processes in the body and get absorbed. Some (e.g., PGA) are absorbed faster while some others (e.g., polyglyconate) are absorbed more slowly, the rate controlled by the chemical constitution, molecular weight, and the degree of packing [38–41]. Although these materials were initially developed for use as biodegradable sutures, they are now also being explored in constructing implant devices. The general idea behind this trend being that as the material biodegrades, the natural tissues will infiltrate and fill the void, leading to a shaped biological implant. The exploratory work along this direction is continuing with some success [42, 43].

Polybutester (Novafil):

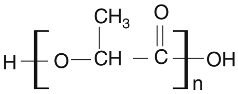


PGA (Dexon):



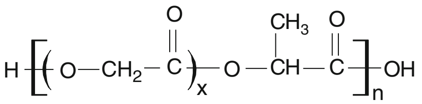
$$\mathrm{H}\left[\mathrm{O}-\mathrm{CH_2}-\overset{\overset{\displaystyle \mathrm{O}}{\|}}{\mathrm{C}}\right]_n\mathrm{OH}$$

PLA:



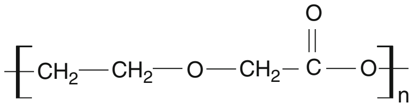
$$\mathrm{H}\left[\mathrm{O}-\overset{\overset{\displaystyle \mathrm{CH_3}}{|}}{\mathrm{CH}}-\overset{\overset{\displaystyle \mathrm{O}}{\|}}{\mathrm{C}}\right]_n\mathrm{OH}$$

Polyglactin acid (Vicryl):



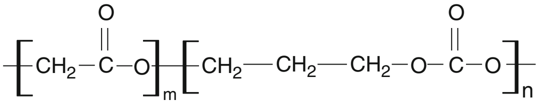
$$H\left[\left(O-CH_2-\overset{\overset{O}{\|}}{C}\right)_x-O-\overset{\overset{CH_3}{|}}{CH}-\overset{\overset{O}{\|}}{C}\right]_n OH$$

Polydiaxanone (Maxon):



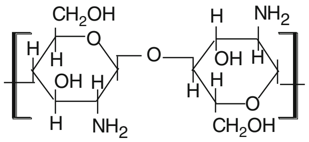
$$\left[CH_2-CH_2-O-CH_2-\overset{\overset{O}{\|}}{C}-O\right]_n$$

Polyglyconate (Maxon):

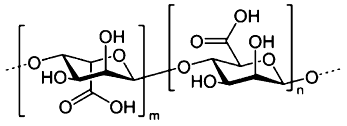


$$\left[CH_2-\overset{\overset{O}{\|}}{C}-O\right]_m\left[CH_2-CH_2-CH_2-O-\overset{\overset{O}{\|}}{C}-O\right]_n$$

Chitosan:



Alginate:



The last two materials in the above list, that is, chitosan and alginate, are polysaccharides. Both, derived from natural polymer sources and biodegradable, are primarily used as wound dressings for complex or bleeding wounds. Chitosan is made from chitin by converting the pendant acetyl group into amino group with a degree of substitution of about 80%. This conversion makes the material highly reactive and soluble. Due to its high hemostatic nature and ability to promote healing, chitosan has been considered as a material of choice for dressings for bleeding wounds [44]. Alginate, which is a block copolymer of mannuronic and glucuronic acids, is derived from seaweeds. Sodium alginate, extracted from the crushed and washed raw material, is solubilized in water and extruded into a calcium bath to produce calcium alginate fiber. When a product, such as a web, comes into contact with blood or body exudates, the sodium ions replace the calcium ions, which makes the material highly absorbent and soluble [45]. Desirable healing and antimicrobial compounds could be incorporated during the production of the fiber. Accordingly, a primary use of the material is in dressings for exuding and contaminated wounds.

Assembly Structures Used in Implants

The textiles used in body are in the form of either one-dimensional structures (threads), plane or two-dimensional structures (sheets), or three-dimensional structures (primarily tubes) [46]. The first, or the thread, is usually braided and used as a suture or ligature. The plane sheet (woven, knitted, or braided) is used as a patch or skin graft, a part of hernia or prolapsed repair device, cover for sewing ring for heart valve, and base material for developing other products (e.g., heart sac) that require a flexible and porous textiles but for which a tubular structure will not serve the purpose. The tubular structure (produced primarily by weaving or warp knitting) is used as a bypass or stent graft for alleviating blood flow disorders in natural vessels. Such tubular devices could be straight, bifurcated, or even trifurcated, depending on the region where corrective action is required. Except the suture or ligature materials, the other textile products are generally required to be porous for healing. The porosity in a fabric is determined by the size of the thread used in constructing the fabric and the thread counts in the long and the cross directions of the fabric. If the constituent thread is a multifilament yarn, then the porosity can also be influenced by the size of the fiber and the bulk given to the yarn, such as by a texturizing process. In ePTFE materials, porosity is greatly influenced by the heating and the stretching conditions used in forming the product.

A vast majority of the textile implants are made by the conventional technologies of weaving, knitting, and braiding, which produce desirably flexible (for conformation and comfort) and porous (for tissue integration and healing) structures. In some applications, however, such as the lenses used for correcting vision and the dental products, tissue integration is not required. For such uses, a molded or machine-shaped product could be made directly from a polymer.

Acknowledgements The author gratefully acknowledges the assistance he has received from associates both from within the College of Textiles and from outside, including several fiber-producing companies, in preparing this chapter.

Introduction

Dyeing

It is difficult if not impossible to determine when mankind first systematically applied color to a textile substrate. The first colored fabrics were probably nonwoven felts painted in imitation of animal skins. The first dyeings were probably actually little more than stains from the juice of berries. Ancient Greek writers described painted fabrics worn by the tribes of Asia Minor. But just where did the ancient craft have its origins? Was there one original birthplace or were there a number of simultaneous beginnings around the world?

Although it is difficult to determine just when each respective civilization began to use dyes, it is possible to date textile fragments and temple paintings, which have survived the ensuing centuries. The ancient Egyptians wove linen as early as 5000 BC, and paintings on tomb walls infer that colored wall hangings were in use by 3000 BC. By 2500 BC, dyer's thistle and safflower were used to produce red and yellow shades. Egyptian dyers developed a full range of colors by 1450 BC.

Another cradle of civilization was the Indian subcontinent where religious and social records dating to 2500 BC refer to dyed silk and woven brocades of dyed yarn. Cotton, first cultivated in the Indus valley of Pakistan was woven as early as 2000 BC. A book written around 300 BC included a chapter on dyes. It is believed that systematic dyeing occurred in China as early as 3000 BC near the city of Xian in the Huang (Yellow) River Valley, although there is no conclusive proof. Empress Si-Ling-Chi is credited with the discovery of silk about 2640 BC. Kermes and indigo were used as dyes as early as 2000 BC. Fragments of silk have been found in the corrosive patina of bronze swords of the Shang dynasty (1523–1027 BC), but most assuredly these samples are not the oldest [1].

The New World was similarly active in developing the textile art. With help from the desert climate in the high Andes of Peru, dyed samples of wool have been preserved and recovered from burial sites. These fragments have been dated to the millennium before the Christian era. The western and southwestern regions of the United States provided homes for the Anasazi, or ancient ones, who dwelt in the region of Mesa Verde National Park in southwestern Colorado, northern Arizona and New Mexico, and eastern Utah. Again the dry climate has helped to preserve samples from these early civilizations.

Very little in the nature of large, intact textile samples has survived in Europe. Remains of a large woolen robe, the Thorsberg Robe, found in northern Germany and dated prior to 750 BC, indicate a highly developed dyeing and weaving technology [2]. Indirect evidence is more plentiful: for example, a tombstone of a purpurarius, a Roman purple dyer, was found near Parma, northern Italy, and a dyer's workshop excavated in Pompeii. This great center of the Roman Empire was destroyed by the eruption of Mount Vesuvius in 79 AD. Similar stone vats for dyeing have been excavated in the tells of Israel and in present-day Turkey.

The Dark Ages following the fall of the Roman Empire were dark indeed, with little development of the dyer's art. The robes of a number of the monastic orders were brown and black, surely a dark age. By the end of the 1300s, however, civilization began making the swift and certain strides that have led to our present level of development. In 1371, the dyers of Florence, a city famous for its Renaissance art, formed a guild, or association of like merchants and craftsmen, which lasted for 11 years. Other guilds were being formed in other centers across Europe. Some of these guilds exist to this day. The Worshipful Company of Dyers was formed in 1471 in London. One of the legacies of this guild is a Publications Trust, which has underwritten the

publication of a number of books on dyeing in cooperation with The Society of Dyers and Colourists (SDC).

The art and craft of dyeing was largely passed down from father to son or from craftsman to apprentice by word of mouth and example until the early 1500s. The *Plictho* of Gioanventura Rosetti, a Venetian armory superintendent, is believed to be the first published book on dyeing. It certainly is the oldest surviving European text to have come down to us in the twenty-first century. Five known Italian editions were published between 1548 and 1672. A French edition appeared in 1716. It is interesting that no known English translation was made until 1968 [3] when Sidney Edelstein of the Dexter Chemical Company and Hector Borghetty collaborated to reproduce a facsimile of the original 1548 edition along with a complete translation into English. During his extensive travels, Rosetti collected dyeing recipes and processes used in the flourishing city states of Venice, Genoa, and Florence. He published: *Plictho de L'arte de Tentori che insegna tenger pani telle banbasi et sede si per larthe magiore come per la comune* or *Instructions in the Art of the Dyers*, *Which Teaches the Dyeing of Woolen Cloths*, *Linens*, *Cottons*, *and Silk by the Great Art as Well as by the Common* or simply *Instruction in the Art of Dyeing*. The book was divided into four sections: the first and second sections were devoted to the dyeing of wool, cotton, and linen; the third to the dyeing of silk and the use of fugitive colors; and the fourth to the dyeing of leather and skins. Approximately 160 complete recipes were preserved in the first three sections. Edelstein and Borghetty labored diligently in determining the meanings of terms in recipes written in the dialect of sixteenth century Italy.

Synthetic Dyes

The father of modern synthetic dyes was William Henry Perkin (1838–1907), who synthesized mauve, or aniline purple, in 1856. The story behind this great story bears telling. William's father was a builder who wanted him to become an architect, but like many others, Perkin did not follow his father's chosen profession. Perkin studied at the City of London School where he became interested in chemistry at the age of 12. A teacher, Mr. Hall, gave him work in the laboratory, which in turn, inspired Perkin to follow his natural curiosity. At age 15, Perkin entered the Royal College of Science and listened to the lectures of the great German chemist, August Wilhelm von Hofmann (1818–1892). He was granted an assistantship under von Hofmann at age 17. Because his work did not allow time for his own research, he set up a separate laboratory at home and it was there that he discovered aniline purple, the first dyestuff to be commercially produced. Another dye, based on naphthalene, and prepared in collaboration with Arthur H. Church, actually preceded aniline purple, but was not commercially produced before aniline purple. Aniline purple was discovered at this home during Easter vacation while looking for quinine, an antimalarial drug. After oxidizing aniline with potassium dichromate and getting a black precipitate, extraction with ethanol gave a brilliant purple solution. Almost immediately, he sent a sample of this dye to a dyer in Perth with a request to dye silk fabric. The dyer's report read: "If your discovery does not make the goods too expensive, it is decidedly one of the most valuable that has come out for a long time." Trials on cotton were not as successful because the need for a mordant was not realized. Perkin later reported, "The value of mauve was first realized in France, in 1859. English and Scotch calico printers did not show any interest in it until it appeared on French patterns, although some of them had printed cloth for me with that colour." [4]

Table 13.1 Dyes in order of discovery

Basic: Mauve or Aniline Purple, Perkin, 1856; Fuchsin, Verguin, 1859
Acid: Alkali Blue, Nicholson, 1862
Vat: Alizarin, Gräbe and Liebermann, 1868
Indigo, von Bayer, 1880, discovered structure and synthesized indigo
Indanthrene, Böhn, 1901
Direct: Congo Red, Böttiger, 1884
Direct Developed: Primuline coupled with beta-naphthol, Green, 1887
Sulfur: Vidal, 1893
Azoics: Zitscher and Laske, 1911
Disperse: A simple azo dye, 1920s
Phthalocyanine: Linstead and Diesbach, 1928–1929
Reactive: commercialized, I.C.I., Rattee and Stevens, 1956

Since that beginning, thousands of dyes have been synthesized; some 1,500–2,000 are commercially successful today. Until 1884, however, all synthetic dyes required a mordant to give acceptable wash fastness on the textile substrate. In 1884, Böttiger produced Congo Red, which could dye cotton directly without a mordant. These dyes were commonly called direct dyes. In order to improve washfastness, the path taken in some synthetic dye chemistry was to build the dye from two or more components, directly in the fiber, or in situ. By building a large molecule without solubilizing groups within the fiber, washfastness was markedly improved. The first practical development along these lines was by A. G. Green who synthesized primuline, a dye that because of poor light fastness was not commercially important but later led the way to many important commercial dyes. Table 13.1 lists a number of classes of dyes along with the date of discovery. Worldwide, 80% of all dyes go into textiles and 20% into paper, leather, food, and the like.

The Development of the US Dyestuff Industry

The natural dyes industry was more than just a cottage industry in Colonial America. Indigo was a very important cash crop in South Carolina among the coastal islands and for some distance inland. Plantations existed well into the early 1900s despite the growth of the synthetic dyestuff industry.

The modern synthetic dye industry in the United States dates from World War I. However, in 1864, Thomas Holliday of Great Britain, and in 1868, the Albany (NY) Aniline Company with participation of Bayer of Germany began coal-tar dye manufacture. In the early 1900s, most synthetic dyes used in the United States were imported from Germany and Switzerland. With the outbreak of World War I, the British naval blockade of Germany prevented export of dyes from Europe. In spite of the blockade, the German submarine, *Deutschland*, ran the British blockade and sailed into American ports twice with dyestuffs and drugs. The Germans needed critical war material and export moneys; the United States and others needed dyes. Ironically, in 1914, German dyes were used by French dyers to dye the official French Army uniforms. The outbreak of war and ensuing blockade showed the United States how important dyes were to the American economy. Several companies began investigative work that would lead to dye synthesis; they found that dyestuffs were very difficult to make; the chemistry was much more complex than imagined. A real boost to the US industry came after World War I, when the German patents were given over to the Allies via the Alien Property Custodian. According to Lehner, DuPont reportedly spend $43 million, a tremendous sum of money in the early twentieth century, before ever showing a profit [5]. Obviously, only financially strong companies could afford to enter the business. The early pioneers included Allied (formed by merging five companies), American Cyanamid, and DuPont, to name only a few who survived to become major factors later in the twentieth century. In 1938, others included Dow, German-owned General Aniline and Film (GAF), and Swiss-owned Cincinnati Chemical Company (Ciba, Geigy, and Sandoz). In the 1960s, 50–60% of all US manufacturing was in the hands of four principal US companies:

- Allied Chemical (later sold to Bayer of Germany and to independent investors as Buffalo Color, 1977)
- American Cyanamid
- GAF, the result of the break-up of the German cartel, I. G. Farben, which was nationalized during World War II and sold to BASF in 1978
- DuPont (sold in 1980–1981 with various lines going to Crompton & Knowles, Ciba, and Blackman-Uhler)

Today, there are at least 42 dyestuff manufacturers, distributors, and repackaging agents in the United States [6]. Of the major companies, Swiss and German-based companies tend to dominate the US market. Those companies include:

- Ciba, formerly Ciba-Geigy, Switzerland
- Clariant (split off from Sandoz in 1995), Switzerland
- DyStar, formed by the merger of Hoechst and Bayer (1995), acquisition of BASF textile colors which include the former Zeneca, and Mitsubishi of Japan, Germany
- Crompton & Knowles sold to Yorkshire Group Plc and is now Yorkshire Americas

There is no major surviving the US-based company. Raghavan [7] and Mock [8] give an interesting description of these mergers and the reasons behind them.

Most of the international companies have limited manufacturing facilities in the United States and major facilities in other countries where environmental laws are not as stringent or where the parent companies have a modern integrated low-pollution facility. These facilities in the USA minimize the tariffs paid and also allow quicker response to the marketplace. Ciba has a manufacturing facility in St. Gabriel, LA; Clariant in Martin, SC; DyStar near Charleston, SC; and Yorkshire Americas at Lowell, NC.

Today well over 1,500 dyes are produced in commercial quantities, although only a select handful in each class are the true “workhorse” colors found in virtually every dyehouse dyeing a particular substrate for a particular end-use. Approximately two-thirds of the dyes and pigments consumed in the United States are used by the textile industry. One-sixth of the dyes and pigments are used for coloring paper, and the rest are used chiefly in the production of organic pigments and in the dyeing of leather and plastics.

Dyes are catalogued and grouped under a set of rules established by the Colour Index committee, consisting of representatives from the SDC, Bradford, England, and the American Association of Textile Chemists and Colorists (AATCC), Research Triangle Park, NC. Table 13.2 shows how over 9,000 dyes are enumerated in the current Index [9]. The Colour Index, now in its fourth edition, is updated periodically with newly released information and is available in book form and on CD-ROM. Volumes 1–3, published in 1971, contain the C. I. name and number, chemical class, fastness properties, hue indication, application, and usage. Volume 4, also published in 1971, contains the structures of all disclosed structures. Volume 5, last published as part of Volume 9 in 1993, contains the commercial names of all known dyes and pigments. Volumes 6–8 are supplements with updates to information in Volumes 1–4 up to 1976, 1981, and 1987, respectively. An online version of the Colour Index containing a significant number of new entries was made available in 2002.

In addition to the Colour Index, AATCC publishes a *Buyer’s Guide* annually in July [6]. Part A lists dyes, pigments, and resin-bonded pigment colors available from companies who choose to list this information.

The textile industry uses a large number of dyestuffs from each of the dye categories, the choice depending on the shade, fiber, and dyeing process, end-use of the textile product, requirements for fastness, and economic considerations.

Table 13.2 Dyes listed in the Color Index

Shade	Yellow	Orange	Red	Violet	Blue	Green	Brown	Black	Sum
Acid	255	178	439	131	356	121	453	236	2,169
Direct	171	121	263	104	303	100	242	189	1,493
Disperse	243	155	371	102	371	9	27	31	1,309

Total									9,475

To provide an understanding of the interrelationships that exist among the various dye classes and fiber types, a brief survey of the major fibers follows.

Textile Fibers

In this survey, commercially important textile fibers are grouped by their origin. First there are the natural fibers from plant sources, cotton and flax, and those from animal sources, wool and silk. A second group consists of those fibers that are regenerated or chemically modified natural materials, the rayon and acetate fibers. The final group consists of synthetic fibers, which include polyester, nylon, acrylics, polyolefins, and elastane.

Natural Fibers

Cotton. Cotton fibers comprise mainly cellulose, a long-chain polymer of anhydroglucose units connected by ether linkages. The polymer has primary and secondary alcohol groups uniformly distributed throughout the length of the polymer chain. These hydroxyl groups impart high water absorption characteristics to the fiber and can act as reactive sites. The morphology of the cotton fiber is a complex series of reversing spiral fibrils. The fiber in total is a convoluted collapsed tube with a high degree of twist occurring along the length of the fiber. This staple fiber occurs in nature in lengths of ½ to 2 in., depending on the variety and growing conditions. The diameter ranges from 16 to 21 μm (1 μm is 1×10^{-6} m).

Flax. Flax is also a cellulosic fiber but has a greater degree of crystallinity than cotton. The morphology of flax is quite different from that of cotton. Flax fibers have a long cylindrical shape with a hollow core. The fibers range in length from ½ to 2½ inches, with a diameter of 12–16 μm. Flax staple comprises bundles of individual fibers. Historians believe that flax was among the first fibers to be used as a textile fiber. In recent years, its commercial importance as a textile fiber has decreased significantly.

Wool. Wool fibers comprise mainly proteins: the polypeptide polymers in wool are produced from some 20 alpha-amino acids. The major chemical features of the polypeptide polymer are the amide links, which occur between the amino acids along the polymer chain, and the cystine (sulfur to sulfur) cross-links, which occur in a random spacing between the polymer chains. The polymer contains many amine, carboxylic acid, and amide groups, which contribute in part to the water-absorbent nature of the fiber.

The morphology of wool is complex. There is an outer covering over the fiber, the cortical. There are also overlapping scales having a ratchet configuration that causes shrinkage and felting. The coefficient of friction in wool fibers is vastly different between the tip and the root, depending on which way the scales point. Wool can be made washable by chemically abrading the scales or coating the fibers with another polymer.

Wool fibers are not round but are oval in cross-section. The cortical cells constitute the major component of the fiber, and are aligned along the axis of the fiber. There is a medulla section at the center region of the fiber. Each fiber has a bicomponent longitudinal crystalline arrangement. One side of the fiber contains alpha-keratin crystalline regions, and the other contains beta-keratin crystalline regions. Alpha-keratin and beta-keratin have different moisture absorption characteristics, and this difference is what gives wool fibers crimp and springiness. It is also the reason why wool fibers kink in conditions of high humidity.

Wool fibers are sheared from about 30 major sheep breeds. The length of the wool fibers varies from 1 to 14 in. and depends on the breed, the climate, and the location on the sheep's anatomy. The fibers can be very fine to very coarse, ranging from 10 to 50 μm in diameter. The longer, coarser fibers normally are used for woolen fabrics, whereas the shorter finer ones are used for worsted fabrics.

Silk. Silk, like wool, is a protein fiber, but of much simpler chemical and morphological makeup. It comprises six alpha-amino acids, and is the only continuous-filament natural fiber. Historians claim that silk was discovered in China in 2640 BC. Silk fiber is spun by the silkworm as a smooth double-strand, each part having a trilobal cross-section. This configuration helps give silk its lustrous appearance. The fiber is unwound from the cocoon the silkworm spins as it prepares its chrysalis. The filaments are smooth and have no twists in their length, which can vary from 300 to 1,800 yards. The diameter of silk is very fine, ranging from 2 to 5 μm. Because of the labor-intensiveness of sericulture and subsequent preparation of the fiber, silk remains a luxury fiber.

Regenerated Fibers

Rayon. Viscose rayon, like cotton, comprises cellulose. In the manufacturing process, wood pulp is treated with alkali and carbon disulfide to form cellulose xanthate. Subsequently, the reaction mass is forced through a spinneret and precipitated in an acid coagulation bath as it is formed into a continuous filament. The fiber has a round striated cross-section. Rayon staple is made by "breaking" the continuous strands into staple-length fibers. Viscose rayon is conventionally produced in diameters varying from 9 to 43 μm.

Acetate. Triacetate and diacetate fibers are manufactured by the chemical treatment of cellulose obtained from refined wood pulp or purified cotton lint. Most of the hydroxyl groups are acetylated (esterified) by treating the cellulose with acetic acid. This determines the chemical configuration of triacetate. Acetate or diacetate is made by the saponification of one of the acetylated groups, thus restoring a hydroxyl to each cellulosic monomer unit. Theoretically, then, diacetate has two acetylated groups in each glycoside unit. The conversion of the hydroxyl groups causes these fibers to be hydrophobic and changes the dyeing characteristics drastically from those of the normal cellulosic fibers. Triacetate fibers are spun by mixing the isolated reaction product (flake) with methylene chloride and alcohol. The spinning solution (dope) is forced through a spinneret and dry-spun into continuous filaments.

An alternate way of wet spinning is also possible. Acetate fibers are spun by mixing the isolated reaction product with acetone and water. The spinning solution is formed into filaments by evaporating the solvent and coagulating the acetate in a manner similar to that for triacetate (i.e., by the dry-spinning method).

Synthetic Fibers

Nylon. In 1939 the DuPont Company introduced the first truly synthetic textile fiber. Dr. Wallace Carothers invented nylon as a result of his basic research into polymer science. Chemically, nylon is a polyamide fiber. The two major types of nylon polymer are used in textiles: type 6,6 which is made by using hexamethylene glycol and adipic acid, and type 6, which is made by polymerizing ε-caprolactam. Nylon fibers are made by melt-spinning the molten polymer. The result is a continuous filament fiber of indeterminate length. It is spun in many deniers, with its diameter varying from 10 to 50 μm. The cross-section usually is round, trilobal, or square with hollow channels when used as carpet fiber.

Polyester. Polyester is made by the polymerization reaction of a diol and a diester. The main commercial polymer is formed by a condensation reaction using ethylene glycol and terephthalic acid. Fibers are formed by melt-spinning. Commercially introduced in 1953 by the DuPont Company as Dacron, polyester fibers have high strength, and very low moisture absorbance. The fiber is usually spun with a round cross-section. Polyester is the most-used synthetic fiber around the world.

Acrylics. The DuPont Company introduced the first commercial acrylic fiber, Orlon, in 1950. Acrylics are made from the polymerization of acrylonitrile and other comonomers to allow dyeability and to open the internal structure. The fibers are produced by either solvent-spinning (Orlon), or wet-spinning (Acrilan). In the solvent-spinning process, the polymer is dissolved in a low-boiling liquid solvent such as dimethyl formamide and extruded in a warm air chamber. In wet-spinning, the polymer is dissolved in a suitable solvent, extruded into a coagulation bath, dried, crimped, and collected. Although the acrylic fibers are extruded as continuous filaments, they subsequently are cut into staple-length fibers. Acrylics have found a niche market as a substitute for wool or in wool blends (blankets, sweaters, etc.) and in awnings and boat covers. The cross-section of the filament varies among manufacturers, Orlon having a dog-bone configuration and Acrilan having a lima-bean shape. Acrylic fibers are quick drying and wrinkle resistant.

Polyolefins. Polyolefin fibers are produced from the polymerization of ethylene or propylene gas. The catalysis research of Ziegler and Natta led to the development of these polymers to form crystalline polymers of high molecular weight. Hercules Inc. produced the first commercial fibers in 1961. The fibers made from these polymers are melt-spun. The cross-sections are round, and the fibers are smooth. They have extremely low dye affinity and moisture absorbance. Colored fiber is normally produced by mixing pigments in the melt polymer prior to extrusion.

Elastane. The DuPont Company commercialized the first manufactured elastic fiber, Lycra, in 1958. Originally categorized as a spandex fiber, the name “elastane” has become more common around the world. This specialty fiber is described as a segmented polyurethane that contains “hard” and “soft” segments; their ratio determines the amount of stretch built into the fiber. Elastane fibers are formed by dry-spinning or solvent-spinning. The continuous filaments can be coalesced multifilaments or monofilaments, depending on the manufacturer. Because most dyeings are applied from water solutions or dispersions, the effect of water absorption by the fiber is an important criterion. Table 13.3 shows the hydrophobic/hydrophilic characteristics of the important fibers. The cellulosic and natural fibers are the most hydrophilic, and polyolefin is the most hydrophobic.

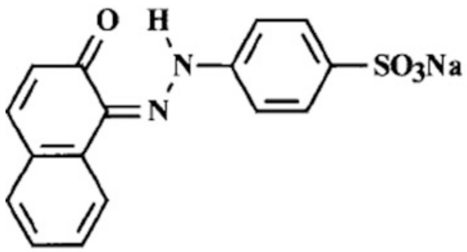
Table 13.3 Hydrophobic/hydrophilic characteristics of various fibers

Fiber	Moisture content, % (at 65% R.H. −70 °F)	Water retention, % (weight change in water)	Swelling, % (volume change in water)
Acetate	6.5	20–25	NA
Acrylic	1.0–1.5	4.5–6	2
Cotton	7	45	45
Elastane	0.3–1.5	Low	Low
Nylon	3.0–5.0	9–12	13
Polyester	0.3–0.5	3–5	0.5
Olefin	0.01–0.1	Very low	Very low
Triacetate	3.2	12–18	NA
Viscose	13	90–100	95
Wool	13–15	42	42

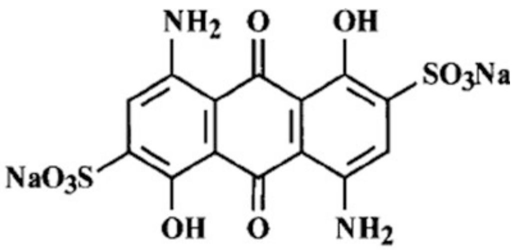
Microdenier fibers. The first commercial production of microfiber in the United States was in 1989 by the DuPont Company. Today microfibers are produced in a variety of synthetic fibers (i.e., polyester, nylon, acrylic, etc.). A microfiber is a fiber that is less than one denier per filament. Yarns made from microdenier filaments are able to give silk-like hand to fabrics.

Dye Classification

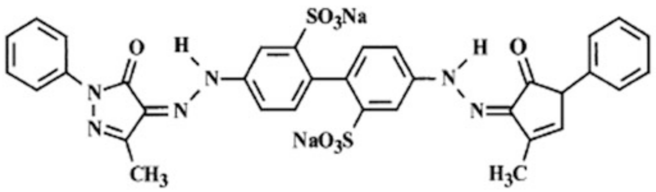
This section covers structural features that govern the classification and application of various dye classes. In this regard, the chemistry of acid, azoic, basic, direct, disperse, reactive, sulfur, and vat dyes is presented. With regard to the application of synthetic yes to textiles, it is well known that dyeing of textile fibers from an aqueous dyebath involves four steps: exhaustion, diffusion, migration, and fixation. In step 1, individual dye molecules move from the dyebath to the fiber surface and in step 2, dye molecules move from the fiber surface into the amorphous regions of the fiber. In step 3, dye molecules move from regions of high concentration to regions of low concentration



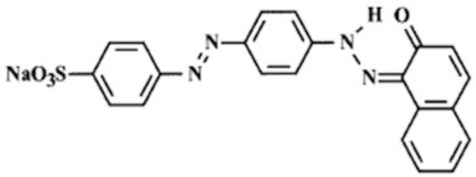
Acid Orange 7



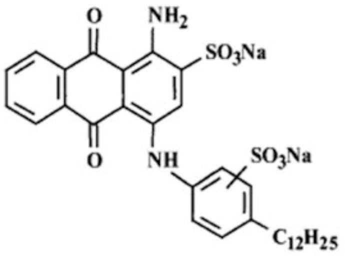
Acid Blue 45



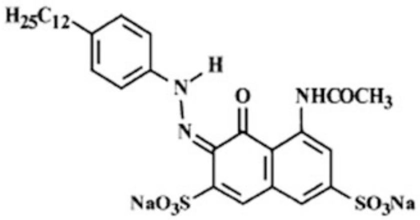
Acid Yellow 42



Acid Red 151



Acid Blue 138



Acid Red 138

(i.e., migrate) to become uniformly distributed within the polymer matrix. In step 4, dye molecules interact with groups along the polymer chain via primary or secondary valency forces. Dye–polymer interactions can involve ionic bonding (e.g., acid dyes on nylon or wool), covalent bonding (e.g., reactive dyes on cotton), mechanical entrapment (e.g., vat dyes and sulfur dyes on cotton), secondary valency forces (direct dyes on cotton), or solid–solid solution (e.g., disperse dyes on polyester).

Acid Dyes

Acid dyes derive their name from the conditions associated with their application, in that they are typically applied to textile fibers from dyebaths containing acid [9]. Most acid dyes have one or two sodium sulfonate ($-SO_3Na$) groups and, therefore, are water soluble and capable of bonding with fibers having cationic sites (cf. Fig. 13.1). They give a wide range of bright colors on textiles, especially when monoazo and anthraquinone structures are used.

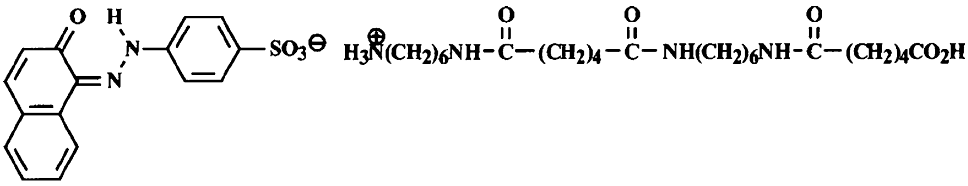


Fig. 13.1 Ionic bond formation between nylon 66 and C.I. Acid Orange 7

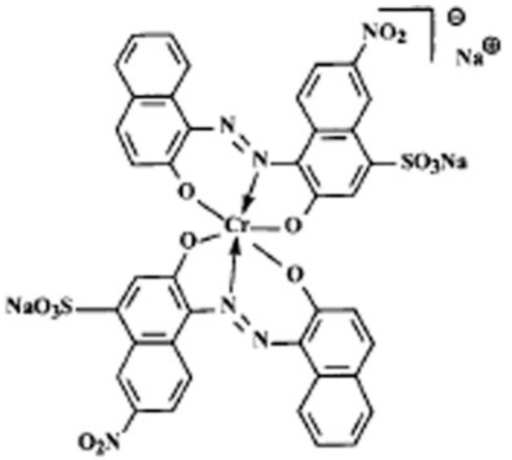
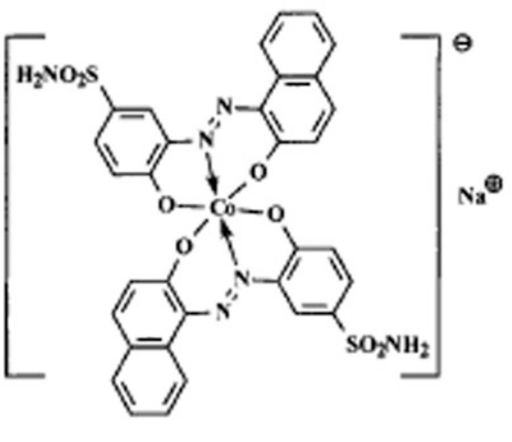
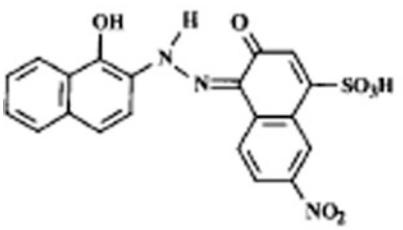
Acid dyes vary widely in molecular structure and in the level of acid required for dye application. They include relatively low molecular weight dyes such as C.I. Acid Orange 7 and C.I. Acid Blue 45, both of which are readily applied to polyamide and protein fibers and are known as *level dyeing acid dyes*. As the name suggests, these dyes are characterized by good migration and, therefore, readily produce level dyeings with time. In addition they give reasonably good lightfastness and barré coverage. The application of level dyeing acid dyes to nylon and wool utilizes weak acid and strong acid, respectively. For applications requiring good washfastness, *milling acid dyes* or *supermilling acid dyes* are employed. Both of these dye types afford relatively poor barré coverage, however. The former type dyes are applied from weakly acidic dyebaths whereas the latter are generally applied at neutral pH, with molecular size increasing as acid strength decreases. Examples of milling acid dyes are C.I. Acid Yellow 42 and C.I. Acid Red 151, and supermilling acid dyes include C.I. Acid Blue 138 and C.I. Acid Red 138.



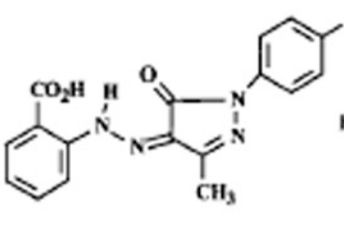
Acid Black 172



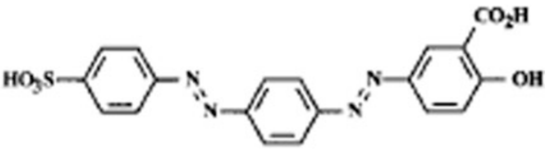
Acid Red 182



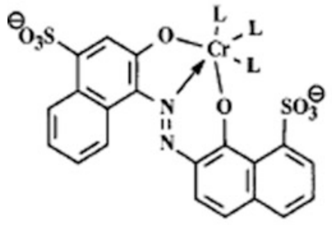
Mordant Black 11



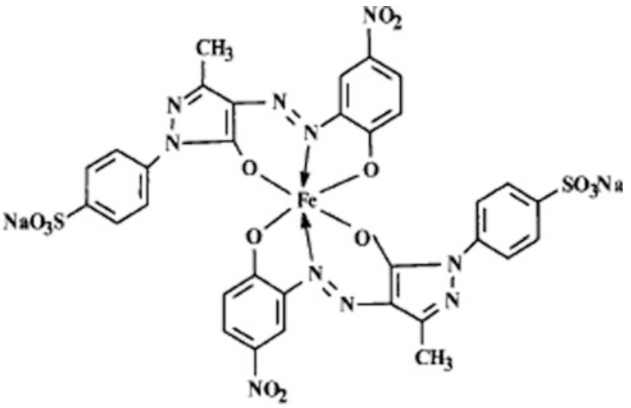
Mordant Yellow 8



Mordant Orange 6



Acid Blue 158



Acid Brown 98

Because it is well known that azo dyes derived from naphthol and pyrazolone intermediates exist predominantly in the hydrazone form, this tautomeric form is given for Acid Yellow 42, Acid Red 151, Acid Red 138, and for the appropriate dyes that follow in this chapter.

Acid dyes include metal-complexed azo structures, where the metals used are cobalt, chromium, and iron [10, 11]. Examples are 1:1 and 2:3 chromium complexes and 1:2 cobalt complexes, where the numbers employed represent the ratio of metal atoms to dye molecules. Metal-complexed dyes can be formed inside textile fibers by treating suitably dyed fibers with a solution containing metal ions [12]. In this case, the metal-free forms of these azo dyes are known as *mordant dyes* and contain mainly *ortho*, *ortho′*-bis-hydroxy or *ortho*-carboxy, *ortho′*-hydroxy groups (e.g., C.I. Mordant Black 11, Mordant Yellow 8, and Mordant Orange 6). When the metal complexes are formed prior to the dye application process, the resultant dyes are known as *premetallized acid dyes* and vary in the acid strength required in the application step [13]. The 1:1 chromium complexes (e.g., C.I. Acid Blue 158) are stable only in very strong acid, making them suitable for wool but not nylon. Neutral dyeing premetallized acid dyes contain $–SO_2NH_2$ or $–SO_2CH_3$ groups in lieu of $–SO_3Na$ groups (see Acid Black 172 vs. Acid Red 182). In this case, dye–fiber fixation occurs because the combination of trivalent metal ion (e.g., Cr^{3+}) and four attached negatively charged ligands gives the complex a net negative charge.

Metallization of azo dyes enhances lightfastness, reduces water solubility, causes a bathochromic shift in color, and dulls the shade. Iron complexes generally give brown shades (e.g., C.I. Acid Brown 98) and are most often used to dye leather.

Azoic Dyes

Azoic dyes are mainly bright orange and red monoazo dyes for cotton, with dull violet and blue colors also possible [14]. They are water insoluble and consequently give high washfastness. They are also referred to as azoic “combinations” rather than “dyes” because they do not exist as colorants until they are formed inside the pores of cotton fibers [15]. They are quite important for printing on cotton and often give good lightfastness in heavy depths. Their bleachfastness is better than direct and sulfur dyes and good crockfastness requires efficient soaping after the application step. The formation of these dyes requires two constituents: an azoic coupling component and an azoic diazo component, examples of which are shown in Figs. 13.2 and 13.3. The azoic coupling components are

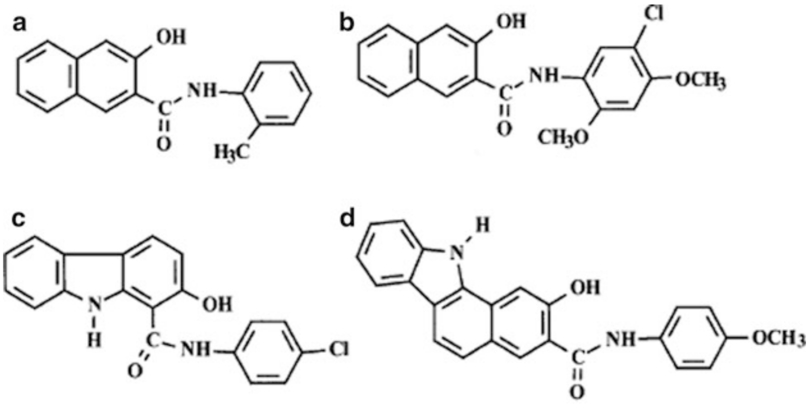


Fig. 13.2 Structures of C.I. azoic coupling components 18 (**a**), 12 (**b**), 15 (**c**), and 13 (**d**)

beta-naphthol and β-oxynaphthoic (BON) acid derivatives and the azoic diazo components are substituted anilines.

Azoic dyes are also known as naphthol dyes, because all employ a naphthol component in their formation, and they can be produced in batch or continuous processes. Because they have a limited shade range, they are best known for their ability to provide economical wetfast orange and red shades on cotton. A generic azoic dye structure is shown in Fig. 13.4.

Basic or Cationic Dyes

Basic dyes were developed to dye negatively charged acrylic fibers, forming ionic bonds in the fixation step (Fig. 13.5) [16]. They owe their name to the presence of aromatic amino (basic) groups, and in this case a cationic amino group is present. Generally, they have excellent brightness and color strength, especially among the triarylmethane types. However, their lightfastness is often low, when they are applied to fibers other than acrylics. Basic dyes include those containing a fixed cation, examples of which are C.I. Basic Blue 22, and C.I. Basic Red 18. The triarylmethane dye C.I. Basic Violet 3 has a mobile cation that produces resonance structures of comparable energy.

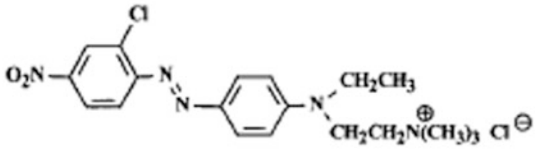
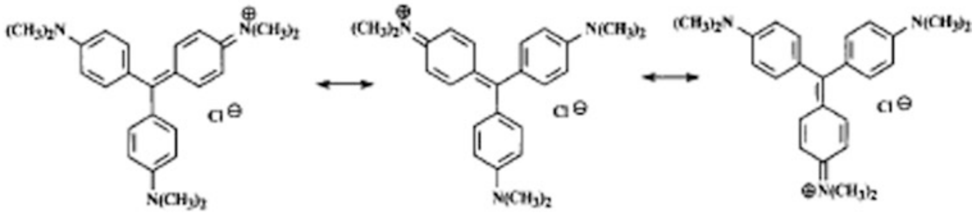
Basic Blue 22



Basic Red 18



Basic Violet 3

Basic dyes are applied from weakly acidic dyebaths ($pH = 4.5–5.5$) and often require the use of anionic or cationic retarding agents to control the rate of dye strike and give level dyeing. Suitable retarding agents either form a weak bond with dyesites along the polymer chain or interact with the dye in the dyebath. In the former case, a significant fraction of the cationic retarder employed is displaced by the dye as dyeing progresses because the dye has higher affinity for the fiber. When anionic retarding agents are used, the dye–retarder bond is broken by increasing the dyebath temperature, giving controlled release of dye molecules to facilitate leveling.

To help determine which basic dyes can be combined for shade matching, key dyebath parameters have been developed [17]. The first parameter pertains to the dyes themselves and is known as the *combinability constant* (k). This value provides a measure of how fast a basic dye will dye the fiber, and the dyes are rated on a scale of 1 (fast) to 5 (slow). The second parameter pertains to the fiber type involved and is known as the *fiber saturation value* (S_F). This value provides an indication of how much dye the fiber will hold at the saturation point. In this regard, the dye used is C.I. Basic Green 4 and typical saturation levels are 1.0–4.0% based on the weight of the fibers (*owf*) for light to deep dyeing. The third parameter is the *dye saturation factor* (f), which is a measure of the capacity of a basic dye for saturating a fiber. This factor is influenced by the molecular size and purity of the dye. In this case, the goal is to avoid placing more dye on the fiber than the number of dye sites, and the standard is C.I. Basic Green 4 ($f = 1\%$).

Direct Dyes

Direct dyes are anionic colorants that have affinity for cellulosic fibers [18]. They were the first dyes that could be used to dye cotton in the absence of a mordanting agent, giving rise to the term *direct-cotton dyes*. Like acid dyes, direct dyes contain one or more $–SO_3Na$ groups, making them water-soluble. Unlike acid dyes, they interact with cellulose (Cell–OH) chains via secondary valency forces (e.g., H-bonding and dipole–dipole interactions), as illustrated in Fig. 13.6. The combined effects of these rather weak forces and sulfonated structures cause direct dyes to have low intrinsic washfastness. Direct dye structures are based on four main chromophores: azo (e.g., C.I. Direct Red 81, C.I. Direct Yellow 28, and C.I. Direct Black 22), stilbene (e.g., C.I. Direct Yellow 12 and C.I. Direct Yellow 11), oxazine (e.g., C.I. Direct Blue 106 and C.I. Direct Blue 108), and phthalocyanine (e.g., C.I. Direct Blue 86 and C.I. Direct Blue 199). About 82% of all direct dyes have disazo or polyazo structures, with stilbene and monoazo structures occupying about 5% each and thiazole, phthalocyanine, and dioxazine structures covering the remaining few percent [19].

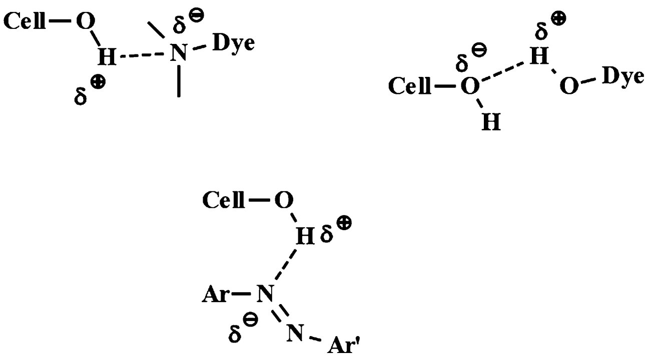


Fig. 13.6 H-bonding interactions between cellulose and polar groups in direct dye molecules

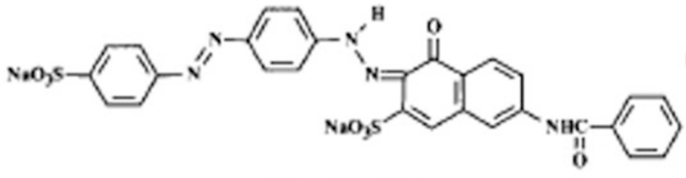
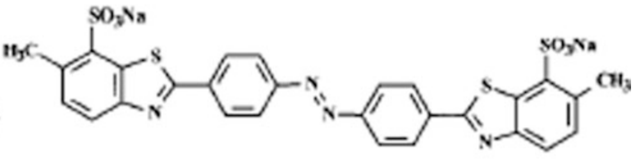
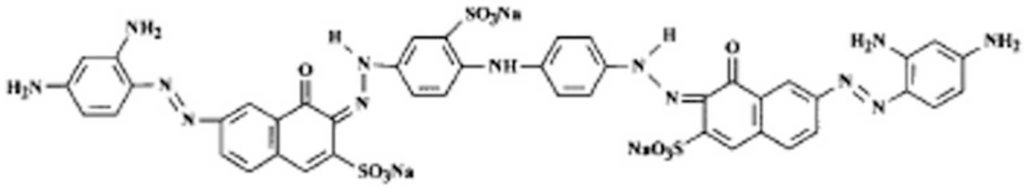


Direct Red 81



Direct Yellow 28



Direct Black 22

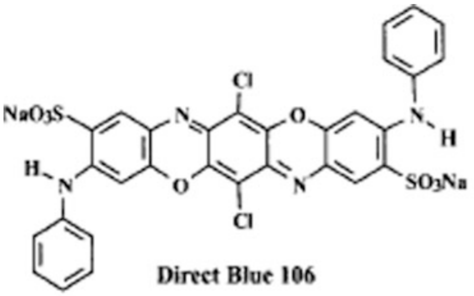
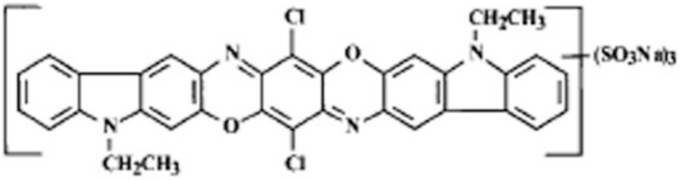
Direct Yellow 11

Suitably substituted direct dyes can be converted to metal complexes. In this regard, Cu is the metal of choice and examples are C.I. Direct Blue 218, C.I. Direct Red 83, and C.I. Direct Brown 95. About 5% of all azo direct dyes are metal complexes and unlike most direct dyes, these dyes have good lightfastness, as would be anticipated.



Direct Blue 106



Direct Blue 108

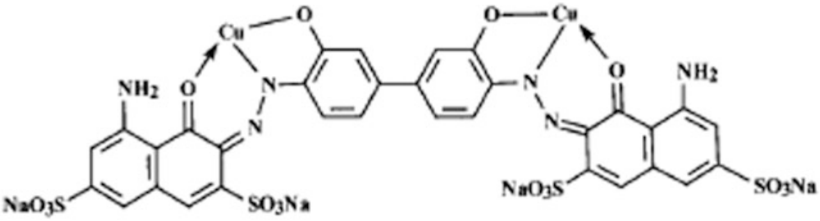
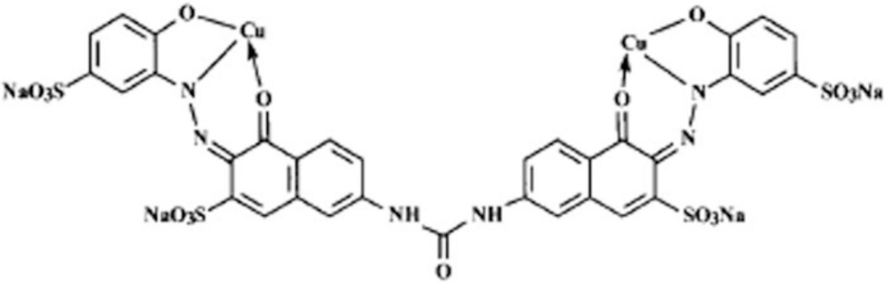
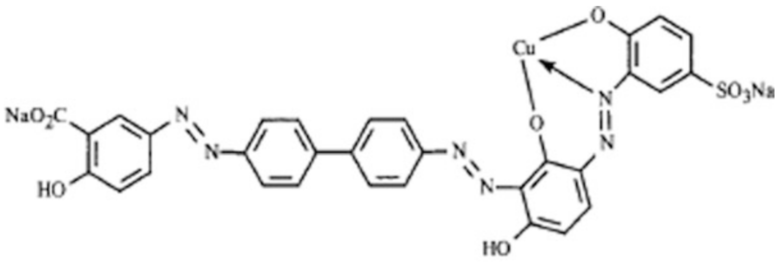
Direct Blue 199



Direct Blue 215

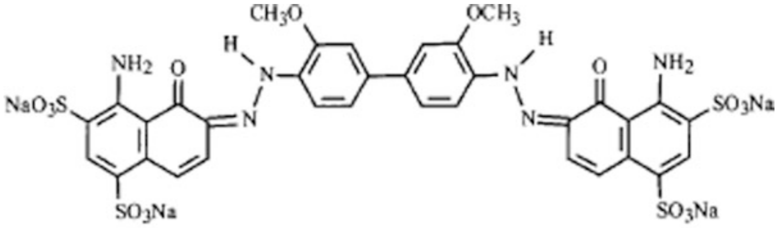


Direct Red 83



Direct Brown 95

Direct dyes are subdivided into three classes (A, B, and C), to assist the dyer in selecting appropriate combinations for color matching [20]. Class A direct dyes give good migration and leveling with time. The dyer employs 5–20% salt for their application and in this case all of the salt may be added at the beginning of the dyeing cycle. An example of this direct dye class is C.I. Direct Yellow 12. Class B direct dyes have poor migration and leveling properties and require the controlled addition of salt to afford level dyeing. They are larger than the former types and have better washfastness. An example is C.I. Direct Blue 1. Class C dyes are the largest of the direct dyes and, consequently, have the best washfastness but poorest leveling properties. Leveling requires careful control of the rate of temperature rise during the dyeing process. Some salt may be added but less than the amount used with classes A and B. An example of this dye class is C.I. Direct Black 22.



Direct Blue 1

The high temperature stability of direct dyes is an important consideration if one wishes to use these dyes as the colorant for cotton when dyeing a polyester/cotton blend at 130 °C [21]. The key to success is to choose dyes that are resistant to hydrolysis. Suitable dyes include C.I. Direct Yellow 105, C.I. Direct Orange 39, and C.I. Direct Blue 80, whereas unsuitable dyes include C.I. Direct Yellow 44, C.I. Direct Red 80, and C.I. Direct Red 83. A quick examination of the structures of the unsuitable dyes reveals that they have groups which are subject to hydrolysis. In the case of Direct Red 83, hydrolysis essentially cuts the molecule in half, eliminating fiber affinity (Fig. 13.7).

Because many direct dyes do not have good washfastness and lightfastness, their dyeing on cotton are often treated with a chemical agent, in what is commonly known as an aftertreatment process. The most widely used aftertreatment methods involve (1) cationic fixatives, (2) copper sulfate, or (3) diazotization and coupling reactions. The first and third methods are designed to enhance washfastness and are illustrated in Figs. 13.8 and 13.9. The use of cationic fixatives ties up sodium sulfonate groups, reducing the water solubility of the treated dye. Diazotization and coupling enlarges the size of the dye, making desorption more difficult, and simultaneously makes the dye less hydrophilic. This process requires the presence of at least one diazotizable primary arylamino (Ar–NH$_2$) group in the dye structure. In this two-step process, the amino group is diazotized by treatment with nitrous acid (HNO$_2$) and the resultant diazonium groups are coupled with a naphthoxide to give new azo groups. It should be pointed out that the addition of new azo groups can also affect dye color. Therefore, this process is most often used for navy and black shades, where the differences in shade variations from batch to batch are less objectionable.

Although copper sulfate aftertreatments are designed mainly to enhance lightfastness, the reduction in water solubility that accompanies Cu-complex formation can have a beneficial effect on washfastness. This treatment also dulls the fabric shade and causes a shift in dye color, so that the resultant color must be the one the dyer is seeking.

The dye used as an example in Fig. 13.10 is C.I. Direct Black 38. It is worthwhile to note that this dye is one of many that were synthesized from benzidine, an established human carcinogen [22]. Nowadays, such dyes are regarded as

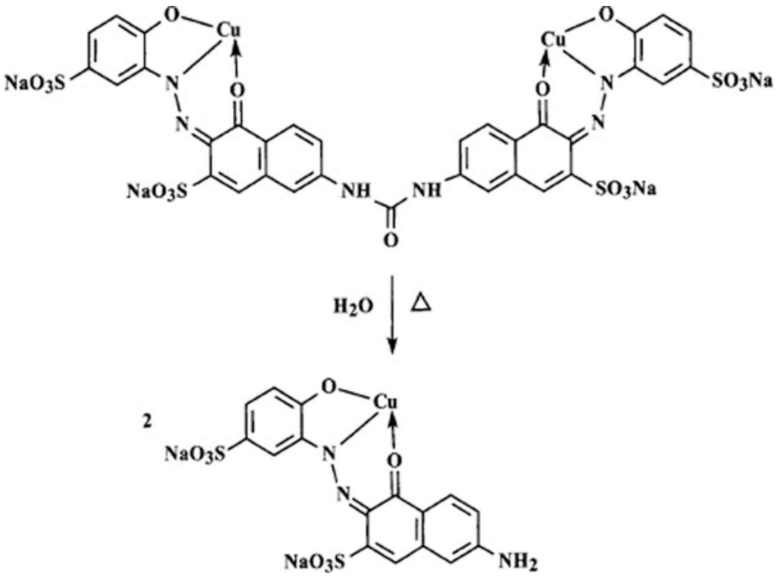


Fig. 13.7 High temperature hydrolysis of Direct Red 83

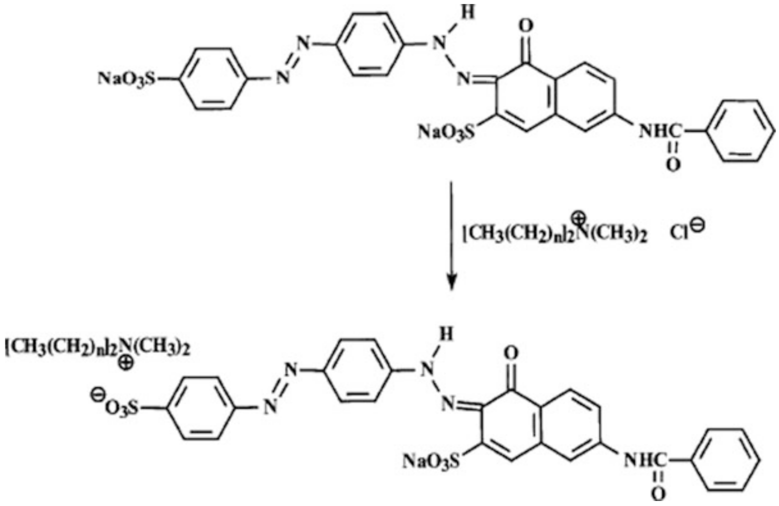

Fig. 13.8 Use of a cationic fixative to enhance direct dye washfastness

cancer-suspect agents because of their potential to generate free benzidine upon metabolic breakdown [23]. With this point in mind, regulations preventing the use of azo dyes derived from benzidine and 20 other aromatic amines in textiles have appeared [24]. This requires dye chemists to consider the genotoxicity of potential metabolites in the design of new azo dyes [25].

Disperse Dyes

Disperse dyes were invented to dye the first hydrophobic fiber developed, namely cellulose acetate, and were initially called acetate dyes [26]. The term disperse dyes is more appropriate, because these dyes are suitable for a variety of hydrophobic fibers and it is descriptive of their physical state in the dyebath. Disperse dyes have extremely low water solubility and to be applied from this medium they must be (1) dispersed in water using a surfactant (dispersing agent) and (2) milled to a very low particle size (1–3 μm). These nonionic hydrophobic dyes can be used on acetate, triacetate, polyester, nylon, acrylic, and polyolefin fibers, and their mechanism of fixation involves solid–solid solution formation.

Disperse dyes provide a wide range of bright colors on textiles and many have excellent build-up and barré coverage properties. In addition, they have good washfastness properties but their lightfastness varies with structure. They are suitable for continuous dyeing, a process that takes advantage of their sublimation properties. Disperse dye end-use applications are often based on their classification. The classification system employed is shown in Table 13.4. Low-energy disperse dyes are the easiest to exhaust under atmospheric dyeing conditions but have the lowest

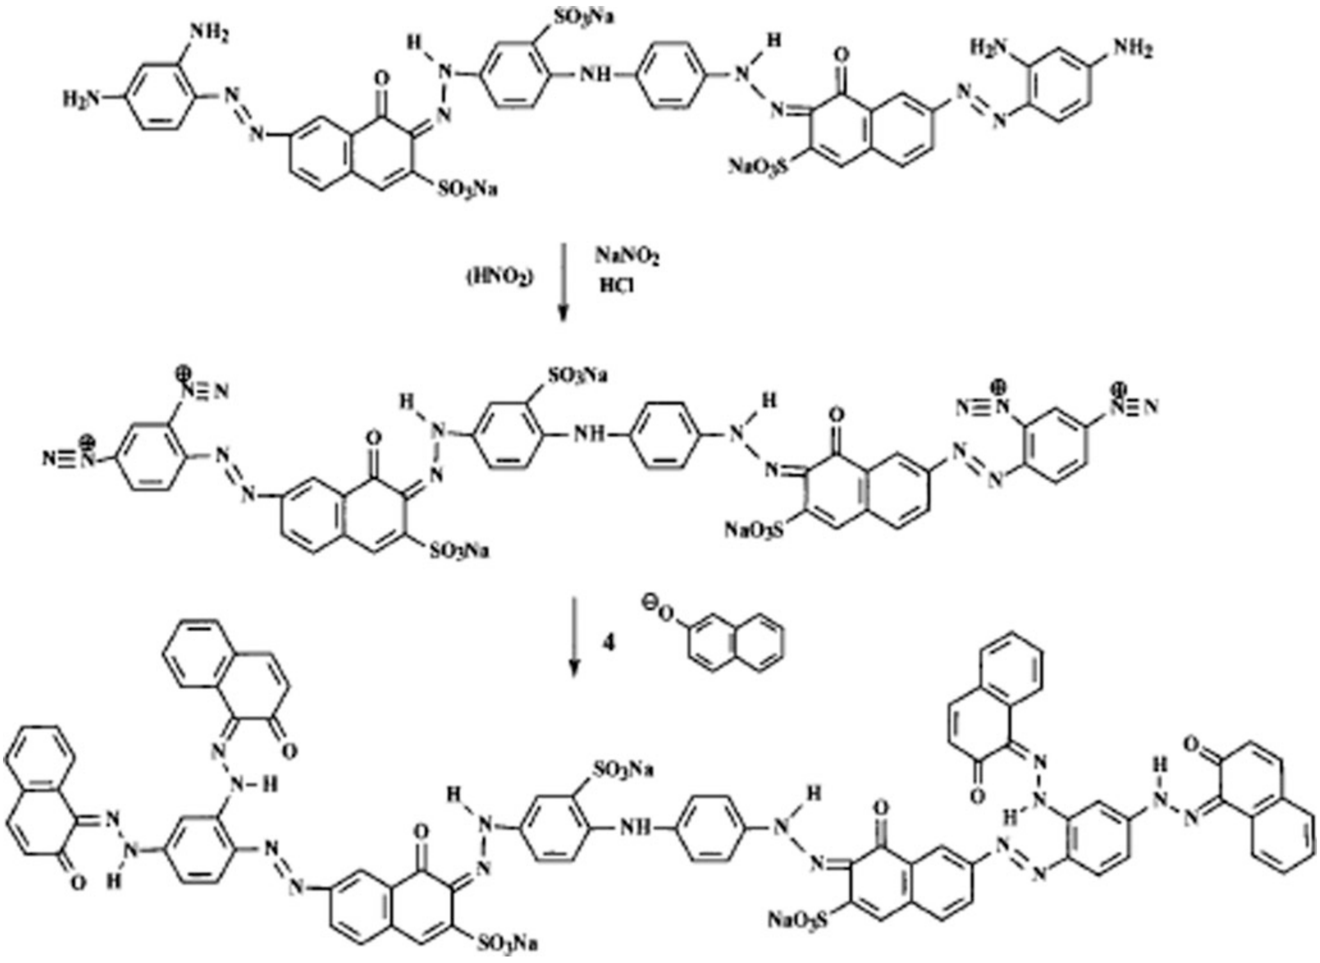

Fig. 13.9 Use of the two-step development process to enhance direct dye washfastness

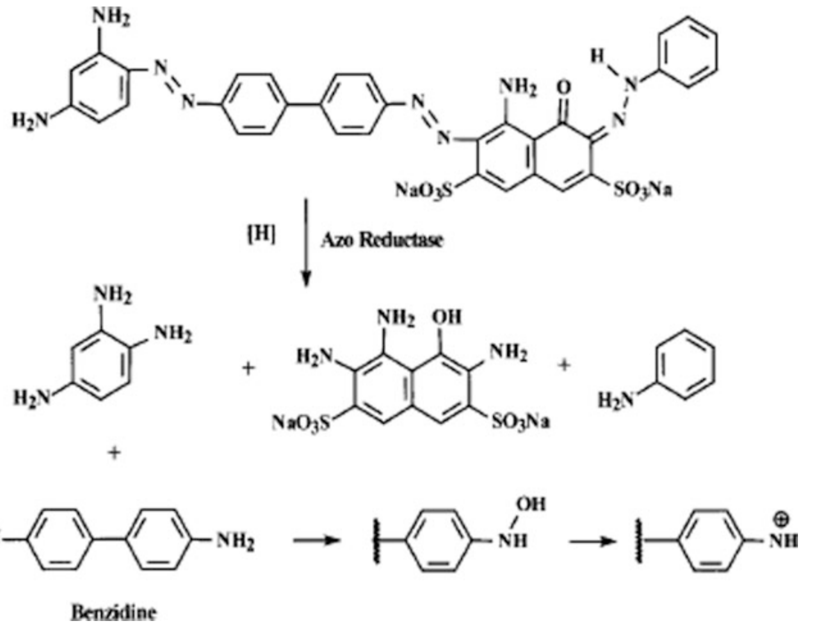

Fig. 13.10 Metabolic breakdown of a direct dye by azo reductase enzymes

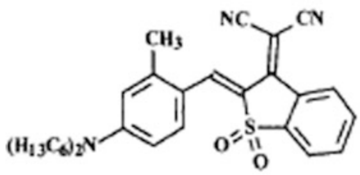
Table 13.4 Disperse dye classification and examples

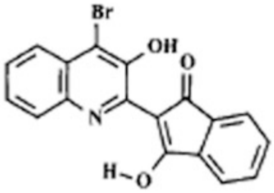
Class	Molecular mass	Sublimation temperature
Low energy	<300	<150 °C
 Disperse Yellow 3 MW=269	 Disperse Blue 1 MW = 269	 Disperse Orange 3 MW=242
Medium energy	300–400	150–210 °C
 Disperse Red 60 MW = 331	 Disperse Yellow 42 MW = 369	 Disperse Yellow 23 MW = 302
High energy	>400	>210 °C
 **Disperse Red 167:1 MW 507**	 **Disperse Blue 165 MW 405**	

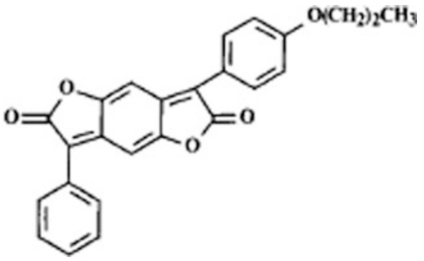
thermostability, with the latter property making them unsuitable for automotive applications. They are used to dye acetate, triacetate, and nylon fibers. On the other hand, the high energy dyes are best applied under pressure ($T = 130$ °C) and are most appropriate for polyester body cloth for automobile interiors. Medium energy dyes are also used to dye polyester and can be applied at atmospheric pressure using a carrier.

Disperse dyes vary in the type of chromophore present and include azo, anthraquinone, nitro, methane, benzodifuranone, and quinoline-based structures. Examples of the first three types are given in Table 13.4, and representative of the latter three types are C.I. Disperse Blue 354, C.I. Disperse Yellow 64, and C.I. Disperse Red 356. Most disperse dyes have azo (~59%) or anthraquinone (~32%) structures. Azo disperse dyes cover the entire color spectrum, whereas the important anthraquinone disperse dyes are mainly red, violet, and blue. The azo types offer the advantages of higher extinction coefficients ($\varepsilon_{\max} = 30{,}000-60{,}000$) and ease of synthesis, and the anthraquinones are generally brighter and have better photostability (lightfastness). The key weaknesses associated with the anthraquinone dyes are their low extinction coefficients ($\varepsilon_{\max} = 10{,}000-15{,}000$) and less environmentally friendly synthesis.

To produce disperse dyes having the brightness of the anthraquinone system and the color strength of the azo







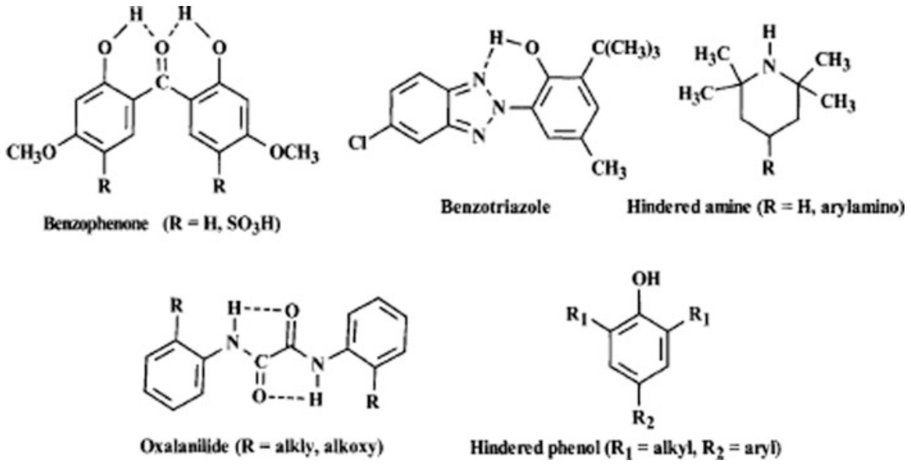


Fig. 13.11 Structures of disperse dye photostabilizers

system, azo dyes based on heteroaromatic amines were developed [27–29]. Examples are C.I. Disperse Red 145, Disperse Blue 148, Disperse Red 156, and C.I. Disperse Blue 339. These dyes employ aminated thiazoles, benzothiazoles, benzisothiazoles, and thiadiazoles in their synthesis. They have $\varepsilon_{max} = 50{,}000-80{,}000$, good brightness, and good washfastness. Another key feature of disperse dyes with heteroaromatic systems is their less complex structures. Compare, for example, the fewer number of substituent groups in the diazo component (left side of the azo bond) of Disperse Red 167 vs. Disperse Red 156 and Disperse Blue 165 vs. Disperse Blue 102. However, these dyes are more expensive than disperse dyes derived from benzeneamines, owing to their low reaction yields, and have lower lightfastness than the anthraquinone dyes.

The use of disperse dyes in applications requiring high lightfastness involves the coapplication of photostabilizers. These agents enhance dye stability by quenching the excited states of disperse dyes, probably via energy transfer, or by preferential absorption (screening) of UV radiation. They are also known as UV absorbers and exhaust from the dyebath like disperse dyes. They encompass benzophenone, benzotriazole, oxalanilide, and hindered amine/phenol structures (see Fig. 13.11) [30].

Reactive Dyes

Reactive dyes are used mainly as colorants for cotton, although they are also suitable for nylon and wool [31]. They are water soluble, due to the presence of one or more $–SO_3Na$ groups, and undergo fixation to polymer chains via covalent bond formation. Reactive dyes have very high washfastness and are used for leisure wear and other applications requiring stability to repeating laundering. Each dye is composed of five basic parts:

$$SG - C - B - RG - LG$$

In this regard, SG = water solubilizing group ($-SO_3Na$), C = chromogen (e.g., azo, anthraquinone), B = bridging or linking group (e.g., –NH–), RG = reactive group (e.g., chlorotriazine, vinylsulfone), and LG = leaving group (e.g., –Cl, –F, $–SO_4H$). These parts are illustrated for the structure in Fig. 13.12. This structure also shows that reactive dye structures can be quite small, much smaller in fact than those characterizing direct dyes. As a consequence, reactive dyes have significantly lower inherent affinity for cotton and can require high levels of salt (200–300 g/L) in their dyebaths to promote exhaustion [32].

In addition to giving high washfastness on cotton, reactive dyes usually give bright shades. The latter property arises from the fact that reactive dyes are often acid dye structures linked to reactive groups, as shown in Fig. 13.13. Reactive dyes have moderate-to-good lightfastness and fair-to-poor chlorine fastness.

Although the most commonly used reactive systems involve the halotriazine and sulfatoethyl sulfone (vinyl sulfone) groups, halogenated pyrimidines, phthalazines, and quinoxalines are also available (Fig. 13.14). For all of these systems, alkali is used to facilitate dye–fiber fixation, and fixation occurs either by nucleophilic substitution or addition (Figs. 13.15 and 13.16).

The requirement for alkali in the application of reactive dyes to cotton leads to an undesirable side reaction, namely hydrolysis of the reactive groups before dye–fiber fixation can occur (Fig. 13.17). Because the hydrolyzed dye cannot react with the fiber, this leads to wasted dye and the need to treat the residual color in the wastewater prior to dyehouse discharges. To improve percentage fixation, dyes with two or more reactive groups were developed (Fig. 13.18). This makes it possible for dye–fiber fixation to occur even when one reactive group undergoes hydrolysis [33].

Sulfur Dyes

Sulfur dyes are water-insoluble dyes that are applied to cotton [34]. They are used primarily for their economy and high washfastness, are easy to apply, and give mainly dull shades. Yellow, red, brown, olive, and blue colors can be produced; however, sulfur dyes are most important for their ability to delivery washfast black shades on cotton. In this regard, C.I. Sulfur Black 1 is the main dye used commercially. Sulfur dyes have acceptable lightfastness but poor bleachfastness.

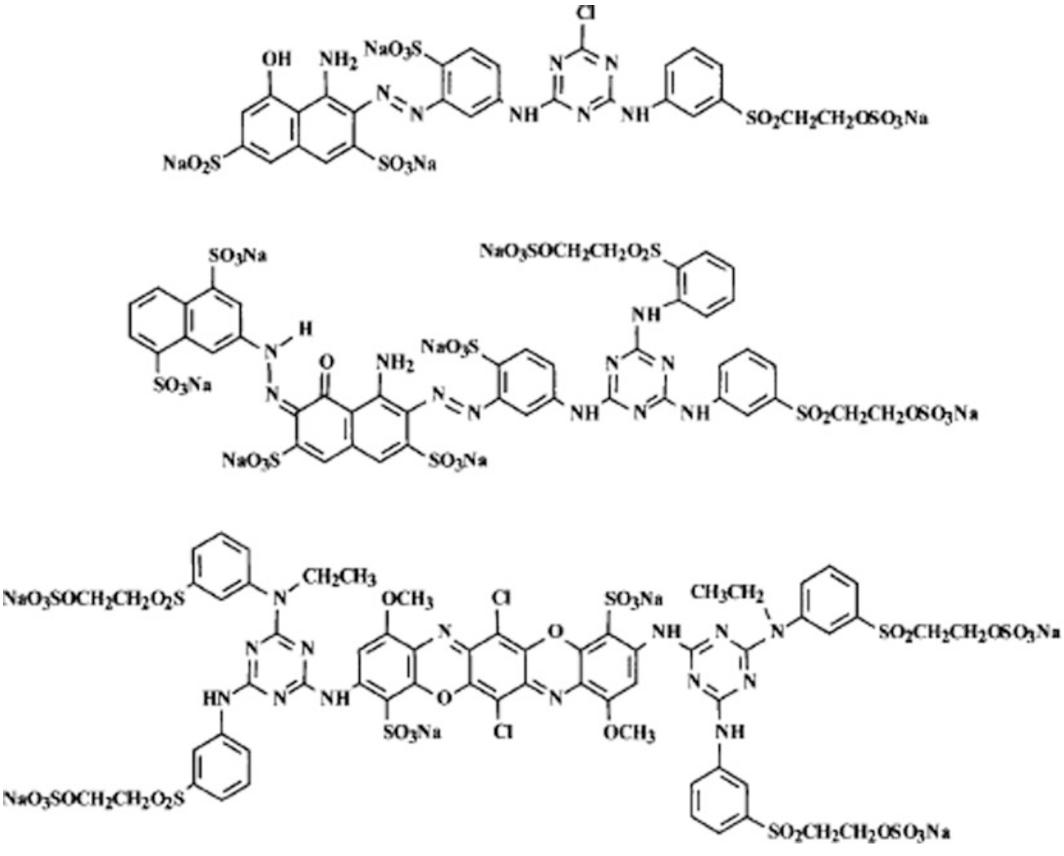

Fig. 13.18 Examples of bireactive and polyreactive dyes for cotton

Due to extremely low solubility, the precise structures of most sulfur dyes remain unknown. Much of what we know about sulfur dye structures arises from the characterization of certain degradation products or reaction precursors [35]. Based on such work, it has been possible to determine that structures of the type shown in Fig. 13.19 are covered in this dye class. A key common feature of sulfur dyes is the presence of sulfide ($-S_n-$) bonds, and it is this feature that makes dye application from an aqueous medium possible.

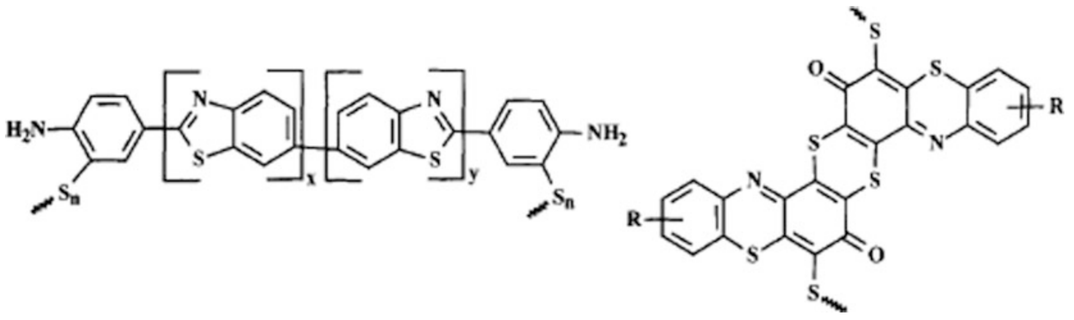

Fig. 13.19 Examples of sulfur yellow (*left*) and red (*right*) dye structures

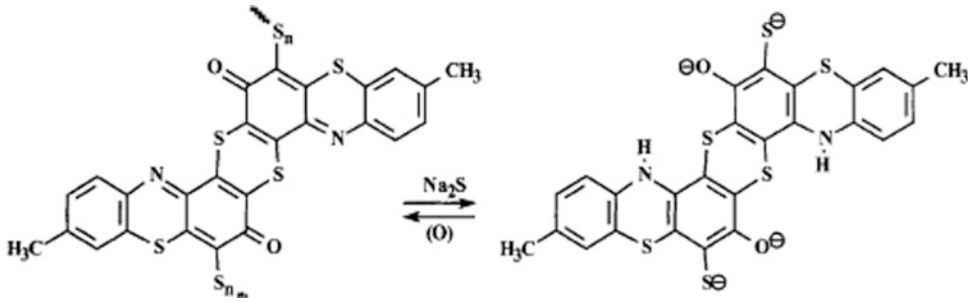

Fig. 13.20 Steps involved in the application of sulfur dyes to cotton

The reaction of sulfur dyes with sodium sulfide (Na_2S) at pH >10 effects the reduction of the sulfide bonds, giving their water soluble (leuco) forms. The reduced forms behave like direct dyes, in that they exhaust onto cotton in the presence of salt. Once applied, the reduced dyes are reoxidized to their water-insoluble forms, giving dyeing with good washfastness. This chemistry is illustrated in Fig. 13.20. Although the oxygen in air can be used for the oxidation step, an agent such as hydrogen peroxide is used because it works faster. Sulfur dyes have also been marketed in their prereduced form (Dye-S^-Na^+), as ready-to-use C.I. Leuco Sulfur dyes. Dye exhaustion in the presence of salt is followed by oxidation. Similarly, water-soluble sulfur dyes containing thiosulfate groups are sold as C.I. Solubilized Sulfur dyes. They are known as “Bunte salts” [36], have better leveling properties than the C.I. Sulfur dyes, and are attractive for package dyeing. The C.I. Solubilized sulfur dyes are applied with Na_2S and the chemistry associated with their two-step application is summarized in Fig. 13.21, along with a representative dye structure.

$$\textbf{Step 1:}\quad \text{Dye-S-SO}_3^{\ominus} + \text{S}_2^{\ominus} \longrightarrow \text{Dye-S}^{\ominus}$$

$$\textbf{Step 2:}\quad \text{Dye-S}^{\ominus} + \text{Dye-S-SO}_3^{\ominus} \longrightarrow \text{Dye-S-S-Dye}$$

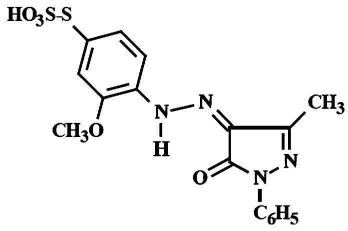

Fig. 13.21 Two-step chemistry employed in the application of C.I. Solubilized Sulfur dyes (*top*) and a representative dye structure (*bottom*)

Vat Dyes

Like sulfur dyes, vat dyes are water-insoluble colorants for cotton that must be reduced to their soluble “leuco” forms to be applied from an aqueous dyebath [37, 38]. Their name originates from their early application from wooden vessels known as vats. The term “vatting” is used to refer to the application of these dyes via chemical reduction followed by oxidation. Vat dyes are easier to reoxidize than sulfur dyes and the oxygen in air is often the agent used. As would be anticipated, most vat dyes display high washfastness. As a class, they have the best lightfastness and bleach fastness among the dyes families suitable for cotton. Some cause catalytic fading or phototendering on cotton [39].

Vat dyes have mainly anthraquinone (82%) or indigoid/thioindigoid (9%) structures, with the former having much better fastness properties. The anthraquinone vat dyes exhibit a bathochromic color shift (λ_{max} of higher wavelength) upon reduction to their leuco forms, whereas the

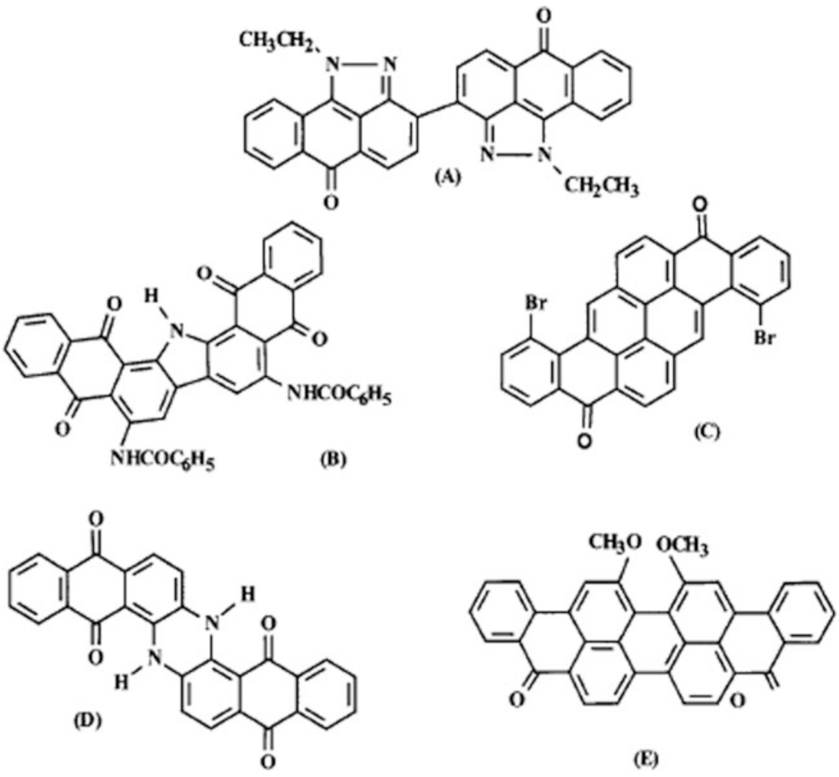

Fig. 13.22 Representative anthraquinone vat dye structures: CI Vat Red 13 (**a**), Vat Black 27 (**b**), Vat Orange 2 (**c**), Vat Blue 4 (**d**), and Vat Green 1 (**e**)

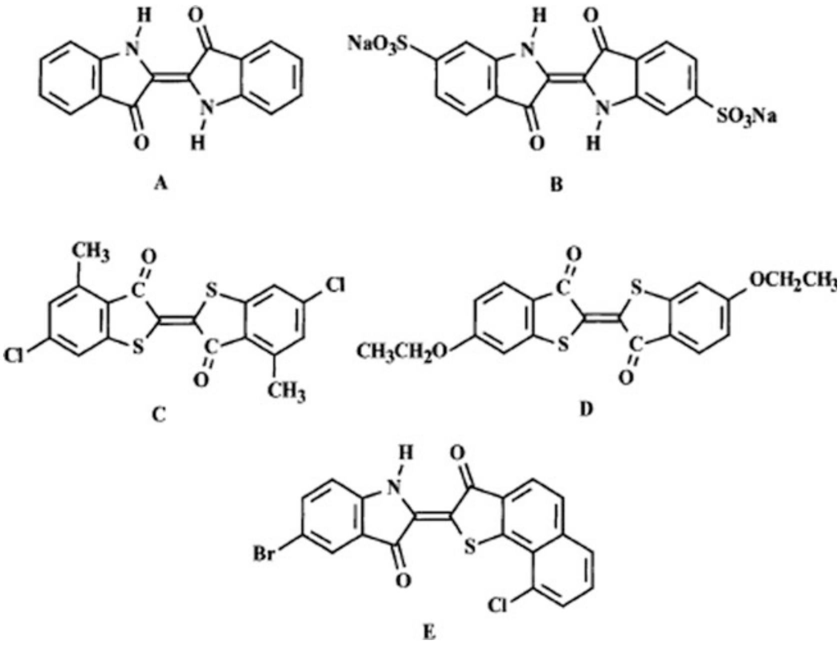

Fig. 13.23 Representative indigoid and thioindigoid vat dye structures: CI Vat Blue 1 (**a**), Food Blue 1 (**b**), Vat Red 1 (**c**), Vat Orange 5 (**d**), and Vat Black 1 (**e**)

indigoids exhibit a hypsochromic shift. Examples of the two structural types are shown in Figs. 13.13 and 13.22. Anthraquinone vat dyes having a single anthraquinone unit exist; however, those with the best fastness properties seem to have the equivalent of two anthraquinone units.

No doubt the best-known and biggest volume vat dye is C.I. Vat Blue 1, indigo, the denim blue dye. Closely related structures are the thioindigoids (4%), which have a sulfur atom in lieu of the –NH– group (Fig. 13.23). The thioindigoids are used mainly as colorants for printing and give orange and red hues. A few dyes having the features of both indigoid types are also known (e.g., Ciba Violet A).

The chemistry associated with the vatting process is illustrated in Fig. 13.24. For the reduction step, a mixture

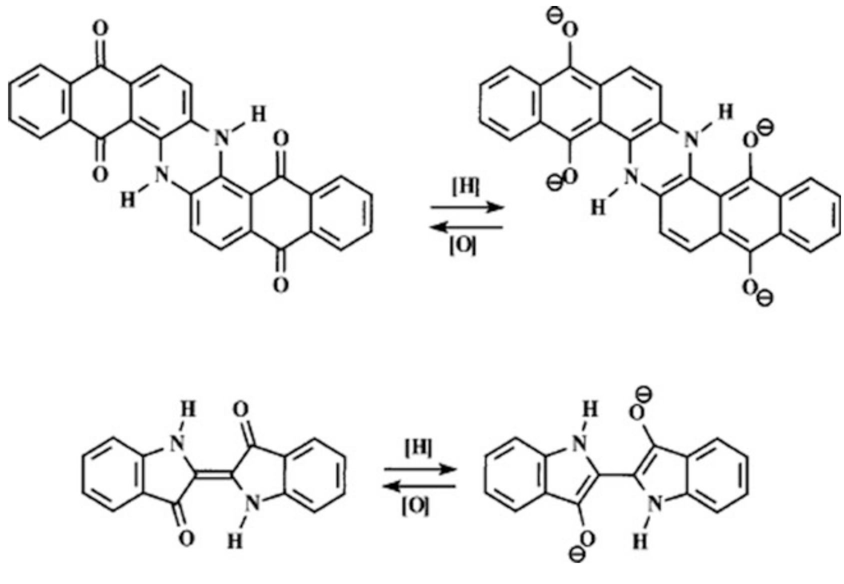

Fig. 13.24 Chemistry involved in the vatting of the CI Vat dyes Blue 4 (*top*) and Blue 1 (*bottom*)

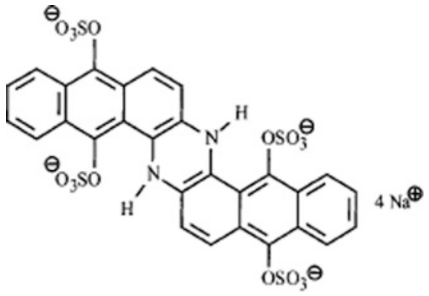
of sodium hydroxide (caustic) and sodium hydrosulfite (hydro, $Na_2S_2O_4$) is used. Depending upon the amount of caustic and hydro employed one or both of the anthraquinone rings may undergo reduction.

Vat dyes are also available in prereduced forms (3%), an example of which is the leuco sulfuric acid ester C.I. Solubilized Vat Blue 4. These water-soluble forms have affinity for cellulose and exhaust like direct dyes. They are oxidized to the insoluble form using hydrogen peroxide.



C.I. Solubilized Vat Blue 4

Vat dyes are brighter than direct and sulfur dyes but less so than reactive dyes. They are the colorants of choice when dye bleachfastness on cotton is important. They span the entire color spectrum and can be applied to cotton using a variety of methods. With regard to the latter point, they can be further classified based on the temperatures involved in their application. Accordingly, there are hot (50–60 °C), warm (40–50 °C), and cold (25–30 °C) dyeing vat dyes. The hot dyeing types are large planar leuco forms having high affinity and no salt is required for their application. The cold types are small molecules with low affinity and require repeated application to get good build-up. Indigo falls into the cold dyeing category.

The Application of Dyes

The process of dyeing may be carried out in batches or on a continuous basis. The fiber may be dyed as stock, yarn, or fabric. However, no matter how the dyeing is done, the process is always fundamentally the same: dye must be transferred from a bath—usually aqueous—to the fiber itself. The basic operations of dyeing include: (1) preparation of the fiber, (2) preparation of the dyebath, (3) application of the dye, and (4) finishing. There are many variations of these operations, depending on the kind of dye. The dyeing process is complicated by the fact that single dyes seldom are used. The matching of a specified shade may require from two to a dozen dyes.

Fiber Preparation

Fiber preparation ordinarily involves scouring to remove foreign materials and ensure even access to dye liquor. Some natural fibers are contaminated with fatty materials and dirt, and synthetic fibers may have been treated with spinning lubricants or sizing that must be removed. Some fibers also may require bleaching before they are ready for use.

Dyebath Preparation

Preparation of the dyebath may involve simply dissolving the dye in water, or it may be necessary to carry out more involved operations such as reducing the vat dyes. Wetting

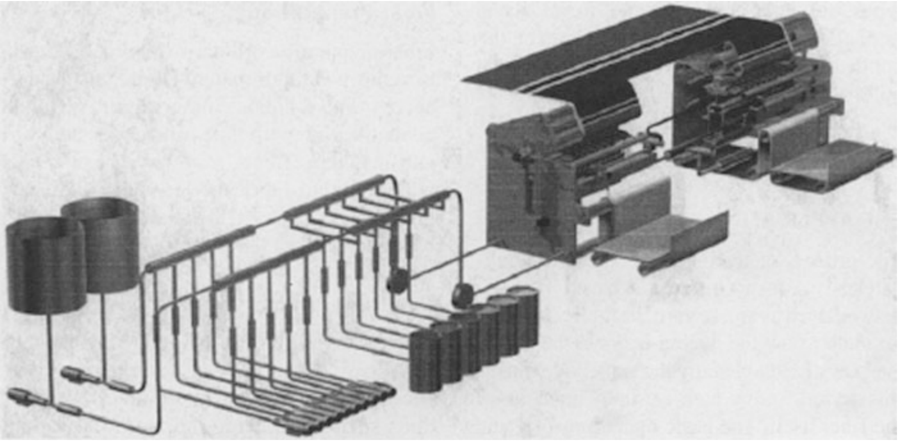


Fig. 13.25 Fluidyer carpet range dye applicator (Courtesy of Zima Corporation)

agents, salts, "carriers," retarders, and other dyeing assistants also may be added. Carriers are swelling agents that improve the dyeing rate of very hydrophobic fibers such as the polyesters. Examples are *o*-phenylphenol and biphenyl. Retarders are colorless substances that compete with dyes for dye sites or form a complex with the dye in the bath and act to slow the dyeing rate. Their use is necessary when too-rapid dyeing tends to cause unevenness in the dyeings.

Finishing

The finishing steps for many dyes, such as the direct dyes, are very simple: the dyed material merely is rinsed and dried. Vat-dyed materials, on the other hand, must be rinsed to remove the reducing agent, oxidized, rinsed again, and soaped before the final rinsing and drying steps are carried out. Generally, the finishing steps must fix the color (if fixation has not occurred during application) and remove any loose dye from the surface of the colored substrate. Residual dyeing assistants such as carriers also must be removed.

The types of textile structures that lend themselves to continuous dyeing methods are woven and tufted carpets. Continuous dyeing is designed for long runs of similar product; it is a high-output method of dye application.

The first volume-yardage continuous process was the continuous pad-steam process for vat dyes on cotton. The vat dye dispersion was padded onto the cloth and dried; this was followed by passage through a reducing bath, steaming for 30 s, passage through an oxidizing bath and, finally, washing. When it was discovered that disperse dyes could be thermosoled into polyesters by treatment with dry heat for 60 s and 400 °F, this procedure was readily adapted to continuous processing. The advent of large volumes of dyed polyester-cotton-blend fabrics in the late 1960s made it possible to combine these two processes into one thermosol pad-steam system.

Tufted nylon carpet grew to be the number-one floor covering in the United States in recent decades. Continuous open-width ranges were developed but not without a great deal of ingenuity to deliver the precise loading of liquid to the tufted surface. This was accomplished by a dye applicator that flooded the dye solution onto the carpet surface. The advancing technology in continuous, metered dyeing systems has created a need for dyes in liquid form, both dispersions and solution. The dyes used in carpet dyeing, for the most part, are supplied by the dye manufacturers as liquids. See Fig. 13.25.

Dyeing Methods/Batch

Virtually all types of textile structures are dyed by batch (or exhaust) methods of dyeing, such as stock, yarn, circular knits, warp knits, woven fabrics, garments, carpets, and so on. Batch methods include beck dyeing, jig dyeing, pad-batch, beam dyeing, and others. These methods are dictated primarily by the physical structure of the textile product and the type of fiber(s) it contains. Each of these batch methods employs a different type of machine. As an example, a circular knit fabric comprises cotton could be dyed in a beck, whereas the same structure comprises polyester most likely would be dyed in a high-pressure jet machine, and a garment constructed from the circular knit cotton likely would be dyed in a garment machine.

Stock dyeing often is carried out in large heated kettles made of stainless steel or other corrosion-resistant metal. These kettles can be sealed and used for dyeing at temperatures somewhat above the boiling point of water at atmospheric pressure.

Yarns are dyed in package machines. In this arrangement the yarn is wound onto perforated dye tubes and placed on spindles that are fit into a closed kettle. The dye solution is heated and pumped through the spindle and yarn package. A cycle of inside-outside flow usually is used to provide level

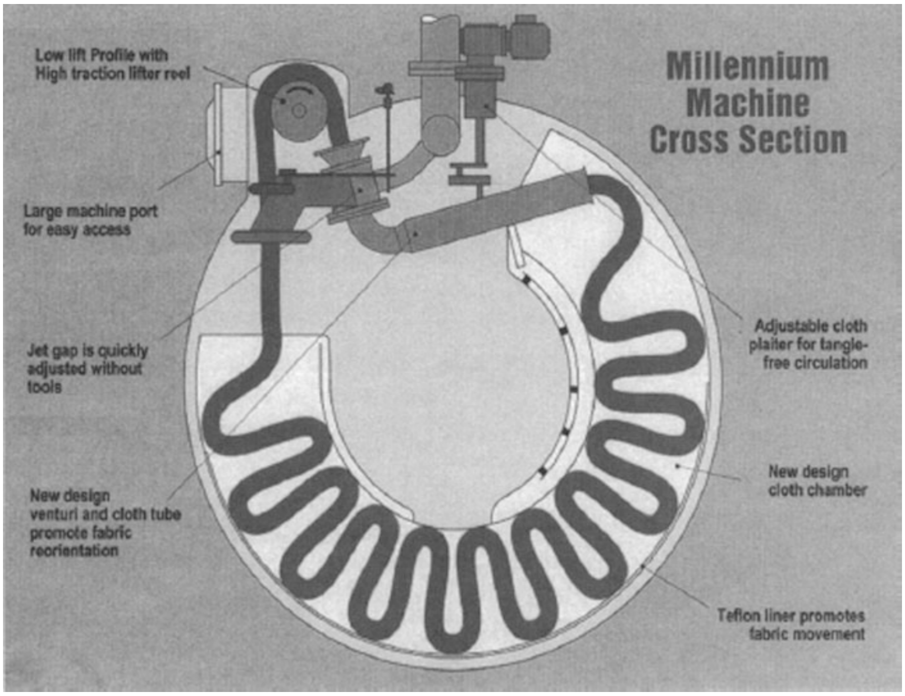

Fig. 13.26 Millennium jet dyeing machine (Courtesy of Gaston County Dyeing Machine Co.)

dyeing by equal exposure of the dye to yarns. Although the basis of package dyeing has not changed, a number of refinements have been introduced in recent years. Precision winding of the yarn has improved quality by giving a more uniform package density. Horizontal machines and valving between chambers to allow reconfiguration of the dye machine to control the size of the dyeing have changed the way package dyehouses are built. Robotization has been widely utilized to load and unload machines. Also lower-ratio dyebaths with higher flow rates have improved the energy efficiency of the newer machines.

Fabrics are dyed in machines that move them through the dye liquor either under tension (jig) or relaxed (beck). Fabrics also can be dyed in full width by winding them on a perforated beam through which hot dye liquor is pumped. This is the principle of the beam dyeing machine.

The pressure-jet dyeing machine is unique in that it has no moving parts. The cloth, in rope form, is introduced into a unidirectional liquid stream enclosed in a pipe. Liquor is pumped through a specially designed xanthen jet imparting a driving force that moves the fabric. The two fabric ends are sewn together to form a continuous loop.

The first jet machine was introduced in 1965. There are two major types of jet dyeing machines: the vertical kier and the elongated horizontal kier (see Fig. 13.26). In general, the kier uses small water volumes, whereas the elongated types use larger-volume ratios in dyeing. The kier types normally are used for more substantial fabrics, and the elongated types are suited for fine or delicate fabric styles. Important features in today's machines are improved corrosion-resistant alloys and the ability to operate at higher efficiencies with minimum energy consumption. The control systems have been refined; there is simultaneous loading and unloading. Larger-capacity machines also are being built; a jet dye machine has been developed for carpet dyeing.

Printing

Printing is a special kind of localized dyeing that produces patterns. Four kinds of printing have long been recognized: (1) direct, (2) dyed, (3) discharge, and (4) resist. In direct printing, a thickened paste of the dye is printed on the fabric to produce a pattern. The fabric then is steamed to fix the dye and is finished by washing and drying. Dyed printing requires that the pattern be printed on the fabric with a mordant. The entire piece then is placed in a dyebath containing a mordant dye, but only the mordanted areas are dyeable. Washing then clears the dye from the unmordanted areas, leaving the pattern in color.

In discharge printing, the cloth is dyed all over and then printed with a substance that can destroy the dye by oxidation or reduction, leaving the pattern in white. When a reducing agent such as sodium hydrosulfite is used to destroy the dye, the paste may contain a reduced vat dye. Finishing the goods by oxidation and soaping then produces the pattern in color. In resist printing, certain colorless substances are printed on the fabric. The whole piece then is dyed, but the dye is repelled from the printed areas, thus producing a colored ground with the pattern in white.

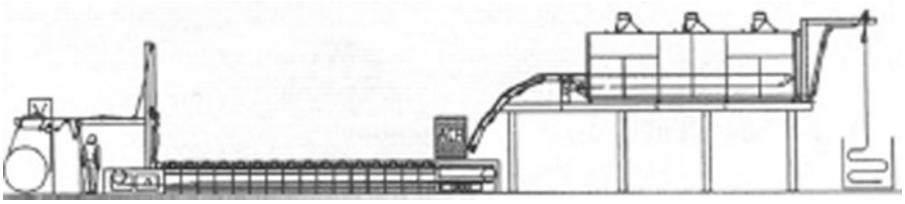

Fig. 13.27 Rotascreen V rotary screen print machine (Courtesy of Zimmer Machinery Co.)

Printing is most often done with rotary screens etched in the design to be printed. Printing paste is fed constantly to the center of the rotating screen from a nearby supply, and a squeegee pushes the colored paste through the holes in the screen, leaving the dye paste only in the intended areas, a separate screen is required for each color in the pattern. See Fig. 13.27.

An important recent advance in the pattern-coloring of textiles is ink-jet or digital printing. Milliken's Millitron and Zimmer's ChromoJet have been successfully used for carpet and upholstery markets for over two decades. Finer-resolution machines began to emerge in the late 1980s when Stork introduced a prototype machine. During the past 5 years a number of manufacturers have introduced digital ink-jet printers that use either CYMK (Cyan, Yellow, Magenta, and Black) to make a composite color or true-color machines that use mixed pigment systems. The current machines are very successful at furnishing one of a kind and for use in rapid prototyping.

Pigment Dyeing and Printing

Pigment dyeing and printing are processes that compete with the more conventional means of dyeing and printing described above. These processes use water-insoluble dyes or pigments that are bound to the surfaces of fabrics with resins. A paste or an emulsion, containing pigment and resin or a resin-former, is applied to the fabric. The goods then are dried and cured by heat to produce the finished dyeing or print. During the heating or curing, fabric, resin, and pigment become firmly bonded together. This method of color application is economical and produces good results. It should be noted that the pigment is confined to the surface of the fabric and can be selected without regard for fiber affinity.

Nontextile Uses of Dyes

Colorants for nontextile use have been developed mainly for use in hair dyeing, photography, biomedical application, and electronics and reprographics [34–41]. Dye application areas involving the latter areas include ink-jet printing, thermal or pressure dye transfer, laser printing, liquid crystal displays, optical data storage, and nonlinear optics. In several nontextile applications, dyes are not used for their ability to deliver color. Instead, they are used because of their potential electrical properties, such as photoconduction and electrostatic charging of toners, and in some cases they are used because they absorb IR radiation, which induces heating effects. The latter property is important in optical data recording.

Liquid Crystal Dyes

Dyes for liquid crystalline media typically have (1) nonionic structures, (2) high purity, (3) solubility and compatibility with the medium, (4) a transition dipole that is parallel with the alignment axis of the molecular structure, and (5) good alignment with the liquid crystal molecule [42]. Examples include the disazo and anthraquinone dyes in Fig. 13.28.

Ink-Jet Dyes

Dyes used in this area must have the following properties: (1) very good water solubility; (2) low toxicity; (3) good stability to UV light, heat, and moisture; (4) quick fixation to paper following application (deposition); and (5) good color strength [43]. To achieve high resistance to removal by water (wetfastness), ink-jet dyes often contain fewer sulfonate groups and one or more carboxylate groups. This change in structural features allows the dyes to have good solubility in alkaline ink formulations but high wetfastness following deposition. This change in solubility behavior is known as *differential solubility* [44]. Structures in Fig. 13.29 illustrate the type changes made to the early ink-jet dye C.I. Food Black 2 to enhance wetfastness.

New water-soluble yellow dyes for ink-jet printing are similar to the initially used dye C.I. Direct Yellow 86, except that they are smaller (Fig. 13.30). The size change is designed to provide the solubility needed for high throughput ink cartridge systems, without clogging the ink-jet nozzles.

Most of the new water-soluble magenta dyes are based on H-acid. Examples include dyes that contain a fluorocyanophenyl group (Fig. 13.31). To improve the lightfastness of magenta dyes, gamma acid can be used as the coupling component. For very bright magenta prints, dyes based on xanthene structures can be used. Examples include C.I. Acid Red 52,

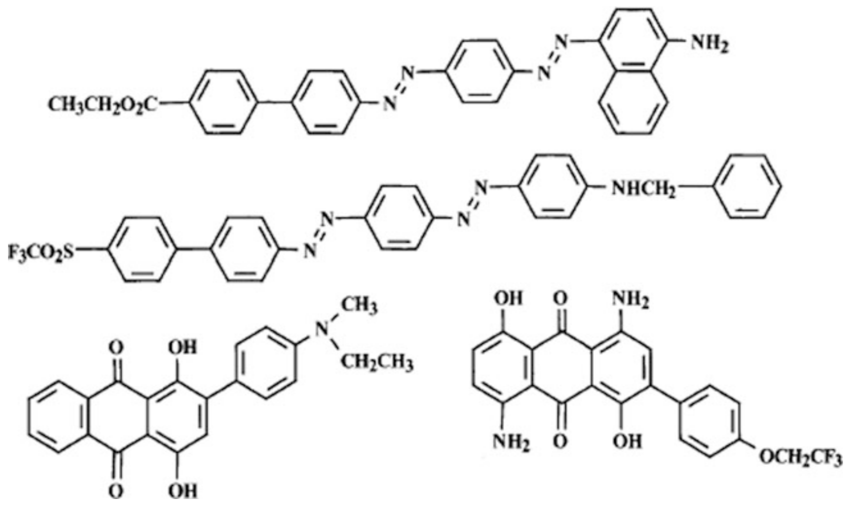

Fig. 13.28 Azo and anthraquinone dyes suitable for liquid crystalline media

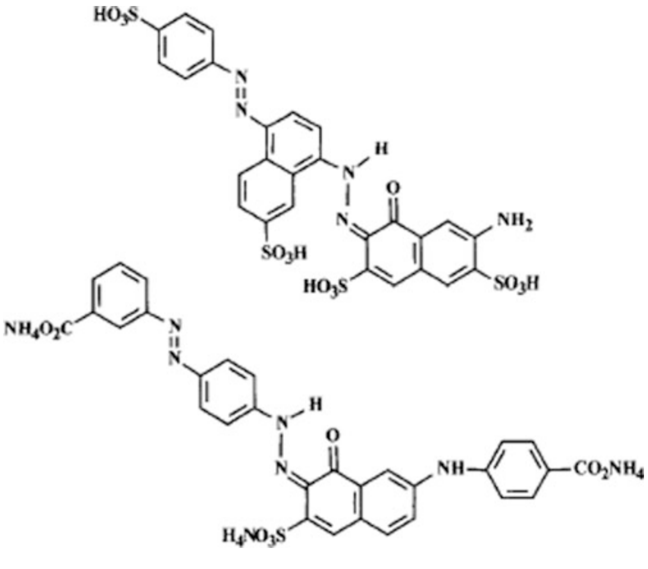

Fig. 13.29 Food Black 2 (*top*) and its wetfast analog (*bottom*)

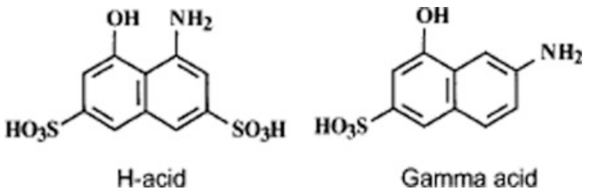

which has low photostability, and a carboxylated analog, which has better photostability and wetfastness (Fig. 13.32).

The water-soluble cyan dyes continue to be based on the copper phthalocyanine (CuPc) system. In this regard, C.I. Direct Blue 199 has proved effective, due to its good color strength and photostability. Carboxylated analogs of this type of dye have been developed to enhance wetfastness on paper (Fig. 13.33).

Thermal and Pressure-Sensitive Printing

In direct thermal printing, a color former (colorless) and a developer (acidic) are brought into contact in the presence of heat, to produce color on paper [45, 46]. The most important color in thermal printing is black and the majority of the color formers are fluorans (Fig. 13.34). The most important application of direct thermal printing is in facsimile machines.

In pressure-sensitive printing technology the color former is dissolved in a solvent and encapsulated [47]. The use of pressure (pen, typewriter key) ruptures microcapsules containing the color former, which generates color upon contacting a developer. Black prints are usually obtained either from fluorans or from color former mixtures. Compounds of the type shown in Fig. 13.35 can be used in two- and three-component mixtures.

Organic Photoconductors and Toners

Photoconductors and toners are used in photocopiers and laser printers to produce images [48]. Organic photoconductors consist of a charge-generating layer and a charge-transporting layer. The former comprises pigments and the latter comprise electron-rich organic compounds that are usually colorless. Suitable organic pigments for charge generation include azo pigments, tetracarboxydiimides, polycyclic quinones, phthalocyanines, perylenes, and squarylium compounds (e.g., Fig. 13.36).

Colorants are used in toners to provide color and control the electrostatic charge on toner particles. Diarylides and monoarylides have been used as the yellow pigments in colored toners. The magenta pigments are often quinacridones and the cyan pigments are CuPcs.

Infrared Absorbing Dyes

Infrared dyes include indoleninecyanines and azulenium compounds, both of which are used in optical recording materials [49]. Other examples are metal (Mn, Fe, Co, Cd, Al, Cu, Pd)-complexed phthalocyanines, quinones, quinonoids, and imminium and diiminium compounds (Fig. 13.37).

Laser Dyes

Lasers in which dyes comprise the active medium have become one of the most widely used types [50]. The key virtue of these systems is their ability to cover virtually the entire fluorescence spectral region. Accordingly, the most commonly used dyes are highly fluorescent and include coumarin, rhodamine, oxazine, and *syn*-bimane structures (Fig. 13.38). Dye lasers are employed in liquid form, which allows them to dispel excessive heat by recirculating the dye solution. Good photostability and efficient laser action under flashlamp excitation are important properties.

Biomedical Dyes

Dyes can be used clinically in bioanalysis and medical diagnostics and in the treatment of certain diseases (cf. Fig. 13.39). For instance, near infrared (NIR) and IR-absorbing dyes can be used in automated DNA sequencing (dye A), fluorescent dyes can be used in cancer detection (dye B), and certain azo and heterocyclic dyes can be used in virus (dye C), cell (dye D), and bacteria (dye E) detection. An in-depth summary of dyes in this area has been published recently [51].

Hair Dyes

About 80% of the dyes used in hair coloring are known as oxidation hair dyes [52, 53]. The remaining 20% of the available hair dyes are mainly synthetic dyes that have affinity for protein substrates. Oxidation dyes are produced directly on hair by oxidizing aromatic diamines (e.g., *para*-phenylenediamine or 2,5-diaminotoluene) with a suitable oxidizing agent. In this regard, the diamines have been referred to as "primary intermediates" and the oxidizing agents (e.g., hydrogen peroxide) as "developers." Other suitable primary intermediates are aminodiphenylamines, amino-methylphenols, and *para*-aminophenol.

When used alone, the primary intermediates give a quite limited shade range following oxidation on hair. To enhance the range of available hair colors, the primary intermediates are oxidized in the presence of suitable "couplers." Whereas most couplers do not produce colors when exposed to developers alone, they give a wide array of hair shades in combination with primary intermediates. Suitable couplers include 3-aminophenol, resorcinol, and α-naphthol.

The chemistry associated with the oxidation of primary intermediates is now reasonably well known. For *para*-phenylenediamine and *para*-aminophenol, this involves the process outlined in Fig. 13.40. It can be seen that dye formation is a two-step process involving oxidation and self-coupling.

C.I. Basic dyes such as Yellow 57, Red 76, Blue 99, Brown 16, and Brown 17 have been used in color refreshener shampoos and conditioners. Similarly, C.I. Acid dyes such

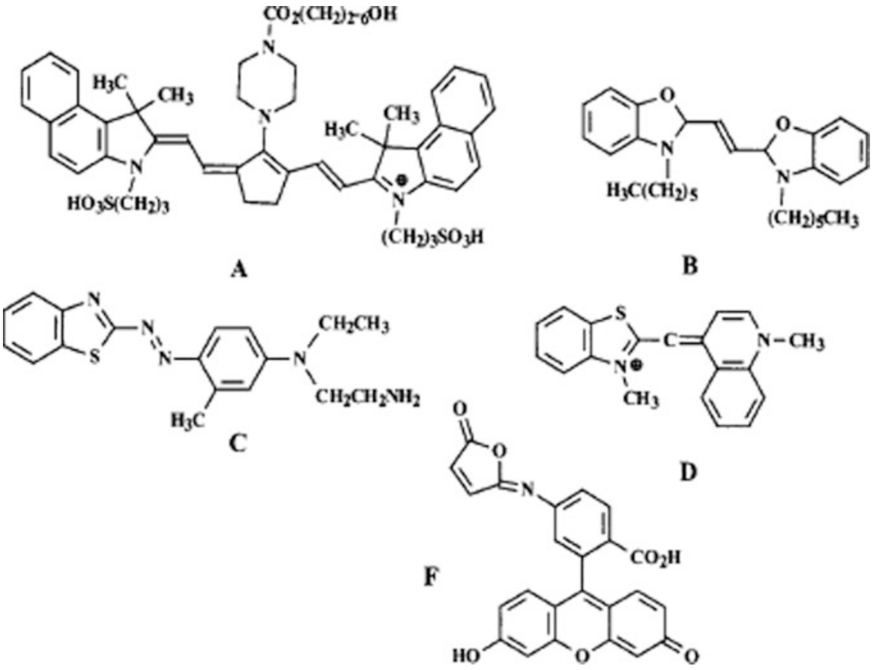

Fig. 13.39 Examples of experimental dyes used in biomedical applications

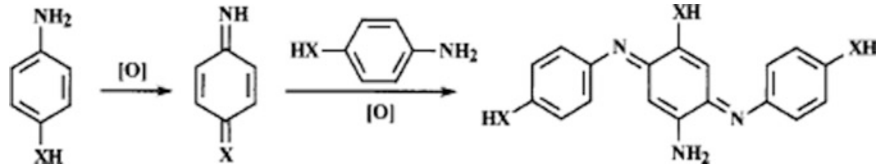

Fig. 13.40 Oxidation of primary intermediates, where X = O, NH

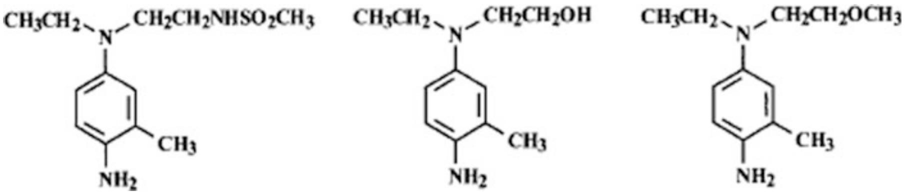

Fig. 13.41 Structures of some developers used in color photography

as Yellow 3, Orange 7, Red 33, Violet 43, and Blue 9 have been used in shampoos, in this case to deliver highlighting effects [54].

Photographic Dyes

Color photography is still one of the most important and interesting nontextile uses for synthetic dyes. The chemistry employed is comparable to that described above for oxidation hair dyes, in that an oxidizable substrate (e.g., phenylenediamine) is combined with a coupler to produce the target colorant. In this case the diamine is referred to as the "developer," and it is oxidized by silver halide in the photographic film. The oxidized developer then reacts with the coupler to form the dye. This process produces a negative dye image consisting of yellow, magenta, and cyan dyes in proportion to the amount of red, blue, and green light absorbed by the film [55].

Some widely used developers are shown in Fig. 13.41. They can be used to produce the yellow, magenta, and cyan dyes shown in Fig. 13.42. These dye structures demonstrate that acetoacetanilide, pyrazolone, and indoaniline intermediates are useful for producing yellow, magenta, and cyan colors, respectively.

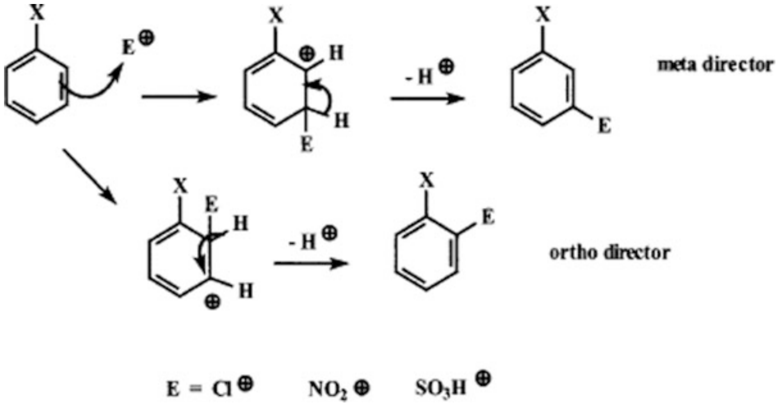

Fig. 13.43 Electrophilic attack of an aromatic ring containing deactivating and activating groups

Dye Intermediates

The raw materials used to synthesize organic dyes are commonly referred to as dye intermediates. Largely, they are derivatives of aromatic compounds obtained from coal tar mixtures. The majority of these derivatives are benzene, naphthalene, and anthracene-based compounds. This section provides an overview of the chemical reactions used to prepare the key intermediates employed in dye synthesis. In this regard, emphasis is placed on halogenated, aminated, hydroxylated, sulfonated, and alkylated derivatives of benzene, naphthalene, and anthraquinone.

Most dye intermediates are prepared by reactions involving electrophilic or nucleophilic substitution processes. The electrophilic processes include nitration, sulfonation, and halogenation reactions, and the nucleophilic processes include hydroxylation and amination reactions. Electrophilic substitution reactions are of the form shown in Fig. 13.43. In this regard, the incoming electrophile (electron-seeking species) reacts with the more electron-rich positions. When the aromatic ring contains ring-activating groups (e.g., hydroxy, alkoxy, amino, alkyl), the incoming group will attack *ortho*/*para* positions. If ring-deactivating groups (e.g., nitro, sulfonic acid, carboxylic) are present, the positions *meta* to the deactivating groups will be attacked.

Other key dye intermediates are prepared by oxidation and reduction processes. Examples of each of these processes are covered in the sections that follow.

Nitration

For dye intermediates, this process involves the introduction of one or more nitro (NO_2) groups into aromatic ring systems. Nitro groups serve as chromophores (color bearers, precursors for amino groups, and as auxochromes (color aiders). Because they are *meta*-directing groups they are also useful in the strategic placement of another incoming group.

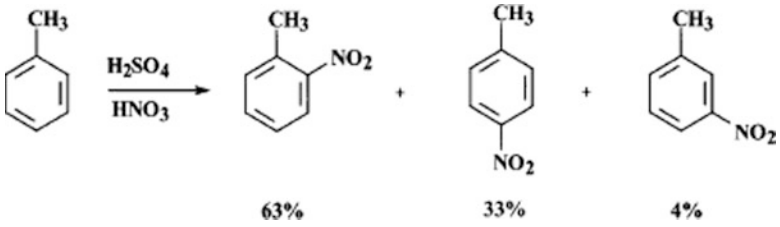

Fig. 13.44 Nitration of toluene using mixed acid

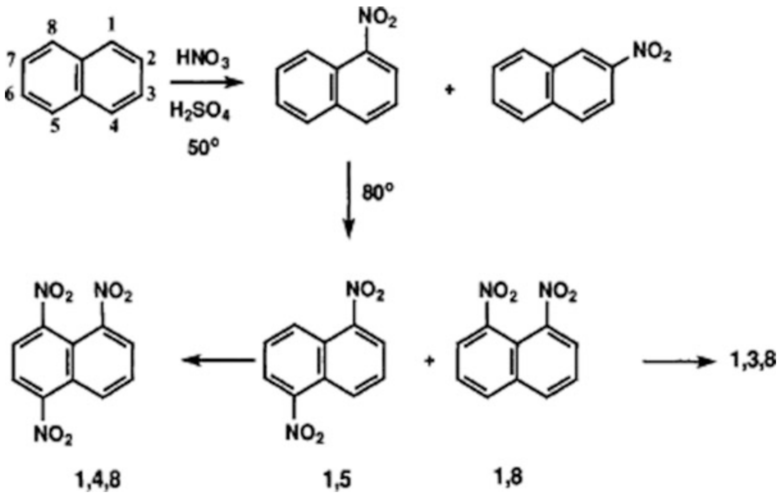

Fig. 13.45 Nitration of naphthalene using mixed acid

Nitric acid (HNO_3) is the chemical agent commonly used in nitration reactions. Depending upon the degree of ring activation, HNO_3 may be used in combination with other acids. In fact, nitrations are often conducted by using a mixture of HNO_3 and sulfuric acid (H_2SO_4). This combination is known as "nitrating mixture" or "mixed acid," and it is especially effective when deactivated ring systems are to be nitrated. Dilute HNO_3 or a HNO_3/acetic acid (CH_3CO_2H) mixture can be used for nitrating very reactive ring systems. When the former is used there is also the potential for ring oxidation to occur rather than the desired nitration, depending upon the actual compound undergoing nitration. Examples of nitration reactions are shown in Figs. 13.44, 13.45, and 13.46. The nitration of toluene (Fig. 13.44) is selected because it illustrates what can happen when monosubstituted benzenes having a ring-activating group are used. In this case, the principal products reflect a statistical mixture of *ortho* and *para* isomers, with only a small amount of the *meta* isomer obtained. Nitration is conducted near 20 °C and the products are separated by distillation.

Nitration of naphthalene gives mostly the 1-nitro isomer (~90%), initially. Introduction of a second nitro group takes place in the opposite ring because the existing nitro group reduces the reactivity of the ring to which it is attached. Although, nitro groups are *meta* directors, in this case they can also direct the incoming second (or third) nitro group to a *peri* position. In the naphthalene ring system, the *peri* positions are those that are 1,8 and 4,5 to each other (Fig. 13.45).

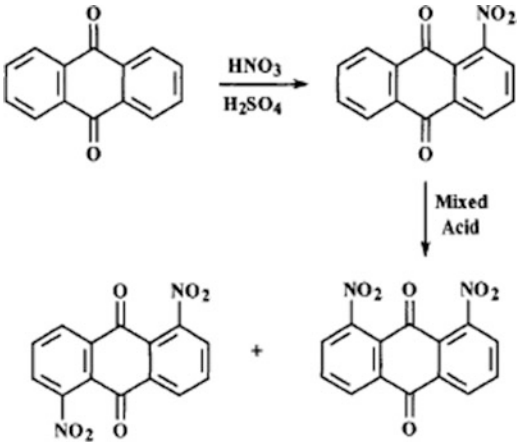

Fig. 13.46 Nitration of anthraquinone using mixed acid

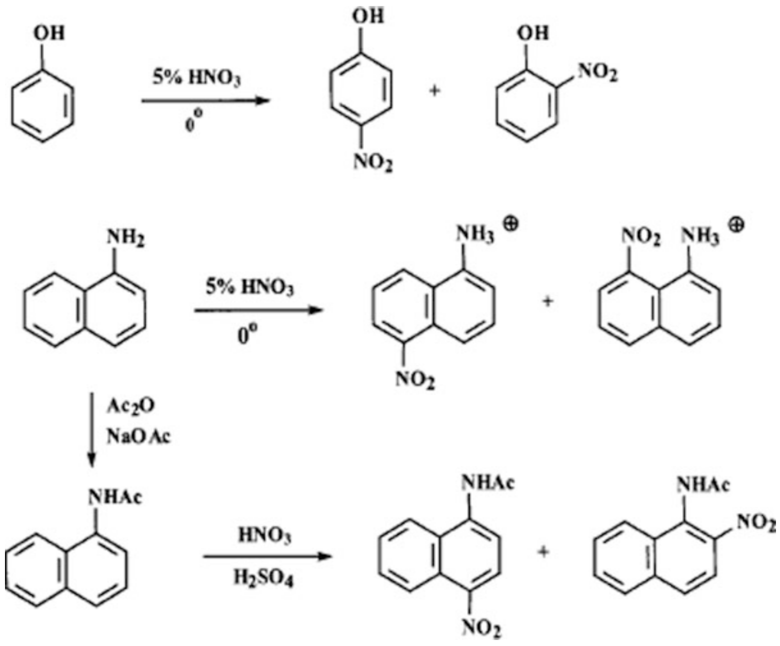
The nitration of anthraquinone at 50 °C gives, initially, the 1-nitro isomer, and if nitration continues at 80–90 °C, the 1,5 and 1,8 isomers are obtained. Further nitration is impractical and serves to point out that the anthraquinone ring is appreciably less reactive than the naphthalene system. This will be more evident as the chemistry reported in this section continues to unfold.

Fig. 13.47 Nitration of phenol and 1-naphthylamine



The nitration of phenols and amines must be conducted with care, as these systems are subject to ring oxidation if the temperature gets too high. For instance, the nitration of phenol itself is conducted near 0 °C using 5% HNO_3. This gives a mixture of *ortho* and *para* isomers that can be separated by steam distillation (Fig. 13.47). Aromatic amines are often protected by *N*-acetylation prior to nitration. This reduces both the potential for ring oxidation and the amount of *meta* isomer that forms when the amino group undergoes protonation. The protonated amino group ($-NH_3^+$) is a *meta* director, unlike the free amino (NH_2) and the acetylated amino (NHAc) groups. This chemistry is illustrated in Fig. 13.47 for 1-naphthylamine. Following nitration, the acetyl group can be removed by hydrolysis.

Reduction

The most important reduction reactions are those leading to aromatic amines that are suitable for azo dye formation. Although this usually involves the reduction of a nitro group to an amino (NH_2) group, the reduction of azo groups to amino groups is also an important process. Agents that are commonly used to effect chemical reductions include: Fe + HCl or H_2SO_4; Na_2S; NaSH; Zn + NaOH; H_2 + transition metal catalysts; and $Na_2S_2O_4$. Examples of these reductions are given in Figs. 13.48, 13.49, 13.50, and 13.51. While the reduction of nitrobenzene can be conducted in a number of ways, a key commercial process involves the method in Fig. 13.48, where high-temperature hydrogenation is used.

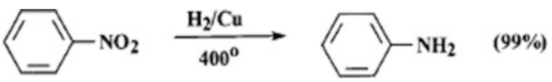


Fig. 13.48 Commercial process for the reduction of nitrobenzene

The reduction of azo compounds using sodium hydrosulfite ($Na_2S_2O_4$) and NaOH is an important reaction, as it provides an indirect method for the amination of phenols and naphthols (Fig. 13.49). The reduction of nitro groups in anthraquinone compounds works best when a mild reducing agent (e.g., sodium hydrosulfide, NaSH) is used. In this way one avoids reducing the quinoid system.

An example of an important reduction reaction involving Fe + H^+ is shown in Fig. 13.50. In this case the sequential use of nitration and reduction is illustrated.

It must also be pointed out that the medium employed in the reduction process can play a major role in the outcome of the reaction. A good example is the reduction of nitrobenzene in the presence of acid or alkali. One should expect the reduction to follow the course shown in Fig. 13.48 under normal conditions, however, in acidic media the product obtained is mainly *para*-aminophenol. In fact, this has long been the key step in the commercial route to acetaminophen [55], which is obtained by *N*-acetylation of the reduction product. When the reduction is conducted in the presence of alkali and Zn, the nitro compound is converted to a hydrazo compound via azoxy and azo intermediates. The hydrazo compound is important because it can be treated with acid to form diaminobiphenyls known as benzidines. These reactions are shown in Fig. 13.51. Because benzidine (4,4′-diaminobiphenyl) itself is known to be a human carcinogen, its use as a dye intermediate is substantially curtailed in the western world.

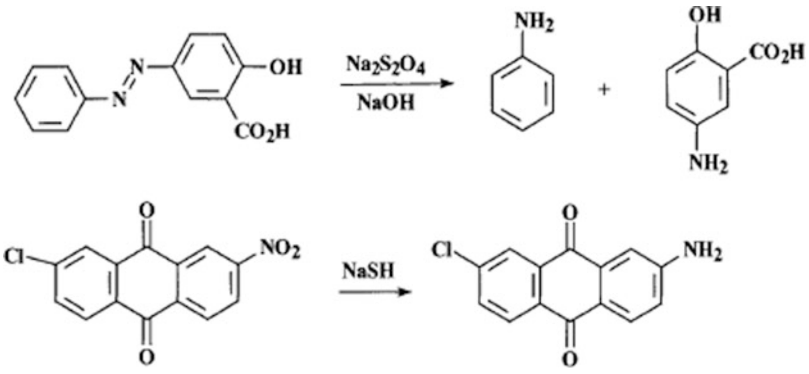

Fig. 13.49 Reduction of azo (*upper*) and nitroanthraquinone (*lower*) compounds

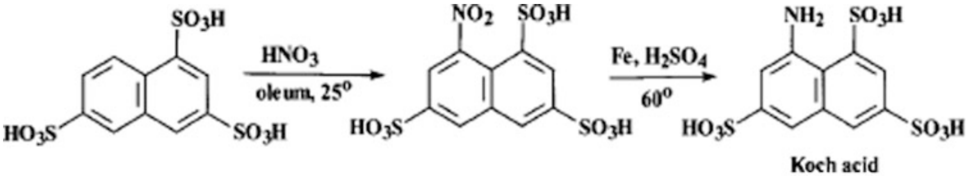

Fig. 13.50 Formation of Koch acid via nitration and reduction steps

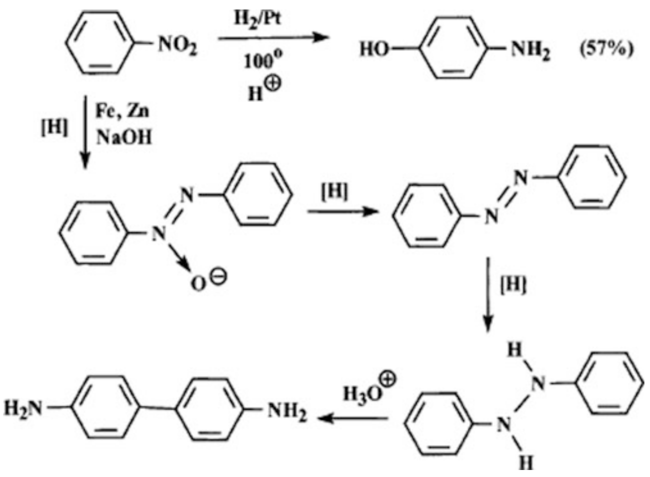

Fig. 13.51 Reduction of nitrobenzene in acidic and alkaline media

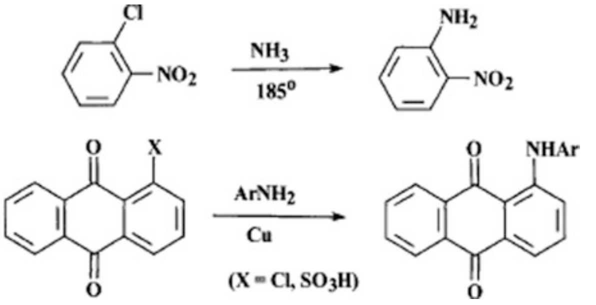

Fig. 13.52 Amination reactions involving benzene and anthraquinone compounds

Amination

In as much as the previous section covers the reduction of nitro and azo compounds as a method for introducing amino groups, the focus of this section is direct aminations involving replacement reactions and examples of indirect amination. In the former case, amination via the replacement of activated halogens using an alkyl or arylamine is widely used. The examples given in Fig. 13.52 show that halogens positioned *ortho* to a nitro group or in an α-position on the anthraquinone ring can replaced by amino groups. The former reaction also works well when the groups are *para*. However, the reaction is difficult and usually impractical when electron-donating rather than electron-attracting groups are situated *ortho* and/or *para* to the halogen. In the case of the anthraquinone system, α-sulfonic acid and α-nitro groups can also be replaced.

An important amination reaction involves hydroxy-substituted naphthalenes (Fig. 13.53). In a process known as the Bucherer reaction, naphthols are heated under pressure with a mixture of ammonia and sodium bisulfite. As the second and third examples indicate, the reaction works with aromatic amines and is selective. Note that the β-hydroxy group reacts preferentially when an α-hydroxy group is also present, and that two hydroxy groups in the same compound can be replaced.

An alternative route to the synthesis of aminoanthraquinones is the two-step sequence shown in Fig. 13.54. In this case, amination occurs via the condensation of *para*-toluenesulfonamide with chloroanthraquinone followed by hydrolysis of the sulfonamide bond. This method provides a way to introduce an –NH_2 group without the use of ammonia gas and the associated high temperatures and pressures.

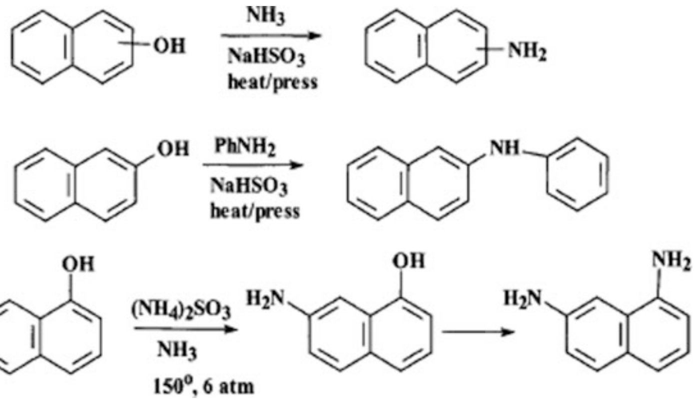

Fig. 13.53 Amination of naphthalene compounds via the Bucherer reaction

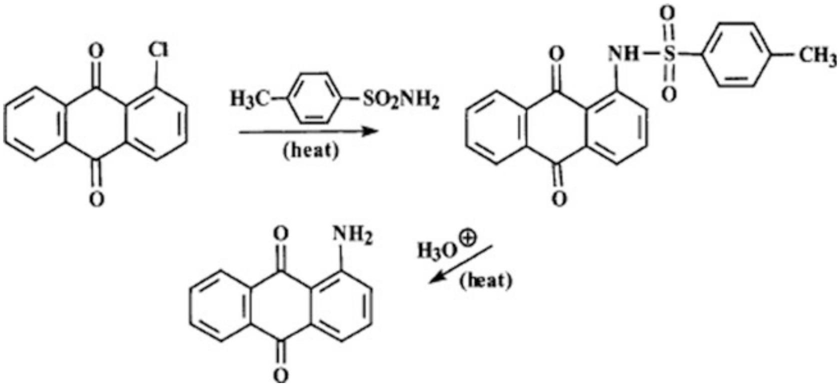

Fig. 13.54 An indirect amination of the anthraquinone ring system

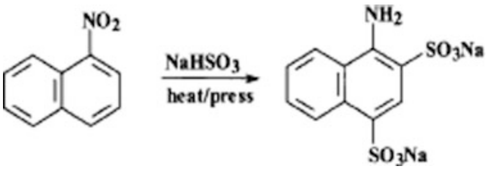

Fig. 13.55 A one-step amination and sulfonation of naphthalene

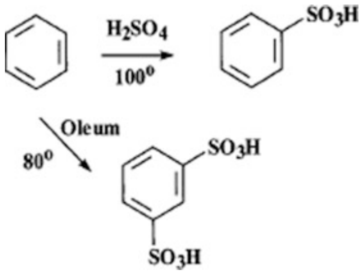

Fig. 13.56 The mono and disulfonation of benzene

Another interesting reaction is shown in Fig. 13.55. In this example, amination and sulfonation occur when α-nitronaphthalene is reduced by heating it under pressure with $NaHSO_3$.

Sulfonation

The introduction of one or more sulfonic acid groups (sulfonation) into dye intermediates is often conducted to confer water solubility, to provide fiber affinity, and to direct other incoming groups in the steps that follow sulfonation. In most cases this process employs sulfuric acid but in difficult cases, for example, deactivated ring systems, oleum (an SO_3/H_2SO_4 mixture) is used. This chemistry is illustrated in Fig. 13.56 for benzene. Here we see that benzene can be sulfonated using sulfuric acid and that the introduction of a second sulfonic acid group requires oleum. When a more reactive system is sulfonated, less stringent conditions are required. For example, naphthalene (Fig. 13.57) is readily sulfonated up to four times without using oleum. It is important to note that it is not possible to have sulfonic acid groups that are *ortho*, *para*, or *peri* to each other in the naphthalene system.

By contrast, the sulfonation of anthraquinone requires oleum and no more than two sulfonic acid groups can be introduced. In this system, sulfonation in the α-position requires the use of HgO as a catalyst. Examples of the possible products are shown in the scheme in Fig. 13.58.

Fig. 13.57 Examples of products obtained from the sulfonation of naphthalene

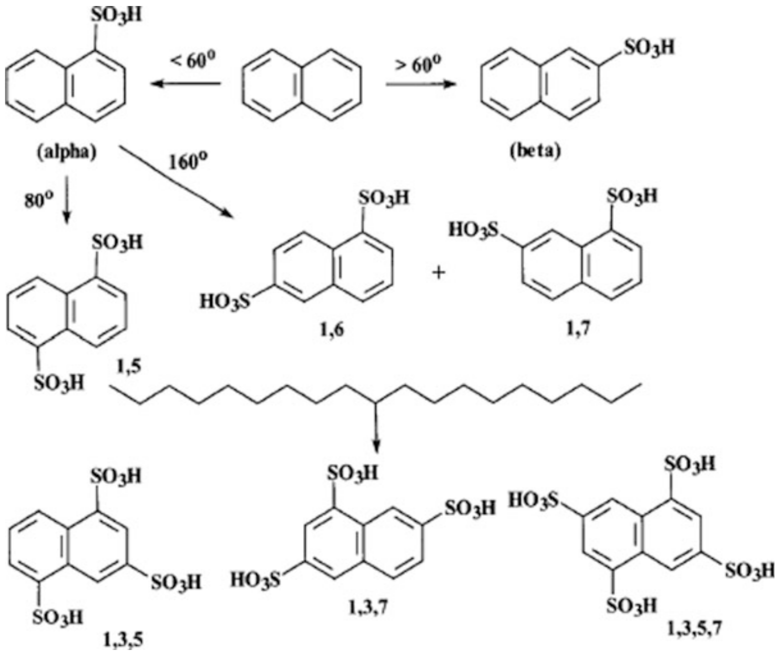

Fig. 13.58 Typical products produced from the sulfonation of anthraquinone

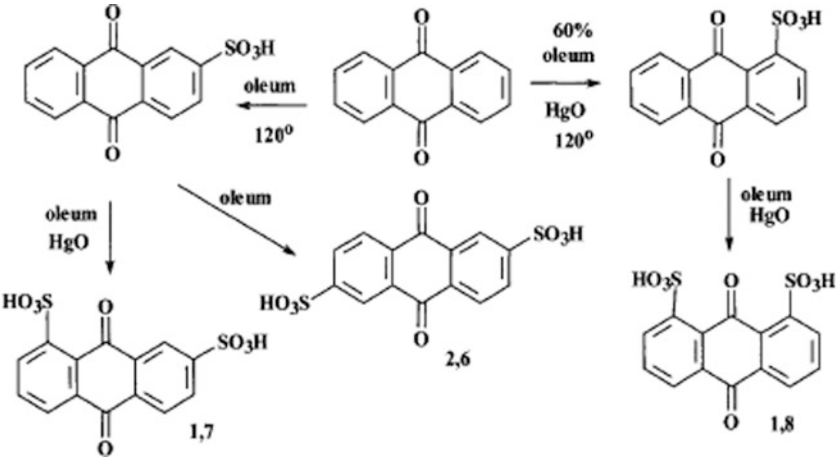

The sulfonation of β-naphthol produces several important dye intermediates, the nature of which depends upon the conditions employed (Fig. 13.59). At low temperatures, sulfonation occurs in the α-position to giveoxy-Tobias acid. Under ambient conditions Crocein acid is produced and at elevated temperatures three other products are obtained, including two that are disulfonated.

The sulfonation of aromatic amines such as aniline can give a mixture of products that must be separated prior to dye synthesis. When a single product is sought, the "baking" reaction is often employed (Fig. 13.60). In this process, the sulfate salt of aniline is prepared, dried, and then "baked" in an oven under vacuum. The product in this case is the important dye intermediate, sulfanilic acid. Similarly, naphthylamine sulfonic acid can be produced, and if the *para*-position is occupied, sulfonation of an *ortho*-position occurs (Fig. 13.61).

Halogenation

For dye intermediates, halogenation most often involves the incorporation of chloro groups. As pointed out earlier, halogens are important as leaving groups in the amination process, but they can also be used to enhance brightness and influence color. Later, we show that halogens are important as leaving groups in reactive dye chemistry, and in this regard chloro and fluoro groups are used.

Figures 13.62, 13.63, 13.64, and 13.65 provide examples of chlorination reactions. In the first example, the commonly

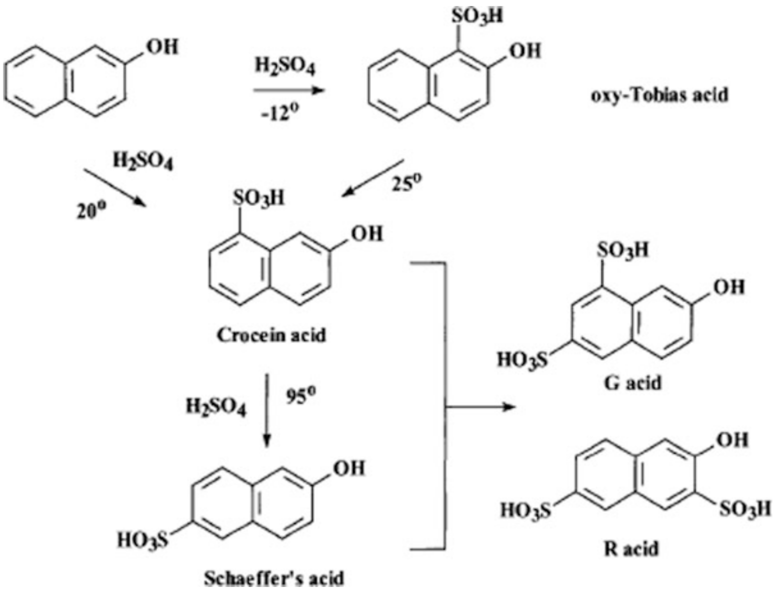

Fig. 13.59 Dye intermediates prepared from the sulfonation of β-naphthol

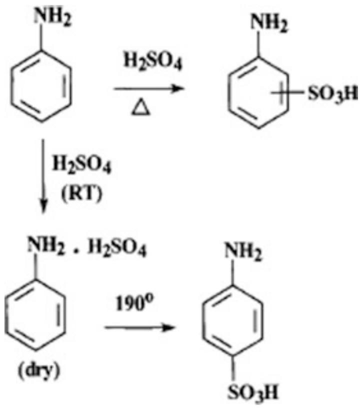

Fig. 13.60 Direct sulfonation of aniline (*upper*) vs. the baking reaction (*lower*)

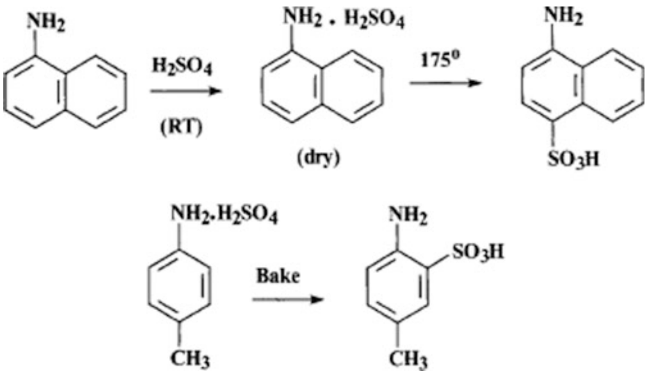

Fig. 13.61 Additional examples of the baking reaction

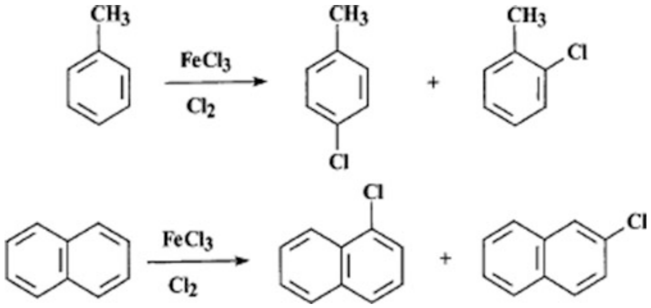

Fig. 13.62 Halogenation of benzene and naphthalene rings

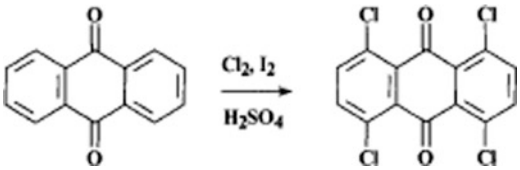

Fig. 13.63 Synthesis of the dye intermediate 1,4,5,8-tetrachloroanthraquinone

used agent $FeCl_3/Cl_2$ is employed for the chlorination of benzene and naphthalene rings. This method is not practical for the chlorination of anthraquinone. In this case the most important reaction is the tetrachlorination process shown in Fig. 13.63.

Because the chlorination of phenols and aromatic amines can be difficult to control, chlorination of these systems usually employs agents that will give a single chloro group when this is the desired outcome. In this regard, NaOCl and

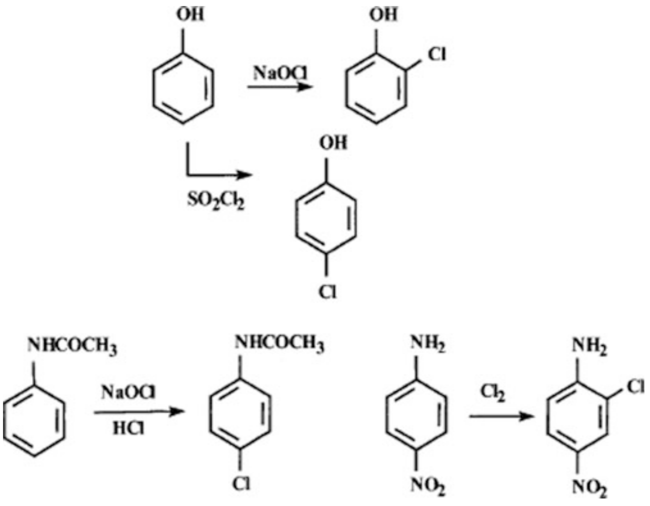

Fig. 13.64 Chlorination of phenol and anilines

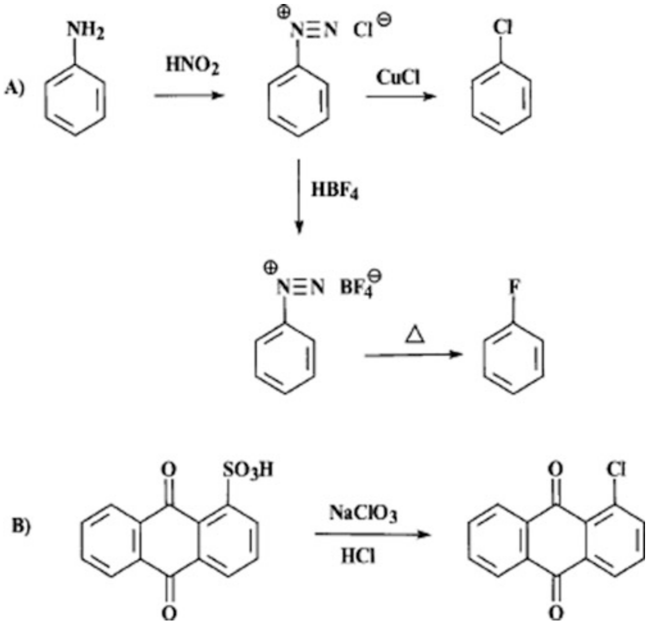

Fig. 13.65 Three important indirect halogenation reactions

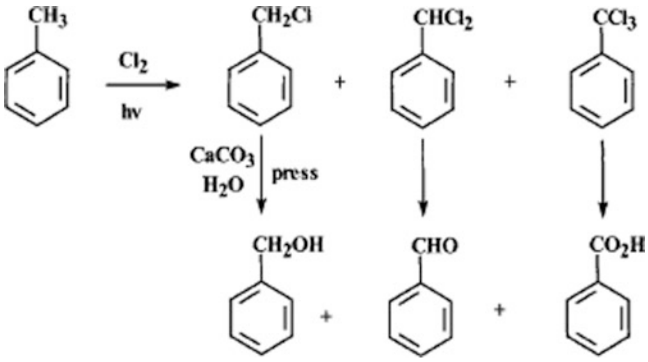

Fig. 13.66 Free radical chlorination of toluene and hydrolysis of the products

SO_2Cl_2 are quite useful chlorinating agents (see Fig. 13.64). In cases involving amines, often such compounds are protected by acetylation prior to chlorination. If the reactivity of the ring has been reduced by the presence of a deactivating group (e.g., $–NO_2$), acetylation may not be needed.

Halogens are also introduced via indirect methods, three examples of which are shown in Fig. 13.65. In the first case (sequence "A"), aniline is diazotized and the resultant diazonium compound is heated with cuprous chloride to give chlorobenzene, in a process known as the Sandmeyer reaction [56]. Alternatively, the diazonium compound can be converted to the tetrafluoroborate salt, which in turn is heated to give fluorobenzene. In sequence "B," anthraquinone-2-sulfonic acid is converted to the corresponding chloro compound by treatment with $NaClO_3$/HCl. All three reactions can be used to prepare a wide array of halogenated aromatics.

Chlorination is also an important step in the synthesis of oxygenated aromatic compounds. In this case, chlorination takes place at alkyl groups attached to the rings and is conducted in the absence of iron. The use of UV light speeds up this reaction, which is illustrated for toluene in Fig. 13.66. This free radical chlorination of toluene gives a mixture of benzyl chloride, benzal chloride, and benzotrichloride, which in turn can be hydrolyzed to benzyl alcohol, benzaldehyde, and benzoic acid.

Hydroxylation

The introduction of hydroxy groups is important in dye chemistry because it opens the door to azo dye formation, using phenols and naphthols, and provides an important auxochrome. Hydroxylation methods include alkali fusion, replacement of labile groups, and the reverse Bucherer reaction. In the alkali fusion reaction, naphthalene sulfonic acids are reacted with molten NaOH, KOH, or combinations of the two, as illustrated in Fig. 13.67. When disulfonated naphthalenes are used, the reaction can be stopped at the mono-hydroxylation stage if this is the desired outcome. The second example shows that the α-sulfonic acid group reacts faster.

When sulfonated anthraquinones are used, hydroxylation is conducted with $Ca(OH)_2$ to avoid over oxidation that occurs when hot NaOH is used. Example reactions are shown in Fig. 13.68.

The short sequence in Fig. 13.69 shows that aqueous alkali can also be used in hydroxylation reactions. In both cases, however, elevated temperatures are required.

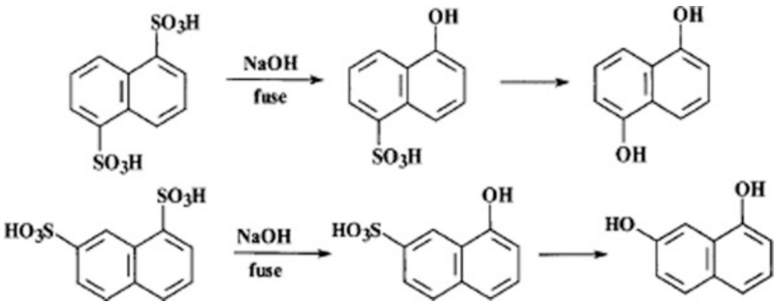

Fig. 13.67 Sodium hydroxide fusion as a hydroxylation process

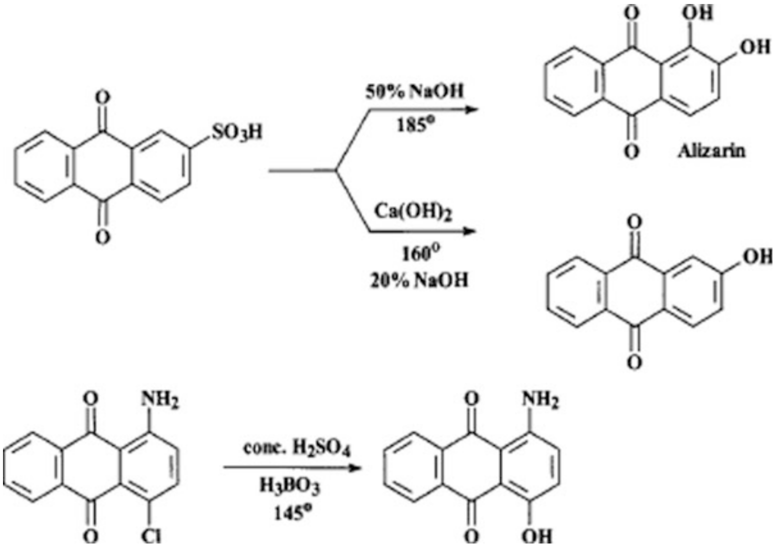

Fig. 13.68 Hydroxylation of the anthraquinone system

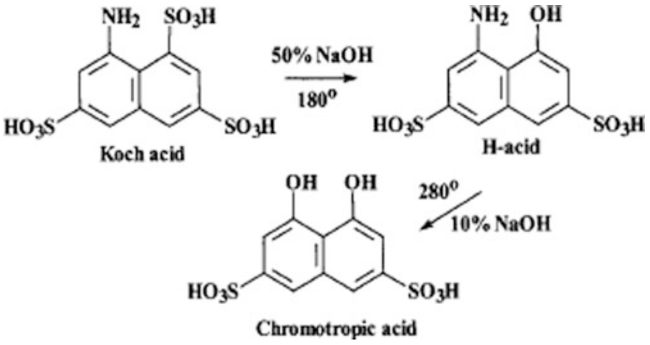

Fig. 13.69 Synthesis of two key dye intermediates using hydroxylation steps

Other important hydroxylation reactions are shown in Fig. 13.70. Here it can be seen that the Bucherer reaction is reversible, that the fusion reaction works for sulfonated benzene compounds, and that diazonium compounds undergo hydrolysis to produce phenols/naphthols.

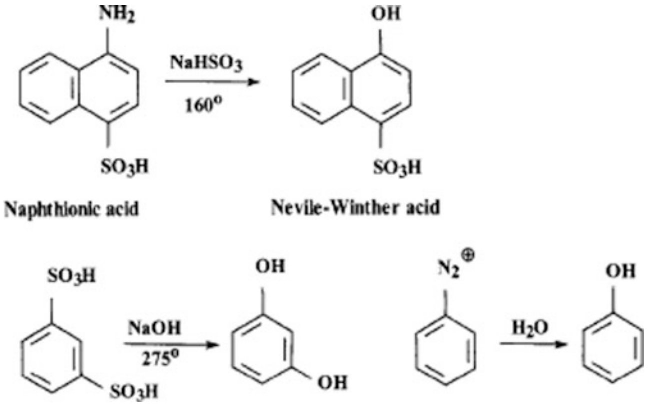

Fig. 13.70 Other examples of hydroxylation reactions

Oxidation

Although the oxidation of aromatic methyl groups can be conducted via the two-step sequence shown in Fig. 13.66, a convenient alternative process involves potassium dichromate.

In this case, the ring system involved must be stable to the conditions of the reactions. Another important oxidation reaction involves the conversion of naphthalene to phthalic anhydride, which can be accomplished using hot $KMnO_4$ or V_2O_5. These two reactions are illustrated in Fig. 13.71. Later we show that the oxygen in air can be used as the oxidant for certain organic dyes.

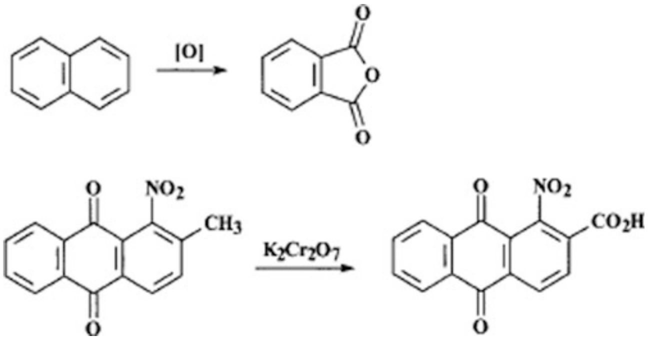

Fig. 13.71 Oxidation of naphthalene (*top*) and a methylated anthraquinone (*bottom*)

Other Important Reactions

Diazotization. The conversion of a primary aromatic amine to a diazonium compound is known as diazotization. Although this process is covered in more detail in our discussion of azo dye synthesis, it is worthwhile to point out that the diazonium group ($-N_2^+$) is used to produce a wide range of intermediates. As indicated in Fig. 13.72 diazotization is often achieved through the action of nitrous acid (HNO_2) and the resultant diazonium group can be replaced by various groups or reduced to give arylhydrazines.

Carboxylation. The introduction of carboxyl groups into the structures of phenols and naphthols produces some important dye intermediates, including salicylic acid and BON acid. This process is conducted under pressure at elevated temperatures using the sodium salts of phenols/naphthols and in the case of β-naphthol, the carboxyl group enters the 3-position (cf. Fig. 13.73). The free acid ($-CO_2H$) group is produced by acid treatment in the final step.

Fig. 13.72 Diazotization of aniline and its conversion to other types of intermediates

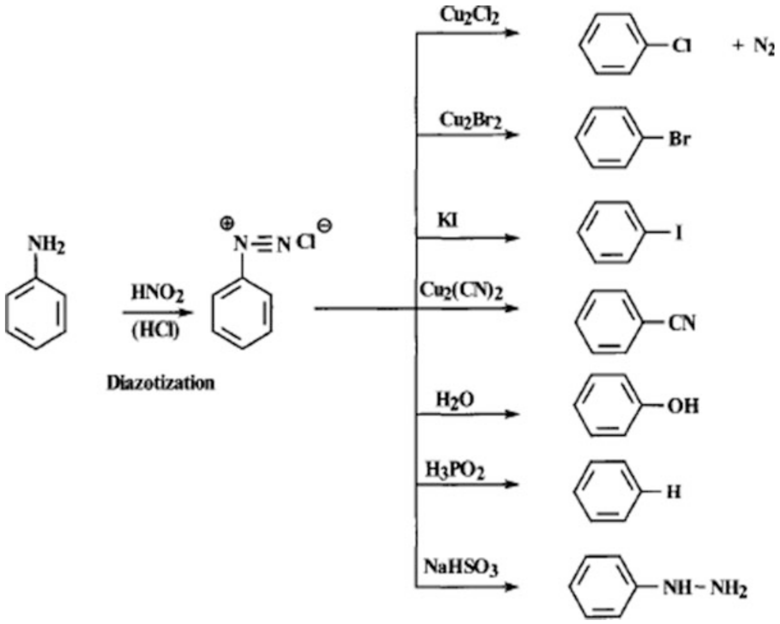

Fig. 13.73 Carboxylation of phenol and β-naphthol

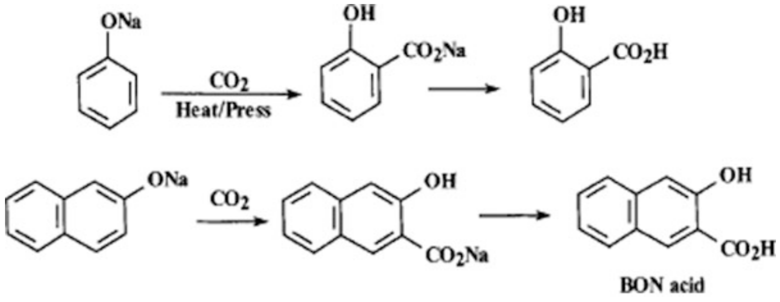

Dye Manufacture

In this section, we summarize the principal methods of synthesis for different dye classes. Emphasis is placed on dyes presently in commerce and the industrial methods suitable for making them. Before doing so, we review the important principles that set dyes apart from other classes of organic compounds.

Unlike other organic compounds dyes possess color because they (1) absorb light in the visible spectrum (400–700 nm), (2) have at least one chromophore (color bearing group), (3) have a conjugated system (system of alternating double and single bonds), and (4) exhibit resonance (a stabilizing force in organic compounds). Table 13.5 shows the relationships between wavelength of visible light and color absorbed/seen and the other three factors are illustrated in Fig. 13.74, 13.75, and 13.76.

Table 13.5 Wavelength of light vs. color

Wavelength absorbed	Color absorbed	Color seen
400–435	Violet	Yellow-green
435–480	Blue	Yellow
480–490	Green-blue	Orange
490–500	Blue-green	Red
500–560	Green	Purple
560–580	Yellow-green	Violet
580–595	Yellow	Blue
595–605	Orange	Green-blue
605–700	Red	Blue-green

Concerning the various factors responsible for color in organic compounds, it is worthwhile to point out that the chromophore must be part of a conjugated system. This is illustrated through the examples in Fig. 13.77. When the azo group is connected to methyl groups the resultant compound is colorless. When it is attached to aromatic rings, the compound possesses color. Similarly, the structures in Fig. 13.75 illustrate the importance of having an extended conjugated system. In this case, doubling the length of the conjugated system for Vitamin A to give β-carotene causes the λ_{max} value to shift from 325 nm to 466 and 497 nm.

Nitro Dyes

As the name suggests, this very small class of organic dyes has at least one nitro group as the chromophore. Nitro dyes invariably are yellow or orange and are important for their economical cost and good lightfastness. Examples include the dyes shown in Fig. 13.78—C.I. Acid Orange 3 (a), C.I. Disperse Yellow 42 (b), C.I. Acid Yellow 1 (c), and C.I. Disperse Yellow 70 (d). A key disadvantage of nitro dyes is their low color strength ($\varepsilon_{max} = 5{,}000$–$7{,}000$). Improvements in color strength have been achieved by incorporating an azo group, as illustrated in dye D.

Representative syntheses are shown in Figs. 13.79 and 13.80. In the first example, C.I. Disperse Yellow 42 is prepared by condensing two molecules of aniline with one molecule of 4-chloro-3-nitrobenzenesulfonyl chloride, using ethanol as the solvent. In the second example, C.I. Acid Orange is prepared in a 3-step synthesis, starting from 2-chloro-5-nitrobenzenesulfonic acid.

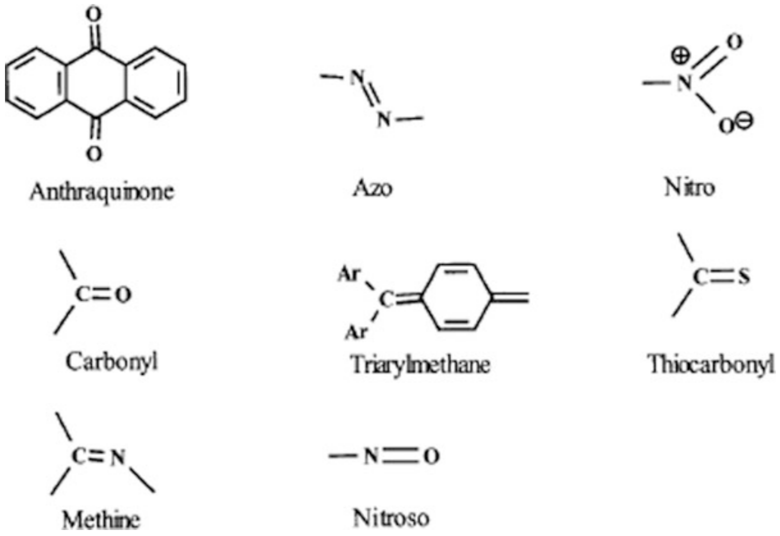

Fig. 13.74 Chromophores commonly found in organic dyes

Azo Dyes

Azo dyes are by far the largest family of organic dyes. They play a prominent role in acid, direct, reactive, azoic, and disperse dye structures, as shown previously, and include structures that cover the full color spectrum. Generally, the synthesis of azo dyes involves a process known as diazo coupling. In this process, a diazotized aromatic amine is coupled to a phenol, naphthol, aromatic amine, or a compound that has an active methylene group, as illustrated in the two-step synthesis in Fig. 13.81. Step 1 is the conversion of aniline to benzenediazonium chloride, a process known as diazotization, and step 2 is the reaction of the diazo compound with phenol to produce the corresponding azo dye, a process known as diazo coupling.

Diazotizations are normally conducted in an aqueous medium containing nitrous acid, generated in situ from HCl + $NaNO_2$, and a primary aromatic amine. When weakly basic or heteroaromatic amines are used in azo dye synthesis, H_2SO_4 is often used as the reaction medium, forming $H(NO)SO_4$ (nitrosylsulfuric acid) as the diazotizing agent [57]. The stoichiometry associated with this reaction is given in Fig. 13.82, and although only 2 moles of acid per mole amine are required, in practice 2.2–2.5 moles are used. Diazotizations are most often conducted at 0–10 °C because the resultant diazo compounds are usually unstable at higher temperatures.

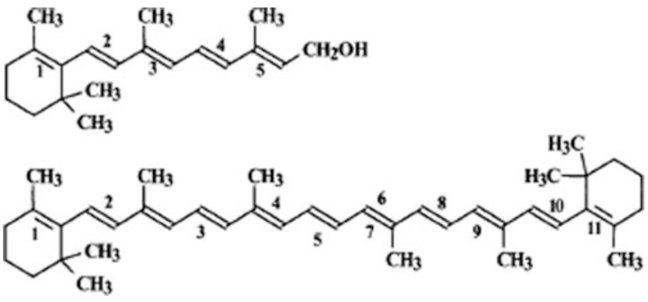

Fig. 13.75 Comparison of the conjugated systems in Vitamin A (*top*) and β-carotene (*bottom*)

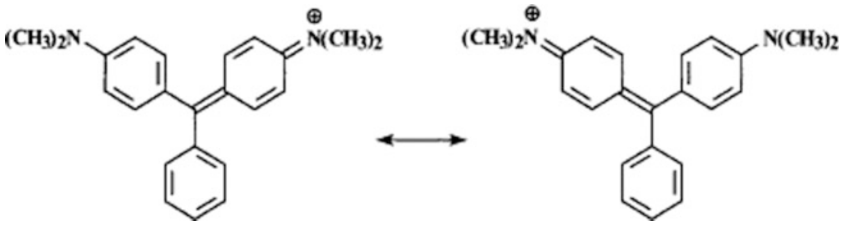
Examples of aromatic amines that can be diazotized are shown in Fig. 13.83. This extremely abbreviated list is designed to show that a wide variety of amines can be used, including hydrophobic, weakly basic, hydrophilic, and heterocyclic compounds. *ortho*-Diamines are not typically used because of their propensity to undergo triazole formation (Fig. 13.84).

Examples of compounds that can be used as coupling components in azo dye synthesis are shown in Figs. 13.85, 13.86, and 13.87. The first group comprises phenols and naphthols, the second group comprises amines that couple, and the third contains couplers that have an active methylene group (see Fig. 13.87). Compounds in the first and third groups require ionization using alkali, to give sufficient reactivity for diazo coupling, and the pH employed is usually 8–9. Because aromatic amines are appreciably more reactive, they couple at pH 5–6. Arrows have been used to indicate the coupling positions for the various couplers. Compounds such as 1-naphthol or 1-naphthylamine give a mixture of monoazo dyes by coupling in the 2-position or the 4-position. When couplers containing –OH and $–NH_2$ groups are employed (see Fig. 13.85), coupling may occur twice, giving disazo dyes. In such cases, coupling is first conducted in acid, *ortho* to the $–NH_2$ group, and then in alkali. This is important because the introduction of the first azo group decreases the reactivity of the coupler. The ability to ionize the –OH group provides sufficient ring activation for the second coupling. In the case of gamma acid, one has the lone option of coupling under acidic or alkaline conditions.

When primary amines are used as couplers, coupling can occur on the ring or at the amino group itself unless the amino group is blocked. One good way to block this group is by converting it to the *N*-sulfomethyl group, as illustrated in Fig. 13.86. The products formed are also known as omega salts [58]. The blocking group can be removed following the coupling step, by treating the resultant azo dye with an alkaline solution.

There are also important examples of phenolic compounds that do not couple (see Fig. 13.88). In these examples, the required coupling positions are blocked, the ring is too deactivated, or the compounds undergo oxidation in the presence of the diazo compound.

Fig. 13.76 Resonance structures for Malachite Green (C.I. Basic Green 4)



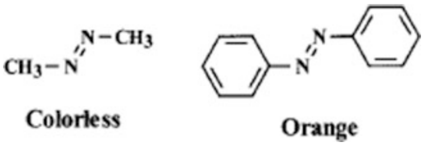


Fig. 13.77 Impact of having a chromophore apart from (*left*) or part of (*right*) a conjugated system

The synthesis of azo dyes can be illustrated using the following letter designations:

- A = Diazotizable amine
- D = Tetrazotizable diamine
- E = Coupler that couples once
- M = 1° Amine that couples once and is diazotized and coupled again

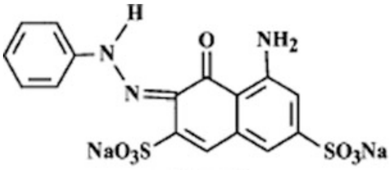
- Z = Coupler that couples twice
- Z·X·Z = Binuclear coupler that couples twice



Acid Red 33

These designations are used to provide an indication of how a given dye has been assembled, and will be used in describing the azo dye syntheses covered in the subsections that follow.

Monoazo Dyes

Azo dyes of this type are manufactured predominantly by the reaction between a diazotized amine ("A") and a type "E" or "Z" coupler. The synthesis can be as simple as coupling diazotized aniline to H-acid, in an A → E process, to produce C.I. Acid Red 33. An example of a reactive dye that is manufactured via an A → E process is C.I. Reactive Red 1. In this case, the target dye is manufactured as shown in Fig. 13.89, which shows that the reactive group can be

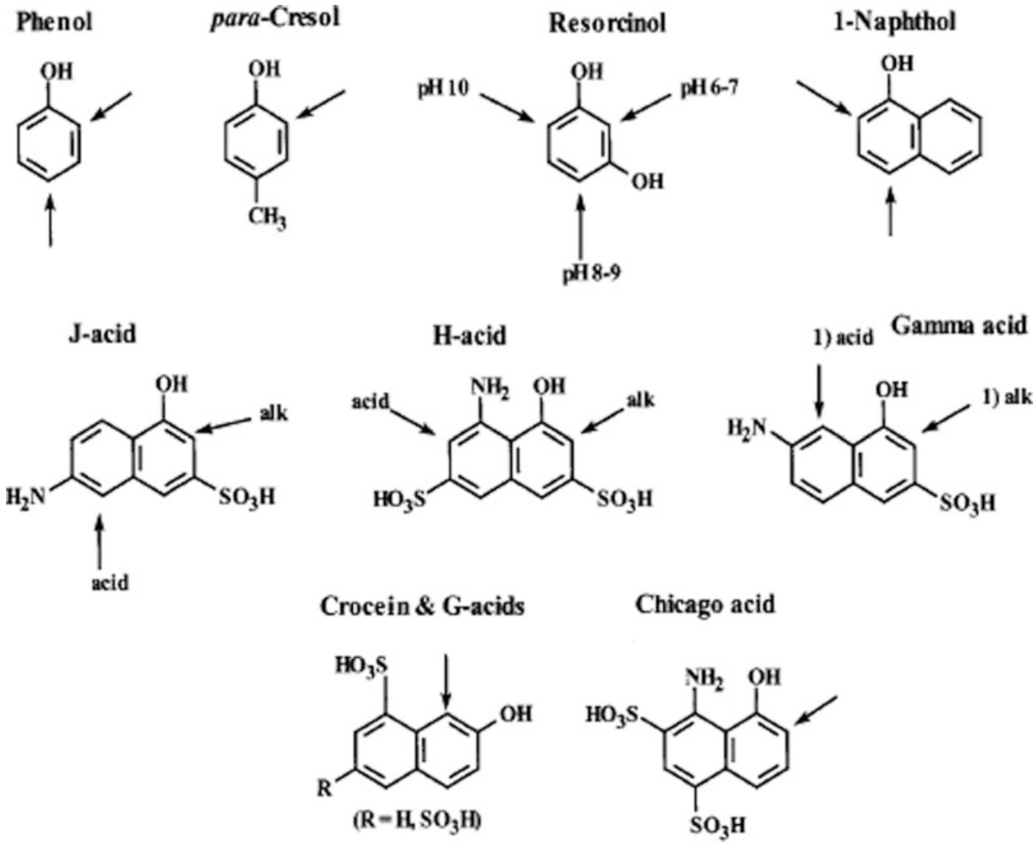


Fig. 13.85 Examples of phenol and naphthol-based couplers

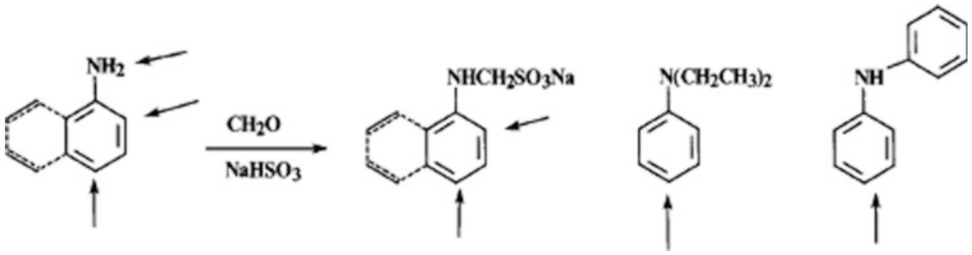

Fig. 13.86 Examples of aromatic amine couplers

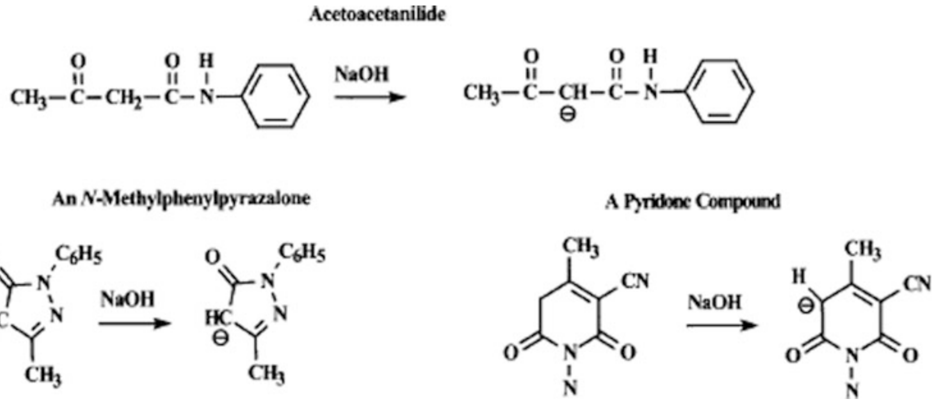

Fig. 13.87 Examples of couplers having an active methylene ($-CH_2-$) group

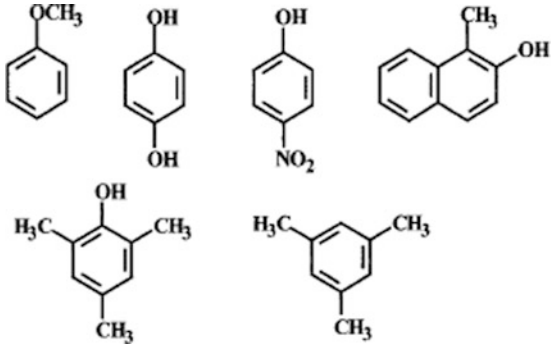

Fig. 13.88 Examples of compounds that do not couple

introduced prior to (sequence 1) or after (sequence 2) the coupling step. Similarly, monoazo bireactive dyes are made by this process (Fig. 13.90). This illustrates that a quite complex arylamine can be used as the diazo compound.

Other examples of monoazo dyes that are synthesized via an A → E process are shown in Fig. 13.91, further illustrating the wide range of structural types that can be manufactured this way.

Disazo Dyes

There are four often-used methods for synthesizing dyes containing two azo linkages, each of which requires two diazo coupling reactions. A nontraditional "disazo" dye involves 1:2 metal complex formation.

Type $A^1 \rightarrow Z \rightarrow A^2$ *synthesis*. Dyes of this type include those shown in Fig. 13.92 (C.I. Acid Black 1 (**7**), C.I. Mordant Brown 1 (**8**), and C.I. Acid Black 17 (**9**), C.I. Direct Orange 18 (**10**)), in which couplers such as H-acid, resorcinol, and *meta*-phenylenediamine are coupled twice. Although A^1 and A^2 are different in the present examples, they need not be different. As pointed out above, coupling *ortho* to the amino group of H-acid is usually conducted first, under weakly acidic conditions, followed by coupling with diazotized aniline under alkaline conditions. This is also true for the structurally similar dye **9**, which is prepared from S-acid. In the case of dye **10**, however, coupling with aniline under slightly acidic conditions is the second step. For dye **8**, both couplings are conducted under acidic conditions, with 2-amino-4-nitrophenol introduced first.

Type $E^1 \rightarrow D \rightarrow E^1$ *synthesis*. Dyes of this type require the conversion of an aryldiamine to a tetrazonium compound (one that has two diazonium groups) in a process know as tetrazotization. See Fig. 13.93 which involves environmentally friendly alternatives to benzidine. Following tetrazotization, one tetrazonium molecule reacts with two coupler molecules to produce the target dye, examples of which are provided in Fig. 13.94 (**11**: C.I. Direct Red 28 (Congo Red), **12**: C.I. Direct Yellow 12, and **13**: C.I. Acid Yellow 42). Disazo dyes prepared this way include dye **14**

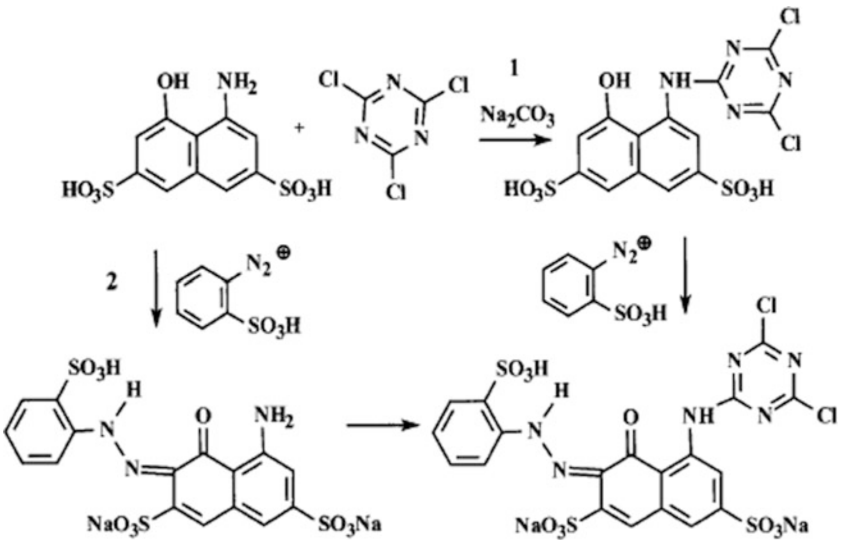

Fig. 13.89 Two approaches to the synthesis of Reactive Red 1

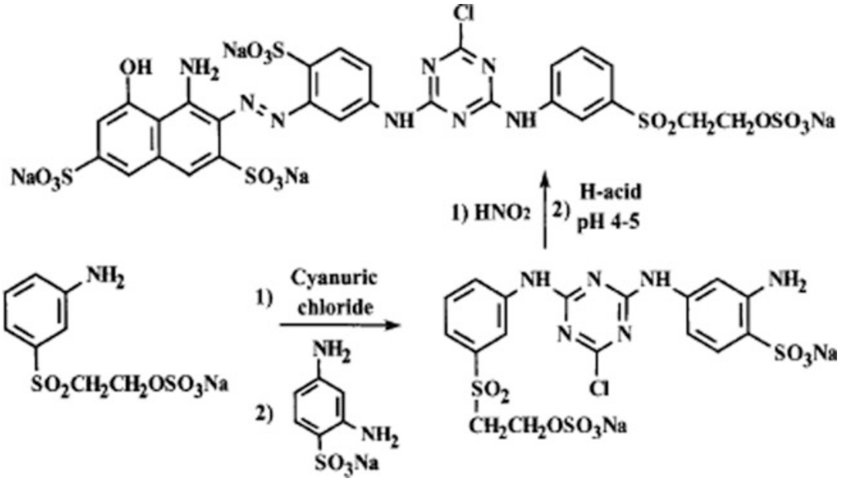

Fig. 13.90 Synthesis of a monoazo dye containing two different reactive groups

(C.I. Direct Blue 15), which is converted to the important bis-copper complex, C.I. Direct Blue 218 (see Fig. 13.95).

Type A → M → E synthesis. This is one of the largest groups of disazo dyes, as they include acid, disperse, direct, and reactive dye structures. A representative synthesis is shown in Fig. 13.96. The second diazotization and coupling steps can be conducted inside certain textile fibers. For instance, disperse black dyes are produced in the presence of cellulose acetate by conducting the chemistry shown in Fig. 13.97 after dyeing cellulose acetate with the monoazo dye.

Examples of dyes made via an A → M → E synthesis are shown in Fig. 13.98. Although most azo disperse dyes are based on monoazo structures, disazo structures such as **15** (C.I. Disperse Orange 13) and **16** (C.I. Disperse Orange 29) are manufactured. An important direct dye of this type is **17** (C.I. Direct Red 81), a reactive dye is **18** (C.I. Reactive Blue 40), and acid dyes include **19** (C.I. Acid Red 151) and **20** (C.I. Acid Blue 116).

Type $A^1 \rightarrow Z \cdot X \cdot Z \leftarrow A^1$ synthesis. Disazo dyes of this type are produced from coupling twice to dye intermediates such as those shown in Fig. 13.99, and are largely direct dyes for cotton. A representative synthesis is shown in Fig. 13.100, for C.I. Direct Red 83. In this case the target dye is prepared by metallization after the coupling step.

Disazo dyes such as C.I. Direct Yellow 44 are prepared according to the sequence shown in Fig. 13.101. In this example, a pair of monoazo dyes is reacted with phosgene.

1:2 Metal complexes. Although somewhat different from the previous examples and methods, dyes containing two azo groups can also be synthesized by forming 1:2 metal complexes of suitably substituted monoazo dyes.

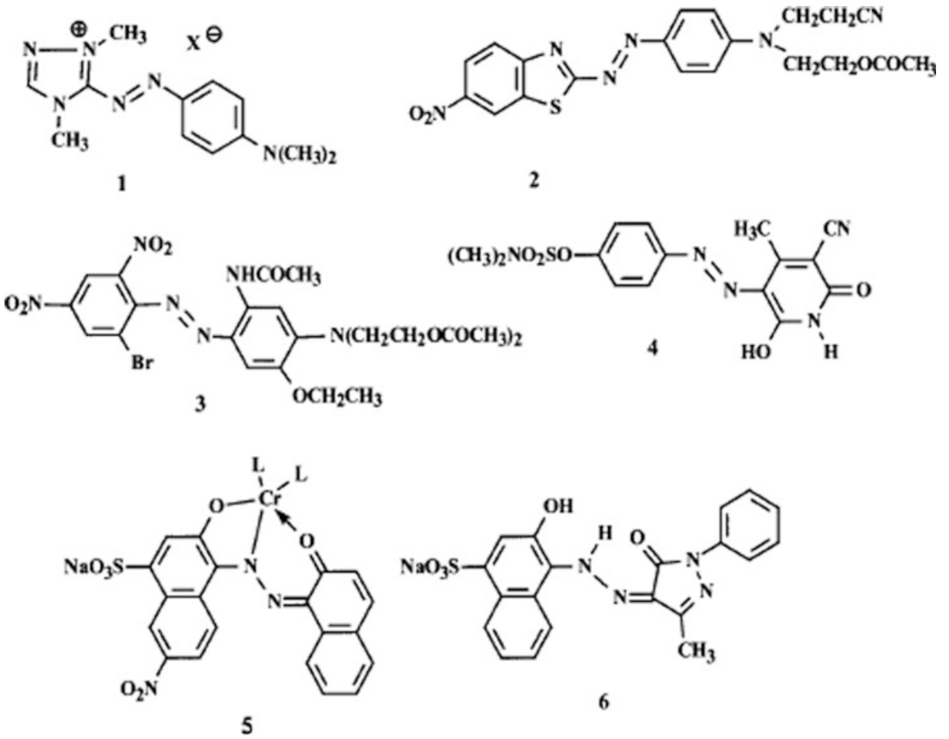

Fig. 13.91 Monoazo cationic (**1**), disperse (**2**–**4**), 1:1 chromium complexed (**5**), and mordant (**6**) dyes prepared via an A → E process

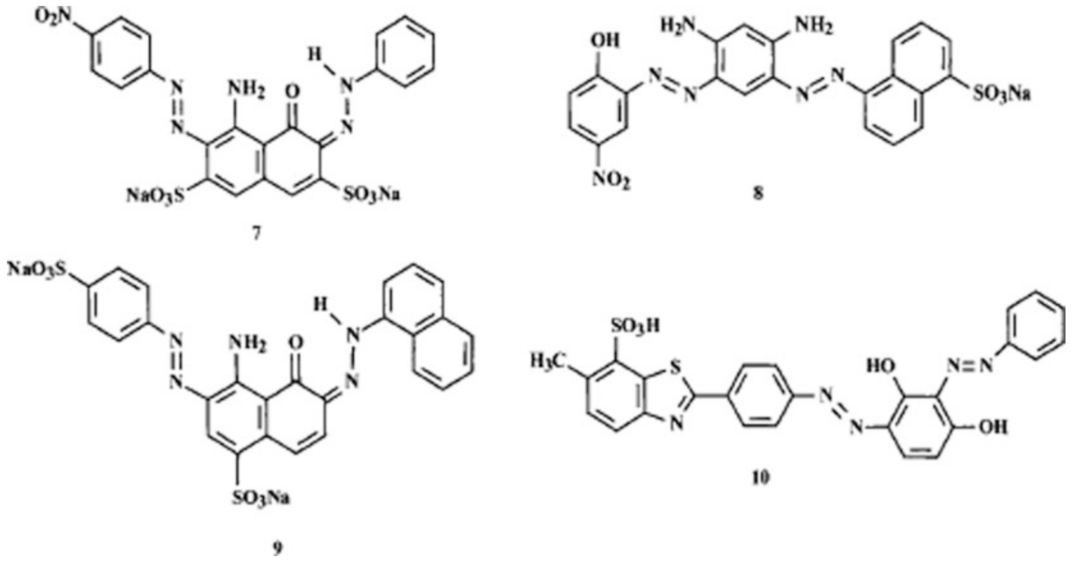

Fig. 13.92 Disazo dyes prepared by coupling twice to H-acid (**7**), *meta*-phenylenediamine (**8**), S-acid (**9**), and resorcinol (**10**)

The resultant dyes are mostly acid dyes for protein and polyamide substrates and the metals employed are Cr, Co, and Fe. Examples shown in Fig. 13.102 are for C.I. Acid Black 172 (**21**) and C.I. Acid Yellow 151 (**22**). In these examples, the corresponding monoazo dye is treated with one-half the molar amount of $Cr_2(SO_4)_3$ or $CoCl_3$, respectively.

Polyazo Dyes

In this section, we cover the synthesis of dyes containing three or more azo linkages. In this regard, methods for producing trisazo dyes (those having three azo linkages) include $E \leftarrow D \rightarrow Z \leftarrow A$ and $A \rightarrow M^1 \rightarrow M^2 \rightarrow E$ syntheses.

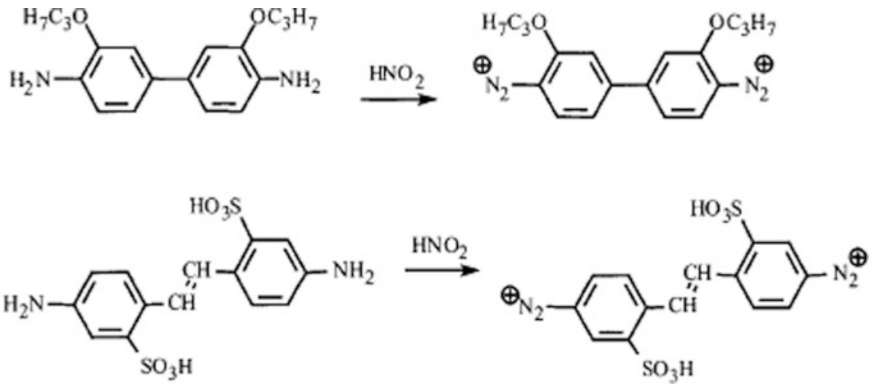

Fig. 13.93 Tetrazotization of a di-*n*-propoxybenzidine (*top*) and a diaminostilbene disulfonic acid (*bottom*)

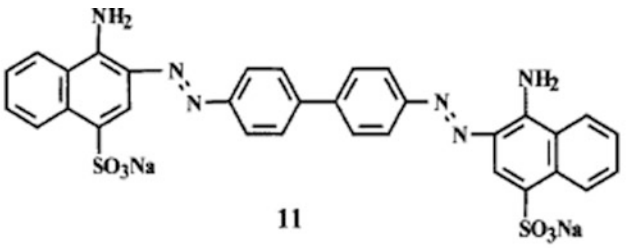
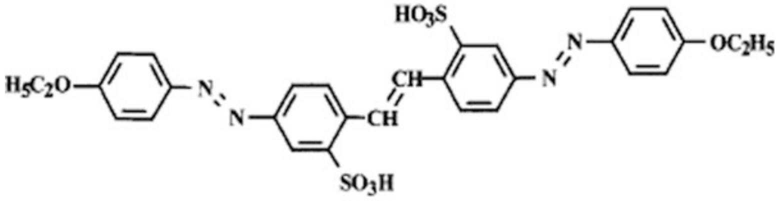
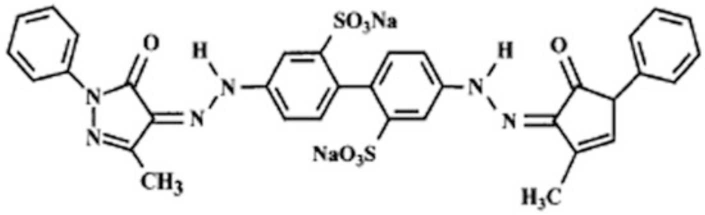


11



12



13

Fig. 13.94 Examples of disazo dyes (**11**–**13**) prepared via a type $E^1 \leftarrow D \rightarrow E^1$ synthesis

Examples are shown in Fig. 13.103 for C.I. Acid Black 234 (**23**) and C.I. Direct Blue 71 (**24**). In the synthesis of dye **23**, an unsymmetrical dye can be made from diamine **25** because the end of the tetrazonium compound (cf. **26**) that is *para* to the $–SO_2$ moiety is more reactive than the one that is *para* to the –NH moiety (Fig. 13.104).

Dyes containing four azo linkages are direct dyes for cotton and can be prepared in several ways, including via $A \rightarrow M \rightarrow Z \leftarrow D \rightarrow E$, $A^1 \rightarrow Z^1 \leftarrow D \rightarrow Z^2 \leftarrow A^2$, $E^1 \leftarrow M^1 \leftarrow D \rightarrow M^2 \rightarrow E^2$, $E^1 \leftarrow D^1 \rightarrow Z \leftarrow D^2 \rightarrow E^2$, and $E^1 \leftarrow D \rightarrow M^1 \rightarrow M^2 \rightarrow E^2$ sequences. Examples of the second and third methods are shown in Fig. 13.105. Note that both are symmetrical molecules, the first of which (C.I. Direct Brown 44) employs *meta*-phenylenediamine as a type “Z” coupler and a type “D” diazo component. In the second example (C.I. Direct Black 22), gamma acid is twice used as the “M” moiety, and the dye is synthesized by (1) coupling tetrazotized benzidine disulfonic acid to two molecules of gamma acid, (2) diazotizing the amino groups on the gamma acid moieties, and (3) coupling to two molecules of *meta*-phenylenediamine.

Fig. 13.95 Formation of Direct Blue 218

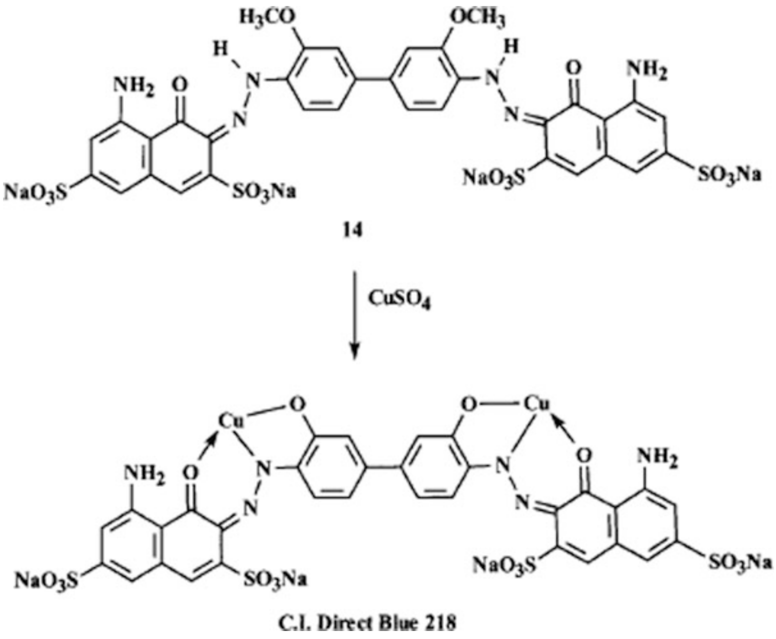


Fig. 13.96 Disazo dye synthesis via an A → M → E process

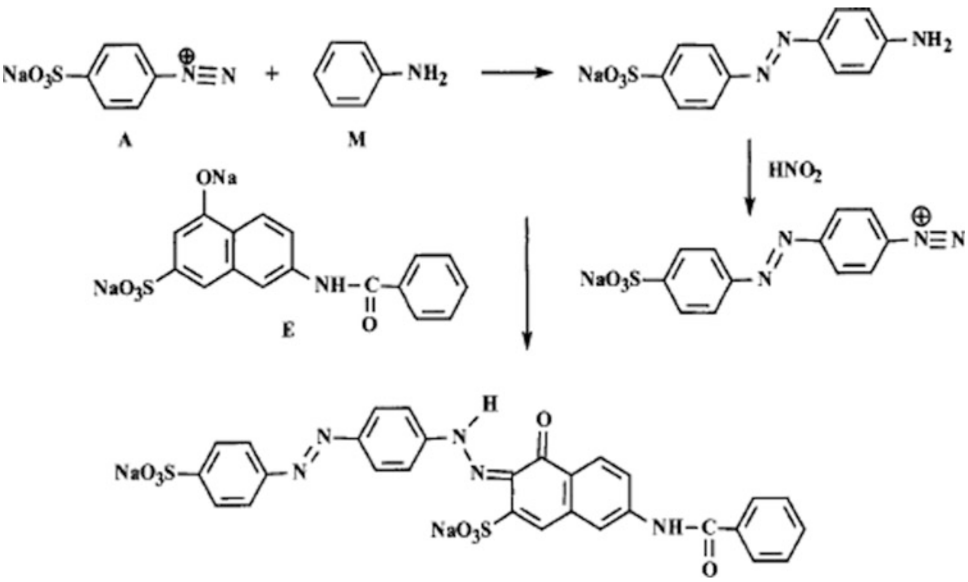

Triphenylmethane Dyes

Triphenylmethane dyes are usually prepared in two steps: (1) condensation of an *N*,*N*-dialkylaniline with a benzaldehyde compound and (2) oxidation of the resultant leuco base (**27**). The synthesis of C.I. Basic Green 4 (Malachite Green) is given as an example in Fig. 13.106. Alternatively, C.I. Acid Green 50 is prepared in three steps: (1) condensation of *N*,*N*-dimethylaniline and *para*-(*N*,*N*-dimethylamino)benzaldehyde to produce Michler's hydrol (**28**), condensation with R-acid to give an intermediate leuco base (**29**), and (3) oxidation to give the target dye. Historically, PbO_2 has been used as the oxidizing agent. However, concerns about its toxicity have led to the use of a more environmentally friendly agent such as tetrachloro-*para*-benzoquinone (chloranil).

In another synthetic variation, C.I. Acid Violet 17 is prepared in the four steps shown in Fig. 13.107. The different steps in this process are the synthesis of the *N*-arylmethyl intermediate **30** and the diphenylmethane intermediate **31**. Oxidation to the intermediate hydrol and condensation with *N*,*N*-dimethylaniline produce the target dye.

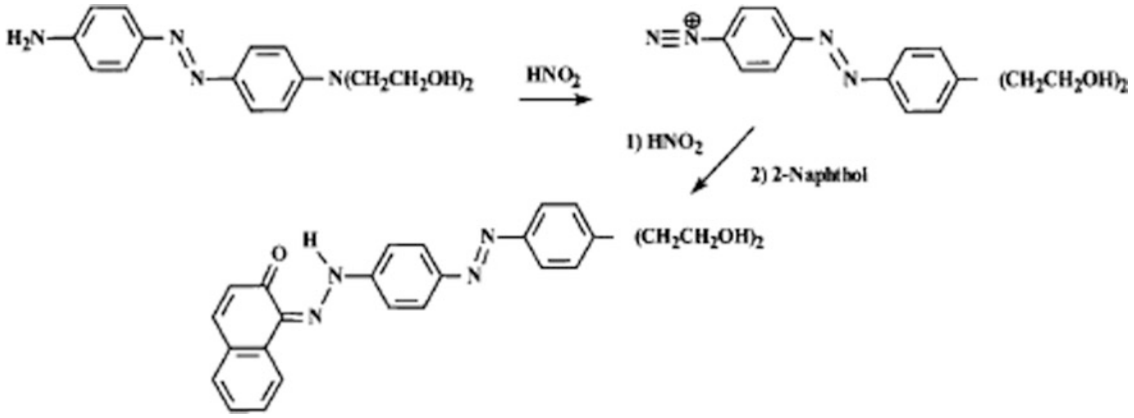

Fig. 13.97 Disazo disperse black dye synthesis conducted inside cellulose acetate fibers

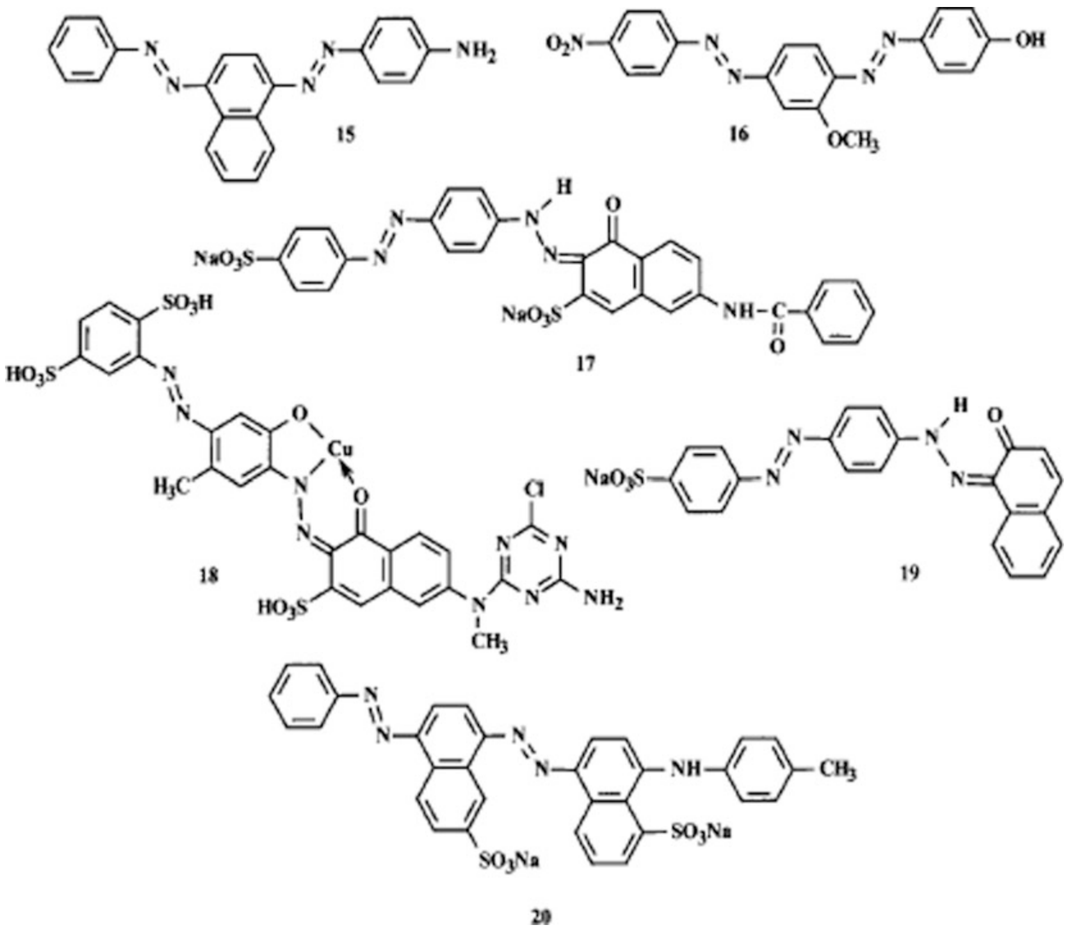

Fig. 13.98 Examples of disazo dyes prepared by a type A → M → E synthesis

Structurally related dyes are synthesized by condensing phenols with phthalic anhydride to give a colorless intermediate lactone (**32**) that reacts with alkali to give the colored form. An example of this dye type is phenolphthalein, the synthesis of which is shown in Fig. 13.108.

Xanthene Dyes

Like phenolphthalein, xanthene dyes are prepared in a condensation reaction involving phthalic anhydride. However, resorcinol is employed instead of phenol. The simplest

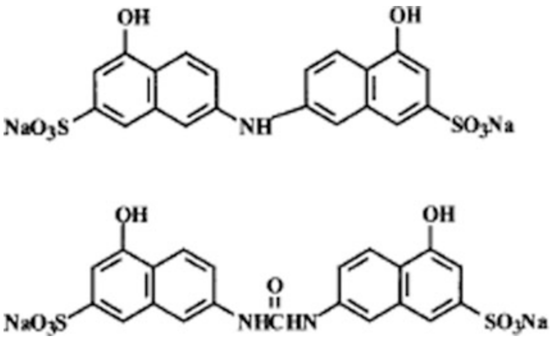

Fig. 13.99 Structures of J-acid imide (*top*) and J-acid urea (*bottom*)

representative of this family is C.I. Acid Yellow 73 (fluorescein), which is made via the sequence of steps shown in Fig. 13.109. Similarly, C.I. Acid Red 92 is made by the condensation of tetrachlorophthalic anhydride and resorcinol followed by bromination.

Anthraquinone and Related Dyes

The commercial preparation of anthraquinone dyes begins with the synthesis of anthraquinone itself. In this regard, the three-step synthesis involves: (1) the oxidation of

Fig. 13.100 Synthesis of Direct Red 83 via an $A^1 \rightarrow Z{\cdot}X{\cdot}Z \leftarrow A^1$ synthesis and metallization

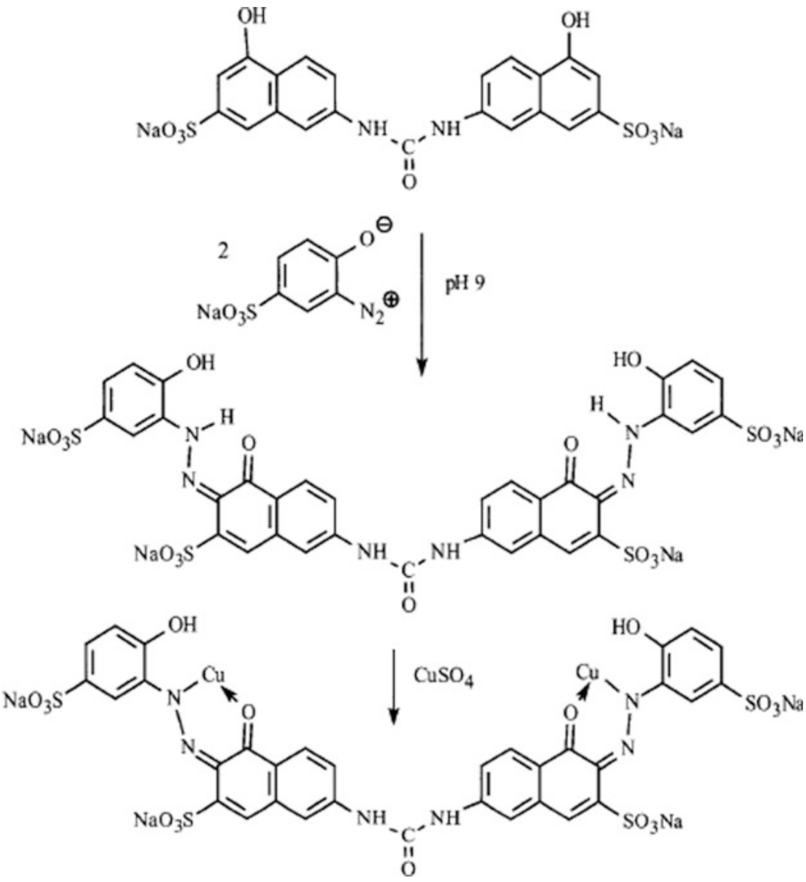

Fig. 13.101 An alternative route to type $A^1 \rightarrow Z{\cdot}X{\cdot}Z \leftarrow A^1$ disazo dyes

naphthalene to phthalic anhydride, (2) Friedel–Crafts acylation of benzene to give a keto acid, and (3) cyclodehydration using H_2SO_4. See Fig. 13.110. The preparation of 1,4-disubstituted anthraquinones utilizes the intermediates prepared in Fig. 13.111, where R = OH corresponds to quinizarin.

The reduction of quinizarin using sodium hydrosulfite produces leuco quinizarin, which, in turn, undergoes condensation with alkyl- or arylamines and reoxidation to produce blue and green disperse and solvent dyes. Although chemical oxidation can be used, air oxidation is normally sufficient. See steps “A” and “B” in Fig. 13.112 for the general reaction scheme. The use of boric acid in the reduction step follows the course outlined in Fig. 13.113, where the synthesis of C.I. Solvent Green 3 is given as an example [59].

Anthraquinone Disperse Dyes

Examples of dyes prepared using the above methods are shown in Fig. 13.114. The C.I. disperse dyes Red 15, Violet 1,

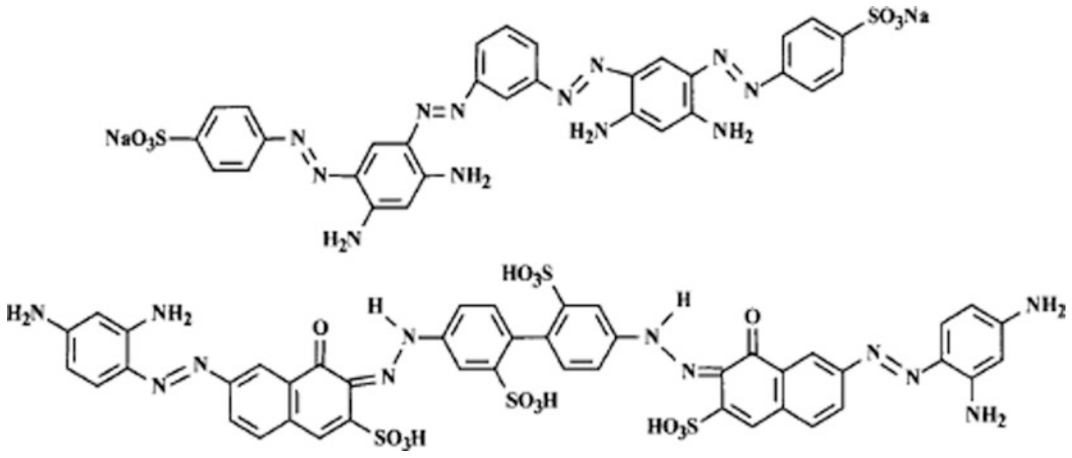

Fig. 13.105 Representative polyazo dyes prepared via the $A^1 \rightarrow Z^1 \leftarrow D \rightarrow Z^2 \leftarrow A^2$ (*top*) and $E^1 \leftarrow M^1 \leftarrow D \rightarrow M^2 \rightarrow E^2$ (*bottom*) methods

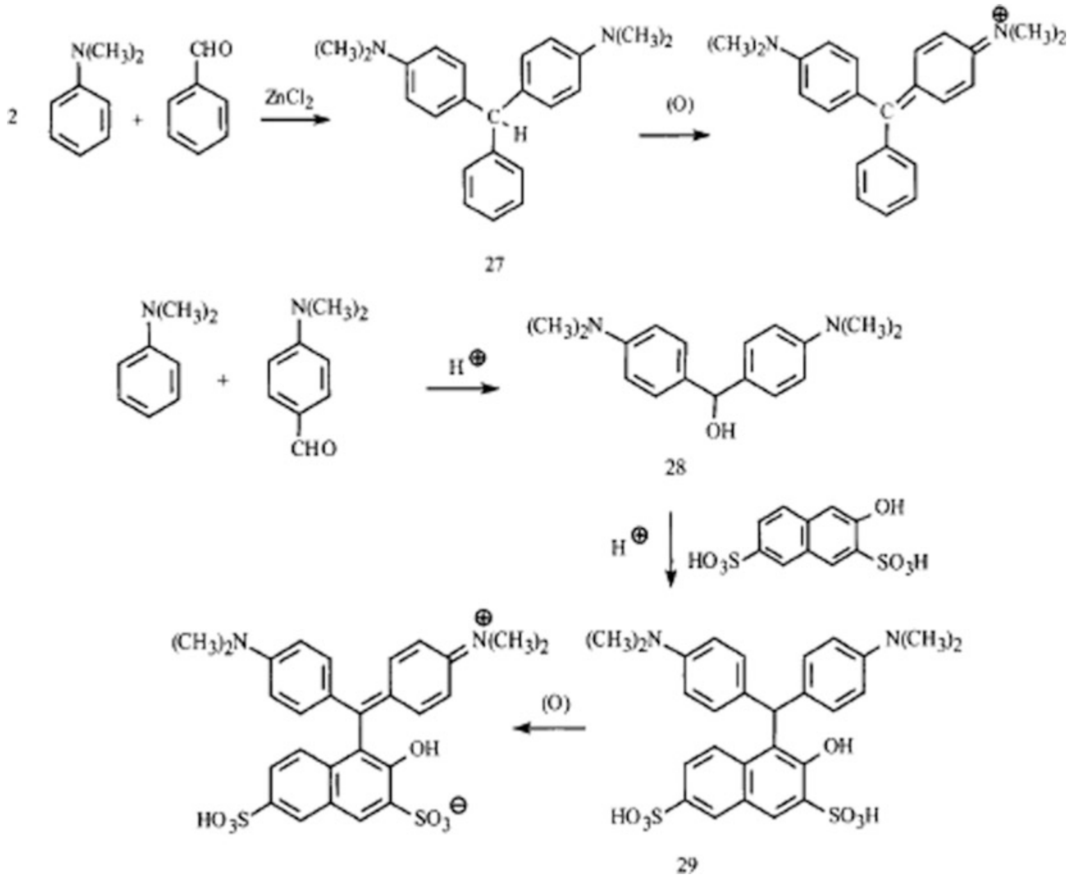

Fig. 13.106 Two-step synthesis of Malachite Green (Basic Green 4). Three-step synthesis of Acid Green 50

Blue 3, Violet 27, Blue 19, and Blue 23, are prepared from leucoquinizarin. When unsymmetrical dyes such as Disperse Blue 3 are made, the use of a mixture of two amines in the condensation step gives the corresponding symmetrical dyes as by-products. In this case, Disperse Blue 23 would be one of the by-products.

The synthesis of Disperse Red 4 employs the dibromoanthraquinone intermediate **33**, which is hydrolyzed to

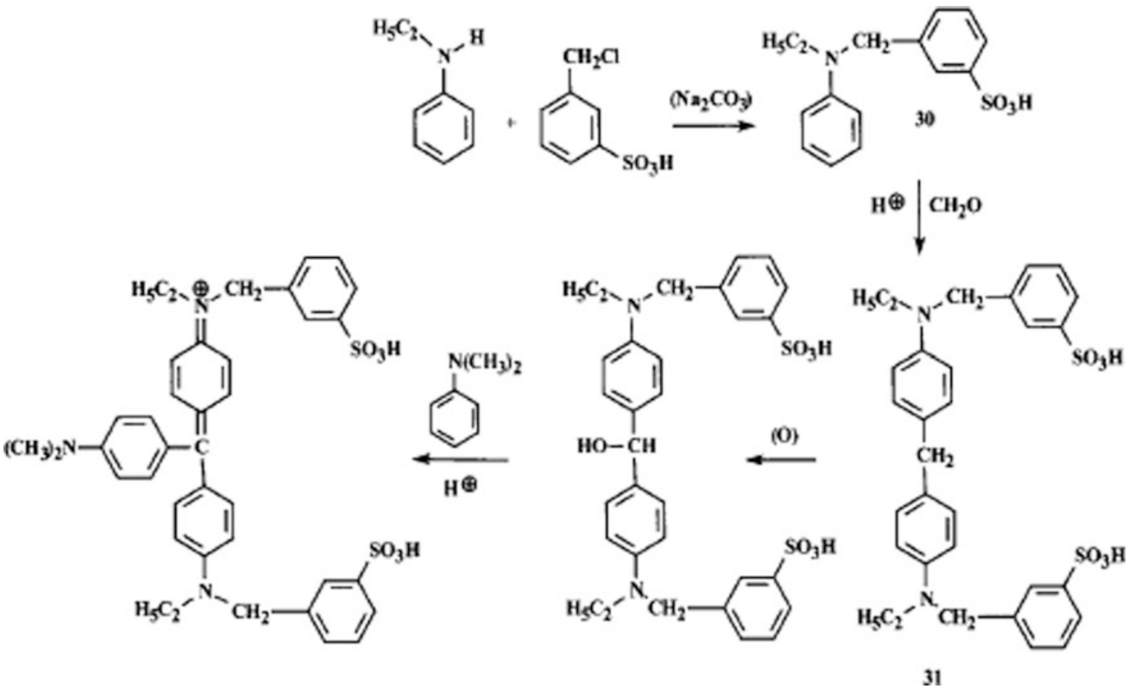

Fig. 13.107 Synthesis of Acid Violet 17 via diarylmethane intermediate **31**

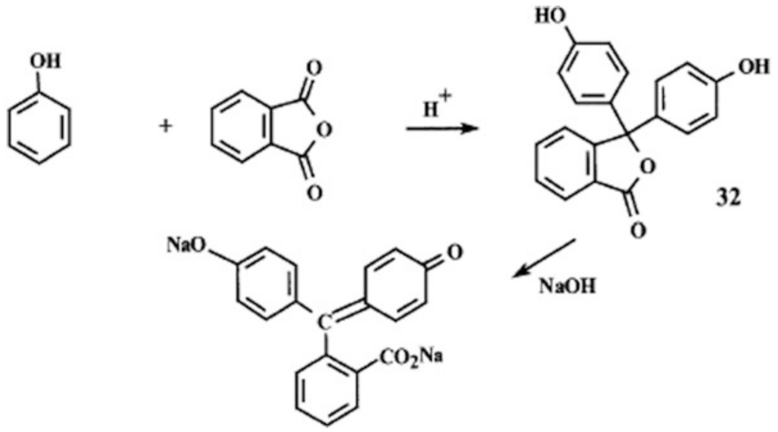

Fig. 13.108 Synthesis of phenolphthalein via colorless lactone **32**

compound **34** and converted to the target dye upon alcoholysis. See Fig. 13.115. The synthesis of Disperse Violet 26 is conducted in two steps: (1) chlorination of Disperse Violet 1 in the 2, 3-positions using SO_2Cl_2 and (2) condensation with phenol.

Disperse dyes containing substituents in both anthraquinone rings are often prepared from dinitroanthrarufin (DNA) and dinitrochrysazin (DNC), the structures of which are shown in Fig. 13.116. Examples of these dyes are C.I. Disperse Blue 56 and Blue 77. The former dye is made by reduction of DNA followed by bromination, and the latter is made by condensing aniline with DNC. The DNC condensation shows that nitro groups in the α-position can be displaced like a halogen.

The dichlorinated precursor for Disperse Violet 26 can be used to make turquoise blue dyes such as C.I. Disperse Blue 60, as shown in Fig. 13.117. In this sequence, the chloro groups are replaced by cyano groups, using NaCN, and the resultant intermediate (**35**) is hydrolyzed to give the corresponding imide (**36**), which in turn is alkylated to give the target dye.

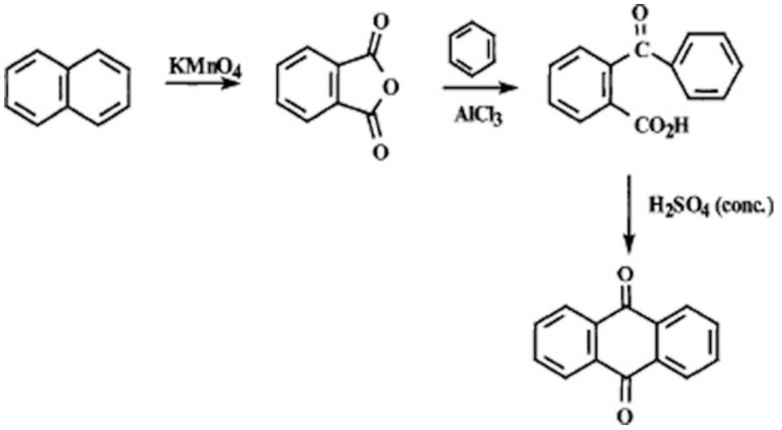

Fig. 13.110 Synthesis of the anthraquinone ring system

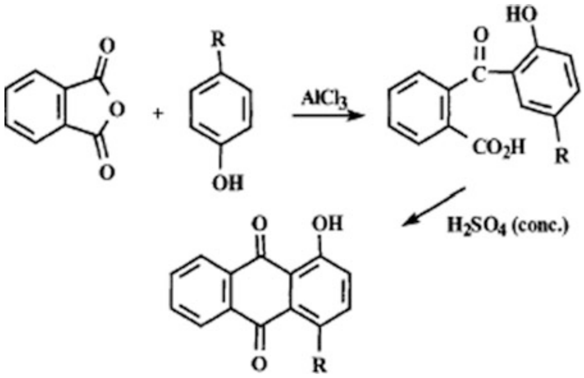

Fig. 13.111 Synthesis of key substituted anthraquinone intermediates, where R = Cl, OH

Anthraquinone Acid Dyes

A key intermediate in the synthesis of anthraquinone acid dyes is bromamine acid. This compound is made via the sequence shown in Fig. 13.118. Acid dyes made from this intermediate include C.I. Acid Blue 25, C.I. Acid Blue 40, and C.I. Acid Blue 127.

The synthesis of C.I. Acid Blue 127 takes place according to the route shown in Fig. 13.119. A key step in the synthesis is the formation of diamine **37**, which is produced in two

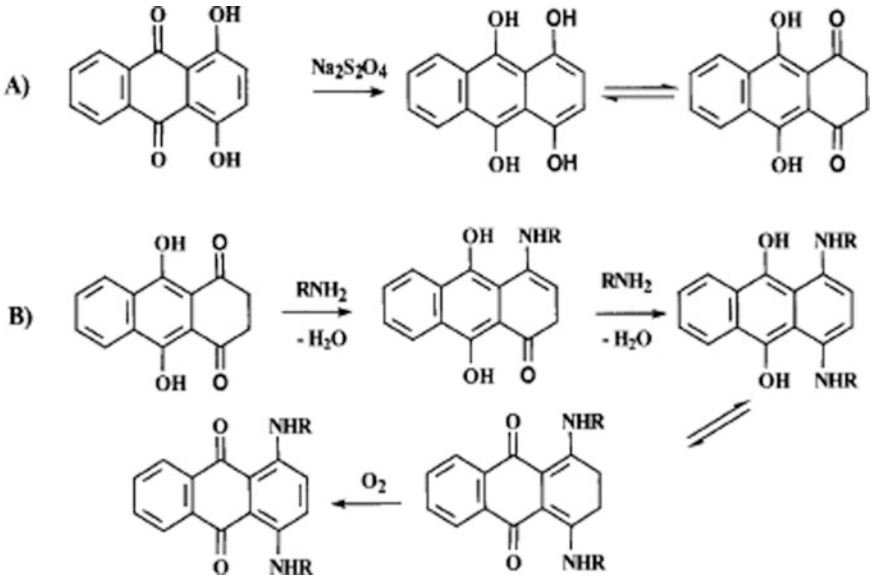

Fig. 13.112 General reaction scheme for the synthesis of 1,4-diaminoanthraquinone dyes

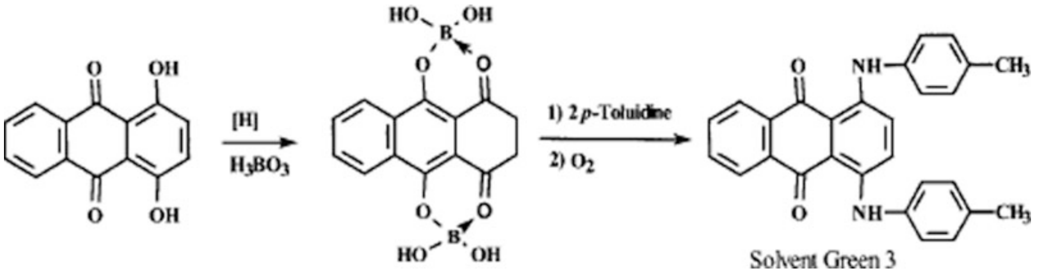

Fig. 13.113 Boric acid catalyzed synthesis of Solvent Green 3

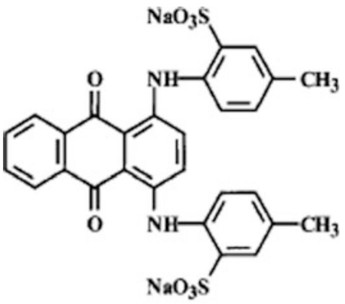
steps from *N*-sulfomethylaniline: (1) condensation with acetone and (2) hydrolysis to remove the protecting group. At this point, one molecule of diamine **37** is condensed with two molecules of bromamine acid to form the dye.

Another important dye is C.I. Acid Green 25. This dye is made by the sulfonation of C.I. Solvent Green 3 (Fig. 13.113). Because the benzene rings are more reactive than the anthraquinone system, sulfonation occurs there preferentially.



Acid Green 25

Anthraquinone Basic Dyes

Dyes of this type include C.I. Basic Blue 22 and Basic Blue 47. The synthesis of Basic Blue 22 is shown in Fig. 13.120, as an example of the type of chemistry required. The sequence begins with the preparation of *N*,*N*-dimethylpropylenediamine, which in turn is combined with methylamine and condensed with leucoquinizarin. Oxidation gives the key intermediate **38**, which is alkylated using methyl chloride to produce the dye.

Anthraquinone Reactive Dyes

Three examples of dyes of this type are C.I. Reactive Blue 19 (**39**), Reactive Blue 2 (**40**), and Reactive Blue 4 (**41**). All three dyes can be synthesized by condensing the appropriate arylamine with bromamine acid. In the case of the high-volume dye Reactive Blue 19, arylamine **44** is the key

intermediate, and its synthesis is shown in Fig. 13.121. Chlorosulfonation and then reduction of the intermediate sulfonyl chloride produce the sulfinic acid **42** Alternatively, the reduction step can be conducted with $Na_2S_2O_4$. Alkylation of the sulfinic acid with 2-chloroethanol or ethylene oxide (a more toxic agent) produces Compound **43**. Treatment of this compound with hot H_2SO_4 gives simultaneous hydrolysis of the acetamido (−NHAc) group and sulfonation of the hydroxyethyl ($-CH_2CH_2OH$) group to give key intermediate **44**.

Similarly, dyes **40** and **41** are prepared by condensing 2,5-diaminobenzenesulfonic acid with bromamine acid,

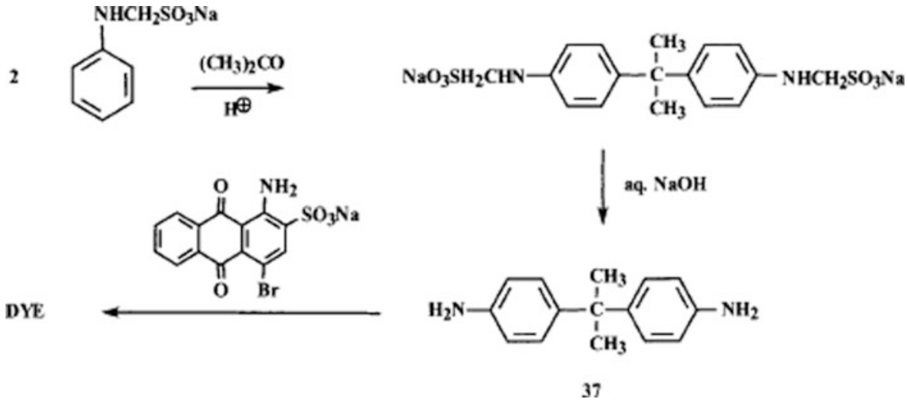

Fig. 13.119 Synthesis of Acid Blue 127

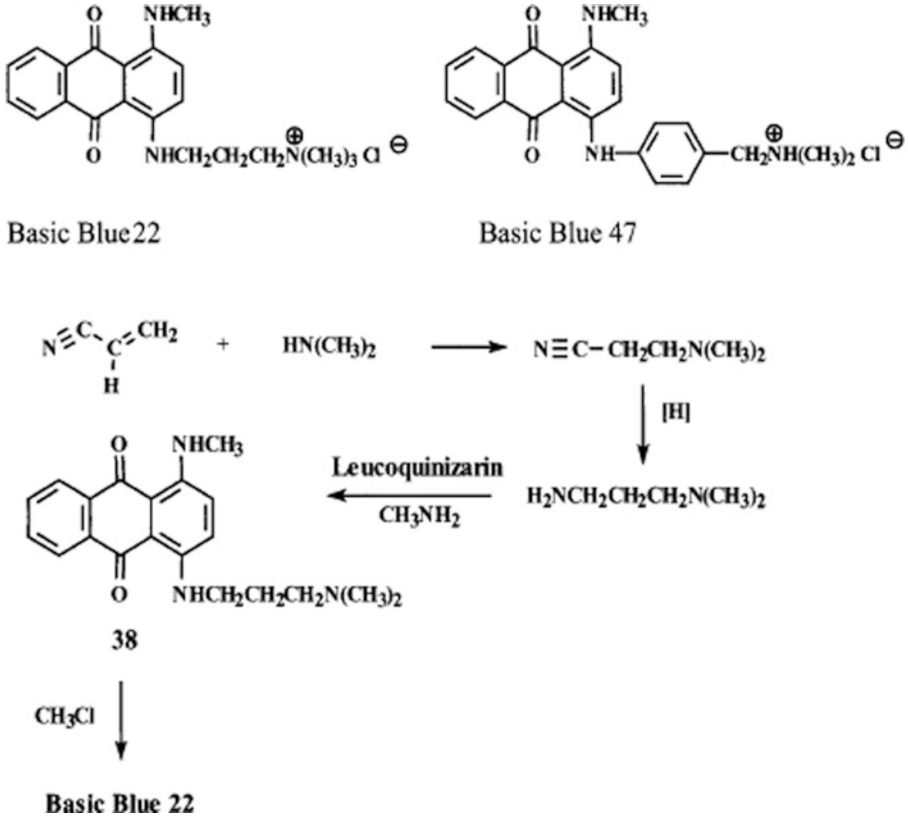

Fig. 13.120 Synthesis of Basic Blue 22

which reacts first at the less hindered amino group, followed by a reaction with cyanuric chloride to introduce the reactive group. These steps produce dye **41** and dye **40** is formed by reacting **41** with a mixture of sulfonated anilines. See Fig. 13.122.

Vat Dyes

The synthesis of vat dyes covers the full gamut of simple to complex chemistry. We have chosen examples to illustrate the broad spectrum of possible structures and synthetic methods. Emphasis is placed on anthraquinone vat dyes, because they dominate the number of commercial dyes.

Anthraquinone

The simplest anthraquinone vat dyes are benzoylated amines such as C.I. Vat Yellow 3 (**45**) and Vat Yellow 33 (**46**). The syntheses are shown in Figs. 13.123 and 13.124.

Anthraquinone vat dyes containing a thiazole ring include C.I. Vat Yellow 2, the synthesis of which is shown in Fig. 13.125. In this case, at least two approaches are

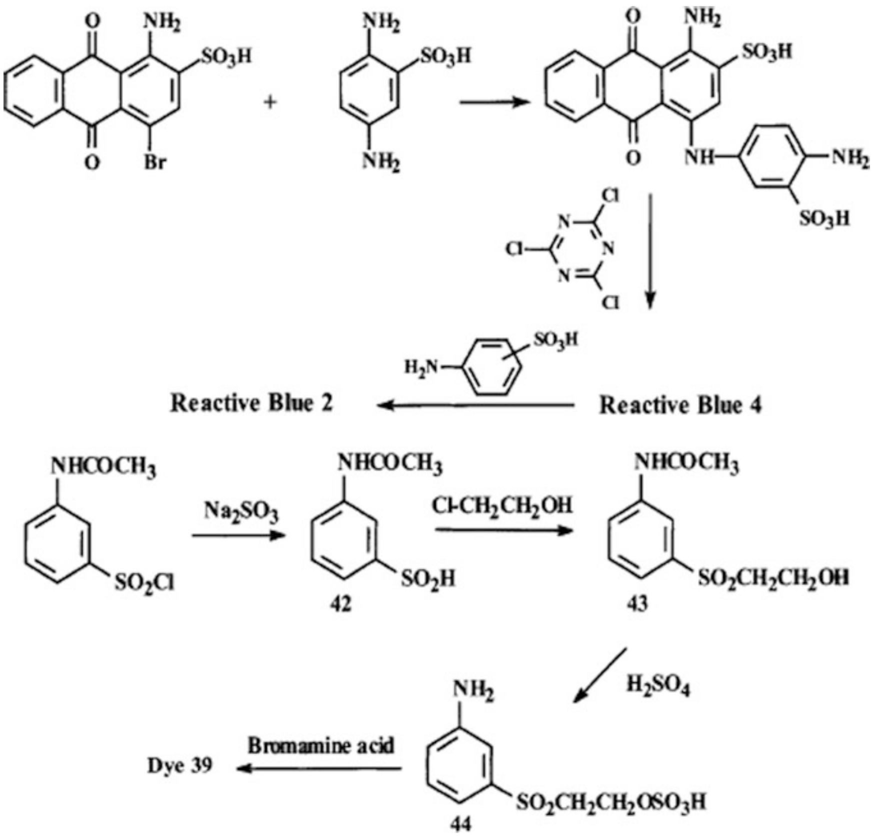

Fig. 13.121 Synthesis of three reactive blue dyes from bromamine acid

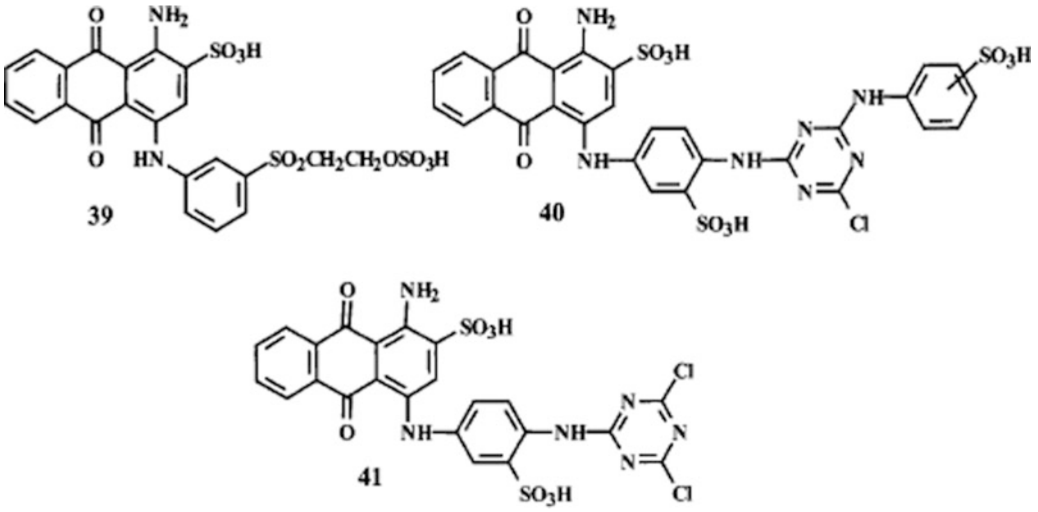

Fig. 13.122 Structures of Reactive Blue 19 (**39**). Reactive Blue 2 (**40**), and Reactive Blue 4 (**41**)

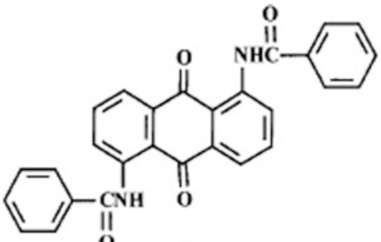
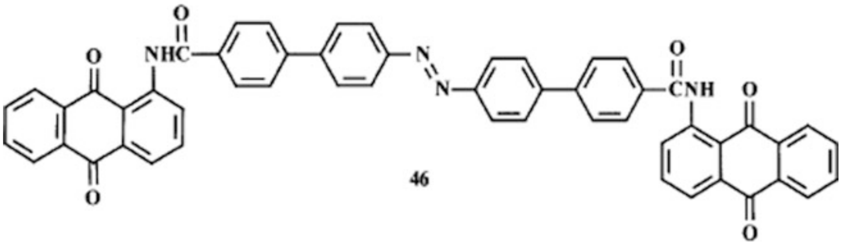
possible. In the first, 2,6-diaminoanthraquinone is condensed with benzotrichloride in the presence of sulfur and the initial product is oxidized without isolation to give the target dye. Alternatively, the starting diamine can be chlorinated and converted to the corresponding dithiol (**47**). At this point condensation with benzaldehyde followed by oxidation (e.g., air or dichromate) gives the dye.

Important vat dyes containing a carbazole moiety include C.I. Vat Brown 3 and Vat Black 27. These dyes are made according to the method shown in Fig. 13.126 for Vat Brown 3.



45



46

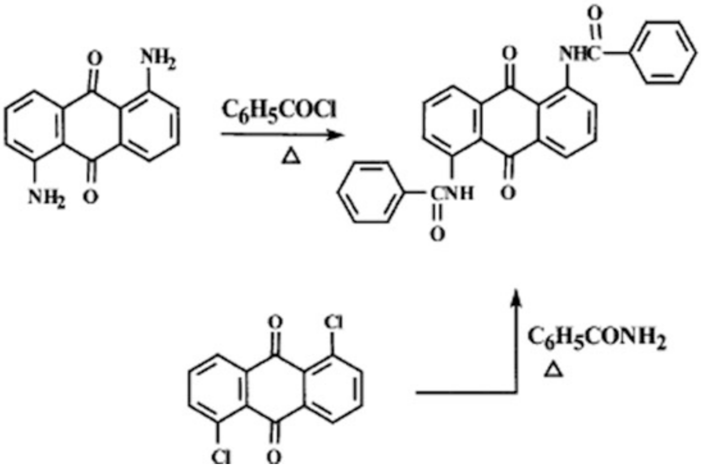


Fig. 13.123 Two approaches to the synthesis of Vat Yellow 3

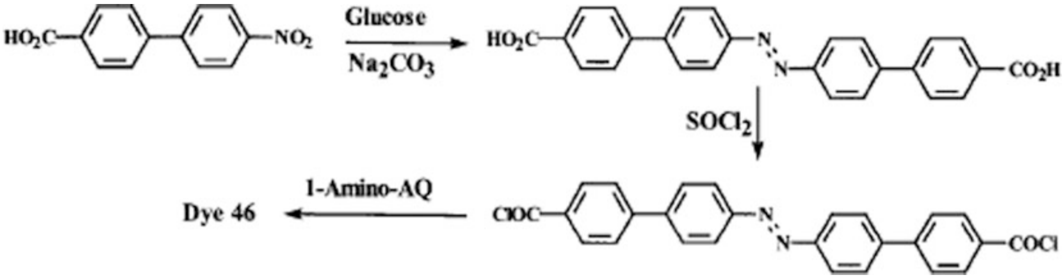

Fig. 13.124 Synthesis of Vat Yellow 33, where AQ = anthraquinone

The synthesis employs an Ullmann-type condensation reaction between compounds **48** and **49** followed by acid-induced cyclization using H_2SO_4.

Vat dyes that do not contain all of the elements of the anthraquinone moiety include benzanthrone-based vat dyes such as C.I. Vat Orange 1 and Vat Green 1, which are made according to the routes shown in Figs. 13.127 and 13.128. The first synthesis is a three-step process: (1) dibenzoylation of naphthalene, (2) Lewis acid-induced cyclization to the benzanthrone system, and (3) dibromination. The second

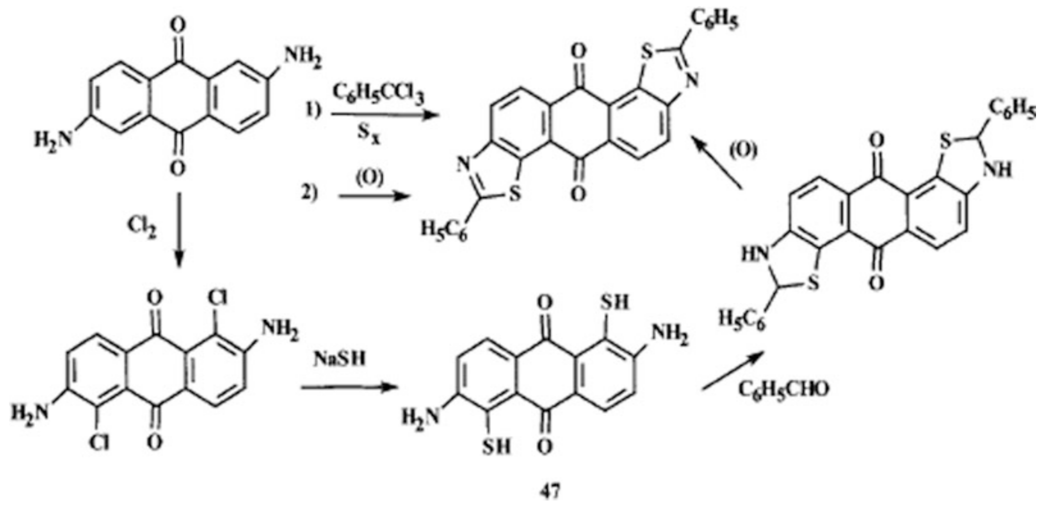

Fig. 13.125 Alternatives to the synthesis of Vat Yellow 2

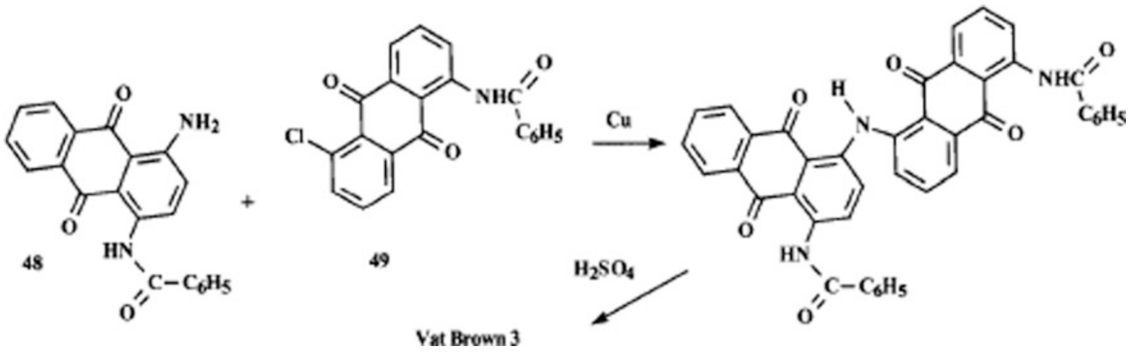

Fig. 13.126 Synthesis of carbazole-based anthraquinone vat dyes

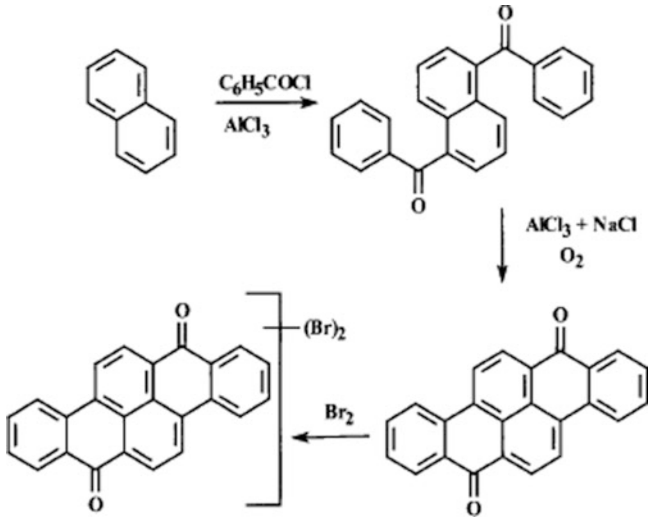

Fig. 13.127 Three-step synthesis of Vat Orange 1

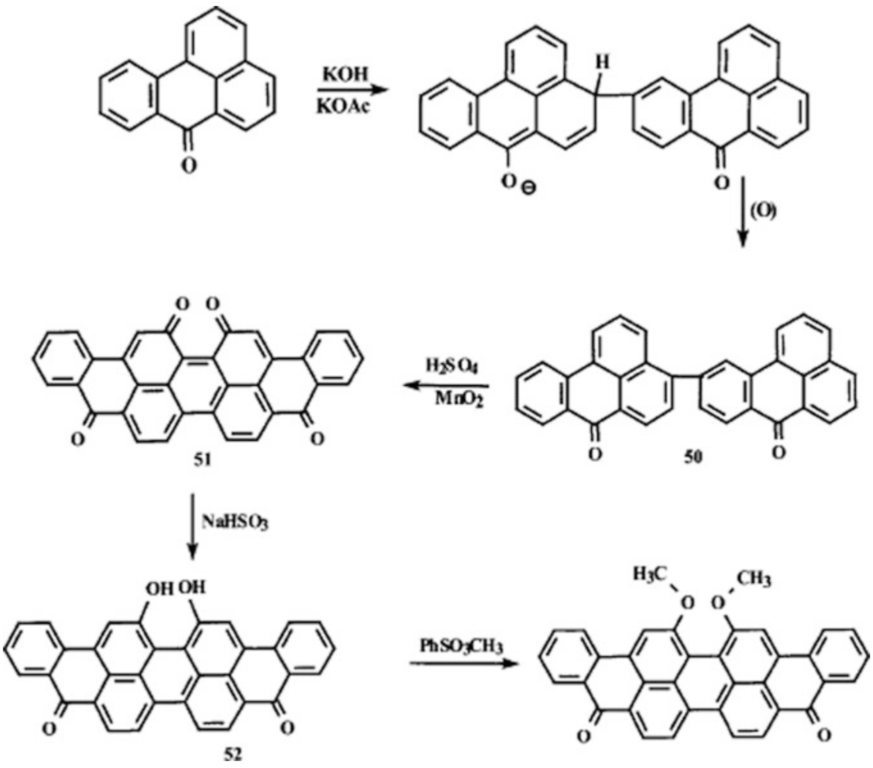

Fig. 13.128 Synthesis of Vat Green 1 from benzanthrone

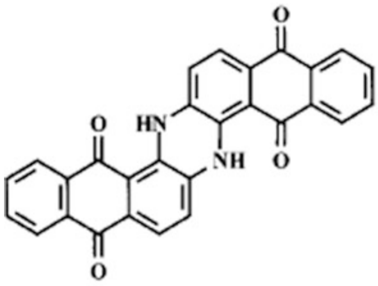
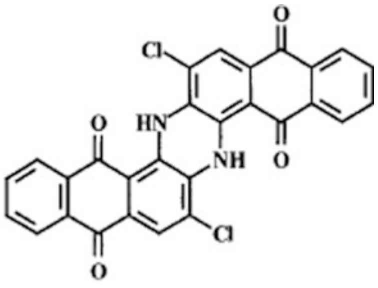
synthesis is a four-step process: (1) oxidative-coupling of benzanthrone in the presence of alkali to give compound **50**, (2) H_2SO_4-induced ring closure to give compound **51**, (3) reduction to compound **52**, and (4) methylation to give the target dye.



Vat Blue 4



Vat Blue 6

Other important anthraquinone vat dyes belong to the family known as indanthrones. Important examples of this structural type are C.I. Vat Blue 4 and Vat Blue 6. Vat Blue 4 is made by heating 1-amino or 2-aminoanthraquinone at 220–230 °C in a KOH/H_2O mixture. The Vat Blue 6 synthesis is a much longer process that requires the synthesis of 2-chloro-3-aminoanthraquinone [60]. The resultant amine is brominated and converted to the target dye via an Ullmann reaction.

Indigoid and Thioindigoid

By far the most important member of these vat dye families is C.I. Vat Blue 1 (indigo). Its synthesis can be achieved via the four-step method shown in Fig. 13.129. The method

Fig. 13.129 Commercial preparation of synthetic indigo

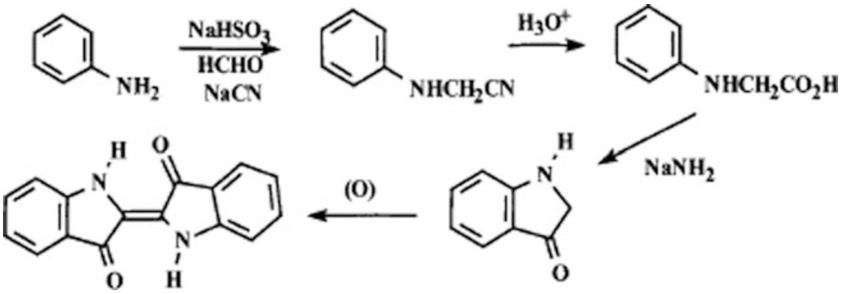


Fig. 13.130 Synthesis of thioindigoid dyes

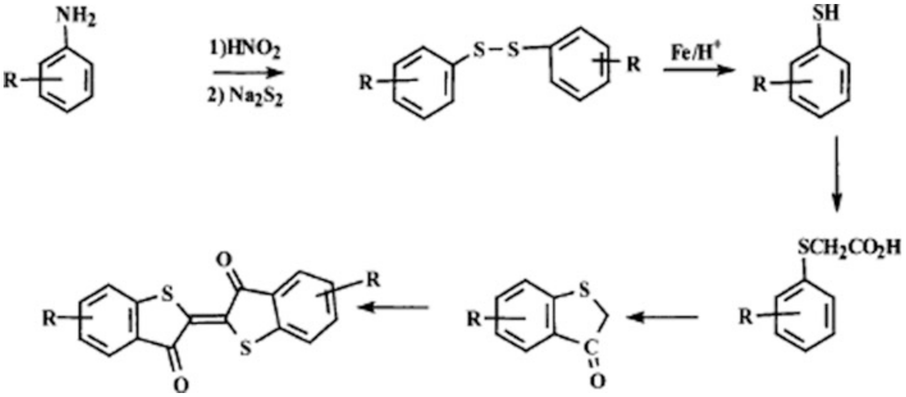

Fig. 13.131 Synthesis of Sulfur Yellow 4 by the sulfur bake process

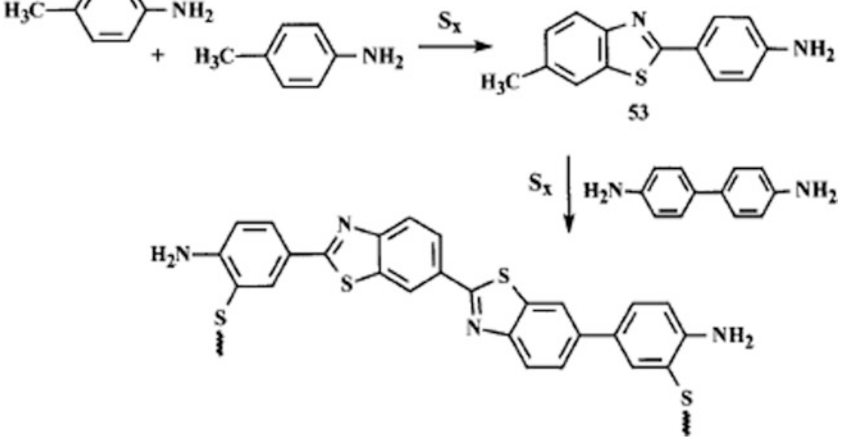

shown is known as the Heumann–Pfleger synthesis [61], where the key intermediate, *N*-carboxymethylaniline, is fused with $NaNH_2$. The cyclic product of the fusion step undergoes air oxidation to give indigo.

Thioindigoids are similarly prepared, in that the synthesis of carboxymethyl intermediates is conducted. The resultant cyclic ketones are much less air sensitive, making oxidation with a chemical agent important. However, this also means that unsymmetrical thioindigoid systems can be synthesized (see Fig. 13.130). Although many have been made, few are in commerce today. Examples are C.I. Vat Red 1 and Vat Red 41.

Sulfur Dyes

Earlier we mentioned that sulfur dye chemistry, although quite old, is still much less well defined than for the other classes of dyes. It is clear, however, that many sulfur dyes are produced by the sulfur bake process and that compounds containing the benzothiazole group (e.g. **53**) are formed in route to the final dyes. For instance, the synthesis of C.I. Sulfur Yellow 4 follows a course of the type outlined in Fig. 13.131. In this regard, heating a mixture of *para*-toluidine and sulfur produces a 2-(*para*-aminophenyl) benzothiazole. The sulfur bake process has also been used to make C.I. Sulfur Orange 1, where benzothiazone intermediate **54** is produced along the way [62]. See Fig. 13.132.

Sulfur blue dyes are often made using an organic solvent such as *n*-butanol, in what is known as the solvent reflux process. Examples are C.I. Sulfur Blue 9 and Sulfur Blue 13. In this case, intermediate structures are indophenols (e.g., **55**). See Fig. 13.133. Similarly, sulfur dyes containing benzothiazine groups can be made from tetrahalogenated benzophenones. See Fig. 13.134.

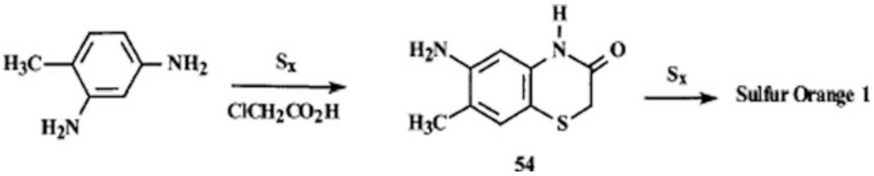

Fig. 13.133 Synthesis of blue dyes by the solvent reflux process

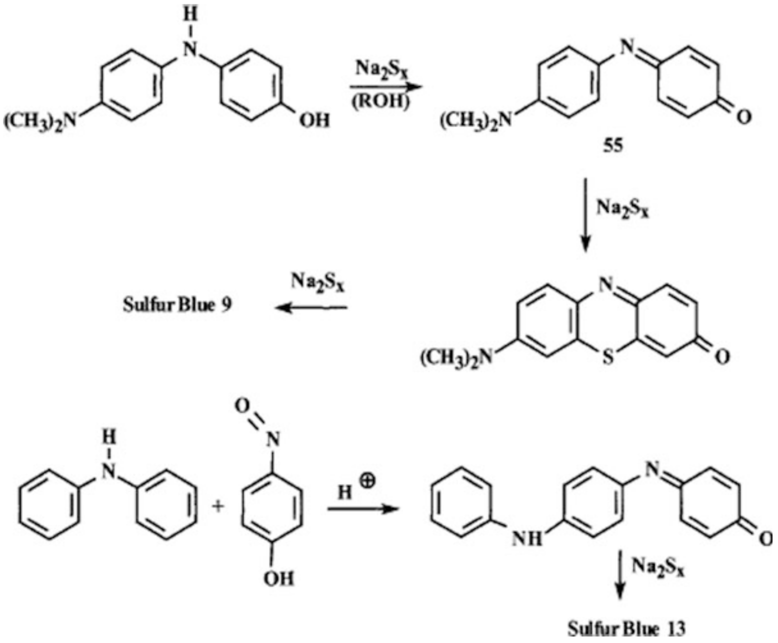

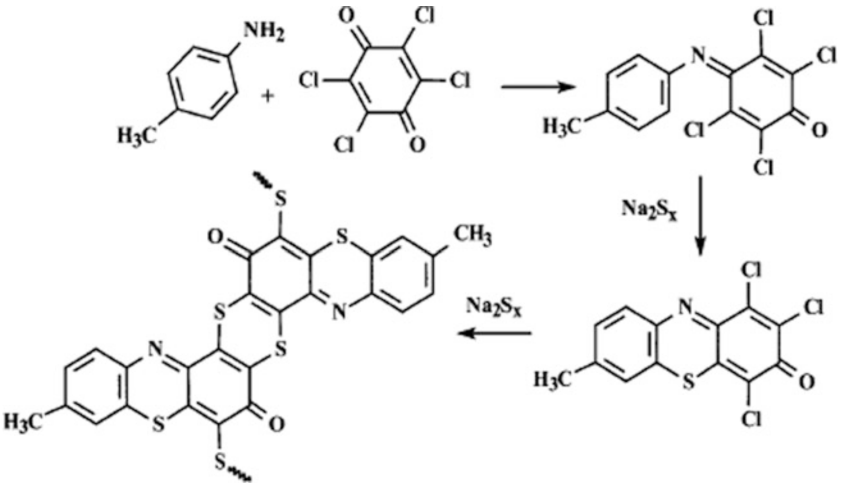

Fig. 13.134 Sulfur dye synthesis from tetrachlorobenzoquinone

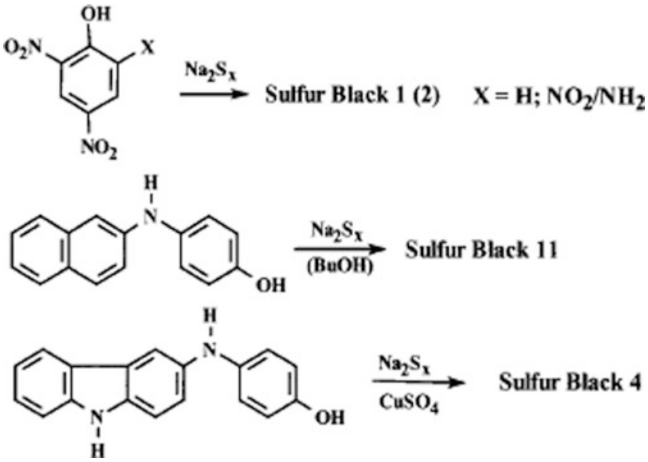

Fig. 13.135 Synthesis of sulfur black dyes

Sulfur black dyes are synthesized according to the methods shown in Fig. 13.135. In these examples sodium polysulfide is the sulfurizing agent employed.

Phthalocyanine Dyes

The synthesis of the CuPc system is achieved as shown in Fig. 13.136. Here it can be seen that any of four precursors can be used. Disulfonation gives C.I. Direct Blue 86 and tetrasulfonation gives C.I. Acid Blue 249.

The chlorosulfonation of the CuPc system opens the door to the synthesis of reactive dyes, as shown in Fig. 13.137. In this case, aminochlorotriazine **56** reacts with a CuPc–SO_2Cl intermediate to give a monochlorotriazine reactive dye (**57**), which in turn can be used to make the cationic reactive dye **58**.

Fluorescent Brighteners (Colorless "Dyes")

Many fluorescent brighteners are derivatives of 4,4′diaminostilbene-2,2′-disulfonic acid (**59**), an example of which is C. I. Fluorescent Brightener 32 (Fig. 13.138). In this case, successive reactions involving diamine **59** with two molecules of cyanuric chloride and two molecules of aniline followed by hydrolysis of the final chloro groups give the target compound.

Structurally related fluorescent brighteners containing a benzotriazole moiety are made according to the route shown in Fig. 13.139. In this case, diamine **59** is tetrazotized, coupled to 2 molecules of 1,6-Cleve's acid, and the intermediate disazo stilbene structure (**60**) is oxidized to C.I. Fluorescent Brightener 40. Nowadays, monosulfonated benzotriazole brighteners are more important [63].

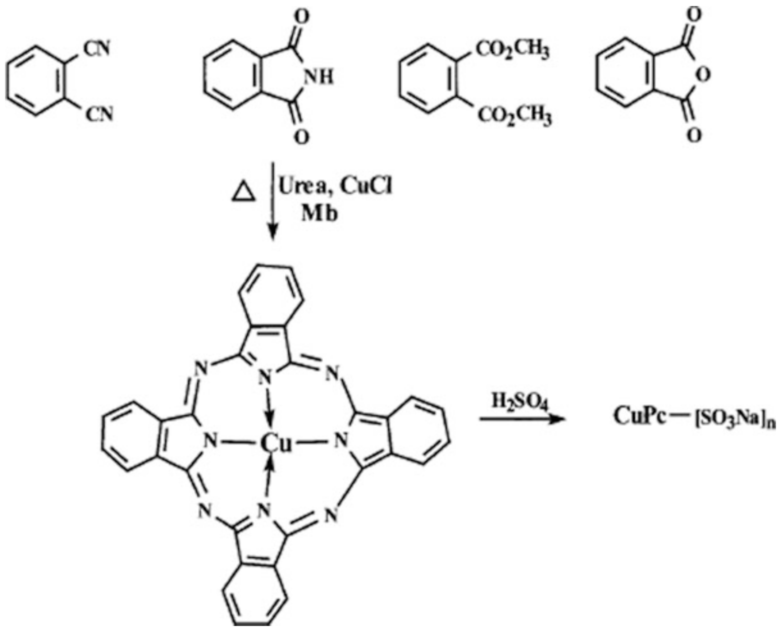

Fig. 13.136 Synthesis of phthalocyanine and sulfonated derivatives

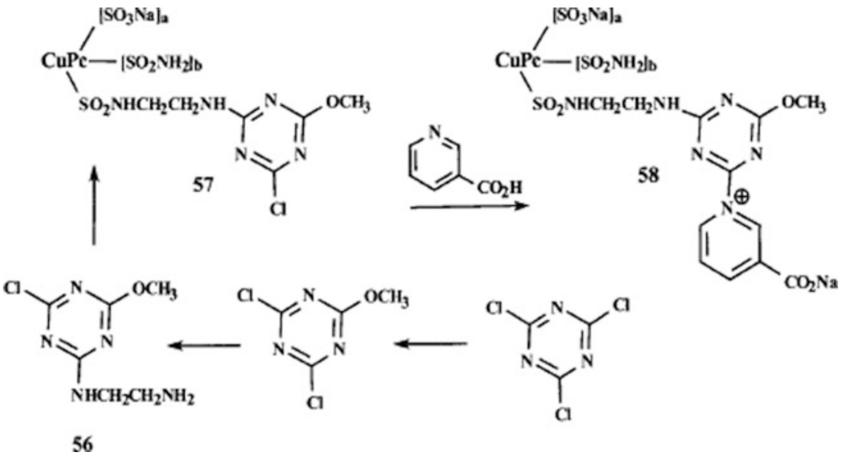

Fig. 13.137 Synthesis of CuPc-based reactive dyes

The synthesis of one example is shown in Fig. 13.140 for C.I. Fluorescent Brightener 46.

Examples of hydrophobic fluorescent brighteners include C.I. Fluorescent Brighteners 199, 130, 236, and 162. The synthesis of these compounds is shown in Figs. 13.141, 13.42, 13.43, and 13.144. In the first of these examples, a *bis*-stilbene structure is made in two steps from *bis*-chloromethyl-xylene, using the traditional reaction of a phosphorus ylide with an aldehyde as the key step in the sequence.

In the second example, the synthesis of a coumarin-type fluorescent brightener is illustrated. Here, *meta*-hydroxy-*N*,*N*-diethylaniline is condensed with ethyl acetoacetate followed by cyclization of the intermediate keto ester **61**. The latter compound undergoes acid-catalyzed cyclization and dehydration to give C.I. Fluorescent Brightener 130. See Fig. 13.142.

A fluorescent brightener containing coumarin and triazole groups is made according to the method shown in Fig. 13.143. The synthesis begins with the preparation of amino-coumarin **62**, which in turn is coupled to Tobias acid with concomitant loss of the SO_3H group and then oxidized to give C.I. Fluorescent Brightener 236.

The final example is for a naphthalimide structure that is made from acenaphthene (**63**) in the four-step sequence shown in Fig. 13.144: (1) sulfonation, (2) chromate oxidation to give the naphthalic anhydride (**64**), (3) condensation with *N*-methylamine, and (4) replacement of the sulfonic acid group in a reaction with methoxide. This process gives C.I. Fluorescent Brightener 162.

Production and Sales

During the 1990s, the large international companies began to form alliances with producers around the world. Hoechst AG, which had done little research on disperse dyes since the 1970s, signed an agreement in 1990 with Mitsubishi of Japan and gained access to a strong line of disperse dyes. BASF AG and Mitsui signed agreements for vat dyes. ATIC resulted from a joint venture between ICI and Atul of India. Finally, a major break came in January 1995, when Bayer AG and Hoechst AG, the parent companies in Germany,

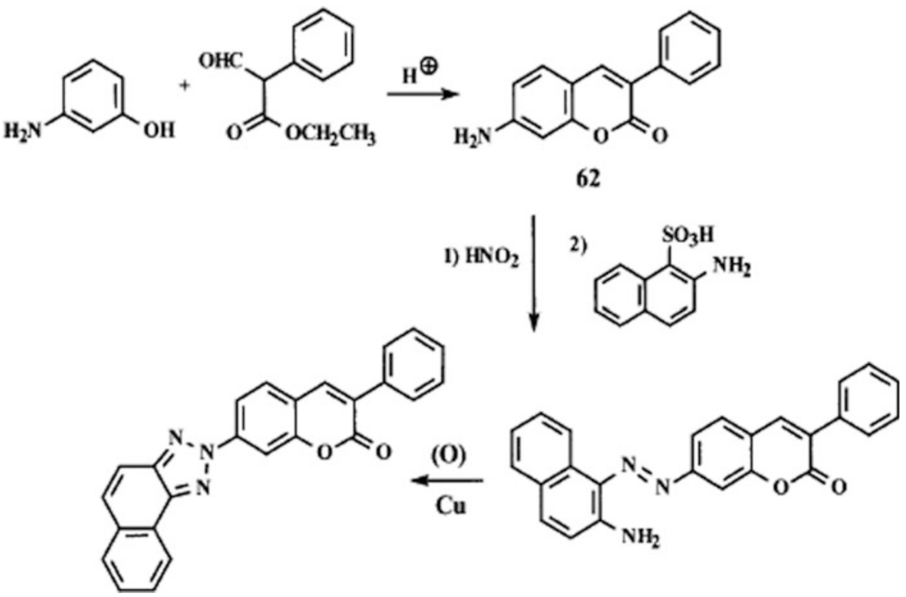

Fig. 13.143 Synthesis of fluorescent brightener 236

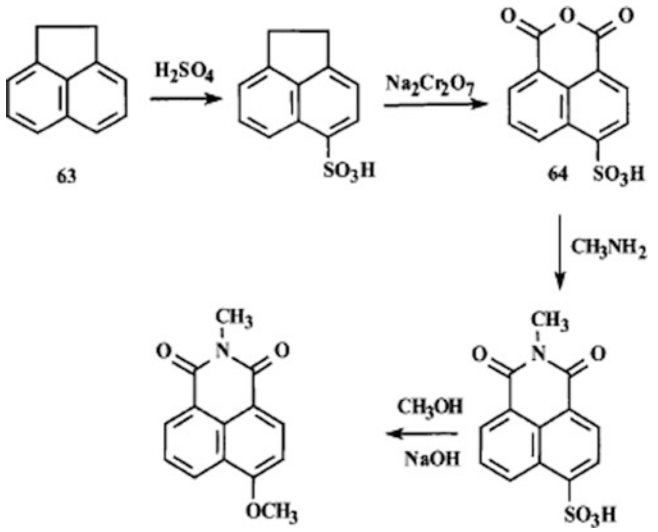

Fig. 13.144 Synthesis of fluorescent brightener 162

announced the formation of DyStar, a worldwide consolidation of their textile dye businesses, which included the US Hoechst Celanese, and Bayer. Within a short time, BASF acquired the textile dyes business of ICI/Zeneca. Swiss companies Ciba and Clariant (derived by consolidating Sandoz and portions of Hoechst in 1995) announced a merger of the textile dyes business but canceled the venture in 1998. Crompton & Knowles (C&K) emerged as the sole US-based major company, but the company struggled during the late 1990s and was sold to Yorkshire Group PLC of the United Kingdom. Yorkshire Pat-Chem and C&K became Yorkshire Americas.

Globalization and establishment of NAFTA meant fewer textile dyes were needed and manufactured in the United States during the late 1990s. The market shrank from 232 million pounds ($955 million) in 1994 to 214 million pounds ($689 million) in 1998 with further cuts expected. Imported dyes expanded but prices fell. Some 1.1 million pounds of disperse dyes were brought in with a value of $5 million in 1992. In 1999, 5.7 million pounds with a value of $10

The Chemistry of Structural Adhesives: Epoxy, Urethane, and Acrylic Adhesives

14

Kirk J. Abbey and Dennis J. Zalucha

Introduction

Adhesives have been used successfully in a variety of applications for centuries. Today, adhesives are more important than ever in our daily lives, and their usefulness is increasing rapidly. In the past few decades there have been significant advances in materials and in bonding technology. People now routinely trust their fortunes and their lives to adhesively bonded structures and rarely think about it.

At the same time, the subject of adhesives and adhesion continues to receive much attention by both industrial and academic researchers as evidenced by many measures including the continued growth of membership and attendance at the annual meeting of The Adhesion Society [1]. The scientific literature continues to grow at a rapid pace. New books devoted to general and specialized aspects of adhesion and adhesives continue to appear [2–23]. New patents on adhesive compositions and processes are granted almost daily. Figure 14.1 shows U.S. Patent activity for the past 10 years as discerned by specifically claimed text. There are more patents that mention the use of one of these types of structural adhesives elsewhere in the patent for assembly of some type of article or use other wording with equivalent meaning. Figure 14.2 shows a sample of the most active world patenting organizations irrespective of adhesive chemistry. There are scientific journals devoted to the science and technology of adhesives and their use (Table 14.1). Specialized Internet sites have also appeared in recent years (Table 14.2). A significant portion of the publications dealing with adhesives is concerned with epoxy, urethane, and acrylic structural adhesives as they are used in a wide variety of commercially important applications. This chapter reviews some of the chemistry of these adhesive types as it applies to structural applications, that is, to those applications where the adhesive bond must carry a load while being resistant to dimensional changes, also known as creep.

Adhesion

Materials are generally defined as adhesives by what they do. Almost any organic polymer and even many inorganic materials can function as adhesives in some situations. However, whether they are organic polymers or inorganic, or perhaps even solders or brazing alloys, all adhesives share common traits in performing their functions.

1. An adhesive, by surface attachment only, transfers and distributes mechanical loads among the components of an assembly.
2. At some time in the course of the bond formation, the adhesive must be liquid or behave as a liquid in order to wet the adherends.
3. An adhesive carries some continuous, and often variable, load throughout its life.
4. An adhesive must work with the other components of the assembly to provide a durable product that is resistant to degradation by elements of the environment in which it will be used.

The expectations of the user are extremely important in determining whether an adhesive is “good” or “bad.” Adhesives are judged on the ability of the whole assembly to meet the user’s expectations, which will, in turn, depend on the way the assembly is loaded and tested and on what and where the weakest points of the assembly are located [8]. Adhesion is not an intrinsic property of any polymer but is rather a property of the whole assembly. Structural adhesives are distinguished from nonstructural adhesives by the magnitude of the load that they carry.

Curing

The chemistry of a structural adhesive is designed to do at least two important things. First, the adhesive must at some time pass through a fluid state in order to wet the adherends. Second, the adhesive in its final state in the bond line must be a solid, high-molecular-weight polymer that is able to carry and transfer mechanical forces. In almost all cases, the polymer matrix of a structural adhesive will be cross-linked. The chemistry must make possible some manufacturing process for the assembly that allows for the liquid state,

Table 14.2 Internet web sites focused on adhesives

http://www.adhesionsociety.org	The Adhesion Society

and there must be some mechanism for passing from the liquid to the solid, load-bearing state. The process of going from the liquid to the solid state is usually termed “curing.”

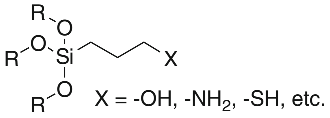
There are three general ways in which adhesives are cured. In the first “hot-melt” method, the adhesive can be applied in a molten state and allowed to cool and solidify in the bond line. In the second method, the adhesive can be applied as a solution or dispersion and the carrier liquid allowed to evaporate, leaving behind the high-molecular-weight polymer. In the third method the adhesive consists of a low-viscosity fluid containing reactive groups that undergo polymerization in the bond line to build the molecular weight sufficiently to carry a load, entailing in most cases forming a cross-linked network. This method is the one most commonly used with epoxy, urethane, and acrylic structural adhesives. The chemistry, methods, and mechanisms for accomplishing this polymerization will be covered in more detail in the following sections.

Adhesion Mechanisms

Focusing on the third cure method, once the liquid adhesive has been applied to the adherends and intimate contact and wetting have been established, the liquid mass is cured by polymerizing it to a solid, high-molecular-weight, load-bearing state. It now transfers load among the components of the assembly. The mechanisms of adhesion can be grouped into three or four categories. Kinloch identifies four categories and devotes an entire chapter to elaborate these in detail [7]. In this review, three mechanisms will be invoked to explain the adhesion of one material to another: (1) mechanical interlocking, (2) electrostatic attraction, and (3) the formation of chemical bonds across the interface. All three mechanisms may play some role in any given bonding situation although often one contributes much more than the others.

Mechanical interlocking is usually invoked when describing the adhesion of ice to glass. Silver amalgam dental fillings are held in place largely by mechanical interlocking. Although there probably are some exceptions, mechanical interlocking usually is not a major factor in bond formation with structural adhesives because, unlike water freezing, most materials contract on cooling or curing. Interdiffusion of polymer chains (i.e., entanglements) may also be considered to be mechanical interlocking at the atomic scale, but it requires mutually compatible and essentially uncross-linked compositions to occur. This is likely to be most important in the welding of plastics.

The other extreme in bonding is the formation of direct covalent chemical links across the interface. These bonds would be expected to be quite strong and durable, but they require special attention not only to the chemistry of the adhesive, but also to that of the substrate. It is necessary that there be mutually reactive chemical groups tightly bound on the adherend surface and in the adhesive. There is evidence that such bonds can be formed under controlled conditions. Silane coupling agents are one example of using specific reactive groups to promote the formation of direct chemical bonds.



By far the dominant adhesion mechanism, particularly in the absence of covalent linkages, is the electrostatic attraction of the polar groups of the adhesive to polar groups of the adherends. These are mainly forces arising from the interaction of permanent dipoles, including the special cases of hydrogen bonding (10–25 kJ/mol) and Lewis acid–base interactions (<80 kJ/mol) [25, 26]. These forces provide much of the attraction between the adhesive and the adherend and also provide a significant portion of the cohesive strength of the adhesive polymer. These interactions are generally classified as attractive long-range forces that drop off inversely to the sixth power of the distance, $1/r^6$, when r is very large compared to the dipole charge separation distance; that is, $r > 1.5$ nm. However, at shorter distances attractive interactions rise more rapidly especially when dipoles are aligned.

In two articles on the cohesive and adhesive strengths of polymers, Mark [27, 28] derives some estimates of what adhesive bond strengths might be achievable with covalent bonds or polar forces across an interface. He concludes that the bonds actually achieved in real life are only a small fraction of what he estimates for the situation in which covalent chemical bonds are the main contributors to adhesion. He further proposes that even if there are a significant number of covalent chemical bonds across the interface, the failing strength of the bond still will depend on the strength of the polar bonds. The polar bonds will fail at a lower strength than the covalent bonds, and the applied load then will be concentrated on the covalent bonds. The measurable mechanical strength of a partially covalent adhesive bond still will be dominated by the polar forces. The implication is that although increasing the proportion of covalent bonds across the interface can enhance durability, the ultimate load-carrying capacity probably will not be significantly affected.

Surfaces

Adhesives must function solely through surface attachment. Therefore, the nature and the condition of the adherend surface are crucial to the formation of strong and durable bonds. By “surface” we usually mean that region of a material which interacts with its surroundings. There is some region of a bonded assembly where the adhesive and the adherend interact, but only rarely is this a sharp boundary. Usually it is a very diffuse, somewhat ill-defined region of interaction that has become known as an interphase rather than an interface. For example, the interaction with a freshly cleaved single crystal of zinc might occur over only a few atomic layers or a few nanometers. Rough or porous surfaces present more surface area than smooth ones of the same dimensions, and the adhesive might reach a depth of several hundred nanometers on a porous adherend such as wood or paper.

One very important aspect of surfaces is that they rarely have the same chemical composition as the bulk material and often seem to be entirely unrelated to the bulk. The surface usually consists of several regions having no clear boundaries. A metal alloy might have a well-defined bulk composition, but at the surface there probably will be a region that is still metallic but is of different chemical composition because of alloying elements or impurities that have segregated at the surface. On top of this region there probably will be a layer of oxides and hydroxides formed by reaction with the atmosphere. There also will be many other contaminants such as nitrogen, sulfur, and halogen compounds formed by interaction with the pollutants in the atmosphere. Finally there will be several layers of adsorbed water. The surface of a metal also might be contaminated with rolling oils, cutting lubricants, drawing compounds, or corrosion inhibitors. Mechanical working of the metal might even mix these contaminants with the other surface materials to create something like an inhomogeneous “frosting” on the surface.

Engineering plastics display some of the same surface phenomena as metals, in that the surface is very different from the bulk. The manufacturing process often introduces anisotropy so that the mechanical properties of the material are different in different directions. In addition, it is common to find that components of the plastic have accumulated at the surface. Low-molecular-weight polymers or oligomers, plasticizers, pigments, mold release agents, shrink control agents, and other processing aids as well as adsorbed contaminants often are present.

The nature of the surface of an engineering plastic can change rapidly in response to its surroundings. The bulk of the material might be in the glassy state, but because of the concentration of low-molecular-weight material and contaminants, the surface region can be quite mobile. Exposure of the surface to a polar environment, such as by wiping with a polar solvent, can cause polar groups in the plastic surface to preferentially orient themselves outward. Exposure to a nonpolar medium can bring out the nonpolar nature of the surface.

The cured adhesive itself can be expected to be inhomogeneous particularly when arising from a formulated composition containing fillers, rubber-toughening agents, and other additives. Low-molecular-weight materials can be drawn into the surface of a porous adherend, leaving higher-weight polymer and fillers behind. The polar or nonpolar nature of the adherend influences the orientation and morphology of adhesive polymers in the interphase. Compounds at the adherend surface can catalyze or inhibit polymerization. Solvents in the adhesive can swell the adherend or dissolve portions of the adherend surface.

The interphase region is complex, and its composition is usually unknown. Primers or surface treatments often are used to improve control of the interphase and provide increased adhesion, durability, and resistance to aggressive environments. The chemistry of primers and surface treatments is as varied as the chemistry of the adhesives, but they will not be considered further in this chapter.

Any bonded construction consists of at least two adherends and one adhesive and contains at least two interphase regions. It is important to remember that the performance of the construction, its durability, its mechanical properties, and its response to tests and challenges, are all properties of the entire assembly. The successful use of adhesives depends on taking account of all parts of the construction and the process. Whereas the adhesive is just one part of the assembly, its chemistry plays an important role in the bonding process.

The following sections discuss the chemistry of some major classes of thermosetting, structural adhesives.

Epoxy Structural Adhesives

Introduction

Epoxy adhesives command a large portion of the structural adhesives market. Many people are probably familiar with epoxy structural adhesives, as these are the typical two-part adhesives found in hardware stores and supermarkets. Epoxy adhesives owe their popularity with both the general public and industry to their ease of use, their relative safety, and their compatibility with many adherends (Fig. 14.3). The various chemical reactions involving the epoxy ring provide a fertile field for the development of a wide range of properties [29]. Even a half century after the first epoxy patents were issued [30], new patents on epoxy adhesive technology continue to appear every month (Fig. 14.1).

Fig. 14.3 Construction of a bicycle frame from carbon fiber composite tubing using an Araldite™ epoxy adhesive (Courtesy of Huntsman Advanced Materials)

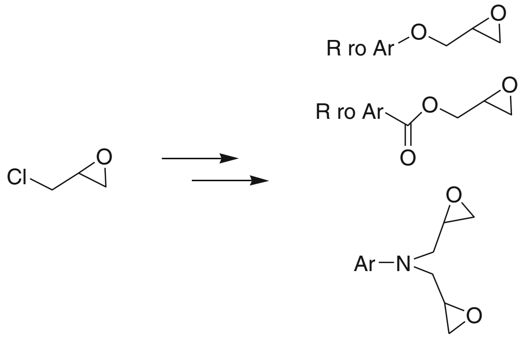
Epoxy adhesives get their name from the portion of the adhesive containing 1,2-epoxy, epoxide, or oxirane ring. This three-member ring consists of two carbon atoms joined to an oxygen atom. The highly strained geometry of this moiety with a strain energy of 114 kJ/mol accounts for its reactivity with many nucleophilic or electrophilic compounds.

Epoxy Ring

Typical epoxy resins used to formulate epoxy adhesives have at least two epoxy rings, usually at the ends of a relatively short-chain prepolymer. The epoxy groups then are reacted with other epoxy groups in a chain-growth polymerization or with another curative in a step-growth polymerization to produce a polymer network, which can be either thermoplastic or thermoset. The polymer linkages created by reaction of the epoxy ring are polar and provide adhesion to a variety of polar surfaces. With the proper backbone polymers and curing agents, cured epoxy adhesives can be very tough and resistant to chemical degradation. Bonded assemblies can have a high degree of durability and environmental resistance. Epoxy adhesives are widely used in the transportation industry where they can greatly reduce the amount of welding required.

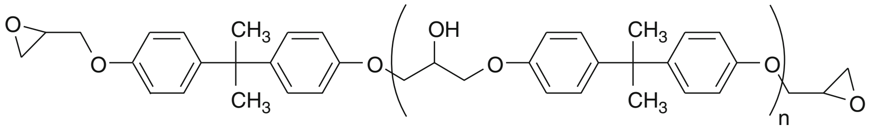
Commercial Epoxy Resins

Epichlorohydrin, or 1-chloro-2,3-epoxypropane, is the key raw material in the manufacture of the most widely used epoxy resins known as glycidyl ethers, amines, and esters. The most commercially important epoxy resins for structural application, for coatings, or for adhesives are the diglycidyl ether of bisphenol A (DGEBA, also referred to as bisphenol A diglycidyl ether, BADGE) and its higher homologues. Pure DGEBA crystallizes after a short time in storage, melting point 42 °C. Because of this, most liquid grades used in epoxy adhesives contain 10–15% higher oligomers, average $n \approx 0.15$–0.20 as well as some side products. Typical commercial resins have molecular weights of about 370 and epoxide equivalent weights in the range of about 180–190, and will have some small percentage of material that is less than difunctional. Various grades of liquid DGEBA resins are manufactured by several companies including Dow Chemical (D.E.R.™) [31], Momentive Specialty Chemicals (formerly, Hexion Specialty Chemicals, Resolution Performance Products, and Shell Chemical, EPON™) [32], Reichhold (Epotuf™) [33], Polystar (ChemRes™) [34], and Huntsman (Araldite™) [35].



Epichlorohydrin derived epoxy resins

The higher-molecular-weight epoxy resins can be produced commercially either through the direct reaction of bisphenol A, NaOH, and epichlorohydrin or by chain extension of the DGEBA with bisphenol A. For resins with $n > 2$, the number of secondary hydroxyls exceeds the number of oxirane groups. They are often used as the reactive site for coatings. The value of n can be as high as 90 [36]. The higher-weight polymers give greater toughness but with a greater tendency for swelling by solvents. Their high T_g's and higher melt viscosity make them less suitable for most adhesive applications.



Bisphenol A resin

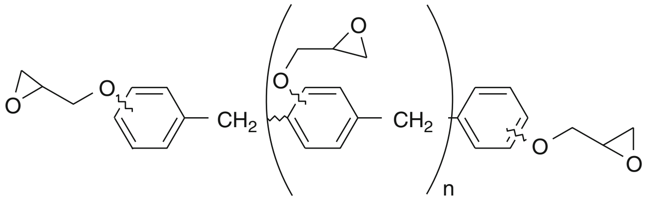
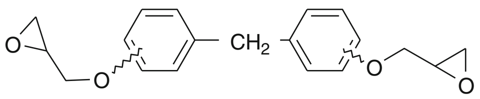
Another important class of aromatic epoxy resins is the epoxy novolac resins. Novolacs are polymers made by condensing phenol or cresol with formaldehyde in the presence of an acid catalyst. The result is a chain of phenol or cresol groups held together by methylene bridges in a mixture of *ortho* and *para* isomers. The hydroxyl groups then can be reacted with epichlorohydrin and dehydrohalogenated with base to produce an epoxy functional novolac. The simplest, containing only two rings, is the diglycidyl ether of bisphenol F. It is a liquid resin having an epoxy equivalent weight (EEW) of about 165.



Epoxy phenol novalac



Diglycidyl ether of bisphenol F

Unlike that of the higher molecular weight bisphenol A resins, the EEW of the epoxy novolac resins remains relatively constant with increasing molecular weight because all of the aromatic rings contain hydroxyl groups that can be epoxidized. Higher-molecular-weight epoxy novolac resins can produce adhesives with higher cross-link densities. The value of *n* for epoxy novolac resins used in adhesives is usually in the range of about 0.2–3.5.

Various aliphatic and aromatic monoglycidyl ethers are available that can be used as reactive diluents of many formulated epoxy structural adhesives. They are used to lower the viscosity of the composition without introducing low-molecular-weight unreactive species that might migrate out of the adhesive after it is cured. These compounds are made in much the same way that the polyfunctional epoxy resins are made. Some of the common reactive diluents are given in Table 14.3.

Butyl glycidyl ether has the lowest viscosity and gives the greatest viscosity reduction for the same weight concentration. However, it has a higher vapor pressure than either cresyl glycidyl ether or the higher alkyl glycidyl ethers, and is more likely to cause problems with skin sensitivity and toxicity. The cresyl glycidyl ether is particularly effective at reducing the tendency of liquid epoxy resins to crystallize on storage. For safety reasons the higher-molecular-weight,

[c]Huntsman

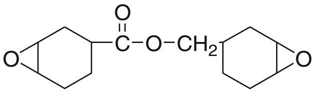
lower-vapor-pressure materials find more use even though they might be less efficient than those with a higher vapor pressure.

Aliphatic and other specialty aromatic polyfunctional glycidyl ethers are also widely used either for viscosity reduction or improving one or more particular properties. Table 14.4 lists examples of some of these.

The diglycidyl ether of 1,4-butanediol is a low-viscosity difunctional epoxy that is a somewhat less efficient diluent than the monoepoxides but does offer the advantage of having two reactive sites. Neopentylglycol diglycidyl ether and cyclohexane dimethanol diglycidyl ether impart greater rigidity than the 1,4-butanediol diglycidyl ether. Resorcinol diglycidyl ether is a very reactive material useful for reducing viscosity and gives higher cross-link densities than bisphenol A resins themselves.

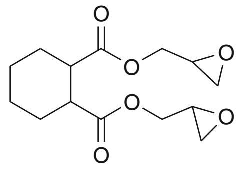
Epoxidized oils such as soybean oil or linseed oil, which are made by oxidizing the internal unsaturation in the fatty acid chain, find much use as plasticizers, particularly in vinyl resins. An internal epoxy ring is much less reactive than a terminal epoxy ring and usually does not take part in typical epoxy curing reactions under mild conditions. These materials can be used as plasticizers in epoxy adhesives but cannot really be considered reactive diluents.

The cycloaliphatic compounds such as 3′,4′-epoxycyclohexylmethyl 3,4-epoxycyclohexane carboxylate (TGY-6110 from Tyger Scientific, Inc. or Uvacure 1500 from Cytec) are made by direct epoxidation of the corresponding cyclohexene with peracetic acid. They produce high T_g polymers too brittle for use as the sole epoxy compound in adhesives. They are marketed towards the ultraviolet cationic cure coatings applications.



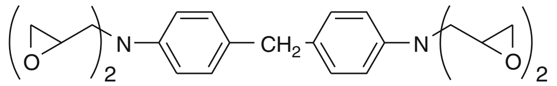
3’,4’ Epoxycyclohexylmethy
3,4-epoxycyclohexane carboxylate

Tougher polymers of somewhat lower T_g are obtained from glycidyl esters such as the diglycidyl ester of hexahydrophthalic acid (Epalloy* 5200, Emerald Performance Materials Co.). The glycidyl esters are prepared by reacting the corresponding cycloaliphatic carboxylic acid with epichlorohydrin and dehydrohalogenating with NaOH.



Diglycidyl ester of hexahydrophthalic acid

There is also a variety of other specialty epoxy resins used in limited quantity for applications demanding some specific performance property. Tri- and tetra-functional materials such as triglycidyl-*p*-aminophenol, triglycidyl isocyanurate, or *N*,*N*,*N*′,*N*′ tetraglycidyl-4,4′-diaminophenyl methane (tetraglycidyl methylene dianiline, Huntsman MY 720) have been used in adhesives requiring high heat resistance and good chemical resistance.



Tetrglycidyl methanedianiline

A typical sales specification for an epoxy resin used in adhesives will include the epoxy equivalent weight (EEW), also sometimes called the weight per epoxy (WPE), viscosity, and density at some specified temperature and the average functionality or number of epoxy groups per molecule. Sometimes a specification on total chlorine is included, which gives some indication of bound chlorine not removed by the NaOH in the dehydrohalogenation process. This bound chlorine is the result of epichlorohydrin side reactions during the epoxy synthesis. A high chlorine content indicates that there will be a large number of molecules of low functionality because each chlorine remaining represents one epoxy ring not formed in the dehydrohalogenation step.

Epoxy Cure Chemistry

Epoxy structural adhesives rely on the chemical reactions of the epoxy group with other reactants to pass from a liquid, wetting state to a solid, load-bearing state. There are a number of ways in which this is done, but all fall under one, or some combination, of three general schemes: step-growth polymerizations through reaction with curing agent, chain-growth polymerizations initiated by Lewis acids, or chain-growth polymerizations initiated by Lewis bases.[1] Often the cure times of the slower step-growth curing adhesives are shortened by including Lewis acid or Lewis base catalysts.

It would be tempting to consider the step-growth and chain-growth polymerization reactions as if they were independent and one could have the choice of either in any particular situation. The truth is that there are aspects of both types of polymerization in the cure of almost every epoxy structural adhesive. Such multiple-cure reactions often make it difficult to calculate the stoichiometry of an epoxy adhesive formulation. One type might predominate, depending on the formulation and cure conditions, but the effects of the other could not be completely discounted. The significance of this statement can be seen by looking at the two generalized reactions.

A typical step-growth reaction is one in which a single epoxy ring reacts with the active hydrogen of the curing agent. The general reaction is:

Model epoxy reaction

In order to form a high-molecular-weight polymer, both the epoxy-containing material and the curative must be at least difunctional. If both behave as difunctional materials, the resulting polymer is linear, and then it is necessary to drive the reaction nearly to completion to obtain a high-enough molecular weight to be useful. Neither of the reactants can contain a significant amount of monofunctional material. Monofunctional impurities or reactive diluents will act as chain terminators and limit the ultimate molecular weight obtainable.

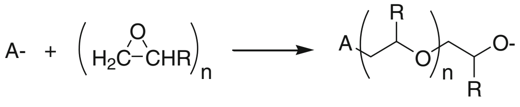
Chain-growth polymerizations occur through the reaction of epoxy rings with the active site on a growing chain and not with each other or with a second curing agent. After being initiated by a Lewis acid or a Lewis base, the growing chain will continue to consume epoxy groups and can reach a high molecular weight very rapidly. Because the epoxy groups are reacting with the growing chain, even a monofunctional epoxy compound can be polymerized. If A* is the initiator and M the monomer unit, the general reaction is:

$$A^* + nM \rightarrow A - M_{n-1}M^*$$

Chain-growth reaction

where the asterisk indicates the active site of the growing chain.

Lewis bases initiate anionic chain-growth polymerizations, the generalized reaction being that of a propagating alkoxide anion.

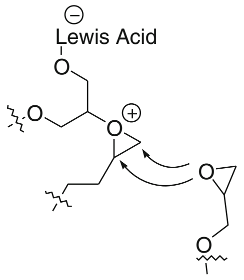


Anionic chain growth

---

[1] Lewis acids and Lewis bases are discussed in "Chain-Growth Polymerizations."

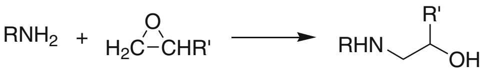
Lewis acids initiate cationic chain-growth polymerizations. There are several possible chain propagation reactions, and the mechanism of cationic chain growth is still open to some debate. However, the propagating species is likely to be an alkylated epoxy cation, or oxonium ion.



In chain-growth polymerizations, epoxy reactants containing more than one epoxy ring per molecule can form tightly cross-linked, three-dimensional networks, as each epoxy group acts as a difunctional reactant.

Step-Growth Polymerization. Only a relative few of the dozens of active hydrogen compounds that undergo reactions with the epoxy ring find widespread use in epoxy structural adhesives. The most common are amines, acid anhydrides, phenols, thiols, and carboxylic acids.

Primary and secondary amines react with epoxy groups to form secondary or tertiary amine linkages. The uncatalyzed reactions proceed at room temperature with the glycidyl ethers and glycidyl esters over many hours with handling strength of >50 psi being achieved in about 2–3 h. The resulting polymer depends on the structure of the reactants and the degree of cure, and thus a variety of final adhesive properties can be had. The reaction is susceptible to general acid catalysis, that is, by hydrogen bonding. Indeed, the reaction is autocatalytic as secondary alcohols are generated during the ring opening reaction. Better hydrogen-bond donors, such as phenols, are commonly used [37–39]. The reaction of the secondary amine with the epoxy group produces a tertiary amine, which can in turn be the Lewis base that initiates an anionic chain-growth polymerization of the remaining epoxy groups, depending on cure conditions.



Epoxy amine reaction

The simple linear aliphatic diamines, $H_2N(CH_2)_nNH_2$, can be used as curatives in adhesives. For small values of n, the short distance between the amine groups can hinder the reaction of the second amine and slow the cure process. Also, the resulting products tend to be brittle for values of n less than about 6.

More flexible, tougher products can be obtained by using liquid diamines or polyamines having more flexible backbones. For example, Jeffamine T-403 (Huntsman) is a low-viscosity liquid (70 mPa/s) having a molecular weight of about 440 and an amine hydrogen equivalent weight of about 81. It is a poly(propylene oxide) triamine made from the polyether initiated by trimethylol propane, and is promoted as a flexible cross-linker for epoxy systems. Their lower reactivity relative to other aliphatic amine may be a consideration in their usage.

Various polyamines also are useful as curatives for epoxy adhesives. An example of a simple polyamine is diethylenetriamine (DETA).

$$H_2NC_2H_4NHC_2H_4NH_2$$

Diethylenetriamine (DETA)

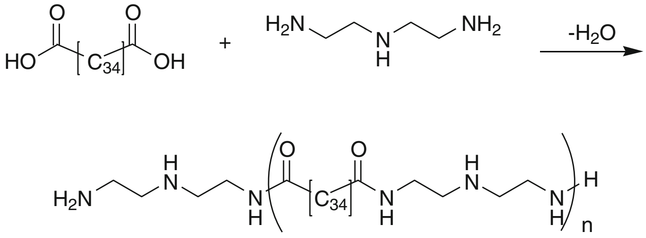
Its higher-weight homologues also are quite useful and are made by adding (CH_2CH_2NH) groups, leading to a homologous series of the form.

$$H_2N-(C_2H_4NH)_n-C_2H_4NH_2$$

where n is two, the material is triethylenetetraamine (TETA), and for $n = 3$ it is tetraethylenepentamine (TEPA), and so on. These three are the most important members of this series for adhesive applications, and are used more often than the simple aliphatic diamines. They often are used in combination with some other curative. Calculating stoichiometry can be difficult with these polyamines. All the active hydrogens might not be available because of steric factors introduced by the first reactions, or because once the first one or two active hydrogens are reacted with epoxy rings, the molecule is anchored into the chain and cannot readily diffuse to other epoxy groups. Therefore, a modest excess of polyfunctional amine is often added to the adhesive formulation. If the amine is used in too much excess, as with any other imbalanced stoichiometry, the final composition may have too many dangling chain ends, that is, be soft and cheesy, or even have unreacted amine that can leach from the product.

Other series of polyamines can be made too. For example, propyl groups can replace some or all of the ethyl groups, or the compound might be modified by reaction with an excess of a monoepoxide to give a hydroxy functional amine. Such modifications are made to improve adhesive properties and sometimes to lower toxicity of the curing agent or make it easier to handle.

Among the most important amine functional epoxy curing agents are the polyamidoamine resins. These are made from dimerized unsaturated fatty acids by reaction of the dimer acid with a polyamine such as DETA.



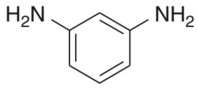
Polyamide Polyamine synthesis

These polyamidoamines are available from several suppliers worldwide (Cognis (Veramide®), Arizona Chemical (Uni-Rez®), Air Products (Ancamide™), and others) and are among the most common curatives in the general-purpose, "do-it-yourself" two-package epoxy adhesives. They have a distinctive odor somewhat like popcorn and are easily recognized in adhesive formulations. The polyamide backbone does contribute to the overall good mechanical properties of the polyamide amine cured adhesives.

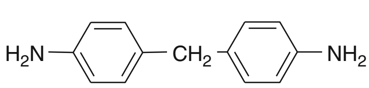
The polyamidoamines are very high-viscosity liquids, some having viscosities over 50,000 mPa/s. Typical amine equivalent weights are 100–150. The polyamidoamines react with bisphenol A epoxy resins at room temperature although the adhesives usually require several hours to reach sufficient molecular weight to carry a load. Cure times can be shortened to a few minutes at about 150 °C.

Epoxy adhesives cured with polyamidoamines are flexible, tough, durable adhesives useful on a wide variety of adherends. They probably have contributed heavily to making the words "epoxy" and "adhesive" equivalent for many people.

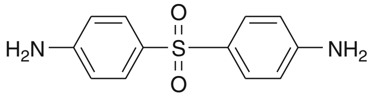
A variety of aromatic polyfunctional amines is also used in curing epoxy adhesives. They generally are slower to react than the aliphatic amines and require a heat cure to be practical. They do provide generally better high-temperature properties than the aliphatic amines. The most commonly used aromatic amine curatives are *m*-phenylenediamine (MPDA, DuPont), methylenedianiline (MDA, Bayer), and diaminodiphenyl sulfone (DDS, Aceto). Albemarle Corporation's Ethacure® 100 is claimed to be a more user-friendly curative that can be used in place of MPDA or MDA.



m-Phenylenediamine



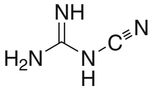
Methylenedianiline



Diaminodiphenyl sulfone

All of the curatives described so far are used to make two-package adhesives in which the curing agent is packaged separately from the epoxy resin. Once they are mixed, they have a limited pot life, usually less than a few hours.

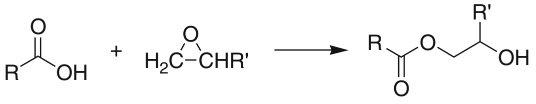
It is possible to make one-package epoxy adhesives that can have very long shelf lives at room temperature but cure rapidly when heated. One amine curative widely used to make single-package heat-cured epoxy adhesives is dicyandiamide (cyanoguanadine), commonly known as dicy.



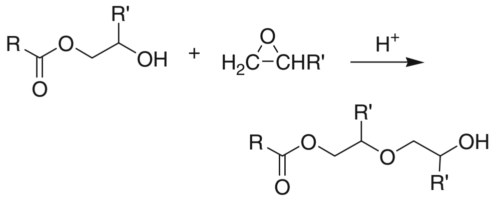
Dicyandiamide

It is made by dimerizing cyanamide in basic aqueous solution, and is a colorless solid melting at 208 °C. Dicyandiamide is soluble in polar solvents, but at room temperature is insoluble in bisphenol A epoxy resins. It can be made into a very fine powder and milled into epoxy resins to form stable dispersions. Because the dicy is insoluble in the epoxy, the only possible reaction sites are at the particle surfaces. Although some reaction certainly occurs over a short time, the adhesives easily can have a useful shelf life of 6 months. On heating to about 150 °C, the dicyandiamide becomes soluble in the epoxy resin, and the adhesive polymerizes rapidly. Cure can be accelerated by incorporation of tertiary aromatic amines or substituted ureas.

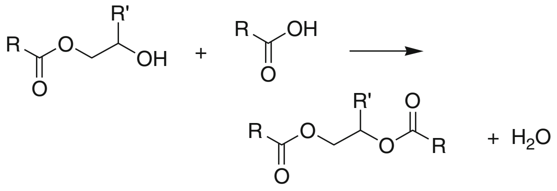
Carboxylic acids can be used to cure epoxy adhesives or otherwise modify epoxy adhesives. The reactions can be complex. If no hydroxyl groups are present initially, the first reaction will be that of the active hydrogen with the epoxy ring to form an ester. This will produce a hydroxyl group on the backbone and allows for competing reactions. The organic acid can catalyze the etherification reaction with the hydroxyl group or undergo a condensation esterification reaction directly with the hydroxyl group.



Epoxy acid reaction



Etherification reaction

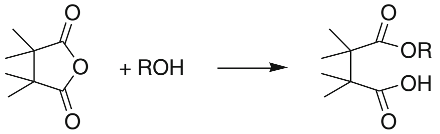


Condensation reaction

These reactions usually are slow at room temperature, and the adhesives must be cured with heat. Tertiary amines or amidines can be used to catalyze the reaction whereby the carboxylate anion is the nucleophile and the ammonium or amidinium ion act as hydrogen-bond donors. Dusek et al. have shown that transesterification only occurs after essentially complete consumption of the carboxylic acid in compositions initially having equivalent amounts of acid and epoxy groups [40, 41]. The transesterification leads to an equilibrium sol–gel composition.

Acid anhydrides also can be used to cure epoxy adhesives although they usually are used only where good service at high temperatures is required. Most of the anhydride-cured epoxy adhesives are cured at high temperature. Because most of the anhydrides are relatively small molecules, the products tend to be tightly cross-linked and can be somewhat brittle.

The first step in the anhydride cure in the absence of a tertiary amine catalyst is ring opening of the anhydride by active hydrogen, perhaps from water or hydroxyl groups already present on the epoxy resin. The resulting acid then reacts as a typical organic acid. In the presence of a tertiary amine, the initial formation of a zwitterionic acylammonium carboxylate salt is possible. The carboxylate anion then reacts with the epoxide as a nucleophile.



Anhydride ring opening by hydroxyl

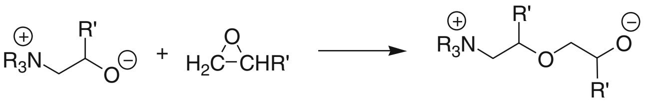
An interesting class of curatives, but with more limited usage, is that of thiols (also known as mercaptans). Thiols react with terminal epoxide groups quite rapidly when a tertiary amine catalyst is present even at temperatures below 0 °C. The reaction is similar to that found with hydroxyl groups and produces a polythioether product. These are the familiar "five-minute" epoxy adhesives and have the characteristic odor of thiols. The rapid cure can be controlled so as to give very good open, or handling, time by the incorporation of very minor amounts of weakly acidic components such as chlorophenol, paraben esters, or carboxylic acids [42]. One limitation on wider application is the commercial availability of suitable polythiols. CapCure™ (Cognis) or GPM™ (Gabriel Performance Products) trifunctional thiols are widely used, but give cured products with low T_g's unsuitable for many structural applications.

Chain-Growth Polymerizations. Chain-growth polymerizations are very important to many commercially successful epoxy structural adhesives. They can be extremely rapid and contribute to the fast cure times needed for high productivity in many manufacturing operations.

A Lewis base is a compound that contains an unshared pair of electrons capable of undergoing chemical reactions. Tertiary amines are examples of Lewis bases, and often are used in epoxy curing agents. In an anionic epoxy polymerization the propagating species is the alkoxide anion generated by the reaction of the Lewis base with an epoxy ring.

Formation of anionic chain initiator

This anion can continue to react with epoxy rings, adding them to the chain until the anion is destroyed in some side reaction.



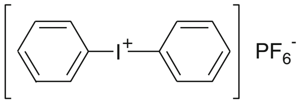
Anionic chain propagation

The product is a polyether, which can be tightly cross-linked when polyfunctional epoxides are used, as each epoxy ring can become part of a different chain.

Lewis acids, compounds with empty orbitals capable of accepting electron pairs, initiate cationic polymerization of epoxy resins. In this case the propagating species is a positive ion. The most commonly used Lewis acids are the boron trihalides, particularly BF_3 and BCl_3. They usually are used in the form of complexes because both are gases at room temperature and are so reactive with epoxy resins that they can be difficult to control. Lewis base complexes with the boron trihalides have much lower reactivity at room temperature but can react quickly on relatively mild heating, depending on the particular complex. Boron trifluoride readily forms complexes with ethers, alcohols, and amines, and several of these complexes are commercially available.

A boron trifluoride ethanolamine complex can be included in the curative portion of a two-package epoxy adhesive. When the two packages are mixed at the time of use, the mixture can have a pot life of hours at room temperature but polymerize in minutes at temperatures of 100–150 °C.

One very interesting new application of Lewis acids in curing epoxy adhesives has appeared within the last 30 years. The Lewis acid initiator for the cationic polymerization is formed by the heat or ultraviolet light-induced decomposition of Lewis acid:Lewis base salts. Several patents by Crivello and coworkers [43–47] describe compounds containing aromatic onium salts such as iodonium or sulfonium, in which the cation is stabilized by the aromatic rings. The field is covered in more detail in a recent review [48].



Diphenyl iodonium salt

The counterion generally is a large stable anion such a $[SbF_6]^-$, $[AsF_6]^-$, $[PF_6]^-$, or, $[BF_4]^-$. The more stable anions are less likely to terminate the growing cationic chains than are typical anions. The salts can be dissociated with heat to release the cation, which appears capable of initiating cationic polymerization of many materials in addition to epoxy rings. If the proper dye sensitizers are added, the cation can be liberated by ultraviolet light to initiate the polymerization. The cations persist for quite some time after the light source is removed. Acids of the form $H^+SbF_5X^-$, where X is a halogen, also have been used to catalyze epoxy reactions [49].

Evolution

The main advances being made on the chemical structure and manufacture of epoxy resins is being driven by microelectronic applications, which are not typically thought of as "structural." For these applications where failure is often induced by mismatched thermal expansion coefficient and fatigue on cycling in temperature, extremely low halide content is essential. The epichlorohydrin route to epoxy resins generally imparts too much residual chlorine content that is not easily removed by subsequent purification steps. A number of alternative routes using hydrogen peroxide have been proposed with various catalysts or coreactants. The patent by Khan et al. [50] proposes one improvement and the patent's background section provides a good review of related processes. The direct oxidation of olefins by molecular oxygen, while limited in scope, can be done to prepare monofunctional epoxies used as reactive diluents [51].

Formulations continue to investigate methods to improve toughness. Several studies of nano-fillers have recently appeared showing improvements with different curing agents and temperatures [52–55]. Nano-dispersed triblock copolymers were also obtained under certain cure temperatures that yielded toughening [56]. Hyperbranched resins terminated with epoxy groups show improvements over linear liquid rubber including lower viscosity at similar toughness [57–60].

Summary

Epoxy structural adhesives have proven to be versatile and reliable compositions. Their widespread use and acceptance is in part due to the varied chemistry of the epoxy ring and the skill of scientists and adhesive formulators in developing high-quality compositions that can produce reliable, reproducible structural joints even when applied by relatively unskilled users. New compositions and chemical reactions continue to be disclosed, and it is certain that the knowledge of epoxy chemistry will continue to grow. Many of the new discoveries will find their way into new epoxy structural adhesives.

Urethane Structural Adhesives

Introduction

The term "urethane adhesive" as it is generally used encompasses a lot of chemistry that is not necessarily urethane chemistry. "Urethane" is the common name for the compound ethyl carbamate. In common usage, "urethane adhesive" generally means an adhesive polymer derived from isocyanate chemistry and reactions of isocyanates with active hydrogen compounds. However, isocyanate reactions do not always lead to urethane linkages, and there are ways of arriving at urethane linkages without involving isocyanates. In this section the common approach is taken; that is, an adhesive that uses reactions of the isocyanate group to bring about polymerization in the bond line is considered a urethane adhesive.

The study of industrial applications of isocyanate chemistry and polymers derived from isocyanates received much attention in Europe, particularly Germany, in the 1930s and during World War II. Patents on aspects of urethane chemistry appeared as early as 1937 [61]. The effort going into understanding isocyanate chemistry and commercializing urethane products continues [62–66].

The isocyanate group consists of a linear arrangement of nitrogen, carbon, and oxygen atoms.

$$-N=C=O$$

Several possible electronic configurations can be drawn, most of which involve a positive charge on the central carbon atom. This partial positive charge on the carbon atom accounts for much of the reactivity of the isocyanate group with nucleophilic groups. Not only does the isocyanate group react with a variety of potential curing agents, but also it is very reactive with many of the adherend surfaces on which urethane adhesives are used.

The same high reactivity that makes the isocyanate a desirable reactant for structural adhesives also renders the unreacted isocyanate more acutely toxic than, for instance, epoxy adhesives. Only a few isocyanates are safe enough and easy enough to handle that they find widespread use in urethane structural adhesives.

Isocyanate Preparation

Organic isocyanates are the major building blocks of urethane structural adhesives. They can be synthesized by a variety of routes, but most of the commercially available isocyanate compounds used in adhesives are made by the reaction of a precursor primary amine or amine salt with phosgene, followed by dehydrohalogenation. The reaction with phosgene usually is carried out at a relatively low temperature of less than 60 °C. The temperature then is raised to 100–200 °C to remove the HCl.

$$\mathrm{RNH_2 + COCl_2} \longrightarrow$$

$$\mathrm{RNHCOCl + HCl} \xrightarrow{\text{heat}} \mathrm{RNCO + 2\ HCl}$$

Isocyanate synthesis by phosgenation

There are many possible side reactions, and the yield depends on the reaction conditions, which usually are specific to the starting materials and desired product. Much work has gone into determining the reaction conditions for manufacturing as clean a product as possible.

The amount of isocyanate in a commercial isocyanate or isocyanate-containing formulation usually will be specified as weight percent isocyanate (as NCO) or as an amine equivalent weight, which is the weight of material containing sufficient isocyanate to react with 1 mol of amine hydrogen.

Isocyanate Reactions

Organic isocyanates can undergo a large number of reactions with active hydrogen compounds. One test commonly used to determine the presence of active hydrogen atoms and the number of active hydrogens per molecule is the Tschugaeff–Zerewitinoff analysis or, more commonly, the Zerewitinoff test. An excess of a Grignard reagent, methyl magnesium iodide, is added to the sample to be tested, and the amount of methane evolved in measured.

$$\mathrm{CH_3MgI + RH \rightarrow CH_4 + RMgI}$$

Zerewitinoff reaction

Urethane adhesives take their name from the product of the most common step-growth polymerization reaction used to generate the adhesive polymers. Isocyanates react with hydroxyl groups to create urethane (or carbamate) linkages:

$$\mathrm{R{-}NCO + R'OH} \longrightarrow \mathrm{R{-}\overset{H}{N}{-}\overset{O}{\overset{\|}{C}}{-}OR'}$$

Urethane formation

If both the isocyanate and the hydroxyl-containing material are difunctional, if the mixture is made up to have one isocyanate per hydroxyl, if there are no side reactions, and if the reaction can be driven to completion, a single linear thermoplastic polymer should result. If one or more of the reactants is more than difunctional, it is possible to create an infinite three-dimensional network.

In general, primary hydroxyl groups are faster to react than secondary hydroxyls, which are in turn faster than tertiary hydroxyls, absent catalysts. When reacted with hydroxyl-containing compounds, aliphatic isocyanates tend to be more sluggish than their aromatic counterparts. Urethane linkages made with tertiary hydroxyls tend to be less stable and at high temperature can dissociate into an olefin and an amine with loss of carbon dioxide. Metal compounds, particularly tin compounds such as dibutyl tin dilaurate, and various amines catalyze the isocyanate–hydroxyl reaction.

Isocyanates will react with amines to produce substituted ureas, primary amines being faster than secondary amines.

$$\mathrm{R{-}NCO + R'NH_2} \longrightarrow \mathrm{R{-}\overset{H}{N}{-}\overset{O}{\overset{\|}{C}}{-}NHR'}$$

Urea formation from 1° amine

$$\mathrm{R{-}NCO + R'R''NH} \longrightarrow \mathrm{R{-}\overset{H}{N}{-}\overset{O}{\overset{\|}{C}}{-}NR'R''}$$

Urea formation from 2° amine

The ureas are more rigid linkages than the urethane structure, but they also are generally more resistant to heat and chemical degradation. The reaction of isocyanates with amines is generally so rapid that it is nearly impossible to control the reaction well enough to make it useful in formulating urethane adhesives. What usually happens is that the reaction takes place faster than it is possible to mix the adhesive. If it is necessary to include urea linkages in the final production, it can be done by making a prepolymer that has the urea linkages in it already or by taking advantage of the slower reaction of isocyanates with water.

Small (much less than stoichiometric) amounts of diamines sometimes are added to the hydroxyl portion of the adhesive to provide a rapid but limited molecular weight increase as soon as the components are mixed [67, 68]. In this way a two-package adhesive can be made that will flow easily before mixing but will not readily flow after mixing. Such adhesives can be applied to vertical surfaces or overhead, and will remain in place until the bonds are closed and cured.

The reactions of amines and isocyanates are important in adhesives because of the possible reaction of isocyanates with water. Because isocyanates react readily with water, raw materials used in formulating adhesives must be dry, and the compositions must be protected from moisture, including atmospheric humidity, during storage. The first reaction with water is the formation of a carbamic acid, which rapidly loses carbon dioxide to form a primary amine.

$$R{-}NCO + H_2O \longrightarrow R{-}NH{-}C(=O){-}OH \longrightarrow RNH_2 + CO_2$$

Water NCO reaction

The primary amine then can react with another isocyanate to produce a urea. Thus 1 mol of water consumes at least two equivalents of isocyanate, builds molecular weight, and liberates carbon dioxide in the process. If this happens in a closed container such as a drum of adhesive, the result can be explosive, particularly as the reaction mass rises in temperature because of the exothermic reactions. On the other hand, these reactions can be useful in a bond line because under the proper conditions desirable urea linkages can be introduced into the curing adhesive through the reactions of small amounts of water normally present on the adherend surfaces.

The hydrogen atom attached to the nitrogen atom of the urethane group is active enough that it can react with another isocyanate group to produce an allophanate. This is an additional cross-linking mechanism for urethane polymers and can disturb the stoichiometry of the system by consuming an additional isocyanate group for each allophanate formed. Elevated temperatures usually are needed to produce allophanates in uncatalyzed systems; allophanation reactions can be catalyzed by tertiary amines.

$$R''NCO + R{-}NH{-}C(=O){-}OR' \longrightarrow R''{-}NH{-}C(=O){-}N(R){-}C(=O){-}OR'$$

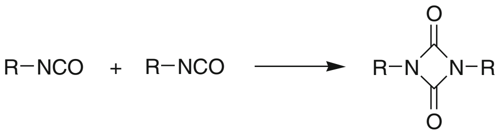
Allophanate formation

In a similar fashion, a urea hydrogen atom can react with an additional isocyanate group to produce a biuret.

$$R''NCO + R{-}NH{-}C(=O){-}NH{-}R' \longrightarrow R''{-}NH{-}C(=O){-}N(R){-}C(=O){-}NH{-}R'$$

Biuret formation

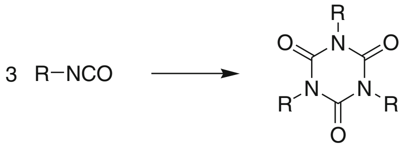
Isocyanate groups also will react with themselves to form a variety of compounds. Two isocyanate groups can react to form a dimer or uretidinedione.



Isocyanate dimerization

These dimers can be dissociated to regenerate the original isocyanates with heat, and some of the dimers, such as the dimer of toluene diisocyanate (TDI), have become commercially important.

Three isocyanate groups can react to form a trimer or substituted isocyanurate ring. Phosphines or bases such as sodium acetate or sodium formate can catalyze this reaction. The isocyanurate ring is thermally stable, has good chemical resistance, and can enhance the resistance of a urethane adhesive to aggressive environments.



Isocyanates also can react with each other to produce carbodiimides with the loss of carbon dioxide. This reaction requires high temperatures unless catalyzed by specific phosphorus compounds. Formation of carbodiimides normally is not an important cross-linking mechanism in polyurethane adhesives. However, carbodiimides are sold by Angus Chemicals, a division of Dow Chemical (ZOLDINE™ XL-29SE), Nisshinbo Industries (Carbodilite™), and Picassain Polymers, a division of Stahl USA (XL-701). They have been recommended as water scavengers, cross-linkers, and stabilizers for carboxyl functional polyurethanes. The carbodiimide can react with water to give a urea, which still can react with additional isocyanate to produce a biuret.

$$R{-}NCO + R{-}NCO \xrightarrow{\text{catalyst}} R{-}N{=}C{=}N{-}R + CO_2$$

Carbodiimide formation

$$H_2O + R{-}N{=}C{=}N{-}R \longrightarrow R{-}NH{-}C(=O){-}NH{-}R$$

Carbodiimide reaction with water

Carbodiimides can react with additional isocyanate groups to form uretone imines, which sometimes are used to modify polyisocyanates used in urethane structural adhesives.

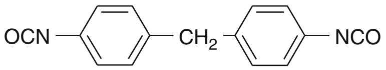
Acrylic acid

Important Isocyanates

Dozens of isocyanate functional compounds have been synthesized, but only a few find much use in urethane structural adhesives. The choices are largely dictated by a combination of performance, price, and safety considerations. Most of the materials used in adhesives are derived from the aromatic isocyanates, toluene diisocyanate (TDI) and 4,4′-diphenylmethane diisocyanate (MDI).

2,4-Toluene diisocyanate 2,6-Toluene diisocyanate

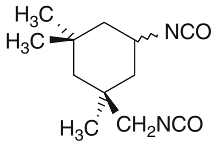
(TDI)



4,4’-Diphenylmethane diisocyanate

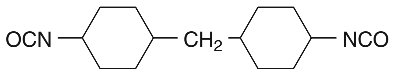
4,4-Methylene bis(phenyl isocyanate) (MDI)

Where color and light stability of the adhesive are important, and cure speed or cost is less important, aliphatic isocyanates are frequently used. Adhesives derived from isophorone diisocyanate (IPDI), hexamethylene diisocyanate (HDI), or 4,4′-dicyclohexylmethane diisocyanate (H$_{12}$MDI) are available.



Isophorone diisocyanate (IPDI)

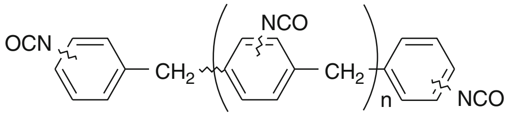
Hexamethylene diisocyanate (HDI)



4,4-Dicyclohexylmethane diisocyanate (H12MDI)

The common commercial TDI is an 80/20 mixture of the 2,4- and 2,6-isomers. The pure 2,6-isomer is available also and is sometimes called TDS. To make TDI, toluene first is nitrated to produce a mixture of the 2,4- and 2,6-dinitro isomers. The dinitrate is reduced to the diamine and reacted with phosgene, which is followed by dehydrohalogenation to give the diisocyanate. Because of its relatively high vapor pressure and toxicity, adhesives rarely contain TDI monomer. Typically, excess TDI is reacted with another material such as trimethylolpropane or a polyester diol or polyether diol to produce a higher-molecular-weight isocyanate functional compound, which is safer and easier to handle than the free TDI. Still, there will be some free TDI present in the adduct, and much work has gone into finding synthesis schemes to minimize the free TDI in prepolymers and adducts [69, 70].

MDI can be considered the first member of a series of polyisocyanates of the general form:

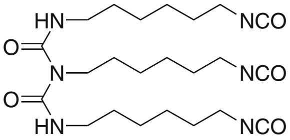


Aromatic polyisocyanates

MDI is the most important member of the series although materials with *n* of 1 or more also are available. The precurser amine is made by condensation of aniline hydrochloride with formaldehyde, followed by reaction with phosgene and dehydrohalogenation. When the aniline is present in excess, the diamine and consequently the diisocyanate are produced in greatest yield, with nearly all of this being the 4,4′-isomer.

MDI is a solid at room temperature with a melting point of about 38°C, which usually is stored and shipped in the molten state for convenience. However, on standing in the liquid state, the MDI slowly dimerizes, and the liquid MDI becomes saturated with dimer at about 1% dimer by weight. The dimer then begins to precipitate. The isocyanate content of the remaining liquid will then remain constant.

HDI can be used as an aliphatic cross-linker in urethane adhesives but presents significant health risks because of its toxicity and high vapor pressure. HDI is more commonly used in the form of its biuret, which is much safer and easier to handle than HDI.



Biuret of hexamethylene diisocyanate

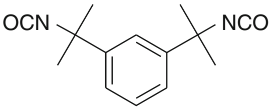
IPDI is another low-viscosity aliphatic diisocyanate that is useful in formulating light-stable polyurethane adhesives, and is somewhat lower in cost than HDI. IPDI has a low vapor pressure at room temperature but, like most low-weight isocyanates, still can present a health hazard. Higher-molecular-weight adducts of IPDI, such as its isocyanurate trimer, are available. The trimer is a high-melting solid (100–115 °C), and one loses the advantage of the low-viscosity liquid in using it but gains in safety and easy handling.

In IPDI, the two isocyanate groups are not equivalent. One is attached directly to the aliphatic ring, and a methylene group separates the other from the ring. Because their environments are different, the reactivity of the two groups are different; and the reactivity can depend on the choice of catalyst. For instance, Ono et al. [71] have shown that when IPDI is reacted with a primary hydroxyl group, the primary NCO is most reactive when the catalyst is 1,4-diazabicyclo [2.2.2]octane. The secondary NCO attached to the ring is the most reactive when dibutyl tin dilaurate is the catalyst.

The saturated analogue of MDI, H_{12}MDI, has found limited use as an aliphatic isocyanate in adhesives. This material is known by a variety of names including Desmodur W™ (Bayer), hydrogenated MDI (or HMDI or H_{12}MDI), reduced MDI (RMDI), and saturated MDI (SMDI). It is a low-viscosity liquid with a fairly high vapor pressure, so it too must be handled with care. In adhesive compositions, the diisocyanate usually is used to make an isocyanate functional prepolymer by reacting excess diisocyanate with a hydroxyl or amine functional polymer such as a polyester diol.

Because it contains two saturated six-member rings, H_{12}MDI can exist in three isomeric forms, in which the orientations of the NCO groups with respect to the rings and each other are different. The *trans–trans* isomer is a solid at room temperature so that over time this isomer can precipitate from the remaining liquid isomers. Samples of H_{12}MDI that have been stored at cool temperatures for a while often have a solid layer of *trans–trans* precipitate in the bottom.

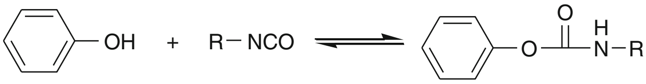
An offering by Cytec Specialty Chemicals, the *meta* isomer of tetramethyl xylene diisocyanate (TMXDI), is interesting because it contains an aromatic ring, but the NCO groups themselves are aliphatic isocyanates and have reaction characteristics typical of aliphatic diisocyanates. It reacts even more sluggishly than the more standard aliphatic isocyanates because of steric interactions, making the reactions easier to control. Compounds such as dimethyl tin dilaurate, lead octoate, or tetrabutyl diacetyl distannoxane have been shown to be effective catalysts for the isocyanate–hydroxyl reaction. The manufacturer claims that it is less toxic than many other isocyanates.



m-TMXDI

Blocked Isocyanates

Blocked isocyanates are compounds formed by the reaction of an organic isocyanate with an active hydrogen compound where the reaction is reversible with moderate heat. The blocked isocyanate can be used in formulating adhesives or other reactive compositions even in the presence of materials that normally would react rapidly with the isocyanate. Phenol is one example of a blocking agent used with isocyanates. There are many other blocking agents in use, including lactams, oximes, and malonates. Even isocyanate dimers such as TDI dimer could be considered blocked isocyanates because they will dissociate with heat to regenerate the isocyanates.



Phenol blocking reaction

There are two major limiting factors to the use of blocked isocyanates in urethane structural adhesives. First, the adherends must be sufficiently heat resistant to withstand the temperatures needed to cause rapid dissociation of the blocked isocyanate. Second, the blocking agent is present to continue competition with the intended curing agent for reaction with the isocyanate. After the adhesive is cured, the blocking agent remains trapped in the bond line and could contribute to poor mechanical properties in the bond, poor resistance to harsh environments, or exude or extract into the environment. Applications on porous substrate, such as wood, or where de-blocking occurs before closure of the bond, such as laminating, are compatible with some of these limitations.

Evolution

Urethane adhesives have also received much attention. New processes are being developed for the phosgene-free

Fig. 14.4 Assembly of an aircraft headliner using an Araldite™ two-part urethane adhesive (Courtesy of Huntsman Advanced Materials)

production of isocyanate-containing raw materials from formamides through reaction with organic carbonates [72, 73]. Methods of stabilizing isocyanate compositions continue to be developed [74, 75]. Formulators continue to produce new mixtures and intermediates from standard materials (Fig. 14.4) [76–78]. New blocking agents for isocyanates are being developed to facilitate the formulation of stable urethane adhesives compositions rapidly curable when heated [79, 80].

Summary

Urethane structural adhesives have proved quite successful in bonding applications that take advantage of their toughness, particularly when the adhesive must function at low temperatures. The reactivity of the isocyanate group may require some extra care in handling and storing the adhesives but the same reactivity provides many opportunities for the polymer chemist and adhesive formulator. The principal reaction used in curing urethane structural adhesives is the reaction of the isocyanate group with primary and secondary hydroxyl groups. Both the isocyanate groups and the hydroxyl groups can be carried on a wide variety of low-molecular-weight oligomers such as polyesters, polyethers, polybutadienes, polyurethanes, and polymer blends so that many of the desired properties of the final adhesive can be built into the polymer before the adhesive is cured.

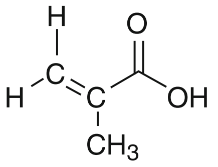
Acrylic Structural Adhesives

Introduction

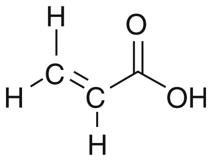
Acrylic structural adhesives are more recently developed products compared to epoxy or urethane adhesives. They first appeared in Europe in the mid-1960s and were commercialized in the United States a few years later [81]. They share many similarities to anaerobic adhesives that preceded them by a few years.[2] The first offerings were rather brittle products of use in limited applications where toughness and flexibility were not critical. However, because these new acrylic structural adhesives polymerized in the bond line through a free-radical chain-growth polymerization mechanism, they did have the big advantage of curing rapidly at room temperature. This polymerization mechanism offered a variety of potential advantages in manufacturing. Bonded structures could be assembled relatively rapidly without the need of curing ovens. Assemblies did not need to be stored for long periods while room-temperature cures were completed. The adhesives could be made at very low viscosities for easy handling and dispensing. In the past 40 years there has been much creative work done with the chemistry of acrylic adhesives so that now they are available in many forms with a wide range of properties.

Acrylic Monomers

All acrylic structural adhesives consist basically of a solution or a mixture of polymers and unsaturated, low-molecular-weight, free-radical-polymerizable monomers with other materials added as needed for the particular intended use. In addition, some precursor of the polymerization initiator will be present. The most common monomers used are methacrylic acid (2-methyl propenoic acid) and its esters or, less commonly, acrylic acid (propenoic acid) and its esters.



Methacrylic acid



Acrylic acid

Several processes for making acrylic acid have been developed [82]. Since the 1980s manufacturers have almost exclusively used a two-step, vapor-phase oxidation of propylene that proceeds through acrolein. The acrylic acid then

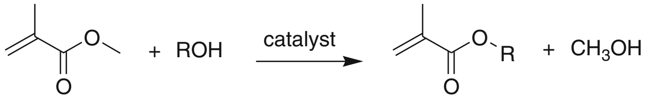
---

[2] See the discussion in [6], pp. 217.

can be esterified with the appropriate alcohols. If current shifts in petroleum prices continue, one of the alternative routes to acrylic acid may become economically preferable.

Unlike acrylic acid, methacrylic acid continues to be produced by a variety of processes including oxidation of ethylene, propylene, or isobutylene [83]. The older commercial process for making methacrylic acid based on propylene proceeded through acetone cyanohydrin. This process is steadily declining in usage because of high waste costs. Rapid development of specialty catalysts in the 1980s by several Japanese companies has moved isobutylene-based production to the forefront. Also, for companies with internal synthesis gas (syngas) production, routes based on ethylene are economically viable.

Direct esterification of methacrylic acid with alcohols using sulfuric acid or other catalysts can be used to prepare methyl methacrylate (MMA) and other esters. Commercial routes for the direct preparation of MMA and some lower alkyl esters also exist. In the 1990s, researchers at Shell developed a direct route to MMA from propyne (methylacetylene), carbon monoxide, and methanol using a Pd(II) catalyst. The limited availability of propyne may slow the expansion of this highly efficient route to high purity MMA. Transesterification of MMA is often the preferred route for the preparation of other esters.



Transesterification of MMA to other methacrylate esters

The choice of monomers that are useful in acrylic structural adhesives is rather limited. Cost always is an important factor, and because acrylic structural adhesives consume only a very small portion of the world's output of acrylic monomer, the formulator usually must rely on acrylic monomers that are made in large quantity for other uses. In addition, the monomers must polymerize readily at room temperature. If a mixture of monomers is to be used, the monomers must copolymerize easily. Finally, the monomers must be good solvents or dispersants for the polymers used in formulating the adhesive. The acrylic monomers finding most use in acrylic structural adhesives are methyl methacrylate and tetrahydrofurfuryl methacrylate. The later, albeit more expensive, has a much higher flashpoint and a generally perceived low odor, yet maintains good solvency.

Curing

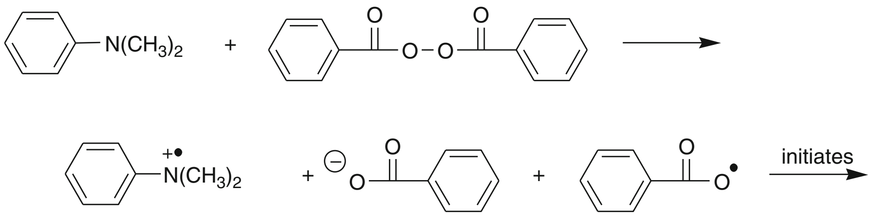
The curing reaction of an acrylic structural adhesive is the chain-growth polymerization of the acrylic monomer. The monomer units are not reactive with each other but react only with a growing chain having an active site on one end. In order to begin a chain, one must generate an initiator in the monomer solution. In the case of acrylic structural adhesives, this initiator nearly always is a free radical, a species having an unpaired, reactive electron. After chains have been initiated, there are three general types of reaction that can occur: propagation, chain transfer, and chain termination. If "*" represents the active site, "A*" represents the initiator, and M is a monomer unit, then the four reaction types are:

Initiation	$A^* + M \rightarrow AM^*$
Propagation	$AM^* + nM \rightarrow AMnM^*$
Chain transfer	$AMnM^* + M \rightarrow AMnM + M^*$
Termination	$RM^* + R'M^* \rightarrow$ RMMR' (combination)
	$RM^* + R'M^* \rightarrow RMC = CH_2 + RMCHCH_3$ (disproportionation)

In addition, a growing chain might undergo chain transfer or be terminated by reaction with a variety of unknown impurities invariably present in any mixture.

The initiating radical is usually created in a redox reaction. Common reactions involve the reduction of an organic peroxide by some reducing agent such as an amine or an ion capable of undergoing a one-electron transfer reaction. Anaerobic adhesives generally rely on metal ions derived from the surface to be bonded as part of the redox system. Acrylic adhesives generally embody the reducing agent in the monomer mixture and place the oxidizer in a monomer free package.

One example of an efficient free-radical initiator generating reaction is the reduction of diacyl peroxides such as benzoyl peroxide (BPO) by tertiary aromatic amines such as *N*,*N*-dimethyl aniline (DMA).



Benzoyl peroxide reaction with N,N-dimethyl aniline

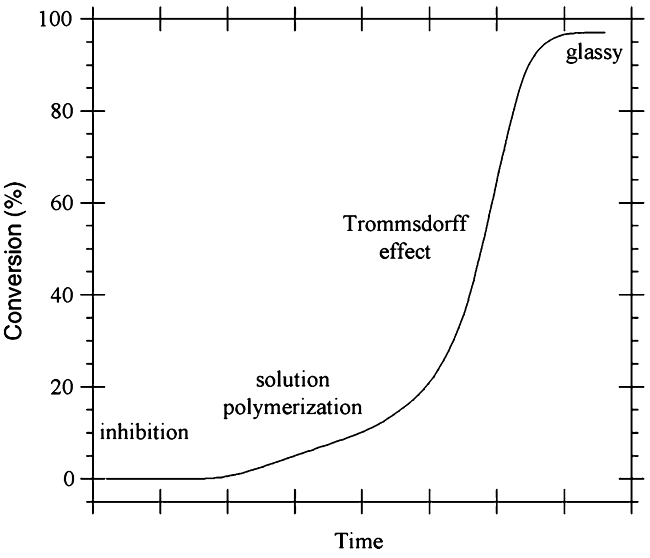


Fig. 14.5 Four stages of free-radical polymerization in bulk

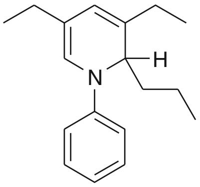
The condensation products of amines and aldehydes have often been used as the reductant. The most common commercial example is that arising from aniline and butyraldehyde for which the active ingredient has been identified as 3,5-diethyl-1,2-dihydro-1-phenyl-2-propylpyridine (DHP). A high purity grade, >85% active, has become available in recent years (Vertellus Specialties Inc., formerly Reilly Industries, Reilly PDHP™ Adhesive Accelerator; R. T. Vanderbilt Company, Vanax™ 808 HP).



DHP

The free-radical polymerization of methacrylate adhesives may show four stages, Fig. 14.5: inhibition, solution polymerization, “gel” polymerization, and glassy polymerization. All commercial monomers have inhibitors added to help prevent premature polymerization during storage. During the inhibition stage, the redox system generates radicals and some minor addition to monomer may occur, but the inhibitors and any dissolved oxygen, a very potent inhibitor of free-radical polymerization, will prevent the formation of polymer and any significant consumption of monomer. Once the oxygen and inhibitors are consumed, very high-molecular-weight polymer will form, $0.1\text{–}1 \times 10^6$, if no efficient chain transfer agents are present. As the reaction progresses, the polymer–monomer solution becomes increasingly viscous and the termination process is retarded. At about 25–30% monomer consumption, the polymer entanglements (gel) become so profound that a rapid rise in observed rate of polymerization is noted as the rate of termination reactions plummets. This rapid acceleration is referred to as the Trommsdorff effect. Because the diffusion of monomer molecules is not appreciably retarded by the “gel,” there is no significant reduction in the propagation rate. Eventually, the polymer–monomer solution will approach the glassy state and even small molecules such as monomer and the redox components cannot move easily. For all practical purposes, the reaction comes to a halt soon thereafter as the smaller, more rapidly diffusing oxygen molecules reenter the bondline and quench the remaining polymer radicals.

Another consequence of oxygen inhibition of free-radical reactions is that the adhesive surface exposed to air will contain a higher concentration of lower-molecular-weight species than the bulk of the adhesive. This can result in the surface being soft, tacky, or even remaining fluid.

Formulation

Although the free-radical chain-growth polymerization brings processing advantages, it also brings limitations. The product of the polymerization of the monofunctional acrylic monomers is a linear thermoplastic polymer. In the case of a copolymer that is largely MMA, the glass transition temperature of the polymer will be well above room temperature if the polymer has been driven to a high-enough molecular weight. The resulting adhesive is brittle, and although its shear strength might be quite high, its ability to withstand peeling forces or impacts will be low. One could use monomer mixtures yielding copolymers having lower glass transition temperatures and expect that the adhesive might be somewhat tougher. However, this parameter is difficult to control because when curing the acrylic adhesive in the bond line, one really is doing a bulk polymerization under uncontrolled conditions and trying to produce a specific polymer with a specific set of material and performance properties. The approach taken by most adhesive manufacturers or formulators is to use “prepolymers,” high-molecular-weight oligomers that can be made under controlled conditions and then dissolved or dispersed in the acrylic monomer. By forming key elements of the polymer chains under controlled conditions, many of the desired properties of the final product can be built into the adhesive when it is formulated and before the material is cured. The prepolymer can cause the solution polymerization stage of polymerization to be skipped, thereby decreasing the cure time substantially.

The simplest approach to improving toughness is to dissolve or disperse a nonreactive rubbery polymer in the monomer mixture that is to be polymerized. Examples of such materials are nitrile rubbers, polyethers, and acrylic rubbers. The choice will depend on cost, desired properties, and the solubility of the polymer in the monomer. As the monomer polymerizes, it will lose its solvating ability for the dissolved polymer. Eventually, when enough of the monomer has been consumed, it can no longer hold the polymer in solution, and the polymer precipitates. The polymer then can segregate as a totally separate phase or as distinct domains heterogeneously dispersed throughout the acrylic polymer matrix, or it can be homogeneously trapped in the acrylic matrix, depending on the rates of reaction, the compatibility with the acrylic polymer, and the relative mobility of the dissolved polymer.

One way of influencing the way in which the added oligomer is distributed in the final cured produce is to provide reactive sites on the oligomer so that it can be incorporated into the acrylic matrix as it forms. For instance, if the added oligomer contains terminal, active, acrylic, or methacrylic unsaturation, it can be easily incorporated into the growing acrylic polymer chains as the adhesive cures. Then it is unable to precipitate as a separate phase and must remain more or less uniformly distributed throughout the matrix. On the other hand, incompatible polymers can be added to deliberately encourage the formation of reinforcing domains. If the oligomer has two or more functional groups capable of participating in the polymerization, there is at least the possibility of forming cross-links in the polyacrylate matrix. Particular advantage has been claimed for combinations of reactive and nonreactive rubbers with attention to their molecular weights [84].

A technology developed at du Pont [85] combines the use of reactive sites on the oligomers with the initiation reaction. The resulting family of acrylic structural adhesives has become popularly known as "second generation acrylics." They consist essentially of solutions of chlorosulfonated polyethylene (formerly made by du Pont as Hypalon, but discontinued in 2010; available from Tosoh Chemical as Toso-CSM™) in acrylic or methacrylic monomers. The chlorosulfonyl groups present on the polymer will react with amine aldehyde condensation products, DHP above, to generate free-radical initiators, at least some of which are claimed to be on the oligomer backbone. The speculation is that the adhesive polymer chains then grow by graft polymerization from various sites on the rubber oligomer. Peroxides and metal ions can be added to accelerate the initiation and polymerization. One of the significant advantages of this type of acrylic structural adhesive is the ability to bond oily or dirty metals with only minimal surface preparation, although some surface preparation usually is necessary to improve bond durability (Fig. 14.6).

Other acrylic structural adhesives can be used on poorly prepared metal surfaces. Inclusion of reactive monomers having phosphate groups can lead to significant improvements in primary bonds to many unprepared metals [86]. Kowa American supplies one such monomer, 2-hydroxyethylmethacrylate acid phosphate.

Fig. 14.6 Applying Fusor™ adhesive for repair of a steel automobile hood (Courtesy of Lord Corporation)

Many other modifications to acrylic adhesives are useful. Improved heat resistance of acrylic adhesives can be achieved by incorporating small amounts of epoxy resin into the formulations [87], or by including cyanate esters and organometallic compounds to provide an additional cross-linking mechanism [88]. Lower sensitivity of oxygen can be achieved by incorporation of a wax that migrates to the monomer–air interface providing a diffusion barrier or by using more efficient initiators [86, 89]. Innovations in acrylic adhesive have led to new initiator reactions that provide rapid initiation and cure while at the same time allowing for improved shelf life [90]. Acrylic adhesives cured by ultraviolet light have been made from mixtures of acrylic functional urethane prepolymers mixed with free radically polymerizable monomers and photo initiators [91–93]. Refined formulations with significantly improved peel strength have recently been introduced [94].

Organoborane initiators for acrylic adhesives have received much attention arising from the observation that they give exceptional adhesion to low energy surfaces, such as polyethylene and polypropylene without surface preparation [95]. Earlier use of tributylborane–amine complexes in MMA and activated with isocyanates, acid chlorides, or sulfonyl chlorides for a dental resin was reported in 1969 [96]. In the mid-1990s, 3M became active in the area of amine-blocked organoboranes with a focus on polyolefin bonding [97]. A commercial product appeared in the mid-1990s that was later twice improved, Scotch-Weld™ DP-8010 [98]. By 2005, more than 30 patents had since appeared covering particular blocking groups, de-blocking agents, and additives to improve adhesive performance. Later Dow Chemical made a push into this field with more than 16 patents on adhesive composition as well as others in specific automotive applications [99]. It has been commercialized under the LESA trademark [100]. The amine-blocked organoborane adhesives generally require refrigeration for good shelf live. A family of more robust, internally coordinated organoboranes has been disclosed [101, 102].

Summary

Acrylic structural adhesives have the advantage of easy handling and processing and rapid cure at room temperature. The ability of some compositions to adhere to unprepared metal surfaces or low surface energy substrates can allow substantial cost savings in manufacturing processes. The brittleness of the polymers made from the monomers often can be overcome by formulating to include tough, reactive oligomers in the liquid adhesive. The variety of possible initiators and mechanisms for generating them has brought many innovative compositions to market.

Hybrid Adhesives

Adhesives usually are classified as epoxy, urethane, or acrylic, based upon the chemistry used to bring about the polymerization of the liquid adhesive. However, the distinction among the various types of adhesives is not always clear, and many hybrid adhesives have been developed and marketed. The objective usually is to take advantage of the desirable mechanical properties or chemical resistance of one polymer while retaining the processing attributes of a different cure system [103].

It is common in acrylic structural adhesives to use oligomers that have a desirable backbone and are terminated with free-radical-polymerizable bonds. A variety of isocyanate-terminated polyurethanes can be adapted for use in acrylic structural adhesives by reacting the terminal isocyanates with a hydroxy functional acrylic monomer such as 2-hydroxyethyl methacrylate [86, 104, 105]. A recent acrylic/siloxane hybrid adhesive using a trialkylborane initiator has recently been described [106].

Sometimes the system is formulated so that multiple-cure mechanisms are possible and can occur sequentially or simultaneously. Compositions that rely on both epoxy and urethane chemistry are examples [68, 107, 108]. These are compositions containing the DGEBA, an isocyanate or isocyanate-terminated prepolymer, amines or other reactants for either epoxy or isocyanates, and catalysts.

Some of the more interesting and innovative work has occurred in areas combining aspects of more than one chemistry type. For instance, moisture-curable thermoplastic adhesives have received much attention. Hot-melt adhesives have been developed that contain active, moisture-curable isocyanate groups. The compositions provide rapid processing on assembly lines because a reasonable bond is formed as soon as the thermoplastic adhesive cools from the melt. However, bond strength and performance improve with time as the composition is slowly cross-linked to a thermoset by reaction of the isocyanates with atmospheric moisture [109, 110].

Evolution

The fundamental chemistry of the structural adhesives described here can change very little. Vinyl and acrylic monomers polymerize by chain-growth polymerization initiated by free radicals or ions. Isocyanate and epoxy compounds react with compounds containing active hydrogen in step-growth polymerizations. Epoxy-containing compounds undergo chain-growth polymerization initiated by certain Lewis acids and Lewis bases. These reactions will remain the most important ones for the polymerization of these raw materials.

Most of the raw materials used in large quantities in structural adhesives are used because they are widely available, relatively safe, and inexpensive. Quite often they are made in large quantities for uses other than adhesives and the adhesive manufacturers have taken advantage of supply and price. Few new basic raw materials are being developed specifically for the adhesive industry although the traditional raw materials are being combined in new ways to enhance desired adhesive properties. New initiators, adhesion promoters, primers, and specialty chemicals are being developed for use in small quantities to provide wider application latitude and improved performance.

The evolution of structural adhesives will certainly continue. Each increment in strength, durability, processing speed and ease, safety, reliability and reproducibility opens new commercial markets, not only to displace older joining methods but also to allow for the manufacture of new structures not possible without adhesives. One area receiving much academic as well as patent activity is “self-healing” systems. One such epoxy system is described by Wu et al. where the healing chemistry can be the same or different such as olefin methathesis [111].

Conclusion

Epoxy, urethane, and acrylic structural adhesives have been commercially successful because each can be used, under the proper conditions, to make reliable, durable, and useful adhesively joined assemblies. The adhesives are classified according to the polymerization reactions used to bring the liquid adhesive to a high-molecular-weight load-bearing state. The reactive sites on the uncured adhesive and the overall polarity of the cured adhesive are important in the adhesion of the polymer to any specific material. The polymerization reactions determine the processing requirements and are important to the mechanical properties and environmental resistance of the cured adhesive. Through the use of specific reactive oligomers it is possible to build certain molecular structures into the composition that will remain in the cured adhesive to provide desired mechanical or chemical properties.

The successful use of adhesive joining in producing any assembly depends on viewing the assembly as a whole from the very beginning of its design. The key is remembering that the adhesive is only one component of the assembly. Adhesion is a property of the whole assembly.

Synthetic Resins and Plastics

15

Rudolph D. Deanin, Joey L. Mead, Ming Wei, and Bridgette M. Bludhlall

Introduction

Definition

Plastic (adj.) is defined by Webster [1] as "capable of being molded or modeled (e.g., clay) ... capable of being deformed continuously and permanently in any direction with-out rupture." Plastic (n.) a plastic substance; *specifically*: any of numerous organic synthetic or processed materials that are mostly thermoplastic or thermosetting polymers of high molecular weight and that can be made into objects, films, or filaments.

History

Commercial plastics began in 1868 when John and Isaiah Hyatt plasticized cellulose nitrate and molded it into billiard balls, and later into combs, brushes, and other useful articles. Commercial *synthetic* plastics began in 1908 when Leo Baekeland reacted phenol, formaldehyde, and wood flour and molded them into electrical insulators and a growing variety of other product specialties. During the next 30 years, a variety of plastics appeared as interesting specialties. During World War II the U.S. and German governments met the severe demands of advanced military technology by supporting vast research, development, plant construction, and manufacturing of a number of major polymers for plastics and rubber applications. With the end of the war in 1945, all of this technology and production capacity converted to civilian products, and commodity plastics began their tremendous growth, first polyvinyl chloride and polystyrene, then polyethylenes, polypropylene, polyesters, and polyurethanes, along with a constantly expanding range of specialized polymers for more demanding applications.

Advantages of Plastics over Conventional Materials

We have had conventional structural materials—metals, ceramics, glass, wood, leather, textiles, and paper—for thousands of years, during which time we have been able to explore and exploit them thoroughly to full maturity. By comparison, plastics are relatively new so that we are still learning to develop and use them. Their rapid growth is due to the fact that they offer many advantages over conventional materials.

Processability and Product Design. It is much easier to convert plastic materials into an almost unlimited range of products.

Modulus. Plastics cover a broad range from extremely rigid to stiffly flexible to very soft and rubbery, sometimes even within a single chemical family.

Elasticity. Plastics recovery from deformation is superior to almost all conventional materials.

Impact Strength. Plastics are much less brittle than ceramics, glass, and paper, and some families can be made nearly unbreakable.

Lubricity and Abrasion Resistance. Specific plastic materials offer outstanding self-lubricating performance and abrasion resistance.

Thermal Insulation. Plastics offer very good insulation against heat and cold, and can be foamed to increase their insulating qualities.

e-mail: Joey.Mead@uml.edu

J.A. Kent (ed.), *Handbook of Industrial Chemistry and Biotechnology*,
DOI 10.1007/978-1-4614-4259-2_15,

Flame-Retardance. Many plastics are less flammable than wood and paper, and most can be formulated to make them much more resistant to burning.

Electrical Insulation. Plastics are generally excellent electrical insulators, however, they can also be formulated to provide semi-conductivity, and high or low dielectric constant and loss.

Transparency/Opacity. Some plastics can approach or equal the transparency of glass. All can be formulated to a wide range of translucency to opacity.

Color and Appearance. Most conventional materials have a very limited color range governed by the material. In contrast, plastics can be produced in an almost infinite range of colors, transparent or opaque, and can have textured surfaces to simulate a variety of other materials (e.g., leather).

Chemical Resistance. Plastics are generally far superior to metals in corrosion resistance. Among the 100 families of commercial plastics, they offer a wide variety of chemical resistance, or solubility/reactivity, as desired for different types of products.

Water Resistance. Plastics are far superior to wood and paper.

Permeability. Different families of plastics offer a wide range from highly impermeable barrier materials to membranes of different separation abilities.

Weathering. Some plastics are very resistant to weather. Others have moderate resistance. Still others can be designed to degrade to alleviate collection of solid waste.

Cost. Contrary to popular belief, plastics are not "cheap," but their superior processability often makes the finished product less expensive.

This economic advantage, plus all the other advantages listed above, accounts for the success of plastics as replacements for conventional materials and in leading to new products not previously possible.

Markets for Plastics

The U.S. plastics market has grown past 98.7 billion pounds/year [2, 3]. The largest share (39%) goes to packaging, both rigid packages and film. Close behind is building and construction (26%) mainly piping, plywood, siding, insulation, and flooring. Smaller, more specialized amounts go into agriculture, aircraft, appliances, autos and trucks, electrical and electronics, furniture, glazing, housewares, luggage, marine, medical, office equipment, optical, tools, toys, and miscellaneous industrial and consumer products. Thus, taken as a whole, plastics is one of the largest and fastest growing industries in the United States.

Major Classes of Plastic Materials

The primary classification is the distinction between thermoplastics and thermosets. Thermoplastics are stable large molecules, typical molecular weights of 10^4–10^6, which soften on heating to permit melt processing, and solidify on cooling to give solid finished products; the process is reversible, so they are essentially recyclable within the limits of their thermal stability. Thermosetting plastics are reactive low molecular weight polymers, which may be melted or even poured, shaped into final products, and then reacted further into cross-linked molecules of essentially infinite molecular weight; the process is essentially irreversible, so they are difficult or impossible to recycle. Thermoplastic processing is simpler and more economical, thus thermoplastics account for more than 70% of all polymers. On the other hand, thermosetting plastics permit many special processes and offer outstanding final properties, which accounts for the health of their share of their more specialized markets.

Another important distinction is based on: (1) filled and reinforced plastics and (2) foams.

1. When any family of polymers is combined with particulate inorganic fillers, this produces a major increase in density, modulus, dimensional stability, heat transfer, dielectric constant, opacity, and frequently a decrease in cost. When the fillers are reinforcing fibers, they can further produce a great increase in strength, impact resistance, and dimensional stability. Thus, these properties may depend more upon the use of fillers and fibers, than upon the choice of the particular polymer in which they are used. Recently, numerous nanoscale fillers, including nanoparticles, nanotubes, and nanoclays have been used to reinforce the polymer at relatively low loadings compared to conventional fillers. In this case, good dispersion is very important to produce high quality materials.
2. When a polymer is liquefied, foamed, and solidified to trap the air spaces within it, the material exhibits drastically different properties compared to the base polymer. The most outstanding effects are flotation by closed-cell foams, softness in open-cell foams, impact cushioning, thermal and electrical insulation, and permeability in open-cell foams.

Following these introductory remarks, we turn to a study of the fundamental aspects of Polymer Chemistry (Part I), followed with a discussion of Commercial Plastic Materials (Part II), and conclude with Plastics Processing (Part III).

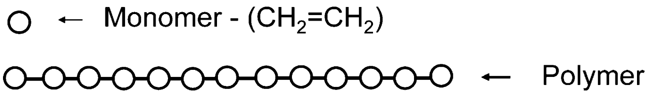

Fig. 15.1 Polymerization

Part I: Polymer Chemistry

Materials can be broadly classified as ceramics, metals, or polymers. Compared to metals and ceramics, polymers exhibit lower moduli, thermal conductivities, and densities. A wide range of products can be manufactured using plastic materials. Polymeric materials are used in automotive, packaging, and consumer goods, just to name a few. The requirements for these diverse applications vary greatly, but through proper control, plastic materials can be compounded or synthesized to meet these varied product requirements. Their lower density offers an advantage over other materials in applications requiring lighter weight.

Molecular Weight

A polymer is prepared by linking a low molecular weight species, called a monomer (such as ethylene), into a long chain, called a polymer (such as polyethylene), similar to stringing together beads to make a necklace (see Fig. 15.1). As molecular weight increases, the properties of the material change. Looking at the alkane hydrocarbon series with the general structure H–(CH_2)$_n$–H, we can see the material change from a gas for values of $n = 1$–4, a liquid for $n = 5$–11, a high viscosity liquid from $n = 16$–25, a crystalline solid for $n = 25$–50, to a tough plastic solid for $n = 1{,}000$–$5{,}000$ [4]. The molecular weight affects both the mechanical and processing behavior of the polymer. In general, higher molecular weights result in improved mechanical properties, but more difficulty in processing. In contrast to low molecular weight species, polymeric materials do not possess one unique molecular weight, but rather a distribution of molecular weights as depicted in Fig. 15.2. Polymer molecular weight can be characterized using two different molecular weight averages, the number average molecular weight, $\overline{M_n}$, and the weight average molecular weight, $\overline{M_w}$. These averages are:

$$\overline{M_n} = \sum_{i=1}^{\infty} \frac{n_i M_i}{n_i}$$

$$\overline{M_w} = \sum_{i=1}^{\infty} \frac{n_i M_i^2}{n_i M_i}$$

where n_i is the number of moles of species i and M_i is the molecular weight of species i.

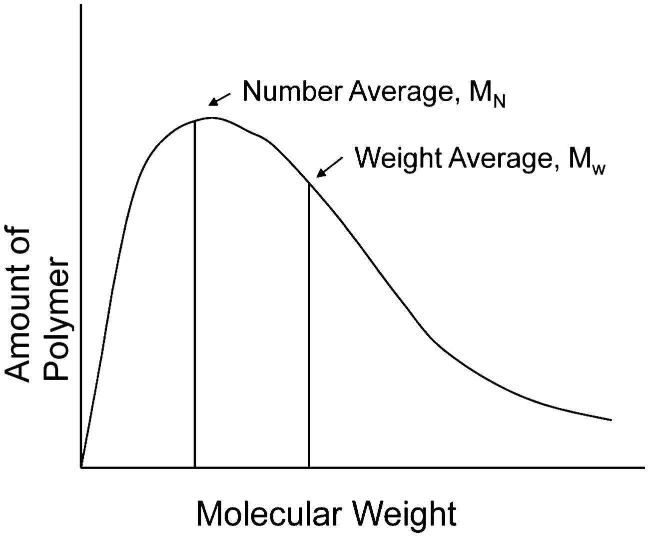

Fig. 15.2 Molecular weight distribution

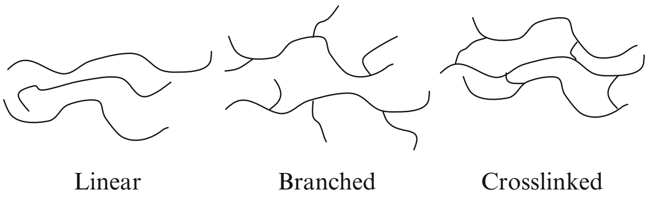

Fig. 15.3 Polymer structures

Chain Structure

Polymerization can produce linear chains, but other structures can also exist. As shown in Fig. 15.3 branched and cross-linked structures can be formed. Linear and branched structures can be shaped and reshaped simply by heating and are called thermoplastics. In the case of a cross-linked structure a three-dimensional network is formed that cannot be reshaped by heating. This type of structure is called a thermoset.

Macromolecular conformations describe the positions of the atoms that occur due to rotation about the single bonds in the main chain [5]. Polymer chains in solution, melt, or amorphous state exist in what is termed a random coil. The chains may take up a number of different conformations, varying with time. Figure 15.4 shows one possible conformation for a single polymer chain. In order to describe the chain, polymer scientists utilize the root mean square end-to-end distance ($<r^2>^{1/2}$), which is the average over many conformations. This end-to-end distance is a function of the bond lengths, the number of bonds, and a characteristic ratio, C, for the specific polymer.

Chemical Structure

The chemical characteristics of the monomer will control the properties of the final polymer. Along the chain axis, primary bonds hold the atoms together and determine molecular properties, such as flexibility and glass transition temperatures. Flexibility of the chain is governed by the ease of rotation about main chain bonds. The presence of methylene units or carbon–oxygen single bonds acts to increase the flexibility of the chain. Groups or interchain interactions (described below) that restrict rotation will decrease the flexibility of the molecule. An extreme example of this principle is the rigid rod polymers. Figure 15.5 shows the structures for two rigid rod polymers. The aromatic groups along the backbone act to stiffen the polymer chain and restrict rotation, causing the polymer to remain straight, much like a log [6]. Materials such as these may exhibit liquid crystalline behavior.

The forces holding the many individual chains together (interchain forces) are determined by secondary bonds, except in the case of thermosets where primary bonds hold the chains together. The type and strength of the secondary bonds (often termed van der Waals forces) [7] will depend on the chemical structure of the polymer. In the case of hydrocarbon polymers, such as polyethylene, the secondary bonds are dispersion forces. For polymers containing carbon and oxygen groups, such as the polyesters, the presence of the –C=O bond results in a dipole from the different electronegativities of the carbon and oxygen atoms. The presence of polarity in the polymer acts to increase the intermolecular forces. In the case of polyamides, hydrogen bonding between the polymer chains leads to high intermolecular forces. The strength of the intermolecular forces affects polymer properties including: viscosity, solubility, miscibility, surface tension, and melting point. As discussed above, interchain forces also affect the flexibility of the chain if they restrict free rotation.

Morphology

Polymer chain structure and processing conditions control the morphology of the solid polymer. Amorphous polymers show no order to the arrangement of the chains. The chains are entangled with each other, much like the strands of spaghetti on one's plate. Polystyrene is an example of an amorphous polymer. If the polymer backbone has a regular, ordered microstructure, then the polymer has the potential to crystallize, however, the material will generally be only semicrystalline. Polyethylene and polypropylene are typical semicrystalline polymers. The amorphous and crystalline chain structures are depicted in Fig. 15.6.

The exact makeup and architecture of the polymer backbone will determine the ability of the polymer to crystallize. Figure 15.7 shows the different types of microstructure that can be obtained for a vinyl polymer. Isotactic and syndiotactic structures are considered stereospecific

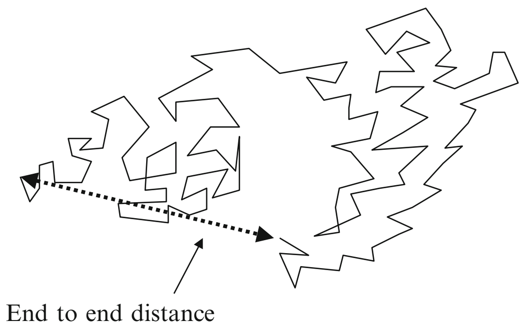

Fig. 15.4 Random coil chain

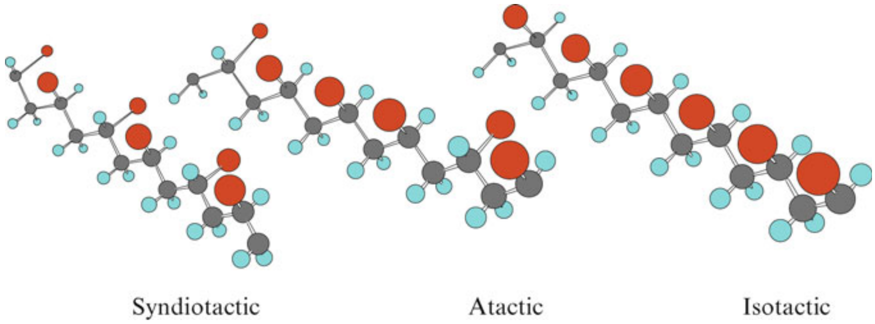

Fig. 15.8 Behavior of volume and modulus at the glass transition temperature

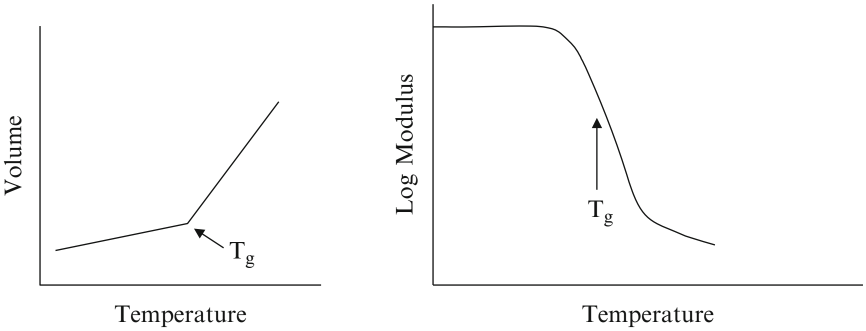

polymers, and their highly regular backbone structure allows them to crystallize. The atactic form is irregular and would produce an amorphous material. This nature of the polymer microstructure can be controlled by using different synthetic methods. As will be discussed below, the Ziegler–Natta catalysts are capable of controlling the microstructure to produce different types of stereospecific polymers.

Transition Temperatures

Glass Transition Temperature (T_g)

Chain flexibility is governed by molecular structure, but is also affected by temperature. As the temperature is reduced, amorphous polymers reach a temperature where large-scale (20–50 chain atoms) segmental motion ceases [8]. This temperature is called the glass transition temperature or T_g. Volume–temperature plots can be used to indicate the T_g. At the glass transition temperature, a several decade change in the modulus occurs and the material changes from a rigid solid to a rubbery material. At higher temperatures, provided the material is a thermoplastic, it becomes a liquid, which can flow and be processed. The behavior in the glass transition region is depicted in Fig. 15.8.

The location of the glass transition temperature will depend on the nature of the polymer. A rubbery material is distinct from a plastic material as a result of the location of its glass transition temperature (T_g). The T_g of a plastic is above room temperature and the T_g of rubber is below room temperature. The flexibility of the chain affects the value of T_g. Flexible groups tend to lower the T_g, while stiffening groups act to increase it. Side groups can also affect the value. The effect of various factors on the value of T_g is shown in Table 15.1. Addition of aliphatic side groups show decreasing T_g's as the length of the side chain increases; however, rigid side groups increase the T_g. Increased polarity of the polymer also increases the glass transition temperature as shown by the polymers polypropylene, polyvinyl chloride, and polyacrylonitrile. Symmetry about the backbone can act to decrease the T_g as illustrated by the pairs polypropylene and polyisobutylene, and polyvinyl chloride and polyvinylidene chloride.

Increases in number average molecular weight, $\overline{M_n}$, and cross-link density both act to increase the T_g. The addition of plasticizers, as in the case of polyvinyl chloride, decreases the value of the glass transition temperature. The glass

transition temperature of the plasticized material can be estimated if the glass transition temperature of the two components (A and B) and their weight fractions are known by [10]

$$\frac{1}{T_g} = \frac{W_A}{T_{gA}} + \frac{W_B}{T_{gB}}$$

where T_{gA} and T_{gB} are the glass transition temperatures of components A and B, respectively, and W_A and W_B are the weight fractions.

One difficulty in obtaining values for the glass transition temperature is its dependence on measurement rate. When experiments are conducted a slow rates, the measured values will be lower than those measured at more rapid rates. Other difficulties include experimental problems and many definitions and interpretations on how to measure the values. Measurement of the temperature at which a step change in the volumetric thermal expansion coefficient occurs, when heating and cooling rates are 1°C/min, is one of the methods [11]. The measured value of the glass transition temperature will increase approximately 3°C (volumetric measurements) to 7°C (maximum in tan δ from dynamic mechanical analysis) for a decade change in rate.

Crystallization and Melting Points (T_m)

A number of polymers may exhibit the ability to crystallize. Such polymers are semicrystalline, meaning they will have regions of amorphous and crystalline material dispersed throughout the part. Both the morphology and degree of crystallinity can be affected by the processing conditions used to manufacture the part. These changes can greatly affect the mechanical behavior of the material. The degree of crystallinity and the melting point are often measured using differential scanning calorimetry (DSC).

The general structure of the crystalline regions is rather complex. Polymer chains appear to fold back and forth into a lamellar structure as shown in Fig. 15.6. These lamellae form layers of ribbon like structures, tied together with amorphous regions.

Semicrystalline polymers do not exhibit a single sharp melting point, but rather melt over a range of temperatures. In addition, the melting point of the material will be higher the greater the lamellar thickness, which can be controlled by the crystallization temperature [12]. Higher crystallization temperatures generally lead to greater lamellar thickness.

The chemical structure of the polymer affects the melting point. Polymers containing polar groups will have higher melting points. Polymers with hydrogen bonding would be expected to have even higher melting points. For example, polyethylene has a melting point of 135°C, while polyamide 6 has a melting point of 265°C. The presence of chain stiffening groups in the backbone will act to raise the melting point of the polymer; contrast the melting point of polyethylene (135°C) with poly-*p*-xylene (400°C). In general, polymers with high interchain forces and rigid chains will tend to have the highest melting points.

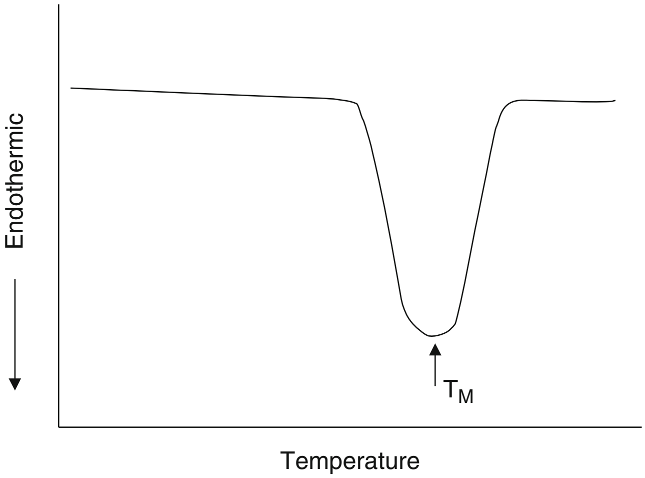

Fig. 15.9 Differential scanning calorimetry (DSC) curve of a melting point

In addition to the melting point, the degree of crystallinity influences the behavior of the polymer. DSC can be used to determine both the melting point and the % crystallinity. Figure 15.9 shows a representative DSC curve for a melting point. The area under the melting peak is related to the % crystallinity of the polymer sample. The percent crystallinity may have a dramatic effect on the mechanical behavior of the material. Above the T_g of the material, the presence of crystalline regions increases the rigidity of the polymer, resulting in an increasing modulus with increasing percent crystallinity [13].

The kinetics of crystallization are a function of the crystallization temperature [14]. As the crystallization temperature is decreased the rate of crystallization increases, up to a maximum. When the crystallization temperature is lowered beyond this point the rate begins to slow down as the molecular motion of the chains is reduced. At temperatures below the T_g crystallization is suppressed.

Polymerization

The two major polymerization approaches are step-reaction and chain-reaction polymerization [15].

Step-Reaction Polymerization

In step-reaction polymerization (also referred to as condensation polymerization) any two polyfunctional (typically bifunctional) monomers of the correct chemical species

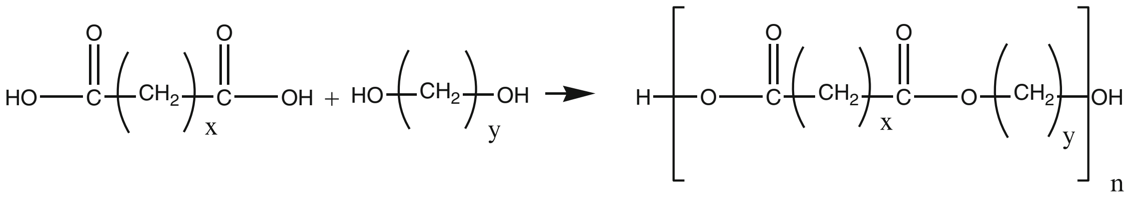

Fig. 15.10 Step-growth polymerization

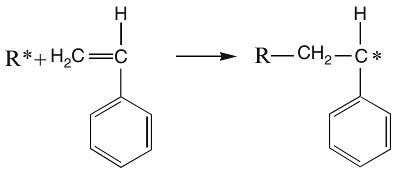

Fig. 15.11 Addition polymerization

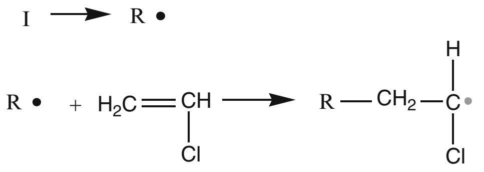
can react. Higher molecular weight species are produced as longer and longer polyfunctional groups react together during the course of polymerization. Monomers may react to form a dimer, then combine to form a tetramer, expressed as x-mer + y-mer → (x + y)mer, where x and y are the number of monomer units for each reactant. Monomer functionalities of two will produce linear polymers, while functionalities of greater than two give branching or cross-linking. The polymer molecular weight increases with time and in order to produce high molecular weight polymers high conversions are usually required. Atoms other than carbon are often found in step-reaction polymers as seen in polyesters and polyamides, which are typical step-reaction polymers. A typical step-growth reaction is shown in Fig. 15.10.

Molecular weight control can be accomplished by stopping the reaction; however, further heating may result in changes in the molecular weight. A stoichiometric imbalance (excess of one of the reactants over another) or a monofunctional reagent can also be used to control the molecular weight [16].

Chain-Reaction Polymerization

In contrast to the slow step-reaction polymerizations, chain-reaction polymerizations are fairly rapid [17]. An initiator is required to start chain-reaction polymerizations (often referred to as addition polymerizations). Free radical, anionic, or cationic species can be used as initiators. The initiator opens the double bond of a vinyl monomer and the reaction proceeds as shown in Fig. 15.11 where * may be a radical, cationic or anionic species. Chain-reaction polymers normally have only carbon in their backbone. Typical chain-reaction polymers are polystyrene and polyvinyl chloride. Once initiated, the chain will continue to add monomer until a termination reaction stops the growth. Termination generally occurs in radical type reactions, but in anionic and some cationic polymerizations termination reactions may not be present and the polymerization is termed a “living polymerization.” This has important commercial implications in that a second monomer may be added to the living end to form block copolymers.

Radical Polymerization. Free radical polymerization consists of three steps, initiation, propagation, and termination or chain transfer. Initiation consists of two steps, decomposition of the initiator to form a radical species, followed by addition of the initiator to the first monomer unit.

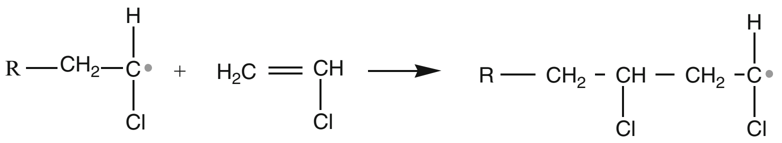


$$I \longrightarrow R\bullet$$

$$R\bullet + H_2C{=}\underset{Cl}{CH} \longrightarrow R{-}CH_2{-}\overset{H}{\underset{Cl}{C}}\bullet$$

Typical initiators include benzoyl peroxide or azobisisobutyronitrile, but other radical generating methods, such as high-energy radiation or photolytic decomposition of compounds, may also be used [12].

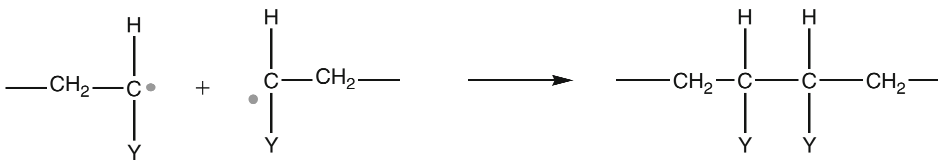
The next step in the reaction is propagation



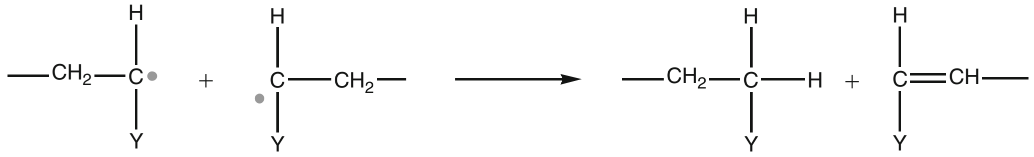
$$R{-}CH_2{-}\overset{H}{\underset{Cl}{C}}\bullet + H_2C = \underset{Cl}{CH} \longrightarrow R - CH_2 - \underset{Cl}{CH} - CH_2 - \overset{H}{\underset{Cl}{C}}\bullet$$

Propagation continues until the radical is terminated. Termination occurs when two radical species meet and react either by coupling or by disproportionation as shown in Fig. 15.12.

In radical polymerizations other reactions occur to prematurely stop chain growth. These reactions are termed chain transfer and when they occur they reduce the molecular weight of the chain. Chain transfer acts to transfer the



Coupling

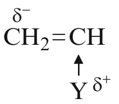


Disproportionation

Fig. 15.12 Termination mechanisms

radical from the growing end of the chain to another species. This may include solvent, initiator, polymer, or a deliberately added chain transfer agent. Propagation now begins from the new radical generated, while the original chain is terminated. When chain transfer to polymer occurs this produces branching along the polymer backbone. Low-density polyethylene (LDPE) is produced via free radical processes, with considerable transfer to polymer. Branching along the polyethylene backbone suppresses the degree of crystallinity, resulting in a lower density material.

Cationic Polymerization. Cationic polymerization follows similar steps as with free radical polymerization. Initiator types are typically acids, such as H_2SO_4 and H_3PO_4, and Lewis acids, such as $AlCl_3$, BF_3, $TiCl_4$, and $SnCl_4$. Lewis acids generally require the presence of a proton source, such as trace amounts of water [18]. Monomers exhibit considerable selectivity in their ability to be polymerized via ionic mechanisms. The nature of the substituent (Y) will influence the electron density of the double bond and thus its ability to polymerize [19]. Substituents that are electron donating, such as alkoxy, phenyl, or alkyl, will increase the electron density of the double bond and allow for polymerization by cationic methods.



$$\overset{\delta^-}{CH_2}=\underset{\underset{Y^{\delta+}}{\uparrow}}{CH}$$

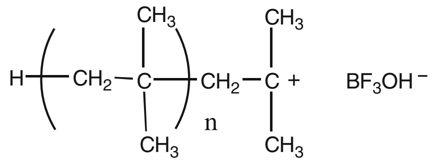


Fig. 15.13 Active cationic propagating species

Typical monomers that may be polymerized by cationic methods include styrene, isobutylene, and vinyl ethers. Unlike radical polymerizations, solvent polarity can influence the rate of polymerization. This is due to the presence of the counterion (see Fig. 15.13). For example, more polar solvents can increase the degree of separation between the growing end and the counterion during the propagation step, increasing the rate of propagation [20]. Chain transfer is the most common chain terminating reaction in cationic polymerization and can include transfer to monomer, solvent, and polymer. Termination by combination with the counterion can also occur in some systems. In some cases, cationic polymerization may be used to prepare stereoregular polymers. Although the exact mechanism is unclear, it is known that stereoregularity varies with initiator and solvent [21]. Lower temperatures also tend to favor more stereoregular polymers.

Anionic Polymerization. Anionic polymerization is similar to cationic polymerizations, except that the propagating species is anionic. Initiator types are typically alkali metals or their compounds. In the case of anionic polymerizations, electron withdrawing substituents, such as cyano, nitro, carboxyl, vinyl, and phenyl, facilitate polymerization by anionic means. Termination in anionic polymerization is generally by chain transfer. If the system is purified so that chain transfer is suppressed, the propagating species may remain active resulting in what is termed “living polymerization” [22]. This allows for the preparation of block copolymers, where one monomer is

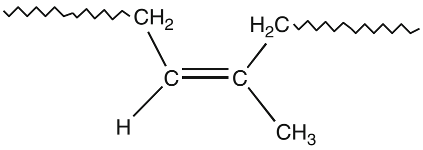

Fig. 15.14 *cis* 1,4 Polyisoprene

polymerized, followed by addition of a second monomer to the living end.

As with cationic polymerization the propagation rate is highly dependent on the solvent. Solvents that reduce the association between the growing chain end and the counterion result in faster rates of propagation [23].

In anionic polymerization of vinyl monomers (nondiene), low temperatures and polar solvents favor the preparation of syndiotactic polymers [24]. Nonpolar solvents tend to favor isotactic polymerization. In the case of diene monomers such as butadiene and isoprene, the use of lithium-based initiators in nonpolar solvents favors preparation of the *cis* 1,4 polymer (see Fig. 15.14).

Coordination Polymerization

In the 1950s, Karl Ziegler discovered a way to polymerize ethylene in a linear structure to produce high-density polyethylene (HDPE) using transition metal compounds and organometallic compounds. Using similar catalysts, Giulio Natta polymerized alpha-olefins, for example propene, with controlled stereoregularity. These catalyst systems are called Ziegler–Natta catalysts, and are widely used for the synthesis of a number of commodity plastics, such as high-density polyethylene and polypropylene [25]. Ziegler–Natta catalysts may be either insoluble (heterogeneous) or soluble (homogeneous) systems.

Ziegler–Natta Catalysts (Heterogeneous). These systems consist of a combination of a transition metal compound from groups IV to VIII and an organometallic compound of a group I to III metal [26]. The transition metal compound is called the catalyst and the organometallic compound the cocatalyst. Typically the catalyst is a halide or oxyhalide of titanium, chromium, vanadium, zirconium, or molybdenum. The cocatalyst is often an alkyl, aryl, or halide of aluminum, lithium, zinc, tin, cadmium, magnesium, or beryllium [27]. One of the most important catalyst systems is the titanium trihalides or tetrahalides combined with a trialkylaluminum compound.

The catalyst system is prepared by mixing the two compounds in the solvent, usually at low temperatures. Polymerization occurs at specific sites on the catalyst surface. There are several proposed mechanisms for polymerization, but the important aspect of both is that the polymerization occurs in coordination with the catalyst. The pi bond of the monomer complexes with the transition metal and is then inserted in between the transition metal and the carbon of the coordinated polymer chain. One of the proposed mechanisms is shown in Fig. 15.15. Isotactic polymers are generally formed with the insoluble catalysts. Syndiotactic polypropylene has been formed with both heterogeneous and homogeneous catalysts.

Metallocene Catalysts (Homogeneous Ziegler–Natta). Solid Ziegler–Natta catalysts suffered from several problems, including the presence of multiple polymerization sites on the catalyst surface and catalyst residue in the final polymer, requiring a secondary purification step [28]. The use of soluble catalysts offered an answer to some of these problems. These catalysts are composed of a metal atom (the active site), a cocatalayst, and a ligand system. Zirconium is the most commonly used metal although other metals such as Ti, Hf, Sc, and Th have been used. The most commonly used ligand is cyclopentadienyl. Methylalumoxane is typically the counterion. Figure 15.16 shows a proposed structure for methylalumoxane and a generalized metallocene structure.

The soluble catalysts can prepare polymers with very good stereospecificity and narrow molecular weight distributions, as a result of the uniformity of the active sites. In fact, these catalysts are often referred to as “single site catalysts” [29]. The polydispersity ($\overline{M_w}/\overline{M_n}$), which is a measure of the molecular weight distribution, is about 2–2.5 for the soluble catalysts and 5–6 for the heterogeneous Ziegler–Natta systems. By proper selection of the catalyst, syndiotactic, atactic and isotactic polypropylene, and higher alpha-olefins can be synthesized. In addition, it has been possible to prepare polypropylene with alternating blocks of isotactic and atactic chains. The resulting material exhibits elastomeric properties.

Polymerization Methods

While polymerization by ionic methods is usually performed in solution, free radical polymerizations can be performed in solution, bulk, suspension, or emulsion [30]. Each of these methods is described below.

Bulk Polymerization

Bulk polymerization is one of the simplest methods of polymerization. It is often used in the polymerization of step-growth polymers [31]. In these types of systems the viscosity remains low for a large portion of the reaction and heat transfer is easily controlled. Chain-growth polymers are more difficult to polymerize by this method due to the rapid and highly exothermic reactions. As the viscosity increases, thermal control becomes more difficult and may result in thermal runaway or localized hot spots.

Metallocene

M = metal (Zr, Ti, or Hf)   X = Cl or alkyl

Z = optional bridging group   R = H or alkyl

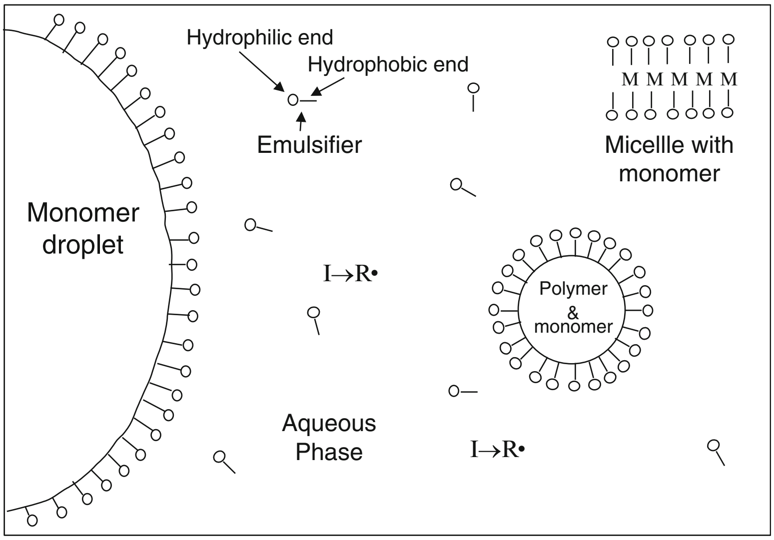
Fig. 15.16 Metallocene catalysts

Commercial use of bulk polymerization for vinyl polymers is rather limited for those reasons. Bulk polymerization may be either homogeneous or heterogeneous, as in the case where the polymer is insoluble in the monomer [32].

Solution Polymerization

Solution polymerization offers improved heat transfer over bulk polymerizations. Proper selection of the solvent is critical to avoid chain transfer reactions. Coupled with

Fig. 15.17 Emulsion polymerization



environmental concerns over organic solvents, the complete removal of solvents from the polymer also poses a potential problem. Recent work has been performed on the use of supercritical carbon dioxide as a solvent, which is easy to remove and poses less environmental concerns [33].

Suspension Polymerization

From an environmental standpoint, the use of water as a solvent is desirable. Unfortunately, many of the monomers of interest are insoluble in water, but suspension polymerization offers a way to utilize water. Suspension polymerization is performed by mechanically dispersing a monomer in an incompatible solvent, most often water. The system is heterogeneous and when polymerization is complete the polymer is collected as granular beads. This method is not suitable for tacky materials, such as elastomers, as the beads will tend to clump together [32].

Monomer droplets are suspended in the water through the use of agitation and stabilizers, such as methyl cellulose, gelatin, polyvinyl alcohol, and sodium polyacrylate [34]. Typical droplet sizes are 0.01–0.5 cm. A monomer soluble initiator is added to begin the polymerization. The kinetics of suspension polymerization are the same as for bulk polymerization, but suspension polymerization offers the advantage of good heat transfer. Polymers such as polystyrene, polyvinyl chloride, and polymethyl methacrylate are prepared by suspension polymerization.

Emulsion Polymerization

Superficially, emulsion polymerization resembles suspension polymerization, but there are a number of important differences. Water is used as the continuous phase and heat transfer is very good for both suspension and emulsion polymerization. In contrast to suspension polymerization, the polymer particles produced in emulsion polymerization are on the order of 0.1 μm in diameter [35]. Another important difference is the presence of an emulsifying agent or soap. At the beginning of polymerization the soap molecules aggregate together in a group of about 50–100 molecules to form what is called a micelle. Some of the monomer enters the micelles, but most of it is contained in monomer droplets. A water-soluble initiator is added, which migrates to the micelles as a result of their large surface to volume ratio and initiates polymerization primarily in the micelles. As polymerization continues, the micelles grow by addition of monomer from the water. The monomer droplets provide additional monomer to the aqueous phase as polymerization continues. Polymerization continues in the micelles until a second radical enters to terminate the reaction. As a result, very high molecular weight polymers may be synthesized [36]. Figure 15.17 shows an overall view of the emulsion polymerization process. Emulsion polymerization is a widely used technique, especially useful for making synthetic rubber, latex paints, and adhesives.

Copolymerization

In many cases the properties of a single type of polymer cannot meet the demands of a particular application. One approach to solving this problem is to combine two monomers into a single polymer through copolymerization. The properties of the resulting copolymer will then depend on the chemical nature of the monomers used and the microstructure of the chain. Monomers may be placed in the chain in a variety of ways, including random, block, and graft copolymers as depicted in Fig. 15.18.

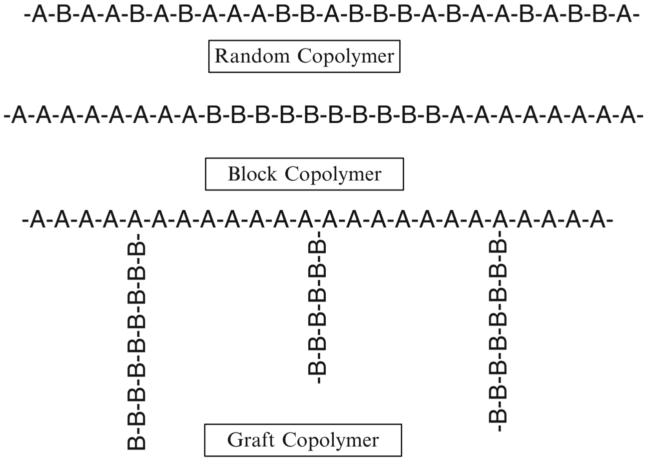


Fig. 15.18 Copolymer structures

Random Copolymerization

Copolymerization can occur through any of the chain-reaction polymerization mechanisms described above; however, the reactivity of a given monomer toward the second monomer can vary. Thus, not all combinations of monomers may be copolymerized. Each active end will exhibit different reactivity toward each monomer, which can be expressed as reactivity ratios, r_1 and r_2 [37]. These reactivity ratios (r_1 in this example) show the tendency of a given active end, for example $M_1{}^*$, to add its own monomer (M_1) over the other monomer (M_2). The copolymer composition at any instant can be determined by the composition of the feedstock and the reactivity ratios by

$$F_1 = \frac{r_1 f_1^2 + f_1 f_2}{r_1 f_1^2 + 2 f_1 f_2 + r_2 f_2^2}$$

where F_1 is the mole fraction of monomer 1 in the copolymer, f_1 and f_2 are the mole fractions of monomer 1 and 2 in the feedstock, and r_1 and r_2 are the reactivity ratios. In general, the copolymer composition will not be the same as the feed composition.

The properties of random copolymers are often a weighted average of the two polymers. For example, the glass transition temperature (T_g) of a single-phase copolymer typically falls somewhere in between the T_g's of the two homopolymers. This can be estimated using [38]

$$a_1 c_1 (T_g - T_{g1}) + a_2 c_2 (T_g - T_{g2}) = 0$$

where T_{g1} and T_{g2} are the glass transition temperatures for the pure homopolymers, a_1 and a_2 depend on the monomer type, and c_1 and c_2 are the weight fractions of monomer 1 and 2. For crystalline polymers, the degree of crystallinity and melting point decrease as the second monomer is added [39].

Block and Graft Copolymers

As mentioned above, the ability to have "living polymerizations" offers the potential to make block copolymers. In the preparation of a block copolymer the sequence of addition can be important to ensure that the second monomer is capable of adding to the living end. An example is the formation of a polystyrene—polymethyl methacrylate block copolymer [40]. In this case polystyrene is polymerized first, followed by addition of the methyl methacrylate. The block copolymer could not be formed if methyl methacrylate were polymerized first, as styrene will not add to the methyl methacrylate living end. An important example of block copolymerization is the synthesis of ABA triblock copolymers from styrene and diene monomers to form thermoplastic elastomers. They may be prepared by sequential polymerization from one end or from the middle using a difunctional initiator. Block copolymers may also be prepared with polymers containing functionalized end groups that are linked together.

There are three basic methods to produce graft copolymers [41]. In the first method a monomer is polymerized in the presence of a polymer and chain transfer provides the branching. Initiator, monomer, and polymer are combined to prepare the copolymer. The initiator may function by polymerizing the monomer, which then reacts with the polymer to form the graft, or by forming a reactive site on the polymer, which then polymerizes the monomer onto the polymer.

The second method of forming a graft copolymer is to polymerize a monomer with a polymer containing a reactive functional group (or sites that may be activated). Irradiation is commonly used to form active sites for graft copolymerization, but other methods may also be used. When irradiation is used the grafting mechanism is free radical in nature. In cases where the monomer is present when the polymer is irradiated homopolymerization may also occur. If homopolymerization is a concern, then the polymer may be irradiated in presence of air (or oxygen) to form hydroperoxide groups. The pretreated polymer is then mixed with monomer and heated to initiate the grafting reaction by decomposition of the peroxide groups.

The third method of preparing a graft copolymer is to combine two polymers with functional groups that can react together. An example is the reaction of oxazoline-substituted polystyrene with polymers containing functional groups such as alcohols, amines, and carboxylic acids.

Unlike the random copolymers, block and graft copolymers separate into two phases, with each phase exhibiting its own T_g (or T_m) [42]. The modulus-temperature behavior of a series of triblock copolymers prepared from styrene and butadiene (SBS) is shown in Fig. 15.19. With increasing styrene content the modulus in the plateau region (between the two glass transition temperatures) increases.

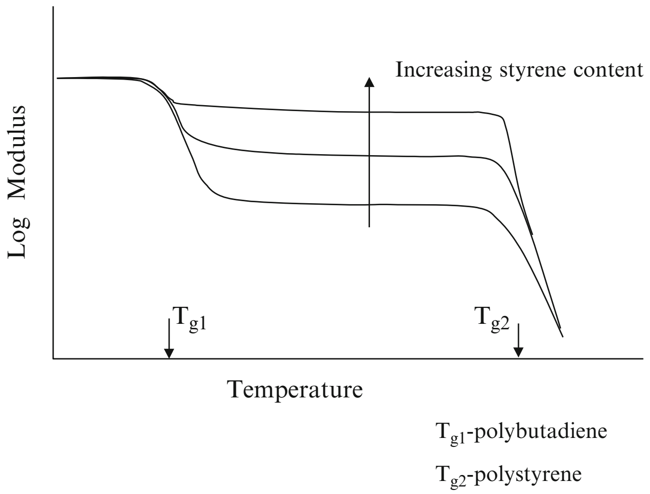

Fig. 15.19 Modulus-temperature behavior of a triblock copolymer

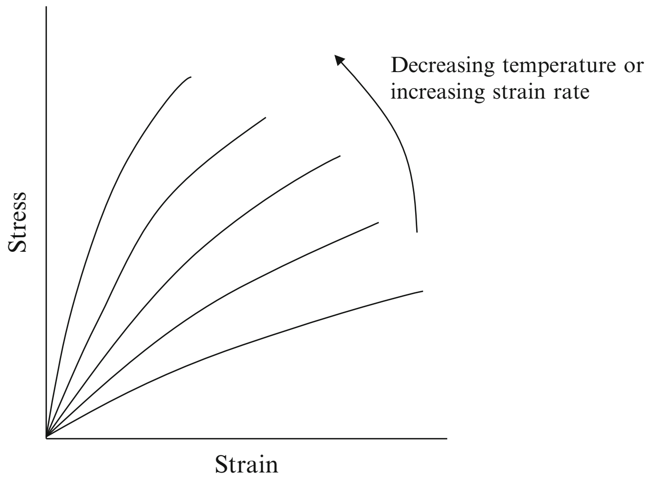

Fig. 15.20 Viscoelastic behavior of polymers as shown by stress–strain curves

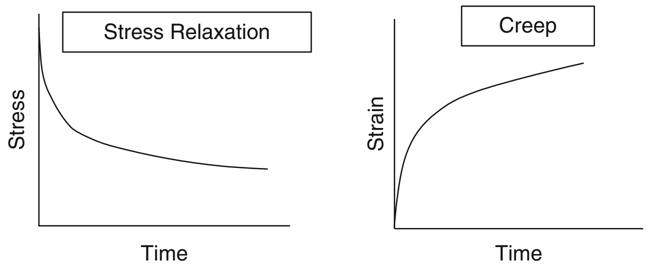

Fig. 15.21 Creep and stress relaxation

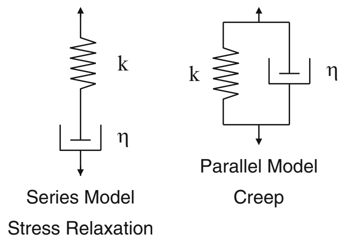

Fig. 15.22 Spring and dashpot models for stress relaxation and creep

Mixing of the two phases may shift the values of the two transition temperatures.

Mechanical Properties

Many factors influence the mechanical behavior of polymers including molecular weight, polymer type, processing conditions, and test procedures. Modulus values may be determined from a standard tensile test with a given rate of crosshead separation. The elastic or Young's modulus, E, is found from the initial part of the curve. Unlike many other materials, polymeric material behavior is affected by factors, such as test temperature and rates. When a product or material is used or tested at temperatures near the glass transition temperature, this becomes particularly important as the properties show dramatic changes (orders of magnitude) in properties (see Fig. 15.8).

Viscoelasticity

Polymer properties may exhibit considerable time-dependent behavior, depending on the polymer type and test conditions. The material appears rigid with an increase in testing rate or decrease in temperature and appears softer with an increase in temperature or decrease in rate. Viscoelastic response of a polymer to changes in testing rate or temperature is shown in Fig. 15.20. Long-term effects such as stress relaxation or creep [43] are the result of this time-dependent behavior. Creep and stress relaxation are shown in Fig. 15.21. A specimen held under a fixed load will continue to elongate with time, a process called creep. A spring and dashpot in parallel is often used as a simple model to predict the creep behavior (see Fig. 15.22). This model predicts the time-dependent strain to be

$$\varepsilon(t) = \varepsilon_o \mathrm{e}^{-t/\tau}$$

where τ is the characteristic relaxation time (η/k).

Stress relaxation is the decrease in load of a material held at a fixed displacement. Figure 15.22 shows the spring and dashpot in series that can be used to model the stress relaxation behavior. Using this model one obtains the following equation for the stress behavior.

$$\sigma(t) = \sigma_o \mathrm{e}^{-t/\tau}$$

These models are useful for understanding the general concept of viscoelasticity, but are typically unable to

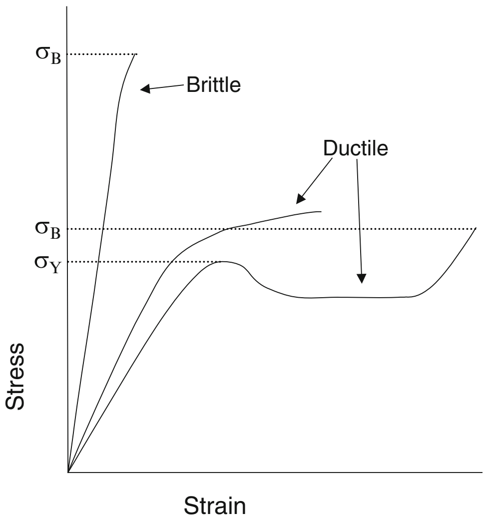

Fig. 15.23 Types of stress–strain behavior

accurately model the time-dependent behavior. More accurate prediction can be obtained by using models with more elements.

If stress relaxation curves are obtained at a number of different temperatures, it is found that these curves can be superimposed by horizontal shifts to produce what is called a “master curve” [44]. This concept of time–temperature equivalence is very important to understanding and predicting polymer behavior. As an example, a polymer at very low temperatures will behave as if it were tested at higher temperatures at much higher testing rates. This principle can be applied to predict material behavior under other rates or temperatures that are difficult to test experimentally by the use of shift factors (a_T).

$$\ln a_T = \ln\left(\frac{t}{t_o}\right) = -\frac{17.44(T - T_g)}{51.6 + T - T_g}$$

where T_g is the glass transition temperature of the polymer. This has practical applications where one may be interested in the mechanical properties of a material at low temperatures under high rate (perhaps impact rate) conditions. The design engineer should recognize that material properties measured at room temperature may not adequately reflect the material behavior at much lower temperatures or higher rates.

Failure Behavior

Part design requires the avoidance of failure without overdesign of the part, which leads to increased part weight and cost. Failure behavior depends on material type, service temperature, and rates. A tensile stress strain test can be used to gather some information on material strength and behavior, for example, stress (or strain) at break, σ_B.

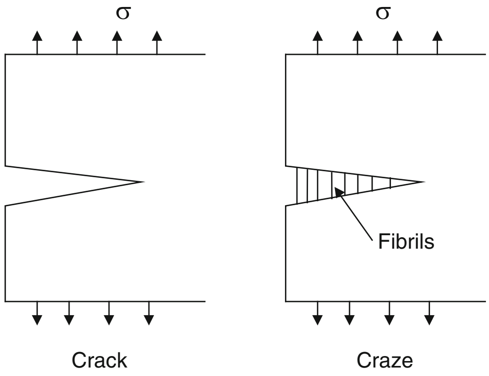

Fig. 15.24 Crazes and cracks

Figure 15.23 shows some different types of failure behavior. Brittle failure is when a materials fails at low elongations (1% strain or less) as exhibited by general purpose styrene and acrylics [45]. Failure initiates at a defect where stresses are concentrated. Once formed, a crack will continue to grow from the stress concentrations at the crack tip. Amorphous polymers can also show will what appear to be cracks, but are load bearing with fibrils of material bridging the two surfaces (Fig. 15.24). These structures are termed “crazes.” Crazing enhances the toughness of a material and is a form of yielding.

Polymers also exhibit ductile failure by yielding of the polymer or slip of the molecular chains past one another. This is found by a maximum in the tensile stress–strain test or the yield point, σ_Y (see Fig. 15.23). With further extension the sample may show lateral contraction, called necking [46]. In the necked regions, molecules are oriented in the direction of deformation, resulting in increased stiffness in the necked region. As a result of this localized stiffness increase, material adjacent to the neck is deformed and the neck region continues to grow, known as cold-drawing (see Fig. 15.25). Elongations of several hundred percent can occur with cold-drawing.

As might be expected, temperature will influence the behavior of the material. The effect of temperature on modulus has been discussed above. Very different behavior may be seen in a single polymer simply by changing the temperature [47]. Beginning at temperatures well below the T_g, the stress–strain behavior will show very low elongations, with no yield point. As the temperature is raised, the material will exhibit a yield point and elongation increases. The yield point is typically seen at temperatures near the glass transition temperature of the polymer. The higher the testing rate, the higher the temperature must be for yielding to occur.

A material may fail at stresses well below the single-cycle failure stress found in a typical tensile test under repeated cyclic stress, a process called fatigue [48]. Fatigue behavior is usually plotted as the maximum stress vs. the number of

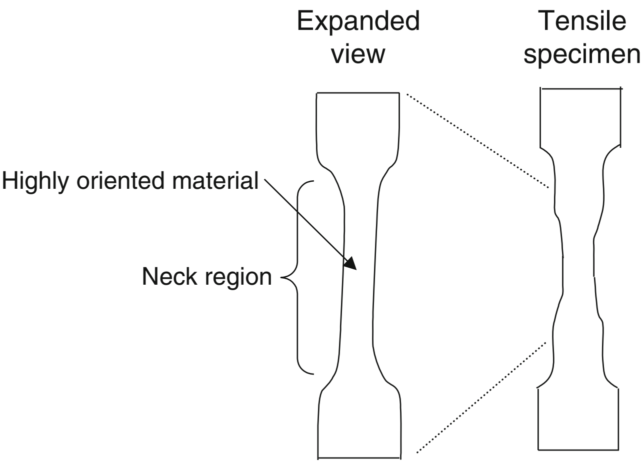

Fig. 15.25 Cold-drawing

cycles to failure. The exact conditions of the fatigue test can be varied and are specified by the service requirements. Type of loading (compression, tension, shear), load or displacement control, frequency, waveform (typically sinusoidal), and ratio of maximum to minimum stress may all be varied. The fatigue life is also influenced by the presence or absence of cracks and thermal effects.

Part II: Commercial Plastic Materials

Classes of Families of Commercial Plastics

Commercial plastic materials may conveniently be divided into five major classes. Commodity thermoplastics are families, which are produced in volumes of a billion pounds or more per year. Engineering thermoplastics are generally designed to withstand use at higher temperatures. Specialty thermoplastics are designed for a greater variety of performance and applications. Thermoplastic elastomers can be processed like thermoplastics, and give many of the properties of conventional thermoset vulcanized rubbers. Thermoset plastics are permanently cross-linked during processing, generally to give higher performance than would be possible with linear thermoplastics.

Commodity Thermoplastics

Seven families of thermoplastics exceed a billion pounds per year in the United States: polyethylenes, polypropylene, PVC, polystyrene and its copolymers, polyethylene terephthalate, acrylonitrile-butadiene-styrene (ABS), and nylon.

Table 15.2 Major members of the polyethylene family: typical properties

Polyethylene	HDPE	LLDPE	LDPE
Density	0.96	0.93	0.92
Melting point (°C)	130	124	108
Modulus (MPa)[a]	1,400	450	180
Tensile strength (MPa)[a]	26	14	12

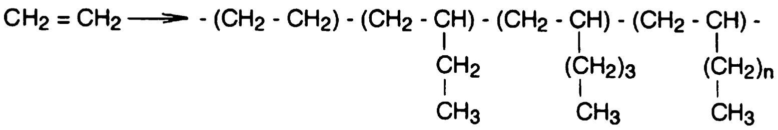
[a] To convert to psi, multiply by 145

Polyethylenes. The major members of the polyethylene family are distinguished primarily by the amount of side-branching, which decreases regularity, crystallinity, density, melting point, modulus (rigidity), and strength (Table 15.2).

High-Density Polyethylene (HDPE). Polymerization of ethylene to polyethylenes is most often carried out at low temperature and pressure, using either the Ziegler aluminum triethyl plus titanium tetrachloride catalyst system, the Phillips chromic oxide plus silica plus alumina system, or more recently the newer metallocene single-site catalyst systems. This produces a regular, linear polymer which is 50–90% crystalline, making it rigid and strong. Its largest use is blow-molded bottles for milk, water, juice, noncarbonated drinks, laundry detergent, antifreeze, and motor oil. Other large uses are large molded containers, pipe and conduit, and shopping bags. For detergent bottles, environmental stress-crack resistance is increased by increasing molecular weight, adding ethylene/propylene rubber (EPR), or copolymerization with a small amount (1–2%) of L-butene to reduce crystallinity. For auto gasoline tanks, impermeability may be increased by dispersing nylon in the polyethylene. For extreme abrasion resistance in materials-handling machinery, and in hip and knee bone replacement, Ultra-High Molecular Weight (UHMWPE: MW 3–6 × 10^6) is outstanding.

$$n\mathrm{CH_2{=}CH_2} \rightarrow -(\mathrm{CH_2{-}CH_2})_n-$$

Low-Density Polyethylene (LDPE). Polyethylene was originally made by polymerization at high temperature and pressure; during the polymerization, side-reactions produced several percent of short-chain branching (ethyl and butyl groups), which reduced regularity/crystallinity (e.g., to 30–40%) and gave a stiffly flexible plastic material; chain transfer reactions also produced some long-chain branching, which gave pseudoplastic melt processability, important in the production of extruded blown film. The largest use is in packaging film; the second largest is for coating and laminating on cardboard, paper, and foil.

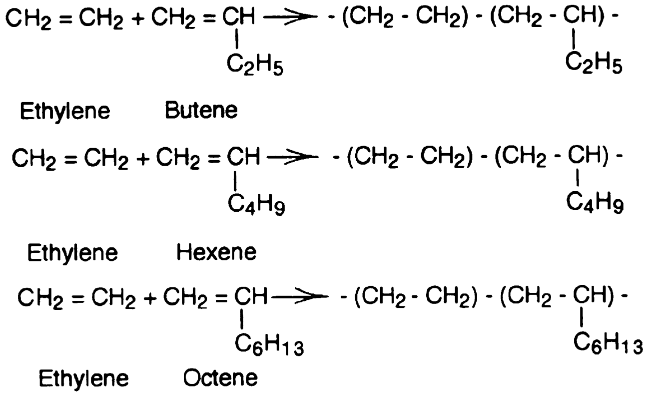


$$\mathrm{CH_2{=}CH_2} \longrightarrow -(\mathrm{CH_2{-}CH_2})-(\mathrm{CH_2}-\underset{\underset{\mathrm{CH_3}}{|}}{\underset{\mathrm{CH_2}}{\underset{|}{\mathrm{CH}}}})-(\mathrm{CH_2}-\underset{\underset{\mathrm{CH_3}}{|}}{\underset{(\mathrm{CH_2})_3}{\underset{|}{\mathrm{CH}}}})-(\mathrm{CH_2}-\underset{\underset{\mathrm{CH_3}}{|}}{\underset{(\mathrm{CH_2})_n}{\underset{|}{\mathrm{CH}}}})-$$

Table 15.3 Typical properties of polypropylenes

Type	General purpose	High impact	40 % Talc	40 % Glass fiber
Modulus (MPa)	1,450	1,100	3,100	7,000
Tensile strength (MPa)	36		32	70
Ultimate elongation (%)	500		10	2
Notched Izod impact strength (J/cm)	1.1	5.6	1.3	3.9
Heat deflection temperature (°C at 1.82 MPa)	57	53	79	149

Linear Low-Density Polyethylene (LLDPE). Ziegler and metallocene polyethylene can be modified by copolymerization with several percent (e.g., 10%) of butene, hexene, or octene, to reduce the regularity/crystallinity and modulus, and thus produce LDPE at low temperature and pressure. The resulting LLDPE is stronger than the original LDPE, and therefore preferred for packaging film and trashcan liners. Lack of long-chain branching makes it difficult for extrusion-blown film, so processors add enough LDPE to improve processability.



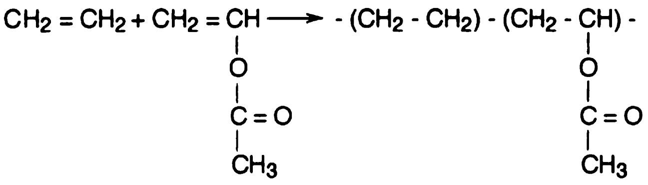
$CH_2=CH_2 + CH_2=\underset{C_2H_5}{CH} \longrightarrow -(CH_2-CH_2)-(CH_2-\underset{C_2H_5}{CH})-$

$CH_2=CH_2 + CH_2=\underset{C_4H_9}{CH} \longrightarrow -(CH_2-CH_2)-(CH_2-\underset{C_4H_9}{CH})-$

$CH_2=CH_2 + CH_2=\underset{C_6H_{13}}{CH} \longrightarrow -(CH_2-CH_2)-(CH_2-\underset{C_6H_{13}}{CH})-$

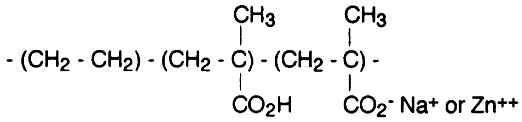
Very Low Density (VLDPE) and Ultra Low Density (ULDPE) Polyethylenes. These are made by copolymerization with increasing amounts of comonomers, especially 1-octene, reducing the regularity/crystallinity (density 0.91–0.86) down toward EPR. These are soft and flexible enough to compete with plasticized polyvinyl chloride and thermoplastic elastomers in some applications.

Ethylene/Vinyl Acetate Copolymers (EVA). LDPE is easily internally plasticized by copolymerization with increasing amounts (2–20%) of vinyl acetate comonomer. This reduces the regularity/crystallinity (melting points 108–70°C), resulting in increasing softness/flexibility (modulus 138–19 MPa), transparency, and polar adhesion, again competing with plasticized PVC and thermoplastic elastomers, particularly in packaging film, coatings, and adhesives.



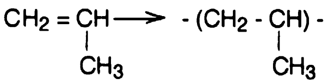
$CH_2=CH_2 + CH_2=\underset{\substack{|\\O\\|\\C=O\\|\\CH_3}}{CH} \longrightarrow -(CH_2-CH_2)-(CH_2-\underset{\substack{|\\O\\|\\C=O\\|\\CH_3}}{CH})-$

Ionomers are generally ethylene copolymers with 5–10% of methacrylic acid, partially-neutralized by sodium or zinc. This reduces the regularity/crystallinity, increasing the softness/flexibility (modulus 250 MPa) and transparency. The ionic groups increase strength (20 MPa) and polar adhesion, again competing with plasticized PVC and thermoplastic elastomers, particularly in packaging films and sporting goods.



$-(CH_2-CH_2)-(CH_2-\overset{CH_3}{\underset{CO_2H}{C}})-(CH_2-\overset{CH_3}{\underset{CO_2^-\ Na^+\ \text{or}\ Zn^{++}}{C}})-$

Polypropylene. Polymerization of propylene to polypropylene (Table 15.3) produces an asymmetric carbon atom, which can be either right-handed or left-handed. Peroxide initiation of free radical polymerization produces a random ("atactic") mixture of right- and left-handed carbon atoms, which is too irregular to crystallize, so the resulting polymer is a soft gummy rubber. Ziegler triethyl aluminum plus titanium chloride catalysis of polymerization pre-orients each monomer unit before inserting it into the polymer chain, and produces an all-right-handed or all-left-handed ("isotactic") polymer, which is very regular and therefore able to crystallize (e.g., 60%). This is a high-melting (165°C), rigid, strong, low-cost commodity plastic, very competitive with more costly polystyrene and ABS. Another unique quality is its ability to form an "integral hinge," so that a rigid packaging container plus lid can be molded as a single part.

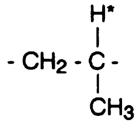


$CH_2=\underset{CH_3}{CH} \longrightarrow -(CH_2-\underset{CH_3}{CH})-$

Table 15.4 Typical properties of rigid PVC

Type	General purpose	High impact	30 % Glass fiber	Chlorinated PVC
Modulus (MPa)	3,300	2,900	8,300	2,800
Tensile strength (MPa)	48	43	90	56
Ultimate elongation (%)	145	130	2	35
Notched Izod impact strength (J/cm)	0.32	8.56	0.70	0.91
Heat deflection temperature (°C at 1.82 MPa)	67	66	76	103

Polypropylene has two major weaknesses: (1) Methyl branching leaves tertiary hydrogen atoms, which are sensitive to thermal oxidative aging.

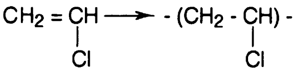


$$-CH_2-\overset{H^*}{\underset{CH_3}{C}}-$$

(2) Bulky methyl groups cause steric hindrance and stiffen the polymer molecule; while this increases modulus, it also causes embrittlement below room temperature. The polypropylene industry has successfully retarded aging by adding phenolic and aliphatic sulfide antioxidants; and it has reduced low-temperature embrittlement by adding or grafting ethylene–propylene–diene (EPDM) rubber. A third common improvement is the addition of fillers to increase rigidity, making it even more competitive with polystyrene.

With these problems solved, polypropylene use has been growing rapidly. Extrusion and stretch orientation produces excellent synthetic fiber for carpeting and synthetic turf, and excellent film for packaging. Other large uses are rigid packaging (replacing polystyrene), automotive parts (replacing ABS), and a great variety of injection-molded consumer products.

Polyvinyl Chloride (Table 15.4). This is the most versatile of the commercial thermoplastic polymers. It is used mainly for rigid and flexible plastics, for rubberlike products, for coatings on steel, cloth, and paper, and in smaller amounts for specialty fibers. It is processed mainly by extrusion and calendering, and in smaller amounts by injection, compression, and blow molding, thermoforming, rotomolding, plastisol/organosol technology, casting, pouring, and foaming. This extreme versatility comes primarily from the use of plasticizers, aided by a host of other types of additives.



$$CH_2=\underset{Cl}{CH} \longrightarrow -(CH_2-\underset{Cl}{CH})-$$

Table 15.5 Typical properties of flexible PVC

Plasticizer	Dioctyl phthalate			Dioctyl adipate		
Parts/hundred of resin	30	50	75	30	50	70

Tensile strength (MPa)	31	21	14	27	20	14
Ultimate elongation (%)	220	300	400	270	395	410
Flex temperature (°C)	+20	0	−26	−15	−48	−75

Vinyl chloride is polymerized primarily by peroxide-initiated polymerization in aqueous suspension, producing a fine porous powder which is easy to blend with compounding ingredients. A smaller amount is polymerized in emulsion and spray-dried for plastisols and organosols and an even smaller amount is copolymerized with vinyl acetate in organic solution, to produce a uniform copolymer which precipitates at a constant composition and molecular weight.

Rigid PVC is polymerized at 55–70°C and then compounded with an organotin stabilizer, acrylic processing aids, lubricants, and optionally with a rubbery impact modifier.

The polymer has high modulus, strength, and resistance to creep, weathering, and chemicals; and compounding with rubbery impact modifiers produces high resistance to brittle failure. It is mainly extruded into pipe, house-siding, and window and door frames, while smaller amounts are injection molded into pipe fittings and blow-molded into bottles for detergents and other chemicals.

Flexible PVC (Table 15.5) is made by polymerizing at 40–55°C and then compounding with 20–80 PHR (parts per hundred of resin) of dioctyl phthalate and/or other monomeric liquid plasticizers (e.g., dioctyl adipate for low-temperature flexibility, oligomeric polyesters for permanence, organic phosphates for flame-retardance), plus a synergistic stabilizer system usually composed of barium or calcium soap, zinc soap, epoxidized fatty ester, and organic phosphite.

This flexible-rubbery material is most often calendered into film and sheet for clothing, luggage, raincoats, upholstery, and flooring, or extruded into garden hose, wire and cable insulation, and medical tubing.

For plastisol/organosol technology, high molecular weight PVC powder is slurried in liquid plasticizer, and poured, dip- or spread-coated onto metal, fabric, or paper to produce dishwasher racks, upholstery, and wallpaper, respectively.

The excellent combustion resistance is one of the most important properties of PVC. The good flame resistance results from the releasing of HCl gas during the combustion of PVC, which is denser than air thus restricts air from reaching the flame. Therefore, PVC occupies around 60%

Table 15.6 Typical properties of polystyrenes

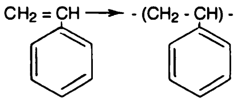
		Impact styrene		
Polymer	Polystyrene	Moderate	Very high	Styrene acrylonitrile
Modulus (MPa)	2,900	1,700	1,100	3,500
Tensile strength (MPa)	46	21	13	73
Notched Izod impact strength (J/cm)	0.17	1.28	3.70	0.26
Heat deflection temperature (°C at 1.82 MPa)	83	81	81	100

of the flame resistant wire and cable plastic market. The good weatherability, easy processing, and high combustion resistance contribute to PVC occupying around 70% of the construction market for plastics. Also, PVC's outstanding capabilities in the plastisol process allow them to serve 25% of the coating market, such as the metal structure coating for dishwasher racks and flooring for wet kitchen and bathroom areas. PVC also has excellent resistance to acids, bases, oils, and other hydrocarbons. This property permits PVC to be widely used in parts for the chemical processing industries. Again, because of the excellent combustion properties, PVC has a large share of the market in electrical enclosures, which requires the materials have the flame resistance with UL 94V-0 ratings [49].

Regardless of their excellent combustion resistance, which can be used to protect people to avoid the loss of life in a fire, the environmentalist groups would like to eliminate the halogen products. Although European market has increasing demand for halogen-free flame-retardant, the fires caused by television set have increased in Europe [50].

There are many suppliers of PVC compounds. The major suppliers include Shin-Etsu, Formosa Plastics Corp., Solvay, Atofina, Georgia Gulf, LG Chem etc.

Polystyrene and Its Copolymers. Polystyrene (Table 15.6) is made by continuous bulk polymerization, initiated by peroxides and heat, with temperature rising continuously to keep the system molten, and optionally adding solvent ("solution polymerization") to facilitate the process. It was the first commodity thermoplastic, combining easy melt processability, rigidity, and glass-like transparency for major applications in packaging, toys, and housewares. When swollen with 10% pentane and heated, it expands to rigid closed-cell foams with densities as low as 0.01 (expanded polystyrene or EPS), which are popular for packaging hot and cold foods, delicate instruments and appliances.

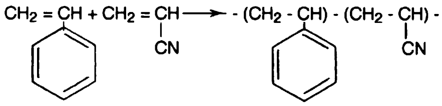


The major weaknesses of polystyrene are brittleness and softening in hot water. Brittleness is remedied by dissolving 2–10% of rubber in styrene monomer before polymerization, producing "high-impact styrene" (HIPS), in which 10-μm rubber particles improve impact strength by an order of magnitude, with some sacrifice of other mechanical properties and transparency; this accounts for more than half of the total "polystyrene" market.

Table 15.7 Typical properties of acrylonitrile-butadiene-styrene (ABS)

Type	Moderate impact	Very high impact
Modulus (MPa)	2,500	2,000
Tensile strength (MPa)	46	38
Notched Izod impact strength (J/cm)	3.5	9.0
Heat deflection temperature (°C at 1.82 MPa)	94	88

Heat resistance is improved by copolymerization with 15–30% of acrylonitrile, producing styrene/acrylonitrile (SAN). Polarity and hydrogen bonding stiffen the polymer molecule, improving mechanical properties and especially resistance to hot water. This improvement is useful in household products, autos, and appliances.



Acrylonitrile/Butadiene/Styrene (ABS). The benefits of impact styrene and SAN are combined in ABS (Table 15.7). Typically, 15–30% acrylonitrile and 45–75% styrene are copolymerized in the presence of 5–30% of polybutadiene rubber, producing some graft terpolymer, and dispersing 1-μm rubber domains in an SAN matrix.

This balance of properties has found particular usefulness in appliances, autos, electronic equipment cabinets, and rain-waste-vent (DWV) pipe.

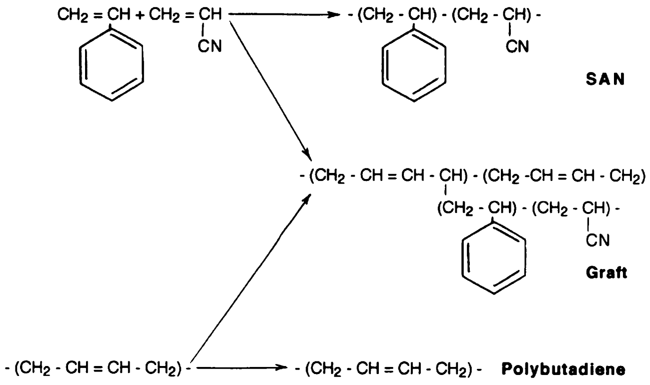


Table 15.8 Typical properties of PET

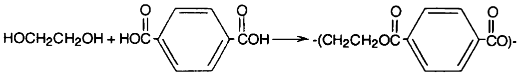
Form	Fiber	Film	Bottles	Reinforced molding 15 % Glass fiber	55 % Glass fiber
Modulus (MPa)		3,600	3,200	5,900	18,000
Tensile strength (MPa)	550	200	120	110	200
Ultimate elongation (%)	29	125		2	1
Notched Izod impact strength (J/cm)				0.64	1.07
Heat deflection temperature (°C at 1.82 MPa)				210	229

Other styrene-based copolymers. The commercial success of ABS has led to the development of other styrene-based copolymers to overcome the disadvantages of ABS, such as poor weathering resistance and lack of transparency. For example, methacrylate-butadiene styrene (MBS) is another typical styrene-based copolymer. In MBS, methyl methacrylate and styrene are grafted onto the polybutadiene backbone. This structure results in two advantages over ABS: higher clarity and better resistance to the discoloration in the presence of ultraviolet light. The disadvantages of MBS over ABS are lower tensile strength and heat deflection temperatures (HDT). The better aging of MBS comes from the inhibition or retardation of methyl methacrylate on the oxidative attack at the double bonds in the polybutadiene backbone. The further improved weathering resistance of styrene polymers has been developed by replacing butadiene rubber with an ethylene-propylene terpolymer rubber of the EPDM type. EPDM rubber has a small amount of a diene monomer in the polymerization formulation. In addition to the higher clarity of MBS, transparent polystyrene polymers with high impact strength are produced by blending polystyrene and styrene-butadiene-styrene (SBS) block copolymers. The SBS block copolymers can be either star or linear shapes. The optical properties depend on the ratio of polystyrene to SBS, the presence of additives, and the processing conditions etc. 1,2-Polybutadiene can also be blended with polystyrene to achieve high impact materials with a degree of transparency. The careful control of processing conditions has to be done to avoid excess cross-linking [51].

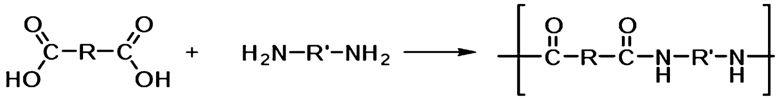
Styrenic poly(phenylene oxides) (PPO) is another important styrene-based engineering material. Its production is about one-tenth that for ABS. This material has useful characteristics similar to polystyrene including good dimensional stability, low water absorption and excellent dielectric properties. In addition, it has higher heat distortion temperatures than PS. Some grades have heat distortion temperatures up to 160°C. More interestingly, it has lower price than heat-resistant materials, such as polycarbonate and polysulphones. Styrenic PPO has applications in the areas, such as autos, electronics, pumps and other plumbing applications [51].

Polyethylene Terephthalate. PET (Table 15.8) is produced by continuous melt condensation polymerization of ethylene glycol plus terephthalic acid, followed by solid-state finish to reach high molecular weight and high purity. It was originally developed for synthetic fibers, replacing cotton as the leading textile fiber worldwide. Later it became popular in packaging film (e.g., boil-in-bag) and magnetic tape because of its high strength, cling, melting point, impermeability, and clarity. Finally, it became the basic material for blow-molding bottles for carbonated beverages, after which it proved completely recyclable into bulk fiber for bedding, furniture, and clothing. More specialized engineering grades for solid molding applications are generally reinforced by short glass fibers.

Although PET has achieved commercial significance for the bottles, films, and fibers etc., it is also being increasingly modified by copolymerizing with isophthalic acid (IPA), cyclohexanedimenthanol (CHDM) or other components to improve the toughness, clarity, water and weathering resistance, and barrier properties. Such commercial products include Kodar, Vestan, and A-Tell.



Nylon. Nylons (Table 15.9) are made of repeating amide units and are frequently referred to as polyamide (PA). The general reaction is the condensation polymerization of diamine and dicarboxylic acid. They can also be polymerized by the self-condensation of an amino acid or ring-opening polymerization of a lactam. A nylon made from diamine and dicarboxylic acid is called Nylon *x*,*y*, where *x* and *y* represent the number of carbons in the diamine chain and dicarboxylic acid chain, respectively. A nylon made from either an amino acid or a lactam is designated Nylon *x*, where *x* is the carbon numbers in the repeating units [52].



$$HO-\overset{O}{\overset{\|}{C}}-R-\overset{O}{\overset{\|}{C}}-OH + H_2N-R'-NH_2 \longrightarrow \left[-\overset{O}{\overset{\|}{C}}-R-\overset{O}{\overset{\|}{C}}-\underset{H}{N}-R'-\underset{H}{N}-\right]$$

Table 15.9 Typical properties of nylon [53]

Type	Nylon 11	Nylon 12	Nylon 46	Nylon 6	Nylon 610	Nylon 612	Nylon 66

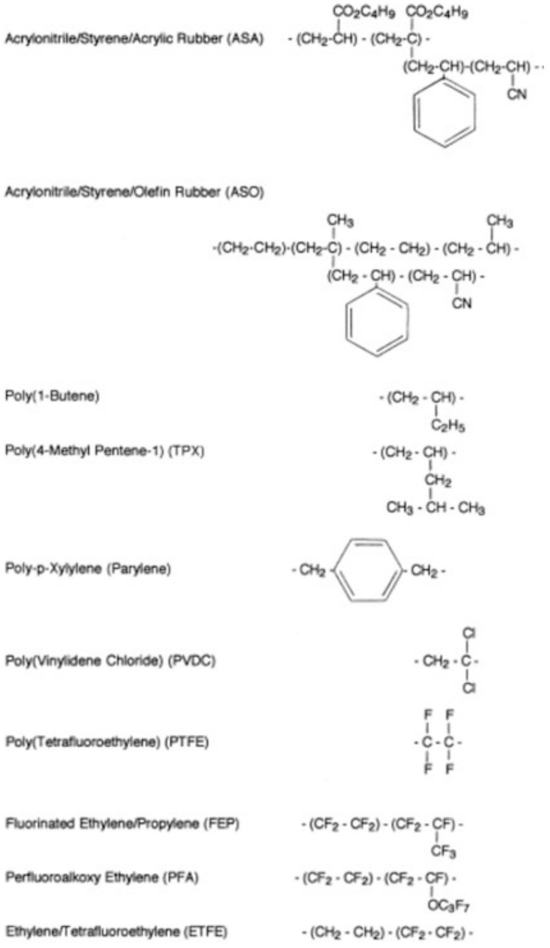
Nylon contains the polar –CONH– groups spaced at regular intervals, which give rise to nylon crystalline structures with a high intermolecular attraction. The aliphatic chain segments give nylon flexibility in the amorphous regions. This combination leads to nylon being characterized by high toughness, modulus, strength, abrasion resistance, flexibility, rigidity, and good hydrocarbon resistance. Because the polar –CONH– group absorbs water, they are generally not suitable for applications in humid conditions but they are quite good electrical insulators at room temperature in dry conditions and low frequencies.

There are a variety of commercial nylons available. In the nylon family, Nylon 6,6 is the most common commercial grade of nylon and Nylon 6 is the most common commercial grade of molded nylon. Nylons are most often used in the form as fibers, which account for almost 90% of the nylon production in the world. Nylon 6,6 and nylon 6 account for almost all of the polyamide in fiber applications. Nylon fibers are used in many applications including fabrics, bridal veils, carpets, hose and belt reinforcement, musical strings, tire cord and rope. The other 10% of nylon production goes into plastics applications. The largest application of solid nylon is for mechanical parts, such as machine screws, gears, cams, bearings, bushes, and other low- to medium-stress components previously cast in metal. Other applications for nylons include sterilizable nylon moldings in medicine and pharmacy, fishing line, package film, and brush bristles. Because of their excellent properties, nylons have found increasing applications in specialty purposes in spite of their relatively higher cost compared to the general purpose materials, such as polystyrene and polyethylene. Glass fiber reinforced nylons occupy the largest market among the glass filled variety of thermoplastics. Glass fiber reinforced nylons have high rigidity, heat deflection temperature and creep resistance, low coefficient of friction, good low-frequency electric insulation properties and nonmagnetic characteristics. All of these excellent properties enable them to be widely used in a range of applications including housings, casings, car components, domestic appliances, and the aerospace and telecommunications fields [54].

In summary, commodity thermoplastics are manufactured readily at low cost, and offer a combination of processability, mechanical, thermal, optical, and chemical properties that are useful in a wide range of mass markets and products.

Engineering and Specialty Thermoplastics

Many present and future applications of thermoplastics make greater demands for higher properties and especially combinations of properties, than are available from the commodity materials. To satisfy these demands, organic polymer chemists and chemical engineers have developed and commercialized over four dozen major types of polymers, offering many improved properties to meet these demands. They may be listed as follows, and then compared in their abilities to satisfy these requirements.



Chlorotrifluoroethylene (CTFE)

$-(\overset{\overset{Cl}{|}}{C}F-CF_2)-$

Ethylene/Chlorotrifluoroethylene (ECTFE)

$-(CH_2-CH_2)-(\overset{\overset{Cl}{|}}{C}F-CF_2)-$

Poly(Vinylidene Fluoride) (PVDF) $-(CH_2-CF_2)-$

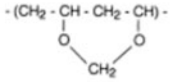
Poly(Vinyl Fluoride) (PVF)

$-(CH_2-\underset{\underset{F}{|}}{C}H)-$

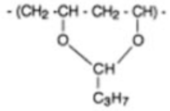
Ethylene/Vinyl Alcohol (EVAL or EVOH)

$-(CH_2-CH_2)-(CH_2-\underset{\underset{OH}{|}}{C}H)-$

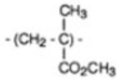
Poly(Vinyl Formal)



Poly(Vinyl Butyral)



Poly(Methyl Methacrylate) (PMMA)

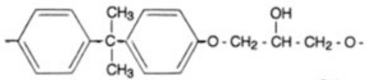


$-(CH_2-\overset{\overset{CH_3}{|}}{\underset{\underset{CO_2CH_3}{|}}{C}})-$

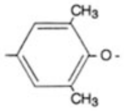
Poly(Acrylonitrile) (PAN)

$-(CH_2-\underset{\underset{CN}{|}}{C}H)-$

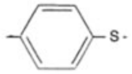
Phenoxy Resin



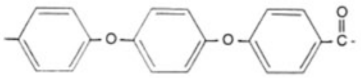
Poly(Phenylene Ether) (PPE or PPO)



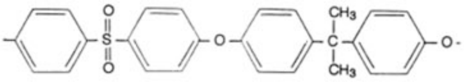
Poly(Phenylene Sulfide) (PPS)



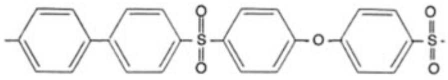
Poly(Ether Ether Ketone) (PEEK)



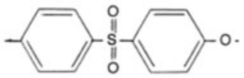
Polysulfone (Udel)



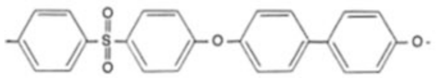
Polyaryl Sulfone



Polyether Sulfone

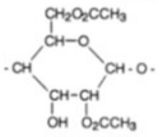


Polyphenyl Sulfone (Radel)

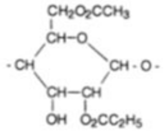


Poly(Oxymethylene) (Polyacetal) $-(CH_2-O)-$

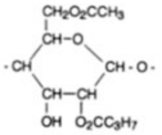
Cellulose Acetate (CA)



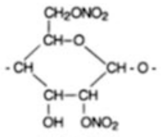
Cellulose Acetate/Propionate (CAP)



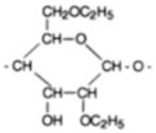
Cellulose Acetate/Butyrate (CAB)



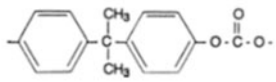
Cellulose Nitrate



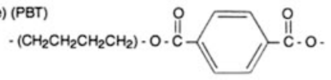
Ethyl Cellulose (EC)



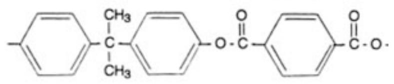
Polycarbonate (PC)



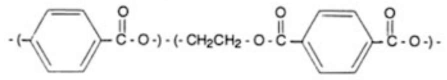
Poly(Butylene Terephthalate) (PBT)



Polyarylate



Liquid Crystal Polyesters (LCP)



Nylon 6 (PA6)

$-CH_2CH_2CH_2CH_2CH_2\overset{\overset{O}{\|}}{C}-\overset{\overset{H}{|}}{N}-$

Nylon 66 (PA66)

$-CH_2CH_2CH_2CH_2CH_2CH_2\overset{\overset{H}{|}}{N}-\overset{\overset{O}{\|}}{C}CH_2CH_2CH_2CH_2\overset{\overset{O}{\|}}{C}-\overset{\overset{H}{|}}{N}-$

Nylon 69 (PA69)

$-(CH_2)_6\overset{\overset{H}{|}}{N}-\overset{\overset{O}{\|}}{C}(CH_2)_7\overset{\overset{O}{\|}}{C}-\overset{\overset{H}{|}}{N}-$

Nylon 610 (PA610)

$-(CH_2)_6\overset{\overset{H}{|}}{N}-\overset{\overset{O}{\|}}{C}(CH_2)_8\overset{\overset{O}{\|}}{C}-\overset{\overset{H}{|}}{N}-$

Nylon 612 (PA612)

$-(CH_2)_6\overset{\overset{H}{|}}{N}-\overset{\overset{O}{\|}}{C}(CH_2)_{10}\overset{\overset{O}{\|}}{C}-\overset{\overset{H}{|}}{N}-$

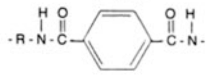
Nylon 11 (PA11)

$-(CH_2)_{10}\overset{\overset{O}{\|}}{C}-\overset{\overset{H}{|}}{N}-$

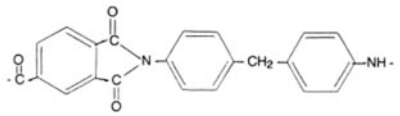
Nylon 12 (PA12)

$-(CH_2)_{11}\overset{\overset{O}{\|}}{C}-\overset{\overset{H}{|}}{N}-$

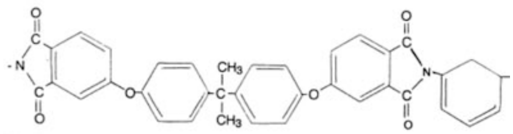
Poly(Phthalamide) (PPA)



Poly(Amide Imide) (PAI)



Poly(Ether Imide) (PEI)



Poly(Ether Imide) (PEI)

Polycarbonate		130	

The leading materials, in terms of market volume, are: nylon, polycarbonate, polybutylene terephthalate, polyphenylene ether, polyoxymethylene, and polyethylene terephthalate.

Perhaps even more important than their structures, most of these polymers are frequently reinforced by glass fibers or even carbon fibers, which contribute tremendously to their properties, and must be considered in any comparison of their practical performance. Reinforcing fibers generally raise modulus two to fourfold and usually increase breaking strength somewhat. In crystalline plastics, they often raise maximum use temperatures dramatically.

Maximum Use Temperature. The most frequent requirement for higher engineering performance is retention of properties at higher temperatures. Whereas most commodity thermoplastics soften and distort in boiling water, engineering thermoplastics are most often characterized by their ability to stand much higher temperatures. This is measured most often by the short-term HDT under a load of 1.82 MPa, less often but perhaps more practically by an estimated Continuous Service Temperature (CST) in long-term use (Table 15.10).

Major applications are primarily in electrical and electronic products, auto parts, industrial products, and appliances.

Impact Strength. When plastics are compared with metals and wood, they often fail under high-speed impact. Flexible molecules, such as nylons have some inherent impact strength. Of the rigid molecules, only polycarbonate and polyphenyl sulfone combine inherent rigidity and high impact strength. Most plastics can be reinforced with long fibers to increase their impact strength, but processing becomes much more difficult. Some plastics have been toughened by dispersing tiny rubber domains in them, and this technique is currently expanding with the development of compatibilization technology. One unique material is poly (1-butene), whose high creep- and puncture-resistance make it particularly desirable in pipe and tubing.

Transparency. Some applications of plastics require transparency. Amorphous plastics should be able to transmit light. Some factors which prevent transparency include unsaturation/light absorption, crystallinity, fillers and reinforcing fibers, and use of rubber particles to increase impact strength. The plastics most often used for their transparency are poly(4-methylpentene-1) (TPX), poly(methyl methacrylate) (almost equal to glass), cellulose acetate, propionate, and butyrate, polycarbonate, and polysulfones (slightly yellow). The advent of nanoscale fillers offers the potential for transparent filled materials, provided the fillers are adequately dispersed.

Processability. Engineering performance generally requires rigid molecules to give maximum rigidity, strength, and high temperature performance. Melt processability, on the other hand, generally requires flexible molecules to give a fluid melt. Several polymers that manage to combine easy melt processability with high rigidity/strength/heat resistance, include nylons, polyoxymethylene (polyacetal), and liquid crystal polymers. The first two combine flexible molecules in the melt, plus high crystallinity in the solid form. The molecular rigidity of liquid crystal polymers explains their high modulus and strength, but they also have easy melt processability.

Lubricity. Plastic gears and bearings are less polar than metals and therefore are relatively self-lubricating, without the need for lubricating oil. Ultra-high molecular weight polyethylene, fluoropolymers, polyoxymethylene (polyacetal), and nylons are the best. To improve other plastics even further, adding powdered polytetrafluoroethylene to them can produce an even greater increase in lubricity, and simultaneously also an increase in abrasion resistance.

Barrier Plastics. When plastics replace metals and glass in packaging, their permeability is often a limiting property. Barrier performance generally increases with density and crystallinity. The most promising barrier plastics include ethylene/vinyl alcohol, polyvinylidene chloride, polyacrylonitrile, and polyethylene naphthoate. These are used most efficiently by laminating them to commodity plastics such as polyethylene and polyethylene terephthalate. The use of nanoclay fillers has also shown improved barrier materials.

Weather-Resistance. For long-lived outdoor products, most plastics can be stabilized somewhat by opaque UV reflectors or at least dissolved UV stabilizers. For inherent resistance to sunlight, rain, and other components of weather, some preferred plastics include acrylonitrile/styrene/acrylic rubber, acrylonitrile/styrene/ethylene-propylene rubber, polyvinyl chloride, fluoropolymers, and polymethyl methacrylate.

Chemical Resistance. Plastics are generally superior to metals in resistance to aqueous inorganic environments. Their resistance to organic solvents depends mainly on crystallinity and difference in polarity: nonpolar polymers are more resistant to polar organics, while polar polymers are more resistant to nonpolar organics.

Table 15.11 Major end use market, 2008

Market	Millions of pounds

Adhesives/inks/coatings	937
All other	1,375
Exports	11,962
Total	*74,156*

Individual Specialties. There are a number of special plastics, which are used for their individual special properties and applications. TPX combines rigidity, impact resistance, heat resistance, transparency, and chemical resistance, making it a unique replacement for glass in chemical equipment. Poly-*p*-xylylene is an extreme specialty coating, applied by vapor deposition to produce thin uniform films for electrical insulation. Polyvinyl formal is used in specialty wire coating. Polyvinyl butyral offers high toughness, adhesion, and clarity, which make it the critical component in safety glass. Phenoxy resin was one of the first engineering plastics, offering a combination of processability, rigidity, strength, toughness, transparency, adhesion, and chemical resistance; its present use is primarily in coatings and adhesives. Cellulose nitrate was the first commercial plastic; its present uses are primarily as high quality coatings on wood furniture and leather goods. Ethyl cellulose is a very tough transparent adhesive material, mainly used in coating bowling pins and specialty papers. Many other commercial polymers are more important in nonplastic applications such as rubber, textiles, paper, coatings, and adhesives (see Table 15.11).

Biopolymers

An alternative source for plastics is animal and vegetable matter. These biobased feedstocks are viable because plastics, chemicals, and petrochemicals currently account for only 2.1% of fossil fuel usage. Therefore, unlike biofuels, they will not affect food prices. Moreover, using biodegradable, biobased plastics (biopolymers)—along with improved recycling systems—can reduce the reviled plastics trash, especially in packaging. In the long term, the potential production of plastics from algae can also reduce green house gases.

Biopolymers, however, create new issues for the scientists and engineers who will use them. First, not all biobased polymers are biodegradable. Second, these bioplastics are far behind petroleum-based plastics in terms of performance and processibility. Third, the properties of biobased polymers tend to vary with the source matter, process, location, and year. Fourth, most biobased polymers are currently more expensive than their fossil fuel-based counterparts; so, noneconomic factors must be considered when specifying these materials for a product.

Depending on the synthesis process and sources, biobased and biodegradable polymers can be classified into four different categories [55]: (1) polymers from biomass such as the agro-polymers from agro-resources; (a) polysaccharides, e.g., starches (wheat, potatoes, maize) [56], ligno-cellulosic products (wood, straws, . . .) [57] and others (pectins, chitosan/chitin, gums) [58]; (b) protein and lipids, e.g., animals (casein, whey, collagen/gelatin) [59–63], and plants (zein, soya and gluten) [64]; (2) polymers obtained by microbial production, e.g., polyhydroxyalkanoates (PHA) such as poly(hydroxybutyrate) (PHB) and poly(hydroxybutyrate cohydroxyvalerate) (PHBv); (3) polymers chemically synthesized using monomers obtained from agro-resources, e.g., poly(lactic acid) (PLA); (4) polymers whose monomers and polymers are both obtained by chemical synthesis from fossil resources, e.g., polycaprolactones (PCL), polyesteramides (PEA), aliphatic co-polyesters (e.g., PBSA), and aromatic co-polyesters (e.g., PBAT). While all of the categories are biodegradable only the first three categories are obtained from renewable resources.

Until recently, biobased were the product of a biosynthetic process. That is, either from natural sources such as plants, animals or microorganisms (e.g., algae) by an extraction process. Today, chemical synthesis can be used on a biopolymer as a starting material leading to a monomer which is then again transformed to a biopolymer by a chemical polymerization process. PLA, a thermoplastic that is derived from corn, as produced by Cargill-Dow Inc. is a well-known example [65]. The plastic coffee mug shown in Fig. 15.26 is produced from PLA.

Companies such as Natureworks LLC and Metabolix have manufacturing facilities capable of producing 300 million pounds (140,000 metric tons) of PLA. Natureworks is the first company to offer a family of commercially available low carbon footprint polymers derived from 100% annually renewable resources with cost and performance that compete with oil-based plastics and fibers. Although both synthetic and biobased routes are known to produce resins of fairly consistent properties, the variability in properties with biobased sources is much higher than resins made from petroleum-based sources. As such, these biobased polymers are not fully competitive with conventional thermoplastics since their properties maybe too weak and/or are difficult to process. Therefore to extend the range of their applications, many biobased polymers are reformulated to include nanoclay fillers for the development of biorenewable nanocomposites with improved properties (e.g., stiffness and permeability) and processability [66].

Fig. 15.26 Poly(lactic acid) (PLA), a thermoplastic derived from corn

In summary, biopolymers have moved beyond the limitations of first generation products and technologies with improved processability and compostability, better cost positions, and an expanding customer base. Today's biobased and biodegradable polymers are proving to be economically feasible and environmentally advantageous. They have already succeeded in packaging and fibers, and are entering the automotive, medical, and consumer electronics markets. Global demand for these polymers is expected to reach $6 billion by 2015.

Thermoplastic Elastomers

Soft flexible-rubbery behavior depends on long flexible polymer molecules in the form of random coils. Strength, heat, and chemical resistance depend on attachment between the coils. Conventional rubber chemistry uses vulcanization, permanent thermoset primary covalent cross-links, usually by sulfur or peroxide, to hold the chains together; but this makes processing and recycling more difficult. In the past 40 years, this technology has been supplemented by the development of thermoplastic elastomers. These are based mainly on block copolymers, in which long flexible blocks form the continuous rubbery matrix, and short glassy or crystalline blocks form the thermoplastic "cross-links," secondary attractions that give strength, heat, and chemical resistance. Once heated these blocks (domains) melt and can be processed. Upon cooling the materials phase separate and

Table 15.12 Typical properties ranges of thermoplastic elastomers [67]

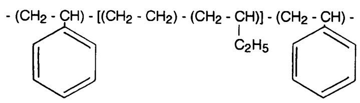
TPE type	Shore hardness	Tensile strength (MPa)	Ultimate elongation (%)	Low temperature limit (°C)	High temperature limit (°C)
Styrenics	5A-60D	1.7–12	400–1,840	−60 to −90	95
Rubber-polyolefin blends	50A-65D	5.4–15	80–940	−60	165
Thermoplastic vulcanizates (TPV)	35A-80D	4–12	375–650	−60	165
Thermoplastic polyurethanes	60A-85D	14–52	250–870	−40 to −60	190
Thermoplastic co-polyesters	90A-72D	14–46	250–550	−40 to −60	185–220
Thermoplastic polyamides	25D-63D	29–49	300–680	−40 to −60	220–275

the glassy or crystalline domains solidify and act as tie points or physical cross-links. These are much more attractive to the plastics processing industry, offering easy thermoplastic processing and good recyclability. They are the fastest growing sector of the elastomers market. There are six major families of commercial thermoplastic elastomers (Table 15.12).

The classes are divided by the type of hard block (segment) used to act as a physical cross-link. In each of the families, the ratio of rubbery soft block to glassy or crystalline hard block, can be varied to give a wide range in properties. The lower temperature range is dependent on the type of elastomer block used, while the high temperature properties are controlled by the hard block type [68].

Styrenic Block Copolymers. These ("styrenic") thermoplastic elastomers are block copolymers of styrene with butadiene (SBS) or isoprene (SIS) in about 30/70 monomer ratio.

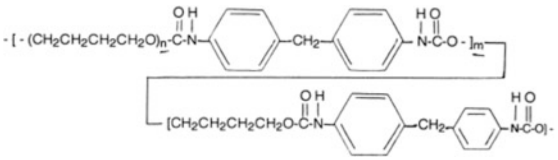
The elastomer segment give the rubbery properties and the glassy polystyrene domains hold the rubber chains together up to the softening point of polystyrene. Since the unsaturation in these elastomers is sensitive to oxygen and ozone aging, SBS is often saturated by hydrogenation (SEBS) to improve age resistance. They are typically compounded with other additives and used mainly in adhesives, shoe soles, wire and cable insulation, kitchen utensils, and auto parts.



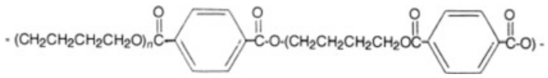
Rubber-Polyolefin Blends. These thermoplastic elastomers are blends of olefins (semicrystalline) with elastomers. The most common blend is polypropylene (PP) with ethylene-propylene rubber (EPR), but other combinations can be used. They have the elastomeric nature of the EPR rubber matrix and the crystalline polypropylene (PP) domains hold them together. The morphology of the blend is important to properties, typically an interpenetrating polymer network is required. The saturated elastomers will have natural resistance to oxygen and ozone aging. They are used in the automotive and wire and cable sectors.

Thermoplastic Vulcanizates. These materials are composed of a blend of polyolefin and an elastomer that is cross-linked during the mixing process (dynamic vulcanization). The most common combination is polypropylene and ethylene/propylene/diene (EPDM) rubber. In this process very small cross-linked rubber particles are dispersed in the thermoplastic matrix. The vulcanized rubber has higher heat and chemical resistance than ordinary EPR, and the PP matrix provides thermoplastic processability. In more specialized grades, the vulcanized rubber may be nitrile rubber for greater oil resistance, or butyl rubber for impermeability. They are used where greater heat and/or chemical resistance are required, for example, in oil wells, mechanical goods, and building and construction.

Thermoplastic Polyurethanes. These elastomers are multi-block, composed of hard polyurethane hard segments and soft polyether or polyester elastomer blocks. The polyether grades offer better stability to hydrolysis, while the polyester grades give better abrasion resistance. They are used in applications ranging from auto parts, wire and cable, medical products, mining screens, shoe soles and caster wheels.



Thermoplastic Co-polyesters. These thermoplastic elastomers are typically block copolymers of polyoxybutylene rubber with polybutylene terephthalate crystalline domains. They are creep resistant, chemically resistant and can sustain high loads. They are used in automotive and other mechanical parts requiring dynamic properties, flexibility, and strength.

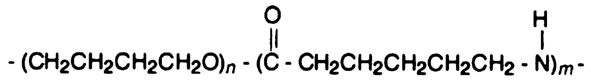


Thermoplastic Polyamides. These thermoplastic elastomers are multi-block copolymers of and elastomer with nylon

Table 15.13 Thermoset plastics market

Family	Percent of thermoset market
Polyurethane	36
Phenol–formaldehyde (phenolic)	29
Urea–formaldehyde	19
Polyester	10
Epoxy	4
Melamine–formaldehyde	2

crystalline domains. They combine the soft flexible properties of polyether or polyester elastomers with the high strength, heat-, oil-, and gas-resistance of nylons, and thus find use in auto parts, wire and cable, and sporting goods.

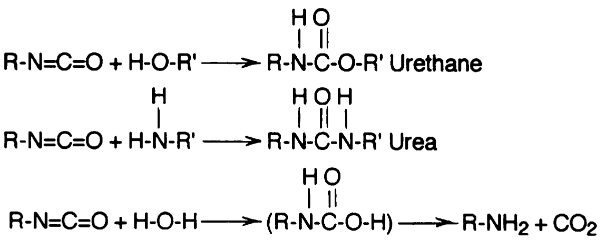


$$-(CH_2CH_2CH_2CH_2O)_n-(\overset{O}{\overset{\|}{C}}-CH_2CH_2CH_2CH_2CH_2-\overset{H}{\overset{|}{N}})_m-$$

Thermoset Plastics

Whereas difunctional monomers produce linear thermoplastic polymers, monomers with higher functionality can react further during processing, cross-linking up to infinite molecular weight. Such thermosetting processing may be more difficult, but infinite cross-linking produces extreme increases in rigidity, creep resistance, dimensional stability, heat resistance, and chemical resistance, which are valuable in many demanding engineering applications. Thus, thermoset plastics account for about 15% of the total plastics market. The major thermoset plastics families may be ranked in order of market size as shown in Table 15.13.

Polyurethanes. Most polyurethane chemistry may be simplified down to three basic reactions:

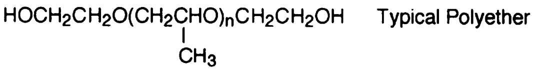


$$R\text{-}N{=}C{=}O + H\text{-}O\text{-}R' \longrightarrow R\text{-}\overset{H}{\overset{|}{N}}\text{-}\overset{O}{\overset{\|}{C}}\text{-}O\text{-}R' \text{ Urethane}$$

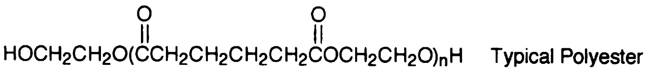
$$R\text{-}N{=}C{=}O + H\text{-}\overset{H}{\overset{|}{N}}\text{-}R' \longrightarrow R\text{-}\overset{H}{\overset{|}{N}}\text{-}\overset{O}{\overset{\|}{C}}\text{-}\overset{H}{\overset{|}{N}}\text{-}R' \text{ Urea}$$

$$R\text{-}N{=}C{=}O + H\text{-}O\text{-}H \longrightarrow (R\text{-}\overset{H}{\overset{|}{N}}\text{-}\overset{O}{\overset{\|}{C}}\text{-}O\text{-}H) \longrightarrow R\text{-}NH_2 + CO_2$$

Polyols are usually aliphatic polyethers or polyesters.



$$HOCH_2CH_2O(CH_2\underset{CH_3}{\underset{|}{C}}HO)_nCH_2CH_2OH \quad \text{Typical Polyether}$$

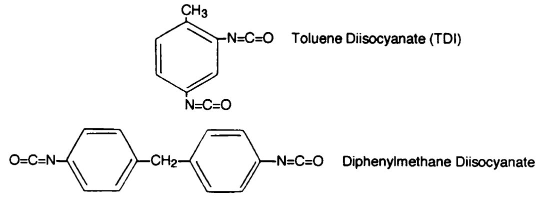


$$HOCH_2CH_2O(\overset{O}{\overset{\|}{C}}CH_2CH_2CH_2CH_2\overset{O}{\overset{\|}{C}}OCH_2CH_2O)_nH \quad \text{Typical Polyester}$$

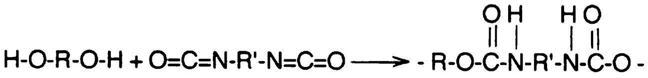
Polyisocyanates are usually toluene diisocyanate (TDI) or diphenylmethane diisocyanate.

Table 15.14 Polyurethane markets

Form	Percent of polyurethane market
Flexible foam	48
Rigid foam	28
Reaction injection molding (RIM)	6
Rubber, spandex, sealants, adhesives, coatings	17

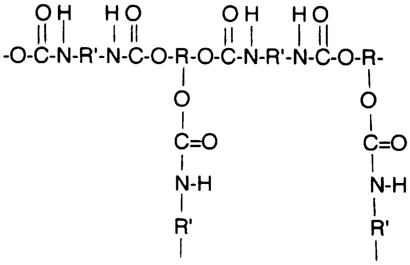


When the polyols are linear (difunctional) they form thermoplastic polyurethanes.



$$H\text{-}O\text{-}R\text{-}O\text{-}H + O{=}C{=}N\text{-}R'\text{-}N{=}C{=}O \longrightarrow -R\text{-}O\text{-}\overset{O}{\overset{\|}{C}}\text{-}\overset{H}{\overset{|}{N}}\text{-}R'\text{-}\overset{H}{\overset{|}{N}}\text{-}\overset{O}{\overset{\|}{C}}\text{-}O-$$

When the polyols are trifunctional or higher, they form thermoset polyurethanes.



In most processes, the reactive liquids are mixed and poured, and polymerized and cured rapidly to the final products (Table 15.14).

Most polyurethane is foamed during the polymerization/cure reaction.

Flexible Foam. This is made by mixing long trifunctional polyol with isocyanate to form the polyurethane, and adding a little excess isocyanate and water to the reaction to produce carbon dioxide, which produces the foam. The largest use is in furniture, with smaller amounts in auto seating, mattresses, rug underlay, textiles, and packaging.

Rigid Foam. This is made by mixing a short polyfunctional polyol with di- or higher polyisocyanate, and foaming either with volatile liquid or with isocyanate and water. The largest use is in building insulation, with smaller amounts in refrigeration, industrial insulation, packaging, autos, and marine flotation.

Table 15.15 Typical properties of molded phenolic plastics

Grade	General purpose	Engineering
Fibrous filler	Wood flour	Glass
Modulus (MPa)	9,000	18,000
Flexural strength (MPa)	76	275
Notched Izod impact strength (J/cm)	0.20	5.3
Heat deflection temperature (°C at 1.82 MPa)	168	240
Maximum continuous use temperature (°C)	149	194

Table 15.16 Phenolics as engineering plastics

Property	Phenolic	Engineering thermoplastics
Creep modulus, 100 h/14 MPa (MPa)	28	5.5–10
Compressive creep, 14 MPa/50 °C (%)	0.02	0.1–1.4
Heat resistance (°C)	315	121–260

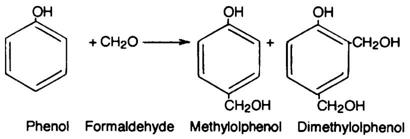
Reaction Injection Molding (RIM). RIM mixes polyol, polyamine, polyisocyanate, and a strong catalyst, and injects the mixture rapidly into a mold, where it cures rapidly to form large parts very economically. It is used primarily for producing front ends and other large parts of autos.

Phenol–Formaldehyde. Phenolic plastics were the first commercial synthetic plastics in 1908, and were the leading commodity plastic for 40 years, until the growth of vinyl and styrenic thermoplastics. Now quite mature, they remain the second largest family of thermoset plastics.

While their largest use is as adhesives for outdoor plywood and glass wool insulation, they provide a group of compression molding fiber-reinforced plastics, which meet high engineering performance requirements (Table 15.15).

For performance under severe conditions, they compare very favorably with more expensive engineering thermoplastics as shown in Table 15.16.

The chemistry of phenolic molding powders begins with the reaction of phenol with formaldehyde.



The high reactivity of the methylol groups makes it easy to polymerize and cure phenolic polymers, and also to copolymerize them with melamine and furan plastics, and with cellulosic reinforcements such as wood, cotton, and paper.

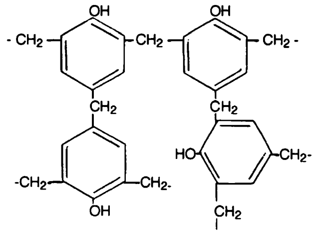
$$\mathrm{P{-}CH_2OH + HOCH_2{-}P \rightarrow P{-}CH_2OCH_2{-}P \rightarrow P{-}CH_2{-}P}$$

$$\mathrm{P{-}CH_2OH + H{-}P \rightarrow P{-}CH_2{-}P}$$

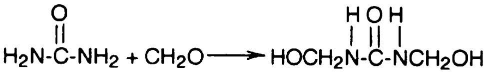
$$\mathrm{P{-}CH_2OH + HOCH_2{-}M \rightarrow P{-}CH_2{-}M}$$

$$\mathrm{P{-}CH_2OH + HO{-}Cellulose \rightarrow P{-}CH_2{-}O{-}Cellulose}$$

It is generally a three-stage process: (1) initial reaction to A-stage resin produces low molecular weight oligomers, which are still soluble, fusible, and reactive. (2) Melt compounding advances them to B-stage resins, which are fairly fusible to doughy melts, and still reactive. (3) Molding them into finished products advances them to C-stage resins, which are fully cross-linked to stable thermoset plastics of three-dimensional infinite molecular weight, high modulus and strength, and very resistant to heat and chemical environments.

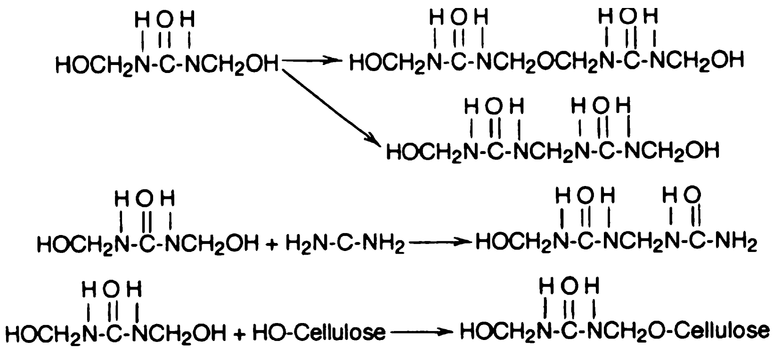


Urea–Formaldehyde. These plastics became commercial about 1929. Urea and formaldehyde react very readily to form methylol compounds, mainly dimethylol urea.



$$\mathrm{H_2N{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}NH_2 + CH_2O \longrightarrow HOCH_2\overset{\displaystyle H}{\overset{|}{N}}{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}\overset{\displaystyle H}{\overset{|}{N}}CH_2OH}$$

The methylol groups are very reactive, condensing with each other, with the N–H groups in urea, and with the –OH groups in cellulose.



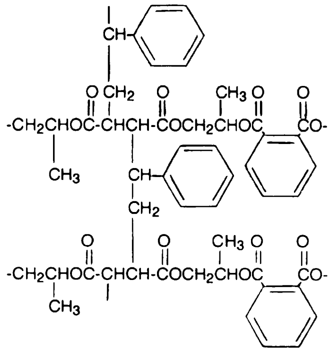
Thermosetting cure produces highly cross-linked three-dimensional molecules of infinite size. The largest use is for binding fibrous and granulated wood into indoor composition board. Smaller uses are for wet-strength paper and permanent-crease textiles. About 4% of urea–formaldehyde resin is combined with alpha-cellulose to make molding powders (Table 15.17). These find use mainly in electrical parts such as switches, wall plates and receptacles, circuit breakers, electric blankets, handles and knobs.

Unsaturated Polyesters. The chemistry of unsaturated polyesters was developed in the 1930s, and manufacture of glass–fiber-reinforced polyesters began in the early 1940s. They matured early, and form about 10% of the present thermosetting plastics market.

Their chemistry is fairly complex. The most common material is made from propylene glycol plus maleic anhydride plus phthalic anhydride. When these are cooked together, maleic anhydride isomerizes to fumaric acid, and they condense to form low molecular weight propylene fumarate phthalate copolyester oligomers. These are mixed with styrene monomer, reinforced by glass fibers, usually extended with low-cost fillers, and cured by peroxide to form rigid strong products which are very resistant to impact and heat (Table 15.18).

Table 15.17 Typical properties of urea–formaldehyde-alpha-cellulose moldings

Flexural modulus (MPa)	10,000
Flexural strength (MPa)	100
Notched Izod impact strength (J/cm)	0.16
Heat deflection temperature (°C at 1.82 MPa)	132



The mechanics of processing are carried out by a number of techniques. *Hand lay-up or spray-up* produces large shapes such as boat hulls, recreational vehicles, mobile homes, truck cabs, and tub-shower units. *Continuous panel processing* produces room dividers and skylights. *Compression molding* of sheet molding compound (SMC) and bulk molding compound (BMC) produces auto body parts, bathtubs, septic tanks, trays, tote boxes, and equipment housings. *Pultrusion* produces flagpoles, archery bows, and park benches. *Filament winding* is highly engineered to produce maximum strength in pipes and storage tanks.

Epoxy Resins. These were developed in the 1940s and offered a unique combination of engineering performance, which made them a popular family of thermoset plastics: fast low-temperature cure with low pressure and low shrinkage; high adhesion to polar surfaces; hardness, heat- and chemical resistance (Table 15.19). Their largest use is in coatings for corrosion protection and electronic equipment. The second largest is in printed circuit boards. Three other important uses are adhesives, flooring, and high performance fiber-reinforced plastics.

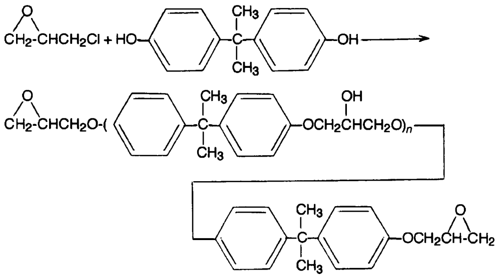
Table 15.18 Typical properties of glass–fiber-reinforced thermoset polyesters

Process	BMC	SMC	Woven cloth	Filament wound
Modulus (MPa)	14,000	11,000	14,000	6,000–24,000
Strength (MPa)	121	159	414	283–586
Notched Izod impact strength (J/cm)	4.0	7.8	9.4	
Heat deflection temperature (°C at 1.82 MPa)	182	225	205+	

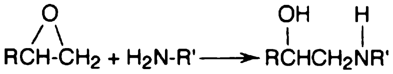
Table 15.19 Property ranges for cured epoxy resins

Flexural modulus (MPa)	14,000–34,000
Flexural strength (MPa)	55–655
Notched Izod impact strength (J/cm)	0.16–21.0
Heat deflection temperature (°C at 1.82 MPa)	93–288

Epoxy chemistry is complex. Most epoxy resins are made by reaction of epichlorohydrin with bisphenol A.

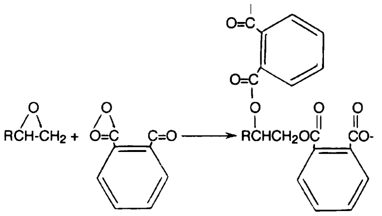


While they are called "resins," they are really monomers to low molecular weight oligomers, liquids to soluble fusible solids, with high reactivity in the epoxy rings, and fair reactivity in the internal hydroxyl groups. They are cured most often by room-temperature reaction with polyamines or polyamide amines.



$$R\overset{\overset{O}{/\ \backslash}}{CH-CH_2} + H_2N\text{-}R' \longrightarrow R\overset{\overset{OH}{|}}{C}HCH_2\overset{\overset{H}{|}}{N}R'$$

For higher temperature cure and heat resistance, they are cured most often by acid anhydrides.



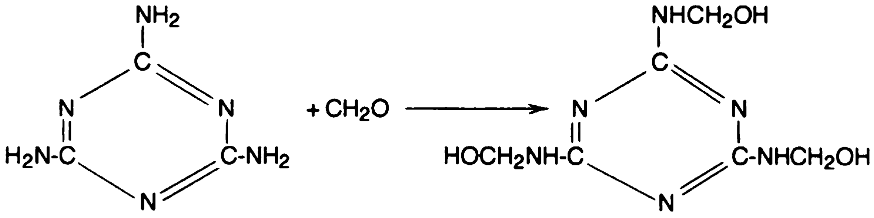
There are also many more types of epoxy resins and curing agents for more specialized applications.

Melamine–Formaldehyde. These resins became commercial in the 1930s. Their combination of high thermosetting reactivity, cured hardness, and resistance to heat, weather, and chemical environments made them particularly valuable for their good appearance and durability (Table 15.20). Their largest use is in coatings, where they are used to cure acrylic automotive coatings and polyester appliance coatings. Their second largest use is in countertops, where they protect the decorative surfaces against abrasion, heat, and chemical attack. Their third use is in dinnerware, where their lightweight, impact resistance, and attractive appearance are very competitive with china.

Table 15.20 Typical properties of cellulose-filled melamine–formaldehyde

Flexural modulus (MPa)	9,000–11,000
Flexural strength (MPa)	70–124
Notched Izod impact strength (J/cm)	0.13–0.21
Heat deflection temperature (°C at 1.82 MPa)	127–143

Melamine chemistry begins with the addition of 2–3 mol of formaldehyde to form methylol melamines.



These are very reactive with each other, with the remaining N–H bonds on melamine, with the hydroxyl groups in acrylic and polyester coatings, and with the hydroxyl groups in paper for countertops and in alpha-cellulose for molded dinnerware.

$$RNHCH_2OH + HOCH_2NHR' \rightarrow RNHCH_2OCH_2NHR' \rightarrow RNHCH_2NHR'$$

$$RNHCH_2OH + R'NH_2 \rightarrow RNHCH_2NHR'$$

$$RNHCH_2OH + HOR' \rightarrow RNHCH_2OR'$$

The combination of resonance stabilization in the melamine heterocycle, and the high cross-linking between methylol melamines and with the other polymers, all produce the outstanding properties which make it a valuable specialty member of the thermoset plastics spectrum.

General Considerations

Structure–Property Relationships

When plastics engineers want to improve properties in an existing product, or when they want to select the optimum material for a new product, a routine search of existing tables of properties may sometimes be sufficient. For more professional judgment and problem-solving, however, and for planning development of new materials, they need to understand the basic relationships between polymer structure and practical properties. Here are some starting guidelines.

Molecular Weight. Low molecular weight gives lower melt viscosity for injection molding, and easier solution processing in general. High molecular weight is preferred for extrusion, and particularly for blow molding, thermoforming, stretch orientation, and thermoplastic foaming. In finished products, high molecular weight generally gives higher mechanical strength and chemical resistance.

Molecular Flexibility/Rigidity. Flexible molecules generally give lower melt viscosity for easier processing; softer, more flexible, more extensible products; and higher impact strength, friction, and acoustic absorption. Rigid molecules generally give higher rigidity, strength, creep resistance, heat deflection temperature, and impermeability; and lower coefficient of thermal expansion, and dielectric constant and loss.

Crystallinity. When polymers crystallize, their melting points are much higher and sharper than the softening points of amorphous plastics. This requires higher processing temperatures, but gives higher maximum use temperatures in the final products. Increasing crystallinity generally increases rigidity, strength, creep resistance, dimensional stability, impermeability, and chemical resistance; but decreases impact strength and transparency.

Orientation. Stretch orientation of extruded fibers and films greatly increases modulus, strength, transparency, and impermeability. It is also useful for producing shrink-packaging; conversely, a disadvantage is thermal dimensional instability. When orientation occurs accidentally in injection molding, calendering, thermoforming, and other processes, it generally produces undesirable anisotropy of final structure and properties.

Polarity and Hydrogen Bonding. Whereas hydrocarbon polymers are nonpolar and have weak intermolecular attraction, introduction of negative atoms into the polymer molecule—oxygen, nitrogen, chlorine—produces permanent polarity, giving strong intermolecular attractions. Increasing polarity generally requires higher processing temperatures, and gives higher modulus, strength, creep resistance, heat deflection temperature, crystalline melting point, dielectric constant and loss, and gasoline and oil resistance.

When the polymer contains oxygen and especially nitrogen, polarity also produces hydrogen bonding, which is an even stronger intermolecular attraction, and produces all the same effects to an even greater extent. Another effect of hydrogen bonding is water absorption. In fabrics this produces greater comfort; but in plastics it decreases modulus, strength, and dimensional and chemical stability. These effects are most noticeable in nylons and cellulosics.

Cross-linking. Thermoplastics are stable linear molecules which are softened by heat and soluble in solvents of similar polarity; this makes for easy processability. Primary covalent cross-linking in thermosets converts them into three-dimensional molecules of infinite size, with tremendous changes in properties: insolubility and infusibility; higher modulus, creep resistance, maximum use temperature, and chemical resistance; and lower extensibility, impact strength, thermal expansion, dielectric constant and loss, solvent swelling, and permeability. Cross-linking produces shrinkage strains, which embrittle the polymer, so most thermoset plastics must be reinforced with fibers; the result is synergistic improvement of modulus, strength, impact resistance, and dimensional stability, producing enhanced engineering performance.

Additives

Polymers are rarely used in pure form. They are almost always improved by use of additives to enhance specific properties. The major classes of additives may be briefly summarized as follows.

Stabilizers. Organic polymers are not perfectly stable. Specific polymers and specific products require additives to improve their stability during processing and/or long-term use of finished products.

Antioxidants are added to polyolefins and rubber-modified impact plastics to protect against atmospheric oxygen; these are primarily hindered phenols and polyphenols, sometimes synergized by aliphatic sulfides or organic phosphites, used in fractions of a percent up to several percent.

Thermal Stabilizers must be added to PVC to prevent dehydrochlorination, discoloration, and cross-linking during melt processing: organotin esters are strongest, used as a fraction of a percent for processing rigid PVC; barium/zinc soaps plus epoxidized fatty esters plus organic phosphites, total concentration several percent, form a synergistic stabilizer system for plasticized flexible PVC; and basic lead oxide compounds, several percent, are best for wire and cable insulation.

Ultraviolet light Stabilizers are needed in products for outdoor applications: cyclic hindered amines and *o*-hydroxy benzophenones and benzotriazoles are used at a fraction of a percent in clear products, while carbon black and especially aluminum flake are extremely effective in opaque products.

Biostabilizers are used to protect natural polymers and monomeric additives against attack by microorganisms; these are chemicals which require a delicate balance between toxicity to microorganisms vs. safety for macroorganisms like ourselves.

Fillers are inorganic powders added in large amounts to increase modulus, dimensional stability, and opacity, and often to reduce cost.

Reinforcing Fibers are mostly glass, occasionally carbon or organic fibers, typically added in concentrations of 10–40%, to increase modulus, strength, impact strength, creep resistance, and dimensional stability; long and continuous fibers give the greatest improvement in properties, while short chopped fibers (1/16–2 in.) permit fairly conventional melt processing.

Coupling Agents are chemical surface treatments applied to fibers, and sometimes to fillers, to strengthen the interface between inorganic fillers and fibers and organic polymer matrixes, to improve dispersion and stress transfer across the interface. Most common are organosilicon compounds of the type $(RO)_{2-3}SiX_{2-1}$, where RO is typically methoxy or ethoxy to react with the silanol surface of glass fibers, and X is an organic group designed to react with a thermosetting polymer matrix, or at least to be attracted toward a thermoplastic polymer matrix.

Plasticizers are typically organic liquids of very low volatility, which are miscible with a polymer, and are added to it to improve processability and, in larger amounts (20–80 PHR), to make it soft and flexible, or even rubbery and/or adhesive. The major portion of the plasticizer market (80%) is aliphatic and aromatic esters, which go to convert rigid PVC into flexible PVC. The remainder goes to improve the processability of cellulosics, and for a variety of specialized uses in other polymers.

Lubricants are a variety of proprietary additives, which are used either to improve melt flow, release from steel process equipment, or self-lubricity in final products such as gears and bearings.

Flame-Retardants may be built into the polymer during polymerization or cure, or they may be physical additives to the finished composition. Organic phosphorus compounds are the most effective, typically requiring about 2% of phosphorus to prevent burning. Organobromine (10–20%) and chlorine (10–40%) are effective when used in larger amounts. Antimony oxide, and some other metal oxides, can synergize the action of bromine and chlorine, reducing total flame-retardant concentrations to 5–10%. Alumina trihydrate and magnesium hydroxide, which release water when heated, are becoming increasing popular when used in large enough amounts to be effective (40–60%).

Colorants. One third of plastic materials are used in their natural color. The other two thirds are colored for esthetic and/or functional reasons, typically using about 1% of colorant. Inorganic minerals and synthetic colors give greater stability and opacity; while organic colors are available in greater variety, miscibility, and efficiency, and less likely to raise questions of toxicity. Thus use of inorganics is decreasing, while use of organics is increasing.

Organic Peroxides are used to initiate free radical polymerization of ethylene, butadiene, styrene, vinyl chloride, vinyl acetate, and methyl methacrylate. They are also used to cure unsaturated polyesters, occasionally to cross-link thermoplastics such as polyethylene and polyacrylates, and increasingly for grafting and compatibilization of polymer blends. A variety of organic peroxides offer useful reactivity over a temperature range from 0 to 130°C or more, for different polymers and different processes.

Polymer Blends. Blending of polymers with each other accounts for approximately 40% of the present plastics market, and the practice is continually growing, because it permits the development of improved properties without the cost of inventing new polymers. When polymers are fairly miscible, as in the case polyethylenes and in polyphenylene ether plus polystyrene, blending can be used to produce a balance of properties. Most polymer blends are not miscible, and separate into microphases; if these can be strongly bonded at the interface, it is often possible to produce synergistic improvement of properties, particularly the balance between rigidity and heat deflection temperature on the one hand, plus ductility and impact strength on the other; or between soft, flexible, rubbery properties on the one hand, plus the strength of “thermoplastic cross-linking” on the other. Some of the newer blends are used to produce barrier properties and other valuable improvements.

Critical Properties: Challenges to the Plastics Industry

There have been numerous accomplishments of the plastics industry, but there still remain areas where major breakthroughs could open major new markets and uses for plastics in the future. It may be stimulating to explore some of these here.

One-Step Conversion of Monomer to Finished Product could reduce processing steps and costs dramatically. Epoxy cure and polyurethane RIM are examples of very fast reactions producing finished products. Monomer casting of acrylics and nylon 6 are commercial one-step processes. Polymer chemists have many more polymerization reactions which can rapidly convert monomers into high molecular weight or even thermoset polymers. What is needed are strong cooperative programs between polymerization chemists and plastics process engineers to develop these possibilities into commercial realities.

Continuous-Fiber Reinforcement gives plastic products which are superior to most present commercial practice. Most plastic processing is limited to conventional melt flow of short-fiber reinforcements, which sacrifices much of the potential benefits of reinforcement. There are a few processes for incorporating continuous-fiber reinforcement—filament-winding, pultrusion, and mixed fabrics of reinforcing fibers and plastic fibers. More vigorous development of such techniques could rapidly produce plastics products with far superior properties.

Modulus and Creep Resistance of plastics are still inferior to metals, ceramics, and glass, which means there are areas where they cannot compete. We know that molecular rigidity, crystallinity, polarity, and reinforcing fibers can all go a long way toward closing the gap.

Abrasion-Resistance of transparent plastics still cannot equal that of glass. We have ways of improving or coating the polymer, but there is still a long way to go.

Coefficient of Thermal Expansion of organic polymers is 1–2 orders of magnitude higher than metals, ceramics, and glass, which gives serious difficulties in product design, and especially in mating plastics parts with inorganic parts in an assembled product. Molecular rigidity, crystallinity, fillers, and especially fibrous reinforcement can go a long way toward bridging the gap, but there remains room for improvement.

Thermal Conductivity of plastics is very low, which makes them excellent insulators against heat and cold. On the other hand, there are times when high thermal conductivity is preferred, for example, in processing, cooking, and heating equipment. Inorganic fillers can help, in proportion to their volume concentration. New developments in nanoscale fillers may help improve these properties.

Heat Resistance of organic polymers is far lower than that of metals, ceramics, and glass. There have been major improvements, based on aromatic and heterocyclic resonance, ladder structures, and other mechanisms, and we may see further improvements in the future. One of the more serious limitations is the high cost of synthesis and the difficulty of processing these polymers into the desired final products. This is an area where the polymer chemist could use more help from the plastics engineer.

Electrical Conductivity of polymers is very low, making them very useful as insulation. On the other hand, there are products where conductivity would be very desirable. Semiconductivity is fairly easily achieved by adding semicompatible hydrophilic organic compounds, and fairly high conductivity can be achieved by metallic fillers, especially fibers. Several polymers are available, that are inherently conductive due to conjugated unsaturation, plus doping with inorganic electron donors.

Dielectric Breakdown occurs when high voltage drop across an insulator causes some current to leak through, turning to heat, and ultimately decomposing the polymer and burning a conductive carbon track right through the insulator. Practically, some polymers are more resistant than others; but more theoretical understanding is needed in order to design polymer structures which will offer superior resistance to dielectric breakdown.

Outdoor Weathering of plastic products has been the subject of both theoretical and practical study. Some plastics can last for many years, others for more limited times, and a few can actually be designed to self-destruct rapidly. Mechanisms involve ultraviolet light, atmospheric oxygen, water, transition metals, acid rain, wind-blown dust, and microbiological action. Polymer structure and additives respond to these mechanisms in various ways. Whereas there presently exist a fair theoretical understanding and practical control measures, there remains much to learn in order to achieve the ultimate goals of long-term weather stability and efficient control of solid waste.

Solvent-Resistance of organic polymers varies with polarity, crystallinity, and cross-linking, so it is usually possible to solve solvent-attack problems by proper choice of polymer; but it is important to remember that they do not easily compete with metals, ceramics, and glass.

Barrier Properties of organic polymers cannot equal metals and glass. Plastics offer so many other advantages that we often try to compromise or laminate to optimize overall balance of properties. It is known that molecular rigidity and crystallinity improve barrier performance, and from practical experience we can identify several very high-barrier polymers; new developments in nanoclay filled materials are helping in this arena.

Cost of engineering performance is a major factor retarding growth. Organic polymer chemists can easily design and synthesize polymer structures with higher properties, but the cost of synthesis and difficulty of processing often inhibit their use for many years. Closer cooperation between chemists and engineers should be the optimum route to more efficient development.

Fire Performance

Wood burns. Most of the fires throughout history, causing death and destruction, have been caused by wood. It is rare that anyone will say “Ban wood.” Plastics are also carbon compounds, and they also burn. When plastics are involved in a fire, even to the slightest degree, there is often an outcry, “Ban plastics.” Thus the use of plastics in building and transportation is seriously restricted by this prejudice.

Plastics are not all equally flammable. Some burn as readily as fuels. Some do not burn spontaneously; but when exposed to a severe fire, they can be burned. Some require enriched or pure oxygen environment before they will burn. Most plastics can be made more resistant to burning, by incorporating flame-retardant elements—phosphorus, bromine, chlorine, antimony, even water—either in the polymer molecule or in physical additives.

Related problems must be considered in individual products. Bromine, chlorine, and antimony add to the smoke of a fire, while phosphorus and water do not, and some metal oxides can actually reduce it. Toxicity of combustion gases is a major concern; but oxidation of carbon compounds in an enclosed space—indoors—produces carbon monoxide, no matter whether the carbon compounds are wood or plastics. Other problems include concern over the effect of brominated flame-retardants on the environment and legislation against their use as an additive, the cost of flame-retardants, difficulties in processing, and loss of mechanical or thermal properties. The designer must balance all of these in each product, and choose the optimum solution to the problem.

Health and Environment

Whenever new chemistry is introduced into the environment, there arises the question of its effect on our health. On the positive side, plastics packaging of food prevents contamination and spoilage, and prolongs its useful life; and use of plastics in medicine has made major contributions to health and longevity. On the negative side, there have been several occasions where plastics chemistry has caused health problems; whenever these have been identified, they have been solved successfully and quickly.

Recycling

Modern science and industry have provided a growing supply of material products. When they reach the end of their useful life, they become solid waste, and disposing of it has become a growing problem. Over-packaging to stimulate sales has been a major contributor to this solid waste. It would be desirable to remove them from solid waste by recycling.

Since 85% of the plastics market is thermoplastic, it is theoretically recyclable. In industry, individual thermoplastic materials are almost always recycled immediately for purely economic reasons. Postconsumer waste, on the other hand, presents serious problems. Voluntary recycling of PET soda bottles has been most successful, because they are easily separated, cleaned, and converted into bulk fiber products. Voluntary recycling of HDPE milk and water bottles has been fairly successful, because they are easily separated and cleaned, but development of markets has been slower in coming. Most other plastics occur in smaller amounts and more diversity, so voluntary efforts have been very limited. The greatest problem is that, when several materials are combined in a single product, separation is difficult. Ultimately, the success of recycling will depend very much on greater cooperative efforts by government, industry, and consumers.

Recycling rarely reproduces virgin plastic materials. With repeated recycling, quality decreases, and potential uses decrease. At some point, the final step should be incineration. This produces useful energy, returns carbon dioxide and water to the ecocycle, and reduces final solid waste to an absolute minimum. Present incineration technology suffers from old inefficient equipment and non optimal operation. New methods to recycle or incinerate waste will help solve this problem.

Part III: Plastic Processing

Rheology

Fundamental Concepts

Plastic processing involves the he flow and shaping of viscous liquids. The scientific study of this flow is called *rheology*. Assuming laminar shear flow, viscosity is defined as the ratio of shear stress to shear rate.

$$\eta = \frac{\sigma}{\gamma}$$

If this ratio is constant, it indicates a simple Newtonian fluid. For most plastic materials, however, increasing shear rate disentangles polymer molecules and aligns them in the direction of flow, so increasing shear rate decreases resistance to flow (viscosity) (Fig. 15.27), and this non-Newtonian behavior is defined as *pseudoplastic*.

With increasing temperature, viscosity decreases in a manner approximately described by the Arrhenius equation,

$$\eta = K\mathrm{e}^{-E/RT}$$

where K is a constant characteristic of the polymer and the test method, E is activation energy, R is the gas constant, and T is absolute temperature (K). With increasing pressure, free volume between polymer molecules decreases, flow becomes more difficult, and viscosity increases. A major factor in polymer viscosity is molecular weight, M, as shown by

$$\eta = KM^a$$

Beyond a critical molecular weight, M_c (typically 5,000–40,000), molecules become entangled and the viscosity increases more rapidly (see Fig. 15.28).

Instrumental Measurement of Flow Properties

Capillary Rheometers measure the effect of pressure on volumetric flow through a cylindrical capillary. They are popular in practical work because shear rate and flow

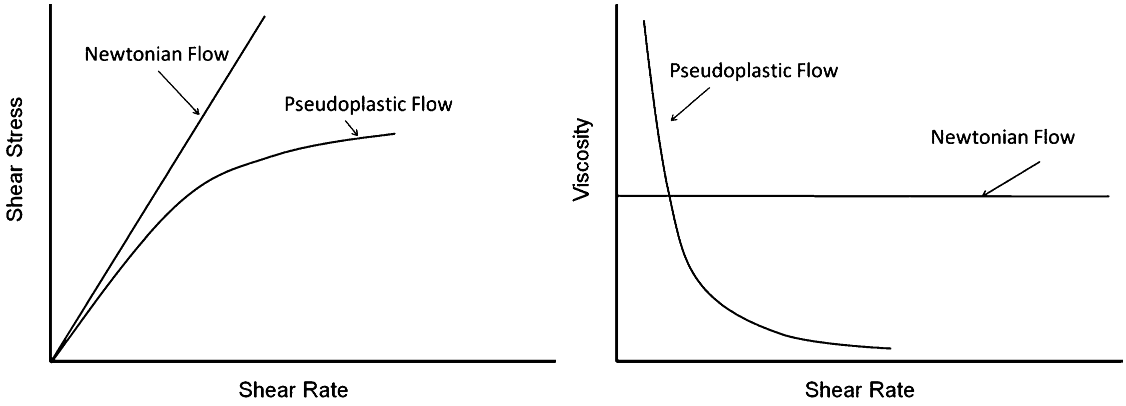


Fig. 15.27 Polymer rheology

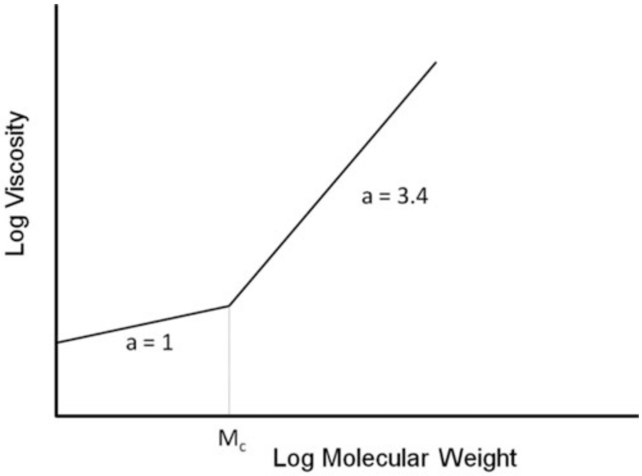

Fig. 15.28 Effect of molecular weight on viscosity

geometry are similar to conditions in extrusion and injection molding. They cover a wide range of shear rates, and they give practical information on die swell, melt instability, and extrudate defects. Their main disadvantage is that they require a number of mathematical corrections to convert to true viscosity.

Cone and Plate Rheometers provide a constant shear rate. They can also be designed to measure torque, dynamic properties, normal stresses, and forces in other directions. A disadvantage is that they are limited to low shear rates.

Parallel Plate Viscometers are used for very high viscosities at low shear rates. Measurement of shear rate is difficult.

Coaxial (Concentric) Cylinder Viscometers provide nearly constant shear rate. A disadvantage is that they are limited to liquids of low viscosity.

Extensional Viscometers are useful to measure tensile viscosity in processes such as stretch orientation.

Dynamic or Oscillatory Rheometers measure viscous and elastic modulus in shear or tension. Energy dissipation produces a phase difference, so stress, strain, and phase angle can be used to characterize complex viscosity behavior.

Practical Effects of Flow Properties

Melt Viscosity is the most critical practical property for the process engineer. When stiff molecules give high viscosity and slow flow rates, higher temperature and/or shear sensitivity (pseudoplasticity) can often be used to decrease the melt viscosity and thus increase processability.

Extrusion Defects are primarily due to melt elasticity. When shear rate occurs faster than polymer molecules can disentangle from each other, they stretch elastically and store potential energy. As the molecules exit from the die, they release this energy and recover elastically. The resulting extrudate diameter is then greater than the die diameter. This is called *die swell*. The effect is aggravated by high molecular weight, high pressure, low temperature, high shear rate, and short *L*/*D* ratio. Two practical ways to compensate for die swell are to: (1) reduce the die diameter, or (2) pull the extrudate away from the die at a velocity at least as great as it went through the die.

Melt Fracture is the occurrence of distorted extrudate coming from the extruder. It is caused by flow disturbance at the point where flow cross-sectional area is rapidly reduced from the large diameter of the melt feed to the much smaller cross-sectional area of the die orifice. Here again it is aggravated by melt elasticity.

Land Fracture is a fine surface roughness on the extruded product. It is caused by friction between the melt and the wall (land) of the die. It is solved by addition of lubricants to reduce melt/die adhesion (see Table 15.21).

Extrusion

Extrusion is the process of forming a material continuously through an opening, forming two-dimensional shapes.

Most extruders do this by rotating a screw inside a stationary heated cylindrical barrel, to melt the polymer and pump the melt through a suitably shaped orifice (Fig. 15.29). This is used for direct manufacture of finished products such as film or pipe. It may also be used to feed a second process such as injection molding, blow molding, coating, laminating, or thermoforming. It is also important in compounding—blending polymers with additives to improve the overall balance of properties—and in recycling plastics out of solid waste.

Basic Functions

The extruder generally performs six successive functions: solids conveying, melting ("plasticating"), melt conveying (pumping), mixing, devolatilization (venting), and forming. While a complete process may involve all six, some processes may omit one or more of these steps.

Solids Conveying is carried out in two steps: the feed hopper and the back (entrance) portion of the screw. The feed hopper is an inverted cone or pyramid, in which solid pellets or powder flow downward from the force of gravity. If they flow poorly ("arcing" or "bridging"), the problem may be solved by installing a vibrator or a stirrer ("crammer/feeder") in the hopper, or by coating the particles with a small amount of a chemical that acts as an "external lubricant."

Table 15.21 Plastics processes

Process	Use in industry (%)
Extrusion	34
Injection molding	31
Blow molding	13
Calendering	6
Thermoforming	6
Coating	5
Compression molding	3
Rotomolding	2

Once the solid particles enter the back end of the screw, they are carried forward and compressed by the rotation of the screw and the friction between the solids and the barrel. Friction can be increased by roughening the surface of the barrel, and particularly by grooving the internal surface of the barrel.

Melting of the solid polymer is the result of heat from two sources: conduction from the heated barrel, and friction between the barrel and the polymer. Most of the heat comes from friction between the barrel, the viscous melt film, and the remaining solid polymer. This frictional heating is most efficient when the melt viscosity is high, and when the melt film is thin. Thinness of the melt film depends on designing and maintaining a very small clearance between the screw flights and the barrel surface.

Melt Conveying is the forward motion of the molten polymer through the extruder, due to the pumping action of the rotating screw. This simple "drag flow" is proportional to melt density, down-channel velocity, and cross-sectional area of the screw channel. In most cases, however, there is also a pressure gradient as the melt moves downstream, either positive pressure approaching the exit die, or negative pressure following the solid/melting zones; so this "pressure flow" must be subtracted from the drag flow to calculate the net output of the extruder. Since pressure flow is inverse to melt viscosity, which is non-Newtonian and temperature sensitive, this complicates the calculation considerably.

Mixing in the extruder is important for homogenization of temperature and pressure, and especially for uniform blending with additives. In a simple single-screw extruder, melt flow is fairly linear and provides little mixing. A variety of modifications of screw design have been developed to build in mixing elements. Some improve distributive mixing of the liquid melt, to homogenize temperature and pressure

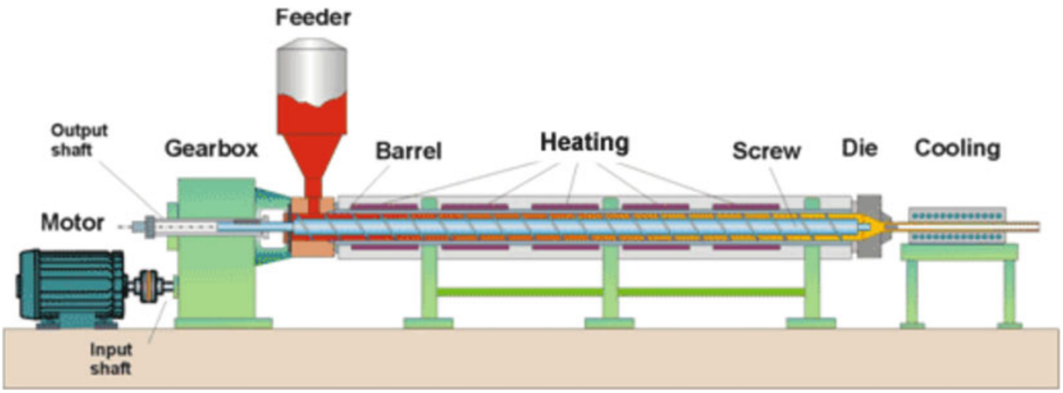

Fig. 15.29 Extruder. (http://www.theadvancedteam.com/AdvancedTeamCapabilitiesStatement.pdf, Accessed 4 Nov 2011)

fluctuations. Others build in higher shear (dispersive mixing), to break down particles of additives and blend them uniformly into the molten polymer, while still others combine the two types of action.

Twin-screw extruders permit much wider variation in design and performance. The screws may be non-intermeshing, just touching ("tangential"), partially or fully intermeshing. They may be corotating or counter-rotating. They are assembled ("programmed") of different sections ("elements"), designed for feed, melting, conveying, distributive melt mixing, dispersive shear for additives mixing, and sealing pressure or vacuum at the vent or the die. The barrels are also programmed of elements to provide functions such as feed ports, venting, and abrasion resistance. Their higher mixing efficiency makes them particularly useful in compounding with additives, processing polyvinyl chloride, reactive extrusion, and devolatilization.

Devolatilization can be used to remove up to 5% of volatile impurities from the plastic melt. The first melt conveying (metering) zone builds up melt pressure. Then channel depth is increased abruptly in the vent zone, the melt is decompressed, and volatiles escape through the vent. After devolatilization, the melt enters a second metering zone, which builds up melt pressure again, and feeds it to the die.

Die Forming forces the melt into the shape and dimensions desired in the final product. Temperature, pressure, viscosity, die design, flow rate, and flow patterns must all be optimized and controlled closely to make a suitable product. Typical guidelines include small approach angles, land length = 10 × land clearance, avoid abrupt changes in geometry, no dead spots, generous radii, and thin uniform wall sections.

Calibration is a technique for maintaining the shape and dimensions of the product from the time the melt exits from the die until it can be cooled enough to solidify and stabilize it. Depending on the size and shape of the product, calibrators can use water-cooled plates, internal mandrel, internal air pressure, external vacuum, or a post-extrusion die to change the shape of the molten extrudate before it solidifies.

Major Processes and Products

Blown Film is produced from a single-screw extruder by extruding a tube, cooling it with external and/or internal air streams, stretching it in the machine direction by pulling it away from the die ("draw-down"), stretching it in the transverse direction (typically 2–4× "blow-up" ratio) by internal air pressure up to 34 kPa (5 psi), flattening it by passing through nip (pinch) rolls, and winding it onto a cylindrical roll. Optional post-stretching operations may include flame or corona surface treatment for wettability/adhesion, sealing, slitting, and bag-making.

Flat Film, Sheet, and Coating are produced from a single-screw extruder with a high *L*/*D* ratio (27–33/1), which feeds the molten polymer through a flat die. The die opening is adjusted to control the thickness of the film, and the film is solidified in a cold water bath, or preferably, for transparency and gloss, over two or more water-cooled steel chill rolls. Compared to air-cooled blown film, water-cooled flat film generally has higher clarity. The take-off and wind-up line may include automatic feedback thickness control, surface treatment, and/or slitting.

For extrusion-coating, the substrate—paper, plastic, or metal foil—is preheated, and may be pretreated, before the extruder deposits a layer of molten polymer onto its surface. Low molecular weight and high temperature help the polymer to flow into a uniform adhesive coating. The laminated layers pass between pressure and chill rolls, and optionally through surface treatment, printing, and slitting before collecting on the final wind-up rolls.

Coextrusion produces multilayer laminates in a single process step. Two or more extruders feed different molten polymers into a multi-manifold die, which layers them directly, or into a modular feedblock which layers them before feeding them into the die. This is used primarily in the packaging field, to sandwich an impermeable barrier layer between two commodity outer-film layers, and often includes adhesive tie layers to bond the barrier layer to the outer layers.

Pipe, Hose, and Tubing are extruded through an annular (ring) die. *L*/*D* ratio is typically 24/1 or greater. Rigid vinyl is the leading material, and often requires a conical twin-screw extruder. The molten pipe is solidified by water-cooling. Pipe dimensions are controlled initially by the die, but then finally calibrated by pull-off rate, internal mandrel, vacuum, or compressed air. Flexible tubing is collected on a wind-up unit; while rigid pipe is hauled off by a caterpillar puller to a cut-off saw and stacker.

Profile Extrusion of siding, window frames, gasketing, and other shapes is complicated by the effects of their asymmetry on heating, viscosity, cooling, and dimensional control. This generally requires modification of the die, and vacuum-driven calibration of the extruded product.

Wire Coating extrudes plastic insulation around electrical wire and cable as it passes through a T-shaped cross-head die. The entire process line includes pay-off and capstan to feed and preheat the wire, extrusion-coating, water-cooling, spark testing, diameter and eccentricity controls, and take up capstan and wind-up. The most common "pressure-coating" die applies the plastic coating inside the die; whereas, for larger wire and cable, the "tubing (tool) die" applies the coating as wire and plastic exit from the die, using internal vacuum to pull the molten coating onto the wire. A fine wire coating line can run at speeds up to 10,000 ft/min.

Injection Molding

Introduction

Extrusion and injection molding are the two leading methods of converting plastic materials into solid products. Extrusion produces continuous products with a fixed cross-section; injection molding produces discrete products with more complex shapes. Modern injection molding is a very fast, automated process for large-scale manufacture of complex products at minimum cost. An injection molding machine can be used for many different jobs and for many years, so the amortization per job can be very low. On the other hand, it requires a different mold to make each product, so the cost of the mold must be amortized over the life of its individual production run.

Injection Molding Cycle (Fig. 15.30)

The injection molding cycle involves a sequence of events:

- Closing the mold
- Melting the plastic material
- Injecting the melt into the mold
- Filling the mold cavity to form the product
- Cooling the molten product to solidify it in the mold
- Opening the mold and ejecting the solid product

The entire cycle is usually completed within a minute or less.

Closing the Mold. One half of the mold is attached firmly to the melting/feeding end of the injection molding machine. The other half slides horizontally to open or close the mold. The moving half is driven mechanically or hydraulically. When it closes the mold, it is held firmly by clamping action to withstand the injection pressure.

Melting the Plastic Material. The plastic pellets are fed through a hopper into an extruder screw, typically with an *L*/*D* ratio of 20/1. The first half of the screw compresses the pellets and squeezes out air. The third quarter of the screw melts the pellets, 70% by friction, 30% by conduction from heater bands on the extruder barrel. This is called "preplastication." The fourth quarter of the screw pumps the melt forward to the front of the extruder, where it goes through a one-way valve to prevent backflow. As the molten plastic accumulates at the front of the screw, this pushes the screw back to form a reservoir of molten material.

Injecting the Melt into the Mold. When the reservoir contains the desired (preset) volume of molten material, hydraulic force pushes the screw forward rapidly, injecting the melt into the mold cavity. For this reason it is called a "reciprocating screw." In order to fill the mold completely, and make up for shrinkage during cooling with or without crystallization, the screw and the one-way valve maintain high "boost" ("hold") pressure during this part of the cycle. An important auxiliary function is "venting," tiny openings to allow air to escape from the mold, so that the molten material can fill the mold completely and flawlessly.

Filling the Mold Cavity to Form the Product. The mold cavity is designed and machined to form the shape of the finished product. Some major considerations are fast, uniform flow, avoidance of degradation, minimization of orientation/anisotropy, fast cooling/solidification, shrinkage and dimensional tolerances, and of course, final properties of the product.

Cooling the Molten Product to Solidify it in the Mold. The molten product must be solidified before it can be removed from the mold. This is accomplished by flowing cold water through channels machined into the mold. Computerized design of the cooling channels and refrigeration of the cooling water to speed the cooling process, are major considerations. Since heat transfer through organic polymers is slow, the design favors thin-wall products, generally under 1/4 in. Polymers which can crystallize rapidly offer promise of faster, more economical molding cycles. Polymers which crystallize slowly, and amorphous polymers which stiffen gradually, often require longer molding cycles.

Opening the Mold and Ejecting the Solid Product. When the plastic product has cooled sufficiently to be solid and retain its shape, the moving half of the mold is opened automatically. Some products will eject from the mold spontaneously; this depends on design of the mold and the product, low polarity of the plastics vs. the high polarity of the metal mold, and the use of external lubricants to help release the product from the mold. In most cases, however, the moving half of the mold is fitted with "knockout pins." When the mold is opened, the knockout pins automatically project into the mold cavity, and press gently on the product to force it away from the mold surface. Then, as the mold closes for its next cycle, the knockout pins automatically retract again.

Variations and Details

Drying. Although most plastics are quite resistant to water, the powder or pellets may still absorb or adsorb small amounts of moisture during storage and handling. In the heat of molding, this moisture evaporates, causing microscopic voids ("blushing") or macroscopic voids (bubbles), or even hydrolysis to lower molecular weight and less desirable properties. Thus many plastics require pre-drying before molding. They may be dried on shallow trays in a circulating-air oven, or by passing hot dry air through the hopper as they are fed into the extruder. They may be dried by opening a vent midway down the extruder screw to allow the steam to escape.

"Two-Stage" Injection Molding Machine. Instead of using a reciprocating screw to melt the plastic and to push the melt into the mold, the extruder screw may feed the molten plastic into a separate reservoir, and then a separate plunger can feed the melt into the mold.

Electric Drive. This may replace the hydraulic drive in some injection molding machines.

Multicavity Molds. While the mold can be machined with a single cavity to produce a single product, in most cases it is more efficient to machine multiple cavities into the mold and fill them all with a single shot of molten material. This requires a system of runners (tunnels) to distribute the melt to all the cavities, which in turn requires much more sophisticated engineering design to balance them all equally.

Hot Runners. When the molten plastic is pumped into the water-cooled mold, the cooling system solidifies both the plastic product in the mold cavities and also the plastic material in the runners. Later the solid runners must be separated, reground, and reused. This is an extra burden on the process. An alternative is to avoid cooling the runners, and keep them hot, so that the molten polymer in runners remains fluid for the next shot into the mold.

Thermosetting Plastics. While injection molding is used primarily for thermoplastic polymers, it is so efficient and economical that processors working with thermosetting plastics may find it attractive. This has led some of them to adapt the injection molding process to thermosets. This may involve some modification of the reactivity of the thermosetting plastics and/or the injection molding machinery, gentle heating to melt the reactive materials without curing them prematurely, and use of warm or hot molds to finish the curing process quickly and thus speed the molding cycle.

In-Plant Recycling. Injection molding produces a certain amount of scrap: runners, gates, flash, and rejects of imperfect products. In theory, thermoplastic polymers should be perfectly recyclable. In practice, in-plant scrap can be kept clean, reground, and recycled. While 100% recycle is theoretically conceivable, most processors simply determine how high a percent of recycle they can blend with their next batch of virgin material without any harm to their process or product. In most cases they reuse all of their scrap internally, without any contribution to solid waste. This is both good economics and good environmental practice.

Reaction Injection Molding

Overview

RIM is a fast, low-pressure, low-temperature, low-cost process for one-step conversion of reactive liquids into large finished solid plastic products. Liquid polyol and liquid diisocyanate are mixed by impingement, pumped instantly to fill a large mold cavity, and polymerized/cured rapidly to form a thermoset polyurethane product. The cured polymer may be a stiffly flexible product such as automotive bumper covers, front ends, and trim; or a rigid foamed product such as furniture and housings (cabinets) for computers, business machines, TV, and radio.

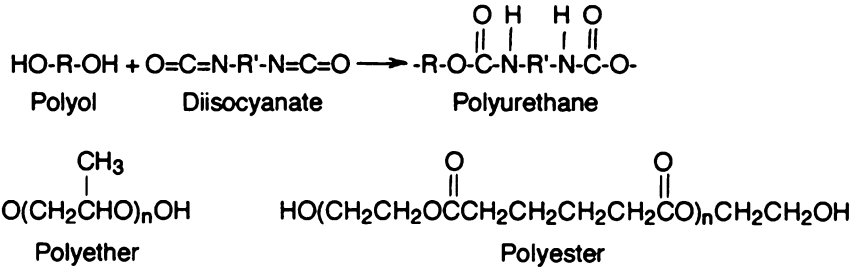
Ingredients

The basic reaction to form polyurethanes is the *polyol*, which may be a polyether or a polyester: Long polyols (high *n*) give flexible polyurethanes; short polyols give stiff, rigid, and/or crystalline polyurethanes. Branched polyols, with three or more –OH groups, give cross-linked thermoset polyurethanes;

short multi-branched polyols give rigid products. Replacing part or all of the polyol by a *Polyamine*

$$H_2N{-}R{-}NH_2$$

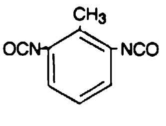
gives faster reaction and therefore shorter cure cycles; and also contributes increased hydrogen bonding, which produces higher rigidity and strength.



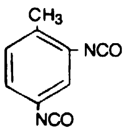
$$\underset{\text{Polyol}}{HO{-}R{-}OH} + \underset{\text{Diisocyanate}}{O{=}C{=}N{-}R'{-}N{=}C{=}O} \longrightarrow \underset{\text{Polyurethane}}{{-}R{-}O{-}\overset{O}{\overset{\|}{C}}{-}\overset{H}{\overset{|}{N}}{-}R'{-}\overset{H}{\overset{|}{N}}{-}\overset{O}{\overset{\|}{C}}{-}O{-}}$$

$$\underset{\text{Polyether}}{HO(CH_2\overset{CH_3}{\overset{|}{C}}HO)_nOH} \qquad \underset{\text{Polyester}}{HO(CH_2CH_2O\overset{O}{\overset{\|}{C}}CH_2CH_2CH_2CH_2\overset{O}{\overset{\|}{C}}O)_nCH_2CH_2OH}$$

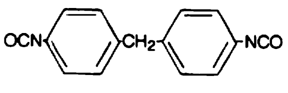
The *diisocyanate* is generally toluene diisocyanate (TDI) or methylene diphenyl isocyanate (MDI) or oligomers based on them.



2,6-TDI



2,4-TDI



MDI

Foaming Agents are either volatile liquids or a trace of water. For flexible products, only a trace of foaming is needed to optimize the product. For rigid products, a higher degree of foaming is used to produce light-weight products. Other ingredients include catalysts to control/balance the polymerization/cure reactions, surfactants for foam uniformity, fillers for stiffening, pigments for coloration, flame-retardants where needed, and short glass reinforcing fibers to increase strength and dimensional stability in Reinforced RIM (RRIM).

Equipment and Process

Raw material holding tanks are warmed to 30–38°C (85–100°F) to keep them at optimum viscosity. The raw materials are measured and pumped by piston pumps, to deliver exactly equivalent amounts of the two reactants, bring them up to 14–21 MPa (2,000–3,000 psi), and shoot them into the mixing head. Here they are mixed by high-speed impingement. The mixed liquid system is very reactive, so it must be pumped into the mold cavity to fill it as rapidly as possible. Molding itself is a low-pressure process, rarely more than 0.7 MPa (100 psi), so the mold can be rather light construction; but since molds and products are generally large, the total force needed to clamp the mold is still considerable. The reaction is exothermic, and the temperature rise could over-cure the product, so mold cooling is required. The entire process is rapid, and can be accelerated further by use of polyamines and catalysts to speed the polymerization/cure reactions. It has proved particularly attractive for mass production of large polyurethane parts.

Structural Foam

Definition

When a solid plastic is expanded to moderately lower its density, it is called a "structural foam." Bone and wood are natural structural foams, which benefit from this moderate degree of expansion. Most plastic materials can similarly be expanded during melt processing, and also gain many benefits as a result.

General Description

A blowing agent is added to the plastic material, to compress gas into the melt during processing. It can be compressed nitrogen gas, which is inexpensive but difficult to disperse; or it can be a "chemical blowing agent," usually an organic azo compound RN=NR, which gives much more uniform dispersion in the melt, and reacts to produce compressed gases in the hot melt.

In extrusion, when the hot melt exits from the die, the compressed gas expands and foams the extrudate. In injection molding, the hot melt is injected into the mold, but the quantity is reduced ("short shot") so that there is not enough melt to fill the mold; the compressed gas expands, and the melt foams and fills the mold. Either way, the foamed melt cools and solidifies, producing a product with a solid skin and a somewhat expanded internal foam structure. It appears to be a solid product, but it is lighter in weight and offers a number of advantages.

Degree of Expansion

Plastics with solid densities of 0.9–1.2 are generally expanded 13–25%, giving foamed densities of 0.75–0.9. At this modest degree of expansion, they look and perform like solid products.

Benefits

Use of 13–25% less material is an obvious economic advantage. Low pressure in the mold (1.4–3.4 MPa, 200–500 psi) permits construction of a lighter mold and operation at lower pressure, both which provide further economic advantage. A low degree of foaming is enough to expand the molding against the walls of the mold, eliminating any accidental "sink marks." Higher degree of foaming increases rigidity 3–4× over a solid part of equal weight. Low-pressure molding also eliminates molded-in stresses, which would weaken the product and could also cause post-molding warpage. This in turn permits design and production of more complex parts in a single molding step, eliminating need for later machining and assembling.

Problems in Structural Foaming

Foamed products tend to be thicker, and contain gas bubbles. Both of these factors reduce heat transfer, taking longer to cool and solidify the product, and thus lengthening the manufacturing cycle.

Tiny foam bubbles in the skin of the product tend to form swirl patterns which are unsightly in consumer products. Several modified injection molding processes offer promise for reducing or eliminating this problem: (1) The *Farrel/USM Process* injects the melt into an expandable mold at high pressure, then expands the mold to lower the pressure and permit foaming. (2) The *Coinjection Process* uses two reciprocating screws to feed the mold; the first feeds a nonfoamable short shot, which will form the solid skin, and then the second feeds a foamable second short shot which expands, pushing the skin ahead of it and filling the interior with foam. (3) The *Gas Counterpressure Process* seals the mold, compresses nitrogen gas into it, injects a short shot of melt containing blowing agent, and then uses gradual controlled venting to release the nitrogen gas and allow the foamable melt to expand, forming a solid skin and a foamed core.

Low-Density Foams

When plastics are foamed to low densities, containing more air than polymer, they have unique properties and applications. Major uses are in crash padding and thermal insulation. Closed-cell foams are outstanding for flotation, rigidity, and insulation; while open-cell foams are outstanding for softness, resilience, and comfort.

While foam production and properties may all belong to one unified theoretical basis, commercial practice is different for each of the major polymer families; so it is best to review them individually.

Polyurethane

The largest quantity of low-density foam is polyurethane, made by mixing liquid polyols with liquid diisocyanates, pouring the mixed liquid and allowing it to foam, polymerize, and cure rapidly into its finished form. The auxiliary ingredients—foaming agent, tertiary amine and organotin catalysts, surfactant, and optionally flame-retardant—are mixed with the polyol prior to mixing with the diisocyanate. The two liquid streams are metered by piston or gear pumps, and fed at high pressure into an impingement chamber where they mix by turbulence. This mixture is very reactive, so it is poured rapidly into the desired form or location, and allowed to polymerize, foam, and cure into the finished product. The largest amount is open-cell soft flexible foam; a smaller amount is closed-cell rigid foam for thermal insulation.

Flexible Foam is made from long-chain diols with a small amount of triols for cross-linking to give strength and resilience. Foaming is produced by reaction between measured amounts of isocyanate and water to liberate carbon dioxide. Molded products are made by pouring the reactive liquid mixture into a mold cavity at 50°C. They foam and cure in 2–10 min, after which they are temporarily crushed or vacuum-shocked to open the cell walls and insure softness. Then they are allowed to condition for several hours to finish the cure. The major products are auto seating and headrests, and furniture cushions.

Large slabstock is made by pouring the reactive liquid mixture into a moving paper form, up to 8 × 5 × 50 ft long, which takes up to 5 min. Polymerization, foam rise, and cure are exothermic, and the interior of the slab can reach 140–170°C. The rough surface is trimmed off, and the slab is conditioned 12–24 h to finish the cure. The finished slab is sliced to the desired thickness for furniture, mattresses, public transportation seating, textile backing (sportswear), carpet backing, and packaging.

Rigid Foam is made from short-chain polyols with a typical average functionality of four hydroxyls per molecule, to give high cross-linking for rigidity. Foaming is produced by volatile organic solvents, which are boiled by the exothermic polymerization/cure reaction. Sheet, slab, and block are made by pouring the reactive liquid mixture onto a moving paper form, or directly onto facing panels for laminated structures. The Pour-in-Place technique is used to fill the wall cavities of refrigerators and freezers, holding them at about 40°C to control the reaction. Spray coating insulation is applied to buildings, tanks, and pipes in the field, using a highly catalyzed mixture that will foam and gel in less than 10 s, so that it will stay in place without running down; the coating can be built up to 2 in. thick in a single pass, more by repeated passes.

Rigid polyurethane foam is used primarily as thermal insulation for buildings, trucks, rail cars, shipping containers, tanks, pipelines, cold-storage warehouses, and frozen food display cases.

Polystyrene

Polystyrene is foamed by swelling with pentane, heating to soften the polymer and vaporize the pentane, and allowing it to expand at atmospheric pressure. Extrusion produces foamed sheet and board stock, which are used mainly as thermal insulation in commercial refrigerators and freezers, and also in food packaging, roof and wall insulation, and pipe insulation.

Moldable beads are produced by suspension polymerization, swelling with pentane, warming to soften and "pre-expand" the beads, pouring them into a mold, and steaming to expand them fully, soften them, and fuse them together into a finished product. This produces drinking cups, molded packaging, board stock, and display and novelty products.

Loose fill for packaging is produced by extruding and chopping polystyrene into various shapes, swelling with pentane, and steaming to expand them into "peanuts."

Polyvinyl Chloride

Flexible PVC foams are generally laminated to layers of cloth and/or solid vinyl, and used for leather-like clothing and luggage, upholstery in autos and furniture, and resilient flooring. They are made by polymerizing vinyl chloride in emulsion, spray-drying to a fine powder, mixing into liquid plasticizer at room temperature to form a viscous paste, compounding with stabilizers/catalysts and azodicarbonamide foaming agent, roller-coating onto a moving belt of textile or paper or solid vinyl film, oven-heating to dissolve the resin in the plasticizer and activate the foaming agent, and cooling to room temperature to gel the plasticized vinyl and stabilize the flexible foam. An alternative for large-scale production is to compound general purpose PVC with plasticizer, stabilizer/catalyst, and foaming agent, calender and/or laminate sheet below the activation temperature of the azodicarbonamide, and then pass it through a hotter oven to foam the sheet.

Polyethylene

Polyethylene foam sheet is used mainly in package cushioning, and also in roof insulation. Extruded profile is also used as construction sealants and pipe insulation. It is made mainly by tandem extrusion. The first extruder melts the polyethylene and blends in liquid volatile organic foaming agent. The second extruder cools it to the optimum foaming temperature, and pumps it through a die into room-temperature air, where it expands into foamed sheet.

For higher performance, cross-linked foamed sheet can be produced by radiation or chemical cross-linking. For radiation cross-linking, polyethylene is melted in an extruder and mixed with powdered chemical foaming agent, extruded into sheet, cross-linked by electron beam radiation, and foamed in an oven. For chemical cross-linking, polyethylene is melted in an extruder and mixed with peroxide cross-linking agent and chemical foaming agent, extruded into sheet, and passed through a two-stage oven for cross-linking and foaming.

Molded foam for package cushioning, flotation devices, and sports equipment is made from foamed pellets. Polyethylene pellets are foamed with volatile organic liquid and cross-linked by peroxide or electron beam. The foamed pellets are poured into a mold, the mold is closed, and the pellets are softened and expanded further to fuse into a molded foam product.

Blow Molding

Blow molding uses compressed air to blow and expand a hot plastic tube ("parison") in a female mold cavity, until the plastic conforms to the walls of the mold. This has developed into a major way to produce plastic bottles, and also more specialized hollow shapes such as fuel tanks, seat backs, tricycles, surfboards, etc. The leading material is HDPE for milk, water, and household chemicals. Second largest is PET for carbonated beverages. A number of other thermoplastics are blow-molded in smaller amounts for more specialized uses.

There are two ways to produce the plastic tube ("parison"): injection molding and extrusion. For injection blow molding, a test-tube shape is first injection molded, then transferred into a bottle mold and blown. For extrusion blow molding, the extruder produces the tube continuously, and a rotating or alternating series of bottle molds take turns clamping around the tube and blowing it. Injection blow molding is used for bottles up to 500 mL in size, while extrusion blow molding is used for bottles 250 mL and larger.

Stretch blow molding holds the parison above its glass transition temperature (T_g) and stretch-orients it to increase modulus, strength, impact resistance, transparency, and impermeability. This is most important for PET, and is also used for PVC, polypropylene, and polyacrylonitrile.

Multilayer blow molding uses a parison containing two or more polymers in concentric layers, and produces a multilayer laminated bottle or fuel tank. In general this can combine the best properties of each layer. Sandwich structure food packaging, with a mid-layer of ethylene/vinyl alcohol copolymer (EVOH), provides impermeability to oxygen. Sandwich structure fuel tanks of HDPE/nylon/HDPE gain impermeability to gasoline.

To speed the cooling portion of the blow-molding cycle, chilled air can help. For more extreme action, liquid carbon dioxide or nitrogen can give even faster cooling.

Surface fluorination has been claimed to make polyethylene less permeable to gasoline and nonpolar solvents in general. Fluorine gas can be used to blow the container, which treats only the inside surface or the finished container can be fluorinated both inside and outside in a single post-treatment. This produces a fluorinated layer 20–40 nm thick.

Thermoforming

Thermoplastic sheet can be softened by warming, placed in or on a mold, pressed gently but swiftly to conform against the walls of the mold, cooled to solidify, and trimmed to separate the product from the surrounding unused sheet.

Sheet can be produced by extrusion or calendering. For use in thermoforming, the sheet must be extremely uniform. For improved properties, the sheet may be biaxially stretch oriented up to 300%. For large automatic production runs, it is fed continuously off a roll; for short runs, large, and/or specialty jobs, it may be cut into individual sheets and fed one at a time.

The sheet must be preheated to make it soft and pliable ("rubbery melt"). For fastest processing and best final uniformity and properties, it should be as hot as possible, without losing melt strength or beginning thermal degradation.

There are three methods of preheating. (1) Convection oven is slow, but very uniform. (2) Conduction heating is done with electrically heated Teflon-coated aluminum plates. (3) Radiant heating is most efficient, especially when the infrared wavelengths are chosen to match the maximum absorption frequencies of the plastic material. There are three ways to press the warm sheet gently and swiftly against the surface of the mold. (1) Vacuum forming is the most popular, pulling the soft sheet against the mold surface, with atmospheric pressure applying the driving force. The vacuum must be at least 25 in. Hg to give the fastest possible cycle. (2) Pressure forming (compressed air), at pressures of 140–860 kPa (20–125 psi), is faster and gives better final properties. (3) Mechanical force (tensile, flexural, or compressive) can also drive the warm sheet to conform to the mold surface. In some cases, two or all three of these methods may be combined for optimum performance.

The best molds are made of aluminum with water-cooling channels cut into them. Tooling costs are low, and heat transfer is high. The formed plastic sheet must be held against the mold surface until it is cooled to the solid state. This is often judged by the HDT at 455 kPa (66 psi).

Whether the process uses continuous sheet or individual sheets, the product is formed from the center of the sheet, and the edges must be trimmed off to give the final product. Die cutting knives are common, but a variety of other mechanical and thermal techniques are also in use. The trim may be 10–70% of the original sheet. It is reground, blended up to 50% with virgin resin, and recycled directly into the same process. Considering the variability of recycle and blending, this requires careful control to maintain quality.

Overall, thermoforming is a very useful method of fast low-cost production for a great variety of plastic products, from packaging to building to automotive parts.

Rotational Molding ("Rotomolding")

Hollow products can be made by placing powdered plastic in a closed mold, tumbling and heating it until the plastic has coated the walls of the mold, cooling it to solidify the product, and opening the mold to remove the product.

Polyethylene is by far the most popular material. Others used occasionally include vinyl plastisol (liquid rather than powder), nylon, polypropylene, and polycarbonate. The powder is usually ground to 35 mesh.

The most popular machine is a carousel design with 3–4 arms operating independently, providing separate stations for loading, heating, cooling, and unloading. Molds are generally made of aluminum, two-piece plus clamps.

Slow rotation gives the most uniform products. The pattern of biaxial rotation must be determined by trial and error. Heating is best done in a gas-fired oven with a fan for circulation.

Cooling is a two-stage process, first a fan and then a cold water spray or mist. Advantages are low capital investment, design freedom, strain-free products, and little or no post-molding secondary operations. For initial costing, multiply the cost of the raw material by 5. Blow molding is faster and uses a wider variety of plastics.

Typical products are tanks (20–85,000 L, 5–22,500 gal), containers for packaging and materials handling, portable outhouses, battery cases, light globes, vacuum cleaners, garbage cans, surfboards, toys, traffic barricades, display cases, and ducting.

Powder Coating

A solid plastic may be ground to a solid powder and then used to apply a plastic coating to a metal product, either for decorative reasons (color) or for functional performance such as insulation or corrosion resistance. Plastics most often used in this way include nylon, vinyl, acrylic, polyethylene, polypropylene, and epoxy. Coating without solvents is beneficial both economically and environmentally, and 100% utilization of material eliminates waste. After the powder is bonded to the metal surface, it is often reheated to flow into a more uniform coating and, in the case of thermosetting resins, to complete the cure reaction.

There are three techniques for applying the powder coating to the surface of the metal product: fluid bed, electrostatic fluid bed, and electrostatic spray.

Fluid Bed Coating

The equipment is simply a horizontal box with a finely-porous shelf near the bottom. Powdered plastic, ground to 20–200 μm, is poured above the shelf. Compressed air is fed in below the shelf, percolating up through the pores, and percolating the powder so that it rises and flows much like a liquid. Sometimes the box is also vibrated to produce greater uniformity.

The metal product to be coated is preheated to a temperature which will melt the powder. Then the product is dipped into the fluid bed. The powder particles melt and flow onto the metal surface. Coatings up to 2.5 mm (0.1 in.) thick can be applied in a single dip.

Typical products are electric motors, electronics, transformers, valves, pumps, refinery equipment, and appliances.

Electrostatic Fluid Bed

In a modification of the fluid bed technique, the product to be coated, instead of being preheated, is passed over the bed, and the powder is attracted to it by a static charge. Then it is passed through a heating oven to fuse it into a finished coating. This process can be used for either discrete or continuous products.

Electrostatic Spray

Conventional electrostatic spray coating pumps a liquid coating formulation through a spray gun, which puts an electrostatic charge on the liquid, and sprays charged droplets toward a grounded metal product. The droplets are attracted to the product, where they discharge and adhere to the metal surface.

Plastic powders can be applied in a similar way. The solid plastic is ground to a 30–200 μm powder, fluidized, and conveyed by compressed air through a spray gun which uses high voltage to apply an electrostatic charge to the particles, and then sprays them at the grounded metal product. Spraying is normally done in a hood, to protect the worker and to collect and recycle the excess powder. The charged powder is attracted to the metal product, attaching a coating 50–75 μm thick on a cold product, or up to 250 μm on a preheated product. A post-fusion step melts and flows the powder into a uniform coating and, in the case of thermosetting resins, also completes the cure reaction.

Calendering

In calendaring a viscous bank of excess thermoplastic or rubber is pressure-formed between a pair of parallel corotating rolls to form a thin "film" or a thicker "sheet." Most calenders consist of four rolls in L- or Z-shape, plus additional feed rolls and post-calender laminating, patterning, and/or wind-up rolls.

PVC is a commonly calendered plastic, especially in plasticized flexible form. Other materials often calendered are rubber, ABS, polyurethane, and thermoplastic elastomers.

The plastic material delivered to the calender must be molten, homogeneous in composition and temperature, and at optimum viscosity for the calendering operation. For rigid vinyl, optimum temperature may be 180–190°C; for flexible vinyl, 10–20°C lower. Nip pressures between the rolls are typically 160–1,050 kN/m (900–6,000 lb/in.) of roll face.

A surface pattern can be applied by the calender roll or by a post-embossing operation. Feeding hot sheet to a cold embossing roll works well. The pattern is measured by a profilometer. Calendering can also be used to apply a plastic surface to a substrate web such as metal, cloth, or paper.

Capital investment for a calender line may be about $5 million. Operating cost may be about $500/h. Calendering is a very high-speed method of producing plastic film and sheet, but high-speed economy must be balanced against quality of the finished product.

Vinyl Plastisol Processing

Plastisol processing is a specialized technique for making flexible vinyl products. It is also sometimes called "paste" or "dispersion" technology. In this method powdered PVC is stirred into liquid plasticizer at room temperature to form a viscous liquid or spreadable paste. This can be poured or spread into the shape of the final product, heated to fuse, and cooled to gel into the final solid product. Simple pouring or gentle spreading requires no heavy equipment, and does not damage delicate substrates, such as paper and cloth. Consequently, this accounts for about 10% of all vinyl production.

About 90% of PVC is made by suspension polymerization and processed as viscous melt at high pressure in heavy-duty equipment. Some 10% of PVC is made by emulsion polymerization and spray-drying, for use in plastisol processing. The resin is stirred into liquid plasticizer at room temperature, along with stabilizer and other optional additives, to form a viscous liquid or easily spreadable paste. This is poured or spread into the form of the desired final product. It is then heated, passing through several phases. At first the resin particles absorb the liquid plasticizer, swell, and form a gel. On further heating, the resin melts and dissolves in the hot plasticizer, forming a hot solution. On cooling, the resin crystallizes somewhat, turning the hot solution into a hot gel. On cooling to room temperature, the gel solidifies to a firm rubbery plastic.

If the plastisol is too viscous for pouring at room temperature, it may be thinned with a volatile solvent; on heating, the solvent evaporates, leaving a firmer final product. This is called "organosol" technology. Alternatively, a polymerizable plasticizer may be added to thin the plastisol; on heating, it polymerizes to a solid ingredient, giving a firmer final product. This is sometimes called a "rigisol."

If molds are required to shape the plastisol into a finished product, they are generally light-weight low-cost molds of aluminum, electroformed nickel, or ceramic. Oven-heating is slow, but common. The major handicap is slow heat transfer, so overall production cycles may take 4–20 min. Several different methods are described below for converting plastisols into finished products.

Dip Coating. A product is preheated and dipped into the plastisol. The plastisol gels onto the surface of the product. It is withdrawn from the liquid, allowed to drain off excess liquid, and then placed in a 191–204°C oven to heat it in a few seconds to about 177°C and fuse the gel to a homogeneous solution. It is then cooled in air or water to solidify the material into the final rubbery coating. Typical products are tool handles, kitchen implements, and electrical insulation.

Dip Molding. Instead of a heated product, a heated male mold is dip-coated in the same way. In this case, the final flexible vinyl product is stripped off of the mold. A typical product is medical gloves.

Slush Molding. This is the reverse of dip molding. A female mold is used to give any desired surface finish on the product. The mold is preheated, plastisol is poured into it, and gels onto the surface of the mold. The excess liquid plastisol is poured out, and the internally coated mold is heated to gel, cooled to solidify the rubbery product, and the product is stripped out of the mold. Typical products are arm rests, head rests, road safety cones, anatomical models, dolls, toys, and auto parts.

Hot–Melt Molding. Hot molten plastisol is injected into a cooled mold to make products like fishing baits and novelties.

Rotational Casting. Like rotomolding, the plastisol is poured into a cold mold, which is rotated and heated to gel the plastisol onto the walls of the mold. It is then heated to fuse, cooled to solidify, opened, and the product removed. Typical products are volley balls, basketballs, dolls, and auto parts.

Open Molding. The plastisol is poured into an open mold, heated to gel and fuse, cooled to solidify, and stripped out from the mold. Typical products are auto air filters, oil filters, truck flaps, and place mats.

Closed Molding. In this process, the plastisol is filled into a closed mold, heated to gel and fuse, then cooled to solidify. A typical product is switch mats for automatic door openers.

Spray Coating. Liquid plastisol can be spray coated up to 1.25 mm (50 mils) in a single pass. The plastisol is formulated to be liquid enough to spray, then firm enough to hold on a vertical surface without running down. It is heated to gel and fuse, then cooled to form the final rubbery coating. A typical product is tank linings.

Continuous Coating. Doctor blade or roll coating applies plastisol continuously to a moving web of metal or cloth, or two successive coatings apply a solid vinyl skin and a foamable vinyl core to a fabric backing. Typical products are house-siding, conveyor belting, and resilient flooring.

Silk-Screen Inks. Plastisol coatings can be applied a few mils thick on cloth to produce T-shirts and athletic uniforms.

Organosol Coatings. The low viscosity of organosol formulations permits coatings under 10 mils thick, particularly for chemical resistance.

Liquid Casting Processes

Reactive liquids may be mixed and poured to form a solid plastic product. They may be two co-reactive monomers or prepolymers, or one monomer/prepolymer, plus a catalyst or curing agent. They are primarily thermosetting plastics and elastomers. Rigid plastics are primarily epoxy, polyester, and acrylic. Elastomers are generally room-temperature vulcanizing (RTV) polymers: polysulfide, polyurethane, and silicone. They are used mostly to provide electrical insulation and mechanical and environmental protection for delicate electrical/electronic products, such as resistors, coils, solenoids, capacitors, transformers, printed circuit boards, optoelectronics, and light-emitting diodes. There are a number of such liquid casting processes, generally carried out at room temperature with or without a later heating step for complete cure.

Casting. The reactive liquid mixture is poured into a mold, and allowed to polymerize and cure. This is used to make solid tires for industrial vehicles, and to make decorative items, such as simulated wood trim, furniture, picture frames, and lamp bases.

Potting. Delicate electronic devices are placed inside an empty shell, and the space is filled by pouring the reactive liquid mixture into it and curing it.

Encapsulation/Embedment. After potting is completed, the outer shell is removed, and the solid plastic is the container.

Conformal Coating. Using a thixotropic reactive liquid, the product is dipped into the liquid and removed with a coating of the liquid on it. This is then heat-cured to solidify the coating and make it permanent.

Impregnation. A porous product can be dipped into a fluid reactive liquid, which soaks into the pores and fills them completely. The liquid is then cured to leave the product completely filled with solid polymer in the pores.

Syntactic Foam. Hollow glass, ceramic, or plastic spheres are dispersed in the reactive liquid system before it is cast. When the liquid is polymerized and cured, the hollow spheres make it a unicellular foam. The air "bubbles" in the cells make it low-density, low dielectric constant and loss, and very resistant to compressive forces such as hydrostatic head in deep-sea equipment.

Aside from simply casting at atmospheric pressure, vacuum is often used to remove air bubbles and volatiles, which would give an imperfect casting, or to help promote porous impregnation. Small specialty runs can be done manually, with no capital investment but high labor cost; larger production runs can be automated with only modest capital investment. Since many of these liquid systems may be volatile and unpleasant to work with, worker protection often includes ventilation and/or protective clothing for eyes, skin, and lungs.

Compression Molding and Transfer Molding

Thermosetting plastics and rubber are heated to soften ("plasticate") them, and then pressed at 14–28 MPa (2,000–4,000 psi) to cross-link ("cure") them. Then the mold is opened and the finished product is removed.

Properties. Compared to engineering thermoplastics, thermosets can offer equal or superior properties at lower cost. Major advantages include rigidity, creep resistance, dimensional stability, impact strength, heat resistance, and chemical resistance.

Typical Applications. Common compression molded thermoset products include electrical equipment, appliance handles and knobs, dinnerware, distributor caps, under-the-hood parts, automatic transmissions, brakes, and pumps.

Compression Molding. This press has two horizontal platens facing each other. The upper one is generally stationary; the lower one moves vertically, driven by mechanical, hydraulic, or pneumatic power. The upper mold half is fastened to the upper platen, the lower mold half to the lower platen. Most molds are electrically heated. In semiautomatic operation, the operator puts the granular molding powder in the lower half of the mold, and presses a button which closes the press, holds it till cure is complete, and opens the press again; then the operator removes the molding from the mold, and repeats the cycle. In fully automatic molding, the entire cycle is automatic and does not require an operator.

Transfer Molding. This preheats the molding powder in the upper part of the mold. Then a plunger pushes the fluid material down into the (lower) mold cavity and holds it there until cure is complete. This gives more fluid flow than compression molding, and avoids damage to delicate molds or molded parts.

Additional Considerations. Compared to injection molding of thermoplastics, compression molding is less capital intensive, more labor-intensive, and takes a longer molding cycle. Transfer molding can equal injection molding cycle times. Compression and transfer molding do less damage to reinforcing fibers, so they can give more impact-resistant products.

The molding cycle can be shortened by preforming and preheating. The granular molding powder is cold-pressed into a pill of the desired weight, and then preheating brings it to near molding temperature before it is inserted into the mold. This gives better flow and faster cure.

"Venting" and "breathing" must often be included in the molding cycle. Venting allows trapped air to escape through small grooves as the molding powder is compressed and flows into a solid part. Breathing opens the mold about 3 mm (in.) for a second or two, early in the molding cycle, to allow escape of water and other volatiles from the condensation cure reaction. This permits production of bubble-free parts. Ejector pins help to separate the finished molding from the mold cavity. These are driven mechanically during the mold-opening stage of the cycle. Post-cure ovens may be used to help complete the cure cycle, especially to control gradual cooling of the molded part. Deflashing is often required to remove excess trim ("flash") from the edges of the molded product. This may be done by tumbling in a rotating drum, or by an air-blast grit.

Reinforced Plastics Processing

Adding short-fiber reinforcements to thermoplastics can produce major increases in modulus, strength, and dimensional stability; it makes melt processing more difficult. Adding fibrous reinforcement to thermosetting plastics produces outstanding modulus, strength, impact strength, dimensional stability, and heat and chemical resistance; but requires entirely new methods of processing to convert them into finished products.

The polymers most often used are unsaturated polyesters and epoxy resins; for ultra-high performance, polyimides and other specialty resins are also used in small amounts. The reinforcing fibers are primarily glass; for ultra-high performance, aramid, carbon/graphite, and metallic fibers are also used.

The polymers are generally polymerized to low molecular weight "A-stage" resins, which are still liquids or fusible solids, and potentially very reactive. In pure form they can

Table 15.22 Typical mix for a bulk molding compound (BMC)

Resin	22%
Fiber	25%
Filler	53%

be stored for months to years. The liquids are easily mixed with reinforcing fibers and other ingredients, and shaped into the form of the ultimate products. Addition of peroxide initiators to polyesters, or amine or anhydride curing agents to epoxies, liberates their high reactivity to permit fast cure cycles to completely cure products. Some processes use heat and/or pressure to complete the shaping and cure cycle, while others are carried out simply at ambient conditions. These variables offer a wide variety of processes which can be used to manufacture reinforced thermoset plastic products.

Matched Die Molding Processes

By analogy with compression molding, thermosetting resins, plus fibrous reinforcement can be pressed between matching mold halves, with heat and moderate pressure, and cured directly into finished products. A typical cure cycle is about a minute. Half of all reinforced thermoset products are made in this way. Major applications are in the automotive, electrical/electronics, appliance, and business machine industries.

Bulk Molding Compound (BMC). Liquid resin, 1/4–1/2 in. long glass fiber, and a simple filler (typically calcium carbonate or clay) are mixed in a dough mixer or cold extruder. A group II metal oxide is added to gel the liquid resin (Table 15.22). This doughy mix ("premix") is placed in a hot mold, pressed to flow and fill the mold cavity, and held until cured.

Sheet Molding Compound (SMC). The SMC machine pours liquid resin and 1-in. glass fiber onto a moving belt, passes it through calender rolls to make a good sheet, and then through an oven to begin cross-linking and gel the resin. The sheet is placed in a hot mold and pressed to shape and cure it. While the short fiber in BMC is easier to mold, the longer fiber in SMC gives greater strength and impact resistance.

Cold Press Molding. Occasionally the mix may be placed in a cold mold and pressed at about 345 kPa (50 psi). The cure cycle is considerably longer.

Preform. A metal screen is made in the shape of the final product. Glass fiber is chopped 2 in. long and sprayed uniformly over the shaped screen, using vacuum on the back side of the screen to assist the process. A small amount of binder, typically 5% of polymer in latex form, is sprayed onto the fiber to hold its shape. It is then removed from the screen, placed in the mold, saturated with an equal weight of liquid resin, and the mold is pressed at 1,380 kPa (200 psi) and heated until cured, typically 3–15 min. This early process has been largely replaced by SMC.

Prepreg. Fabric is impregnated with 25% of liquid resin and laid in the mold. To insure isotropic properties, or to maximize properties in a specific direction, successive layers of impregnated fabric are carefully oriented in different directions. The mold is closed, pressed, and heated till cured. Products made from such impregnated fabrics have much higher strength than simple random fiber reinforcements.

Resin Transfer Molding (RTM). Reinforcing fibers are distributed uniformly in the mold and the mold is closed. Liquid resin is injected into the mold until the excess comes out of the vents. The mold is pressed and heated, similarly to preform molding, until cure is complete.

Open Molding

Instead of applying pressure in a closed mold, the mix of liquid resin and reinforcing fiber may be laid into an open mold, and optionally pressed gently at room temperature until cured. To accelerate low-temperature cure, more active catalyst systems are added. Alternatively, the assembly may be UV or oven-cured. This requires less capital investment, but more skilled labor, so it is useful for prototype and small production runs. It permits unlimited size, so the largest reinforced thermoset products are made in this way, for example, large tanks and whole boat hulls.

Hand Lay-Up (Contact Molding). A layer of liquid resin is applied to the surface of the mold. A layer of glass fiber mat (low strength) or fabric (high strength) is hand laid over it. Liquid resin is poured over it, and brushed or rolled (squeegeed) into it. The process is repeated to build up the desired thickness of the product. The assembly is allowed to stand until cured.

Spray-Up. Instead of hand lay-up, continuous glass roving and liquid resin are fed into a gun, which chops the glass fiber, mixes it with the resin, and sprays it into the mold. This can be automated for lower labor cost and greater uniformity. Spraying is often followed by hand-rolling to expel air and densify the assembly. Then it is allowed to stand until cured. Products are similar to those from simple hand lay-up.

Vacuum-Bag Molding. After hand lay-up, the assembly is covered with an air-tight film, typically polyvinyl alcohol, occasionally nylon or other material. Then a vacuum is pulled on the underside of the film, to squeeze out air and excess resin. Use of a hand-held paddle may help. The assembly is allowed to stand until cured. Products are void-free, and quality is better than simple hand lay-up.

Pressure-Bag Molding. This is similar to vacuum-bag molding, but 345 kPa (50 psi) air pressure is applied to the outside of the cover film. A rubber bag may be used to facilitate the process.

Autoclave Molding. This is similar to pressure-bag molding, but it is carried out in an autoclave to apply the pressure to the outside of the cover film.

Rubber Plug Molding. Liquid silicone rubber is cast into a female mold cavity and cured. The plug is removed, and layers of mat or fabric are built onto the plug. This assembly is then inserted into the mold cavity, pressed, and heated until cured.

Special Processes

Filament Winding. This requires a mandrel to shape the desired finished product. Continuous filament or woven tape is fed through a liquid resin bath to impregnate it, and then wound onto the mandrel in a calculated pattern to optimize the final properties. The assembly is oven-cured. A collapsible mandrel can then be removed from the plastic product; or the mandrel can be left as a part of the finished product. Typical products are pipes, tanks, and pressure bottles. Other suggested products include rocket motor cases, railroad hopper cars, automotive springs, drive shafts, ship hulls, housing modules, helicopter rotor blades, and helicopter tail sections.

Pultrusion. Filaments, woven tapes, or fabrics are fed continuously through a liquid resin bath, through a shaping die, through a curing oven, and then cut to any desired length. This makes continuous products of any desired cross-section. Typical products include fishing rods, flag poles, tool handles, ladder rails, tubing, and other electrical, corrosion resistant, construction, and transportation applications.

Continuous Laminating. Reinforcing fiber and liquid resin are deposited on a moving belt, densified between squeeze rolls, passed through a curing oven, and cut to length. This process is used for mass production of glazing, paneling, and roofing.

Centrifugal Casting. Reinforcing fibers are distributed inside a circular mold. The mold is rotated, and liquid resin is distributed inside it to impregnate the fibers. Rotation of the assembly is continued inside an oven until it is cured. This process is used for making pipes, tanks, and hoops.

Foam Reservoir Molding. Flexible open-cell polyurethane foam is impregnated with liquid resin, faced with glass fiber mat, and gently compression molded. This squeezes the liquid resin into the glass fiber surface mat. Heat curing produces a sandwich structure of low density, high flexural and impact strength.

Rubber

16

D.F. Graves

Introduction

The word "rubber" immediately brings to mind materials that are highly flexible and will snap back to their original shape after being stretched. In this chapter a variety of materials are discussed that possess this odd characteristics. There will also be a discussion on the mechanism of this "elastic retractive force." Originally, rubber meant the gum collected from a tree growing in Brazil. The term "rubber" was coined for this material by the English chemist Joseph Priestley, who noted that it was effective for removing pencil marks from paper. Today, in addition to Priestley's natural product, many synthetic materials are made that possess these characteristics and many other properties. The common features of these materials are that they are made up of long-chain molecules that are amorphous (not crystalline), and the chains are above their glass transition temperature at room temperature.

Rubber products appear everywhere in modern society from tires to biomedical products. The development of synthetic rubber began out of the need for countries to establish independence from natural products that grew only in tropical climates. In times of conflict the natural product might not be available, and its loss would seriously threaten national security. Synthetic rubber, then, became a strategic concern during World Wars I and II [1]. Beyond the security issue, the need for materials with better performance also provided a strong impetus for the development of new rubbery materials. In particular, improvements in oil resistance, high-temperature stability, and oxidation and ozone resistance were needed [2]. Research today is driven to develop materials with even better performance in these areas. In the 1980s and 1990s tires with lower rolling resistance were demanded by car manufacturers to improve fuel economy. This was accomplished, in part, by developing functional tread polymers which chemically bond to fillers resulting in a dramatic reduction in the hysteresis (energy loss) of the tire tread. These new functional polymers will be discussed in this chapter.

The worldwide demand for rubber was estimated to be 23.0 million metric tons for 2011 [3], excluding latex materials. Of this demand, 36% is synthetic rubber of various kinds. Rubber has been classified by use into general purpose and specialty.

The major general purpose rubbers are natural rubber, styrene–butadiene rubber (SBR), butadiene rubber, isoprene rubber, and ethylene–propylene rubber. These rubbers are used in tires, mechanical goods, and similar applications. Specialty elastomers provide unique properties such as oil resistance or extreme heat stability. Although this differentiation is rather arbitrary, it tends also to classify the polymers according to volumes used. SBR, butadiene rubber, and ethylene–propylene rubber account for 78% of all synthetic rubber consumed.

The 2009 synthetic rubber capacity by type is presented in Table 16.1, and Table 16.2 lists the worldwide rubber consumption forecast by type for 2011.

Rubber Concepts

Several key principles (outlined below) greatly help in understanding the performance of elastomeric materials. This outline should present these concepts well enough for use in the following discussions of specific polymer types. However, the reader should consult the references for a more complete understanding of these principles. The concepts are classified as those that relate to polymer structure, those that relate directly to physical properties, and those that relate to the use of the material, as listed below.

Polymer Structure

Macrostructure

Molecular weight. The single most important property of any polymer is the size or length of the molecule. The polymerization process consists of combining many of the simple monomer molecules into the polymer chain. Most of the monomers used to produce rubbers are either gases or low-viscosity liquids under normal conditions; upon polymerization they form liquids whose viscosity increases to extremely high values as the chain length is increased. At very low chain length, this increase is linear with molecular weight until the chains are long enough to become entangled. Above the entanglement molecular weight, the viscosity increases to the 3.4–3.5th power of molecular weight increase [4]. In addition to viscosity, a great many other physical properties of any polymer depend upon the molecular weight [5].

Molecular weight distribution. A given polymer sample is composed of many polymer chains, which in most cases are not of the same length. This variability can be a result of the synthesis process or of possible random scission and cross-linking that can occur upon processing. For economic reasons, it is not possible to separate the various polymer chains by length prior to use; so it is important to characterize this distribution in order to describe the polymer and understand its performance. As with any distribution, no single number is a totally satisfactory descriptor.

The commonly used molecular weight parameters are the number, weight, and z average molecular weight, which are defined, respectively, as: [6]

$$M_n = \frac{\Sigma N_i M_i}{\Sigma N_i}$$

$$M_w = \frac{\Sigma N_i M_i^2}{\Sigma N_i M_i}$$

$$M_z = \frac{\Sigma N_i M_i^3}{\Sigma N_i M_i^2}$$

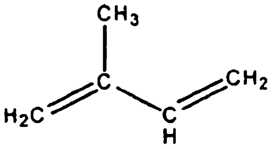
where N_i is the number of moles of species i, and M_i is the molecular weight of species i.

Although there are many different statistical ways to describe any population, the above parameters have been widely used because they are readily understood in physical terms, and they can be measured directly in the laboratory [7]. A fourth parameter, the dispersion index, frequently is used to characterize the breadth of the distribution. This parameter is simply the ratio of the weight to the number average molecular weight, with 1.0 being the lowest possible number (i.e., all chains of exactly the same length). Typical values for commercial polymers are in the 2–5 range, with those under two considered relatively narrow and those over 2.5 considered broad in distribution. The measurement of these molecular weight averages once was a time-consuming task, but with the development of gel permeation chromatography (GPC), also referred to as size exclusion chromatography, the measurement of these distributions has become commonplace [8]. Units are even available that automatically sample polymerization reactors, process the sample, and perform all necessary calculations to provide data for process control. These units can have multiple detectors, thereby providing compositional distribution as a function of molecular weight.

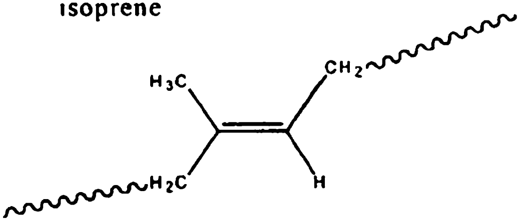
Branching. The concept of a polymer chain implies two ends per chain. However, because of the nature of the process used to form the polymer, the chain may contain one or more branch points, resulting in multiple ends per chain. These chain ends can have an adverse effect on polymer performance. Branching, molecular weight, and molecular weight distribution have been shown to affect process ability as well [9]. The optimum macrostructure often represents a compromise between processing and ultimate performance. Branching can also be measured using the GPC technique with special detectors.

Microstructure

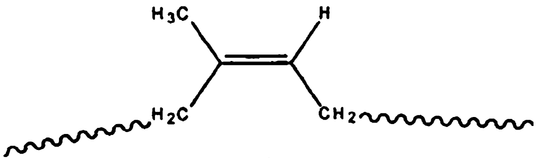
In the formation of elastomers from diolefin monomers such as butadiene or isoprene, there are a number of possible structures. Since the control of these structures is critical in obtaining optimum properties, this area has received great attention from the synthesis chemist. The possible polyisoprene structures are:



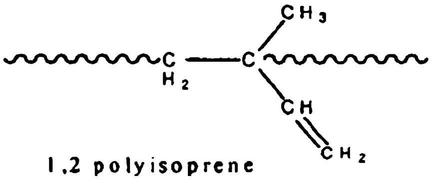
isoprene



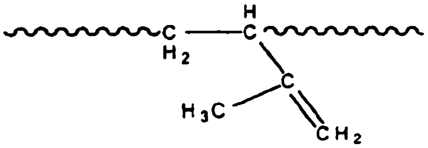
trans-1,4 polyisoprene



cis-1,4 polyisoprene



1,2 polyisoprene



3,4 polyisoprene

For butadiene (no methyl group) the 3,4 form does not exist. The 1,2 addition is referred to as *vinyl addition*.

The polymer in natural rubber (from the *Hevea brasiliensis* tree) is pure *cis* polyisoprene; gutta percha and balata are composed of the *trans* isomer.

Many of the commercial synthetic elastomers are synthesized from more than one monomer, such as styrene–butadiene and ethylene–propylene rubbers. The properties of the resultant polymer depend on the ratio of the two monomers in the polymer and upon the distribution of the monomers within the chain.

If the monomers are uniformly distributed within the polymer chain, the ratio of monomers will define the flexibility of the polymer chain [10]. Because many properties depend on this chain mobility, polymer composition is carefully controlled. In addition to chain mobility, polymer composition also defines the solubility parameter of the polymer, which is a critical property relative to the type of solvents in which the polymer is soluble, the ability of the polymer to accept and hold oil, and the relative compatibility of the polymer with other polymers [11]. Basically, these properties all involve polymer–solvent interaction, with the difference being the increasing molecular weight of the solvent.

In addition to the relative ratio of the monomers, the arrangement of the units in the chain is important. This arrangement is referred to as the copolymer *sequence distribution*. In the previous discussion, the assumption was made that the comonomer units were well mixed in the polymer chain. If this is not the case, parts of the chain can reflect properties of the corresponding homopolymer. It is thus possible to produce polymers that have significantly different properties in different parts of the polymer chain. A most dramatic example of this can be found in styrene–butadiene–styrene (SBS) or styrene–isoprene–styrene thermoplastic elastomers (TPE). The properties of these unique materials will be discussed in the section "Thermoplastic Elastomers."

Network Structure

A critical requirement for obtaining engineering properties from a rubbery material is its existence in a network structure. Charles Goodyear's discovery of vulcanization changed natural rubber from a material that became sticky when hot and brittle when cold into a material that could be used over a wide range of conditions. Basically, he had found a way to chemically connect the individual polymer chains into a three-dimensional network. Chains that previously could flow past one another under stress now had only limited extensibility, which allowed for the support of considerable stress and retraction upon release of the stress. The terms "vulcanization," "rubber cure," and "cross-linking" all refer to the same general phenomenon.

For most rubber systems the network is formed after the polymer is compounded and molded into the desired final shape. Once cross-linked, the material no longer can be processed. If cross-linking occurs prior to compounding or molding, the material is referred to as *gelled*, and it cannot be used. Most rubber is used in a compounded and cured form. There is an optimum *cross-link density* for many failure properties such as tensile strength and tear which will be discussed in the next section.

The one general class of polymers that fall outside this concept is the thermoplastic elastomers, which will also be discussed later.

Rubber Properties

Elasticity: The Retractive Force

The fact that cross-linked rubber materials can be extended to several times their original length and return to that original length when released is certainly their most striking feature. This is in contrast to crystalline solids and glasses, which cannot normally be extended to more than a fraction of their original length and also to ductile metals which can be extended to large deformations but do not return to the original length after the stress is removed.

There have been both statistical and thermodynamic approaches to solving the problem of rubber elasticity leading to a phenomenological treatment; however, these methods are beyond the scope of this chapter. The important, and most interesting, result of these theories is that rubber elasticity arises from changes in entropy of the network. Rubber molecules are capable of geometric isomerization, examples of which are *cis* and *trans*, just like any other unsaturated organic molecule. Upon stretching the network of chains, no "configurational" changes take place. That is, *cis* is not changed to *trans* and thus there is no configurational contribution to entropy. Elasticity *does not* arise from stretching or deforming covalent bonds either. What does take place are rotations about single bonds in the chain backbone during stretching. It is these "conformational" changes which give rise to the entropy decrease upon stretching. The chains do not like being in a stretched state because there are many conformational states not available to them until the stress is released. The chain ends are held apart at a statistically unfavorable distance, which gives rise to the entropy decrease. The following expression, for extensions $>10\%$, shows that the elastic force, f, is directly proportional to the absolute temperature, or the elastic response of the rubber is entirely governed by the decrease in entropy (S) which it undergoes upon extension [12]. The term ∂L is the change in length of the sample:

$$f = -T\left[\frac{\partial S}{\partial L}\right]_{T,V}$$

This expression was derived for constant temperature and volume experiments.

The shear modulus of the rubber network is related to the molecular weight between cross-link points or M_c. The lower the molecular weight of chains between cross-links (network chains), the higher the cross-link density and the higher the modulus. This is shown in the following expression:

$$G_0 = \frac{\rho RT}{M_c}$$

where G_0 is the elastic shear modulus, ρ is the density, R is the gas constant, and T is absolute temperature. There is an optimum cross-link density for ultimate strength properties, above which the highly cross-linked network no longer can dissipate strain energy in the form of heat (hysteresis) so all the energy goes into breaking network chains and the material becomes brittle. Below this optimum cross-link level the material simply has too much viscous flow and pulls apart easily. Therefore, the rubber chemist must optimize the state of cure if high strength is desired.

Glass Transition Temperature

In order for a polymer to behave as a rubbery material, it is necessary for the chain to have great mobility. As the temperature is lowered, the ability of the chain segments to move decreases until a temperature is reached where any large-scale motion is prevented. This temperature is referred to as the glass transition temperature (T_g). Below this temperature the rubber becomes a glassy material—hard and brittle. Above this temperature amorphous plastics, such as polystyrene, can exhibit a rubbery character if the molecular weight is sufficiently high. All rubbery materials, then, must have glass transition temperatures below room temperature. For good low-temperature properties, it obviously follows that a low glass transition temperature polymer is required. The control of the glass transition temperature of the polymer is critical for many properties other than low-temperature use. For example, the wet traction and wear of a passenger tire have been shown to greatly depend directly on the polymer glass transition temperature [13].

Control of this property is possible by controlling the structure of the polymer chain. Monomers with bulky side groups restrict chain mobility and thus raise the glass transition temperature. The composition of copolymers and the ratio of polymer blends often are determined by the desired glass transition temperature of the final product.

The glass transition temperature is usually measured using thermal methods such as differential scanning calorimetry (DSC) which looks at the change in heat capacity when a material goes through its glass transition.

Another very useful method is to use dynamic mechanical properties where the polymer is subjected to a temperature sweep in a dynamic mechanical spectrometer from very low temperature ($-120°\mathrm{C}$) to well above room temperature ($+100°\mathrm{C}$). If the modulus is plotted vs. temperature, there will be a sharp decrease as the polymer warms to above its T_g. There will also be a peak in the energy loss property known as tan delta. The tan delta vs. temperature plot is very useful for predicting tire properties such as rolling resistance and wet traction.

Crystallinity

Polymer chains can exist in spatial arrangements that are orderly enough to allow the chains to form crystalline structures. The existence of strong interchain interactions via polar forces, hydrogen bonding, or ionic groups can facilitate crystallization. The existence of crystallization is very important for many plastics and fibers, but crystallinity cannot be appreciably present in rubbery materials, as the corresponding restriction in chain mobility could preclude the very chain mobility needed for rubbery properties. Rubbery materials must have both their melting temperature (if they have a crystalline point) and their glass transition temperature below the use temperature.

Crystallinity can be reduced by disruption of the order in the chain by copolymerization [14]. For example, both polyethylene and polypropylene are crystalline plastics, whereas ethylene–propylene rubber produced at about a 50:50 ratio is an amorphous elastomer. Compositional excursions much outside this range lead to crystalline materials [15]. For some materials, such as natural rubber, that are close to crystallizing, stretching the chains can align them sufficiently for crystallization to occur. Such polymers can exhibit excellent gum properties and improved strength in the uncured state that greatly facilitate processing.

Attempts have been made with some success to produce other polymers that exhibit this property of natural rubber. Although the melting temperature can be matched by appropriately disrupting the crystallizable structure through controlled introduction of another monomer, an exact match is not possible because the extent of crystallinity and the kinetics of crystallization will differ.

Crystallinity can be measured using the same thermal and dynamic mechanical methods described for measuring T_g; however, the melting transition is much sharper than the T_g because it is a first-order transition compared with second-order for the T_g.

Rubber Use

Compounding

The rubber industry began when Charles Goodyear developed the first useful rubber compound: natural rubber plus sulfur. The concept of mixing materials into rubber to improve performance is still of primary importance today. Without compounding, few rubbers would be of any commercial value. Any given rubber application will have a long list of necessary criteria in addition to cost, encompassing appearance, processing, mechanical, electrical, chemical, and thermal properties. Developing such compounds requires a broad knowledge of material science and chemistry combined with experience. The use of designed experiments can greatly facilitate selecting the optimum compound formulation.

The major components in a compound are curatives, reinforcing agents, fillers, plasticizers, and antidegradants.

Curatives. The function of curatives is to cross-link the polymer chains into a network; the most common ones are the sulfur type for unsaturated rubber and peroxides for saturated polymers. Chemicals called accelerators may be added to control the cure rate in the sulfur system; these materials generally are complex organic chemicals containing sulfur and nitrogen atoms. Stearic acid and zinc oxide usually are added to activate these accelerators. Metal oxides are used to cure halogenated polymers such as polychloroprene or chlorosulfonated polyethylene.

Reinforcing agents. Carbon black and silica are the most common reinforcing agents. These materials improve properties such as tensile strength and tear strength; also, they increase hardness, stiffness, and density and reduce cost. Almost all rubbers require reinforcement to obtain acceptable use properties. The size of the particles, how they may be interconnected (structure), and the chemical activity of the surface are all critical properties for reinforcing agents. In tire applications, new polymers are currently being developed which contain functional groups that directly interact with carbon black and silica, improving many properties.

Fillers. Fillers are added to reduce cost, increase hardness, and color the compound. Generally they do not provide the dramatic improvement in properties seen with reinforcing agents, but they may have some reinforcing capability. Typical fillers are clays, calcium carbonate, and titanium dioxide.

Plasticizers. These materials are added to reduce the hardness of the compound and can reduce the viscosity of the uncured compound to facilitate processes such as mixing and extruding. The most common materials are petroleum-based oils, esters, and fatty acids. Critical properties of these materials are their compatibility with the rubber and their viscosity. Failure to obtain sufficient compatibility will cause the plasticizer to diffuse out of the compound. The oils are classified as aromatic, naphthenic, or paraffinic according to their components. Aromatic oils will be more compatible with SBR than paraffinic oils, whereas the inverse will be true for butyl rubber. The aromatic oils are dark colored and thus cannot be used where color is critical, as in the white sidewall of a tire. The naphthenic and paraffinic oils can be colorless and are referred to as nonstaining.

Antidegradents. This group of chemicals is added to prevent undesirable chemical reactions with the polymer network. The most important are the antioxidants, which trap free radicals and prevent chain scission and cross-linking. Antiozonants are added to prevent ozone attack on the rubber, which can lead to the formation and growth of cracks. Antiozonants function by diffusion of the material to the surface of the rubber, thereby providing a protective film. Certain anti-oxidants have this characteristic, and waxes also are used for this purpose.

Processing

A wide range of processes are used to convert a bale of rubber into a rubber product such as a tire. The first process generally will be compounding. Typical compounding ingredients were discussed previously. In many compounds more than one rubber may be needed to obtain the performance required. Uncured rubber can be considered as a very high-viscosity liquid; it really is a *viscoelastic* material possessing both liquid and elastic properties. Mixing materials into rubber requires high shear, and the simplest method is a double roll mill in which the rubber is shear-mixed along with the other compounding ingredients in the bite of the mill. Large-scale mixing is most commonly done with a high-shear internal mixer called a Banbury. This mixing is a batch process, although continuous internal mixers also are used.

The compounded rubber stock will be further processed for use. The process could be injection or transfer molding into a hot mold where it is cured. Tire curing bladders are made in this fashion. Extrusion of the rubber stock is used to make hose or tire treads and sidewalls. Another common process is calendaring, in which a fabric is passed through rolls where rubber is squeezed into the fabric to make fabric-reinforced rubber sheets for roofing membranes or body plies for tires. The actual construction of the final product can be quite complex. For example, a tire contains many different rubber components some of which are cord or fabric reinforced. All of the components must be assembled with high precision so that the final cured product can operate smoothly at high speeds and last over 50,000 miles.

Natural Rubber

More than 500 years ago, the people of Central and South America were using a product that they collected from certain trees to make balls and to coat fabric to make it waterproof. This material they called cauchuc, which means “weeping wood.” Today we know the tree as the *H. brasiliensis* and the material as natural rubber. Although a number of plants produce rubber, the only significant commercial source is the *Hevea* tree. Natural rubber initially had only limited applications because it flowed when hot and had poor strength. In 1839 Charles Goodyear found that when combined with sulfur and heated, the material changed into cured rubber with properties much as we know them today. The development of the pneumatic tire in 1845 combined with the dramatic growth of the automotive industry led to a rapid increase in the demand for natural rubber.

Although the tree was indigenous to Brazil, seeds were taken to England where they were germinated, and the plants were sent to the Far East. Rubber plantations were in existence by the late 1800s, and in the 1920s plantations were begun in West Africa. Because of a leaf blight disease, essentially all natural rubber now comes from plantations in Africa and the Far East rather than Central and South America [16].

The production process starts with the trees. Over the years considerable biological research has been done to produce trees that grow faster, produce more latex, and are resistant to wind and disease damage. Once such an improved tree has been identified, buds are grafted from the tree onto root stock. All such trees are referred to as clones and will have the same characteristics. It typically takes 6–7 years of growth before a tree is ready for rubber recovery. Peak rubber production is reached at 12–15 years of age. Another major development in improving tree performance has been the use of tree stimulants, which has resulted in an overall yield increase of 30% without adverse effects on the trees.

The production process of natural rubber in the tree is not yet fully understood. However, it involves a long series of complex biochemical reactions that do not involve isoprene as a monomer, even though the resulting polymer is 100% *cis* 1,4 polyisoprene. Because the tree makes the product, the rubber production process is really one of recovery.

The recovery process starts with tapping of the tree, which involves manually removing thin sections of bark at an angle so that as the latex is exuded from the damaged living latex cells, it will flow down to be collected in a cup. The depth of the cut is critical, as a tool shallow cut will not allow optimum latex yield, and too deep a cut will damage the tree. The damaged latex vessels will seal off after several hours. A preservative is added to the collection cup to prevent coagulation of the latex. The tapper then collects the latex and takes it to a collection station, from which it is shipped to the rubber factory. Additional preservative is added at the collection station to assure stable latex. The latex contains around 30–45% rubber. Approximately 3% of the solid material is nonrubber materials, consisting primarily of proteins, resins, and sugars.

The latex is processed in one of several ways, depending on the desired final product. If it is going to be used in the final product application in the latex form (such as for dipped goods and adhesives), it will be concentrated to 60% or higher solids. The most common process is centrifugation. The latex separates into the high-solids product and a low-solids skim material that contains a much higher percentage of the nonrubbery components; rubber produced from skim is generally of a lower quality because of these impurities. A variety of chemicals can be added to the latex to provide the necessary preservation and mechanical stability. As the final use of the latex will involve destabilizing the rubber particles, care must be taken not to overstabilize the latex concentrate. Being a natural product, the latex tends to change upon aging, a factor that also must be compensated for in the process.

Dry rubber is produced from the latex first by dilution, then by coagulation with organic acids, and finally by formation into sheets or crepe. Rubber smoked sheets are made by working the coagulated sheets between rolls to remove as much of the nonrubbery components as possible, followed by drying for up to a week in a smokehouse. The smoke serves as a fungicide that prevents biological attack of the rubber. To provide a more well-defined uniform product, Technically Specified Rubber (TSR) processes have been developed. These processes involve converting the coagulated rubber into rubber crumb, which is further washed, dried, and baled. Constant-viscosity grades of natural rubber have been developed by chemically reacting the aldehyde groups, which otherwise would lead to cross-linking upon storage. In the pale crepe process the latex is carefully selected for colored bodies (from carotene) and treated with sodium bisulfite to stop enzyme activity. The rubber is extensively washed through rollers to remove serum, as this can lead to yellowing. The wet crepe is dried under carefully controlled temperatures and in the absence of light to assure optimum properties. The previously described processes involve considerable investment and are practical only for plantation operations. Small shareholders may allow their latex to coagulate naturally and sell it to processors. Such a product will vary greatly, depending on the specific history of each rubber slab [17].

Uses

The largest use of natural rubber is in the manufacture of tires. Over 70% of its consumption is in this area. The next largest use is as latex in dipped goods, adhesives, rubber thread, and foam. These uses account for approximately another 10%. The remainder is used in a variety of applications such as conveyor belts, hoses, gaskets, footwear, and antivibration devices such as engine mounts.

Because of the high stereoregularity of natural rubber, the units in the polymer chain can form very orderly arrangements, which result in crystallization upon storage at low temperatures or upon stretching. Stored crystallized rubber may be converted to its original amorphous state by heating. Several crystalline forms are reported, with melting points varying from 14 to 36°C [18]. Although crystallization upon storage can be a problem to users, the ability to crystallize reversibly upon stretching accounts for many of the unique properties of natural rubber. Specifically, the ability of natural rubber to be used as a gum polymer (unfilled vulcanizate) depends on this property. The crystallites that form act both as filler and as temporary cross-links, providing high tensile properties [19]. In tire fabrication this property is reflected in natural rubber stocks possessing high green (uncured) strength and excellent building tack. In the final product, strain-induced crystallization provides tear and cracking (cut growth) resistance.

Although many other polymers can crystallize, only natural rubber has been found to have the necessary combination of rate of crystallization, degree of crystallization, and melting point to provide all the properties discussed above. Natural rubber has good flexibility and resilience. In truck and bus tires, it is used extensively with blends of polybutadiene to give the low heat buildup needed as well as wear and cut growth resistance. In passenger tires, natural rubber is used in the sidewalls and carcass areas. These areas require the building tack, ply adhesion, and hot strength properties that it imparts. Synthetic rubber is used almost exclusively in passenger tire treads.

The largest use of natural rubber latex is in the dipped goods area. Products include balloons, surgical and examination gloves, and prophylactics. The rapid spread of AIDS has led to a dramatic increase in the surgical and examination glove market. Latex also is used to make adhesives, rubber thread, and foams. However, natural rubber is being replaced in these two latex areas by urethanes and synthetic rubber latex. Some of the replacement has been driven by skin allergy problems which are caused by the natural proteins in the latex.

Although natural rubber latex is a mature product, research continues on improving its uniformity, stability, and performance [20].

Polyisoprene

Faraday discovered in 1826 that natural rubber was composed of a hydrocarbon with a ratio of five carbons to eight hydrogen atoms; and in 1860, G. Williams isolated isoprene by collecting the distillate from the heating of natural rubber. By 1887, scientists in France, England, and Germany had converted isoprene back into a rubbery material. Because this offered a potential for manufactured "natural" rubber, research was undertaken to find ways to obtain isoprene from sources other than rubber itself [21].

Monomer Production

The primary source of isoprene today is as a by-product in the production of ethylene via naphtha cracking. A solvent extraction process is employed. Much less isoprene is produced in the crackers than butadiene, so the availability of isoprene is much more limited. Isoprene also may be produced by the catalytic dehydrogenation of amylenes, which are available in C-5 refinery streams. It also can be produced from propylene by a dimerization process, followed by isomerization and steam cracking. A third route involves the use of acetone and acetylene, produced from coal via calcium carbide. The resulting 3-methyl-butyne-3-ol is hydrogenated to methyl butanol and subsequently dehydrogenated to give isoprene. The plants that were built on these last two processes have been shut down, evidently because of the relatively low cost of the extraction route.

Polymer Production Process

The free-radical catalysts were found to produce a product that did not have the tack, green strength, or gum tensile of natural rubber. Whereas natural rubber is an essentially pure *cis*-1,4 structure, the emulsion product was of mixed microstructure. This precluded the ability of the latter to undergo strain-induced crystallization, which is required to obtain many of the desired natural rubber properties.

In 1955 investigators from the Firestone Tire and Rubber Company and the B. F. Goodrich Company announced the synthesis of polyisoprene with over 90% *cis*-1,4 structure. The work at Firestone was based on lithium metal catalysts, whereas the work at Goodrich was the result of using Ziegler–Natta type coordination catalysts [22,23].

Use

Although considerable interest was generated by these discoveries, their commercial success has been rather limited. The lithium-based polymers were found to produce up to 94% *cis*, which still was not high enough to provide the properties of natural rubber. Polymers made with the coordination catalysts have *cis* contents of up to 98%, providing products that can more closely serve as replacements for natural rubber than the lithium-based polymers. In comparison with natural rubber, they offer the advantage of a more highly pure rubber (no nonrubber material) and excellent uniformity. For economic reasons, polyisoprene has seen only limited success. Several of the plants built to produce polyisoprene have been either shut down or converted for use to produce other polymers. In terms of synthetic rubber production in 2003, only 258,000 metric tons were produced (excluding centrally planned economy countries, CPEC), which represented only 3% of total synthetic rubber production. In comparison, in 2003 natural rubber usage was 7,554,000 metric tons [24]. Evidently because of its strategic importance, the Former Soviet Union (FSU) continues to rely heavily on polyisoprene.

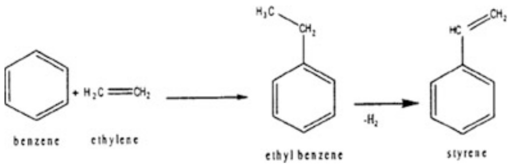
Styrene–Butadiene Rubber

The largest-volume synthetic rubber consumed is SBR. In 2009, SBR solid rubber accounted for 34% of all synthetic rubber. If SBR latex and carboxylated SBR latex are included, its share increases to 50%. The major application of solid SBR is in the automotive and tire industry, accounting for approximately 70% of the use. Therefore, SBR has been tightly tied to the tire business [25].

Initially, SBR was developed as a general purpose alternate material to natural rubber. In the United States the thrust came early in World War II when the US supply of natural rubber was cut off. The basic technology was developed in Germany in the late 1920s, and by 1939 Germany had 175,000 metric tons of capacity in place. The first US production was 230 metric tons in 1941, but by 1945 there were more than 850,000 metric tons of capacity. Basically, in a period of 5 years the emulsion SBR business as we know it today was put in place. By 1973 US capacity had increased to almost 1,400,000 metric tons, but in 1989 it had contracted to 881,000 tons close to the 1945 capacity [26].

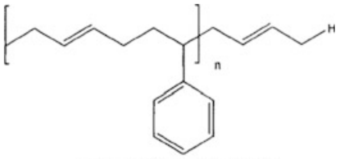
Monomer Production

The production of butadiene monomer is discussed below in section "Polybutadiene." The largest volume of styrene is produced by the alkylation of benzene with ethylene to give ethyl benzene, which is then dehydrogenated to give styrene [27].



Polymer Production Process

SBR is produced by two different processes: emulsion and solution. The emulsion process involves a free-radical mechanism, whereas solution SBR is based on alkyllithium catalysis.



copolymer of butadiene and styrene

Emulsion Process

The formula developed to provide SBR during World War II was standardized, with all rubber plants owned by the US government. The standard recipe is listed below[28].

Component	Parts by weight
Butadiene	75
Styrene	25
n-Dodecyl mercaptan	0.5
Potassium peroxydisulfate	0.3
Soap flakes	5.0
Water	180

Initiation occurs through reaction of the persulfate with the mercaptan, as shown below:

$$K_2S_2O_8 + 2RSH \rightarrow 2RS\bullet + KHSO_4$$
$$RS\bullet + M \rightarrow RSM\bullet$$

Chain propagation occurs by the growing chain free radical attacking either the butadiene or styrene monomer. The active radical chain can react with mercaptan to form a new mercaptyl radical and a terminated chain. The mercaptyl radical then can initiate an additional chain. The molecular weight of the chain P can be controlled by the concentration of mercaptan via this chain transfer mechanism.

$$P\bullet + RSH \rightarrow PH + RS\bullet$$
$$RS\bullet + M \rightarrow RSM\bullet$$

Termination also can occur by the reaction of two free radicals, through either combination or disproportionation reactions.

$$P\bullet + P\bullet \rightarrow P - P \text{ combination}$$
$$\text{(bimolecular coupling)}$$

$$P\bullet + P\bullet \rightarrow P - CH = CH_2$$
$$+ PH \text{ disproportionation}$$
$$\text{(hydrogen-free radical transfer)}$$

The mercaptyl radical also can react with growing chains, to lead to termination [29].

Polymerization is initially carried out at 50°C until conversion of 70–75% is reached, at which time the polymerization is terminated by the addition of a free-radical scavenger such as hydroquinone. Polymerization beyond this point results in excessive free-radical attack on the polymer chains. Products made under such conditions have poor properties due to excessive branching and gelation. Unreacted butadiene and styrene are removed by flashing and steam stripping. Antioxidant is added to the latex, followed by coagulation with the addition of polyelectrolytes and salt-acid. The coagulated crumb then is washed, dried, baled, wrapped, and packaged for shipment. Because of the soap and other chemicals in the formulation, most emulsion polymers will contain about 7% of nonrubber residues. The emulsion process flow sheet is shown in Fig. 16.1.

It was soon discovered that polymers made at lower temperatures had significantly better properties, especially in tire treads. This was mainly because they contained fewer low-molecular-weight species. A lower temperature process, using "redox" chemistry, was eventually developed. It used peroxides or hydroperoxides with a reducing agent such as a water-soluble transition metal salt which were active even at 0°C.

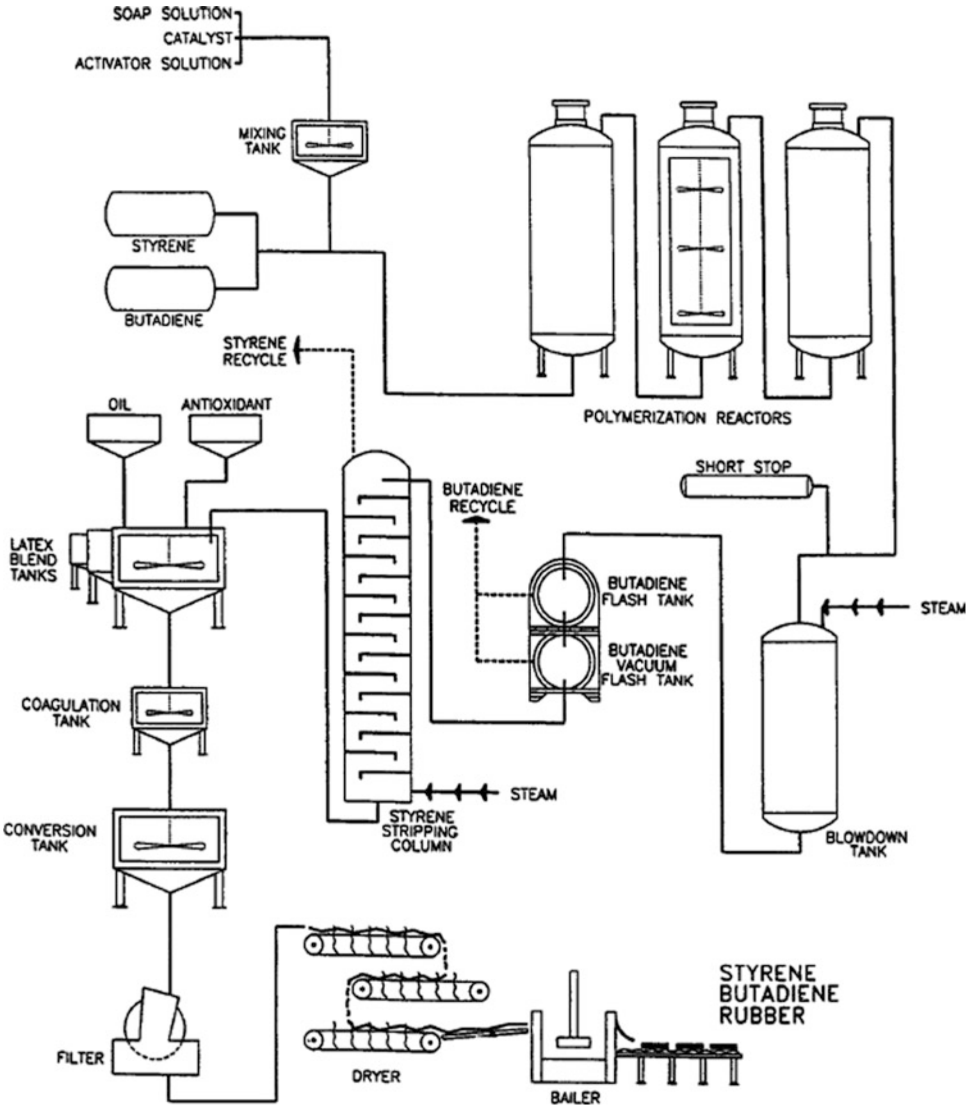


Fig. 16.1 The production of styrene-butadiene rubber (modified by Graves DF from a drawing in the Vanderbilt Rubber Handbook, 1990 Edition, Copyright the R. T. Vanderbilt Company, Inc., by permission)

Mercaptans are also used as chain transfer agents to provide a mechanism for molecular weight control. Commercially these types of polymerization are carried out at 5°C and are referred to as "cold" polymerizations to differentiate them from the previously discussed "hot" systems. A typical formula is listed below [30].

Component	Parts by weight
Butadiene	71
Styrene	29
tert-Dodecyl mercaptan	0.18
p-Methane hydroperoxide	0.08
Ferrous sulfate heptahydrate	0.03
Trisodium phosphate decahydrate	0.50
Tetrasodium ethylenediaminetetraacetate	0.035
Sodium formaldehyde sulfoxylate	0.08
Rosin acid soap	4.5
Water	200

The improved tire wear of cold polymerization SBR led to the very rapid replacement of hot SBR for most applications. This change was relatively easy to make, as all the equipment could be used with the only modification required being the addition of reactor cooling, which is achieved with either the reactor jacket, internal coils, or both.

It later was found that even more improvements could be realized by polymerizing to very high molecular weights and then adding petroleum-based oils to the latex prior to coagulation. The oil is absorbed by the rubber which, upon coagulation, produces oil-extended polymers. For tread applications, oils of higher aromatic content were preferred because of their excellent compatibility with the rubber. Typically 37.5 parts of oil are added, although grades containing up to 50 parts have been produced. Very high molecular weight polymers thus can be processed without requiring excessive energy to mix them. The oil also allows these tough polymers to be processed without excessive degradation. Carbon black master batches also are produced. In this process carbon black is added to the latex prior to coagulation, and the black, along with oil, is incorporated into the latex in the coagulation step. These products offer the user the advantage of not having to handle free black in their mixing operation, and can provide additional compounding volume for manufacturers with limited mixing capacity.

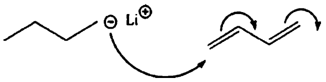
Not all emulsion SBR is converted to dry rubber for use. There is a variety of applications where the latex can be used directly in the final fabrication process. This technology logically grew out of the latex technology developed for natural rubber. For latex applications the particle size distribution can be critical because of its effect on viscosity and performance variables, as when used to provide impact strength in plastics such as ABS [31]. Careful control of the mechanical stability of the latex also is critical, as these systems must destabilize under relatively mild conditions such as those in a coating operation. A number of processes have been developed to control particle size via partial destabilization of the latex. Among the commercial methods are careful control of a freeze–thaw cycle, controlled shear agitators, high-pressure colloid mills, and the addition of chemicals such as hydrocarbons or glycols.

A special variation of SBR latex containing terpolymerized vinyl pyridine is used in the tire industry to provide adhesion of organic fiber tire cords to rubber stock. The vinyl pyridine SBR latex is combined with resins and coated on the fiber by a dipping process. The adhesive is set by a controlled temperature and tension process to control the shrinkage properties of the cord.

Solution Process

The discovery of the ability of lithium-based catalysts to polymerize isoprene to give a high *cis* 1,4 polyisoprene was rapidly followed by the development of alkyl lithium-based poly-butadiene. The first commercial plant was built by the Firestone Tire and Rubber Company in 1960. Within a few years the technology was expanded to butadiene–styrene copolymers, with commercial production under way toward the end of the 1960s.

The copolymerization with alkyl lithium to produce uniformly random copolymers is more complex for the solution process than for emulsion because of the tendency for the styrene to form blocks. Because of the extremely high rate of reaction of the styryl-lithium anion with butadiene, the polymerization very heavily favors the incorporation of butadiene units as long as reasonable concentrations of butadiene are present. This observation initially was somewhat confusing because the homopolymerization rate of styrene is seven times that for butadiene. However, the cross-propagation rate is orders of magnitude faster than either, and it therefore dominates the system. For a 30 mole percent styrene charge the initial polymer will be almost pure butadiene until most of the butadiene is polymerized. Typically two-thirds of the styrene charged will be found as a block of polystyrene at the tail end of the polymer chain:



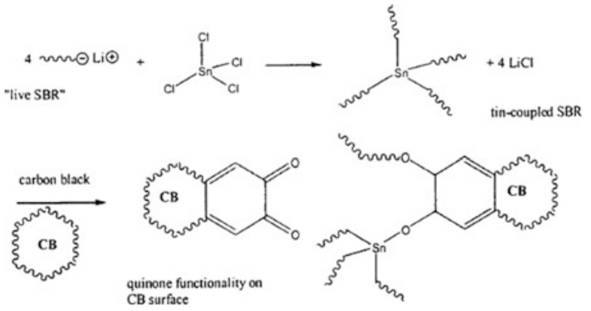
Several methods have been proposed to overcome this problem. In one, the styrene and part of the butadiene are charged initially with butadiene metered at a rate equivalent to its incorporation into the chain. A second approach involves adding both monomers at a relatively slow rate so that the equilibrium monomer concentration reaches a pseudosteady state that will produce polymer at the desired composition [32]. This process can be done in either a batch or a continuous mode [33].

In addition to these reaction engineering approaches to produce uniformly random copolymer, the chemistry may be changed by the addition of polar agents such as amines and ethers. This action results in bringing the reactivity rates much closer together. The change in chemistry also is reflected in the microstructure of the butadiene portion of the polymer. Whereas in the nonpolar system the vinyl content of the butadiene portion is around 10%, in polar systems vinyl contents of 30–40% typically are obtained when a 20% styrene polymer is randomized. Higher styrene contents require higher modifier levels, resulting in even higher vinyl contents. An added complication with polar modifiers is their ability to react with the growing chain, resulting in undesired termination.

In spite of these complications, all recent US expansions or announced plants for SBR have been for solution polymers. The ability to better design the polymer structure and produce special functional polymers (described below) accounts for most of this shift.

Functional Solution SBR

The driving force toward functional solution SBR is its improved hysteresis properties for passenger tire treads. The fact that anionic SBR has a much more narrow molecular weight distribution compared with emulsion gives it lower hysteresis. However, the big advantage is the relatively stable growing chain ends which can be chemically modified to improve interaction with carbon black and silica in tire compounds [34]. This modification can lead to a dramatic reduction in rolling resistance, which is critical for automotive manufacturers who must meet government-mandated fuel economy targets. The most active functional end-groups contain either organotin or certain amines. Termination with tin tetrachloride is the easiest and most popular method which generates a four-armed star polymer. The polymer–tin bonds break down during mixing of the compound and both lower the compound viscosity and create active sites for reaction with carbon black surfaces. The creation of this "carbon-bound rubber" effectively prevents the carbon black from agglomerating on a micro-scale to form hysteretic, three-dimensional networks. The breaking of these networks during the deformation of a tire tread is a major source of rolling resistance. Polymers with amine end-groups also show good activity with carbon black. Termination with silane esters is usually used to obtain interaction with silica fillers producing the same decrease in hysteresis. There have recently been efforts to make functional anionic initiators, some of which could be used to make low hysteresis rubber [35]. However, the main use for such polymers has been in adhesives and other nontire applications. One study comparing an emulsion polymer, its solution counterpart, and a chemically modified version of the solution polymer showed a 23% hysteresis reduction in going from emulsion to solution and an additional 15% reduction for the chemically modified polymer, to provide an overall reduction of 38% [36]. To date, this type of chemical modification is only possible using anionic techniques.



Polybutadiene (BR)

Next to SBR, polybutadiene is the largest volume synthetic rubber produced. Consumption was approximately 2,166,000 metric tons in 2009 [37].

Monomer Production

Butadiene monomer can be produced by a number of different processes. The dominant method of production is as a by-product from the steam cracking of naphtha to produce ethylene. The butadiene is recovered from the C-4 fractions by extractive distillation [38]. "On-purpose" butadiene is generally produced by dehydrogenation or oxidative dehydrogenation of four-carbon hydrocarbons [39,40].

Polymer Production Process

Polybutadiene is usually produced by alkali metal, and transition metal coordination solution processes. Most production is based on the solution processes because of the ability to obtain preferred microstructures by these routes.

Alkali-metal-based polymerization (usually organolithium) produces a product with about 36% *cis*, 54% *trans*, and 10% vinyl. The polymerization process is conducted in an aliphatic hydrocarbon under an inert atmosphere in either a batch or a continuous mode. Because of the characteristics of this polymerization system, polymers of extremely narrow molecular weight distribution and low gel can be produced [41]. The narrowest distribution is produced via batch polymerization. Coupled (star branched) and end-functional polybutadienes are possible using organolithium technology due to the living anion on the chain end which is available for further reactions. Upon the addition of polar agents, such as ethers or amines, the organolithium initiators can produce polybutadienes with vinyl contents up to 100% [42]. The vinyl content can be controlled by the ratio of modifier to catalyst and the polymerization temperature, with lower temperatures favoring increased vinyl formation. Even with high vinyl contents such polymers do not crystallize because of the atactic nature of the vinyl units. High *cis* polybutadiene is produced via solution processes using Ziegler–Natta type transition metal catalysts. The major commercial catalysts of this type are based on titanium, cobalt, nickel, and neodymium [43]. Typically the transition metal is used in the form of a soluble metal salt, which can react with an organoaluminum or organoaluminum halide as a reducing agent to give the active species. Because of the active nature of transition metals, the polymer solutions are treated to deactivate or remove such materials from the final product.

All of these catalysts produce products with 90% or higher *cis* content. The neodymium system is reported to produce the highest *cis* (98–99%) with the most linear chain structure [44]. The highest branched *cis* BR is produced with the Co system with Ni giving intermediate branching.

All the solution processes require high efficiency in recovering the solvent. The most widely used process consists of termination of the polymerization and the addition of antioxidant to the polymer solution. The solution may be treated to remove catalyst residue and then transferred into an agitated steam stripping vessel in which unreacted monomer and solvent are flashed off, leaving the rubber as a crumb slurry in water. The water–crumb slurry then is dewatered and dried. The recovered monomer/solvent is recirculated to a series of distillation columns to recover

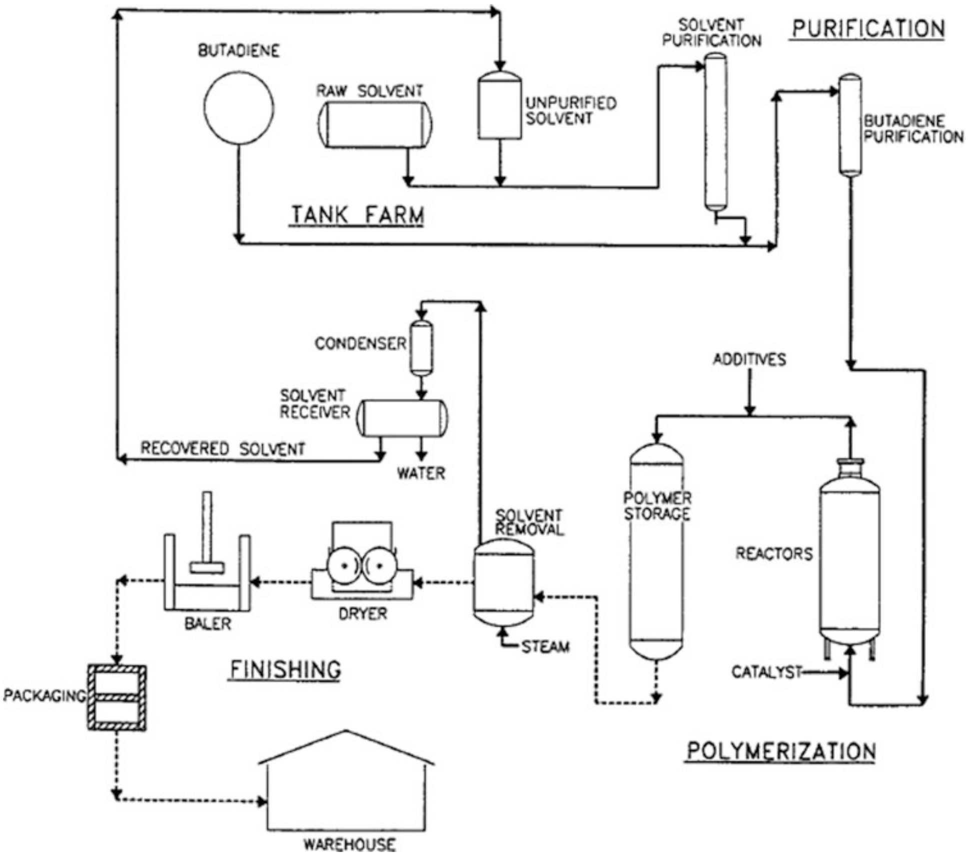


Fig. 16.2 Flow diagram for a typical solution process for the manufacture of polybutadiene (courtesy of Firestone Polymers, Akron, Ohio)

monomer and purify the solvent. As both the anionic and the coordination catalyst systems are highly sensitive to impurities such as water, the purification system is very critical for satisfactory process control (Fig. 16.2).

Uses

The major use for polybutadiene is in tires, with over 70% of the polymer produced used by the tire industry. Cured polybutadiene has excellent low-temperature properties, high resiliency, and good abrasion resistance due to its low glass transition temperature. However, this same fundamental property also leads to very poor wet skid resistance. For this reason, polybutadiene is blended with other polymers such as natural rubber and SBR for use in tread compounds. In general, polybutadiene is a poorer-processing polymer than SBR, but this is generally not a problem as it is blended with other polymers in use. The very high *cis* polymers have the potential for strain-induced crystallization, which can lead to improved green strength and increased cut growth resistance in the cured product. High *cis* polybutadiene is reported to have a melting point of 6°C [45].

The other major use for polybutadiene is as an impact modifier in plastics, in particular high impact polystyrene (HIPS) and acrylonitrile–butadiene–styrene resin (ABS). In the HIPS application the rubber is dissolved in the styrene monomer, which is then polymerized via a free-radical mechanism. A complex series of phase changes occurs, resulting in small rubber particles containing even smaller polystyrene particles being incorporated into a polystyrene matrix. The rubber is added to increase impact strength. Because of the unique morphology that is formed, low levels of rubber (typically around 7%) provide rubbery particles having a volume fraction of 30–40%. This morphology leads to high impact at very low rubber levels, providing good stiffness and hardness [46].

There is also a fairly large market for high *cis* BR in solid core golf balls. In this application, the polymer is compounded with zinc acrylate and the mixture is cured with peroxide [47]. This produces an ionically cross-linked compound that has outstanding resilience. The covers are also ionomers with superior cut resistance. In the last few years the golf ball market has been shifting away from the traditional wound ball to these new solid core balls that use polybutadiene.

Ethylene–Propylene Rubber

There are two general types of polymers based on ethylene and propylene: ethylene–propylene rubber (EPM) and ethylene–propylene terpolymer (EPDM). EPM accounts for approximately 20% of the polyolefin rubber produced. Comprising a totally saturated polymer, these materials require free-radical sources to cross-link. EPDM was developed to overcome this cure limitation. For EPDM a small amount (less than 15%) of a nonconjugated diene is terpolymerized into the polymer. One of the olefinic groups is incorporated into the chain, leaving its other unsaturated site free for vulcanization. This ensures that the polymer backbone remains saturated, with corresponding stability, while still providing the reactive side group necessary for conventional cure systems. The nonconjugated dienes used commercially are ethylidene norbornene, 1,4 hexadiene, and dicyclopentadiene. The selection of the termonomer is made on the basis of the reactivity of the termonomer, both in polymerization and in vulcanization. The estimated 2009 worldwide consumption (excluding CPEQ) was 932,000 metric tons.

Monomer Production

Ethylene and propylene are produced primarily by the cracking of naphtha. They also are available from the fractionation of natural gas. Ethylidene norbornene is produced by reacting butadiene with cyclopentadiene. 1,4 Hexadiene is produced from butadiene and ethylene. Dicyclopentadiene is obtained as a by-product from the cracking of heavy feedstocks to produce ethylene.

Polymer Production

There are two processes used to produce EPM/EPDM: solution and suspension. In either case a Ziegler–Natta type catalyst is used (aluminum alkyl or aluminum alkyl chlorides and a transition metal salt). The most generally used transition metal is vanadium in the form of the tetrachloride or the oxytrichloride [48]. The solution process is similar to that used for other solution polymers. The polymer cement can be finished by stream stripping and drying of the resulting crumb [49].

In the suspension process, the polymer is suspended in the monomer propylene. This process offers the advantages of being able to operate at higher solids owing to the lower viscosity of a suspension compared with a solution at comparable solids. Other advantages are simple heat removal by the evaporative cooling of the propylene, more uniform reactor temperature profile, and ease of production of high molecular weight or semi-crystalline polymers [50].

A specially developed titanium-based catalyst has been used in the suspension process for EPM and EPDM where the termonomer is low-boiling. The advantages claimed, in addition to those characteristic of the suspension process, are better structural control and high catalyst efficiency, resulting in a high-purity product without requiring catalyst removal [51].

The polymer composition for both EPM and EPDM is usually in the 40/60 to 60/40 ethylene/propylene ratio. Outside these ranges, the polymer will start to crystallize because of either polyethylene or polypropylene blocks.

Use

EPM/EPDM polymers exhibit outstanding resistance to heat, ozone, oxidation, weathering, and aging due to the saturated backbone. They have low density, are miscible with aliphatic and naphthenic oils, and maintain acceptable properties at high filler loadings. They are used in single-ply roofing, wire and cable, automotive parts, impact modification of polypropylene, and viscosity index additives for automotive oils. They also can be used in producing thermoplastic olefin elastomers by blending with polypropylene, which may be partially grafted or cross-linked by dynamic vulcanization. These “polymer alloys” will be discussed in the section “Thermoplastic Elastomers.” Although at one time EPDM was expected to become the major polymer for tires, this market has not materialized for a variety of processing and performance reasons [52].

Butyl Rubber

Butyl rubber is one of the older synthetic rubbers, having been developed in 1937. Because of the saturated nature of a polyolefin elastomer, the commercial polymer is actually a copolymer of isobutylene and isoprene. The isoprene is added to provide cure sites. In addition, halogenated (bromo or chloro) derivatives are available. The halogenated products improve the mixing and cure compatibility with the more common unsaturated rubbers such as natural or SBR.

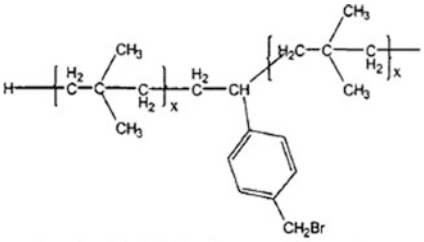
Monomer Production

Isobutylene is obtained as a by-product from petroleum and natural gas plants. The monomer must be highly purified to assure high molecular weight.

Production Process

Butyl rubber is produced at very low temperature (below −90°C) to control the rapid exotherm, and to provide high molecular weight. The process consists of charging isobutylene along with isoprene (2–4%) with an inert diluent such as methyl chloride to a reactor to which a Friedel–Crafts catalyst is added. The polymerization is very rapid, and the polymer forms in a crumb or slurry in the diluent. Heat is removed via the reactor jacket. The slurry is steam-stripped to remove all volatiles. The catalyst is neutralized, and antioxidants are added to the slurry prior to drying [53]. The halogenated derivatives are produced by the direct addition of the halogen to a solution of the isobutylene–isoprene polymer.

During the last 10 years another type of butyl rubber was developed which is derived from a copolymer of isobutylene and *p*-methylstyrene [54]. They are subsequently brominated to varying degrees producing different grades of the elastomer. Bromination occurs selectively on the methyl group of the *p*-methylstyrene providing reactive benzylic bromine functionality, which can be used for grafting and curing reactions.



brominated poly(-isobutylene-*p*-methylstyrene)

Properties and Use

The most important characteristics of butyl rubber are its low permeability to air and its thermal stability. These properties account for its major uses in inner tubes, tire inner liners, and tire curing bladders. Because of the poor compatibility of butyl with other rubbers (with respect to both solubility and cure), the halobutyls are preferred. The brominated *p*-methylstyrene-containing butyl rubbers are used in a number of grafting reactions for tire applications and adhesives. Other uses for butyl rubber are automotive mechanical parts (due to the high damping characteristics of butyl), mastics, and sealants [55].

Nitrile Rubber

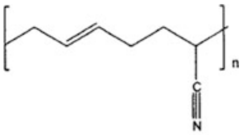
Nitrile rubber was invented at about the same time as SBR in the German program to find substitutes for natural rubber [56]. These rubbers are copolymers of acrylonitrile–-butadiene, containing from 15 to 40% acrylonitrile. The major applications for this material are in areas requiring oil and solvent resistance. The estimated worldwide consumption in 2003 was 303,000 metric tons [57].

Monomer Production

The production of butadiene is discussed in the diene section "Polybutadiene." Although several routes have been developed to produce acrylonitrile, almost all now is produced by the catalytic fluidized-bed ammoxidation of propylene.

Polymer Production

The polymerization process parallels the emulsion process used for SBR. Either a hot or a cold process can be used, with the cold polymerization providing the same improved processing and vulcanizate properties as seen in SBR. Polymerizations are carried to 70–80% conversion and terminated to avoid gel formation. The latex must be stripped to remove unreacted butadiene and acrylonitrile.



butadiene-acrylonitrile copolymer

Properties and Use

As the acrylonitrile content increases in the polymer chain, the properties change predictably. The glass transition temperature increases approximately 1.5°C for each percent increase in acrylonitrile. Properties such as hysteresis loss, resilience, and low-temperature flexibility will correspondingly change. The oil resistance increases with increased acrylonitrile content, as does the compatibility with polar plastics such as PVC. The major market for nitrile rubber is in the automotive area because of its solvent and oil resistance. Major end uses are for hoses, fuel lines, O-rings, gaskets, and seals. In blends with PVC and ABS, nitrile rubber acts as an impact modifier. Some nitrile rubber is sold in latex form for the production of grease-resistant tapes, gasketing material, and abrasive papers. Latex also is used to produce solvent-resistant gloves [58].

Hydrogenated Nitrile Rubber

During the last 25 years several companies have developed hydrogenated grades of nitrile rubber to improve both its thermal stability and solvent resistance. Although the hydrogenation of a polydiene backbone was done as early as the 1920s, real commercial products with acrylonitrile were not introduced until the mid-1980s [59].

Hydrogenated NBR (HNBR) is produced by first making an emulsion-polymerized NBR using standard techniques. It then must be dissolved in a solvent and hydrogenated using a noble metal catalyst at a precise temperature and pressure [60]. Almost all the butadiene units become saturated to produce an ethylene–butadiene–acrylonitrile terpolymer. These "post-polymerization" reactions are very expensive so HNBRs usually command a premium price. HNBR is usually cured with peroxides, similar to ethylene–propylene elastomers, because it has no unsaturation for a conventional sulfur cure system.

Uses

HNBR has many uses in the oil-field, including down hole packers and blow-out preventers, because of its outstanding oil resistance and thermal stability. For the same reasons, it has also found uses in various automotive seals, O-rings, timing belts, and gaskets. Resistance to gasoline and aging makes HNBR ideal for fuel-line hose, fuel-pump and fuel-injection components, diaphragms, as well as emission-control systems.

Chloroprene Rubber

Chloroprene rubber (Neoprene—trade name of DuPont) was one of the earliest synthetic rubbers, first commercialized in 1932. It has a wide range of useful properties but has not become a true general purpose synthetic rubber, probably because of its cost. It does possess properties superior to those of a number of general purpose polymers, such as oil, ozone, and heat resistance; but for these properties other specialized polymers excel. Polychloroprene thus is positioned between the general purpose elastomers and the specialty rubbers.

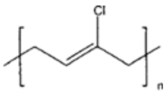
Monomer Production

Chloroprene monomer production starts with the catalytic conversion of acetylene to monovinylacetylene, which is purified and subsequently reacts with aqueous hydrogen chloride solution containing cuprous chloride and ammonium chloride to give chloroprene [61].

Production Process

Polychloroprene is produced by using an emulsion process. Two general types of processes are used: sulfur modified and unmodified. In the sulfur modified process, sulfur is dissolved in monomer and is incorporated into the polymer chain. Upon the addition of thiuram disulfide-type materials and under alkaline conditions, some of the sulfur bonds are evidently cleaved to give the soluble polymer. In the unmodified process chain transfer agents are used. If neither the sulfur modified nor the chain transfer system is used, the resulting polymer is a gelled tough material. Typical polymerization systems consist of rosin acid soap emulsifier and persulfate catalyst. Conversions of 80–90% are obtained. Polymerizations are run at around 40°C. For the modified polymer, the thiuram disulfide is added after polymerization, and the latex is aged to allow the peptization (chain scission) reaction to occur. Acidification stops the peptization reaction. The latex is vacuum-stripped and coagulated using a cold drum dryer process. The coagulated rubber is washed and dried.

The polymerization produces primarily *trans*-1,4-polychloroprene. The *trans* content can be increased somewhat by lowering the polymerization temperature [62,63]:



polychloroprene

Properties and Uses

Polychloroprene is stable to oxidation and ozone. It also is flame resistant, and its oil resistance is better than that of general purpose rubbers. Its major disadvantage, other than cost, is relatively poor low-temperature properties. Because of the high stereoregularity, polychloroprene will strain crystallize, giving good tensile to unfilled stocks. At low temperatures the polymer can crystallize, making processing more difficult. Polymer made at lower temperatures will show higher unfilled tensile properties and more rapid crystallization due to the higher *trans* content (i.e., less disruption of the crystal structure). The major end uses are conveyor belts, V-belts, hoses, and mechanical goods such as wire insulation, O-rings, and gaskets. It also has found use in single-ply roofing and adhesives [64].

Silicone Elastomers

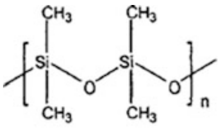
Silicone elastomers represent a rather unique group of polymers in that they consist of alternating silicon–oxygen bonds to form the polymer chain backbone. Side groups off the silicon atoms are selected to provide very specific properties that differentiate one type from another. The most common side group is the dimethyl structure. Replacement of small amounts of the methyl group with vinyl provides sites for cross-linking. Phenyl groups are used to improve low-temperature properties. Fluorosilicones are produced by replacing the methyl with trifluoro-propyl units. The addition of bulky phenyl side groups leads to an increase in the glass transition temperature. However, the disruption caused by such groups leads to the desired reduction or elimination of crystallization, which is critical for low-temperature properties. Such polymers have glass transition temperatures around −110°C, which is the range of the lowest T_g carbon-backbone polymers.

Monomer Production

The actual polymerization process involves a ring-opening reaction of dimethyl-substituted cyclic siloxanes. The preparation of the cyclic materials starts with the production of pure silicon via the reduction of quartz with coke in an electric arc furnace. The silicon metal then reacts with methyl chloride to give a mixture of silicones, from which dimethyldichlorosilane is removed by distillation [65]. Subsequent hydrolysis gives the cyclic dimethylsiloxane.

Polymer Production

The polymerization process involves an equilibrium ring-opening reaction carried out in the bulk state, which can be catalyzed by acids or bases:



polydimethylsiloxane

Uses

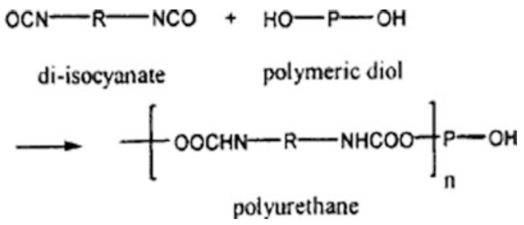
Silicone rubber offers a set of unique properties to the market, which cannot be obtained by other elastomers. The Si–O backbone provides excellent thermal stability and, with no unsaturation in the backbone, outstanding ozone and oxidative stability. The very low glass transition temperature, combined with the absence of low-temperature crystallization, puts silicones among the materials of choice for low-temperature performance. The fluoro-substituted versions provide solvent, fuel, and oil resistance along with the above-mentioned stability advantages inherent with the silicone backbone.

The gum polymer has rather poor tensile properties when cured, but these properties can be greatly improved by the use of silica-reinforcing agents. These systems exhibit some of the greatest improvements in properties by filler addition; and because this improvement is significantly higher for silica than for other reinforcing agents, it is assumed that direct bonding occurs between the silica and the polymer. The silicone materials also may have very low surface energy, which accounts for their nonstick characteristics. Because of the inherent inertness of the materials, they have been widely used for medical purposes within the body. The largest use of silicone is in sealant and adhesive applications.

Several different methods have been developed to cure silicones. Free-radical cures are possible for those polymers containing vinyl groups. The largest-volume process, however, involves room-temperature ulcanizetions, which can employ either a one-component or a two-component system. In the one-component system, a cross-linking agent such as methyltriacetoxysilane is used. With exposure to moisture, hydrolysis of the cross-linking agent leads to the silanol reactive cure site, so such materials must be compounded and stored free of moisture [66].

Polyurethane Rubber

A wide range of materials is included in this class. The common feature is the use of chain extension reactions to provide products with acceptable commercial properties. The chain extension reaction effectively reduces the actual number of chain ends, thereby eliminating the generally poor properties observed when very low-molecular-weight polymers are cross-linked. The chain extension step involves the reaction of a difunctional polymeric polyol with difunctional organic isocyanates to give the polyurethane:



The most used polyols have a polyester or a polyether backbone. A wide variety of isocyanates are used, with toluene di-isocyanate, *m*-phenylene di-isocyanate, and hexamethylene di-isocyanate the most common.

Raw Materials

The largest-volume polyether used is obtained from propylene oxide polymerized under basic conditions. Polyester polyols are produced from a number of different materials involving diacids and diols to give the ester linkage. Aliphatic polyesters generally are used for elastomers to impart chain flexibility.

The production of isocyanates is based on the reaction of phosgene with primary amines. Toluene di-isocyanate is the most frequently used di-isocyanate.

Uses

The urethane elastomers are complex-segmented or block polymers. Soft, noncrystalline blocks are provided by the polyether or aliphatic polyester long chains, whereas stiff, hard blocks are produced by the reaction of aromatic diisocyanates with low-molecular-weight materials such as diols or diamines. The hard blocks can phase-separate to provide a physical rather than a chemical cross-link, similar to those to be discussed for the butadiene–styrene TPE, although the domain size is much smaller for the polyurethanes. Chemical cross-links can be introduced by using tri-functional materials or by adjusting the stoichiometry to allow additional reactions with the urethane or urea structures to give allophanate or biuret linkages.

Polyurethane rubbers can have high tensile strengths, excellent tear strength, and good abrasion and chemical resistance. The greatest disadvantage is the hydrolytic instability of the urethane linkage. A major use is in automotive bumpers and facias. These materials are made in a reaction injection molding process. Castable urethanes are used to produce solid rubber wheels and printing rolls. Millable urethanes can be processed on conventional rubber equipment. Unsaturation can be introduced to allow the use of conventional rubber cure systems. Cures also are possible by reaction of the active hydrogens with materials such as high molecular weight polyfunctional isocyanates that are nonvolatile at cure temperatures.

Thermoplastic polyurethane elastomers are processed by injection molding and other processes used for thermoplastics. Small gears, seals, and even automotive fender extensions can be produced by this means.

By selecting from the large number of possible reactions and stoichiometry, properties can be tailored to meet a very wide range of applications [67–69].

Modified Polyethylene Rubbers

Elastomeric polymers can be produced by the chlorination or chlorosulfonation of polyethylene. Both products start with polyethylene, either in solution or in aqueous suspension, which then is reacted to give the specified degree of substitution to obtain the desired properties. Sufficient substitution is necessary to disrupt the regularity of the polymer chain, changing it from the crystalline polyethylene plastic into amorphous elastomers.

Chlorinated Polyethylene

The chlorinated products contain around 40% chlorine. These materials must be stabilized with metal salts, like other chlorinated elastomers and plastics. Peroxide cross-linking generally is used. Being saturated, the materials have excellent weather and ozone resistance and can be used over a temperature range of −65 to 300°F. The high chlorine content imparts oil resistance and relatively slow rates of burning. Typical applications where this combination of properties is required include hoses for chemical or oil resistance, tubing, and belting. In comparison with plasticized PVC, these materials have better low-temperature properties and do not suffer a loss of plasticizer because none is required.

Chlorosulfonated Polyethylene

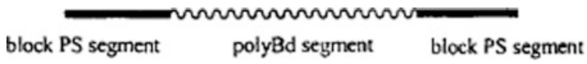
Reaction with sulfur dioxide in addition to chlorine introduces cross-linking sites into the polymer chain. Sulfur contents in the range of 1.0–1.5% are used, with chlorine contents of 25–40%. Curing is accomplished by using metallic oxides, sulfur-bearing organic compounds, and epoxy resins. These materials have outstanding ozone resistance and show little color change upon light exposure. Good resistance to oils, heat, oxidation, weather, and corrosive materials also is exhibited. Applications include pond and pit liners, coated fabrics, light-colored roofing membranes, wire and cable insulation, chemical hose, and belting [70,71].

Thermoplastic Elastomers

This class of elastomeric materials is called “thermoplastic” because they contain thermally reversible cross-links of various types. The types of crosslinks vary from phase-separated polystyrene domains, such as in SBS elastomers to ionic cluster cross-links in the ionomers. The beauty of these noncovalent interactions to form cross-links is that when the material is heated, the cross-links are broken. This allows the polymer to flow and be processed, and also recycled. When cooled, the cross-links reform and the material becomes strong again. All TPEs are two-phase systems where there is a soft, rubbery “continuous phase” and a hard “dispersed phase” which does not flow at room temperature. The first two polymers to be discussed are “block copolymers” and “ionomers.”

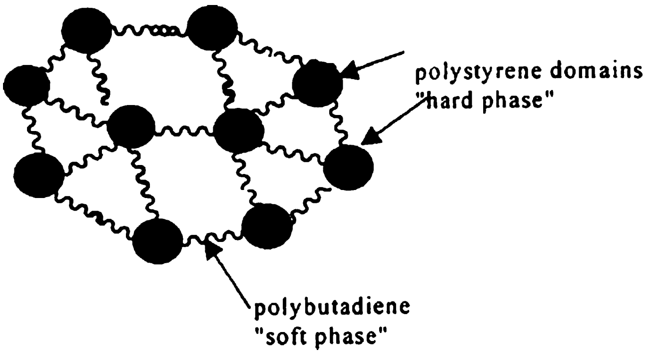
Block Copolymers

A very popular and useful TPE is made from blocks of styrene and butadiene monomers using anionic polymerization techniques, which was described in the solution SBR section above. They are made up of short chains of polystyrene (usually 8,000–15,000 MW), followed by a much longer chain of polybutadiene (about 60,000 MW), and capped off by another short chain of polystyrene, hence the name SBS. Similar polymers are prepared using isoprene instead of butadiene (SIS). The differences between SBS and SIS will be discussed later in the subsection "Uses."



The linear polymers, as shown above, can be built up by the sequential addition of monomer or by coupling the living anionic chains using compounds like dichloro dimethylsilane. Hence, the base polymer would have styrene polymerized first, followed by butadiene, and then addition of the coupling agent. If a multifunctional coupling agent such as silicon tetrachloride is used, a radial block or "star-branched" SBS is formed.

The polystyrene is highly insoluble in the polybutadiene so the PS chains cluster together and phase-separate into domains. Since there is much more polybutadiene (PBD) than polystyrene, the PBD becomes the continuous phase containing dispersed particles of PS which act both as cross-links and reinforcing agents. Every PBD chain is tied to a PS chain on both ends so a very strong cross-linked network is formed. If the PBD is tied to only one PS, then a "diblock" polymer is formed which has very little strength. When this network is heated to above the glass transition of polystyrene (100°C) the PS domains break down and begin to flow, so the polymer can be processed by injection molding or extrusion. Upon cooling to below 100°C, the domains (cross-links) reform and the material becomes strong again. SBS elastomers can have tensile strength as high as conventional thermoset elastomers which may approach 4,000 psi.



The butadiene blocks can be hydrogenated, as mentioned above with hydrogenated nitrile, to form SEBS polymers having better thermal stability and chemical resistance. The EB stands for ethylene–butylene, which are the structures formed after the butadiene segments have been hydrogenated.

Other block copolymers which are useful are based on polyesters, polyurethanes, and ethylene–propylene. The first two have been discussed in other sections and the ethylene—propylene blocks will be discussed below in the subsection "Metallocene Polymers."

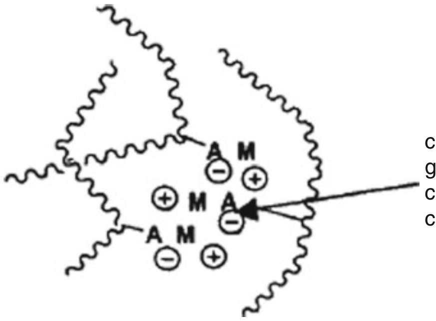
Uses

SBS copolymers are used in a wide variety of applications because of their clarity, toughness, and ease of processing. A major application is hot melt adhesives where they are compounded with hydrocarbon resins and oil [72]. The SIS polymers are very popular in adhesives because the isoprene segments tend to undergo chain scission during aging instead of cross-linking, which is observed in butadiene polymers. This leads to better retention of adhesion after aging; however, the SIS polymers usually have poorer initial strength compared with SBS. Another high-volume use is in toughening of asphalt compounds for paving, crack sealants, and roofing. The SBS improves rutting and low-temperature performance in paving and crack resistance in roofing applications [73]. SEBS would be the elastomer of choice in many adhesive and asphalt applications because of its superior aging properties; however, its high cost is prohibitive. SBS also is used widely to toughen polystyrene and high-impact polystyrene. This polyblending technique is used to toughen a number of plastics. Various other injection molding and extrusion applications include shoe soles and toys. SBS is limited in use because of its poor high-temperature performance.

Ionomers

Ionomers are copolymers in which a small portion of the repeat units have ionic pendant groups on usually a nonpolar backbone. The ionic groups tend to separate themselves into domains similar to the polystyrene segments in the SBS rubber because they are insoluble in the nonpolar polymer chains. Therefore, these ionic clusters serve as cross-links up to temperatures where they tend to disassociate. Most commercial grades of ionic elastomers are based on ethylene and propylene monomers.

The polymer backbone usually contains sulfonyl or carboxylic acid groups and the metal counterion can be zinc, calcium, sodium, or lithium. The properties are highly dependent on the metal cation because they determine the temperature at which the ion clusters disassociate. The ionic cross-links usually impart outstanding tensile and tear strength properties because these cross-links are very good energy absorbers (hysteretic) due to their mobility. A process known as ion hopping provides one source for absorbing energy.



clusters of ionic groups forming a crosslink M+ = metal cation, A− = anion

Uses

Solid golf balls are a good example of ionic cross-linked materials [74]. The covers are usually lithium or sodium cross-linked plastics but the cores are also a type of ionomer. The cores are high *cis* polybutadiene which is compounded with zinc diacrylate (ZDA) and then peroxide cured. During the curing process, the ZDA grafts to the BR backbone creating a material with a very high cross-link density where the cross-links are clusters of zinc carboxylates with very high resilience. Other applications include heat-sealable food packaging, automotive trim, footwear, foamed sheets (mats), and interlayers for bulletproof glass.

Metallocene Elastomers

Metallocene catalysts are the latest innovations to make a big impact in the polymer industry. They have been used mostly to make new poly-olefin plastics, such as very-high-molecular-weight, bullet-proof polyethylene, but they have also been used to make elastomers. The catalysts make very regular "stereospecific" polymers similar to the Ziegler–Natta catalysts. They are based on various metals, such as zirconium, complexed with cyclopentadienide anions. This type of compound is called a "zirconocene" and is used with organoaluminum to make highly regular polymers. The catalyst has the ability to flip back and forth from making *atactic* to *isotactic* polypropylene in the same polymerization. The alternating tacticity of the polymer breaks up the crystallinity of the chains and yields an elastomer. Metallocene catalysts are currently very expensive and cannot yet polymerize dienes such as butadiene, so they have only enjoyed limited commercial success in elastomers. However, this is one of the most intense fields of polymer research and many new product breakthroughs are expected in the near future.

Rubber–Plastic Alloys

A discussion on TPE would not be complete without mentioning the elastomers produced by simply blending rubbers and plastics in an internal mixer using a process known as "dynamic vulcanization." The simplest of these elastomers is based on polypropylene and EPDM rubber. Products are made with various rubber contents (hardness values) by simply mixing the rubber and plastic in a Banbury or an extruder at high temperature while cross-linking the EPDM in situ with a phenolic curing resin or other curing agents such as sulfur or peroxides. The resulting blend processes like polypropylene but is actually an elastomer because of the cross-linked rubber phase which it contains. It can be reprocessed and recycled like other TPEs. The process is described in an excellent review article by Abdou-Sabet [75]. Other alloys are based on nylon and NBR to obtain better thermal stability and solvent resistance. Constant improvements are being made in polymer alloys by using different combinations of plastics and rubbers and also new grafting and cross-linking chemistry to achieve properties more like conventional thermoset rubbers.

Uses

The applications for this type of elastomer have been limited because of the melting point of the plastic phase and poor compression set. For these reasons, alloys probably will never be successful as tire materials but they have many other automotive applications, including instrument panels, cowl vents, body panels, and bumpers. They also are used in appliances, lawn and garden equipment, and as grips on tools.

Plasticized Polyvinyl Chloride

Generally one thinks of polyvinyl chloride as a rigid plastic, which it is, with a glass transition temperature around 85°C. However, the addition of polar chemicals such as dioctyl phthalate can reduce the glass transition temperature below room temperature, producing a rubbery material.

Monomer Production

Vinyl chloride is produced primarily from ethylene, which is converted to ethylene dichloride either by chlorination or oxychlorination. The ethylene dichloride is cracked to give vinyl chloride and hydrogen chloride.

Production Process

Polyvinyl chloride is produced by the free-radical polymerization of vinyl chloride. Bulk, emulsion, solution, and suspension polymerization processes have been used.

The plasticized product can be produced by mixing the polymer and plasticizers at elevated temperatures, also by dry blending in which the plasticizer is absorbed into the resin and then heated. Solution blending is sometimes used, as well as the plastisol process, in which fine polyvinylchloride powder is dispersed in the plasticizer which is relatively stable until it is heated.

Properties and Use

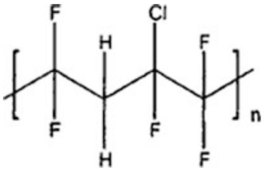
Plasticized polyvinyl chloride can be regarded as the first thermoplastic elastomer, as it is used in an uncross-linked form. Because of the lack of cross-linking, this material exhibits high rates of creep and stress relaxation. As with other TPE, these disadvantages worsen as the temperature is increased. Although the polymer is saturated, it must be stabilized for use to prevent dehydrochlorination at processing temperatures. Because of the high chlorine content, polyvinyl chloride has excellent flame resistance as well as good electrical properties. Even at high plasticizer levels, these materials have marginal elasticity when compared with most other elastomers. Despite their shortcomings, they are used in many areas where they compete with other rubbers.

One of the larger uses is for wire and cable insulation. The flame resistance makes this the material of choice for residential wiring, extension cords, and so on. Inexpensive garden hose represents another large-volume use. Sports balls can be produced by rotational molding of plastisols. The low fabrication cost allows such products to dominate the lower-price-range market [76,77].

Fluorocarbon Elastomers

The fluoroelastomers were developed as specialty materials for high heat applications and solvent resistance. By 2009 there was over 15,800 metric tons of fluoroelastomer capacity worldwide [78]. The elastomers were by-products of Plunkett's 1938 discovery of polytetrafluoroethylene. Copolymers of olefins with vinylidene fluoride were found to be leathery, whereas elastomers were made if tetrafluoroethylene (TFE) or trifluoropropene was used. The first commercial product was produced as a copolymer of vinylidene fluoride and chlorotrifluoroethylene (CTFE) and was called Kel-F. The later, more stable polymers used hexafluoropropene (HFP) with TFE. They were first commercialized by DuPont under the trade name Viton and then a few other companies added their own fluoroelastomers. These elastomers are usually prepared by radical polymerization in emulsion using catalysts such as ammonium persulfate and sometimes with chain transfer agents such as carbon tetrachloride or halogen salts [79]. Caution must be exercised when using these polymerizations because the fluoromonomers can be explosive. They are usually isolated by coagulation and normal rubber drying techniques and sold in the form of pellets, slabs, or rubber crumb.

As a result of being very unreactive, the fluoroelastomers cure very slowly and usually require a high-temperature post-cure. The curatives are designed to remove hydrogen fluoride to generate a cure site which can react with a diamine or bisphenol. They are also cured with organic peroxides. Most fluoroelastomers can be compounded using normal rubber processing equipment such as rubber mills and internal mixers. Processing aids such as dioctyl phthalate or waxes can be used to obtain smoother extrusions and better mold release.



Uses

Fluoroelastomers have outstanding heat resistance when cured. Some vulcanizates have almost indefinite service life at temperatures up to 200°C. The perfluoro polymers, such as DuPont's Kalrez, have short-term usage at up to 316°C and extended service as high as 288°C. This polymer is extremely expensive and is only offered in the form of finished parts, usually O-rings, seals, or gaskets. The fluoroelastomers also have excellent solvent and ozone resistance making them ideal for automotive fuel hoses. Although many of the applications involve small seals, O-rings, gaskets, and hose, the single largest application is flue-duct expansion joints. The polymer's resistance to high temperature and wet acidic flue gases are critical in this application.

The Agrochemical Industry

17

K.N. Singh and Kavita Merchant

Introduction

Agrochemical Industry comes under life science segment of Chemical Industry and deals with production and distribution of pesticides and fertilizers to increase the crop yields. As Pharmaceuticals are meant for life, Agrochemicals are for livelihood.

Although overall agrochemicals are very small part of chemical industry, their role in sustainable growth is very important as the world's population is estimated to grow from 6.8 billion today to >9.0 billion by 2050. Global demand for food is expected to double by then as per UN projections and estimate.

There is no dispute whatsoever that for meeting the growing food need we will essentially be called upon to produce more and more food with less cultivable land. This necessitates use of agrochemicals in general and pesticides in particular under integrated crop and pest management program to enhance productivity and prevent 30–40% avoidable losses caused by various pests during production, processing and storage. Pesticides were and continue to be an integral part of high-yield farming success.

This chapter describes mainly pesticide active ingredients and formulations manufactured for treatment of seeds, crops and farm products to protect from various insect pests, weeds, plant pathogens, microbes and germs. Pesticides used in non-crop sectors like animal and public health, disinfectant, home care, etc. are also covered. Fertilizers or fundamental nutrients are arbitrarily excluded from discussion in this chapter.

The global pesticide market is divided into three basic categories based on intellectual property rights (IPR) viz.: Proprietary products; Proprietary off-patent products; Generic products.

A proprietary product has a granted patent in force. The market share of proprietary products is approximately 30%, i.e. ~13 billion of the total pesticide market. For proprietary off-patent products, though the patent has expired, there is no generic competition. The majority of these products are owned by the proprietary companies and adding together both proprietary and off-patent proprietary products, the market share is approximately 70%, which is controlled by a few multinational companies viz. Syngenta, Bayer Crop Sciences, BASF, Dow AgroSciences, Monsanto, Du Pont, FMC, etc.

For a generic product, patent protection has expired and local companies have obtained sales authorization from Federal and State Governments that are independent of the proprietary company's registrations. Generic products account roughly for ~30% of total pesticide market, i.e. $13 billion.

Special mention is provided in the chapter to products introduced in the recent past and going off-patent in 2010 and beyond (please refer Annex 17.1). This section will help the readers to identify and develop generic active ingredients to meet the global demand for food, feed, fibre, plastics and energy as well as to maintain the general hygiene of homes.

The global pesticide market with sales revenue of approximately $44 billion during 2009 comprises of the crop protection sector with sales of $38 billion (86%) and non-crop sector with sales of $6 billion (14%) according to data from market research consultancy Phillips McDougall.

The crop protection sector over the period of last 10 years has achieved growth of 34% from $28.1 billion during 1999 to $31.2 billion during 2005 to $38 billion during 2009. There is significant optimism in the industry that there will be a period of sustained growth in the next 5 years. This optimism is mainly due to increased consumption of pesticides in Latin American countries like Brazil, Argentina, Mexico and Asian countries mainly India and China.

The non-crop sector has a wide variety of applications including forestry, timber treatment, public health, industrial (mainly weed control on railways, highways), home and garden markets, etc. There are many drivers affecting growth of this sector including increase in urban population and more disposable income per capita, part of which is used in hygiene and pest control operations.

Pesticides

Pesticide active ingredients (AI) are chemicals designed to be harmful to a target pest. These are purposely converted into plant protection products (PPP) and introduced into environment for preventing, destroying, repelling or mitigating pests.

People often think pesticide means insecticide. However, it also includes herbicides, fungicides and various other substances used to control target pests viz. rodents and other animals, unwanted plants (weeds), fungi or microorganisms like bacteria and viruses.

Farmers use pesticides to control the pests that can destroy or damage food, fibres and other crops. Health agencies use pesticides to control insects and other organisms known to carry diseases. Hospitals use disinfecting pesticides to destroy viruses and other germs on floor and equipments. Pest control operators use pesticides to free houses from cockroaches, termites, ants, bed bugs and other house pests. Pesticides are also used for maintaining lawns, gardens and turfs, for freeing cattle and companion animals from ectoparasites viz. ticks, fleas, mites, etc.

Since most pesticides are designed to be toxic to their target pest, it can be harmful if used improperly. Its use therefore is strictly regulated. A rigorous regulatory evaluation process is applied for checking quality, toxicity, efficacy and residue levels of pesticides before it can be manufactured, sold or used in designated country/state.

Pesticides can be classified in a number of ways such as mode of entry, application, chemical class, mode of action and toxicity. Broad categories are defined in Fig. 17.1.

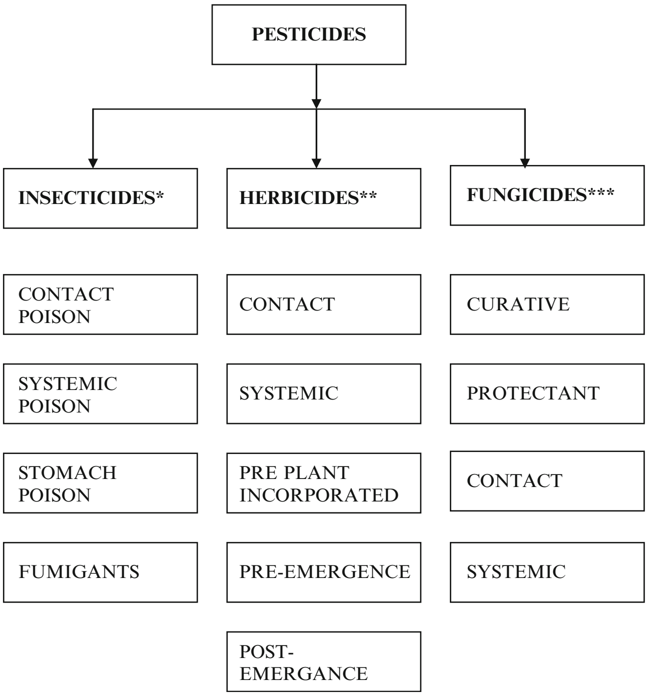

Fig. 17.1 Categories of pesticides.* Including nematicides, acaricides, molluscicides, rodenticides, repellants, attaractants, chemosterilant, antifeedents, growth regulators, etc. ** Including plant growth regulators, defoliants or desiccants, etc. ***Including bactericides, virucides, etc.

Insecticides

An insecticide is a chemical that kills the insects or inhibits their growth. Broad types of insect pests controlled by insecticides are:

- Insect pests of agricultural importance viz. field crops, vegetable crops, ornamental and horticultural crops including forestry, turf and lawns.
- Insects feed on stored products and cause economic loss.
- Household and disease carrying insects viz. cockroaches, furniture beetle, termite, ants, mosquitoes, houseflies, bedbugs, silverfish, fleas, bees, wasps, etc.
- Pest attacking cattle and companion animals such as houseflies, flesh fly, head lice, ticks, fleas and mites, etc.

Classification Based on Mode of Entry

Contact poison:
Insects get killed when they come in contact with the insecticides. It reaches into insect's body via contact with the cuticle and penetration through the sutures, membranes, tracheal system and bases of setae, etc.

This can be achieved by the direct application of the insecticide on the insects or by the insects crawling or passing over the treated surface having residue of the toxic material.

Systemic poison:
Systemic insecticides penetrate into the plant tissues through the roots, stem and leaves of the plant and translocate through the vascular tissues. Insects that feed on such treated plants are killed by stomach poison effect.
Systemic insecticides are applied in a variety of ways viz. seeds treatment, foliar treatment, broadcast application, in-furrow application to soil, etc.

Stomach poison:
When ingested by insects they act on their digestive system to kill them. All the systemic insecticides are stomach poison but all the stomach poisons are not the systemic insecticide.

Fumigants:
Fumigants are gaseous poison, which penetrate into the body through respiratory system and are used to kill insects, nematodes, rodents, etc.

Fumigants are employed to control stored products, household articles, soil inhabiting insects and nematodes, agricultural pests and live plants during export and import.

Classification Based on Chemical Class and Mode of Action

Following classification (Table 17.1) is based on IRAC (Insecticide Resistance Action Committee) "mode of action classification" version Sept 2010 [1]. It provides a guideline to crop protection professionals, growers and researchers for selection of an insecticide for use in sustainable insecticide resistance management program.

Herbicides

Herbicide is a chemical that kills the weeds or inhibits their growth. Weeds are the plants, which grow where they are not wanted. They grow in the fields where they compete with crops for water, soil nutrients, light and space and thus reduce crop yields. Annuals weeds live and produce their seeds in a single growing season. Biennials need two growing seasons; in one season they complete vegetative growth and second season they complete their reproductive stage. The multiplication of both the annuals and the biennials weeds is through seed. However, Perennials weeds live indefinitely and are propagated not only through seeds but also often vegetatively such as rhizomes, stolons, bulbs and tubers.

Weeds are divided into three sub classes: (1) grassy weeds, (2) broad-leaved weeds (3) sedges.

Herbicides have largely replaced mechanical methods of weed control in countries where intensive and highly mechanized agriculture is practiced. They provide a more effective and economical means of weed control than cultivation, hoeing and hand pulling.

Classification Based on Mode of Entry

Contact:
Contact herbicides kill only the plant parts on which the chemical is deposited and are most effective against annual weeds.

Table 17.1 Classification of insecticides based on chemical class and mode of action

Group	Mode of action	Subgroup and Chemical class	Active ingredients
1	Acetycholinesterase (AChE) inhibitors Nerve action	1A Carbamates	Aldicarb Aminocarb Bendiocarb Carbaryl Carbofuran Formetanate Methiocarb Pirimicarb Propoxur Thiodicarb Thiofanox Trizamate Xylylcarb
		IB Organophosphates	Acephate Azamethiphos Azinphos-methyl Chlorfenvinphos Chlorpyrifos Diazinon Dichlorvos (DDVP) Dimethoate Ethion Fenthion Heptenophos Malathion Methamidophos Omethoate Parathion Phenthoate Phorate Quinalphos Temephos Tebufos Tetrachlorvinphos Triazophos
2	*Gamma-amino butyric acid (GABA)*-gated chloride channel antagonists Nerve action	2A Cyclodienes Organochlorines	Chlordane Endosulfan
		2B Phenylpyrazoles (Fiproles)	Ethiprole Fipronil

24	Mitochondrial complex IV electron transport inhibitors Energy metabolism	24A Phoshphine	Aluminium phosphide Calcium phosphide Phoshphine Inc Phosphide
		24B Cyanide	Cyanide
25	Mitochondrial complex II electron transport inhibitors Energy metabolism	Pyrazole	Cynopyrafen
28	Ryanodine receptor modulators Nerve and muscle action	Diamides	Chlorantraniliprole Flubendiamide
29	Compounds of unknown or uncertain mode of action	Bridged diphenyl	Benzoximate Bromopropylate
		Hydrazine carboxylate	Bifenazate
		Aryloxyphenoxypropionic acid	Diclofol
		Unclassified	Pyridalyl

Systemic:
Systemic herbicides are absorbed either by roots or foliar parts of a plant and are then trans-located within the plant system to tissues that may be remote from the point of application. Systemic herbicides are effective against both annual and perennial weeds and they are particularly advantageous against established perennial weeds.

Classification Based on Application and Crop Selectivity

Pre-plant incorporated:
Treatment made to soil in advance before planting of seed. This is popularly known as "chemical follow treatment".

Pre-emergence:
Treatment made at planting or afterwards but before the weeds emerge.

Early post-emergence:
Treatment made when the weeds first emerge.

Post-emergence:
Treatment made after weeds emerge from the soil and during their active growth and development stage. It may be a contact or a systemic herbicide and may be soil applied or directed to the weeds.

Classification Based on Chemical Class and Mode of Action

Following classification (Table 17.2) is based on HRAC (Herbicide Resistance Action Committee) "mode of action classification" version January 2005 [2]. It is developed by HRAC in cooperation with WSSA (Weed Science Society of America) and provides a guideline to crop protection professionals, growers and researchers for selection of best suited herbicides to combat specific weeds in herbicide resistance management program.

Fungicides

A fungicide is a chemical, which inhibits or kills the pathogens. Most fungicides need to be applied before disease occurs (protectants) or at the appearance of symptoms (curative) to be effective.

Protectant fungicide is effective when applied prior to fungal infection. Prophylactic application is mandatory to prevent damage to growing crops whereas curative fungicide is capable of eradicating the fungus after it has caused infection.

Classification Based on Mode of Entry

Contact: A fungicide that remains on the surface where it is applied but does not go deeper into the plant system.

Table. 17.2 Classification of herbicides based on chemical class and mode of action

Group				
HRAC	WSSA	Mode of action	Chemical class	Active ingredients
A	1	Inhibitors of acetyl CoA carboxylase ACCase These chemicals block an enzyme called ACCase. This enzyme is helpful in formation of lipids in roots of grass plants. Without lipids susceptible weeds die	Aryloxyphenoxypropionate “FOPS”	Clodinafop-propargyl
				Cyhalofop-butyl
				Diclofop-methyl
				Fenoxaprop-p-ethyl
				Fluazifop-p-butyl
				Haloxyfop-R-methyl
				Propaquizafop
				Quizalofop-p-ethyl
			Cyclohexanediones “DIMS”	Alloxydim
				Butroxydim clethodim
				Cycloxydim
				Profoxydim
				Tepraloxydin tralkoxydim
			Phenylpyrazolin “DEN”	Pinoxeden
B	2	ALS/AHAS inhibitors These chemicals block the normal function of an enzyme called acetolactase (ALS) acetohydroxy acid (AHAS). This enzyme is essential in amino acid synthesis, without protein plants starve to death	Sulfonylureas	Amidosulfuron
				Azimsulfuron
				Bensulfuron-methyl
				Chlorimuron-ethyl
				Chlorsulfuron
				Cyclosulfamuron
				Ethoxysulfuron
				Foramsulfuron
				Imazosulfuron
				Metsulfuron-methyl
				Nicosulfuron
				Oxasulfuron
				Rimsulfuron
				Sulfosulfuron
				Tritosulfuron, etc.
			Imidazolinone	Imazapic
				Imazamethabenz-methyl
				Imazamox
				Imazapyr
				Imazaquin
				Imazethapyr
			Triazolopyrimidine	Cloransulam-methyl
				Diclosulam
				Florasulam
				Flumetsulam
				Metosulam
				Penoxsulam
			Pyrimidinyl(thio)benzoate	Bispyribac-Na
				Pyribenzoxim
				Pyriftalid
				pyrithiobac-Na
				Pyriminobac-methyl
			Sulfonylaminocarbonyl-triazolinone	Flucarbazone-Na
				Propoxycarbazone-Na
C1	5	Inhibition of photosynthesis at photosystem II. Site A These chemicals interfere with photosynthesis and disrupt plant growth, ultimately leading to death These chemicals interfere with photosynthesis and disrupt plant growth, ultimately leading to death	Triazine	Ametryne
				Atrazine
				Cyanazine
				Desmetryne
				Dimethametryne
				Prometon
				Prometryne
				Propazine
				Simazine
				Simetryne
				Terbumeton
				Terbuthylazine
				Terbutryne
				Trietazine
			Triazinone	Hexazinone
				Metamitron
				Metribuzin
			Triazolinone	Amicarbazone
			Uracil	Bromacil
				Lenacil
				Terbacil

Table. 17.2 (continued)

Group				
HRAC	WSSA	Mode of action	Chemical class	Active ingredients
C1	5	Inhibition of photosynthesis at photosystem II. Site A	Pyridazinone	Pyrazon
				Chloridazon
			Phenyl-carbamate	Desmedipham
				Phenmedipham
C2	7	Inhibition of photosynthesis at photosystem II. Site B	Urea	Chlorobromuron
				Chlorotoluron
				Chloroxuron
				Dimefuron
				Diuron
				Ethidimuron
				Fenuron
				Fluometuron (see F3)
				Isoproturon
				Isouron
				Linuron
				Methabenzthiazuron
				Metobromuron
				Metoxuron
				Monolinuron
				Neburon
				Siduron
				Tebuthiuron
			Amide	Propanil
				Pentanochlor
C3	6	Inhibition of photosynthesis at photosystem II	Nitrile	Bromofenoxim
				Bromoxynil
				Ioxynil
			Benzothiadiazinone	Bentazon
			Phenyl-pyridazine	Pyridate
				Pyridafol
D	22	Photosystem-I-electron diversion	Bipyridylium	Diquat
				Paraquat
E	14	Inhibition of protoporphyrinogen oxidase (PPO)	Diphenylether	Acifluorfen-Na
				Bifenox
				Chlomethoxyfen
				Fluoroglycofen-ethyl
				Fomesafen
				Halosafen
				Lactofen
				Oxyfluorfen
			Phenylpyrazole	Fluazolate
				Pyraflufen-ethyl
			N-phenylphthalimide	Cinidon-ethyl
				Flumioxazin
				Flumiclorac-pentyl
			Thiadiazole	Fluthiacet-methyl
				Thidiazimin
			Oxadiazole	Oxadiazon
				Oxadiargyl
			Triazolinone	Azafenidin
				Carfentrazone-ethyl
				Sulfentrazone
			Oxazolidinedione	Pentoxazone
			Pyrimidindione	Benzfendizone
				Butafenacil
			Nitrile	Pyraclonil
			Pyridazinone	Flufenpyr-ethyl
F1	12	Bleaching: Inhibition of carotenoid biosynthesis at the phytoene desaturase step (PDS)	Pyridazinone	Norflurazon
				Flurtamone
			Pyridinecarboxamide	Diflufenican
				Picolinafen
			Amide	Beflubutamid
			Unclassified	Fluridone
				Flurochloridone

(continued)

Table. 17.2 (continued)

Group				
HRAC	WSSA	Mode of action	Chemical class	Active ingredients
F2	27	Bleaching: Inhibition of 4-hydroxyphenyl-pyruvate-dioxygenase (4-HPPD)	Triketone	Mesotrione
				Sulcotrione
			Isoxazole	Isoxachlortole
				Isoxaflutole
			Pyrazole	Benzofenap
				pyrazolynate
				Pyrazoxyfen
			Unclassified	Benzobicyclon
F3	11	Bleaching: Inhibition of carotenoid biosynthesis (unknown target)	Triazole	Amitrole (in vivo inhibition of lycopene cyclase)
	13	Inhibition of all diterpenes	Isoxazolidinone	Clomazone
F3	13	Inhibition of all diterpenes	Urea	Fluometuron
			Diphenylether	Aclonifen
G	9	Inhibition of EPSP synthesis	Glycine	Glyphosate
				Sulfosate
H	10	Inhibition of glutamine synthetase	Phosphinic acid	Glufosinate-ammonium
				Bialaphos = bilanaphos
I	18	Inhibition of DHP (dihydropteroate) synthase	Carbamate	Asulam
K1	3	Microtubule assembly inhibition	Dinitroaniline	Benefin = benfluralin
				Butralin
				Dinitramine
				Ethalfluralin
				Oryzalin
				Pendimethalin
		These chemicals inhibit the cell division in roots		Trifluralin
			Phosphoroamidate	Amiprophos-methyl
				Butamiphos
			Pyridine	Dithiopyr
				Thiazopyr
			Benzamide	Propyzamide = pronamide
				Tebutam
			Benzoic acid	DCPA = chlorthal-dimethyl
K2	23	Inhibition of mitosis/microtubule organization	Carbamate	Chlorpropham
				Propham
				Carbetamide
K3	15	Inhibition of VLCFAs (inhibition of cell growth and division)	Chloroacetamide	Acetochlor
				Alachlor
				Butachlor
				Dimethachlor
				Dimethanamid
				Metazachlor
				Metolachlor
				Pethoxamid
				Pretilachlor
				Propachlor
				Propisochlor
				Thenylchlor
			Acetamide	Diphenamid

			Oxyacetamide	Flufenacet
				Mefenacet
			Tetrazolinone	Fentrazamide
			Organophosphate	Anilofos
				Piperophos
			Triazole	Cafenstrole
L	20	Inhibition of cell wall (cellulose) synthesis	Nitrile	Dichlobenil
				Chlorthiamid
			Benzamide	Isoxaben
			Triazolocarboxamide	Flupoxam
			Quinoline carboxylic acid	Quinclorac (for monocots) (also group O)
M	24	Uncoupling (membrane disruption)	Dinitrophenol	*DNOC*
				Dinoseb
				Dinoterb

(continued)

Table. 17.2 (continued)

Group				
HRAC	WSSA	Mode of action	Chemical class	Active ingredients
N	8	Inhibition of lipid synthesis—not ACCase inhibition These chemicals inhibit the cell division and elongation in the seedling shoots before they emerge above ground	Thiocarbamate	Butylate Cycloate Dimepiperate EPTC Esprocarb Molinate Orbencarb Pebulate Prosulfocarb Thiobencarb = benthiocarb Tiocarbazil Triallate Vernolate
			Phosphorodithioate	Bensulide
			Benzofuran	Benfuresate Ethofumesate
			Chloro-carbonic-acid	TCA Dalapon Flupropanate
O	4	Synthetic auxins These chemicals disrupt plant cell growth in the newly forming stems and leaves; they affect protein synthesis and normal cell division leading to malformed growth and tumours	Phenoxy-carboxylic-acid	Clomeprop 2,4-D 2,4-DB Dichlorprop = 2,4-DP MCPA MCPB Mecoprop = MCPP = CMPP
			Benzoic acid	Chloramben Dicamba TBA
			Pyridine carboxylic acid	Clopyralid Fluroxypyr Picloram Triclopyr
			Quinoline carboxylic acid	Quinclorac (also group L) Quinmerac
			Benzothiazolone	Benazolin-ethyl
P	19	Inhibition of auxin transport	Phthalamate	Naptalam
			Semicarbazone	Diflufenzopyr-Na
Z	17	Unknown	Organoarsenical	DSMA MSMA
			Amide	Bromobutide
			Morphactin	Chloroflurenol
			Monoterpene	Cinmethylin
			Urea	Cumyluron
			Dithiocarbamate	Dazomet Metam
			Organophosphate	Fosamin
			Unclassified	Oxaziclomefone
			Biopesticide	Pelargonic acid
	25		Arylaminopropionic acid	Flamprop-M-methyl/-isopropyl
	26		Pyrazolium	Difenzoquat

Note: While the mode of action of herbicides in Group Z is unknown it is likely that they differ in mode of action between themselves and from other groups

Fungicides have no after-infection activity. Repeated applications are needed to protect new growth of the plant and to replace material that has been washed off by rain or irrigation, or degraded by environmental factors.

Systemic: A fungicide that is absorbed into plant tissue and may offer some after-infection activity. Very few fungicides are truly systemic (i.e. move freely throughout the plant); however, some are upwardly systemic (i.e. move only upward in the plant through xylem tissue) and some are locally systemic (i.e. move into treated leaves and redistribute to some degree within the treated portion of the plant).

Classification Based on Chemical Class and Mode of Action

Following classification (Table 17.3) is based on FRAC (Fungicide Resistance Action Committee) "mode of action

Table. 17.3 Classification of fungicides based on chemical class and mode of action

FRAC Code	Mode of action	Chemical class	Active ingredients
1	Inhibition of B-tubuline assembly in mitosis and cell division	Benzimidazoles	Benomyl
			Carbendazim
			Fuberidazole
			Thiabendazole
		Thiophanates	Thiophanate
			Thiophanate-methyl
2	Inhibition of mitogen-activated-protein (MAP)/Histidine-kinase in osmotic signal transduction	Dicarboxamides	Chlozolinate
			Iprodione
			Procymidone
3	Inhibition of sterol biosynthesis (C14-demethylase) in membrane	Piperazines	Triforine
		Pyridines	Pyrifenox
		Pyrimidines	Fenarimol
			Nuarimol
		Imidazoles	Imazalil
			Oxpoconazole
			Pefurazoate
			Triflumizole
		Triazoles	Azaconazole
			Bitetranol
			Bromuconazole
			Cyproconazole
			Difenconazole
			Diniconazole
			Epoxiconazole
			Etaconazole
			Fenbuconazole
			Flusilazole
			Flutriafol
			Hexaconazole
			Ipoconazole
			Metconazole
			Penconazole
			Propiconazole
			Simeconazole
			Tridimenol
4	Inhibition of RNA polymerase1 in nucleic acid synthesis	Acylalanines (Phenyl amides)	Benalaxyl
			Furalaxyl
			Metalaxyl
		Oxazolidinones (Phenyl amides)	Oxadixyl
		Butyrolactones (Phenyl amides)	Ofurace
5	Inhibition of isomerase in sterol biosynthesis	Morpholines	Aldimorph
			Dodemorph
			Tridemorph
		Piperidines	Fenpropidin
			Piperalin
		Spiroketal-amines	Spiroxamine
6	Inhibition of phospholipid biosynthesis methyltransferase in lipid membrane synthesis	Phosphorothioates	Edifenphos
			Iprobenfos
			Pyrazophos
		Dithiolanes	Isoprothiolane
7	Inhibition of complex II, succinate dehydrogenase (SDHI) in respiratory chain of fungal mitochondria	Phenyl benzamides	Benodanil
			Flutolanil
			Mepronil
		Pyridinyl-ethyl-benzamides	Fluopyram
		Furan-carboxamide	Fenfuram
		Oxathiin-carboxamide	Carboxin
			Oxycarboxin
		Thiazole-arboxamide	Thifluzamide
		Pyrazole-carboxamide	Bixafen
			Furametpyr
			Isopyrazam
			Penflufen
		Pyridine-carboxamide	Boscalid
8	Inhibition of adenosine-deaminase in nucleic acid synthesis	Hydroxy-(2-amino-)pyrimidines	Bupirimate
			Dimethirimol
			Ethirimol
9	Inhibition of amino acid (methionine) biosynthesis	Anilino pyrimidines	Cyprodinyl
			Mepanipyrim
			Pyrimethanil

Table. 17.3 (continued)

FRAC Code	Mode of action	Chemical class	Active ingredients
10	Inhibition of B-tubuline assembly in mitosis and cell division	N-phenyl carbamates	Diethofencarb
11	Inhibition of complex III Cytochrome bc1 (ubiquinol oxidase) at Qo site in respiratory chain of fungal mitochondria	Methoxy-acrylates Methoxy-carbamates Oximino-acetates Oximino-acetamides Oxazolidine-diones Dihydro-dioxazines Imidazolinones Benzyl-carbamates	Enestrobin Picoxystrobin Pyraclostrobin Pyrametastrobin Dimoxystrobin Metoministrobin Famoxadone Fluoxastrobin Fenamidone Pyribencarb
12	Inhibition of mitogen-activated-protein (MAP)/Histidine-kinase in osmotic signal transduction	Phenylpyrroles	Fenpiclonil Fludioxonil
13	Inhibition of signal transduction by unknown mechanism	Quinolines Quinazolinones	Quinoxyfen Proquinazid
14	Inhibition of lipid peroxidation synthesis in lipid membrane synthesis	Aromatic hydrocarbons 1,2,4-Thiadiazoles	Biphenyl Chloroneb Dicloran Quintozin Etridiazole
16.1	Inhibition of reductase in melanin biosynthesis in cell wall	Isobenzo-furanone Pyrrolo-quinolinone Triazolobenzo-thiazole	Pthalide Pyroquilon Tricyclazole
16.2	Inhibition of dehydratase in melanin biosynthesis in cell wall	Cyclopropane-carboxamide Carboxamide Propionamide	Carpropamid Diclocymet Fenoxanil
17	Inhibition of sterol biosynthesis (3-keto reductase, C4-de-methylation) in membrane	Hydroxyanilides	Fenhexamid
18	Squalence-epoxidase inhibition in sterol biosynthesis in membrane	Thiocarbamates Allylamines	Pyributicarb Naftifine Terbinafine
19	Inhibition of Chitin synthase in glucan synthesis	Peptidyl pyrimidine nucleoside	Polyoxin
20	Mitosis and Cell division inhibition (proposed)	Phenyl ureas	Pencycuron
21	Inhibition of complex III Cytochrome bc1(ubiquinone reductase) at Qi site in respiratory chain of fungal mitochondria	Cynoimidazole Sulfamoyltriazole	Cyazofamid Amisulbrom
22	Inhibition of B-tubuline assembly in mitosis and cell division	Toluamides (Benzamides)	Zoxamide
23	Amino acid and protein synthesis inhibition	Encopyranuronic acid	Blasticidin-S
24	Amino acid and protein synthesis inhibition	Hexopyranosyl antibiotic	Kasugamycin
25	Amino acid and protein synthesis inhibition	Glucopyranosyl antibiotic	Streptomycin
26	Inhibition of trehalase and inositol-biosynthesis in glucan synthesis	Glucopyranosyl antibiotic	Validamycin
27	Unknown	Cyanoacetamideoxime	Cymoxanil
28	Inhibition of cell membrane permeability in lipid and membrane synthesis	Carbamates	Iodocarb Propamocarb Prothiocarb
29	Respiration inhibition (uncouplers of oxidative phosphorylation)	Dinitrophenyl crotonates 2,6-Dinitroanilines Pyrimidinone hydrazones	Binapacryl Dinocap Fluazinam Ferimzone
30	Inhibitors of oxidative phosphorylation, ATP synthase in respiration	Tri phenyl tin compounds	Fentin acetate Fentin chloride Fentin hydroxide
31	Nucleic acid synthesis inhibition in DNA topoisomerase type II (gyrase)	Carboxylic acids	Oxolinic acid
32	Nucleic acid synthesis inhibition in DNA/RNA synthesis (proposed)	Isoxazoles Isothiazolones	Hymexazole Octhilinone
33	Unknown	Phosphonates	Fosetyl-Al Phosphorus acid and salts

Table. 17.3 (continued)

FRAC Code	Mode of action	Chemical class	Active ingredients
34	Unknown	Phthalamic acid	Teclofthalam
35	Unknown	Benzotriazines	Triazoxide
36	Unknown	Benzene sulfonamides	Flusulfamide
37	Unknown	Pyridazinones	Diclomezine
38	Inhibition of ATP production in respiration (proposed)	Thiophene carboxamides	Silthiofems
39	Inhibition of Complex1 NADH oxido-reductase in respiration	Pyrimidinamines	Diflumetorim
40	Inhibition of phospholipid biosynthesis and cell wall deposition in lipids and membrane synthesis	Cinnamic acid amides	Dimethomorph Flumorph
		Valinamide carbamates	Benthiavalicarb Iprovalicarb Valifenlate
		Mandelic acid amides	Mandipropamid
41	Protein and amino acid synthesis inhibition	Tetracycline antibiotic	Oxytetracycline
42	Unknown	Thiocarbamate	Methasulfocarb
43	Delocalization of spectrin-like proteins in mitosis and cell division	Pyridinylmethyl-benzamides (Benzamides)	Fluopicolide
44	Microbial disrupters of pathogen cell membranes in lipids and membrane synthesis	*Bacillus subtilis* and the fungicidal lipopeptides they produce	*Bacillus subtilis* strain QST 713
45	Inhibition of Complex III Cytochrome bc1 (ubiquinone reductase) at Qu (unknown) site in respiratory chain of fungal mitochondria	Triazolo-pyrimidylamine	Ametoctradin
P	Activators of host plant defense system	Benzothiadiazole	Acibenzolar-s-methyl
		Benzisothiazole	Probenazole
		Thiadiazole-carboxamide	Tiadinil Isotianil
		Natural compounds	Laminarin
M	Inactivates fungal pathogens by multi site activity	Inorganic	Copper (different salts)
		Inorganic	Sulphur
		Dithiocarbamates and relatives	Ferbam Mancozeb Maneb Metiram Thiaram Zineb Ziram
		Phthalimides	Captan Captafol Folpet
		Chloronitriles	Chlorothalonil
		Sulfamides	Dichlofluanid Tolyfluanid
		Guanidines	Guazatine Iminoctadin
		Triazines	Anilazin
		Quinones	Dithianon
NC	Unknown	Diverse	Mineral oils Organic oils Potassium bicarbonate Materials of biological origin
U5	Microtubule disruption in mitosis and cell division (proposed)	Thiazole carboxamide	Ethaboxam
U6	Unknown	Phenyl acetamide	Cyflufenmid
U8	Actin disruption (proposed)	Benzophenone	Metraphenone
U12	Cell membrane disruption (proposed)	Guanidines	Dodine

Table. 17.4 WHO toxicity classification of pesticides

WHO Class	Description	LD_{50} for the rat (mg/kg body weight) Oral	 Dermal
Ia	Extremely hazardous	<5	<50
Ib	Highly hazardous	5–50	50–200
II	Moderately hazardous	50–2,000	200–2,000
III	Slightly hazardous	$>2,000$	$>2,000$
IV	Unlikely to present acute hazard	$\geq 5,000$	$\geq 5,000$

Table 17.5 Classification and labelling system

Globally harmonized system category	Classification criteria Oral LD_{50} (mg/kg bw)	 Hazard statement	 Dermal LD_{50} (mg/kg bw)	 Hazard statement
Category 1	<5	Fatal if swallowed	<50	Fatal in contact with skin
Category 2	5–50	Fatal if swallowed	50–200	Fatal in contact with skin
Category 3	50–300	Toxic if swallowed	200–1,000	Toxic in contact with skin
Category 4	300–2,000	Harmful if swallowed	1,000–2,000	Harmful in contact with skin
Category 5	2,000–5,000	May be harmful if swallowed	2,000–5,000	May be harmful in contact with skin

Table 17.6 Classification of pesticides based on toxicity

Toxicity and signal word	Category I	Category II	Category III	Category IV
Acute oral	Up to and including 50 mg/kg	>50–500 mg/kg	>500–5,000 mg/kg	$>5,000$ mg/kg
Acute dermal	Up to and including 200 mg/kg	>200–2,000 mg/kg	$>2,000$–5,000 mg/kg	$>5,000$ mg/kg
Acute inhalation	Up to and including 0.05 mg/L	>0.05–0.5 mg/L	>0.5–2 mg/L	>2 mg/L
Primary eye irritation	Corrosive (irreversible destruction of ocular tissue) or corneal involvement or irritation persisting for more than 21 days	Corneal involvement or other eye irritation clearing in 8–21 days	Corneal involvement or other eye irritation clearing in 7 days or less	Minimal effects clearing in less than 24 h
Primary skin irritation	Corrosive (tissue destruction into the dermis and/or scarring)	Severe irritation at 72 h (severe erythema or edema)	Moderate irritation at 72 h (moderate erythema)	Mild or slight irritation at 72 h (no irritation or slight erythema)
Signal word	Danger	Warning	Caution	Not required

classification” version December 2009 [3] with an objective to help development of a strategy for the management of fungicide resistance risk.

Pesticide Classification Based on Toxicity

Assignment to a Toxicity Class is based typically on results of acute toxicity studies such as the determination of LD_{50} values in animal experiments, notably rodents. The Toxicity Class generally does not address issues of other potential harm of the agent, such as bioaccumulation issues of carcinogenicity, mutagenicity, etc.

World Health Organization Toxicity Classification of Pesticides [4]

US EPA Toxicity-based Classification of Pesticides [5]

See Table 17.6.

Chemistry of Agrochemicals

Rationale of Design

Launching a successful pesticide in the market requires a great deal of money, effort and time. First step is to develop a chemical compound with defined biological activity. It is tested in glass house/screen house conditions for favourable bio effectiveness. Its biochemical mode of action is established or predicted. A large number of molecules have to undergo initial screening against variety of insect pests, diseases and weeds to discover selected few candidates for further evaluation. This lead discovery can be done by "random screening" on the basis of historic compound collections, or a rational approach can be followed to develop structure-based design. It is a process in which structural information about binding of a molecule (usually an inhibitor) to an enzyme (very often at or near the active site) is used to design other molecules with improved binding properties in an iterative process, i.e. modifying structure gradually and repeating the evaluation process till desired result is obtained. Besides this, 3D-QSAR (quantitative structure activity relationship) studies or biochemically inspired design approach can also be employed for rationale designing of new molecules [6].

Importance of Physico-chemical Properties

Most biologically influential properties are Solubility and Reactivity. Hence, it is essential to take into consideration a suitable physicochemical profile to ensure uptake and translocation of pesticide.

Solubility is important for developing formulation in appropriate form and for bio-disposition of active ingredient in the living system after application. This includes absorption, distribution/translocation and metabolism.

The solubility is expressed in terms of its affinity/philicity or repulsion/phobicity for either an aqueous (hydro) or lipid (lipo) solvent.

Majority of active ingredients have some degree of solubility in both aqueous and lipid media as there is a need for them to move through both aqueous (plasma, extracellular fluid, cytoplasm, etc.) and lipid media (biological membranes) in the biological systems.

It is possible to estimate the solubility properties, i.e. (hydrophilic vs. lipophilic) by examining the structure and noting whether its structural features promote affinity for aqueous or lipid media.

The relative solubility of a pesticidal agent can be determined in the laboratory as partition coefficient (P; the ratio of the solubility of the compound in an organic solvent, usually *n*-octanol, to the solubility of the same compound in aqueous environment and is often expressed as a log value).

The relative solubility of a pesticidal agent is the sum of the contributions of each group and substituent to overall solubility. The presence of oxygen and nitrogen containing functional groups usually enhances water solubility while nonionizable hydrocarbon chains and ring systems enhance lipid solubility.

If the activity of pesticide is dependent on physical properties like solubility, partition coefficient and vapour pressure and not on the presence or absence of some chemical groups it is termed as structurally non-specific activity on the other hand if the activity is dependent on factors such as presence or absence of certain functional groups, intramolecular distance and shape of molecules and not easily co-related with any physical property it is termed as structurally specific activity.

Structural Features

Structurally specific activity is dependent on the interaction of the molecule with a cellular receptor and a small change in structure often leads to change in activity.

Receptor could be cellular constituent or it could be protein or enzyme. Receptors have a specific chemical affinity and structural requirements for a pesticidal agent for necessary interaction. The effect could be agonist in nature, i.e. generated after combining with the receptor or antagonistic, i.e. produced after blocking the receptor.

Stereochemistry or space arrangement of the atoms/3D structure of the molecule is a very important consideration while designing a pesticidal agent.

Any change in stereo specificity results in change of activity to certain degree. Since isomeric pairs have different physical properties, they differ in biological activity.

The following pesticide activity cases are possible for stereo isomeric pesticides:

1. Both of the stereoisomers exhibit comparable pesticide activity.
2. Only one of the stereoisomers exhibits pesticide activity. The other stereoisomer is inactive.
3. Both stereoisomers exhibit pesticide activity, but one is more active than the other.

Following classes stereoisomers are most important for bioactive compounds.

Geometric and Optical Isomers

Geometric isomers are referred as *cis* and *trans* isomers. When a molecule has a carbon-to-carbon double bond (−C=C–), a substituent group (or atom) can be positioned at the same side (*cis* isomers) of a double bond or at opposite side (*trans* isomers). These are not mirror images and have different physico-chemical properties and sometimes altogether different activity profiles.

They generally do not fit the same receptor equally well and if these functional groups are responsible for molecules biological activity a very different activity profile is resulted.

Optical isomerism originates from the presence of an atom containing four different substituents (i.e. the presence of an asymmetric atom, mostly referred to as a "chiral atom)". In most molecules, chirality is associated with a tetrahedral carbon atom. However, it is not restricted to tetrahedral carbon. Examples of chirality at the phosphate-P atom are found among some organophosphate pesticides.

Optical isomers or enantiomers have exactly the same physical and thermodynamic properties and differ only in their ability to rotate plane of polarized light.

Chirality plays a very important role because all organisms constitute a chiral environment and most enzymatic pathways are stereoselective.

Chirality is a very common phenomenon. As many as 25% of all pesticide active ingredients are chiral. Among insecticides all pyrethroids (having more than one chiral centres) and 30% of organophosphorus insecticides are chiral. Among herbicides chirality is observed in phenoxies, oxyphenoxypropionates, imidazolinones and cyclohexanediones. Fungicidal classes which exhibit chirality are triazoles and acylalanines.

Enatiomers differ in their toxicity, both to target and non-target species.

Example: two S-enantiomers of metolachlor are ten times more toxic to target weeds than the two R-isomers [7]. All fungicidal activity of metalaxyl and herbicide activity of Clodinafop reside with the R-enantiomer.

In spite of the fact that main biological activities or toxicities are associated with only one or a few enantiomers, most of these pesticides have been produced and used as racemates, which cause excessive contamination and pollution in the environment.

When agrochemicals have chiral structure efforts should be made to define the mode of action, elucidate metabolic pathways and define the human and environmental toxicity of each enantiopure isomer. If there are large differences in the biological activities of individual enantiomers in racemates, it is desirable to develop and use only the enantiopure isomer with the highest sought-after biological activities.

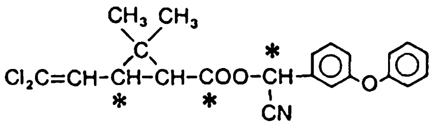
The separation of an enantiomeric pair or chiral synthesis is often a technically difficult and/or laborious and expensive process. However, techniques for asymmetric syntheses and separations of enantiomers with chiral HPLC and GC columns have been developed for several agrochemicals.

For industrial scale preparation of optically pure compounds naturally occurring, chiral compounds such as amino acids, carbohydrates and terpinoids constitute the "chiral pool" that can be used for transferring chirality to reagents. The chiral reagents are then used to synthesize the desired enantiomer. This is in contrast with "conventional" syntheses that result in racemic mixtures and not in a specific enantiomer. An example of a pesticide that uses a terpinoid chiral pool is *S*-Metolachlor, which results in an 80% enrichment of the most herbicide active *S*-enantiomer. Use of chiral solvents is sometimes used as the reaction media for non-chiral synthesis [8].

Production of single or enriched enantiomer pesticide is a green chemistry development, because it reduces the environmental loading of the inactive enantiomer.

The pyrethroid insecticides are typically esters of chrysanthemic acid and provide an excellent example of optical and geometric isomerism. Pyrethroid toxicity is highly dependent on the 3D of the molecule. Acute toxicity of a mixture of 2 isomers depends on the ratio of the amounts of the two isomers in the formulation. For example, the female rat's acute oral LD50 of permethrin increases from 224 to 6,000 mg/kg as the proportion of *trans* isomer increases from 20 to 80%.

Cypermethrin molecule has three chiral centres



This gives rise to eight stereoisomers (Fig. 17.2), four *cis* and four *trans* isomers, the *cis* isomers being the more biologically active.

Of the eight possible isomers, 1R *Cis* S isomer is the most biologically active isomer.

Racemic mixture of 1R *Cis* S and 1S *Cis* R is Alphacypermethrin. Alphacypermethrin is two to three times more effective than Cypermethrin.

Bioisosterism

Bioisosterism is the procedure of the synthesis of structural analogues of a lead compound by substitution of an atom or a group of atoms in the parent compound for another similar electronic and steric characteristics.

Any compound derived from another by such replacement is called bioisostere.

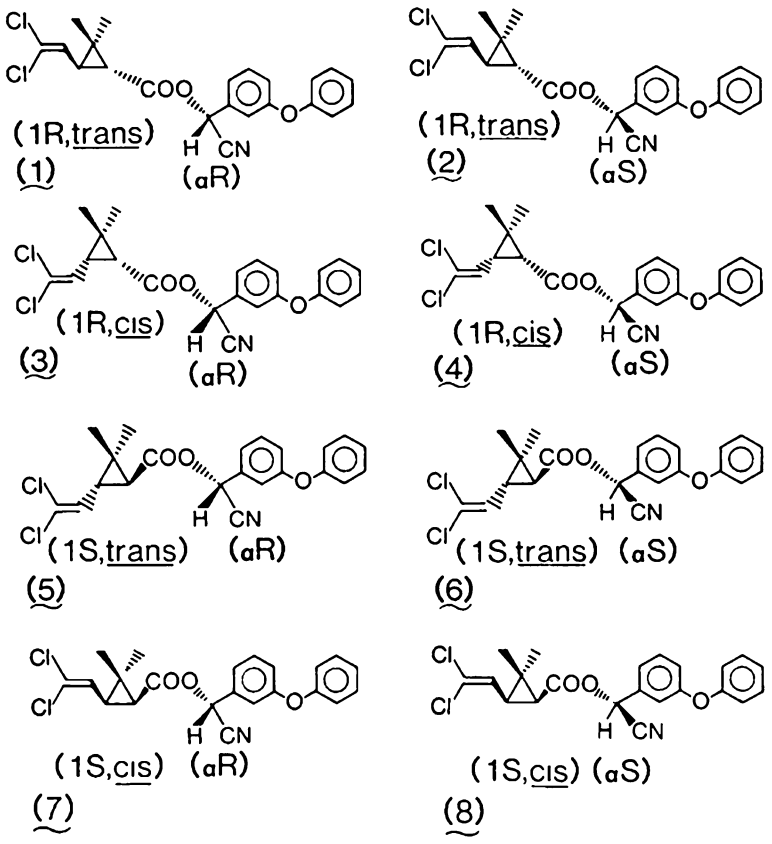
Bioisosterism is a useful strategy for molecular modification to design new agrochemical. Since molecules maintain similar biological properties this approach is used to modify molecules for acceptable efficacy, safety, stability, etc.

There are many examples of bioisosteres, which may be equivalent in some instances but not in others depending on what factors are important in binding (electronegativity, size, polarity, etc.).

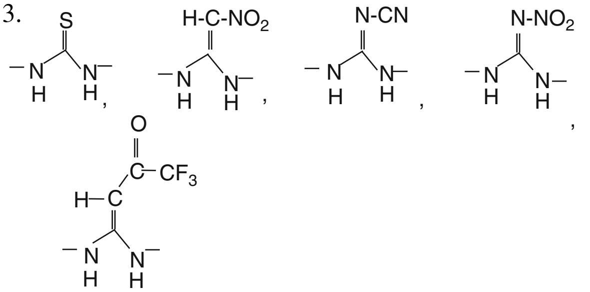
Examples of bioisosterism [9]:

1. $-CO_2H$,$-SO_2NHR$,$-SO_3H$,$-PO(OH)_2$,$-PO(OH)NH_2$,– CO NHCN
2. –F,–Cl,–Br,$-CF_3$,–CN,–SCN,$-N(CN)_2$,$-C(CN)_3$

Fig. 17.2 Stereoisomers of cypermethrin

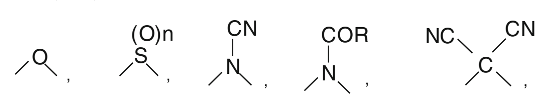


3.

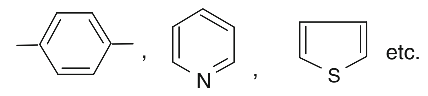


4. –OH,–NHCOR,–NHSO$_2$R,–CH$_2$OH,–NHCONH$_2$,–NHCN, –CH(CN)$_2$

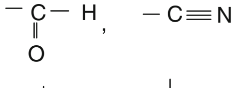
5.



6. — CH=CH)n,

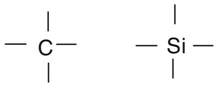


7.



$-\underset{\underset{O}{\|}}{C}-H, \quad -C\equiv N$

8.



$-\overset{|}{\underset{|}{C}}- \quad -\overset{|}{\underset{|}{Si}}-$

Synthesis of Agrochemicals

Synthesis of agrochemicals is typically a multi-step process and different routes can be followed to reach at the target active ingredient. Several factors are considered before deciding and standardizing feasible route for synthesis. Main factors that influence the choice are availability and cost of raw materials and reagents, engineering capabilities for performing desired reactions, amount and profile of impurities obtained by reaction sequence, yield and purity of intermediates and final product, cost benefit ratio, effluent generated during process, status of process patent, etc.

There is a lot of emphasis to shift towards reagents and chemicals which are less polluting for environment for instance use of Diphosgene/Triphosgene/Diarylcarbamates in lieu of phosphene in the manufacture of carbamates and sulfonyl ureas.

Backward synthesis or retro synthesis approach is often followed to work out synthetic route both in the synthesis of specific building blocks, key intermediates, penultimate intermediates or target active ingredient whole range of chemical reactions are deployed, e.g. aromatic electrophilic and nucleophilic substitution, chlorination, diazotization, sandmeyer reaction, diels alder cycloadditions, telemerizations, “N”, “O” alkylations, etc.

Pesticide Formulation (Commonly Known as Products or Plant Protection Products)

The active ingredient in a pesticide formulation controls the pest. Active ingredient is seldom used as such. It needs to be mixed with other inert materials viz. solvents, adjuvants, safeners, synergists, bulk carriers, etc. during the formulation process. Inerts may simply be added as bulk carriers to aid in handling the product or added to increase the stability, performance and safety of the product. The combination of an active ingredient with inert material is referred to as a formulation.

Sometimes two or more pesticides are combined as a premix referred as “Combination formulation” for:

- Providing better performance than either product would alone.
- Increasing the length and spectrum of control of pests.
- Saving money by reducing labour and wear on equipment (due to fewer applications).

When two or more pesticides provide a greater response than the added effects of each material applied separately, the response is considered synergistic. People often mistake additive effects for synergism. However, unlike with additive effects, the chemicals in a synergistic combination are not neutral toward each other. Rather, they interact in some way that increases efficacy beyond simple addition. Thus, not only does synergism save time, labour and wear on equipment, it enhances control compared to applying each of the materials separately.

Different formulations may be used differently. Some are to be used direct from the package, while others need to be diluted typically with water or oil. Some are recommended with the addition of certain adjuvants in spray tank to enhance the biological function.

Depending on intended use a single active ingredient can be formulated in various forms and concentrations in solid, liquid or gaseous forms and can be grouped into following categories:

Dry or solid formulations

(a) Ready to use : Dust (DP), baits (BB), granules (GR)
(b) Concentrates which have to be mixed with water before application: Tablets (TB) wettable powder (WP), water dispersable granule (WG) or Dry flowables (DF), soluble powder (SP)

Liquid formulations

(a) Emulsifiable cocentrates (EC)
(b) Ready-to use low concentrate solutions (RTU)
(c) Ultra low volume (ULV)
(d) Flowables/Suspension concentrates (SC)
(e) Soluble concentrates (SL)
(f) Aerosols(AE)

Other formulations: which can not be classified clearly as solid or liquid include.

(a) Microencapsulated materials
(b) Water soluble packets
(c) Insect attractants/repellents and pheromones
(d) Pesticide/fertilizer combinations
(e) Fumigants

Nanoformulation

The current trend is towards development of Nanoformulation or Nanotechnology. Nanoencapsulated formulations enable smaller quantities of the pesticides to be used effectively over a given period of time. Their design enables them to resist the severe environmental processes that act to eliminate conventionally applied pesticides, i.e. leaching, evaporation and photolytic, hydrolytic and microbial degradation. When the nanoformulations are applied as foliar spray or in the soil, the carrier and pesticide interact with the soil, insect, plant and atmosphere. Currently there is little knowledge how these nanoencapsulated pesticides are degraded in the plant soil and environment.

While, the benefits and prospects of the nanocapsulated pesticides are huge, but addressing some of the following issues are also equally important while designing the nanocarriers. They are

- Cost of the material and processing of the nanoencapsulated formulations should be low compared to the existing formulation.
- Fate of the nanocarriers in the environment, plant and soil.
- Fate of nanocarrier additives like fillers, stabilizers, antioxidants, etc.
- Environmental impact of the degradation of the carriers and additives in response to heat, hydrolysis, oxidation, solar radiation and biological agents.

Role of Adjuvants in Formulations

“A substance other than water, without pesticidal properties, which enhances stability or is intended to enhance the effectiveness of a pesticide when added either in the pesticide formulation or in the spray tank mixture”.

Adjuvants are helping to revolutionise the pesticide business as an important tool for users to improve application and achieve more cost-effective, better targeted and more environmentally acceptable pest control.

Though there is no “magic bullet” or single adjuvant product that can perform all these functions, technology

Table 17.7 Classification of adjuvants based on chemistry

Classes	Sub-classes
Emulsifiable oils	Mineral oil Seed oil (triglycerides) Alkoxylated triglycerides
Fatty acids from vegetable origin	Esterified Alkoxylated and esterified
Surfactants	Based on: alcohols, fatty acids, alkylphenols, alkylamines, sorbitol, sorbitan, trisiloxane, and alkylpolyglycosides
Salts	Ammonium sulphate, ureum, ammonium nitrate, calcium nitrate
Monoterpenic alcohols	
Waxes	Acid wax, ester wax, ethoxylated acid wax
Phospholipids	soya phospholipids
Polymers	Polyacrylamides, polyethylene oxide, polyvinyl

has advanced to the point where many of these functions can be incorporated into fewer high value products.

The physical–chemical properties of an adjuvant determine its usefulness in a certain application. Different chemical structures may have similar physical-chemical properties required for a certain adjuvant function. That's why so many different structures are sometimes recommended for the same function.

On the basis of chemistry adjuvants can be classified as in Table 17.7.

Characteristics of Main Formulation Types

See Table 17.8.

Formulation Types and Their Codes [10]

The following types of formulations are listed as per the "Catalogue of Pesticide Formulation types and International Coding Systems", GCPF (GIFAP) Technical Monograph No 2, 6th Edition, 2008. (See Table 17.9).

Adjuvant Types with Terms and Definitions

The following terminology for adjuvants has been approved by ASTM (American Society for Testing and material), and approved by the Adjuvants and Inerts committee (AIC) of the Chemical Producers and distributors Association (CDPA) [11]. (See Table 17.10).

Challenges and Way Ahead for Pesticide Industry

Resistance to Pesticides

Pesticide resistance is the adaptation of pest population targeted by a pesticide resulting in decreased susceptibility to that chemical. By the nature of co-evolution process, resistance most often develops to pesticides that are initially very effective and frequently used for control of pests. Pests develop a resistance to a chemical through genetic mutation and selection.

The United Nations Environmental Program listed pest resistance to pesticides as one of the most serious threat to global agriculture. World wide there are >550 insects and mite species, >150 plant pathogens species, and >270 weed biotypes that have been reported to have developed resistance to pesticides and more than 10% crop is lost annually due to pest resistance.

Rotation of different classes of pesticides and in some cases pre-mixes/tank mixes of two or more pesticides are useful strategies since an individual pest is less likely to develop resistance to two or more differing classes of pesticides. Such strategies are incorporated in Integrated Pest Management (IPM) program, which is being promoted globally by pesticide companies as an effective tool to combat pesticide resistance.

IPM programs use current and comprehensive information on the life cycles of pests and their interaction with the environment. This information, in combination with available pest control options, is used to minimize pest damage by the most economical means, and with the least possible hazard to people, property, and the environment.

Common strategy could be as follows to delay the resistance to pesticides:

1. Set action thresholds

   The emphasis is on control by judicious use of pesticides, not eradication of pests. By not killing 100% pests there is some susceptible population left that dilute resistant genes in the given population. Thus, before taking any pest control action, first set an action threshold, a point at which pest control action must be taken to stop the population to reach economic injury level where control of pests become difficult and un-economical.
2. Monitor and identify pests

   IPM programs work to monitor and identify the pests accurately, so that appropriate control decisions can be made in conjunction with action thresholds. The monitoring and identification removes the possibility of overuse, misuse and unnecessary uses of pesticides.

Table 17.8 Characteristics of main formulation types

Type	Main ingredients	Advantages	Disadvantages
Granule (GR)	Active ingredient Binder Stabiliser Carrier	Easy to handle and pack Low drift Low phytotoxicity Long residual activity	May be consumed by non-target organisms especially birds Need specialist application equipment like horn seeder
Tablets (TB)	Active ingredient Binder Lubricant Disintegrant	Easy to use Minimal packaging Less risk of incorrect dosage	Only suitable for highly active AIS High value low volume application
Wettable powder (WP)	Active ingredient Absorbent/carrier Wetting agent Antifoaming agent Dispersant	Easy to produce, pack and handle Tolerant to low temperature Low phytotoxicity No solvents	Produce dust Difficult to measure and mix Poor wettability and suspensibility May block lines and nozzles Poor stability Sticks inside packaging material
Water dispersible granule (WG)	Active ingredient Filler/carrier Disintegrant Wetting agent Dispersant	Low dusting Easy to pack, dispose handle and measure No solvent Tolerant to freezing	Long development effort Need expensive production equipment Dispersion may be affected by low temperature
Emulsifiable concentrates (EC)	Active ingredient Stabiliser Solvent Emulsifier	Easy to produce, handle and mix Useful for water-insoluble low melting AIS	Expensive to pack and transport Crystallization at low temperature Chances of phytotoxicity May be corrosive to metal and plastic Increased dermal toxicity May be sensitive to water hardness
Soluble concentrates (SL)	Active ingredient Antifreeze Wetter Water miscible solvent	Easy to produce Low phytotoxicity No flammability hazard	Expensive to pack and transport Frost sensitive May corrode metal
Suspension concentrates (SC) or flowables	Active ingredient Thickener Wetting agent Preservative Dispersant Anti-freezing agent Anti-foaming agent Water	No solvent Easy to measure and mix Can contain high concentration of AI Improves adhesion Compatible with aqueous concentrates Improved bio-efficacy as finer particle size	Difficult to produce successfully Can bleed, settle and cake out in storage Sensitive to freezing Can cause phytotoxicity Sensitive to AI purity and polymorphic form
Oil-in water emulsions (EW)	Active ingredient Emulsifier Solvent Thickener Anti-freezing agent Anti-foaming agents Preservative Water	Minimal skin and eye irritation Less or no solvent Minimal phytotoxicity Low or no flammability Ease of incorporating adjuvants Environmentally safer	Container disposal problem May be temperature sensitive Stabilization more difficult than for SC
Micro emulsions (ME)	Active ingredient No or minimum solvent Emulsifier Co-surfactant Water	Thermodynamically stable Good bio-efficacy Low flammability Easy application	High emulsifier level Low loading of active
Capsule suspension (CS)	Active ingredient Polymer Surfactant Water	Water based Low toxicity Reduced phytotoxicity Reduced loss on evaporation Reduced leaching Extended activity Lower doses Controlled release of AI	Expensive process High cost of inert ingredient Problems in achieving desired release of AI
Aerosols (AE)	Active ingredient Solvent Emulsifier Inhibitors Water Fragrances Propellant	Ready to use Safe and convenient for user Long shelf life Short application time	Inhalation risk Many propellants have environment issues and are highly flammable

Table 17.9 Formulation types and codes

Code	Description	Definition
AE	Aerosol dispenser	A container-he1d preparation which is dispersed generally by a propellant as fine droplets/particles upon actuation of a valve
AL	Any other liquid	A liquid not yet designated by a specific code, to be applied undiluted
AP	Any other powder	A powder not yet designated by a specific code, to be applied undiluted
BR	Briquette	Solid block designed for controlled release of active ingredient into water
CB	Bait concentrate	A solid or liquid intended for dilution before use as a bait
CP	Contact powder	Rodenticidal or insecticidal formulation in powder form for direct application formerly known as tracking powder (TP)
CS	Capsule suspension	A stable suspension of capsules in a fluid normally intended for dilution with water before use
DC	Dispersible concentrate	A liquid homogeneous preparation to be applied as a solid dispersion after dilution in water
DP	Dustable powder	A free-flowing powder suitable for dusting
DS	Powder for dry seed treatment	A powder for application in dry state directly to the seed
DT	Tablet for direct application	Formulation in the form of tablets to be applied individually and directly in the field, and/or bodies of water, without preparation of a spraying solution or dispersion
EC	Emulsifiable concentrate	A liquid, homogenous preparation to be applied as an emulsion after dilution in water
EG	Emulsifiable granule	A granular formulation, which may contain water insoluble formulants, to be applied as an oil-in water emulsion of the active ingredient(s) after disintegration in water
EO	Emulsion, water in oil	A fluid, heterogeneous preparation consisting of a dispersion of fine globules of pesticide in water in a continuous organic liquid phase
EP	Emulsifiable powder	A powder formulation, which may contain water insoluble formulants, to be applied as an oil-in water emulsion of the active ingredient(s) after dispersion in water
ES	Emulsion for seed	A stable emulsion for application to the seed either direct treatment or after dilution
EW	Emulsion, oil-in water	A fluid, heterogeneous preparation consisting of a dispersion of fine globules of pesticide in an organic liquid in a continuous water phase
FS	Flowable concentrate for seed treatment	A stable suspension for application to seed, either directly or after dilution
FU	Smoke generator	A combustible formulation, generally solid, which upon ignition releases the active ingredient(s) in the form of smoke
GA	Gas	A gas packed in pressure bottle or pressure tank
GE	Gas generating product	A preparation which generates a gas by chemical reaction
GL	Emulsifiable gel	A gelatinized formulation to be applied as an emulsion in water
GR	Granule	A free-flowing solid preparation of a defined granule size range ready for use
GS	Grease	Very viscous preparation based on oil or fat
GW	Water soluble gel	A gelatinized formulation to be applied as an aqueous solution
HN	Hot fogging concentrate	A formulation suitable for application by hot fogging equipment, either directly or alter dilution
KK	Combi-pack solid/liquid	A solid and a liquid formulation, separately contained within one outer pack, intended for simultaneous application in a tank mix
KL	Combi-pack liquid/liquid	Two liquid formulations, separately contained within one outer pack, intended for simultaneous application in a tank mix
KN	Cold fogging	A preparation suitable for application by cold fogging concentrate equipment, either directly or after dilution
Code	Description	Definition
LN	Long-lasting insecticidal net	A slow or controlled release formulation in the form of netting, providing physical and chemical barriers to insects
LS	Solution for seed treatment	A solution for application to the seed either directly or after dilution
MC	Mosquito coil	A coil which burns (smoulders) without producing a flame and releases the active ingredient into the local atmosphere as a vapour or smoke
ME	Micro-emulsion	A clear to opalescent oil and water containing liquid, to be applied directly or after dilution in water, when it may form a diluted micro-emulsion or a conventional emulsion
OD	Oil dispersible	A stable suspension of active ingredient(s) in a water-immiscible fluid, which may contain other dissolved active ingredient(s) intended for dilution with water before use
OF	Oil miscible flowable	A stable suspension of concentrate fluid intended for dilution in an organic liquid before use

(continued)

Table 17.9 (continued)

Code	Description	Definition
OL	Oil miscible liquid	A liquid, homogenous preparation to be applied as a homogenous liquid after dilution in an organic liquid
OP	Oil dispersible powder	A powder preparation to be applied as a suspension after dispersion in an organic liquid
PA	Paste	A water-based film forming composition
PR	Plant rodlet	A small rodlet, usually a few centimetres in length and a few millimetres in diameter containing active substance
PS	Seed coated with a pesticide	Self-defining
RB	Bait (ready for use)	A preparation designed to attract and be eaten by the target species
SC	Suspension concentrate/ flowable concentrate	A stable suspension of active substance(s) in a fluid intended for dilution with water before use
SD	Suspension concentrate for direct application	A stable suspension of active ingredient(s) in a fluid, which may contain other dissolved active ingredient (s) intended for direct application, to rice paddies, for example
SE	Suspo-emulsion	A f1uid, heterogeneous preparation consisting of a stable of active substance(s) in the form of solid particles and of fine globules in a continuous water phase
SG	Water soluble granules	A preparation consisting of granules to be applied as a true solution of active substance after dissolution in water but may contain insoluble inert ingredients
SL	Soluble concentrate	A liquid homogenous preparation to be applied as a true solution of the active substance after dilution with water
SO	Spreading oil	A preparation designed to form a surface layer on application to water
SP	Water soluble powder	A powder preparation to be applied as a true solution of the active substance after solution in water but which may contain insoluble inert ingredients
ST	Water soluble tablet	Formulation in form of tablets to be used individually, to form a solution of the active ingredient after disintegration in water. The formulation may contain water-insoluble formulants
SU	Ultra low volume (ULV) suspension	A suspension ready for use though ULV equipment
TB	Tablet	Pre-formed solids of uniform shape and dimensions, usually circular, with either flat or convex faces
TC	Technical material	A material resulting from manufacturing process comprising the active ingredient, together with associated impurities. This may contain small amounts of necessary additives
TK	Technical concentrate	A material resulting from manufacturing process comprising the active ingredient, together with associated impurities. This may contain small amounts of necessary additives and appropriate diluents
UL	Ultra low volume (ULV) liquid	A homogenous liquid ready for use through ULV equipment
VP	Vapour-releasing product	A preparation containing one or more volatile ingredients, the vapours of which are released into the air. Evaporation rate normally is controlled by using suitable preparations and/or dispensers
WG	Water dispersible	A preparation granule consisting of granules to be applied after dis-integration and dispersion in water
WP	Wettable powder	A powder preparation to be applied as a suspension after dispersion in water
WS	Water dispersible powder for seed treatment	A powder to be dispersed at high concentration in water before application as a slurry to the seed
WT	Water dispersible tablet	Formulation in the form of tablets to be used individually, to form a dispersion of the active ingredient after disintegration in water
XX	Others	Temporary category of all the formulations not listed above
ZC	A mixed formulation of CS and SC	A stable suspension of capsules and active ingredient(s) in fluid, normally intended for dilution with water before use
ZE	A mixed formulation of CS and SE	A fluid, heterogeneous formulation consisting of a stable dispersion of active ingredient(s) in the form of capsules, solid particles and fine globules in a continuous water phase, normally intended for dilution with water before use
ZW	A mixed formulation of CS and EW	A fluid, heterogeneous formulation consisting of a stable dispersion of active ingredient(s) in the form of capsules, and fine globules in a continuous water phase, normally intended for dilution with water before use

Note: Suffix “SB” should be added to the formulation code, if the material is packed in a sealed water soluble bag (e.g. WP-SB)

3. Prevention and control
   Selecting pest resistant varieties best suited for local growing conditions, maintaining healthy crops and rotation between different crops together with judicious use of pesticides in conjunction with action threshold.

Spurious Pesticides

One of the biggest challenges for the industry is rampant use of spurious pesticides. D’Arcy Quinn, anti-counterfeit director at Crop Life International, estimated up to 40% of

Table 17.10 Approved adjuvants terminology

Term	Definition
Acidifier	Material that can be added to spray mixtures to lower pH
Activator	Material that increases biological efficacy of agrochemicals
Amphoteric surfactant	A surfactant capable of forming, in aqueous solution, either surface active anions or surface active cations, depending on the pH
Anionic surfactant	A surface-active agent in which the active portion of the molecule containing the lipophilic segment forms exclusively a negative ion (anion) when placed in aqueous solution
Antifoaming agent	Material used to inhibit or prevent the formation of foam
Attractant	Material that attracts specific pests
Buffer/Buffering agent	A compound or mixture that, when contained in solution, causes the solution to resist change in pH. Each buffer has a characteristic limited range of pH over which it is effective
Canopy penetrating agent	An adjuvant that increases the penetration of the spray material into the crop canopy
Cationic surfactant	A surface-active agent in which the active portion of the molecule containing the lipophilic segment forms exclusively a positive ion (cation) when placed in aqueous solution
Colourant	A material used to alter the colour of tank mix
Compatibility agent	A surfactant that allows simultaneous application of liquid fertilizer and agrochemical formulations, as a uniform tank mix, or improves the homogeneity of the mixture and the uniformity of application
Crop oil concentrate	An emulsifiable petroleum oil-based product containing 15–20 % w/w surfactant and a minimum of 80 % phytoblend oil
Crop oil (emulsifiable)	An emulsifiable petroleum oil-based product containing upto 5 % w/w surfactant and remainder of phytoblend oil
Crop oil (nonemulsifiable)	Same as phytoblend oil
Defoaming agent	Material that eliminates or suppresses foam in the spray tank mix
Disposition aid	Material that improves the ability of agrochemical sprays to deposit on targeted surfaces
Dormant oil	A horticulture mineral oil applied during the dormant phase of the targeted plant
Drift control agent	A material used in liquid spray mixture to reduce spray drift
Emulsifier	A surfactant that promotes the suspension of one immiscible liquid in another
Evaporation reducing agent	A material that reduces the evaporation rate of a spray mix during or after application or both
Extender	A material that increases the effective life of an agrochemical after application
Foam suppressant	Same as defoamer
Foaming agent	A material that increases volume or stability of foam formed in spray mixture
Humectant	A material that increases the equilibrium water content and increases the drying time of an aqueous spray deposit
Modified vegetable oil	An oil extracted from seeds which has been chemically modified (e.g. methylated)
Modified vegetable oil concentrate	An emulsifiable, chemically modified vegetable oil product containing 5–20% w/w surfactant and remainder chemically modified vegetable oil
Naptha-based oil	A petroleum oil containing majority of the naphtha fraction
Nonionic surfactant	A material having no ionizable polar end groups but comprised of hydrophilic and lipophilic segments
Oil	Paraffinic oil or petroleum oil or vegetable oil
Paraffinic oil	A petroleum oil (derived from peraffinic crude) whose paraffinic carbon type content is typically greater than 60%
Penetrant	A material that enhances the ability of an agrochemical to enter a subtract or penetrate a surface
Petroleum oil	Oil derived from petroleum, contains a mixture of hydrocarbons that are broadly classified as paraffins, napthenes, aromatics, or other unsaturates or combinations thereof
Phytoblend oil	A highly refined paraffinic material with a minimum unsulfonated residue of 92% w/w
Spreader	A material which increases the area that a droplet of a given volume of spray mixture will cover on a target
Spreader/sticker	A material that has the properties of both a spreader and a sticker
Sticker	A material that assists the spray deposit to adhere or stick to the target and may be measured in terms of resistance to time, wind, water, mechanical action, or chemical action
Surfactant/surface active agent	A material that when added to a liquid medium modifies the properties of the medium at a surface or interface
Vegetable oil	Oil extracted from seeds typically those of corn, cotton, peanut, rapeseed, sunflower, canola or soya beans
Vegetable oil concentrate	An emulsifiable vegetable oil product containing 5–20% w/w surfactant and a minimum of 80% w/w vegetable oil
Wetting agent	Synonymous with spreading agent in function

pesticides in some countries would be faked. Unlike registered products, which undergo rigorous independent testing before being placed in the market, illegal pesticides are neither tested nor suitable for use. Nothing guarantees that a counterfeit product contains what is described on the label; a reality that can have damaging consequences for crops, human health and environment. They pose threats to farmers through crop and reputation destruction, as well as dangerous exposure during application. Residues may be carried on food to consumers.

All the relevant players from industry, regulatory, customs and enforcement agencies need to be brought together to determine the best ways solve the problem.

Safe Use of Pesticides

If pesticides are used improperly or excessively, they can have harmful effects on pests, crops and environment. Lack of proper knowledge among farmers/users leads to improper handling, use and disposal of pesticides. This is a common scenario in developing and underdeveloped countries.

If labels are read and instructions regarding protective clothing and correct dose are followed carefully, risk in pesticide handling and chances of harming crops by overdose can be reduced drastically. The number of applications and amount of pesticide used can be decreased by better timing, e.g. spray at economic threshold level when the pest is most vulnerable; young caterpillars are easier to kill than bigger ones.

One such example is Global Safe Use Pilot Projects launched by the pesticide industry in June 1991 in 3 countries, Guatemala, Kenya and Thailand with aid from Global Crop Protection Federation (GCPF). The Safe Use program in Guatemala that was aimed to “provide education and training and ensure that pesticides are used rationally and safely in the agricultural production process” claims to have reduced cases of pesticide poisoning considerably [12].

Increasing Development and Registration Cost

Bringing new molecules in the market is getting more and more expensive. It takes, on an average, 10–12 years from discovery of new Active substance to launching it in the market. Discovery and development cost of a new crop protection product is on the rise. This cost was approximately $150 million in 1995 and reached to more than $250 million in 2010. The cost is going to rise further as data requirement is becoming more complex and cost of data development is on a rise too as meeting regulatory framework for pesticides is mandatory before it is manufactured and used in a given country and states. This approval process is governed by national and regional/federal laws depending on locally applicable regulations.

Further, registered pesticides are subject to periodic review. Depending on the prevailing national regulations, authorities may review approvals at set intervals or at any time if new information comes to light.

Besides nationals authorities intergovernmental organizations, such as OECD, FAO, WHO and the Codex Commission also play a vital role in the regulation of pesticides.

The FAO has developed a voluntary Code of Conduct for the distribution and use of pesticides, which is very broad in scope and sets minimum standards at all points of the manufacture, marketing and use chain. The Codex Alimentarius Commission along with National Authorities sets limits on the permitted levels of pesticide residues in produce, so that the quality of food on supermarket shelves is assured. Other major international bodies like OECD and WHO provide forum for the discussion of pesticide regulatory issues at international level.

Companies seeking approval have to submit data package to the national regulatory authority. This data is used to support the proposed uses of the product. The data can be generated or commissioned by the company itself, derived from published material or purchased from third parties by paying data compensation. The cost of preparing the application for a new active substance is considerable, in the range of US$15–20 million.

As part of determination of chemical equivalence, a generic manufacturer is required to supply to the authority conducting the risk assessment, a data package covering its products. This package must include acute toxicology information, and, in addition, must provide information relating to manufacturing process and impurity profile of the technical material as produced in its plants as well as Five batch analysis of typical manufacturing lots, supporting the impurity limits. The authority then reviews the data package, and on a confidential basis, makes a comparison between the impurity profile and manufacturing data with the reference material, i.e. the primary sponsor of the specification, and those from the secondary manufacturer, in order to judge the equivalence of the second product with the reference material. Assuming that the impurity profiles are within the variance parameters specified in the FAO/WHO manual, the products may be judged to be equivalent for purposes of quality comparison for risk assessment. If, however, there are differences among the provided data as defined in the manual, the authority may require the generic manufacturer to supply additional data, even including sub-acute and chronic toxicology and ecotoxicology data, to support the equivalence assessment.

A complete assessment of the impurity content in a technical material under equivalence evaluation is very important since differences in impurity content may significantly affect the toxicological properties of pesticide products. This widely accepted principle is the basis for the rigorous requirement for complete “fingerprinting” (an impurity-by-impurity comparison over the entire range of impurities) during the equivalence assessment process.

Each country has different requirements for product registration, and this can be a daunting prospect for manufacturers seeking to offer their product for sale in many countries. Moves are underway to harmonize product registration requirement across regions or trading partners. OECD member governments and pesticide regulators have agreed to take a number of steps towards full harmonization of data requirements by 2014. Comprehensive information on registration system and requirements for each country can be obtained from their respective website referred in Annex 17.2 for certain countries.

Other examples of harmonization are the NAFTA agreement led to cooperative efforts to harmonize pesticide regulatory requirements between the US, Canada and Mexico and to Joint Review projects in the region. Similar agreements are in place in Latin America (Mercosur) and Asia Pacific (ASEAN).

Entry of Biotechnology/Transgenic Crops

There is a general belief that genetically modified (GM) crops overall reduce pesticide use but there are contradictions in practicality. For example recent surveys in the USA suggest that Bt-corn that targets corn borer has not lowered pesticide use, since most pesticides are directed against other corn pests. In India, consumption of insecticides increased many fold in Bt cotton for the control of sucking pests viz. whitefly, mealy bugs, thrips, aphids and bugs.

The introduction of glyphosate resistant soya beans in 1996 gave farmers an opportunity to reduce the cost of weed control; however, the increasing areas and continuous use of glyphosate has resulted in an increase in the types of weeds that are now glyphosate resistant.

Hence, new-generation “Roundup Ready” (RR) 2 soya beans seed, to be introduced on a widespread basis soon. Dicamba tolerance trait is expected to be stacked with the high yielding Genuity Roundup Ready 2 yield soya beans trait. These next generation technologies are aimed at offering farmers multiple modes of action and superior application timing and flexibility but the cost will be 40–45% more than the original RR seeds they are displacing.

Further, these new GM crops may give rise to super weeds and cause outbreaks of new pests and diseases that would need newer and more potent chemicals to control them. It remains to be seen how much impact GM crops will have on the pesticide industry for the development, registration and use of new pesticides to combat these super weeds, pests and diseases.

Delivery Systems and Application Technology

Application technology is now seen as an enabling technology, which can add significant value to pesticide products, and at the same time improve operator safety and reduce the dose rate and wastage of pesticides applied to crops, thereby reducing environmental impact and increasing food safety.

As per Dr. Zabkiewicz of the Forest research Institute, New Zeeland, the application of pesticides to leaf surfaces was a complex and often inefficient process. He pointed out that the efficiencies of the various stages of spray application are as follows:

Deposition 80%, retention 50%, Uptake 50% and Translocation 10%. This means for a systemic pesticide it is likely that no more than 2% of the active material actually reaches the target site [13].

New more precise delivery techniques are being investigated as a tool to increase efficacy and reduce input costs for growers. The emphasis on safety of users and environment is driving the move towards minimal contact with the product, more accurate placement of the active ingredient, and the use of safer formulations such as water-based suspensions, emulsions, microcapsules and water dispersible granules. The production of nanoparticle-based formulations has shown to increase the activity of an otherwise poorly dispersing product.

Seeds are an effective way of ensuring correct placement. Seed coating formulations are a value added technology that has found application in the establishment of a safe environment that protects the seed when it is most vulnerable, i.e. the time of storage and during initial seed germination. Seed treatments are estimated to enhance productivity by 8–10%. Seed treatment market is continuously growing. It was approximately US$900 million in 2001 and reached US $2.5 billion by 2009. Most GM seeds in US/Canada have minimum 4 coats. Use of microcapsule treatments or coated seeds will apart from improvements in safety give the potential for controlled release.

Cleaner Technology and Products

Manufacturing of certain pesticides involves use of hazardous chemicals and wastes. Clean production is defined as any practice which eliminates the use or formation of hazardous substances at source through the use of non-hazardous chemicals in production processes, or through product or process redesign, and thereby prevents releases of hazardous substances into the environment by all routes, directly or indirectly.

Recently, China Ministry has formed a new management scheme about clean production in pesticide industry.

Molecules with high eco toxicity, human carcinogens/mutagens, endocrine disruptors, persistent organic pollutants and persistent bio accumulative are being picked up by regulatory authorities for thorough investigation and those with unfavourable profiles are being phased out.

Preference is for pesticides that are significantly safer to humans or environment.

R&D efforts are also directed towards evolution of new agrochemicals, in terms of mode of action, structure and specificity for better yield.

Summary

In agriculture, there is no single solution that will be capable of addressing the problems that farmers and the growing world population face today and in the future. Neither biotechnology nor chemistry has all the answers. Instead, combinations of solutions and collaborations across the public and private sectors will be required to save the lives of billions of people from hunger and diseases of malnutrition.

Among toughest challenges the world is facing today are reducing carbon credits and saving rapidly decreasing non-renewable fossil fuels reserves. The alternative energy race to replace fossil fuels is gearing up. The concepts of renewable supply, reduced greenhouse gases, and energy security are driving biofuels opportunities globally. Currently, biofuels provide approximately 2% of the world's transportation fuel and is expected to reach 7% in 2020. This has created a big dilemma of Food vs. Fuel as the risk of diverting farmland or crops for biofuels production will affect the availability of the food, feed and fibre supply on a global scale. Hence, productivity improvements will remain the most important factor in sustainable agriculture. Low yields are not sustainable in the decades ahead.

For a sustainable agriculture there is a need for comprehensive and effective international pest and pesticide management schemes, education and training in proper pesticide management, solid national and legislative framework, global harmonization of pesticide registration requirement and fixing loopholes in the legislative framework to counter illegal trafficking in counterfeit pesticide products.

Recent trends in agrochemical industry, viz. consolidation of multinational agrochemicals companies, rapid growth of transgenic crop markets, vertical integration of agrochemical firms with seed companies and food processors, use of better quality seeds, and thrust towards environment friendly products and technologies, are driving the Agrochemical industry forward and paving the way towards ever green revolution.

Acknowledgments The authors express their sincere thanks and gratitude to Dr. K.H. Gharda, Chairman and Managing Director, Gharda Chemicals Limited, Mumbai, for his help and support in preparing this chapter. We also wish to thank Mr. Nitin Girase, Manager-Product Development and Ms Revti Chandrashekhar, Sr. Officer, Regulatory Affairs, Gharda Chemicals Limited, for their help in literature search, and preparation of manuscript.

Annex 17.1 Products going off patent from 2010 to 2015 and beyond

Sr No	AI common name and structure	Chemical class	Mode of action/Biochemistry	Launch year	Year of patent expiry
Insecticides becoming generic between 2010 and 2015					
1	Acetamiprid 	Neonicotinoid	Systemic with translaminar activity having both contact and stomach action. Acetylcholine receptor (nAChR) agonist Uses: for the control of sucking pests especially aphids and thrips	1995	US 2011 EU 2010 SPC 2015
2	Bifenazate 	Hydrazine carboxylate	Neuronal inhibitor, non-systemic having contact and residual action Uses: effective against phytophagous mites	1999	US 2011 EU 2012
3	Clothianidin 	Neonicotinoid	Translaminar and root systemic activity. Acetylcholine receptor (nAChR) agonist Uses: for the control of sucking and chewing pests on a range of crops	2002	US 2009 EU 2009 SPC 2014
4	Chromafenozide 	Diacylhydrazine	Ecdysteroid agonist. which competes at the binding site of the receptor protein of the insect moulting hormone Uses: for the control of various Lepidopteran species	1999	–
5	Dinotefuran 	Neonicotinoid	Systemic, with contact and stomach action. Nicotinic Acetylcholine receptor agonist/antagonist Uses: to control a wide range of sucking pests, including whiteflies, mealybugs and plant hoppers, in vegetables, fruit, turf and rice crops	2002	–

(continued)

Annex 17.1 (continued)

Sr No	AI common name and structure	Chemical class	Mode of action/Biochemistry	Launch year	Year of patent expiry
6	Emamectin benzoate 	Biopesticide	Non-systemic, acts by causing insect paralysis. Chloride channel activator Uses: effective against caterpillars in particular but also helps control mites, thrips and leaf miners	1997	US 2011 EU 2011 SPC 2015
7	Fipronil 	Phenylpyrazole	Broad spectrum with contact and stomach action. GABA-gated chloride channel antagonist Uses: for the control of a broad range of pests including thrips, rootworms, wireworms, weevils and termites	1993	US 2010 EU 2008 SPC 2008
8	Flonicamid 	Pyridine compound	Systemic, selective with long-term activity. Distrub insect feeding pattern Uses: To control aphids, thrips and whitefly in a range of situations	2000	–

9	Indoxacarb  	Oxadiazine	Contact and stomach action. Voltage-dependent sodium channel blocker Uses: on a wide range of crops to control caterpillars in general and Helicoverpa in particular	2000	US 2012 EU 2011
10	Nitenpyram  	Neonicotinoid	Acetylcholine receptor (nAChR) agonist. Systemic with translaminar activity, contact and stomach action Uses: To control sucking insects on rice and in greenhouse crops. Mainly used to kill external parasites in livestock and domestic pets	1995	–
11	Spinosad  	Biopesticide	Contact and stomach action. Acts by exciting the insect nervous system, leading to involuntary muscle contractions and paralysis Uses: for control of Lepidoptera caterpillars	1997	US 2013 EU 2009 SPC 2014
12	Spirodiclofen  	Tetronic acid	Selective, non-systemic, distrupts mite development Uses: foliar applied acaricide active against a range of mites on fruit and nut	2003	–

(continued)

Annex 17.1 (continued)

Sr No	AI common name and structure	Chemical class	Mode of action/Biochemistry	Launch year	Year of patent expiry
13	Spiromesifen 	Tetronic acid	Non-systemic. Inhibitors of lipid synthesis Uses: against whiteflies and two-spotted spidermite	2002	–
14	Thiacloprid 	Neonicotinoid	Contact and stomach action with some systemic properties. Acetylcholine receptor (nAChR) agonist Uses: for control of sucking and chewing insects	1999	US 2007 EU 2007 SPC 2012
15	Thiamethoxam 	Neonicotinoid	Acetylcholine receptor (nAChR) agonist. Broad spectrum, systemic with contact and stomach action Uses: To control a wide range of pests including aphids, whiteflies, thrips, mealybugs, wireworms and ground beetles	1997	–
16	Tolfenpyrad 	Pyrazole	Broad spectrum, contact activity, exhibits antifeedant activity especially against lepidoptera Uses: for use in vegetables, particularly cruciferous leafy vegetables, fruits and other high-value markets. Also shows some fungicidal activity against powdery mildew	2002	–

Insecticides (likely to become generic post 2015)

1	Bistrifluron 	Benzoylurea	Chitin synthesis inhibitor Uses: for the control of aphids, whiteflies and other lepidopterous insects	Under development	–
2	Chlorantraniliprole 	Anthranilic diamide	Exhibits larvicidal activity post ingestion by targeting and disrupting the Ca^{2+} balance causing muscle contraction Uses: Broad spectrum control of caterpillars in field, vegetable crops and vine	2007	–
3	Cyantraniliprole 	Diamide	Exhibits larvicidal activity as an orally ingested toxicant by targeting and disrupting the Ca^{2+} balance, second generation ryanodine receptor Uses: Foliar and systemic activity on a wide range of crops that is effective against many key chewing and sucking pests including whitefly, thrips, aphids and fruitflies	2008	–
4	Cyenopyrafen 	Pyrazole	Mitochondrial complex II electron transport inhibitor Uses: An acraicide for fruit, vegetables and tea	2006	–

(continued)

Annex 17.1 (continued)

Sr No	AI common name and structure	Chemical class	Mode of action/Biochemistry	Launch year	Year of patent expiry
5	Cyflumetofen 	Bridged diphenyl	Highly selective and causes loss of motor coordination leading to paralysis and death Uses: novel acaricide active against phytophagous mites at all development stages	2004	–
6	Flubendiamide 	Benzene-dicarboxamide	Exhibits larvicidal activity as an orally ingested toxicant by targeting and disrupting the Ca^{2+} balance Uses: lepidopteran insecticide for use in wide range of annual and perennial crops	2006	–
7	Gamma-cyhalothrin  	Pyrethroid	Non-systemic acting by contact and/or ingestion. Sodium channel modulator Uses: broad-spectrum control of insect pests in a wide range of crops	2003	–

8	Imicyafos 	Phosphonothioate	High contact activity with fast diffusion in soil Uses: A novel nematicide that is effective against knot root, root lesions, cyst nematodes	2006	–
9	Iodomethane 	Alkyl iodide	Fumigant action thought to be via the nucleophilic displacement (SN2) reaction in various amino acids and peptides within target organisms Uses: to control insects, plant parasitic nematodes, soil borne pathogens and weed seeds	2004	–
10	Metaflumizone 	Semicarbazone	Broad-spectrum, attacks insect nervous system causing paralysis Uses: against key insect pests including Lepidoptera, Coleoptera, Hymenoptera, Isoptera and Diptera	2008	–
11	Metofluthrin 	Pyrethroid ester	Vapour active, knock-down action. Sodium channel modulator Uses: as a mosquito repellent impregnated on to paper strips and positioned in outdoor areas such as gardens and campsites	2004	–

(continued)

Annex 17.1 (continued)

Sr No	AI common name and structure	Chemical class	Mode of action/Biochemistry	Launch year	Year of patent expiry
12	Noviflumuron 	Benzoylurea	A chitin synthesis inhibitor Uses: insect growth regulator to control termites, ants, cockroaches, fleas and flies in a wide range of pest management solutions	2003	–
13	Pyrifluquinazon 	Quinazinalone	Modifies insect behaviour, rapidly stopping feeding such that insects starve to death Uses: to control aphids, thrips, mealybugs and scale on vegetables and ornamentals	2006	–
14	Pyriprole 	Phenylpyrazole	Causes uncontrolled activity of parasites nervous system and hence its death, broad-spectrum, non-systemic Uses: Insecticide, Ectoparasiticide, Acaricide for the treatment for fleas and ticks on animals	2004	–
15	Spirotetramet 	Tetramic acid	Stomach acting, broad spectrum, systemic insecticide that is rapidly translocated, inhibition of lipogenesis in treated insects Uses: for the control of a wide range of sucking insects including aphids, whiteflies and psyllids on crops such as fruit, vegetables and potatoes	2007	–

16	Sulfoxaflor 	Sulfilimine	Mode of action not fully understood Uses: for the control of aphids in cotton and peaches	2007	–
17	Tetramethylfluthrin 	Pyrethroid ester	Mode of action not fully understood Uses: A novel insecticide	2008	–
Herbicides becoming generic between 2010 and 2015					
1	Amicarbazone 	Triazolone	Contact action, absorbed by foliage, photosynthesis II inhibition Offers pre- and post-emergence control of annual dicotyledonous weeds and grasses in sugar cane and other crops	1999	US 2009 EU 2010
2	Carfentrazone-ethyl 	Triaolinone	Contact, absorbed by foliage with limited translocation. Cell membrane disruption—PPO inhibitor Post-emergence control of a wide range of broad-leaved weeds	1997	US 2009 EU 2009 SPC 2012

(continued)

Annex 17.1 (continued)

Sr No	AI common name and structure	Chemical class	Mode of action/Biochemistry	Launch year	Year of patent expiry
3	Cloransulam-methyl 	Sulfonanilide	Inhibits acetolactate synthesis. The primary site of activity is in plant meristem It is used to control broad-leaved weeds in soya beans and other crops	1997	–
4	Cinidon-ethyl 	Dicarboximide	Contact action Post-emergence control of annual broad-leaved weeds	1998	US 2008 EU 2007 SPC 2012
5	Cyclosulfamuron 	Sulfonyl urea	Inhibition of acetolactate synthase (ALS) stopping cell division and plant growth Post-emergence control a variety of dicotyledonous and sedge weeds in cereals and rice	1997	US 2010 EU 2011
6	Florasulam 	Triazolopyrimidine	Selective, absorbed by roots and shoots. Inhibits plant enzyme acetolactate synthase (ALS) Post-emergence control of broad-leaved weeds	1999	US 2008 EU 2009 SPC 2013

7	Flupyrsulfuron-methyl-sodium 	Sulfonylurea	Inhibition of acetolactate synthase Post-emergence control of broad-leaved weeds in cereals	1998	US 2012 EU 2012 SPC 2013
8	Indanofan 	Unclassified	Selective, systemic, acts by the inhibition of very long chain fatty acid biosynthesis Post-emergence control of sedges such as *Echinochloa oryzicola*, and some dicotyledonous in rice crops	1999	US 2010 EU 2010
9	Iodosulfuron-methyl-sodium 	Sulfonylurea	Acetolactate synthase (ALS) inhibitor Post-emergence control grass and broad-leaved weeds in cereals	2000	–
10	Isoxaflutole 	Isoxazole	Broad-spectrum, systemic absorbed by roots and leaves. Acts by carotenoid biosynthesis inhibition Post-emergence control of broad-leaved weeds and grasses in maize and sugar cane	1998	EU 2010
11	Mesosulfuron-methyl 	Sulfonylurea	Amino acid synthesis inhibitor Post-emergence control of grasses and some broad-leaved weeds in cereals	2001	–

(continued)

Annex 17.1 (continued)

Sr No	AI common name and structure	Chemical class	Mode of action/Biochemistry	Launch year	Year of patent expiry
12	Mesotrione 	Triketone	Selective, absorbed by roots and translocated, inhibition of carotenoid biosynthesis Post-emergence control of some grasses and broad-leaved weeds mainly in maize crops	2001	US 2008 EU 2005 SPC 2010
13	Oxasulfuron 	Sulfonylurea	ALS inhibitor Absorbed by shoots and roots and translocated. Post-emergence herbicide for grass and broad-leaved weed control	1996	–
14	Oxaziclomefon 	Unclassified	Blocks plant growth by inhibiting cell expansion in grass roots Effective in controlling grasses and annual sedges in paddy fields	2000	–
15	Picolinafen 	Pyridine compound	Selective, with rapid foliar absorption Post-emergence to control broad-leaved weeds in cereals	2001	US 2011 EU 2011 SPC 2017
16	Propoxycarbazone 	Triazolone	Absorbed by leaves and roots and translocated. Inhibits amino acid synthesis Residual post-emergence herbicide for grass and some broad-leaved weeds mainly in winter wheat	2000	US 2014 EU 2012 SPC 2016

17	Pyriftalid 	Pyrimidinyloxybenzoic	Inhibits amino acid synthesis, taken up mainly by roots Used to control grass weeds in rice and other crops	2000	–
18	Sulfosulfuron 	Sulfonylurea	Systemic, absorbed by roots and leaves and translocated. Acetolactate synthase (ALS) inhibitor Used for annual grass and broad-leaved weed control in cereals	1999	US 2013 EU 2011
19	Trifloxysulfuron 	Sulfonylurea	Inhibitor of acetoacetate synthase, absorbed by shoots and roots and translocated Post-emergence control of grasses, sedges and broad-leaved weeds in cotton, sugar cane and other crops	2000	–
20	Tritosulfuron 	Sulfonylurea	Inhibits amino acid synthesis Uses: to control a wide range of broad-leaved weeds in cereals and maize	–	US 2012 EU 2011

(continued)

Annex 17.1 (continued)

Herbicides (likely to become generic post 2015)					
1	Aminopyralid  	Pyridine carboxylic acid	Systemic, post-emergence action, absorbed by leaves and roots Uses: for the long-term control of noxious and invasive broad-leaved weeds in grassland	2005	–
2	Bencarbazone  	Triazalone	Protox inhibitor, absorbed by roots and foliage and translocated Uses: Post-emergent control of broad-leaved weeds in cereals, sugar cane and corn	2005	–
3	Benzofenap  	Benzoylpyrazole	Systemic, absorbed through roots. Bleaching inhibition of 4-hydroxyphenyl-pyruvate-dioxygenase Uses: mainly to control broad-leaved weeds and sedges in rice crops	2002	–
4	Difunon  	Phenylfuranone	Selective contact and residual action. Bleaching: inhibition of carotenoid biosynthesis Uses: Post-emergence herbicide active against grassy weeds	2005	–

5	Flucetosulfuron 	Sulfonylurea	Broad spectrum, absorbed by roots, stem and leaves, acetolactate synthase (ALS) inhibitor Uses: post-emergence herbicide for the control of broad-leaf weeds, some grass weeds and sedges particularly *Echinochloa* sp. in rice and some cereal crops	2003	–
6	Flufenpyr-ethyl 	Pyridazinone	Rotoporphyrinogen oxidase inhibitor Uses: on potatoes, maize, soya and wheat	2003	–
7	Indaziflam 	Fluoroalkyltriazine	Non-selective, broad spectrum activity Uses: broad spectrum of weeds, including species which are difficult to eliminate such as annual bluegrass, goosegrass, ryegrass and goosefoot	2008	–
8	Metamifop 	Aryloxyphenoxy propionate	Acetyl CoA carboxylase (ACCase) inhibitor, causes chlorosis leading to growth retardation Uses: post-emergent herbicide for the control of a wide range of annual grass weeds in cereal crops and rice	2002	–

(continued)

Annex 17.1 (continued)

Sr No	AI common name and structure	Chemical class	Mode of action/Biochemistry	Launch year	Year of patent expiry
9	Methiozolin 	Oxazole	Mode of action not fully understood Uses: A novel herbicide for turf	2008	–
10	Pebulate 	Thiocarbamate	Selective, systemic, absorbed through roots and translocated Uses: for control of grass and broad-leaved weeds	2001	–
11	Penoxsulam 	Triazolopyrimidine sulfonamide	Broad spectrum, absorbed mainly by leaves and, to lesser extent, roots and translocated, exhibits knockdown and residual control Uses: on rice crops for the control of sedges, broad-leaved weeds, aquatic plants and certain grasses	2004	–
12	Pinoxaden 	Phenyl pyrazoline	Systemic. acetyl CoA carboxylase (ACCase) inhibitor, inhibiting fatty acid synthesis	2006	–

13	Propyrisufuron 	Pyrimidinylsulfonylurea	Mode of action not fully understood Uses: new herbicide for use on paddy rice	2008	–
14	Pyrasulfotole 	Pyrazolone	Selective, acts by the inhibition of carotenoid biosynthesis specifically inhibits the enzyme 4-hydroxyphenylpyruvate dioxygenase (HPPD) Uses: for post-emergent control of various broad-leaf weeds in cereals, used with the safener mefenpyr-diethyl	2004	–
15	Pyrimisulfan 	Sulfonanilide	Acetolactate synthase (ALS) inhibition Uses: for the control of perennial weeds predominately in rice crops	2004	–
16	Pyroxasulfone 	Pyrazole	Sulfonylioxazoline acetolactate synthase (ALS) inhibitor, mode of action not fully understood. Good residual action Uses: pre-emergent grass and broad-leaved weed herbicide which is selective in wheat and corn	2005	–

(continued)

Annex 17.1 (continued)

Sr No	AI common name and structure	Chemical class	Mode of action/Biochemistry	Launch year	Year of patent expiry
17	Pyroxsulam 	Triazolopyrimidine sulfonamide	Broad spectrum having both foliar and soil activity, translocates and inhibits acetolactate synthase (ALS) Uses: control of annual grass and broad-leaf weeds in winter wheat	2007	–
18	Saflufenacil 	Uracil/amide	Select, contact and residual action, PPO inhibitor Uses: solo or mixed with glyphosate for rapid control of many dicotyledonous weeds by pre-plant and pre-emergence applications to a wide range of food crops	2009	–
19	Tembotrione 	Triketone	Uses: post-emergence broad spectrum herbicide for the control of grassy and broad-leaf weeds in corn and other crops	2007	–
20	Thiencarbazone-methyl 	Triazolone	Acetolactate synthase (ALS) inhibitor, systemic, absorbed by roots and leaves, contact and residual action Uses: in mixtures with isoxaflutole for pre-emergence control of grassy and broad-leaved weeds in corn, soya and other crops	2008	–
21	Topramezone 	Benzoylpyrazole	Systemic, highly selective, rapidly absorbed and translocated Uses: post-emergence herbicide for broad-leaved weeds and grasses mainly in corn	2006	–

Fungicides becoming generic between 2010 and 2015

1	Azoxystrobin 	Strobilurin	Systemic translaminar and protectant action having additional curative and eradicant properties. Respiration inhibitor. Broad spectrum fungicide mainly for cereals	1992	EU 2010 SPC 2011
2	Benthiavalicarb 	Carbamate	Protective and curative action with residual effects, inhibits phospholipid biosynthesis Uses: against Oomycetes fungal plant pathogens	2003	–
3	Boscalid 	Carboxamide	Protectant, foliar absorption, translocates, inhibits spore germination and germ tube elongation Uses: against a broad range of fungal pathogens for use on a wide range of crops including fruit, vegetables and ornamentals	2002	–
4	Cyazofamid 	Cyanoimidazole	Foliar and soil preventative action with some residual activity. Respiration inhibitor Recommended for controlling Oomycete and Plasmodiophora diseases on potatoes and tomatoes	2001	US 2008 EU 2008 SPC 2013

(continued)

Annex 17.1 (continued)

Sr No	AI common name and structure	Chemical class	Mode of action/Biochemistry	Launch year	Year of patent expiry
5	Cyflufenamid 	Amide	Preventative and curative activity, acts by inhibiting the infection process Uses: for the control of powdery mildew in cereals and other crops	2002	–
6	Cyprodinil 	Anilinopyrimidine	Systemic, absorbed through foliage. Inhibits protein synthesis Uses: to control a range of pathogens including *Tapesia yallundae*, *Botrytis* spp., *Alternaria* spp. and *Rhynchospium secalis*	1998	US 2008 EU 2008 SPC 2013
7	Dimoxystrobin 	Strobilurin	Protectant, curative and translaminar action. Respiration inhibitor Uses: for disease control in cereals, vegetables and turf	2003	–

8	Ethaboxam 	Thiazole carboximide	Systemic with protective and curative action Used to control Oomycetes in vines and late potato blight	1995	–
9	Famoxadone 	Oxazole	Protectant with residual activity, interferes with plant respiratory system Used to control a broad spectrum of plant pathogenic fungi including downy mildew and blights	1998	US 2010 EU 2010 SPC 2015
10	Fenamidone 	Imidazole	Protective and curative action. Respiration inhibitor Used against Oomycete diseases such as downy mildew and certain leaf spot diseases	2001	US 2014 EU 2012
11	Fenhexamid 	Hydroxyanilide	Foliar applied with protective action. Disrupts membrane function. Inhibits spore germination Used to control *Botrytis cinerea* and related pathogens in fruit, vegetables and ornamentals	1999	US 2009 EU 2009 SPC 2013
12	Iprovalicarb 	Carbamate	Systemic with protective, curative and eradicative action. Lipid synthesis inhibitor Used to control Oomycete pathogens	1999	US 2012 EU 2011

(continued)

Annex 17.1 (continued)

Sr No	AI common name and structure	Chemical class	Mode of action/Biochemistry	Launch year	Year of patent expiry
13	Kresoxim-methyl 	Strobilurin	Protective, curative, eradicative action and long residual effects, acts by blocking electron transfer and respiration of the fungi Recommended for the control of scab on apples and pears and other fungal diseases on a wide range of crops	1998	US 2007 EU 2007 SPC 2011
14	Picoxystrobin 	Strobilurin type-methoxyacrylate	Strobilurin type-methoxyacrylate Uses: to control a wide range of diseases including brown rust, tan spot and powdery mildew	2001	US 2008 EU 2008 SPC 2013
15	Quinoxyfen 	Quinoline	Systemic with protective properties, translocates and inhibits appressoria development stopping infections Used to control *Erysiphe graminis*—powdery mildew in cereals	1996	US 2009 EU 2009 SPC 2012

16	Silthiofam 	Thiophene	Protective action with long-lasting activity Used for cereals mainly to control "take-all"	1999	EU 2012
17	Simeconazole 	Conazole	Sterol demethylation inhibitor. Systemic, absorbed by roots and translocates A broad spectrum biofungicide used to control a range of diseases on rice, fruit, soya and vegetables	2001	–
18	Spiroxamine 	Morpholine	Systemic with protective, curative and eradicative action. Disrupts membrane function Used to control powdery mildew, leaf spots, rusts and other diseases	1998	US 2008 EU 2008 SPC 2012
19	Trifloxystrobin 	Strobilurin	Broad spectrum with preventative and curative action. Respiration inhibitor Used for cereals which is particularly active against Ascomycetes, Deuteromycetes and Oomycetes	1999	US 2011 EU 2011 SPC 2013

(continued)

Annex 17.1 (continued)

Sr No	AI common name and structure	Chemical class	Mode of action/Biochemistry	Launch year	Year of patent expiry
20	Triticonazole 	Triazole	Inhibits sterol demthylation Used for the control of common bunt, loose smut and covered smut on barley, oats and wheat	1993	US 2010 EU 2009
21	Zoxamide 	Benzamide	Rainfast preventative action with residual properties, acts by inhibiting nuclear division Used for the control of various fungal inflections including blight in potatoes and tomatoes	2001	US 2012 EU 2013
Fungicides (likely to become generic post 2015)					
1	Ametoctradin 	Triazolopyrimidine	Selective, preventive, mitochondrial respiration inhibitor Uses: for the control of late blight and Downy mildew on potatoes and other crops including vines	2009	–
2	Benalaxyl-M 	Phenylamide	A systemic fungicide with protective, curative and eradication action Uses: to control Oomycetes particularly late blights on potatoes and tomatoes, and Downy mildew on a variety of crops	2003	–

3	Bixafen 	Pyrazole	Mode of action not known Uses: cereals for key disease control including strobilurin-resistant septoria in cereals	2006	–
4	Fenamidone 	Imidazole	Protective and curative action. Respiration inhibitor Uses: against Oomycete diseases such as downy mildew and certain leaf spot diseases	2001	–
5	Fluopicolide 	Benzamide	Protectant Uses: for the control of a range of diseases including downy mildew and blight	2006	–
6	Fluopyram 	Benzamide, pyramide	Mode of action not known Uses: for foliar application and as a seed treatment to control botrytis, powdery mildew and other diseases	2008	–
7	Fluoxastrobin 	Strobilurin	Systemic with protectant and curative properties Uses: for disease control of potatoes and a wide range of vegetables	2002	–

(continued)

Annex 17.1 (continued)

Sr No	AI common name and structure	Chemical class	Mode of action/Biochemistry	Launch year	Year of patent expiry
8	Iminoctadine triacetate 	Guanidine	Protectant. Mode of action not known Uses: on fruit, trees and lawns to control a variety of pathogens including *Alternaria* and Gloeodes	2004	–
9	Isopyrazam 	Benonorbene	Protectant, foliar absorption, translocates, inhibits respiration and spore germination and germ tube elongation Uses: for the control of *Septoria tritici*, rusts and other diseases in cereals and some other crops	2008	–
10	Isotianil 	Thiazole	Mode of action not known Uses: to control rice blast	2007	–

11	Mandipropamid 	Mandelamide	Inhibits spore germination with preventative action Uses: to control Oomycete pathogens such as *Plasmopara viticola* on grapes and *Phytophthora infestans* on potatoes and tomatoes	2005	–
12	Meptyldinocap 	Dinitrophenol	Protectant, curative and eradicant activity by inhibiting spore germination Uses: active against powdery mildew mainly on grapes, cucurbits and strawberries	2007	–
13	Metrafenone 	Benzophenone	Protective and curative action. Interferes with hyphal morphogenesis Uses: to control eyespot and powdery mildew on cereals	2006	–
14	Orysastrobin 	Strobilurin	Systemic, broad spectrum with protective and curative properties. Interferes with the respiration process Uses: rice fungicide highly effective against *Magnaporthe oryzae, Pyricularia oryzae, Thanatephorus cucumeris* and *Rhizoctonia solani*	2006	–

(continued)

Annex 17.1 (continued)

Sr No	AI common name and structure	Chemical class	Mode of action/Biochemistry	Launch year	Year of patent expiry
15	Penthiopyrad 	Carboxamide	Broad spectrum, inhibits mitochondrial functions Uses: to control rust and *Rhizoctonia* diseases and also shows activity against grey mould, powdery mildew and apple scab	2003	–
16	Proquinazid 	Quinazolinone	Preventative and curative activity Uses: to control powdery mildew in a range of crops including cereals and grapes	2005	–
17	Prothioconazole 	Triazolinthione	Systemic with protective, curative and eradicative action. Long-lasting activity Uses: both as a seed treatment and foliar spray to treat a variety of diseases in cereals	2002	–
18	Pyrametostrobin 	Carbanilate	Systemic translaminar and protectant action having additional curative and eradicant properties. Respiration inhibitor Uses: active against powdery mildew and other diseases	–	–

19	Sedaxane 	Pyrazole anilide (isomer mix)	Broad spectrum Uses: for the control of pathogens such as Ascomycetes and Oomycetes species in crops such as fruit and wheat	2008	–

Petroleum and Its Products

18

Paul R. Robinson

Introduction

Petroleum makes the world go around. In the realm of global economics and politics, that statement is hard to dispute. Petroleum is uniquely versatile. When wisely handled, it is safe and clean. It is still abundant, and it can be stored for years at a time simply by leaving it in the ground. Under ambient conditions, it is a liquid and relatively noncompressible, so it can be carried across oceans in large tankers or pumped through pipelines hundreds of miles long. Its distilled products have high energy densities. Fifteen gallons of gasoline can move a 3,300-lb automobile across 350 flat miles at 65 miles per hour. (In metric units, those values are 57 L, 1,480 kg, 565 km, and 105 kph.) We transform petroleum into thousands of useful substances: fuels, lubricants, and chemicals with exceedingly different properties—from baby oil to pesticides, from adhesives to laxatives, from artificial sweeteners to sulfuric acid (Tables 18.1 and 18.2).

Crude oil and its coproduced cousin, natural gas, provide nearly 60 % of our energy (Fig. 18.1). Petroleum makes poor countries rich, and the economic health of rich countries depends on its cost and availability. Petroleum and its derivatives—especially fuels and explosives—have played a major role in all major wars since the start of the twentieth Century. And lest we forget: our unabating dependence on petroleum, natural gas, and other fossil hydrocarbons impacts the quality of our air, our water, and the earth itself.

Economics and politics. One cannot overstate the impact of petroleum on world economics and politics. The supply/demand picture is heavily skewed. As shown in Table 18.3, in 2008 the Middle East consumed far less oil than it produced, accounting for 7.7 % of global consumption but 30 % of global production; the 7.7 % is misleadingly high, because it includes the energy consumed to convert crude oil into exported products. Conversely, the United States and Western Europe consumed far more than they produced. The United States holds only 1.6 % of proven reserves, but it was the third largest producer (10.0 %) and by far the largest consumer (22.8 %). From January 2010 through March 2011, petroleum-related imports were responsible for 34–50 % of the total US trade deficit (Fig. 18.2).

Due to the need to import so much of such a valuable commodity—much of which is obtained from hostile and/or sensitive environs such as the North Sea, the North Slope of Alaska, and offshore California—the world's largest economies are vulnerable. Politics can be hostile, too. The Arab Oil Embargos of 1967 and 1973–1974 and the Iranian Revolution of 1979 caused prices to increase dramatically. The events correspond to price spikes in Fig. 18.3, which shows how petroleum prices have varied since 1861. Figure 18.3 also shows that prices in 2010 were at historical highs, both in present-day and inflation-corrected dollars. Both in the 1970s and recently, the higher prices led to reduced consumption (Fig. 18.4).

Consumption began to fall immediately, but it took a few years to reach "bottom." People started buying smaller cars, but not all at once. And while it's easy for people to drive less and install low-wattage light bulbs, it takes time to replace old equipment with newer, more-efficient equipment in power plants and factories. Unfortunately, the consumption "bottom" was transitory. When prices fell, consumption went back up.

Data selected from [3] show that 2009 was a year of milestones for the following reasons:

1. Global primary energy consumption fell by 1.1 %, the largest decline since 1980
2. OPEC oil production fell by 7.3 %, the largest decline since 1983
3. Natural gas production fell by 2.1 %, the first decline on record
4. Coal's share of world energy consumption rose to 29.4 %, the highest since 1970

Table 18.1 Selected petroleum products

Product	Uses, comments
Fuels	
Propane	Home heating, motor vehicles
n-Butane	Gasoline blend stock, portable lighters
i-Butane	Gasoline blend stock, production of C7 alkylate for gasoline
Naphtah/ gasoline	Spark-ignition engine fuel. Several different grades
Kerosene/jet	Home heating, illumination. Airplane fuel. Several grades
Gas oil/diesel	Diesel fuel. Four major grades including ULSD[a]
Fuel oil	Six major grades
Petroleum coke	Power plant fuel, fuel, and anodes for making steel
Lubricants	
>> 800 products—from "baby oil" to axle grease—all with stringent specifications	
Construction materials	
Asphalt	Paved roads, water-proofed buildings. Four major classes
Waxes	Coated paper packaging, water-proofing, candles
Miscellaneous	
Sulfur	Sulfuric acid and fertilizers
Needle coke	Anodes for making aluminum and high-grade steel
Graphite	Metallurgy, specialty fibers, paints, pencils

[a] ULSD stands for ultra-low-sulfur diesel

5. China and the United States accounted for similar percentages of total world energy consumption. Per Table 18.4: in 2009 China consumed 0.2% less than the United States—2,177 MTOE vs. 2,182 MTOE, respectively, where MTOE stands for million tonnes of oil equivalent. On a per capita basis, US consumption was 4.2 times higher than China's.

The first four milestones can be attributed to the record-high cost of oil and gas. As mentioned, people can and do conserve when energy prices go high enough.

Table 18.2 Selected petrochemicals and uses

Petrochemicals	Used to make
Alcohols	
Methanol	MTBE, acetic acid, formaldehyde . . .
Acetic acid	Vinyl acetate ⇒ plastics, latex paints. Cellulose acetate
Cellulose acetate	Yarns, sheet plastic, films, lacquers
Formaldehyde	Resins, butanediol, inks, nylon
Ethyl alcohol	Gasoline, solvents, personal care products, ethyl chloride, ethyl acetate . . .
Ethyl acetate	Solvent (e.g., nail polish remover)
Isopropyl alcohol	Solvents, personal care products
Higher alcohols	Solvents, plasticizers, detergents
Aromatics	
Benzene	Styrene, cumene, cyclohexane, maleic anhydride . . .
Toluene	Polyurethane, gasoline
Xylenes	Polyester fibers, resins, plasticizers, gasoline
Aromatics derivatives	
Cyclohexane	Nylon precursors
Cumene and phenol	Phenolic resins, epoxy, and polycarbonate resins
Olefins	
Ethylene	Polyethylene, ethylene dichloride, ethylene oxide
Ethylene dichloride	Polyvinyl chloride (PVC) ⇒ plastics
Ethylene oxide	Polystyrene, ethylene glycol
Ethylene glycol	Antifreeze, polyethylene terephthalate (PET) ⇒ plastic bottles
Propylene	Polypropylene, propylene oxide ⇒ propylene glycol
Propylene glycol	Antifreeze, polyesters, pharmaceuticals, hand sanitizers
Butenes	Maleic anhydride . . .
Butadiene	Complex polymers, including synthetic rubbers
Alpha olefins	Polymers, surfactants, synthetic lube oil and additives, fatty acids
Other	
Acrylointrile, acrylic acid	Polymers, including transparent polymers (Plexiglass, Lucite)
Aldehydes and ketones	Acetic acid, acetone, other solvents
Isobutane	Methylmethacrylate resins
Maleic anhydride	Polyesters, resins, plasticizers, dicarboxylic acids, Nylon precursors

Insert: primary energy sources vs. energy vectors. Periodically, news reporters tout zero-emission electric cars or hydrogen-powered vehicles that produce nothing but water. But when one considers the ultimate source of the electricity and hydrogen, such vehicles can be very dirty indeed.

Electricity is not a primary source of energy. It is an energy vector, generated from primary sources and carried through power lines to energy consumers.

Molecular hydrogen also can serve as an energy vector. (In the Sun, of course, where hydrogen undergoes nuclear fusion, it is a primary energy source.) On Earth, commercial hydrogen production plants employ the steam reforming of hydrocarbons or the electrolysis of water. Steam reforming coproduces CO_2, a significant "green-house gas." Electrolysis also produces CO_2 if the required electricity comes from coal, oil, or natural gas. Thanks to environmental laws, burning fossil fuels is cleaner than it used to be, but it still generates CO_2, sulfur compounds, nitrogen compounds, and in the case of coal, significant amounts of ash. If the electricity comes from hydroelectric or nuclear power plants, then electrolytic hydrogen is carbon-neutral. Compared to electricity, hydrogen is easier to store. As hydrogen gas, it is kept in salt domes, high-pressure tanks, and caverns such the ones near Borger and Sweeney, Texas. It is also stored as a hydride in special metal alloys. Hydrogen is transported from production plants or storage facilities through pipelines or in tube trailers.

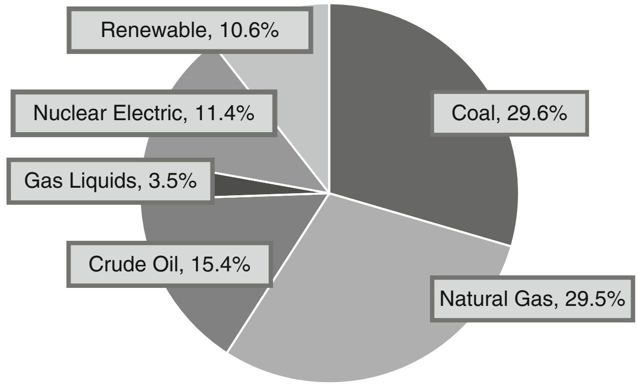

Fig. 18.1 Worldwide primary production of energy, 2007. Based on data from the U.S. Energy Information Administration (EIA) [1, 2]

Insert: conservation and production efficiency. When discussing the future of energy supply and demand, it is important to consider the potential for increased conservation and power production efficiency.

According to a report by the Rocky Mountain Institute [4], energy production efficiency in the United States increased 65–75 % since 1970. The ten top-performing states accounted for a large portion of the increase, creating a huge efficiency gap between the top-performing states and the rest of the nation; the data were normalized for differences in climate and the ratio of residential vs. industrial consumption. If the rest of the country achieved the same electric productivity as the Top Ten, the country would save about 1.2 million gigawatt-hours annually. This is equivalent to 30 % of the nation's total power consumption and 62 % of its coal-based power. The return on investment for efficiency improvement depends on several factors, especially economy of scale and the cost of capital, but the top-performing states achieved significant returns when interest rates were 3–5 times higher than in 2011. Power production from fossil fuels is responsible for 39 % of all CO_2 emissions in the United States, so a 30 % improvement in power production efficiency would lead to a huge reduction in CO_2 production [5].

Based on data [1]

Fossil Hydrocarbons: Categories

Industry professionals divide fossil hydrocarbons into several categories. As with many things in the oil industry, the definitions are functional and the distinctions can be fuzzy, especially between heavy oil and bitumen. Natural gas is often lumped with liquid petroleum in articles such as this, because underground oil is always associated with gas, and because we use similar technology to discover and recover them.

Gases

Natural gas is fully discussed in Chap. 20. Here, it is sufficient to say the following:

- Natural gas contains mostly methane (CH_4)
- So-called *wet gas* contains significant amounts of butanes, pentanes, and heavier hydrocarbons, which can

Fig. 18.2 United States total trade deficit and the trade deficit due to petroleum. Based on data from the U.S. Energy Information Administration [1]

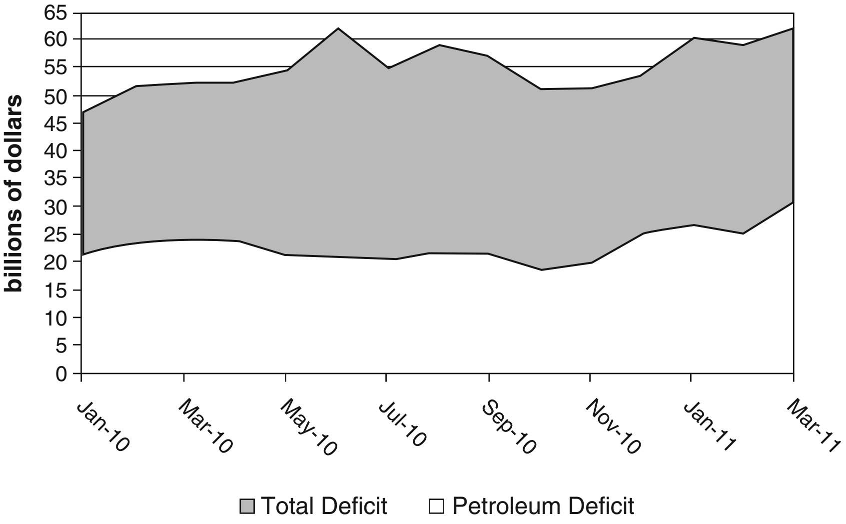

Fig. 18.3 Cost of petroleum since 1861. Based on data from [3]

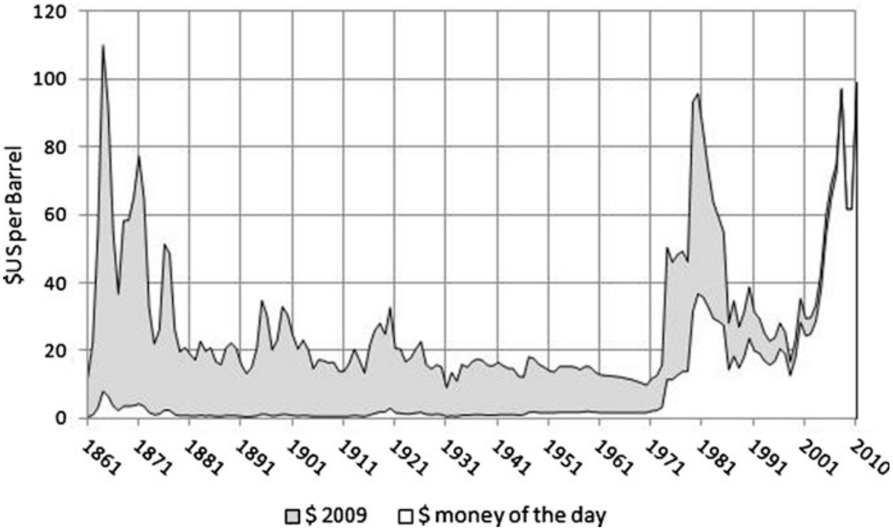

be recovered as liquid condensate in natural gas processing plants

- *Dry gas* includes only traces of higher hydrocarbons
- *Sour gas* contains hydrogen sulfide, and *acid gas* contains carbon dioxide and/or hydrogen sulfide. Sour-gas processing plants coproduce elemental sulfur, which is used to make sulfuric acid and fertilizers

Some natural gas contains commercial quantities of inert gases—helium, neon, and/or argon. Almost all commercial helium comes from natural gas plants [6].

Liquids

Crude oil is the common name for liquid petroleum. People refer to crude oil as a single substance, but there are hundreds of different crudes with significantly different compositions. Crudes typically are named for their source country, reservoir, and/or some distinguishing physical or chemical property. Table 18.5 presents selected physical and chemical properties for ten crude oils.

In sweet crudes such as Tapis, the sulfur content is low. Sour crudes have more sulfur, which gives them a tart taste. (That's right: In the old days, prospectors did indeed characterize crude oil by tasting it.) Synthetic crude oil is produced from coal, kerogen, or natural bitumen. Processing costs are higher for conventional or synthetic crudes with high density and large amounts of sulfur, nitrogen, and trace contaminants. *Heavy oil* has a density greater than 1.0, so it sinks in water. The viscosities of heavy oil range from about 5,000 to 10,000 cP.

For the examples in Table 18.5, the sulfur content ranges from 0.14 wt.% to 5.3 wt.%, and the nitrogen content ranges from nil to 0.81 wt.%. The density (specific gravity) ranges from 0.798 to 1.014.

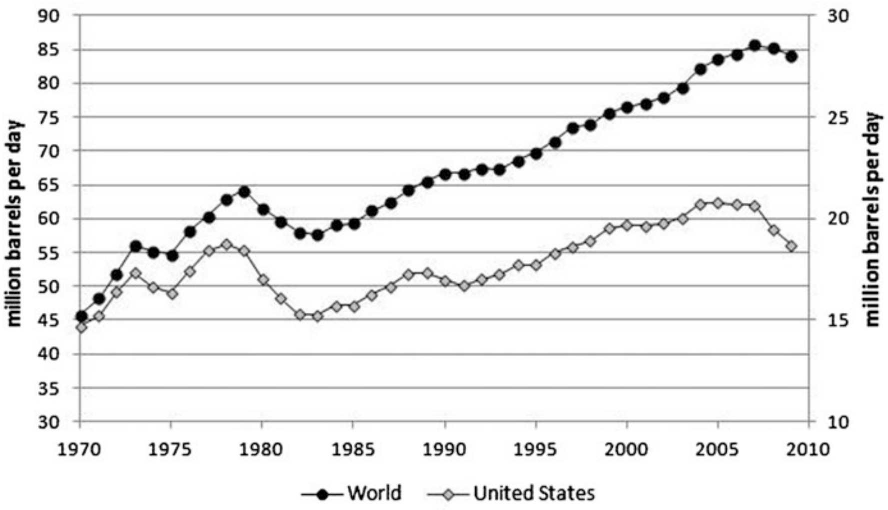

Fig. 18.4 Petroleum consumption since 1970 [3]

Table 18.4 Global changes by region in total energy consumption: 2009 vs. 2008

Region/country	Change 2009 vs. 2008 (%)	2009 Share of world total (%)

Data selected from [3]

A commercial crude oil assay determines the chemical and physical properties of the whole crude and several distilled fractions. The fractions correspond to boiling ranges for common fuels. Using assay reports, refiners and oil traders determine the value of a crude by comparing its properties with refinery specifications, which include distillate properties and limits on trace contaminants. Limits on sulfur content can be set by sulfur-plant constraints or by the metallurgy of process equipment. Other common constraints include TAN (total acid number) and trace-metal content. Traders do purchase off-spec crudes, but usually for subsequent trading.

Table 18.6 shows an abbreviated template for a detailed assay report. Table 18.7 shows distillation yields for four common crudes. The naphtha content of Brent is twice as high as Ratawi, and its vacuum residue content is 60 % lower. Bonny Light yields the most middle distillate and the least amount of vacuum residue.

Table 18.5 Selected properties of ten crude oils [7]

Crude oil	API gravity[a]	Residue[b] (vol%)	Sulphur (wt%)	Nitrogen (wt%)
Alaska North Slope	27.1	53.7	1.2	0.2
Arabian Light	33.8	54.2	1.8	0.07
Arabian Heavy	28.0	46.6	2.8	0.15
Athabasca	8	50.8[c]	4.8	0.4
Brent (North Sea)	39	38.9	0.3	0.10
Boscan (Venezuela)	10.2	82.8	5.5	0.65
Kuwait export	31.4	49.5	2.6	0.21
Shengli (China)	24.7	72.5	1.0	
Tapis blend (Malaysia)	45.9	26.3	0.028	0.018
West Texas	40.2	36.4	0.3	0.08

[a] *API Gravity* is related to specific gravity by the formula: API = 141.5 ÷ (specific gravity @ 60°F)--131.5

[b] Unless otherwise stated, cut point = 343 °C–plus (650 °F–plus)

[c] Cutpoint = 525 °C (913 °F)

Bitumen

Like heavy oils, natural bitumens have densities greater than 1.0, but the viscosities are higher—more than >10,000 cP. Under ambient conditions, natural bitumen is a tar or a solid, but when heated it softens and flows. In practical terms, it is recovered as a solid but transported and processed as a liquid.

(It is important at this point to distinguish between natural bitumen and refined bitumens. The latter are specialty products with rather tight specifications. Refined bitumens are used primarily for paving and construction.)

Natural bitumen was probably the first form of petroleum used by man. In 3000 BCE, Mesopotamians were lining water canals, sealing boats, and building roads with natural

bitumen. Egyptians were greasing chariot wheels with pitch and embalming mummies with asphalt [8, p. 2].

In tar sands, bitumen is associated with sand and clay, from which it can be recovered with hot water or steam. Tar sands (also known as oil sands) contain much of the world's recoverable oil. The largest deposits are in Alberta, Canada, where the proven reserves are 170 billion barrels; in addition, the province holds 1.4 billion barrels of conventional crude [9]. In the United States, tar sands are found primarily in Eastern Utah, mostly on public lands. These deposits contain 12–19 billion barrels of recoverable oil. In 2008, proven oil reserves in Venezuela totaled 87 billion barrels, mostly bitumen. In comparison, for that same year, Saudi Arabian reserves of conventional crude oil were 267 billion barrels [10].

Solids

Compared to liquids and gases, solids are harder to recover, transport, and refine. Liquids and gases can be pumped

Averages are based on data taken from [1]

through pipelines and into refineries with relative ease. Slurries of coal and water can be transported as liquids, but the water must be removed and eventually purified at considerable expense before the coal can be burned or gasified. Solid coal is consumed on a large scale to produce heat, steam, and electricity. These days, coal-powered transportation vehicles are rare. Coal-burning steam ships and railway locomotives are less efficient than their oil-powered counterparts. Typically, the specific energy of petroleum is 90 % greater than a ton of bituminous coal and 40 % greater than a ton of anthracite [11]. Even if for some reason a railroad or shipping company wanted to burn coal, doing so wouldn't be practical due to the present lack of coaling stations.

Kerogen is the solid organic matter in sedimentary rocks. Unlike bitumen, it doesn't flow even when heated. But at high-enough temperatures—e.g., 900 °F (480 °C)—it decomposes into gases, liquids, bitumen, and refractory coke. Huge amounts of kerogen are trapped in oil shale deposits. Fenton et al. [12] estimated that 1.3 trillion barrels of shale oil could be recovered from the world's oil shale reserves. Table 18.8 presents composition information on Green River oil shale from the western United States. About 91 % of the kerogen is hydrogen and carbon, but only 15 % of the sample is kerogen. Shale oil—synthetic crude from oil shale—tends to contain high amounts of arsenic, a severe poison for refinery catalysts. Usually, the arsenic is removed in existing hydrotreating units with special high-nickel chemisorption catalysts, which trap the arsenic by forming nickel arsenides.

Coal and coal technology are fully discussed in Chap. 19. Here we just say that coal is a black or brown combustible rock composed mostly of carbon, hydrocarbons, and ash. Generally, it is classified into four ranks—anthracite, bituminous, sub-bituminous, and lignite. Anthracite contains 86–97 % carbon and has a high heating value. Anthracite is relatively rare. Bituminous coal is far more common. It contains 45–86 % carbon and is burned to generate electricity. It is also used extensively in the steel and iron industries. Sub-bituminous coal contains 35–45 % carbon, and lignite contains 25–35 % carbon. Lignite is crumbly, has a high moisture content and a relatively low heating value.

Over the years, special circumstances have driven the large-scale conversion of coal into liquids, both directly and indirectly. Direct processes convert coal into various combinations of coal tar, oil, water vapor, gases, and char. The coal tar and oil can be refined into high-quality liquid fuels. Slurry-phase hydrocracking technology achieves very high direct conversion of coal into liquids. Several coal conversion processes are described in a recent book by Speight [13].

Developed in 1925, the Fischer-Tropsch (F-T) process is the main indirect route for converting coal into liquids. The coal is first gasified to make synthesis gas—a balanced mixture of CO and hydrogen. Over F-T catalysts, synthesis gas is converted into a full range of hydrocarbon products, including paraffins, alcohols, naphtha, gas oils, and synthetic crude oil. The F-T process was used extensively in Germany between 1934 and 1945. In South Africa, an improved version of the F-T process is used on a large scale to manufacture chemicals and fuels.

Synthesis gas is also derived from natural gas via steam-methane reforming. It can be converted into hydrogen and petrochemicals such as methanol. Worldwide, vast amounts of hydrogen are used to produce ammonia via the Haber-Bosch process.

Chemical Composition

The chemistry of the hydrocarbons in petroleum, bitumen, and kerogen is exceedingly complex. To one extent or another, they all contain water, inorganic salts, and dirt. After these are removed, most of the remaining compounds are hydrocarbons, some of which contain hetero atoms such

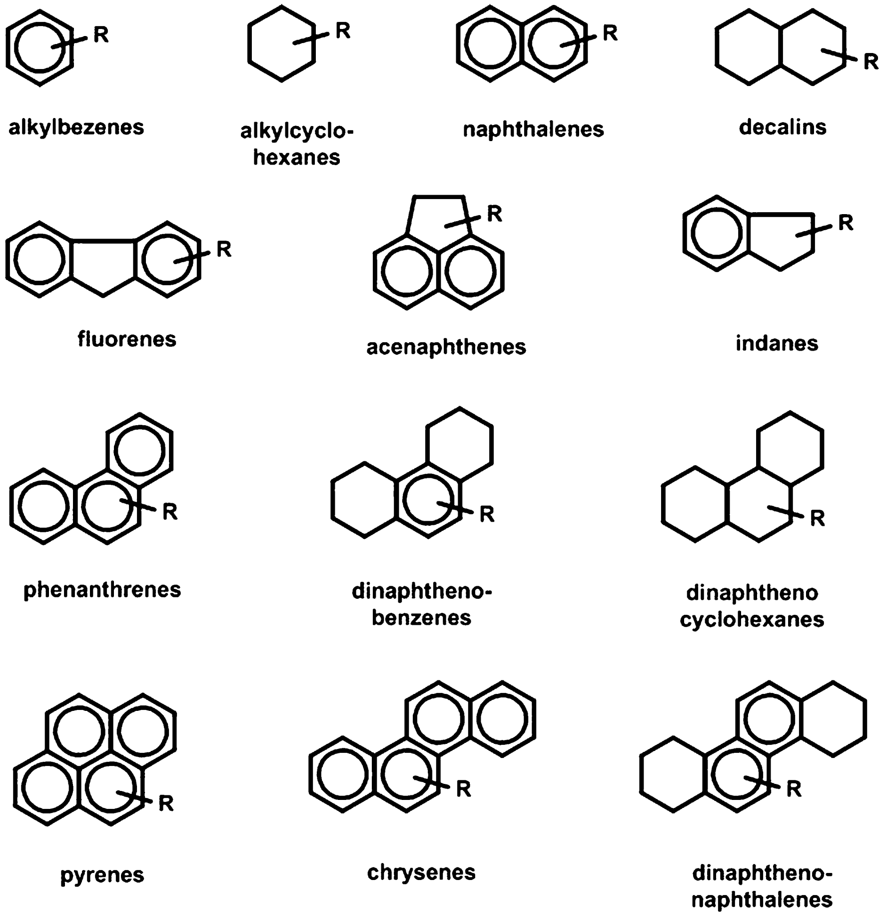

Fig. 18.5 Examples of hydrocarbon ring compounds

as sulfur, oxygen, and nitrogen, and trace metals. The non-hydrocarbon compounds can include different types of elemental sulfur. More than any other element, carbon binds to itself to form straight chains, branched chains, rings, and complex three-dimensional structures. The most complex molecules are biological—proteins, carbohydrates, fats, and nucleic acids. This is significant here because petroleum was formed from the remains of ancient microorganisms—primarily plankton and algae.

Figures 18.5, 18.6, and 18.7 show the complexity of petroleum. In addition to normal and isoparaffins (alkanes), it contains a large number of mono- and poly-ring hydrocarbons, to which paraffin chains can be attached (Fig. 18.5). Many compounds contain hetero atoms, especially sulfur, nitrogen, and/or oxygen (Fig. 18.6). Sulfur compounds also include aliphatic sulfides and disulfides.

Figure 18.7 shows plots of carbon number vs. atmospheric equivalent boiling point (AEBP) for different classes of compounds—aromatics, polynaphthenes, disulfides, benzothiophenes, etc. The indicated boiling points are for pure compounds. In mixtures, the boiling points are shifted by molecular interactions. Molecular interactions are greatest for polar compounds, such as those with hetero atoms. According to the Continuity Principle, physical and chemical properties for a given class of compound vary continuously with the number of carbon atoms in attached alkyl groups. Boiling points are crucial, because fractional distillation is the primary means by which petroleum is separated into useful products. Boiling ranges for typical cuts—naphtha, kerosene (including jet fuel), AGO (atmospheric gas oil, including diesel fuel), vacuum gas oils, and residue—appear at the top Fig. 18.7. In practice, due to imperfect separation in commercial distillation towers, the fractions overlap.

Curve A is for normal paraffins. Branched isomers with the same carbon number boil at lower temperatures. Fully saturated poly ring compounds fall on *Curve B*. Fully unsaturated poly aromatics fall on *Curve C*. Phenanthrene ($C_{14}H_{10}$), a three-ring poly aromatic compound, is found in the AGO boiling range. Adding seven hydrogen molecules (14 hydrogen atoms) converts phenanthrene into perhydrophenanthrene ($C_{14}H_{24}$), which ends up in the kerosene cut. *Curve D* shows how adding alkyl groups to pyrene makes makes *Curve D* parallel to *Curve A*. *Curves E, F*, and *G* represent compounds containing hetero atoms—sulfur, nitrogen, and oxygen.

Figure 18.8 also illustrates the Continuity Principle, in this case with a plot of density versus molecular weight for

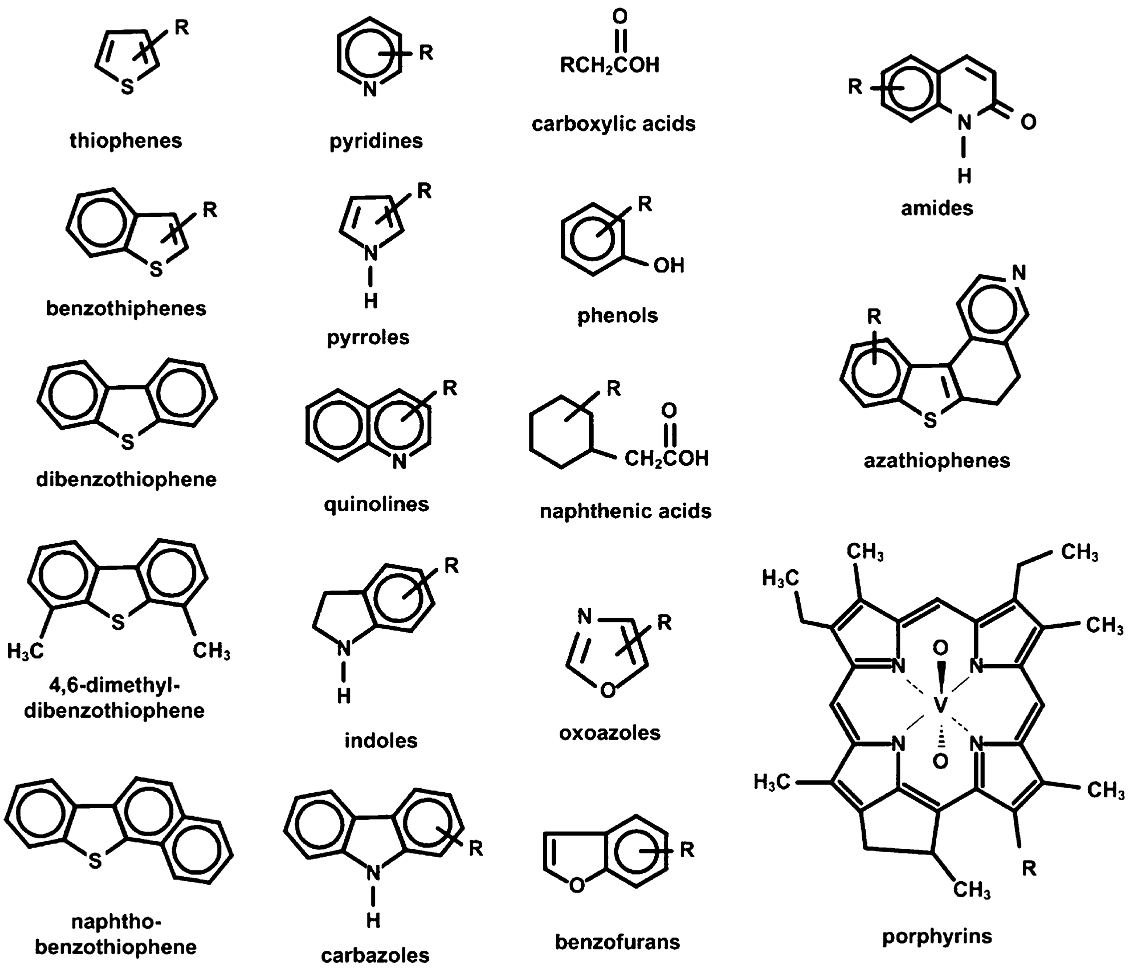

Fig. 18.6 Examples of hetero-atom compounds

five families of hydrocarbons. The "Z" number indicates hydrogen deficiency vs. paraffins. It comes from the subscript for hydrogen in the chemical formula C_nH_{2n+z}. For paraffins such as methane (CH_4) and octane (C_8H_{18}), $z = +2$, and the general formula is C_nH_{2n+2}. For benzene (C_6H_6) and alkylbenzenes, $z = -6$, and the general formula is C_nH_{n-6}.

Origin

Petroleum is complex due to its origin. According to Walters [17], eighteenth Century scientists concluded that coals were derived from plant remains. Mikhailo Lomonosov gets credit for suggesting that petroleum and bitumen were produced underground from coal at high pressure and temperature. In the mid-nineteenth Century, T.S. Hunt concluded that the organic matter in certain rocks comes from marine plants or animals.

Modern scientists believe petroleum came primarily from plankton and algae in the following way: the remains of dead organisms accumulated at the bottoms of ancient lakes or seas, along with sand, clay, salts, and other material. Over time, pressure, and heat transformed the deposits into sedimentary rock. Depending on the origin of the organic matter and the environment in which it aged, it became coal, kerogen, bitumen, petroleum, or natural gas.

Biomarkers. In 1936, Alfred Treibs linked the chlorophyll in plants to the porphyrins in petroleum (Fig. 18.9). Even after millions of years, porphyrins and other biomarkers retain much of their original structure. Biomarkers can be found in crude oil, rocks, sediments, and soil extracts.

Exploration

A book by Conaway [18] presents a good overview of how we look for and produce petroleum. Commercially significant petroleum systems include the following:

- Organic-rich source rock in which oil and gas were formed

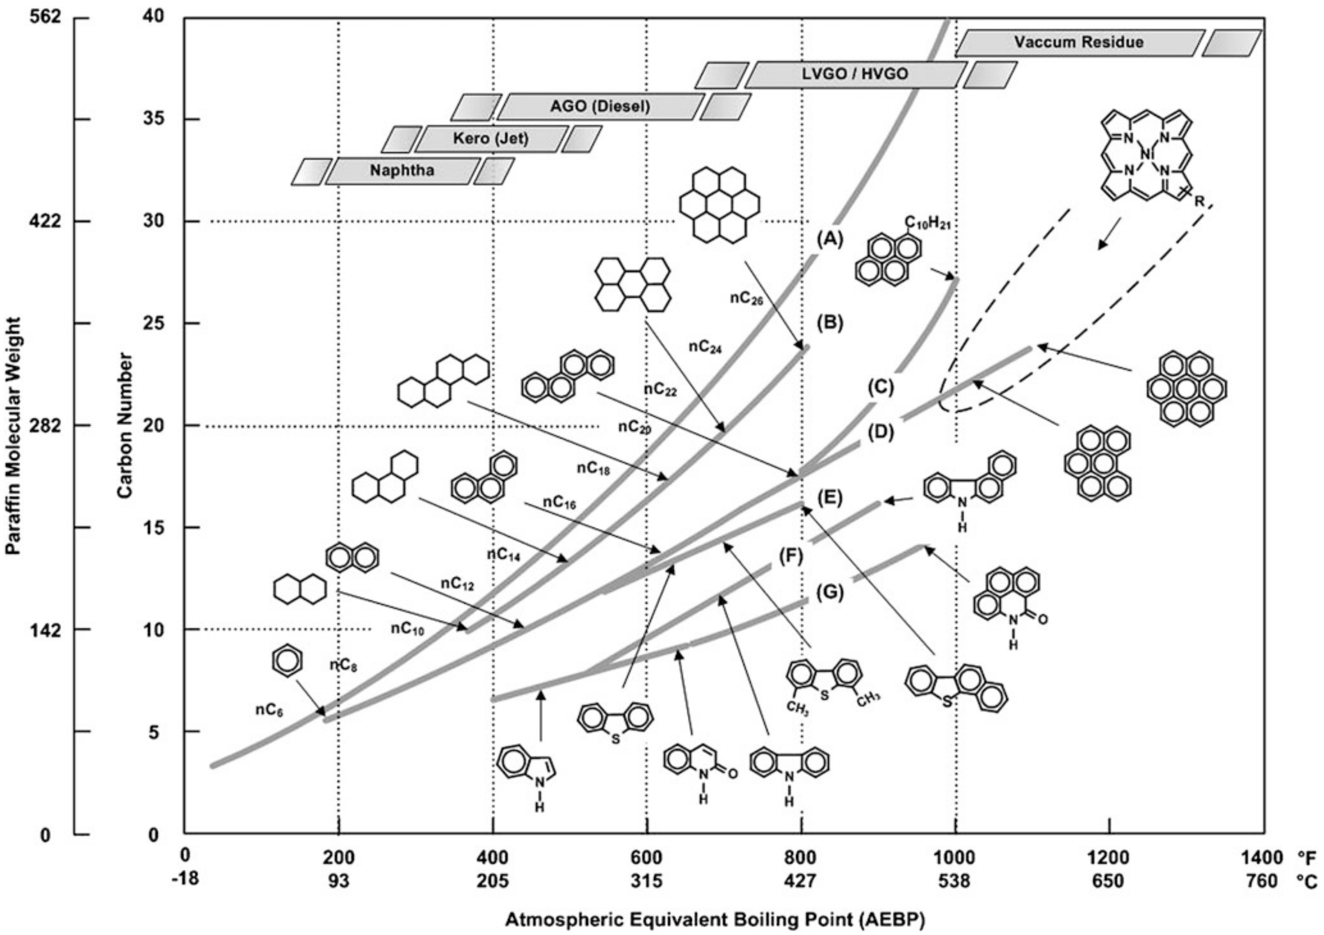

Fig. 18.7 Carbon number and atmospheric equivalent boiling points for different compounds [14, 15]. Shown at the *top* of the figure are the straight-run products that correspond to AEBPs of the compounds. Note how the saturation of polyaromatics such as chrysense (4 rings), phenanthrene (3 rings), and naphthalene (2 rings) can move them into different distillation fractions

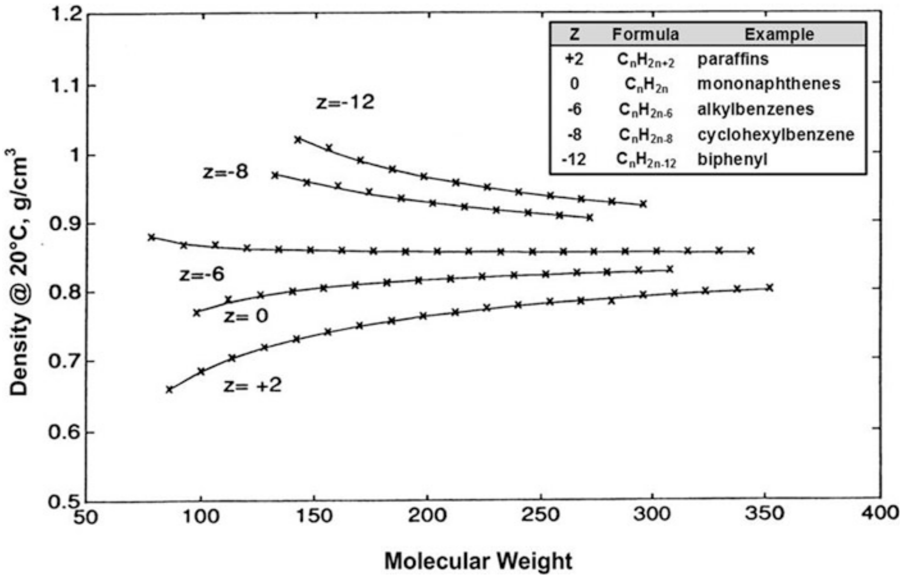

Fig. 18.8 Density vs. molecular weight for hydrocarbon families [16]

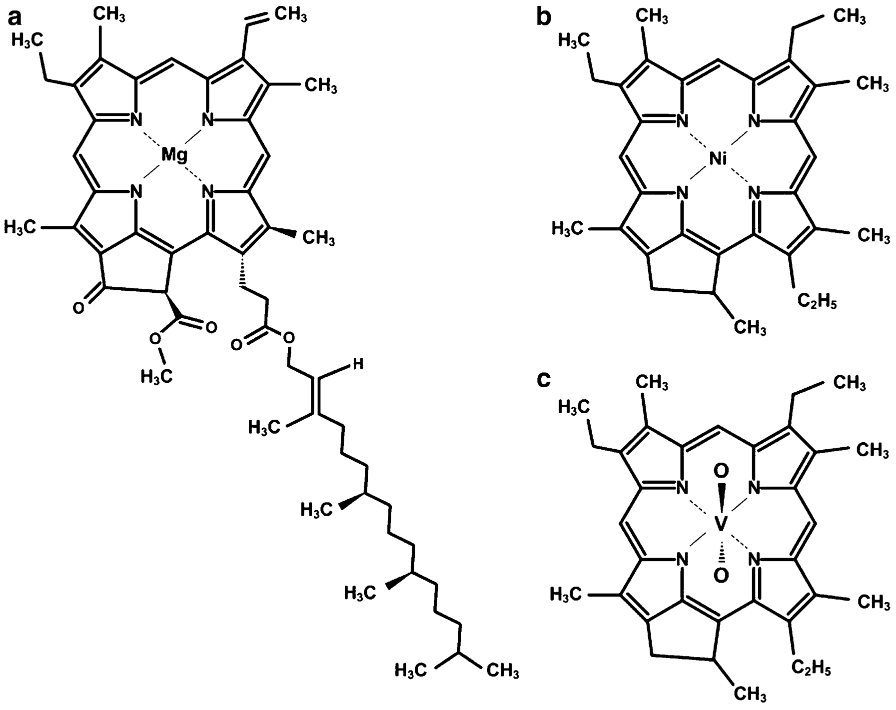

Fig. 18.9 Biomarkers: a comparison of Chlorophyll A with porphyrins found in petroleum

- Pathways comprised of permeable rock such as sandstone and limestone, which allow oil and gas to migrate. Often, the movement of oil and gas is promoted by the flow of underground water
- Porous, permeable reservoir rock capped by impermeable rock, which prevents fluids from migrating to the surface. Shale and salt domes are common caps

Searching for traps. When petroleum geologists look for oil and gas, they search for geological structures that might serves as traps. In so doing, they rely heavily on reflection seismology. During seismic exploration, explosives, or thumper devices send sound waves through the earth. Reflected sound waves are measured with hydrophones (in water) and geophones (on land). Different layers reflect sound in different ways. With the help of sophisticated software, geophysicists transform seismic data into 3-dimensional maps that show the structure of subsurface rock formations.

For petroleum, there are four major kinds of reservoir traps, three of which are illustrated in Fig. 18.10.

- Anticline traps are, in essence, inverted bowls. They can be symmetrical or asymmetrical. A steep anticline might be called a dome. Anticline traps hold most of the world's conventional crude oil
- Faults are formed at the boundaries of cracks in the earth's crust. The four major kinds of faults are thrust, lateral, normal, and reverse. Thrust and lateral faults are created by horizontal movement The San Andreas Fault in California is a well-known example of a lateral fault. To be more specific, the San Andreas is a right-lateral, strike-slip fault. Normal and reverse faults are created by vertical movement and are more likely to create fault traps for petroleum
- A salt-dome trap is created when a mass of underground salt is pushed up by underground pressure into a dome. The salt dome breaks through layers of rock and pushes them aside as it rises. The salt is impermeable, and if it abuts porous rock, it can serve as a reservoir cap
- In stratigraphic traps, the reservoir is capped by another reservoir or by layers of rock with lower porosity or permeability

Role of biomarkers in exploration. Biomarkers can indicate the relative amounts of oil and gas in a source rock, the age of a source rock, the environment in which organic matter was deposited, the maturity of a source rock, etc. Often, biomarker data are included in reservoir models of prospective oil fields.

Drilling and Production

Drilling. Key components of a drilling rig are shown in Fig. 18.11. To drill a well, a bit is attached to the end of a drill string, which is comprised of sections of steel pipe that are 30-ft (9 m) long. The drill string is lengthened as the well gets deeper by attaching additional sections of pipe to the top. Drill collars are thick-walled sections of drill pipe at the

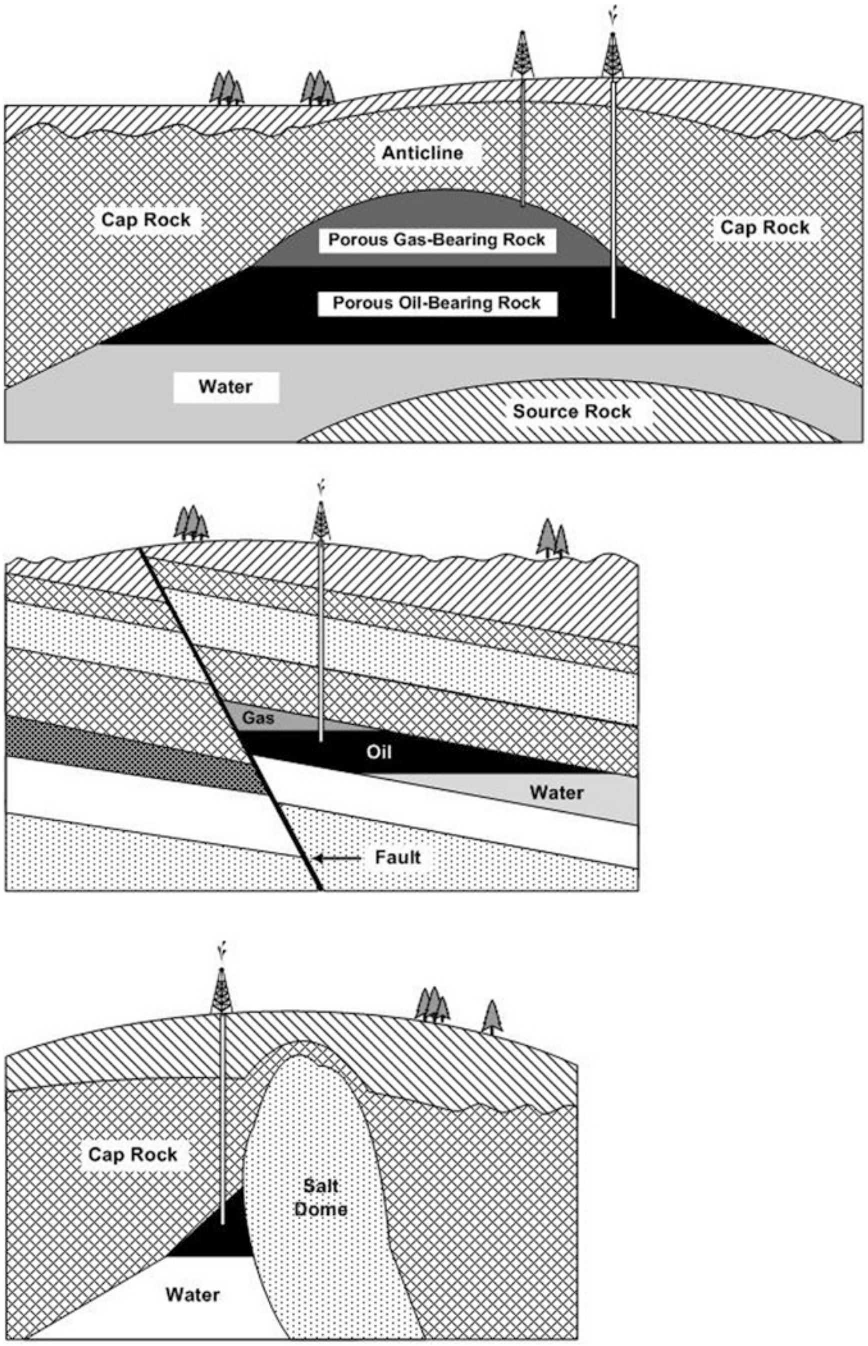

Fig. 18.10 Three types of hydrocarbon traps—anticline, fault, and salt dome. As with oil and gas, the water layers are not pools, but water-saturated porous rock

bottom of the drill string; collars apply extra weight to the bit. As the bit cuts through rock, mud is pumped down through the inside of the drill string, out the bit, and up through the space between the drill string and the well bore. Despite its dirty name, drilling mud is a designed blend of fluids, solids, and chemicals. It cools the drill bit and brings rock cuttings back to the surface. The cuttings are removed in shakers, and the fluid goes back to the mud pit, from which it is recycled.

The derrick must be tall enough to accommodate a 90-ft-long "triple" comprised of three sections of pipe. The derrick, pulleys, and hawser must be robust enough to support the lifting and manipulation of the entire drill string. The kelly is the top joint of a drill string. It has flat sides that fit inside a bushing on the rotary table, which turns the drill string and bit. Note that not all drilling rigs use a kelly system.

A surface blowout is a sudden increase in well pressure resulting in loss of containment and uncontrolled flow of oil and gas into the atmosphere. The blowout preventer (BOP) is a safety valve or other device beneath the floor of the drilling rig. When activated, it stops a blowout by sealing off the top of the well.

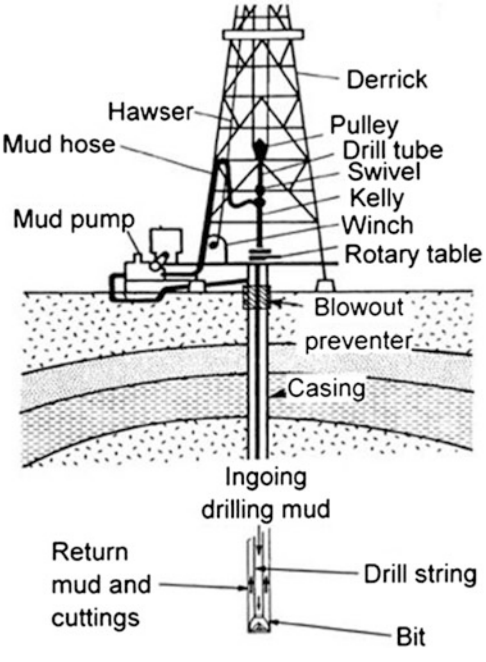

Fig. 18.11 Components of a typical drilling operation [19]

The density of drilling mud is crucial. If the mud density is too low, a well is susceptible to a surface blowout. If the mud density is too high, it can cause an underground blowout—the rupture of the reservoir underground—pushing drilling mud into another formation. Underground blowouts are the most common of all well control problems. Many surface blowouts begin as underground blowouts. Prompt, correct reaction to an underground event can prevent a dangerous and costly surface blowout [20].

Completion. Wells are completed by casing the well bore with steel pipe and cementing the casing into place. Casing prevents the well from collapsing. The outside diameters of casing pipe range from 4.5 to 16 in. (114–406 mm). Cementing is a key step. In a good cement job, the entire space between the casing and the well bore is filled with cement. Centralizers keep the casing from resting against the well bore, which could block the flow of cement, resulting in a poor cement job and increasing the risk of a blowout.

After cementing, perforation guns punch small holes through the casing into the reservoir rock, providing a path for the flow of oil and gas into the well. In open-hole completion, the last section of the well is uncased. Instead, the installation of a gravel pack stabilizes the casing and allows fluids to enter the well at the bottom. After perforation, special acid-containing fluids are pumped into the well to increase porosity and stimulate production. Usually, a smaller diameter tube is inserted into the casing above the production zone and packed into place. This provides an additional barrier to hydrocarbon leaks, raises the velocity at which oil flows under a given pressure, and shields the outer casing from corrosive well fluids.

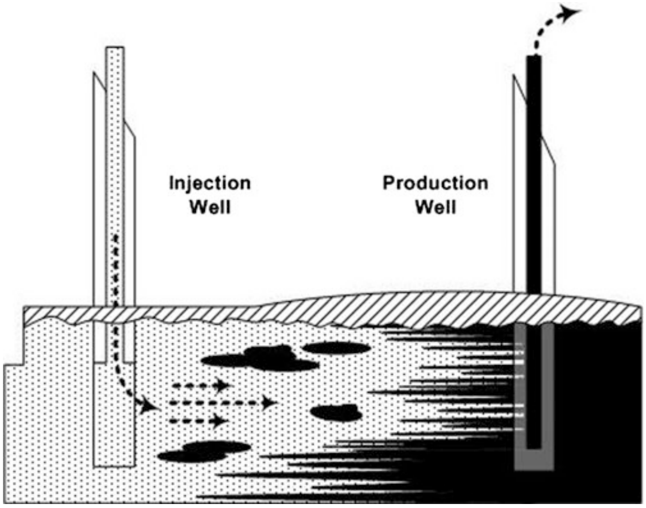

Fig. 18.12 Injection and production wells

Production. Liquid petroleum may flow on its own due to underground pressure, or it may be forced to the surface by the injection of treated water, natural gas, or CO_2. Figure 18.12 illustrates using an injection well to stimulate production.

Heavy oil and bitumen are recovered in several ways. They can be dug out with conventional mining techniques, or they can be liquefied by the injection of high-pressure steam. In so-called “huff and puff” operations, production is stopped, either naturally or on purpose. Hot steam is injected into the reservoir and left to soak, usually for a few days. During the soak, heat flows from the steam into the oil and surrounding rock, and the reservoir pressure increases. After the soak, the well is reopened and oil production resumes, at first by natural flow and then by artificial lift. Production decreases over time as the temperature and pressure of the reservoir go down. When the flow of oil drops below a certain limit, the process is repeated.

At surface facilities, notably in Venezuela and Canada, recovered bitumen is diluted with lighter hydrocarbons. The resulting “Dilbit” (diluted bitumen) flows under ambient conditions, so it can be transported conventionally in pipelines and oil tankers.

Kerogen is recovered from oil shale by several methods. From 1985 to 1990, Unocal recovered some 4.6 million barrels of synthetic crude oil from oil shale in a complex mining and upgrading venture at Parachute Creek, Colorado [21]. The plant yielded roughly 40 gal of oil per ton of rock. In the vertical-shaft retort, crushed kerogen-containing shale was pumped up from the bottom of the retort vessel. Hot

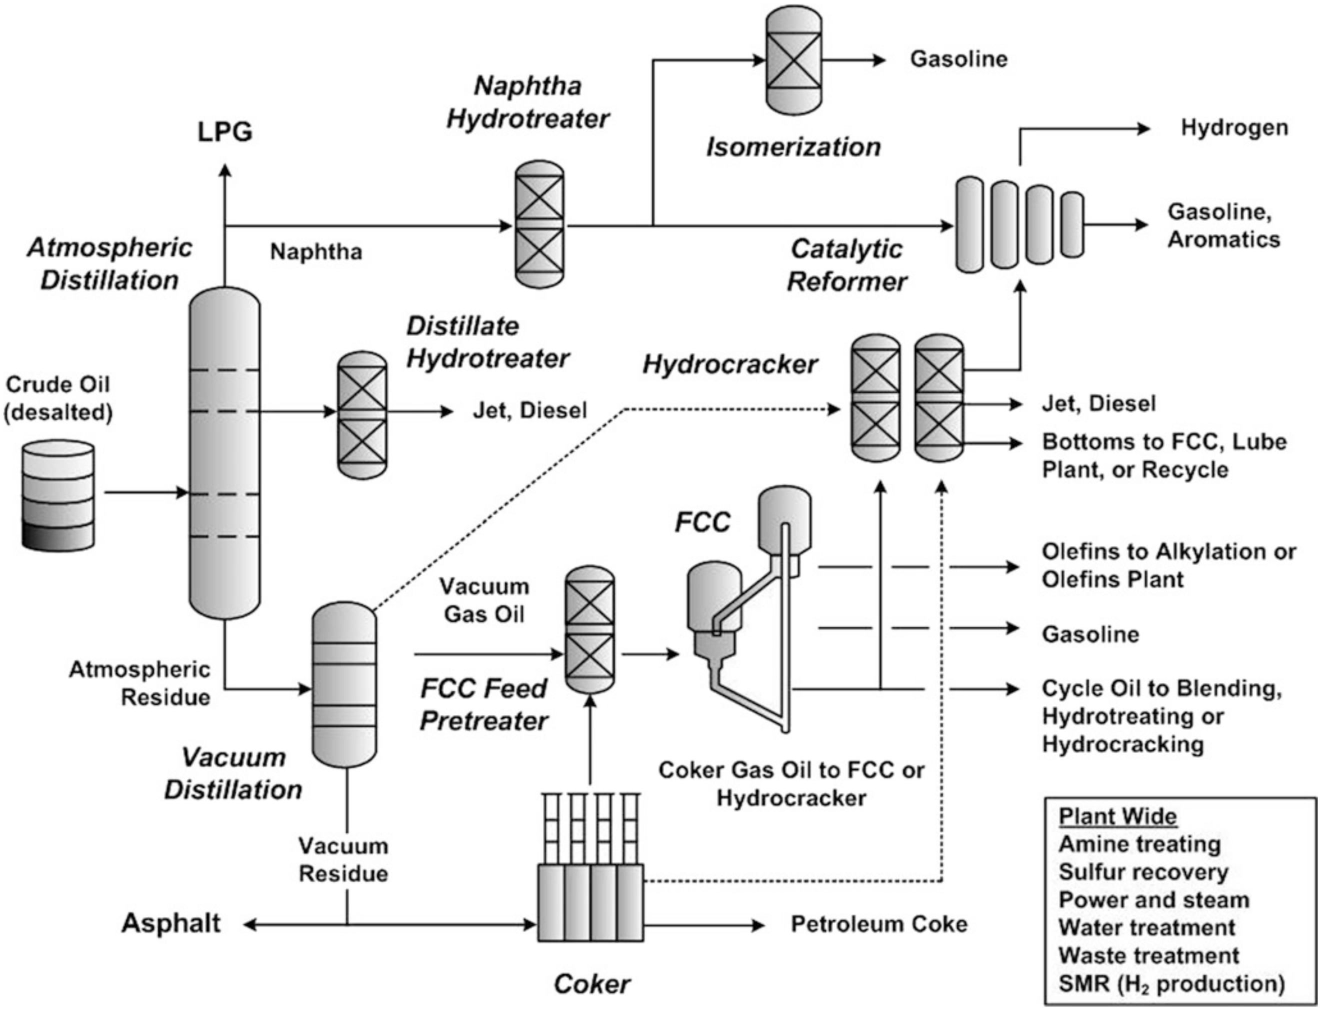

Fig. 18.13 Schematic diagram of a high-conversion petroleum refinery [15, Fig. 10.1]

recycle gas flowed counter-currently downward, decomposing the rock and releasing hydrocarbons. Condensed shale oil was removed from the retort at the bottom. Part of the hot gas was recycled. The rest either was used to produce heat and hydrogen, or recovered as product. The spent shale was removed from the top of the retort, cooled, and stored in pits or returned to the mine. In the reducing environment of the retort, sulfur and nitrogen were converted to H_2S and NH_3, which were recovered from product gases by conventional means. The plant yielded high-quality synthetic crude oil suitable for further refining in conventional facilities.

Other oil shale processes involve partial combustion, either underground, at the surface, or in shafts drilled horizontally into kerogen-rich formations. From 1972 to 1991, Occidental Petroleum developed an in situ process, in which explosives were used to create underground chambers of fractured oil shale. The oil shale was ignited with external fuel, and air and steam were injected to control combustion. The hot rock fractured and released shale oil, which was pumped to the surface from a separation sump and collecting well.

Bitumens derived from oil shale and many tar sands contain small-but-significant amounts of arsenic, which are severe poisons for catalysts in refineries.

Refining

Refining petroleum is like cooking crab: you boil it, crack it, and pull out the bits. In a refinery, a given molecule might be boiled and recondensed hundreds of times. Cracking big molecules into small ones is the key to economic success. Pulling out the bits—the removal and disposition of contaminants—improves the cracking processes and protects the environment.

Figure 18.13 shows a simplified schematic diagram for a “typical” North American refinery. The word “typical” is inside quotation marks, because no two refineries are identical. European and Asian facilities include different process units because they make less gasoline and more middle distillates. They are less likely to employ delayed coking and more likely to use visbreaking for upgrading residue. Plants that produce substantial amounts of lubricants and/or petrochemical monomers include additional sections.

A petroleum refinery transforms the complex tangle of molecules in crude oil into a wide array of products, all of which must meet tight specifications. Listed below are some basic refinery operations.

- Separation
  - Distillation
  - Solvent processes
- Hydrotreating
- Conversion
  - Thermal cracking
  - Thermal hydrocracking
  - Catalytic cracking
  - Catalytic hydrocracking
- Catalytic reforming and isomerization
- Recombination of light intermediates
  - Alkylation
  - Polymerization
- Product treating and blending
- Protecting the environment
  - Gas treating
  - Sulfur recovery
  - SO_x and NO_x abatement
  - Waste treatment
- Related operations
  - Asphalt production
  - Lubricant manufacturing
  - Hydrogen production
  - Hydrogen recovery and purification
  - Production of petrochemical monomers

The Need for Conversion

The demand for petroleum remained relatively flat throughout the last half of the nineteenth Century. In the 1860s the most valuable fraction distilled from crude oil was kerosene. In 1878, thanks to the inventions of Thomas Edison, electric lighting slowly but surely began to displace kerosene as a preferred illuminant. But the advent of the gasoline-powered automobile dramatically increased the demand for petroleum. In addition to increasing overall crude oil demand, the automobile increased demand for naphtha, from which gasoline is derived.

During 1991–2011, the United States consumed, on average, 70 % of its petroleum as gasoline and middle distillates. But as shown in Table 18.7, yields of naphtha plus middle distillates for four selected (relatively common) crudes range from 33.8 to 61.8 %. This leaves sizeable supply/demand gaps, which create a sizeable light-product/heavy-product price differential. A common measure of this differential is the "heating oil crack spread." Since 2010, crack spreads ranged between \$6 and \$25 per barrel. In January 2011, they exceeded \$24 per barrel [22]. At that differential, for a refinery that processes 200,000 barrels of oil per day, 30 % conversion is worth about \$1.4 million per day—about \$500 million per year.

In response to such huge incentives, refiners, and licensors have developed an array of processes for converting heavy products into light ones. Many of these are described below. But before discussing the hardware, let's look at the chemistry around which the hardware is built.

Petroleum Refining Chemistry

"Cracking" and "pulling out the bits" involve the chemical reactions listed below.

- Hydrotreating and saturation
  - Saturation of aromatics (ASAT) and olefins (OSAT)
  - Hydrodesulfurization (HDS)
  - Hydrodenitrogation (HDN)
  - Hydrodeoxygenation (HDO)
  - Hydrometalation (HDM)
- Cracking (making little ones out of big ones)
  - Thermal cracking
  - Catalytic cracking
  - Hydrocracking (catalytic and thermal)
- Dehydrogenation, isomerization (no change in carbon number)
- Alkylation, polymerization (making big ones out of little ones)
- Acid/base processes: amine treating, caustic scrubbing
- Mercaptan oxidation (Merox)

Hydrotreating reactions: saturation of olefins. On a macro scale, the saturation of olefins is rapid and essentially irreversible. It releases considerable heat.

Hydrotreating reactions: saturation and condensation of aromatics and polyaromatics. Figure 18.14 provides examples of the reversible saturation of aromatics and polyaromatics. Figure 18.15 [8] summarizes thermodynamic calculations for the competition between the saturation of naphthalene and the condensation of naphthalene with *o*-xylene to form chrysene. At high pressures and low temperatures, equilibrium favors saturation. At low pressures and high temperatures, equilibrium favors dehydrogenation. At high-enough temperatures, equilibrium favors condensation (Fig. 18.16).

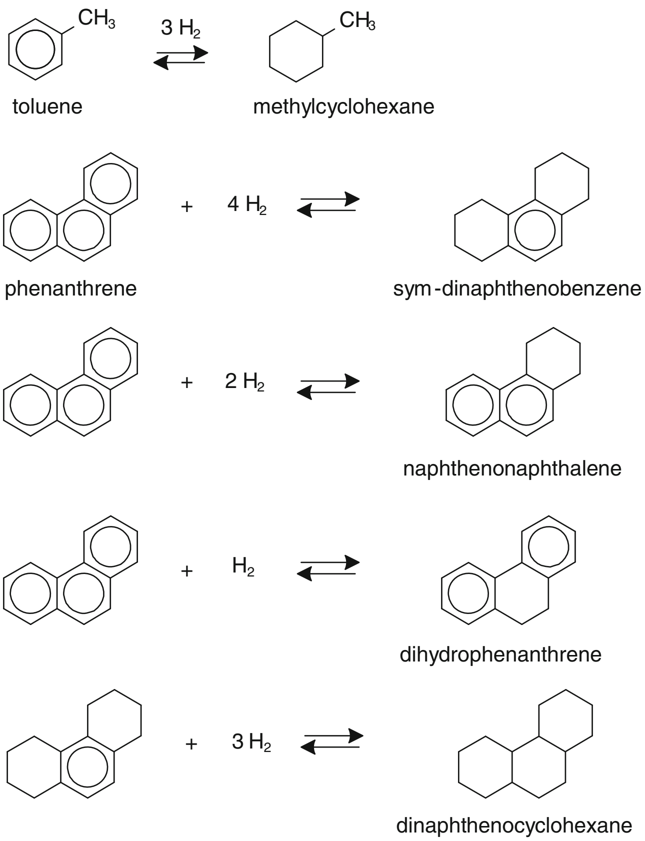

Fig. 18.14 Saturation of aromatics and polyaromatics

Figure 18.6 shows the so-called zig-zag mechanism for the production of large polyaromatics by adding 2-carbon and 4-carbon species to smaller polyaromatics. The condensation of large polyaromatics via the Scholl reaction can lead eventually to coke formation [25].

Figure 18.17 shows a mechanism for the one-at-time build up of rings on a nucleus of coke. The mechanism includes the following steps, all of which are to some extent reversible:

- Hydrogen abstraction by gas-phase radicals
- Addition of radicals to the coke surface
- Reaction of a gas-phase olefin with a radical on the surface
- Reaction of a gas-phase radical with an olefin group on the surface
- Cyclization
- Dehydrogenation

Hydrotreating and hydrocracking units operate in the crossover region between 315 and 425 °C (600 and 800 °F). Per Fig. 18.15, at temperatures below the crossover region, saturation is favored. Temperatures above crossover favor aromatics.

Hydrotreating reactions: HDS. Figure 18.18 shows representative hydrodesulfurization (HDS) reactions. Note that for sulfur removal from the first three reactants, the mechanism is direct. That is, the sulfur-containing molecule interacts with an active site on the catalyst, which removes the sulfur atom and replaces it with two hydrogen atoms. Additional hydrogen converts the sulfur atom into H_2S, which desorbs from the catalyst, leaving behind a regenerated active site.

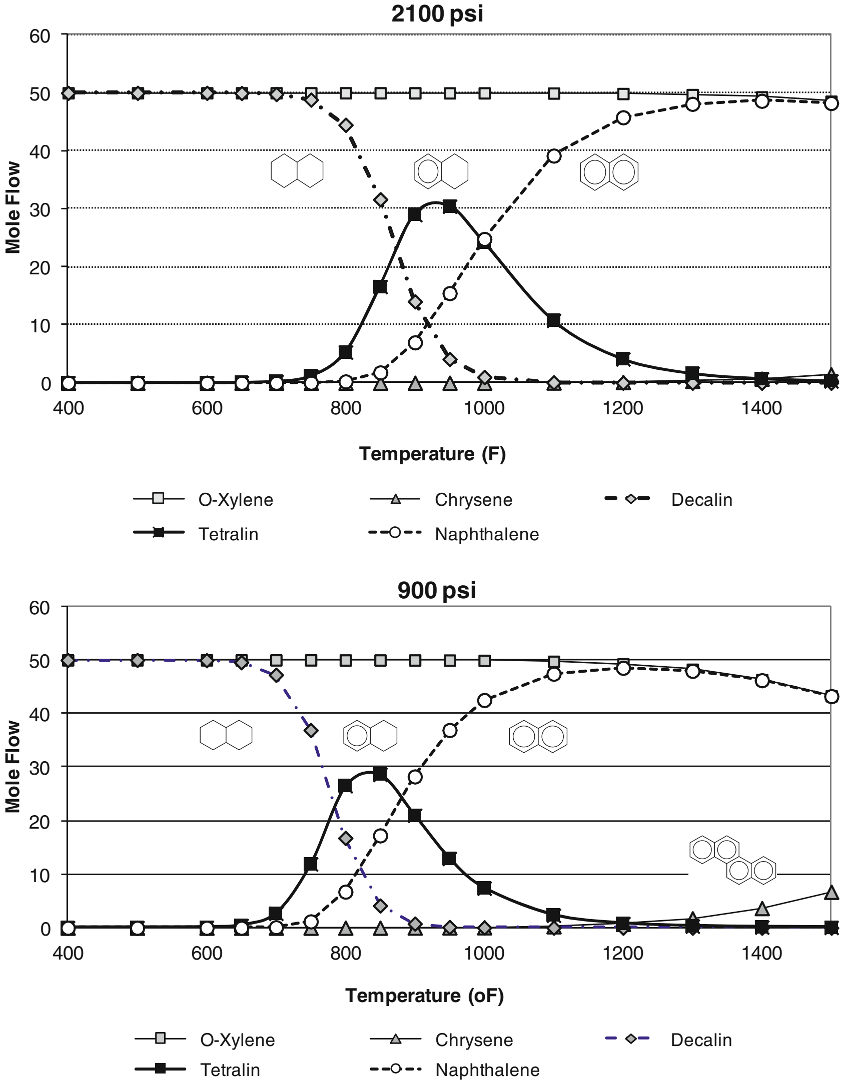
For the fourth reactant—4,6-dimethyldibenzothiophene (4,6-DMDBT)—the reaction proceeds via both a direct and an indirect route. The 4,6-DMDBT molecule is planar, and the two methyl groups are adjacent to the sulfur atom. This protects the sulfur atom from active sites on the catalyst, thereby inhibiting direct HDS. In the indirect route, saturating one of the aromatic rings that flank the sulfur atom converts the planar structure into a puckered arrangement with tetrahedral C–C bonds. This puckering rotates one of the inhibiting methyl groups away from the sulfur atom, giving it better access to the catalyst.

Making ultra-low-sulfur diesel (ULSD), in which the sulfur content is less than 10–15 wppm, requires severe hydrotreating, after which the only remaining sulfur compounds are the above-mentioned 4,6-DMDBT and other di- and trimethyl dibenzothiophenes. Because the removal of sulfur from these compounds is more facile after prior saturation, the crossover phenomenon affects the production of ULSD significantly, so much so that it governs the design of commercial units.

Hydrotreating reactions: HDN. Figures 18.19 and 18.20 show representative HDN reactions. Figure 18.19 illustrates the mechanism for the HDN of quinoline. As with sulphur removal from hindered DMDBTs, the crossover phenomenon is important for deep HDN, because nitrogen removal requires prior saturation of an aromatic ring adjacent to the nitrogen atom.

Hydrotreating reactions: HDO. In feeds to industrial hydroprocessing units, oxygen is contained in organic acids, ethers, peroxides, and other compounds. Some form by reacting with air during transportation and storage of crude oil, distillates, and cracked stocks generated by delayed coking and Fluid catalytic cracking (FCC) units (see below). Hydrodeoxygenation (HDO) proceeds rapidly, so rapidly that it can cause problems with excessive heat release. Also, oxygen compounds can form gums and polymers, which inhibit flow and increase pressure drop.

Hydrotreating reactions: HDM. Metals such as nickel and vanadium are present in high-boiling fractions, mostly in asphaltenes. Asphaltenes are mixtures of waxy solids with porphyrins (Fig. 18.9). Corrosion generates soluble iron, and entrained salt brings in alkali and alkaline earth metals,



°C	°F

Fig. 18.15 Thermodynamic calculations illustrating the competition between the saturation and the condensation of polyaromatics [23]. Data for the graphs were generated by Aspen Plus for a six component system comprising naphthalene ($C_{10}H_8$), tetralin ($C_{10}H_{12}$), decalin ($C_{10}H_{18}$), *o*-xylene (C_8H_{10}), chrysene ($C_{18}H_{12}$), and hydrogen (not shown)

primarily sodium and calcium. Synthetic crudes from oil sands and oil shale tend to contain small-but-significant amounts of arsenic. Silicones are added to crude oil to facilitate flow though pipelines. Silicones are also used to control foaming in delayed coking units.

All of these metals poison refinery catalysts. Refiners remove them by hydrotreating over special wide-pore guard catalysts. Guard materials remove some contaminants by chemisorption. Other contaminants, such and Ni, V, and soluble Fe, are removed by HDM reactions. HDM converts the metals into sulfides, which adhere to the guard material.

Conversion. Table 18.10 illustrates a fundamental aspect of conversion. For a given class of hydrocarbons, "lighter" means a lower molecular weight, lower boiling point, lower density, and a higher hydrogen-to-carbon ratio (H/C). Methane, the lightest hydrocarbon, has an H/C ratio of 4.0. Benzopyrene has an H/C ratio of 0.6. The H/C ratio of common crude oils ranges from 1.5 to 2.0, while the H/C ratio for asphaltenes is about 1.15.

Some conversion processes—FCC, thermal cracking, and deasphalting—increase the H/C ratio by rejecting carbon. Hydrotreating and hydrocracking increase the H/C ratio by adding hydrogen. In this context, "rejecting carbon" does not mean that a few carbon atoms are removed from every large molecule. Rather, it means that heavy molecules are split ("cracked") into lighter molecules with higher H/C ratios and heavier molecules with lower H/C ratios.

Conversion: definition. Refiners define conversion as a change in boiling point. The goal of a conversion process is to crack material that boils above a particular cutpoint into

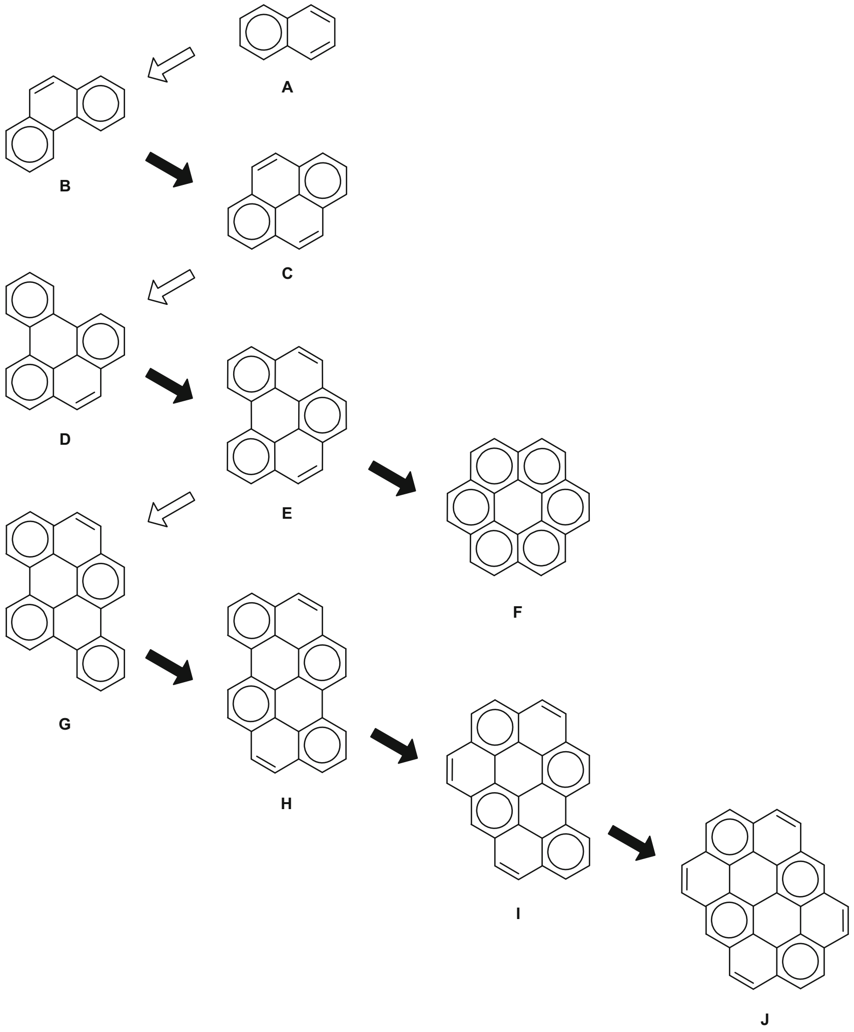

Fig. 18.16 Zig-zag mechanism for the condensation of polyaromatics by sequential addition of 2-carbon and 4-carbon units [24]. The isomers shown are (**a**) naphthalene, $C_{10}H_8$; (**b**) phenanthrene, $C_{14}H_{10}$; (**c**) pyrene, $C_{16}H_{10}$; (**d**) benzo[*e*]pyrene, $C_{20}H_{12}$; (**e**) benzo[*ghi*] perylene, $C_{22}H_{12}$; (**f**) coronene, $C_{24}H_{12}$; (**g**) dibenzo*[b,pqr]*perylene, $C_{26}H_{14}$; (**h**) benzo(pqr)naphtho(8,1,2-bcd)perylene, $C_{28}H_{14}$; (I) naphtho[2′.8′,2.4]coronene, $C_{30}H_{14}$; and (**j**) ovalene, $C_{32}H_{14}$. Note how the H/C ratio goes down as condensation increases, from 0.8 for naphthalene to 0.4375 for ovalene

Aromatics					
Benzene	78.11	C_6H_6	1.0	80.1	176.2
Naphthalene	128.17	$C_{10}H_8$	0.8	218	424.4
Benzopyrene	252.32	$C_{20}H_{12}$	0.6	–	–

material that boils below that particular cutpoint. A typical cutpoint for naphtha-oriented conversion is 400 °F (204 °C), while a typical cutpoint for diesel-oriented conversion is 650 °F (343 °C). The equation for conversion is simple:

$$\text{Conversion} = P/\text{FF} * 100\%$$

where P = the amount of material in the product that boils below the chosen cutpoint and FF = the total amount of fresh feed. In "true conversion" calculations, the amount of P in the FF prior to conversion is subtracted from the numerator.

Conversion Chemistry

Thermal cracking. Figure 18.21 outlines the mechanism for the thermal cracking of hydrocarbons. This chain-reaction mechanism includes the following steps:

1. Chain reaction initiation: Free radicals form due to the direct thermal rupture of a carbon–carbon bond
2. Chain reaction propagation: A small radical reacts with a large hydrocarbon to give a small alkane and a large primary radical
3. Cracking: The large primary radical decomposes into ethylene and a primary radical with two fewer carbon atoms
4. Isomerization: A primary radical isomerizes into a secondary radical
5. Cracking: A secondary radical decomposes into propylene and a primary radical with three fewer carbon atoms
6. Radical addition: A radical reacts with an olefin to produce a larger radical. Addition reactions such as this eventually generate coke
7. Chain reaction termination: Two radicals react to produce an olefin and hydrogen. The olefin can undergo further reactions per Step 6
8. Chain reaction termination: Two radicals react to produce a large alkane
9. Chain reaction initiation: In this case, the initiator is external, e.g., an organic peroxide

The free-radical mechanism is consistent with the fact that thermal cracking produces significant amounts of hydrogen, methane, ethane, ethylene, and higher olefins.

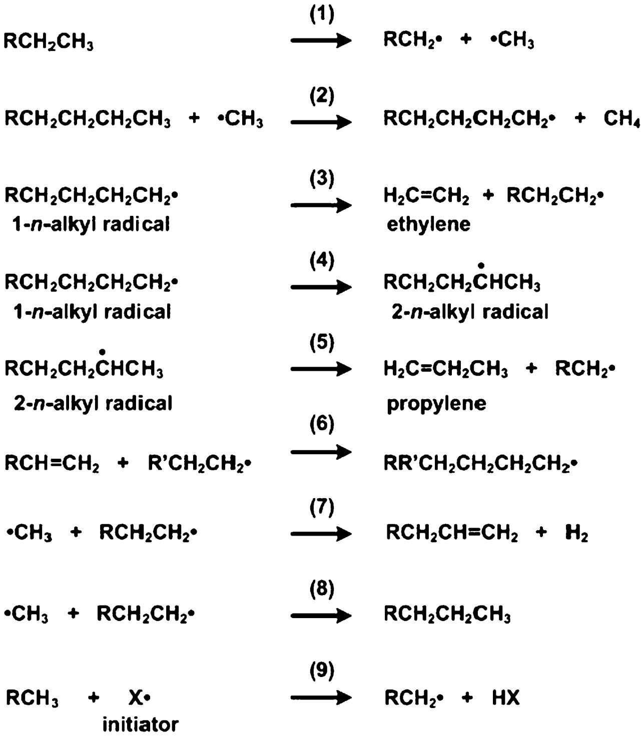

Fig. 18.21 Thermal cracking mechanism [28]

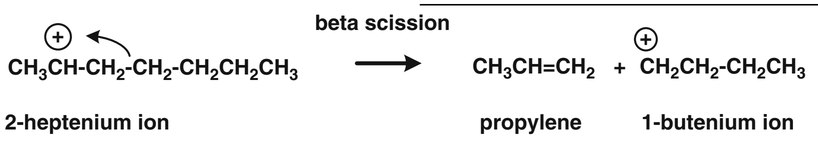
Real-world feeds contain sulfur, nitrogen, oxygen, and other hetero atoms. These form H_2S, ammonia, and water, along with a wide range of hetero-atom organic compounds. Consequently, products (including the water) from delayed coking units contain sulfur and nitrogen compounds.

Catalytic cracking. Figure 18.22 illustrates the mechanism for the catalytic cracking of paraffins. The catalysts contain strong acid sites, and the reactions involve carbocations (also known as carbenium ions or carbenium ions.)

Beta scission is illustrated below. The C–C bond that breaks during acid-catalyzed cracking is two carbons away from the positively charged carbon atom. Also, terminal (1°) carbocations ions are very reactive and quickly rearrange into 2° or 3° carbonations. Therefore, the smallest stable cracked fragment is a C_3 moiety.



The main steps in catalytic cracking are:

1. Dehydrogenation to form a heptene molecule. The reaction is catalyzed by metal sites on the catalyst. It is also reversible. At any point, an olefin can undergo hydrogenation to form a paraffin
2. Abstraction of a hydride ion from *n*-heptane by a Lewis acid site to make a carbocation
3. Addition of a proton to a heptene molecule to make a carbocation, which may or may not be the same as the one produced by Step 2. This reaction is reversible. At any point in the mechanism, a C_3 or higher carbocation can undergo proton elimination to form an olefin
4. Cracking via β scission. This means that cracking occurs two carbon atoms away from the carbon atom holding the positive charge
5. Rearrangement (alkyl shift). As an alternative to Step 4, carbocations can rearrange to form more-stable branched intermediates, which lead to branched products. This explains why the products of catalytic cracking are rich in branched isomers. (In a 3° carbocation, the carbon with the positive charge is attached to three other carbon atoms. In a 2° carbocation, the positive carbon is attached to two other carbons. In a 1° "terminal" carbocation, the positive carbon is attached to only one other carbon. The order of stability is: $3° > 2° > 1°$.)
6. Double-bond shift. After an olefin undergoes double-bond shift, the new olefin can react as before with an acid site per Step 3. It can also undergo alkylation by reacting with a carbocation (Fig. 18.21)
7. Isomerized carbocations can undergo β scission per Step 4

Catalytic cracking units also make aromatics and other heavy products via cyclization, alkylation, and polymerization of intermediate olefins. Figure 18.23 shows the kinds of ring-formation reactions that lead to the generation aromatics and polyaromatics during catalytic cracking. As shown in Fig. 18.16, polyaromatics can grow into larger polyaromatics, which eventually can form coke.

Catalytic hydrocracking. In many respects, the mechanism for catalytic hydrocracking is the same as for catalytic cracking. The main differences are:

- During hydrocracking, aromatic rings are saturated into naphthenic rings, which can then be cracked per the reactions in Fig. 18.24
- The presence of high-pressure hydrogen and metal sites favor the saturation of olefin intermediates. This inhibits ring-formation and ring-growth reactions

For the hydrocracking of fluorene ($C_{13}H_9$), Lapinas et al. [30] propose a mechanism that might apply generally to the hydrocracking of polyaromatics. In simplified form, Fig. 18.24 shows the sequence of reactions by which

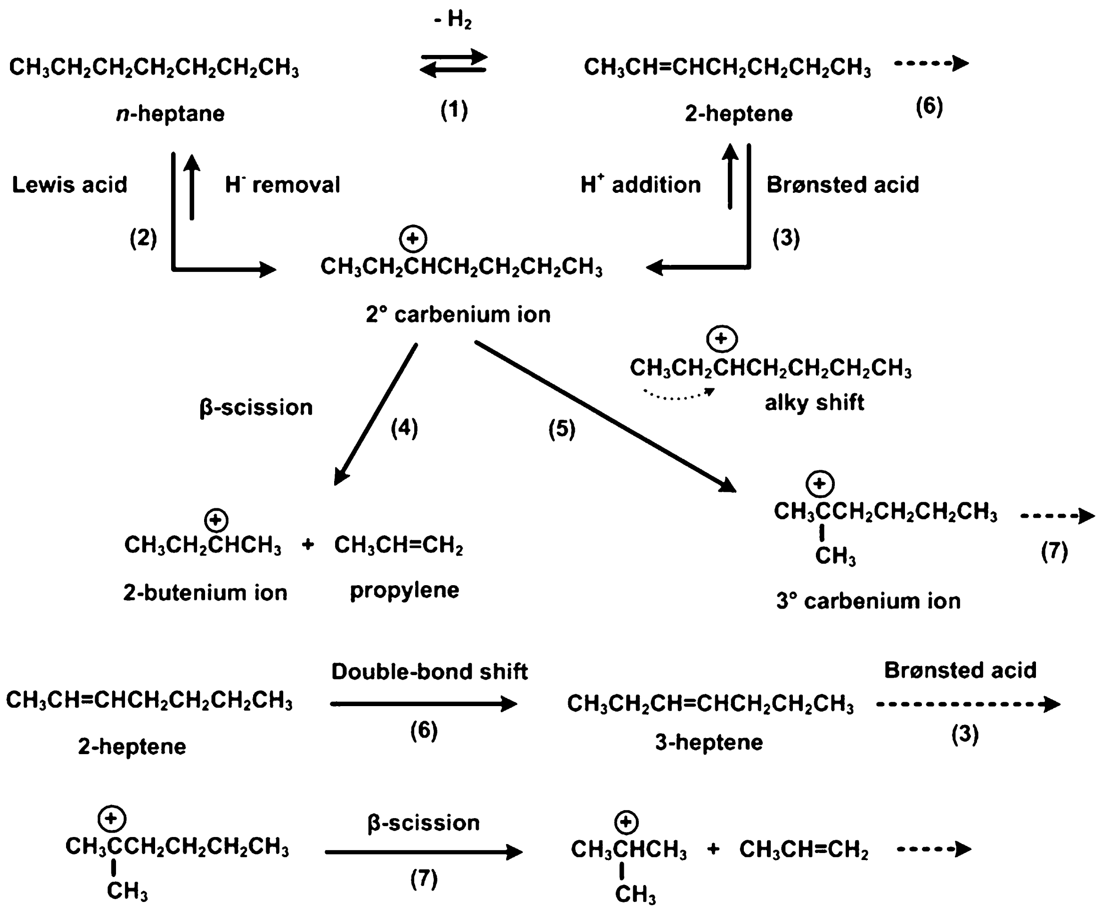


Fig. 18.22 Catalytic cracking of *n*-heptane [28]

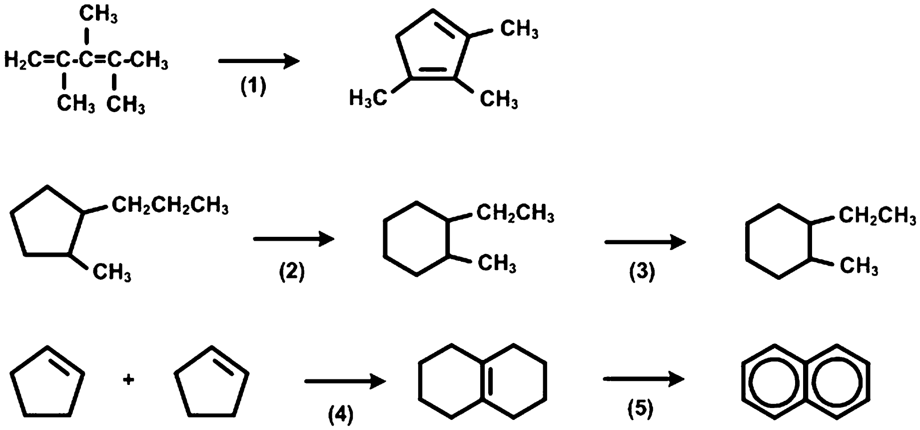

Fig. 18.23 Ring-formation reactions during catalytic cracking [29]

hydrocracking converts a heptyl ethyl naphthalene isomer into lighter compounds. The reactions include:

- Removal of part of a side chain by dealkylation
- Saturation of an aromatic ring
- Isomerization of the saturated ring
- Opening the saturated ring
- Paraffin hydrocracking

The first dealkylation reaction removes hexanes, not heptanes. The ethyl group is not removed, because (a) the production of methane by the β-scission of a two-carbon

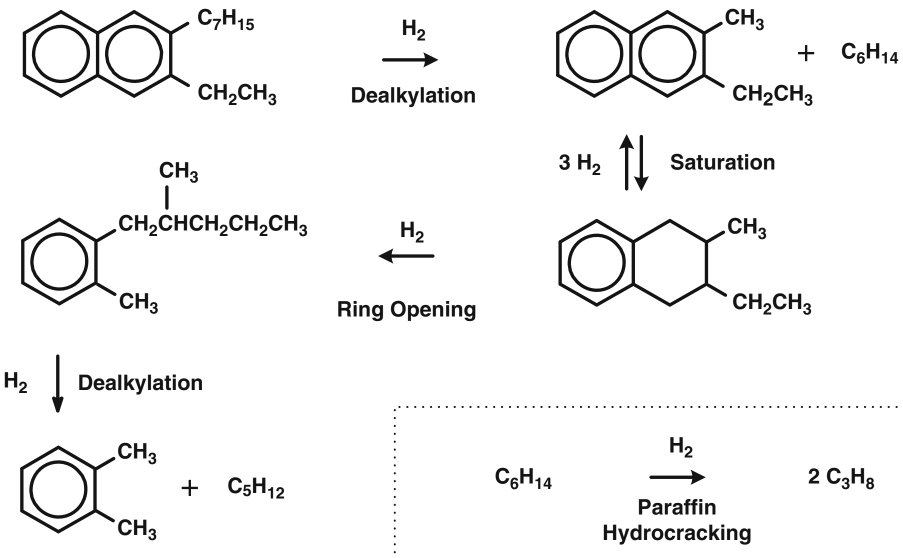

Fig. 18.24 Simplified reaction sequence for the hydrocracking of polyaromatics

C–C bond isn't possible, and (b) it is difficult to form the required intermediate from an aromatic ring stabilized by resonance energy.

Comparison of catalytic and thermal cracking. Based on [28], Table 18.11 provides a comparison between the catalytic and thermal cracking processes:

Alkylation chemistry. Figure 18.25 shows the mechanism for the alkylation reaction of 2-butene with isobutane. During the process, 2-butene can isomerize. Reactions 2a and 2c show how different isomers lead to different products. Reaction 4 illustrates how additional alkylation reactions could eventually produce sludge, coke, and other heavy products.

Catalytic reforming chemistry. Figure 18.26 shows the reactions involved in catalytic reforming, the purpose of which is to transform naphthenes and C_6 to C_{11} paraffins into aromatic compounds. The process yields considerable amounts of hydrogen, which is used in hydrotreaters, hydrocrackers, and other units requiring hydrogen. In contrast to hydrocracking, catalytic reforming operates at low pressure and high temperature, which favors production of aromatics. The conversion of cyclopentanes into cyclohexanes (Reaction 3) is a key step in the production of benzene and alkylbenzenes.

Isomerization chemistry. In refineries, isomerization units convert *n*-paraffins into isoparaffins. In C_4 isomerization, *n*-butane is converted to isobutane in a two-stage process, which employs HCl-promoted $AlCl_3$ for the first stage and a supported noble metal catalyst in the second stage. C_5/C_6 isomerization converts normal pentanes and hexanes and 1° hexanes into highly branched isomers.

Table 18.11 Comparison of product yields for catalytic and thermal cracking processes

Process	Type	Product characteristics
FCC	Catalytic cracking	C_1 and C_2: low Branched/normal paraffin ratio: high Light olefin yields: significant Heavy olefin yields: low Aromatics: higher than feed Coke formation: high Olefin reactivity: higher than paraffins Alkyl aromatics: scission next to the ring
Hydrocracking	Catalytic cracking in the presence of hydrogen	C_1 and C_2: low Branched/normal paraffin ratio: high Olefins: removed by pretreating Aromatics: lower than feed Coke formation: minimal Alkyl aromatics: scission next to the ring
Coking visbreaking	Thermal cracking	C_1 and C_2: high Branched/normal paraffin ratio: similar to feed Olefin production: high Aromatics: low Coke formation: high Olefin reactivity: similar to paraffins Alkyl aromatics: scission within the side chain

Based in part on Table A in [28]

During lube stock production, heavy *n*-paraffins are converted into isoparaffins with minimal cracking over silica-alumina phosphate (SAPO)-based catalysts or similar materials.

Fig. 18.25 Alkylation of 2-butene by isobutane [31]

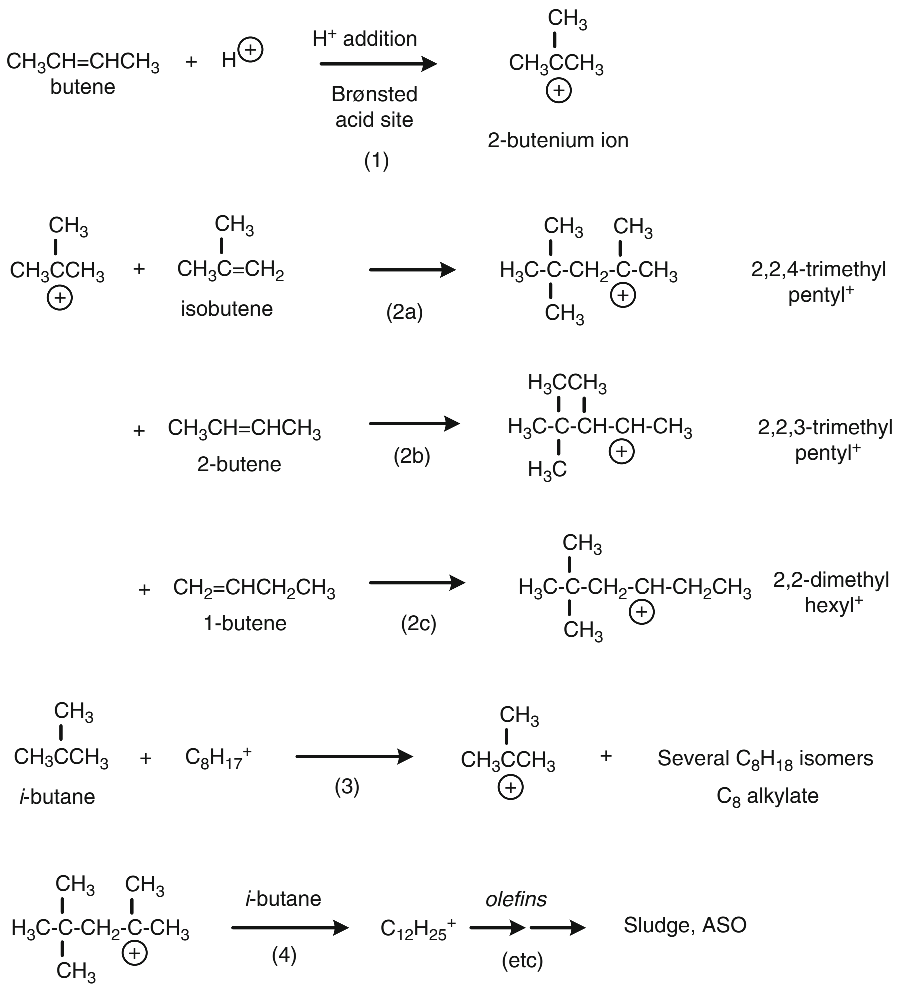

Fig. 18.26 Catalytic reforming reactions

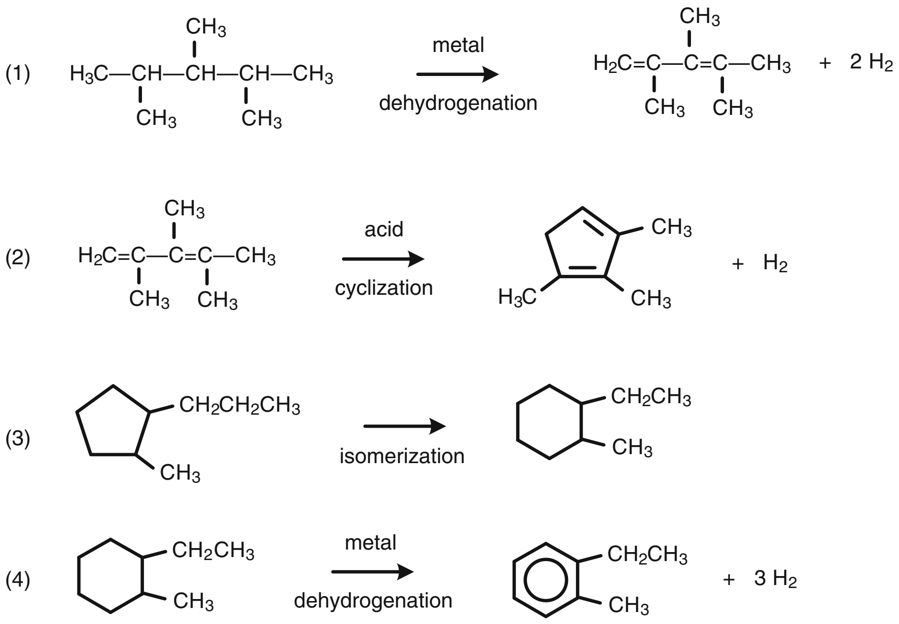

Olefin isomerization converts straight-chain C_4–C_6 olefins into corresponding iso-olefins.

Steam-hydrocarbon reforming (SMR) chemistry. Steam-hydrocarbon reforming produces hydrogen through the reaction of steam with light hydrocarbons at very high temperatures—around 1,500 °F (816 °C). The hydrocarbon feed usually is methane, so even though other hydrocarbons are used, a generic term for the process is steam-methane reforming (SMR). The product of the initial reaction is a mixture of H_2, CO, CO_2, residual methane, and in some cases traces of other hydrocarbons. The initial product goes to one or more shift reactors, where the shift reaction between H_2O and CO yields CO_2 and additional hydrogen.

$$\text{Primary reaction}: CH_4 + H_2O \rightarrow CO + 3H_2$$

$$\text{Shift reaction}: CO + H_2O \rightarrow CO_2 + H_2$$

In older units, residual CO was removed by methanation over a nickel-based catalyst, and residual CO_2 was removed by adsorption with activated molten potassium carbonate (Benfield process). The product hydrogen contained up to 5 % methane.

$$\text{Methanation}: CO + H_2 \rightarrow CH_4$$

In newer units, pressure-swing adsorption (PSA) removes nearly all contaminates, yielding a product containing 99.99 % hydrogen.

Sulfur recovery (*Claus process*) *chemistry*. Claus-process sulfur recovery units burn hydrogen sulfide in just enough air to form a mixture of H_2S and SO_2 in a 2:1 molar ratio. In downstream beds of alumina catalyst, the H_2S reacts with the SO_2 to form elemental sulfur and water.

$$3H_2S + O_2 + S \rightarrow 2H_2S + SO_2 + H_2O$$

$$2H_2S + SO_2 \rightarrow 3S + 2H_2O$$

The product sulfur can include many different isomers of S_x.

Acid/base treating reactions. Several processes entail seemingly simple acid–base reactions. Amine treating removes acid gases—H_2S and CO_2—from fuel gas and off-gas streams. In some hydrotreaters and hydrocrackers, high-pressure amine units remove H_2S from the recycle gas. Caustic scrubbers are used in several ways, including removing the last traces of H_2S from the hydrogen used for processes that are highly sulfur sensitive.

Catalytic NOx removal chemistry. Selective catalytic reduction (SCR) removes nitrogen oxides (NOx) by reaction with ammonia to produce nitrogen via the following main reactions. Secondary reactions involve sulfur oxides and ammonium sulfates.

$$4NO + 4NH_3 + O_2 \rightarrow 4N_2 + 6H_2O$$

$$2NO_2 + 4NH_3 + O_2 \rightarrow 3N_2 + 6H_2O$$

$$NO + NO_2 + 2NH_3 \rightarrow 2N_2 + 3H_2O$$

Petroleum Refining Processes

Some passages in this section are abstracted from [8] and are used with kind permission from the publisher: Springer Science+Business Media, Inc. The *2011 Refining Process Handbook* published by *Hydrocarbon Processing* is an excellent source of additional information on individual processes.

Crude oil pretreatment. Crude oil comes from the ground mixed with a variety of substances: gases, water, salt, and dirt. These must be removed before the crude can be transported effectively and refined without undue fouling and corrosion. Some cleanup occurs in oil fields. In refineries, crude desalting units provide subsequent cleanup.

A field separator is often no more than a large covered vessel that provides enough residence time for gravity separation into four phases: gases, crude oil, water, and solids. Generally, the crude oil floats on the water. The water is withdrawn from the bottom and is disposed of at the well site. Gases are withdrawn from the top and piped to a natural gas processing plant or reinjected into the reservoir to maintain well pressure. Crude oil is pumped either to a refinery through a pipeline or to storage to await transportation by other methods.

At the refinery, the crude is treated with hot water in one or more desalters. Desalters employ either chemical or electrostatic precipitators to remove dissolved salts and collect remaining solids. In chemical desalting, water and surfactants are added to the crude, heated to dissolve salts and other impurities, then sent to a settling tank, where the water and oil separate. In electrostatic desalting, chemicals are replaced with a strong electrostatic charge, which drives the separation of water from oil.

If the crude isn't desalted, residual solids can clog downstream equipment and deposit on heat-transfer surfaces, thereby reducing heat-transfer efficiency. Salts can induce corrosion in major equipment and deactivate catalysts.

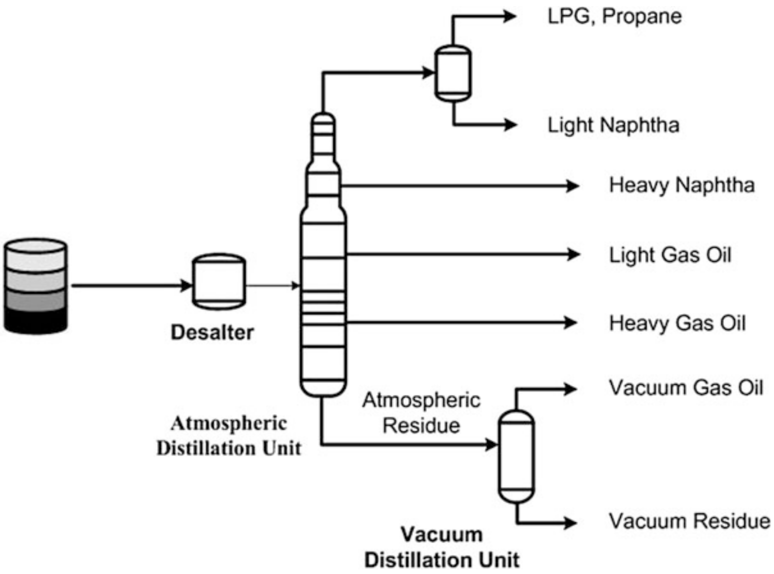

Fig. 18.27 Two-stage crude oil distillation unit [8], Fig. 9, with kind permission from Springer Science+Business Media, Inc

Figure 18.27 presents an overview of a typical two-stage crude oil distillation unit (CDU), and Fig. 18.28 shows an atmospheric distillation tower with bubble-cap internals.

Before reaching the atmospheric tower, desalted oil goes through a network of preheat exchangers to a fired heater, which brings the temperature up to 657–725 °F (347–385 °C). If the oil gets much hotter that this, it starts to crack, generating carbon. The carbon would deposit inside the pipes and equipment through which the oil flows.

The hot crude enters the tower just above the bottom. Steam is added to enhance separation; it does so largely by decreasing the vapor pressure of hydrocarbons in the column. When it enters the tower, most of the oil vaporizes. Unvaporized oil drops to the bottom of the tower, where it is drawn off. The vapors rise through the distillation trays, which contain perforations, bubble caps, downcomers, and/or modifications thereof. Each tray permits vapors from below to bubble up through the relatively cool condensed liquid on top of the tray. This vapor/liquid contacting knocks heavy material out of the vapor. Condensed liquid flows down through a pipe (downcomer) to the hotter tray below, where the higher temperature causes re-evaporation. A given molecule evaporates and condenses many times before finally leaving the tower.

Products are collected from the top, bottom, and side of the column. Side-draw products are taken from trays where the temperature corresponds to the cutpoint for a desired product. Some of the side-draws can be returned to the tower as a pump-around or pump-back stream to control tower temperatures, improve efficiency, and further enhance separation. Reflux plays a major role in controlling temperature at the top of the tower, where gases and light naphtha are drawn off overhead.

The bottom stream from the main fractionator is called atmospheric bottoms, atmospheric residue, or long resid. It goes to a second fired heater, where the typical outlet temperature is about 750–775 °F (400–413 °C). From the second heater, the atmospheric residue goes to a vacuum tower. Steam ejectors reduce the absolute pressure to about 7.0 psia (0.5 bara). Under vacuum, hydrocarbons vaporize at lower temperatures. Thus, molecules with normal boiling points above 650 °F (343 °C) can be vaporized at lower temperatures, where they are less likely to undergo thermal cracking.

Products from the crude distillation unit go to other process units, as shown in Table 18.12.

Solvent refining. Solvent refining processes include solvent deasphalting, solvent extraction, and deoiling/dewaxing processes.

Solvent deasphalting takes advantage of the fact that aromatic compounds are insoluble in paraffins. Propane and *n*-pentane are used to precipitate asphaltenes from residual oils. The deasphalted oil (DAO) is sent to hydrotreaters, FCC units, hydrocrackers, or fuel-oil blending. In FCC units, DAO is easier to process than the corresponding straight-run residue. This is because the asphaltenes in straight-run residue easily form coke and often contain catalyst poisons such as nickel and vanadium; the asphaltene content of DAO is (by definition) almost zero. In hydrocrackers, DAO is harder to process than straight-run VGO and FCC cycle oils, because although DAO no longer contains asphaltenes, it still has a very high endpoint.

In traditional propane deasphalting, residual oil and propane are pumped to an extraction tower at 150–250 °F (65–120 °C) and 350–600 psig (2,514–4,240 kPa). Separation occurs in a tower, which may include a rotating disc

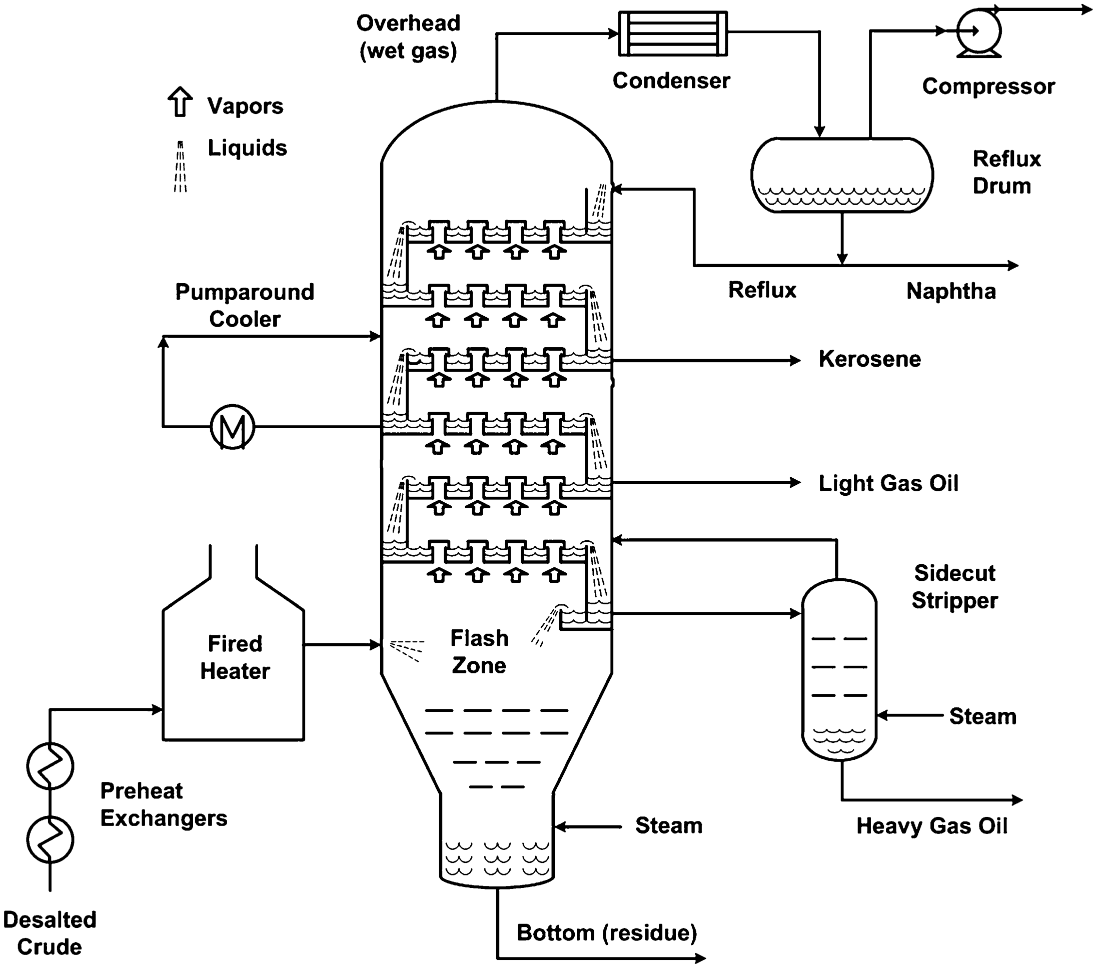

Fig. 18.28 Atmospheric distillation with bubble-cap trays [8], Fig. 10, with kind permission from Springer Science+Business Media, Inc

Table 18.12 Destinations for straight-run distillates

	Approx. boiling range fraction			
	°C	°F	Next destination	Ultimate product(s) or subsequent destination
LPG	−40 to 0	−40 to 31	Sweetener	Propane fuel
Light naphtha	39–85	80–185	Hydrotreater	Gasoline
Heavy naphtha	85–200	185–390	Cat. Reformer	Gasoline, aromatics
Kerosene	170–270	340–515	Hydrotreater	Jet fuel, No. 1 diesel
Gas oil	180–340	350–650	Hydrotreater	Heating Oil, No. 2 diesel
Atmos. resid	340+	650+	Visbreaker Resid hydrotreater Ebullated-bed hydrocracker	FCC or hydrocracker feed, low-viscosity resid Resid FCC Naphtha, gas oils, FCC
Vacuum gas oil	340–566	650–1,050	FCC Hydrotreater Hydrocracker Solvent refining	Gasoline, LCO, gases including C_3/C_4 olefins Fuel oil, FCC, lubes Naphtha, jet, diesel, FCC, olefins, lubes DAO, asphalt
Vacuum Resid	+540	+1,000	Coker Solvent refining Slurry-phase hydrocracker	Coke, coker gas oil, coker naphtha, gases DAO, asphalt Traditional hydrotreater or hydrocracker

Resid is an abbreviation for residue, and 340+ (etc.) means everything that boils above 340 °C (etc.)

contactor. Liquid products are evaporated and steam stripped to recover the propane solvent, which is recycled.

An advanced version of solvent deasphalting is "residuum oil supercritical extraction," or ROSE. The ROSE™ Process was developed by the Kerr-McGee Corporation and now is offered for license by KBR. In this process, residue and solvent are mixed and heated to above the critical temperature of the solvent. Liquid yields are higher under supercritical conditions, because the lighter part of the oil becomes more soluble. In addition to giving higher yields, the process is more energy efficient and has lower operating costs due to improved solvent recovery. The ROSE process can employ three different solvents, the choice of which depends upon process objectives:

Propane	Preparation of lube base stocks
Butane	Asphalt production
Pentane	Maximum recovery of liquid

Solvent extraction is used to remove aromatics and other impurities from lube base stocks and grease stocks. The feedstock is dried, then contacted with the solvent in a counter-current or rotating disk extraction unit. The solvent is separated from the product stream by heating, evaporation, or fractionation. Remaining traces of solvent are removed from the raffinate by steam stripping or flashing. Electrostatic precipitators can enhance separation of inorganic compounds. The solvent is then regenerated and recycled. Today, phenol, furfural, and cresylic acid are widely used as solvents. Liquid sulfur dioxide, chlorinated ethers, and nitrobenzene also have been used.

Solvent dewaxing removes wax (normal paraffins) from deasphalted lube base stocks. The main process steps include mixing the feedstock with the solvent, chilling the mixture to crystallize wax, and recovering the solvent. Commonly used solvents include toluene and methyl ethyl ketone (MEK). Methyl-isobutyl ketone (MIBK) is used in a *wax deoiling* process to prepare food-grade wax, which is used to coat the paper used for milk cartons and other such products.

Visbreaking. Visbreaking is a mild form of thermal cracking that achieves about 15 % conversion of atmospheric residue into gas oils and naphtha. At the same time, a low-viscosity residual fuel is produced. The two main types of visbreaking are "short-contact" and "soaker." In short-contact visbreaking, the feed is heated to about 900 °F (480 °C) and sent to a soaking zone reactor at 140–300 psig (1,067–2,170 kPa). The elevated pressure allows cracking to occur while restricting coke formation. To avoid overcracking, the residence time in the soaking zone is short—several minutes compared to several hours in a delayed coker. The hot oil is quenched with cold gas oil to inhibit further cracking and sent to a vacuum tower for product separation. Soaker visbreaking keeps the hot oil at elevated temperature for a longer time to increase the yield of middle distillates. Low-viscosity visbreaker gas oil can be sent to an FCC unit or hydrocracker for further processing, or used as heavy fuel oil.

Delayed coking. Delayed coking is a cyclic process that employs several coke drums. The drums operate on staggered 18 to 24-h cycles. Each cycle includes preheating the drum, filling it with hot oil, allowing coke and liquid products to form, cooling the drum, and decoking. As it is pumped into a drum, vacuum residue feed is heated to about 900–970 °F (487–520 °C). Thermal cracking begins immediately, generating coke and cracked products. Coke accumulates in the drum while the vapors go to a product fractionator. Meanwhile, hot feed keeps flowing into the drum until it is filled with solid coke. At the end of a cycle, the top and bottom heads of the drum are removed. A rotating cutting tool uses high-pressure jets of water to drill a hole through the center of the coke from top to bottom. In addition to cutting the hole, the water also cools the coke, forming steam as it does so. The cutter is then raised, step by step, cutting the coke into lumps, which fall out the bottom of the drum.

Light products include coker naphtha, light coker gas oil (LCGO), and heavy coker gas oil (HCGO). All of these require further processing due to their high content of olefins, which makes then unstable and poorly suited for direct blending into finished products. The coker naphtha and LCGO are hydrotreated. The HCGO can go either to an FCC unit or a hydrocracker.

Coke can account for up to 30 wt.% of the product. It can be shipped by rail, truck, or conveyor belt to a calciner, which converts *green coke* fresh from the unit into various grades of petroleum coke. Green coke can also be used as-is for fuel.

Sponge coke is named for its sponge-like appearance. It is produced from feeds that have low-to-moderate asphaltene concentrations. If sponge coke meets certain specifications, it can be used to make carbon anodes for the aluminum industry. Otherwise, it serves as a fuel. Sponge coke must be calcined before it can be formed into anodes. Fuel coke sometimes is used without prior calcination.

Needle coke, named for its needle-like structure, is a high-value product made from feeds that contain nil asphaltenes, such as hydrotreated FCC decant oils. Needle coke is converted into graphite electrodes for the electric-arc furnaces used in the steel industry.

Shot coke is undesirable because it tends to be unstable. It forms when the concentration of feedstock asphaltenes and/or coke-drum temperatures are too high. A block of shot coke is a cluster of discrete mini-balls 0.1–0.2 in. (2–5 mm) in diameter. The clusters can be as large as

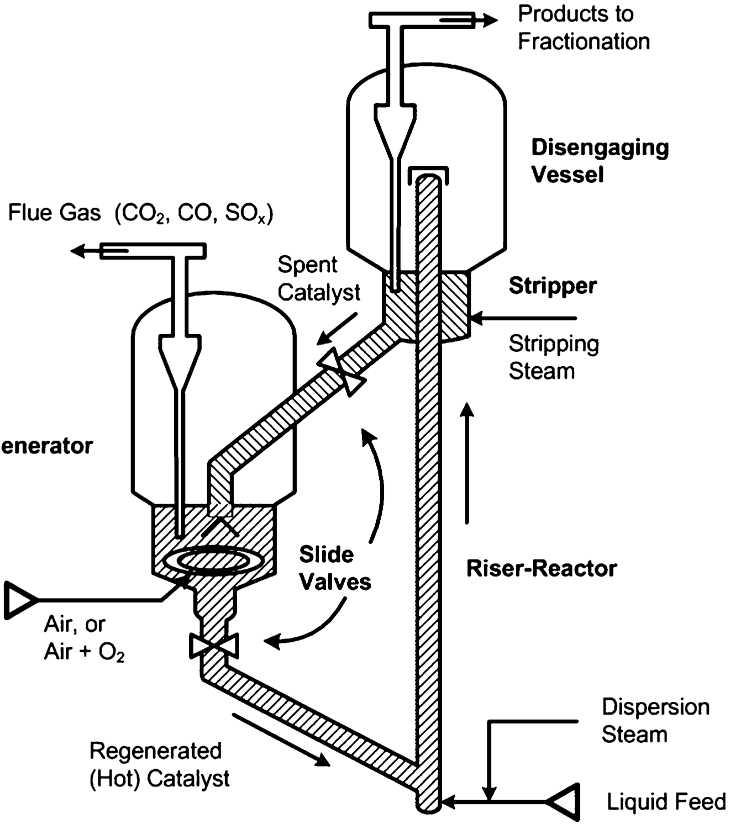

Fig. 18.29 FCC process flow [8], Fig. 13, with kind permission from Springer Science+Business Media, Inc

10 in. (25 cm) across. If a cluster breaks apart when the coke drum is opened, it can spray a volley of hot mini-balls in every direction. Adding aromatic feeds, such as FCC decant oil, can eliminate shot coke formation. Other methods of eliminating shot coke—decreasing temperature, increasing drum pressure, increasing the amount of product recycle—decrease liquid yields, which is not desired.

Specialty carbon products made from petroleum include recarburizer coke, which is used to make special steels, and titanium dioxide coke, which is used as a reducing agent in the titanium dioxide pigment industry.

Fluid coking. Fluid coking, also called continuous coking, is a moving-bed process for which the operating temperature is higher than the temperatures used for delayed coking. In continuous coking, hot recycled coke particles are combined with liquid feed in a radial reactor at about 50 psig (446 kPa). Vapors are taken from the reactor, quenched to stop any further reaction, and fractionated. The coke goes to a surge drum, then to a classifier, where the larger particles are removed as product. The smaller coke particles are recycled to a preheater, where they are mixed with fresh feed. Coking occurs both in the reactor and in the surge drum. Installation costs for fluid coking are somewhat higher than for delayed coking, but feeds can be heavier and heat losses are lower. Fluid coking makes more fuel gas than delayed coking.

Fluid catalytic cracking (*FCC*). FCC produces more than half the world's gasoline.

FCC process flow. A typical FCC unit (Fig. 18.29) comprises three major sections—riser/reactor, regenerator, and fractionation. In the riser/reaction section, preheated oil is mixed with hot, regenerated catalyst. The mixture acts as a fluid because the catalyst particles are about the size of sifted flour. The hot catalyst vaporizes the oil, and the vaporized oil carries the catalyst up the riser/reactor. The cracking reaction is very fast. It produces light gases, high-octane gasoline, and heavier products called light cycle oil (LCO), heavy cycle oil (HCO), slurry oil, and decant oil. It also leaves a layer of coke on the catalyst particles, rendering them inactive.

At the top of the riser, the riser outlet temperature (ROT) can reach 900–1,020 °F (482–549 °C). The ROT determines conversion and affects product selectivity, so FCC operators control it as tightly as possible. Higher temperatures favor production of olefin-rich light gases, especially propylene, at the expense of gasoline; many FCC units maximize propylene for use in nearby olefin plants. Moderate temperatures favor gasoline production. Lower temperatures decrease gasoline yields and increase heavier products—LCO and HCO.

In the disengaging section, steam helps separate the now-deactivated catalyst from the reaction products. The catalyst goes to the regenerator, where the coke is burned away by fluidized combustion in the presence of air or oxygen-enriched air. The regenerated catalyst is hot, with temperatures up to 1,350 °F (732 °C). It is returned to the riser/reactor, where the cycle begins again.

In a 60,000 barrels-per-day unit processing a typical mixture of vacuum gas oils, the total catalyst in the unit (the "inventory") is 400–500 tons. To maintain activity, about 0.5–1 wt.% of the inventory is replaced each day. If the feed to the unit contains significant amounts of residue, the replacement rate is higher. The discharged catalyst is cooled and shipped either to a land fill for disposal or to another refiner, which may have a particular use for "conditioned" FCC catalyst.

FCC feed pretreating. These days, most refiners pretreat FCC feeds in a fixed-bed hydrotreater. The hydrotreater removes trace metal contaminants such as nickel and vanadium. Nickel increases coke formation and decreases liquid yields. Vanadium reduces conversion, decreases liquid yields, and destroys the catalyst. In addition to removing Ni and V, the pretreater decreases concentrations of sulfur, nitrogen, and aromatics. In the FCC regenerator, sulfur on the coked catalyst is converted to sulfur oxides (SOx) in the flue gas. Clean air regulations restrict SOx emissions, which cause acid rain. Therefore, removing sulfur from the FCC feed—thereby reducing SOx formation—is highly beneficial. Removing nitrogen is beneficial, too, because basic feed nitrogen suppresses the activity of highly acidic FCC catalysts. Pretreating also saturates aromatics. As we have seen, saturating aromatics makes them more crackable, so pretreating increases FCC conversion, often by more than 10 vol.%.

FCC heat balance. FCC units must be heat-balanced, or they won't run. The burning of coke in the regenerator provides all of the heat required by the process. In fact, FCC units are significant sources of high-quality steam for other refinery units. Table 18.13 gives a representative breakdown of FCC heat requirements.

Table 18.13 Representative FCC heat balance

Factor	Portion of total
Heat up and vaporize fresh feed	40–50 %
Heat recycled oil	0–10 %
Heat of reaction (endothermic)	15–30 %
Heat steam	2–8 %
Heat losses	2–5 %
Heat air to regenerator temperature	15–25 %
Heat coke from the reactor to regenerator temperature	1–2 %
Total heat duty	500–1,000 Btu/lb 1160–2,325 kJ/kg

Residue FCC. Some FCC units process significant amounts of residue. These units use catalyst coolers (e.g., steam coils) in the regenerator or a second regeneration zone to remove excess heat from the unit. This is because residue generates substantially more coke than conventional FCC feeds, and excess heat is generated when the extra coke is burned off the catalyst. The trace-metal content of residues can be very high. Trace metals destroy FCC catalysts, so removing them—usually with hydrotreating—is essential.

Hydroprocessing. Hydrotreating and hydrocracking are similar processes. Their flow schemes are similar. Both use high-pressure hydrogen to catalytically remove contaminants from petroleum fractions. Both employ the same kinds of equipment—pumps, compressors, furnaces, heat exchangers, and product recovery hardware. In most cases, fixed-bed hot-wall reactors are used. Feeds and products for typical hydrotreaters and hydrocrackers are shown in Table 18.14.

Hydrotreating. Hydrotreating is used to convert sulfur-containing hydrocarbons into low-sulfur liquids and hydrogen sulfide. It also removes nitrogen, oxygen, and other trace contaminants. Hydrotreater feeds range from naphtha to vacuum residues. Generally, each fraction is treated separately. Materials with higher boiling points require more severe treatment conditions. For example, naphtha hydrotreating can be done at 200–500 psia and at 500–650 °F with a hydrogen consumption of 10–50 scf/bbl of feed. Conversely, a residue hydrotreating process might operate at 2,000 psia and at 650–800 °F, with a hydrogen consumption of 600–1,200 scf/bbl.

Figure 18.30 presents a process flow scheme for a two-reactor fixed-bed hydrotreater. Units designed for light feeds usually are simpler, with only one reactor and sometimes only one catalyst bed. Reaction conditions depend on feed quality and process objectives. Oil and hydrogen-rich gas flow down through reactors loaded with catalysts. Makeup gas comes in to replace consumed hydrogen. Gas flow can be once-through in naphtha hydrotreaters, but in distillate and VGO hydrotreaters, unconsumed hydrogen is recycled.

Hydrotreating produces both H_2S and NH_3. Under reaction conditions, these remain in the gas phase. But at lower temperatures, they combine to form solid ammonium bisulfide (NH_4SH). Ammonia also reacts with chlorides to form NH_4Cl; chloride can come with makeup gas, feed, or wash water. These salts can deposit in air coolers and heat exchangers, blocking flow and—even worse—inducing corrosion. Fortunately, they are water-soluble, so they can be controlled by injecting wash water into the reactor effluent.

FCC gasoline post-treating. Conventional hydrotreating does a good job of removing sulfur from FCC gasoline.

Table 18.14 Feeds and products for hydroprocessing units

Feeds	Products from hydrotreating	Products from hydrocracking
Naphtha	Catalytic reformer feed	LPG
Straight-run light gas oil	Kerosene, jet fuel	Naphtha
Straight-run heavy gas oil	Diesel fuel	Naphtha
Atmospheric residue	Lube base stock, low-sulfur fuel oil, RFCC[a] feed	Naphtha, middle distillates, FCC feed
Vacuum gas oil	FCC feed, lube base stock	Naphtha, middle distillates, FCC feed, lube base stock, $C =$ plant feed
Vacuum residue	RFCC[a] feed	See note[b]
FCC light cycle oil	Diesel blend stocks, fuel oil	Naphtha
FCC heavy cycle oil	Blend stock for fuel oil	Naphtha, middle distillates
Visbreaker gas oil	Diesel blend stocks, fuel oil	Naphtha, middle distillates
Coker gas oil	FCC feed	Naphtha, middle distillates, FCC feed, lube base stock, $C =$ plant feed
Deasphalted oil	Lube base stock, FCC feed	Naphtha, middle distillates, FCC feed, lube base stock

[a] RFCC = "residue FCC unit" or "reduced crude FCC unit," which are specially designed to process feeds that contain high concentrations carbon-forming compounds

[b] Traditional fixed-bed hydrocrackers cannot process vacuum residue. However, ebullated-bed and slurry-phase hydrocrackers can. Products from the latter include naphtha, middle distillates, and FCC feed

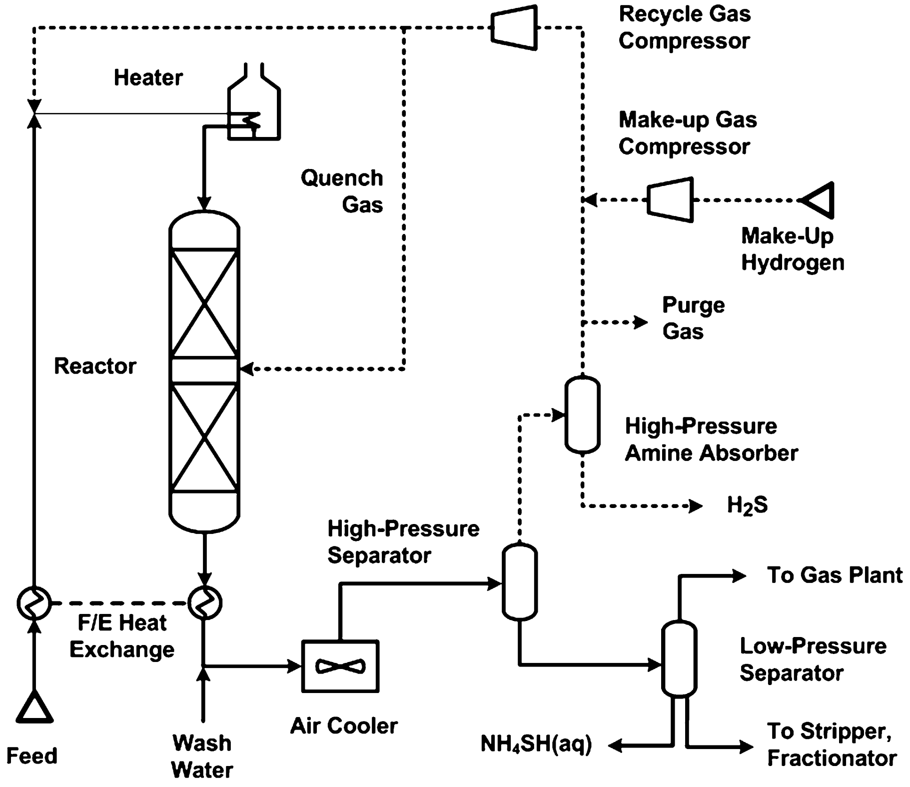

Fig. 18.30 Fixed-bed hydrotreating process flow [15], Fig. 10.20, with kind permission from Woodhead Publishing

Unfortunately, it also does a good job of reducing octane by saturating C_6–C_{10} olefins. Several processes remove sulfur at minimum octane loss. Licensors include Axens (IFP), CDTECH, ExxonMobil, and UOP. The ConocoPhillips S Zorb process uses selective adsorption to remove sulfur from FCC gasoline. The feed is combined with a small amount of hydrogen, heated, and injected into an expanded fluid-bed reactor, where a proprietary sorbent removes sulfur from the feed. A disengaging zone in the reactor removes suspended sorbent from the vapor, which exits the reactor as a low-sulfur stock suitable for gasoline blending. The sorbent is withdrawn continuously from the reactor and sent to the regenerator section, where the sulfur is removed as SO_2 and sent to a sulfur recovery unit. The clean sorbent is

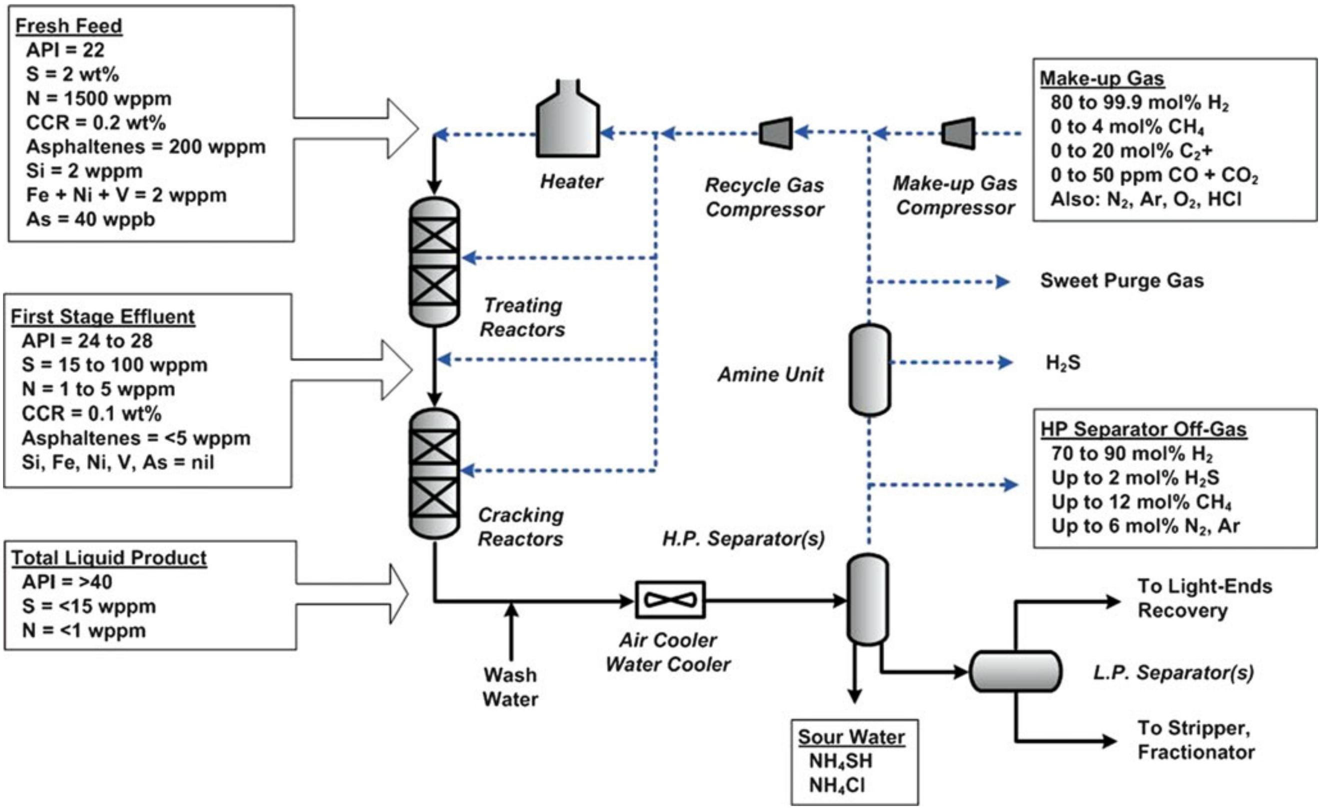

Fig. 18.31 Once-through hydrocracking process flow [15], Fig. 10.21, with kind permission from Woodhead Publishing

reconditioned and returned to the reactor. The rate of sorbent circulation is controlled to help maintain the desired sulfur concentration in the product.

Fixed-bed hydrocracking. As with other conversion processes, the purpose of hydrocracking is to break carbon–carbon bonds, thereby converting heavy hydrocarbons into lighter ones. Figure 18.31 shows a two-reactor once-through hydrocracker with some typical properties for feed and product streams. Figure 18.32 shows a two-stage hydrocracker, in which unconverted oil from the first two reactors goes to a third reactor for additional conversion. With respect to equipment and process flow, fixed-bed hydrocrackers are similar to fixed-bed hydrotreaters. Hydrotreating is an integral part of hydrocracking, because hydrotreating is used to remove organic nitrogen from the feed. Organic nitrogen poisons acidic cracking sites, so its removal is essential.

As shown in Table 18.15, a fixed-bed hydrocracking unit can have significant product flexibility, producing either large amounts of C_4-plus naphtha or large amounts of middle distillates. In petroleum refining, this kind of flexibility is unique.

Ebullated-bed hydrocracking. In contrast to fixed-bed hydrocrackers, ebullated-bed (e-bed) units can process large amounts of residual oils. Catalyst life does not limit these units, because fresh catalyst is added and spent catalyst is removed continuously. In e-bed units (Fig. 18.33), hydrogen-rich recycle gas is bubbled up through a mixture of oil and catalyst particles. This provides three-phase turbulent mixing, which is needed to ensure a uniform temperature distribution. At the top of the reactor, catalyst is disengaged from the process fluids, which are separated in downstream flash drums. Most of the catalyst is returned to the reactor. Some is withdrawn and replaced with fresh catalyst. When compared to fixed-bed processes e-bed technology offers the following advantages:

- The ability to achieve more than 50 wt.% conversion of atmospheric residue
- Ample free space between catalyst particles, which allows entrained solids to pass through the reactor without accumulation, plugging, or build up of pressure drop
- Better liquid-product quality than delayed coking

Disadvantages versus fixed-bed processes include high catalyst attrition, which leads to high rates of catalyst consumption; higher installation costs due to larger reactor volume and higher operating temperatures; and sediment formation. Recent improvements include second-generation catalysts with lower attrition; catalyst rejuvenation, which allows the reuse of spent catalysts; improved reactor design leading to higher single-train feed rates; and two-reactor layouts with inter-stage separation.

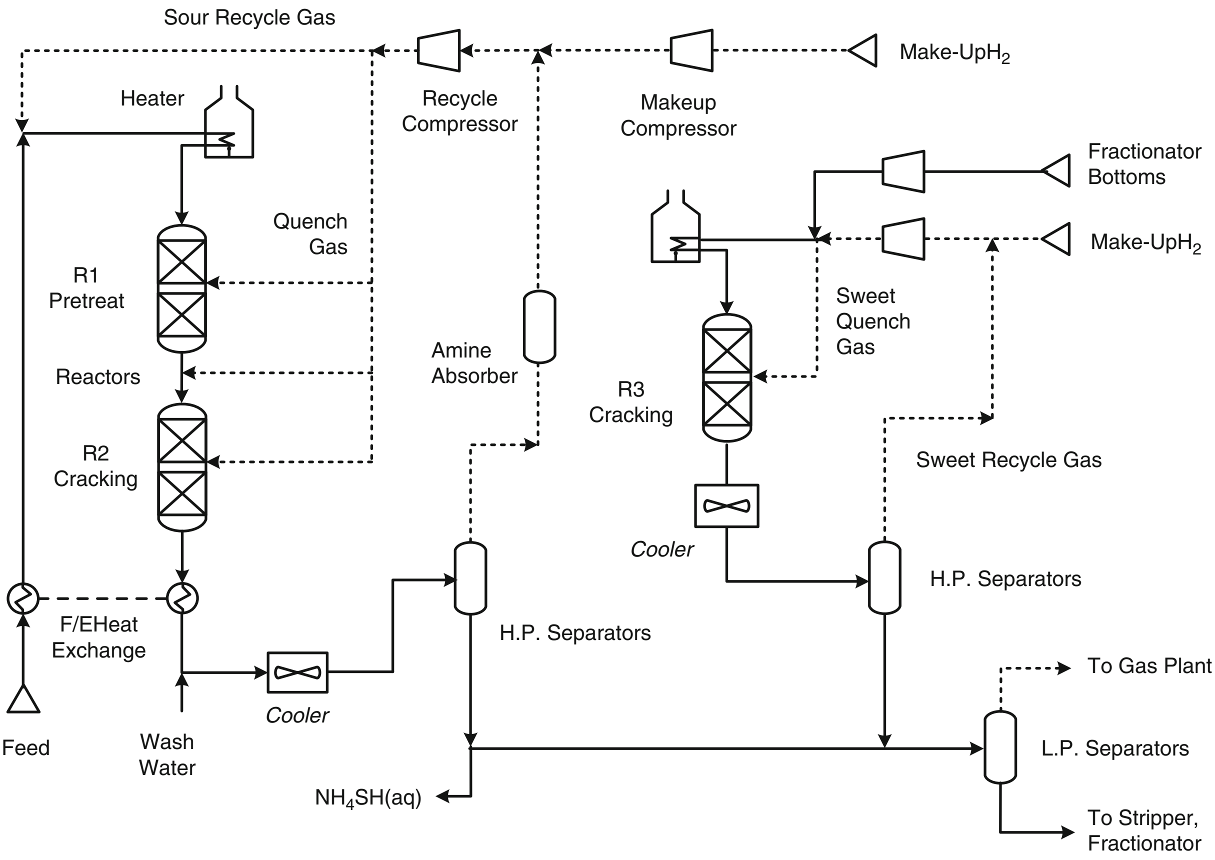

Fig. 18.32 Two-stage hydrocracking process flow [15], Fig. 10.22, with kind permission from Woodhead Publishing

Slurry-phase hydrocracking. Slurry-phase hydrocracking (Fig. 18.34) achieves 95 wt.% conversion of vacuum residue or coal tar. Process conditions are severe—more than 840 °F (450 °C) and 2,000–3,000 psig (14,000–20,800 kPa). The catalysts are nonacidic, comprising finely divided carbon or powered iron sulfate. Inside the reactor, the liquid/powder mixture behaves as a single phase due to the small size of the additive particles. The additives prevent bulk coking by providing highly dispersed nucleation sites for "micro coking" per [26]. The additive isn't recovered. Instead, it ends up in a pitch fraction, which comprises <5 wt.% of the vacuum residue or coal tar feed.

The advantages of slurry-phase processes include:

- The ability to achieve more than 95 wt.% conversion of vacuum residue and other feedstocks, including coal [33]
- Good product quality in two-stage designs, which incorporate a fixed-bed hydrotreating/hydrocracking reactor
- Feedstock flexibility
- Low-cost, micron-size disposable catalysts
- For a given volume of residue feed, lower reactor volume than e-bed processes

Disadvantages include the need to dispose of the coproduced pitch.

Catalytic reforming. The three major process flows for catalytic reforming are:

- Semi-regenerative
- Cyclic
- Continuous catalyst regeneration (CCR)

Figure 18.35 shows a fixed-bed semi-regen reformer. Catalyst cycles last from 6 to 12 months. A cycle ends when the unit is unable to meet its process objectives—typically octane and overall C_5-plus yields. At the end of a cycle, the entire unit is brought down and coke is burned off the catalyst. Desulfurized naphtha is mixed with hydrogen, heated to >900 °F (>480 °C) and passed through a series of fixed-bed reactors. At mentioned the feed is spiked with an organic chloride, which converts to hydrogen chloride in the reactors. This provides the required catalyst acidity and helps minimize catalyst coking.

The major chemical reactions—dehydrogenation and dehydrocyclization—are endothermic and the reactors are adiabatic. Consequently, the temperature drops as reactants flow through a reactor. Between reactors, fired heaters bring the process fluids back to desired reactor inlet temperatures (RIT). The last reactor effluent is cooled and sent to a separator, from which hydrogen-rich gas is removed and

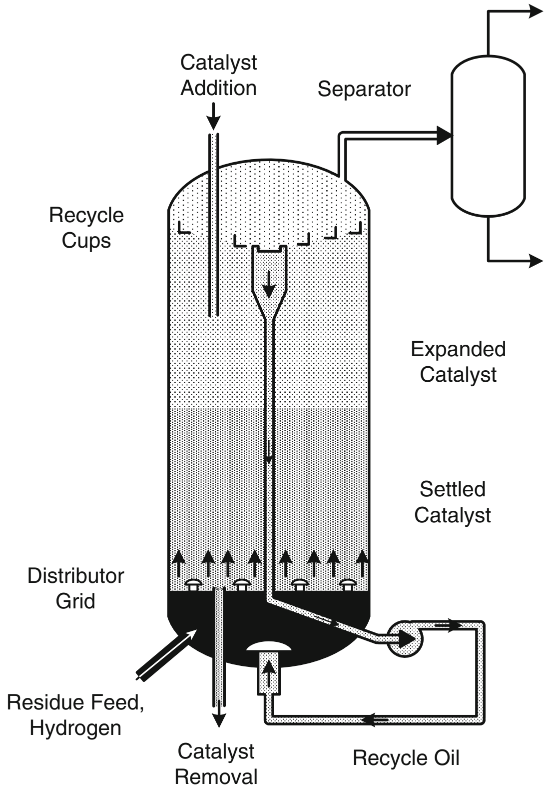

Fig. 18.33 Ebullated-bed hydrocracking process flow [32], Fig. 21, with kind permission from Springer Science+Business Media, Inc

recycled to the reactors. The liquid product flows to a stabilizer column, where entrained gases are removed, before going to the gasoline blender or aromatics plant.

A cyclic reformer has more reactors, and catalyst cycles are shorter—20 to 40 h. Shutdowns are staggered so that only one reactor is down at a given time.

In the CCR Platforming process (Fig. 18.36) hydrotreated feed mixes with recycle hydrogen and goes to a series of adiabatic, radial-flow reactors arranged in a vertical stack. Catalyst flows down the stack, while the reaction fluids flow radially through the catalyst beds. Heaters are used between reactors to reheat the reaction fluids to the required temperature. Flue gas from the fired heaters is typically used to generate steam. A CCR can operate at very low pressure (100 psig, 791 kPa). This improves yields of aromatics and hydrogen, but it accelerates catalyst deactivation by increasing the rate of coke formation. But faster coke formation is okay in a CCR reformer, because the catalyst always is being regenerated.

Isomerization. As mentioned, isomerization units convert *n*-paraffins into isoparaffins and straight-chain olefins into iso-olefins. Butane isomerization provides isobutane for subsequent alkylation. Pentane/hexane isomerization improves the octane of light naphtha streams.

In butane isomerization, the feed contains *n*-butane or, more typically, mixed butanes. The catalyst is highly sensitive to water, so the feed must be thoroughly dried. In the low-temperature first stage, the catalyst comprises aluminum chloride promoted by HCl. Hydrogen gas is added to inhibit olefin formation. In the high-temperature second stage, the catalyst contains a noble metal such as platinum. Temperatures range from 230 to 340 °F (110–170 °C) and pressure ranges from 200 to 300 psi (14–20 bar). The reactor effluent goes to a flash drum, from which hydrogen is recovered and recycled. HCl is removed in a stripper column. The liquids go to a fractionator (deisobutanizer), which separates unconverted *n*-butane from the isobutane product. The *n*-butane is mixed with fresh feed and recycled.

In the Shell Hysomer process for pentane/hexane isomerization, the feed is combined with hydrogen-rich gas, heated to 445–545 °F (230–285 °C) and routed to the

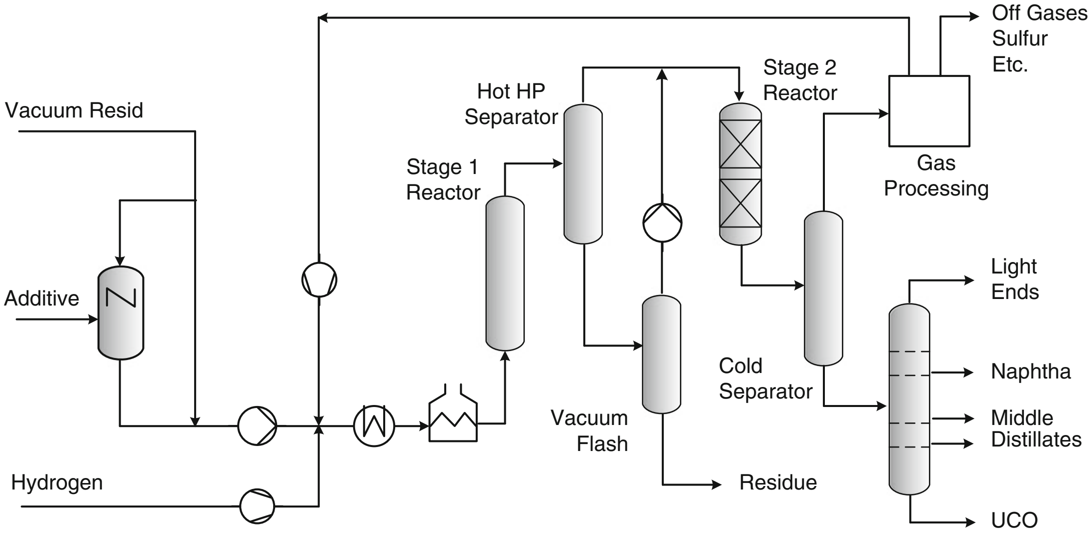

Fig. 18.34 Two-stage slurry-phase hydrocracking process flow. Based on drawings supplied by KBR Technology. Used with kind permission from KBR, Inc

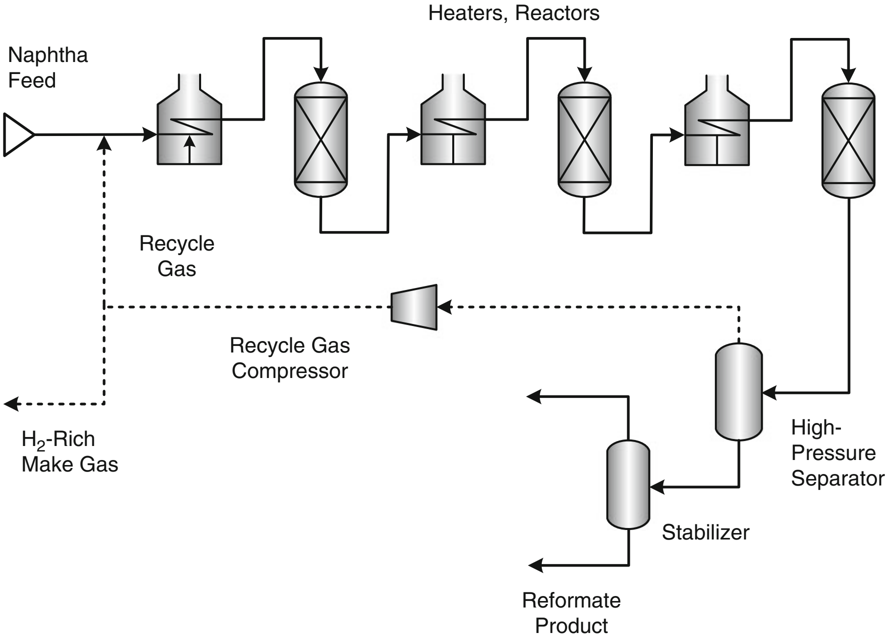

Fig. 18.35 Semi-regen catalytic reforming process flow [8], Fig. 18, with permission from Springer Science+Business Media, Inc

Hysomer reactor at 190–440 psi (13–30 bar). As with fixed-bed hydrotreating and hydrocracking, the process fluids flow down through the catalyst bed, where a part of the *n*-paraffins are converted into branched paraffins. The catalyst is comprised of a noble metal on a zeolite-containing support. The reactions are exothermic, and temperature rise is controlled by injecting relatively cold quench gas. The reactor effluent is cooled and sent to a flash drum, which separates hydrogen from the liquid product. The hydrogen is recycled. The liquid is fractionated, and the *n*-paraffins are recycled. The net conversion of *n*-paraffins into branched products can be as high as 97 %, and the octane can be boosted by 8–10 numbers.

Often, the heat-exchanger and fractionation systems of isomerization units are integrated with those of other process units, such as catalytic reformers. In the total isomerization process (TIP), C5/C6 isomerization is integrated with molecular sieve separation, which provides complete conversion to *n*-paraffins.

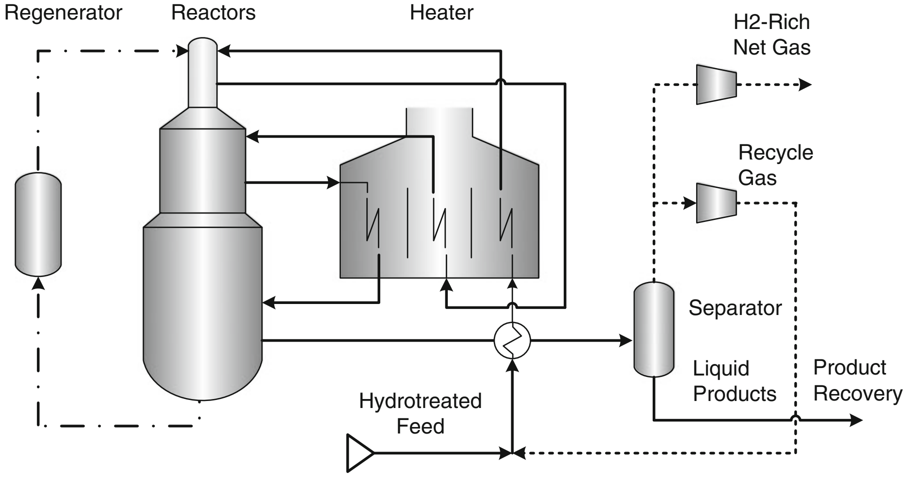

Fig. 18.37 HF Alkylation process flow [8], Fig. 24, with kind permission from Springer Science+Business Media, Inc

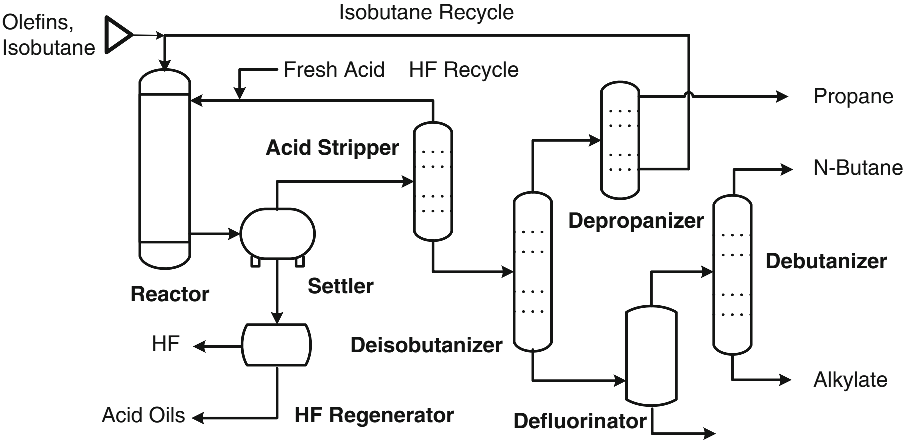

The CDTECH® ISOMPLUS process achieves near-equilibrium conversion of *n*-butenes into isobutylene, and n-pentenes into isoamylene over a zeolite catalyst.

Alkylation. During alkylation, isobutane reacts with light olefins such propylene, butylenes, and amylenes in the presence of strong acids to form branched chain hydrocarbons. These hydrocarbons, often referred to as alkylate, have high-octane values and high vapor pressures, making them an excellent contributor to the gasoline blending pool.

Alkylation employs either hydrofluoric acid or sulfuric acid. The process usually runs at low temperatures to avoid polymerization of the olefins. Temperatures for HF catalyzed reactions are approximately 100 °F (38 °C). For sulfuric acid they are approximately 50 °F (10 °C). Figure 18.37 describes HF alkylation.

Petroleum Refining Catalysts

Most of the processes we have discussed require catalysts. Except for alkylation units, where the acids are in liquid form, most refinery catalysts are solids supported on high-strength solids such as γ-alumina, silica, or alumino silicates.

Solid acids, especially synthetic zeolites, are used extensively in catalysts for FCC and hydrocracking. Zeolites occur naturally, but the ones used for refinery catalysis are synthetic. Synthetic zeolites are also used as drying agents, ion-exchangers, and molecular sieves for gas separation. Their microporosity provides them with high surface area, which contributes to their superb catalytic activity. They also possess a mesopore structure that affects the kinds of molecules they crack and the products formed by the cracking.

Related materials are used in other processes. For example, metal-promoted silica-alumina phosphates such as SAPO-11 are used to isomerize normal paraffins in catalytic dewaxing (CDW) units.

Figure 18.38 shows six zeolite structures. In cracking catalysts, HY zeolite is the most common, but beta and ZSM-5 are used as well. The building blocks of A, X, and other zeolites are tetrahedral units of Si and Al oxides. In the ultra-stable Y (USY) zeolites employed in cracking catalysts, the Si/Al ratio is >10.

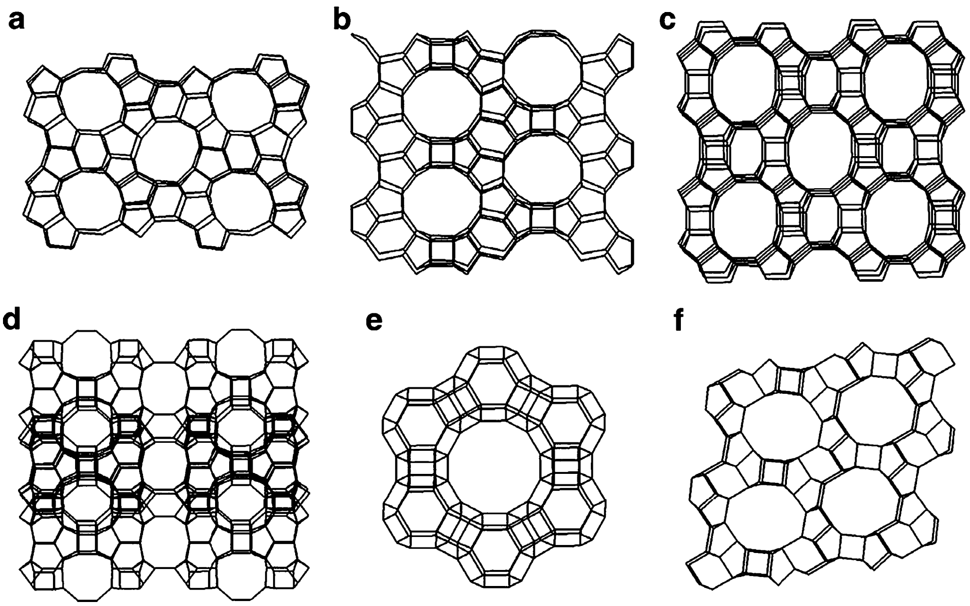

Fig. 18.38 Structures of zeolites ZSM-5 (**a**), mordenite (**b**), beta (**c**), MCM-22 (**d**), zeolite Y (**e**), and zeolite L (**f**). This image is Fig. 1 in [34]

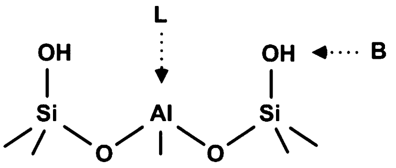

Fig. 18.39 Brønsted (B) and Lewis acid sites (L) in zeolites. Adapted from Fig. 6 in [35]

The acidity of zeolites comes from their structure. Figure 18.39 shows how one can picture these materials as a silica (SiO_2) superstructure, in which every so often an aluminum atom replaces a silicon atom. The silicon atoms have a valence of +4, and each one binds to four oxygen atoms. The oxygen atoms in hydroxyl groups are Brønsted acids (proton donators). Replacing Si (+4) with Al (+3) creates electron-rich Lewis acid sites, which are associated with positive counter-ion such as Na^+, K^+, $NH_4{}^+$, or H^+. The counter ions can be swapped via ion exchange. For example, when Na-Y zeolite is exchanged with an ammonium salt, the Na^+ ion is replaced by $NH_4{}^+$. When NH_4-Y is heated to the right temperature, the ammonium ion decomposes, releasing NH_3 (gas) and leaving behind highly acid HY zeolite.

ZSM-5 is a shape-selective zeolite made by including a soluble organic template in the mix of raw materials. (Templates for this kind of synthesis include quarternary ammonium salts.) ZSM-5 enhances distillate yields in FCC units and CDW in hydroprocessing units, where due to its unique pore structure, it selectively cracks waxy n-paraffins into lighter molecules.

Amorphous silica-alumina (ASA) catalysts are also used for hydrocracking. ASA catalysts are less active but better for producing middle distillates. Figure 18.40 provides a conceptual comparison of amorphous ASA catalysts with crystalline zeolite catalysts. The pore diameters of HY zeolite catalysts are uniform and relatively small—around 7.5 Ångstroms, give or take. Mesopores have larger diameters, which admit mid-sized molecules such as those found in vacuum gas oils. ASA catalysts include small, medium, and large pores. The width of ASA pores can exceed 100 Å. The larger pores can accommodate larger molecules, which explains why ASA catalysts do a better job of cracking feeds with very high endpoints. The pore diameter for ZSM-5 is 6.3 Å.

Catalyst Manufacturing

The following steps are used to prepare solid refinery catalysts:

- Precipitation
- Filtration (or centrifugation), washing, and drying
- Forming
- Calcining
- Impregnation and/or co-mulling
- Activation

Other steps, such as kneading, mulling, grinding, and/or sieving also may be used.

In the precipitation step, two solutions are combined to form a desired solid. For example, mixing a solution of aluminum nitrate [$Al(NO_3)_3$] with a solution of sodium aluminate [$Na_2Al_2O_4$] yields a gel of aluminum hydroxide [$Al(OH)_3$]. As the gel ages, tiny crystals grow larger and a pore structure starts to develop.

Filtration, washing, and drying remove salts and other impurities. In our example, after the precipitation of Al

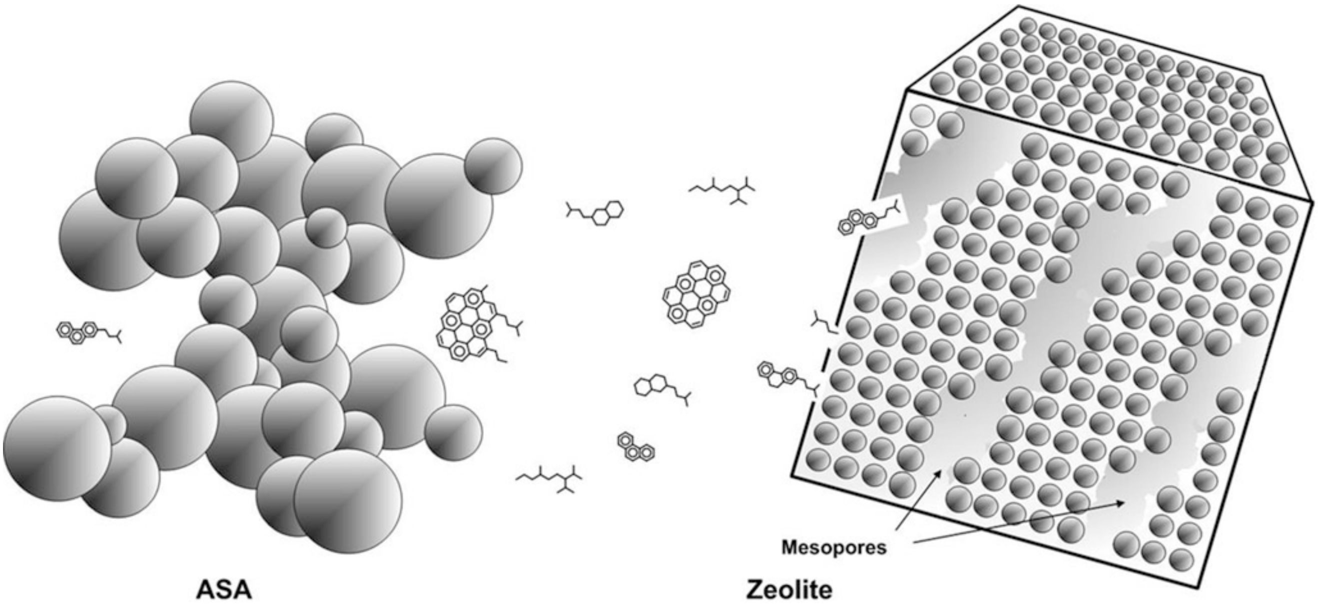

Fig. 18.40 Comparison of amorphous alumina silica (ASA) and zeolite cracking catalyst structures

$(OH)_3$ from aluminum nitrate and sodium aluminate, the coproduced sodium nitrate is washed away with water. Adding ammonium hydroxide expedites sodium removal. Subsequent drying removes excess water and initiates the transformation of $Al(OH)_3$ into alumina [Al_2O_3].

Catalysts can be shaped like wagon wheels, spheres, cylinders, hollow cylinders, lobed extrudates, pellets, etc. (Fig. 18.41). A cross-section of a lobed extrudate can look like a 3-leaf or 4-leaf clover without the stem. Compared to cylindrical extrudates, shaped extrudates have a higher surface-to-volume ratio, and the average distance from the outside of a particle to the center is shorter. To make extrudates, a paste is formed and forced through a die. The resulting spaghetti-like strands are dried and broken into short pieces with a length/diameter ratio of 2:4; for main-bed hydrotreating catalysts, diameters range from 1.3 to 4.8 mm. The particles are calcined, which hardens them and removes additional water and volatile molecules such as ammonia.

Spherical catalysts are made by (a) spray-drying slurries of catalyst precursors, (b) spraying liquid onto powders in a tilted rotating pan, or (c) dripping a silica-alumina slurry into hot oil. Pellets are made by compressing powders in a dye. FCC catalysts are made by spray drying.

Impregnation distributes active metals within the pores of a catalyst support. Like sponges, calcined supports are especially porous. Far more than 99 % of the surface area is inside the pores. When the pores are exposed to aqueous solutions containing active metals, capillary action pulls the aqueous phase into them. After drying, the catalyst might be soaked in another solution to increase the loading of the same (or a different) active metal. Catalysts can also be made by co-mulling active metal oxides with the support. Co-mulling tends to cost less because it requires fewer steps. It also produces materials with different activities—sometimes higher, sometimes lower—than impregnation.

Catalyst Deactivation

Over time, refinery catalysts deactivate and must be replaced. The major causes of deactivation are feed contaminants (trace metals, particulates, etc.) and catalyst coking; the latter is discussed above in some detail. In FCC, continuous catalyst replacement (CCR) processes, and ebullated-bed hydrocracking, aged catalysts are continuously removed and replaced with fresh. But in fixed-bed units, catalyst replacement requires a shutdown. Large hydrocrackers can process >40,000 barrels of feed per day. With a typical net margin of \$15–20 per barrel for hydrocracking alone, every day of down time costs \$600,000 to \$800,000. When the hydrocracker comes down, refiners may have to shut down (or reduce feed rates in) other units, such as the catalytic reformer, which gets feed from the hydrocracker (see Fig. 18.13). Therefore, the refinery-wide cost of hydrocracker down time can be far greater than \$1 million per day.

For a fixed-bed hydrotreating or hydrocracking unit, catalyst cycles range from 12 to 36 months. At the start of a cycle, average reactor temperatures are low, ranging from 550 to 660 °F (288–349 °C). As the cycle proceeds, the catalyst deactivates, so operators must raise temperatures

Fig. 18.41 Catalyst loading scheme showing size/shape grading. Photo provided by Criterion Catalysts & Technologies, LLP

to maintain HDS, HDN, or conversion. A catalyst cycle ends for one of the following reasons:

- The temperature required to achieve the unit's main process objectives hits a metallurgical limit
- The main process objective can be met only at reduced feed rate
- Pressure drop across the unit reaches the upper limit
- Selectivity decreases. If the production of light gases exceeds the capacity of one or more towers in the downstream gas plant, operators must decrease feed rate or reduce conversion. Both options are expensive
- Feed upsets. For a fixed-bed hydrotreater, a slug of residue can poison part of the catalyst with trace contaminants or foul it with particulates, asphaltenes and/or refractory carbon
- Equipment failure. Hardware problems occur most frequently in rotating equipment—pumps and compressors

Petroleum Products

Product Specifications

Products from modern refineries comprise several individual streams, which are blended to meet desired specifications. Product specifications developed by ASTM International are widely used throughout the world. (Until 2001, ASTM was an acronym for the American Society for Testing and Materials.) Table 18.16 lists some common refinery products along with their ASTM designations.

Analogous institutions in other countries, such as British Standards Institution (BSI), serve similar functions. In addition to setting specifications, these institutions develop and publish test methods used to analyze a wide variety of materials. ASTM and its international cousins cooperate both with each other and with government regulators. For example, recent low-sulfur gasoline and diesel directives from the U.S. Environmental Protection Agency are incorporated into D975-04 and D4814-03a, respectively.

Other widely used tests and specifications are defined by licensors. For example, UOP's *Laboratory Test Methods*, distributed by ASTM, defines several hundred procedures for analyzing catalysts, chemicals, and fuels.

Additives are essential components of finished fuels. They increase stability, improve flow properties, and enhance performance. Cetane-improvers are routinely added to diesel fuel, and additives that prevent intake-valve

Table 18.16 ASTM specification numbers for hydrocarbon fuels

Product	ASTM specification	Description
Gasoline	D4814	Standard specification for automotive spark-ignition engine fuel
Jet	D1655	Standard specification for aviation turbine fuels
Kerosene	D3699	Standard specification for kerosene
Diesel	D975	Standard specification for diesel fuel oils
Fuel oil	D396	Standard specification for fuel oils

deposits are now required in all grades of gasoline in the United States.

Gasoline. In the mid- to late-twentieth Century, making gasoline was a relatively simple task. If a mixture of components met specifications for volatility and octane, it could be shipped to retail outlets and sold as-was. If the octane was low, the problem could be fixed by adding a little tetraethyl lead. Butanes could be added or left out as needed to adjust volatility. In 2010, due to environmental regulations, refiners must also meet restrictions on Reid Vapor Pressure (RVP), sulfur content, and oxygen content. Thanks to such restrictions, especially the limit on RVP, the air is much more breathable in large American and European cities.

Octane numbers for hydrocarbons. In a spark-ignition engine, some compounds start to burn before they reach the spark plug. This premature ignition causes knocking, which reduces the power of the engine, increases engine wear, and can cause serious damage. Octane number is a measure of the propensity of fuels to knock in gasoline engines. It is based on a scale in which the octane number of n-heptane is zero and the octane number of isooctane (2,2,4-trimethylpentane) is 100. When a fuel is tested in a standard single-cylinder engine, mixtures of isooctane and n-heptane are used as standards. ASTM D2699 and ASTM D2700 describe methods for measuring research octane number (RON) and motor octane number (MON), respectively.

In North America, the pump octane of gasoline is the average of RON and MON: $(R + M)/2$. This is the number displayed on pumps at filling stations. Typical grades are "regular" with a pump octane of 87, "mid-grade" with a pump octane of 89, and "premium" with a pump octane of 91–93. In some locales, customers can dial in any octane they want between 87 and 93.

Several refinery streams have the right vapor pressure, boiling range, sulfur content, and octane to end up in the gasoline pool. Table 18.17 shows properties for blend stocks from which gasoline might be made. The raffinate comes from an aromatics extraction unit, and the pyrolysis gasoline comes from a nearby ethylene plant.

Table 18.17 Gasoline blend stock composition and properties: examples

Component	Density (kg/m^3)	RVP (bar)	Boiling range °C	°F	RON	MON
Butanes	0.575	3.6	−12 to −0.5	10.4–31	97	95
Straight-run Gasoline	0.64	1.15	27–80	81–176	80.2	76.6
Reformate	0.815	0.08	78–197	172–387	100.5	89.5
Raffinate	0.685	0.3	65–112	149–234	60.3	54.5
Heavy FCC Gasoline	0.76	0.2	43–185	109–365	90.5	79.5
Light FCC Gasoline	0.66	1.3	25–89	77–192	94.5	81.5
Pyrolysis gasoline	0.845	0.3	47–180	117–356	101.5	86.5
Alkylate	0.705	0.3	39–195	102–383	98	93.5
MTBE	0.746	0.5	48–62	118–144	115	97

Reformulated gasoline (*RFG*). In 1970, gasoline blending became more complex. The U.S. Clean Air Act required the phase-out of tetraethyl lead, so refiners had to find other ways to provide octane. In 1990, the Clean Air Act was amended. It empowered EPA to impose emissions limits on automobiles and to require reformulated gasoline (RFG). RFG was implemented in several phases. The Phase I program started in 1995 and mandated RFG for ten large metropolitan areas. Several other cities and four entire States joined the program voluntarily. In the year 2000, about 35 % of the gasoline in the United States was reformulated.

Tier 1 reformulated gasoline regulations required a minimum amount of chemically bound oxygen, imposed upper limits on benzene and RVP (RVP), and ordered a 15 % reduction in volatile organic compounds (VOC) and air toxics. VOC react with atmospheric NOx to produce ground-level ozone. Air toxics include 1,3-butadiene, acetaldehyde, benzene, and formaldehyde.

The regulations for Tier 2, which took force in January 2000, were based on the EPA Complex Model, which estimates exhaust emissions for a region based on geography, time of year, mix of vehicle types, and—most important to refiners—fuel properties. As of 2006, the limit on sulfur in the gasoline produced by most refineries was 30 wppm.

Initially, the oxygen for RFG could be supplied as ethanol or C_5–C_7 ethers. The ethers have excellent blending octanes and low vapor pressures. But due to leaks from filling station storage tanks, methyl-t-butyl ether (MTBE) was detected in ground water samples in New York City, Lake Tahoe, and Santa Monica, California. In 1999, the Governor of California issued an executive order requiring the phase-out of MTBE as a gasoline component. That same year, the California Air Resources Board (CARB) adopted

Table 18.18 Additives used in gasoline

Additive type	Function
Oxygenates anti-oxidation	Decrease emissions
	Minimize oxidation and gum formation during storage
Metal passivation	Deactivate trace metals that can accelerate oxidation
Corrosion inhibition	Minimize rust throughout the gasoline supply chain
Anti-icing	Minimize ice in carburetors during cold weather
IVD control (detergent)	Control deposition of carbon on intake valves
CCD control	Control deposition of carbon in combustion chambers

California Phase 3 RFG standards, which took effect in stages starting in 2002. The standards include a ban on MTBE and a tighter cap on sulfur content—less than 15 wppm.

In many other countries, including Finland, MTBE is still considered a premium blend stock, as safe as other components when filling station storage tanks are properly maintained.

Gasoline additives. Table 18.18 lists the kinds of additives used to prepare finished gasoline. Additive packages vary from season-to-season, region-to-region, and retailer to retailer. After-market additives contain similar types of ingredients, and usually are more concentrated. They are packaged to be added by consumers to their own vehicles.

Low-sulfur gasoline and ultra-low-sulfur diesel. In recent years, the U.S. Environmental Protection Agency (EPA) and the European Parliament promulgated clean-fuel regulations that are lowering the sulfur content of gasoline and diesel fuel. New sulfur-content standards for on-road diesel fuel range from 10 wppm in EU countries to 15 wppm in the United States.

Diesel fuel. The most important property of diesel fuel is cetane number, which indicates how the fuel will perform in diesel engines. Other important diesel-fuel properties include flash point, cloud point, pour point, kinematic viscosity, lubricity—and of course sulfur. Cloud point and pour point indicate the temperature at which the fuel tends to thicken and then gel in cold weather. Viscosity measures the tendency of a fluid to flow. In a diesel engine, viscosity indicates how well a fuel atomizes in spray injectors. It also measures its quality as a lubricant for the fuel system. Lubricity measures the fuel's ability to reduce friction between solid surfaces in relative motion. It indicates how the engine will perform when loaded. Table 18.19 lists cetane numbers for selected pure compounds. As with octane, blended cetane numbers can differ significantly from those for pure compounds.

Table 18.19 Cetane numbers for selected pure compounds

Compound	Type	Carbons	Formula	Cetane No.
n-Decane	Paraffin	10	$C_{10}H_{22}$	76
Decalin	Naphthene	10	$C_{10}H_{18}$	48
α-Methylnaphthalene	Aromatic	11	$C_{11}H_{10}$	0[a]
n-Pentylbenzene	Aromatic	11	$C_{11}H_{16}$	8
3-Ethyldecane	Paraffin (iso)	12	$C_{12}H_{26}$	48
4,5-Diethyloctane	Paraffin (iso)	12	$C_{12}H_{26}$	20
3-Cyclohexylhexane	Naphthene	12	$C_{12}H_{24}$	36
Biphenyl	Aromatic	12	$C_{12}H_{10}$	21
α-Butylnaphthalene	Aromatic	14	$C_{14}H_{16}$	6
n-Pentadecane	Paraffin	15	$C_{15}H_{32}$	95
n-Nonylbenzene	Aromatic	15	$C_{15}H_{24}$	50
n-Hexadecane (cetane)	Paraffin	16	$C_{16}H_{34}$	100[a]
2-Methyl-3-cyclohexylnonane	Naphthene	16	$C_{16}H_{34}$	70
Heptamethylnonane	Paraffin (iso)	16	$C_{16}H_{34}$	15[a]
8-Propylpentadecane	Paraffin (iso)	18	$C_{18}H_{38}$	48
7,8-Diethyltetradecane	Paraffin (iso)	18	$C_{18}H_{38}$	67
2-Octylnaphthalene	Aromatic	18	$C_{18}H_{24}$	18
n-Eicosane	Paraffin	20	$C_{20}H_{42}$	110
9,10-Dimethyloctane	Paraffin (iso)	20	$C_{20}H_{42}$	59
2-Cyclohexyltetradecane	Naphthene	20	$C_{20}H_{40}$	57

[a] Used as standards for ASTM D976

Diesel additives. Table 18.20 lists some of the additives used in diesel fuel and the reasons they are used.

Turbine fuel. Kerosene, jet fuel, and turbine fuel have similar boiling ranges. The key product properties are flash point, freezing point, sulfur content, and smoke point. The flash point is the lowest temperature at which a liquid gives off enough vapor to ignite when an ignition source is present. The freezing point is especially important for jet aircraft, which fly at high altitudes where the outside temperature is very low. Sulfur content is a measure of corrosiveness. The measurement of smoke point goes back to the days when the primary use for kerosene was to fuel lamps. To get more light from a kerosene lamp, you could turn a little knob to adjust the wick. But if the flame got too high, it gave off smoke. Even today, per ASTM D1322, smoke point is the maximum height of flame that can be achieved with calibrated wick-fed lamp, using a wick "… of woven solid circular cotton of ordinary quality."

Table 18.20 Diesel fuel additives

Additive type	Function
Anti-oxidation	Minimize oxidation and gum formation during storage
Cetane improvement	Increase cetane number
Dispersion	Improve behavior in fuel injectors
Anti-icing	Minimize ice formation during cold weather
Detergent	Control deposition of carbon in the engine
Metal passivation	Deactivate trace metals that can accelerate oxidation
Corrosion inhibition	Minimize rust throughout the diesel fuel supply chain
Cold-flow improvement	Improve flow characteristics in cold weather

Table 18.21 Turbine fuel specifications

Specification	Jet A	Jet B	JP-4	JP-5	JP-8
Flash point, °C (min)	38	–	–	60	38
Freeze point, °C (max)	−40 (Jet A) −47 (Jet A-1)	−50	−58	−46	−47
API gravity	37–51	45–57	45–57	36–48	37–51
Distillation, °C					
10 % max	205	–		205	205
20 % max	–	145	145	–	–
50 % max	–	190	190	–	–
90 % max	–	245	245	–	–
EP	300	–	270	290	300
Sulfur, wt% max	0.3	0.3	0.4	0.4	0.3
Aromatics, vol% max	22	22	25	25	25
Olefins, vol% max	–	–	5	5	5

The smoke point of a test fuel is compared to reference blends. A standard 40 %/60 % (volume/volume) mixture of toluene with 2,2,4-trimethylpentane has a smoke point of 14.7, while pure 2,2,4-trimethylpentane has a smoke point of 42.8. Clearly, isoparaffins have better smoke points than aromatics. Table 18.21 lists specifications for common turbine fuels.

Lube base stocks. Refiners prepare lube base stocks from residual oils by removing asphaltenes, aromatics, and waxes. Lube base stocks are hydrofinished, blended with other distillate streams for viscosity adjustment, and compounded with additives to produce finished lubricants. In the past, solvent-based technology was used to prepare lube base stocks. Propane deasphalting was used to remove asphaltenes. Furfural and related substances were used to extract aromatics, and MEK, or MIBK were used to remove wax. With the advent of CDW, some or all of these solvent-based methods can be replaced with hydroprocessing. CDW was developed by Mobil in the 1980s. The process employs ZSM-5, which selectively converts waxy *n*-paraffins into lighter hydrocarbons. The Isodewaxing Process, commercialized in 1993 by Chevron, reduces wax catalytically by isomerising *n*-paraffins into isoparaffins. Isodewaxing also removes sulfur and nitrogen, and it saturates aromatics. Products have a high viscosity index (VI), low pour point, and excellent response to additives.

Waxes. In a traditional lube plant, the raffinate from the solvent extraction unit contains a considerable amount of wax. To recover the wax, the raffinate is mixed with a solvent, usually propane, and cooled in a series of heat exchangers. Further cooling is provided by the evaporation of propane in the chiller and filter feed tanks. The wax forms crystals, which are continuously removed, filtered, and washed with cold solvent. The solvent is recovered by flashing and steam stripping. The wax is purified by heating with hot solvent, after which it is re-chilled, re-filtered, and given a final wash.

Making food-grade wax requires wax deoiling with solvents such as methyl-isobutyl ketone (MIBK).

Greases. Greases are made by blending salts of long-chained fatty acids into lubricating oils at 400–600 °F (204–315 °C). Antioxidants are added to provide stability. Some greases are batch-produced, while others are made continuously. The characteristics of a grease depend to a great extent on the counter-ion (calcium, sodium, aluminum, lithium, etc.) in the fatty-acid salt.

Asphalt. Asphalt can be produced directly from vacuum residue or by solvent deasphalting. Vacuum residue is used to make *road-tar asphalt*. To drive off light ends, it is heated to about 750 °F (400 °C) and charged to a column where a vacuum is applied to prevent thermal cracking.

In road-paving, the petroleum residue serves as a binder for aggregate, which can include stone, sand, or gravel. The aggregate comprises about 95 % of the final mixture. Polymers are added to the binder to improve strength and durability. The recommended material for paving highways in the United States is Superpave32 hot-mix asphalt. Superpave was developed in 1987–1993 during a US$50 million research project sponsored by the Federal Highway Administration.

Roofing asphalt. Roofing asphalt is produced by bubbling air through liquid asphalt at 260 °C (500 °F) for 1–10 h. During this "blowing" process, organic sulfur is converted to H_2S and SO_2. Catalytic salts such as ferric chloride ($FeCl_3$) may be used to adjust product properties and increase the rates of the blowing reactions, which are exothermic. To provide cooling, water is sprayed into the top of the blowing vessel, creating a blanket of steam that captures sulfur-containing gases, light hydrocarbons, and other gaseous contaminants. These are recovered downstream. Cooling water may also be sprayed on the outside of the vessel. The length of the blow depends on desired product properties, such as softening temperature and penetration rate. A typical plant blows 4–6 batches of asphalt per 24-h day. There are two primary substrates for roofing asphalt—organic (paper felt) and fiberglass. The production of felt-based roofing shingles consists of:

- Saturating the paper felt with asphalt
- Coating the saturated felt with filled asphalt
- Pressing granules of sand, talc, or mica into the coating
- Cooling with water, drying, cutting and trimming, and packaging

If fiberglass is used as the base instead of paper felt, the saturation step is eliminated.

Insert: the future for petroleum: ethanol in gasoline. In the petroleum industry, few topics are more controversial than ethanol in gasoline. Expert opinions provided during US Congressional hearings confirm the following: For every PhD, there is an equal and opposite PhD. Some facts are indisputable.

- In 2009, the United States and Brazil produced 87.8 % of the world's fuel ethanol, making 10.6 billion gallons and 6.6 billion gallons, respectively [36]
- In the United States, the advantages of putting bio-derived fuels into transportation fuels include cleaner air and less dependence on imported oil. Indeed, replacing 10–15 % of the gasoline in the United States with ethanol would be significant. Most sources say that corn can give 1.1–1.7 times more energy than is required for growing and processing [37]. This energy includes, of course, the production of ethanol. The unfermented "distillers grain" is high in fats and proteins and serves as an excellent animal feed. In contrast, sugar cane gives an energy gain of 8:1
- Thanks to ethanol from sugar cane, Brazil is now energy self-sufficient. Among large Western countries, it is the first to have a sustainable biofuel economy [38]. The eventual production of significant amounts of ethanol from sugar in the United States is unlikely, because it would require substantial investments in infrastructure. In China, the government is investing heavily in obtaining Biofuels from inedible vegetables (not including broccoli). Such fuels include ethanol [39] made from sweet sorghum, sweet potatoes, and cassava

(continued)

- Using corn ethanol for fuel increases food prices, increases consumption of fertilizer and pesticides, and puts pressure on water resources
- Ethanol increases the vapor pressure of gasoline. Therefore, to meet vapor-pressure specifications, refiners must remove butanes and even pentanes from the gasoline blend pool, creating periodic gluts of these compounds in certain areas. The gluts, of course, depress prices for these commodities
- In October 2011, the US government was paying an ethanol subsidy of 45 cents per gallon to oil refining companies and imposing a 54 cents per gallon tariff on imported ethanol. On June 16, 2011 the US Senate voted 73–27 to eliminate the subsidy. The vote did not become law due to White House opposition [40]
- Efficient production of ethanol from cellulose could answer many of the objections to ethanol from corn. Possible substrates are abundant. They include corn stover, switchgrass, miscanthus, and wood chips. The most promising routes involve multistage biological processes such as enzymatic hydrolysis and microbial fermentation. Research in this area is lively [41]

Protecting the Environment

Oil spills. In April 2010, the petroleum industry solidified its reputation for making deadly mistakes that cause titanic damage to the environment. The *Deepwater Horizon* blowout killed 11 people, injured 17 others, and released up to 4.9 million barrels of oil into the Gulf of Mexico. For additional details, please consult the Report to the President prepared by the National Commission on the BP Deepwater Horizon Oil Spill [42].

Previous oil spills include the following [43]:

> On March 16, 1978, the super tanker Amoco Cadiz ran aground on the Portsall Rocks three miles off the coast of Brittany. The wreck broke up completely before any of the remaining oil could be pumped out, so the entire cargo—more than 1.6 million barrels of crude oil—spilled into the sea. The resulting slick was 18 miles wide and 80 miles long. It polluted 200 miles of coastline, including the beaches of 76 Breton communities. The Amoco Cadiz incident caused more loss of marine life than any previous oil spill. Nearly 20,000 dead birds were recovered. About 9,000 tons of oysters died. Fish developed skin ulcerations and tumors. Years later, echinoderms and small crustaceans had disappeared from many areas, but other species had recovered. Evidence of oiled beach sediments can still be seen in sheltered areas, and layers of subsurface oil remain under many impacted beaches.

In March 1989, the super tanker *Exxon Valdez* ran aground in Prince William Sound in Alaska, spilling more than 250,000 barrels of oil into the Sound. Eventually, 33,000 birds and 1,000 otters died because of the spill. To clean up the mess, eleven thousand workers treated 1,200 miles (1,900 km) of shoreline, using 82 aircraft, 1,400 vessels, and 80 miles (128 km) of oil-containing booms. In response to the disaster, the US Congress passed the Oil Pollution Act of 1990. The Act streamlined and strengthened the ability of the U.S. Environmental Protection Agency (EPA) to prevent and react to oil spills. A trust fund, financed by a tax on oil, was established to pay for cleanups when a responsible party cannot afford to do so. The Act requires oil storage facilities and vessels to submit plans that tell how they intend to respond to large oil discharges. EPA published regulations for above-ground storage facilities, and the US Coast Guard published regulations for oil tankers. The Act also requires the development of area contingency plans to prepare for oil spills on a regional scale.

On January 25–27, 1991, during the occupation of Kuwait, Iraqis pumped 4–6 million barrels of oil—16 to 25 times more than the amount spilled by the Exxon Valdez—into the Arabian Gulf. On January 27, allied bombers stopped the spill by destroying the pumping stations. Ad Daffi Bay and Abu Ali Island experienced the greatest pollution. Despite the ongoing war, the clean up of the oil spill proceeded rapidly. Kuwaiti crude is rich in light ends, and water in the Arabian Gulf water is relatively warm. For these reasons, about half of the spilled oil evaporated, leaving behind a thick emulsion which eventually solidified and sank to the bottom of the sea. Another 1.5 million barrels were recovered by skimming. But on February 23–27, 1991, retreating Iraqi soldiers damaged three large refineries and blew up 732 Kuwaiti oil wells, starting fires on 650 of them. Up to six million barrels per day were lost between February 23 and November 8, 1991. Crews from 34 countries assembled to fight the oil-well fires. Initially, experts said the fires would rage for several years. But due to the development of innovative fire-fighting technology, the job took less than 8 months.

The oil-well fires burned more than 600 million barrels.

Air quality. In the 1970s and 1980s, environmental laws compelled refineries to reduce emissions of SO*x*, NO*x*, CO_2, and hydrocarbons. In the atmosphere, SOx reacts with water vapor to make sulfurous and sulfuric acids, which return to earth as acid rain. Volatile hydrocarbons react with NOx to make ozone. CO_2 is a major "greenhouse" gas. To reduce these pollutants, the industry tightened its operation by:

- Reducing fugitive hydrocarbon emissions from valves and fittings
- Removing sulfur from refinery streams and finished products
- Adding tail-gas units to sulfur recovery plants
- Reducing the production of NOx in fired heaters
- Scrubbing SOx and NOx from flue gases
- Reducing the production of CO_2 by increasing energy efficiency

Sulfur recovery. Conversion processes, hydrotreaters, and sweetening units remove chemically bound sulfur from petroleum fractions. The sulfur can end up as SOx, H_2S, NH_4SH, or NaSH.

Fuel-oil fired heaters and the regenerators of FCC units are major sources of refinery SOx and NOx emissions. The most obvious way to reduce SOx emissions from a heater is to use low-sulfur fuels. Unfortunately, although that solution requires no investment, it is probably the most expensive due to the relatively high cost of buying low-sulfur fuel oil and/or hydrotreating high-sulfur fuel oil.

A large fraction of the sulfur in the feed to an FCC unit ends up in coke on the catalyst. SOx are formed in the regenerator when the coke is burned away. Therefore, removing sulfur from the feed, usually by hydrotreating, decreases SOx emissions. FCC feed pretreating has other substantial benefits. Removing basic nitrogen decreases deactivation of acid sites on the FCC catalyst, which allows the FCC to reach a given conversion at lower temperatures. The saturation of aromatics in the feed pretreater provides the biggest benefit, because it converts hard-to-crack aromatics into easier-to-crack naphthenes. This alone can justify the installation of an FCC feed pretreater.

FCC SOx transfer additives. SOx transfer additives, first developed by Davison Chemical, react with SOx in the FCC regenerator to form sulfates. When the sulfated additive circulates to the riser/reactor section, the sulfate is reduced to H_2S, which is recovered by amine absorption and sent to the sulfur plant. In some units, these additives reduce FCC SOx emissions by more than 70 %. Consequently, if a pretreater or post-treater still must be installed, its size can be reduced. The chemistry of SOx transfer is summarized below:

FCC regenerator (oxidizing environment)

$$\text{Coke on catalyst (solid)} + O_2 + H_2O \rightarrow CO_2 + SO_2,\ SO_3,\ HySO_x\ \text{(gases)}$$

$$SO_2,\ SO_3,\ HySO_x\ \text{(gas)} + \text{MO (solid)} + O_2 \rightarrow MSO_4\text{(solid)}$$

FCC Riser-Reactor (reducing Environment)

$$\mathrm{MSO_4\,(solid) + 5H_2 \rightarrow MO\,(solid) + H_2S\,(gas) + 4H_2O\,(gas)}$$

Flue-gas scrubbing is a refiner's last chance to keep NOx and SOx out of the air. In wet flue-gas desulfurization, gas streams containing SOx react with an aqueous slurry containing calcium hydroxide $Ca(OH)_2$ and calcium carbonate $CaCO_3$. Reaction products include calcium sulfite ($CaSO_3$) and calcium sulfate ($CaSO_4$), which precipitate from the solution. NOx removal is more difficult. Wet flue-gas scrubbing removes about 20 % of the NOx from a typical FCC flue gas. To remove the rest, chemical reducing agents are used. As mentioned above, in the SCR process, anhydrous ammonia is injected into the flue gas as it passes through a bed of catalyst at 500–950 °F (260–510 °C). The chemical reaction between NOx and ammonia produces N_2 and H_2O.

When sulfur-containing feeds pass through hydrotreaters or conversion units, most of the sulfur is converted into H_2S, which eventually ends up in off-gas streams. Amine absorbers remove the H_2S, leaving only 10–20 wppm in the treated gas streams. H_2S is steam stripped from the amines, which are returned to the absorbers. The H_2S goes to the refinery sulfur plant.

Claus process. At the sulfur plant, H_2S is combined with sour-water stripper off-gas and sent to a Claus unit. Almost every refinery in the world uses some version of this process to convert H_2S into elemental sulfur. H_2S and a carefully controlled amount of air are mixed and sent to a burner, where about 33 % of the H_2S is converted to SO_2 and water. From the burner, the hot gases go to a reaction chamber, where the reactants and products reach equilibrium. In several units, the air is enriched with oxygen to increase plant capacity. Elemental sulfur is produced by the reversible reaction between SO_2 and H_2S. Ammonia comes in with the sour-water stripper off-gas. In the Claus process, it is thermally decomposed into nitrogen and water.

In the Claus burner, combustion temperatures reach 2,200 °F (1,200 °C). Much of the heat is recovered in a waste-heat boiler, which generates steam as it drops the temperature to 700 °F (370 °C). Next, the process gas goes to a condenser, where it is cooled to about 450 °F (232 °C). At this temperature, sulfur vapors condense, and the resulting molten sulfur flows through a drain to a heated sulfur-collection pit. At the bottom of the drain, a seal leg maintains system pressure and keeps unconverted gases out of the pit. Uncondensed sulfur and other gases flow to a series of catalyst beds, which recover additional sulfur by promoting the reaction between leftover H_2S and SO_2. With fresh catalyst and a stoichiometric gas composition, the cumulative recovery of sulfur across four condensers is about 50 %, 80 %, 95 %, and 96–98 %, respectively.

Tail-gas treating units (TGTU) bring the total sulfur recovery up to >99.9 %. Most tail-gas treating processes send the tail gas to a hydrotreater, which converts all sulfur-containing compounds (SO_2, SO_3, COS, CS_2, and various forms of S_x) into H_2S. In the SCOT process, offered by Shell Global Solutions, the H_2S is absorbed by an amine and returned to the front of the Claus furnace. In the LO-CAT® process, offered by Merichem, H_2S is air-oxidized to sulfur in an aqueous solution containing a chelated iron catalyst. For all tail-gas treatment processes, the last traces of unrecovered sulfur go to an incinerator, where they are converted into SO_2 and dispersed into the atmosphere.

Wastewater treatment. Wastewater treatment is used to purify process water, runoff, and sewage. As much as possible, purified wastewater steams are reused in the refinery. Wastewater streams may contain suspended solids, dissolved salts, phenols, ammonia, sulfides, and other compounds. The streams come from just about every process unit, especially those that use wash water, condensate, stripping water, caustic, or neutralization acids.

Primary treatment uses a settling pond to allow most hydrocarbons and suspended solids to separate from the wastewater. The solids drift to the bottom of the pond, hydrocarbons are skimmed off the top, and oily sludge is removed. Difficult oil-in-water emulsions are heated to expedite separation. Acidic wastewater is neutralized with ammonia, lime, or sodium carbonate. Alkaline wastewater is treated with sulfuric acid, hydrochloric acid, carbon dioxide-rich flue gas, or sulfur.

Some suspended solids remain in the water after primary treatment. These are removed by filtration, sedimentation, or air flotation. Flocculation agents may be added to consolidate the solids, making them easier to remove by sedimentation or filtration. Activated sludge is used to digest water-soluble organic compounds, either in aerated or anaerobic lagoons. Steam stripping is used to remove sulfides and/or ammonia, and solvent extraction is used to remove phenols.

Tertiary treatment processes remove specific pollutants, including traces of benzene and other partially soluble hydrocarbons. Tertiary water treatment can include ion exchange, chlorination, ozonation, reverse osmosis, or adsorption onto activated carbon. Compressed oxygen may be used to enhance oxidation. Spraying the water into the air or bubbling air through the water removes remaining traces of volatile chemicals such as phenol and ammonia.

Solid waste handling. Refinery solid wastes may include spent catalyst and catalyst fines, acid sludge from alkylation units, and miscellaneous oil-contaminated solids. All oil-contaminated solids are treated as hazardous and sent to sanitary landfills. Recently, supercritical extraction with carbon dioxide has been used with great success to remove oil from contaminated dirt.

The Future

Petroleum is one of mankind's primary sources of energy, so anything that affects global energy affects petroleum demand.

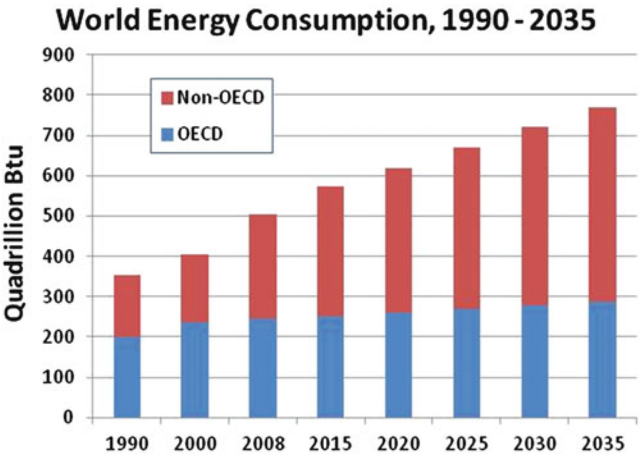

Fig. 18.42 Historical and projected world energy consumption, 1990–2035 [2]

Demand growth in China and India. According to Fig. 18.42, world consumption of energy grew from 350 to 500 quadrillion Btu between 1990 and 2008 and is expected to grow to 780 quadrillion Btu. Non-OECD countries [44], especially China and India, will account for most of the growth. Most likely, on a per capita basis, consumption in OECD countries will still exceed consumption in China and India by wide margin (Fig. 18.43).

Alternatives to petroleum. On average, conventional crude oil is getting harder to find. Over time, unconventional alternatives will supply more and more of our energy and petrochemical monomers. Liquid hydrocarbons will come from natural gas, biomass, bitumen, kerogen, and coal. Some of these contain daunting amounts of contaminants. Even biomass, which includes ethanol and vegetable oils, presents challenges, due the presence of high concentrations of oxygen and olefins. Compared to conventional oil, converting these materials will be costly and more difficult.

EIA's Annual Energy Outlook 2012 [2] projects supplies of unconventional liquids through 2035. The projections were based on three scenarios. In the high-oil-price scenario, future prices will reach $200 per barrel in 2012. In the reference scenario, which is based on present-day prices, the future price in 2035 reaches $150. In the low-price scenario, oil reaches $60 per barrel in 2035. As shown in Fig. 18.45, the largest expected increases come from bitumen and biofuel; biofuel is biomass that has been converted into fuels. In 2009, unconventional liquids supplied about 5 % of world demand. In

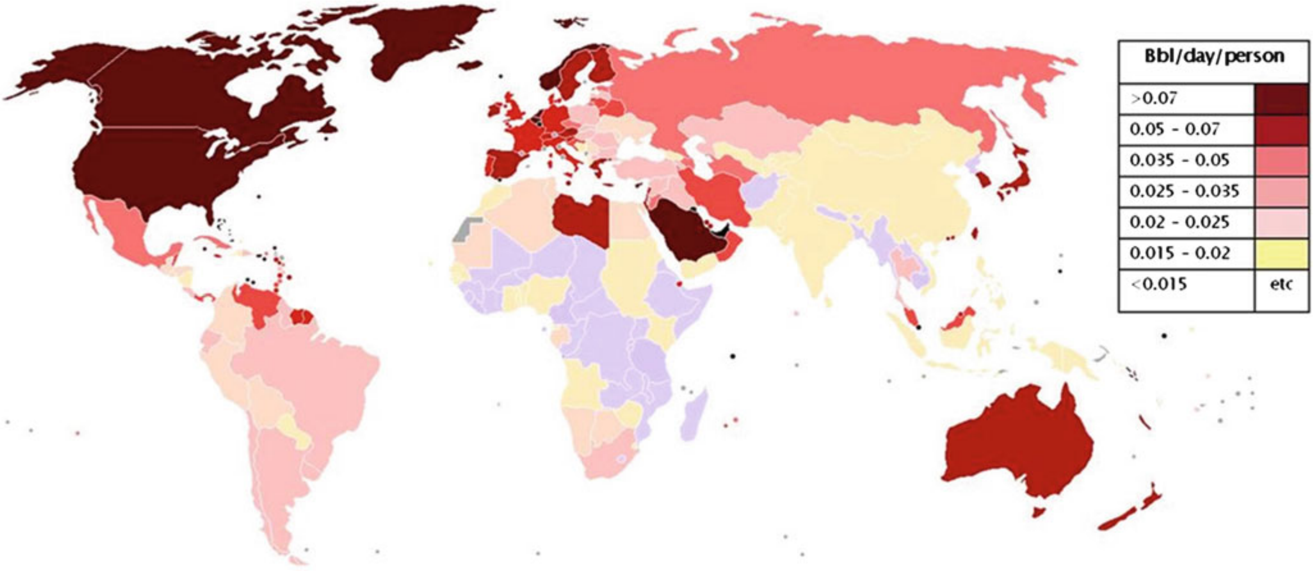

Fig. 18.43 Per capita energy consumption by country, 2009 [45]

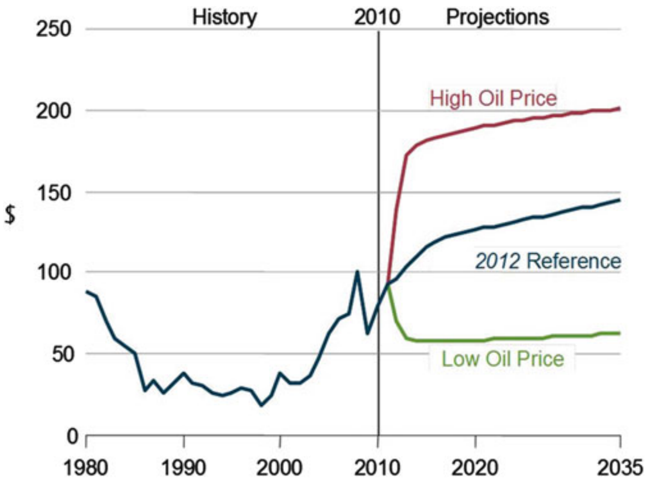

Fig. 18.44 Basis for the EIA forecast on the future use of unconventional liquids as replacements for conventional petroleum

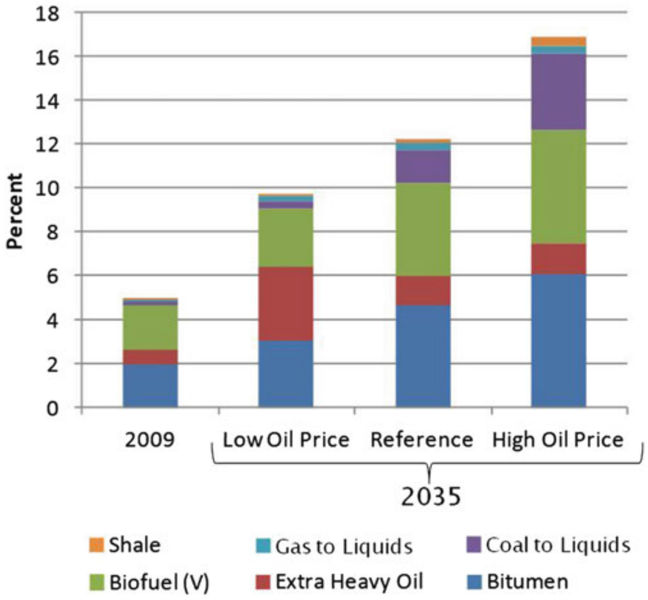

Fig. 18.45 Projected sources of unconventional hydrocarbon liquids in 2035, as a function of the scenarios shown in Fig. 18.44

EIA's high-oil-price scenario, by 2035 they will account for nearly 17 %. In the low-price scenario, by 2035 they will supply less than 10 %. The percentage of unconventional liquids will be higher at high oil prices, because the relative production cost (compared to conventional crude) will be lower.

Ethanol and other biofuels. Many countries now require the blending of ethanol or other oxygen-containing chemicals into gasoline. The oxygen content of fossil hydrocarbons is low. So is the oxygen content of most petrochemical monomers. In contrast, ethanol, cellulose, and vegetable oil contain a lot of oxygen, which must be removed before they can replace petroleum or natural gas in existing petrochemical plants. Removing oxygen is expensive and inefficient. Given enough time, we could develop a new bio-based chemical industry [46]. But in meantime, if we would decrease the amount of petroleum we burn, we would extend the time we could use it for polymers and plastics.

Adding 10 % ethanol to gasoline decreases the demand for petroleum, not by 10 %, but to some extent. This is because the production of ethanol requires energy. As mentioned, the estimated energy gain for ethanol from corn ranges from 1.1 to 1.7, while the energy gain for ethanol from sugar is 8:1 [36–38].

Automation. The ever-increasing development and use of better instruments and analyzers, engineering models, and real-time online optimization continue to improve the efficiency and safety of petroleum processing plants. In one case [47], implementing advanced process control increased production by 2.5 % at the Chemopetrol ethylene plant in Litvinov, Czech Republic. Other examples are provided on the web sites of companies such as Applied Manufacturing Technologies, Aspen Technology, Emerson Process Management, Honeywell Process Solutions, Invensys Operations Management, Yokogawa, and others.

Hampton and Robinson [48] provide an example of the use of advanced regulatory control to improve the safety of hydrocracking units.

Protection of the environmental. The push to control anthropogenic CO_2 emissions is gaining momentum (see the inset for additional comments). Government agencies around the world continue to tighten regulations on sulfur in fuels, air quality, wastewater quality, and the disposal of hazardous solids. Such regulations are now being adopted in less developed countries. They improve the quality of air, water, and land, but they also require investment.

Conservation. Conservation also decreases the demand for petroleum. As mentioned above, with modest investment in proven, widely applied technology, the United States could increase the efficiency of power production by 30 % [4]. Prices have a tremendous effect on energy conservation, which can be accomplished by turning off lights and driving less, but also due to innovation.

Encouraging energy conservation is an obvious, low-cost, win–win way to reduce CO_2 generation on a very large scale [4]. Other solutions, such as replacing coal-bed methane with CO_2, are technically sound, but their potential impact is minor. However, the sum of several minor solutions can be quite significant.

At present, it looks like the world is moving toward punitive measures, such as carbon taxes and/or cap-and-trade. The impact of these could be limited, because businesses with high emissions can avoid investing in energy efficiency by purchasing carbon credits [49].

Never underestimate the ingenuity of a hungry human.

Coal Technology for Power, Liquid Fuels, and Chemicals

19

Burtron H. Davis and James Hower

Introduction

The United States contains about 23% of the world's coal reserves, with Russia, China, Australia, and India each having more than 5% of the reserves. Coal represents over 90% of US proven reserves of fossil fuels. Recoverable reserves of US coal are estimated to be 227 Gt (billion tons; all numbers quoted are in metric tons). Bituminous coals (with a heating value of 23.26–34.89 MJ/kg) comprise nearly one-half of total US coal reserves. Eastern US coals are generally bituminous. Western and southwestern US coals are mainly subbituminous (with a heating value of 20.93–27.91 MJ/kg) and lignite (with a heating value of 18.61–23.26 MJ/kg). Coal is a major source of energy for electric power production and process heat and can serve as a source of synthetic fuels and feedstock for the petrochemical industry.

Historically, interest in coal technology has been cyclic, depending primarily on the price of petroleum. Coal dominated the US energy picture until the discovery of petroleum. Each subsequent threat to oil supplies spurred is new interest in coal, which rapidly faded as major new oil discoveries increased the supply of oil and lowered its price. The threat to oil supplies in 1973 produced the historic response, generating increased interest in converting coal to more convenient, cleaner fuels. Coal use for electric power generation has increased, but the economic conversion of coal to clean transportation fuels still stands as one of the key technical challenges of our time.

Bituminous and subbituminous coals account for the major share of all coal produced in the United States. In 2000, production of all types of coal totaled almost 1 Gt, of which about 95% was bituminous or subbituminous (Fig. 19.1). Despite its clean burning characteristics, anthracite, most of which is mined in northeastern Pennsylvania, accounts for a diminishing share of total coal production. Figure 19.2 presents data on coal consumption in the United States. Environmental concerns have led to an increased demand for low-sulfur coal, which is concentrated in the West. Also, surface mining, with its higher than average productivity, is much more prevalent in the West than in the East. Although more coal is mined east of the Mississippi than west, the share of western production has increased significantly since 1965, when production of western coal was only 24.5 Mt (5% of the total). By 1999, western production had increased to 518 Mt (52% of the total). In the period from 1990 to 1998, medium- and high-sulfur coal production decreased from 635 to 577 Mt.

Electric utilities are the dominant consumers of coal with consumption growing from 76 Mt in 1949 (a 17% share) to 892 Mt in 2000 (a 90% share). The percentage of total consumption in 2000 for all other sectors was lower than it was in 1949. The most dramatic declines occurred in the transportation sector (as railroads switched to diesel engines) and the residential and commercial sectors (transitions from coal to oil and gas for heating). In 1949, residential and commercial use accounted for 170 Mt (39% of the total), but in 2000, consumption in these sectors totaled less than 5.5 Mt, less than 1% of US coal usage. Consumption by the industrial sector trended downward after the mid-1960s, falling to about 59 Mt in 2000 from 186 Mt in 1966. As Table 19.1 shows, the United States is the second largest producer of coal in the world, trailing China. Average productivity of all types of mines in the United States has increased each year since 1949, reaching 3.36 t per miner per hour in 1989. In 1998, average productivity reached 5.5 t per miner per hour, largely due to increased production from large western surface mines and increased use of longwall mining in the eastern United States. Continued improvements in mine productivity (averaging 6.7% a year since 1978) are projected to cause falling real mine mouth prices. Higher electricity demand and lower prices, in turn, yield increasing coal demand. However, this demand is subject to a fixed sulfur emissions cap set by the

Clean Air Act Amendments of 1990 (CAAA 90), which has led to progressively greater reliance on low-sulfur western coal. Anticipated US Environmental Protection Agency guidelines for mercury control will further complicate the mix of coal utilization.[1] The use of western coals can result in up to 85% reduction in sulfur emissions compared with many eastern coals. As coal demand grows, however, new coal-fired generating capacity is required to use the best available control technology: scrubbers and other advanced techniques that can reduce sulfur emissions by 90% or more. Further, the need to reduce Hg emissions has led to increased retrofitting of scrubbers. Thus, there will still be a market for low-cost, higher-sulfur coal.

The literature on the subject of coal composition, structure, and use has grown significantly during the last two decades, as interest in coal research has continued. The future of coal science looks bright as researchers continue to make significant contributions to the elucidation of the structure, composition, and physicochemical behavior of coal. New analytical techniques have made an important contribution to these advances. The objective of this chapter is to provide a brief review of the state of the art of coal science and technology.

Origin and Classification of Coal

Coal is a brown to black carbonaceous sedimentary rock composed of macerals (organic material) and minerals (inorganic material), both subject to metamorphism. Coal cannot be understood outside of the context of all three end members of its composition.

Coal originated from the remnants of various forms of plant life (mosses, ferns, shrubs, trees, etc.) that flourished in swamps and bogs millions of years ago during prolonged periods of warm temperatures and abundant rainfall. This accumulated organic matter, known as peat, was the precursor of coal. Although the peat may have been altered by bacterial and chemical action, overlying water excluded oxygen and retarded the rate of decay. This exclusion of oxygen from the peat was critical for preserving the organic matter. Over time, inorganic sediments accumulated on top of the deposits of plant debris. The gradual rising and lowering of the sea level over time led to deposits of peat alternating with deposits of sand and mud, resulting in the current situation of coal seams interlayered with rock layers.

As overlying sediments became thicker, the peat was compressed into a solid rock by the process of lithification. (Typically, 6 m of peat will form 1 m of coal.) This was followed by coalification, the complex progressive chemical changes that convert peat into coal. A major reaction occurring during coalification is the loss of oxygen (in the form of water) from the organic material. Thus, as coalification proceeds, the oxygen and hydrogen contents of the coal decrease, with a concomitant increase in carbon content. The length of time that these reactions proceed, the temperatures, and, to a lesser degree, the pressures to which the organic molecules are exposed determine the degree of coalification (maturity) of the coal. Coal rank is a measure of the degree of coalification; as coalification proceeds, coal rank increases from lignite through subbituminous and bituminous to anthracite.

Coal is an inhomogeneous rock, because different types of plant material behave differently under coalification conditions, and mineral matter is not uniformly distributed, either by type or by amount. Microscopic examination reveals this inhomogeneity by showing that different areas of the coal structure have a different appearance. The organic components of coal are classified into three maceral groups: vitrinite, liptinite, and inertinite. Each group includes a number of macerals; the vitrinites further divided

---

[1] The US Environmental Protection Agency's Clean Air Interstate Rule (CAIR) (http://www.epa.gov/CAIR/) and Clean Air Mercury Rule (CAMR) (http://www.epa.gov/camr/) would have dictated limits the amount of Hg emissions from coal-fired power plants. In 2008, CAIR and CAMR were vacated by the United States Court of Appeals District of Columbia Circuit (http://pacer.cadc.uscourts.gov/common/opinions/200807/05-1244-1127017.pdf; http://pacer.cadc.uscourts.gov/docs/common/opinions/200802/05-1097a.pdf), the latter upheld by the United States Supreme Court. In place of CAIR, the US EPA proposed the cross-state air Pollution Rule (CSAPR) on 6 July 2011, on 21 August 2012, the US Supreme court of appeal for the D.C. circuit nocated the ruling.

Table 19.2 Classification of coals by rank[a]

		Fixed carbon limits (%) (dry, mineral-matter-free basis)		Volatile matter limits (%) (dry, mineral-matter-free basis)		Calorific value limits (BTU/lb) (moist[b], mineral-matter-free basis)		
Class	Group	Equal or greater than	Less than	Greater than	Equal or less than	Equal or greater than	Less than	Agglomerating character
I. Anthracite	1. Meta-anthracite	98	–	–	2	–	–	–
	2. Anthracite	92	98	2	8	–	–	–
	3. Semianthracite	86	92	8	14	–	–	Nonagglomerating[c]
II. Bituminous	1. Low volatile bituminous coal	78	86	14	22	–	–	–
	2. Medium volatile bituminous coal	69	78	22	31	–	–	Commonly
	3. High volatile A bituminous coal	–	69	31	–	14,000[d]	–	Agglomerating
	4. High volatile B bituminous coal	–	–	–	–	13,000[d]	14,000	Agglomerating
	5. High volatile C bituminous coal	–	–	–	–	11,500	13,000	Agglomerating[e]
III. Subbituminous	1. Subbituminous A coal	–	–	–	–	10,500	11,500	Nonagglomerating
	2. Subbituminous B coal	–	–	–	–	9,500	10,500	–
	3. Subbituminous C coal	–	–	–	–	8,300	9,500	–
IV. Lignitic	1. Lignite A	–	–	–	–	6,300	8,300	–
	2. Lignite B	–	–	–	–	–	6,300	–

[a] This classification does not include a few coals, principally nonbanded varieties, that have unusual physical and chemical properties and which come within the limits of fixed carbon or calorific value of the high-volatile bituminous and subbituminous ranks. All these coals either contain less than 48% dry, mineral-matter-free fixed carbon or have a heating value of more than 15,500 moist, mineral-matter-free British thermal units per pound

[b] Moist refers to coal containing its natural inherent moisture but not including visible water on the surface of the coal

[c] If agglomerating, classify in low volatile group of the bituminous class

[d] Coals having 69% or more fixed carbon on the dry mineral-matter-free basis shall be classified according to fixed carbon, regardless of calorific value

[e] It is recognized that there may be nonagglomerating varieties in these groups of the bituminous class, and there are notable exceptions in high volatile C bituminous group

into the huminite group for lignite and subbituminous coal [1] and the vitrinite group for higher-rank vitrinite forms [2]. The first two of the maceral groups are reactive (relatively easily hydrogenated or oxidized). Inertinites [3], with the exception of the lower-reflectance semifusinite, are relatively inert. Most coals are banded, that is, show a banded structure. Besides banded coals, there are two types of dull, nonbanded coals: (1) cannels, which are rich in spores, and (2) bogheads, which contain abundant remains of algae.

Coals can be classified by rank and/or type. Table 19.2 presents a classification of coals in the United States according to rank. The parameters used to quantify rank (degree of coalification/metamorphism) are moisture, volatile matter (material that is volatilized when coal is heated at a certain temperature for a certain length of time), fixed carbon (the ash-free residue after the loss of moisture and volatile matter), heating value, caking tendency, and weathering properties. Vitrinite reflectance (a commonly used rank indicator for high-rank coals) is measured by comparing the intensity of a beam of light incident on a polished vitrinite surface with the light reflected directly back from that surface.

An international coal classification (Table 19.3) classifies high-rank coals according to their volatile-matter content, calculated on a dry, ash-free (daf) basis. Because volatile matter is not a suitable parameter for classifying coals containing more than 33% volatile matter, the calorific value on a moist, ash-free basis is included as a parameter for such coals. The resulting classes of coal, based on volatile-matter content and calorific value, are grouped according to their plastic properties by employing either the free-swelling or the Roga test. They are then placed in subgroups according to plastic properties, by using either the Audibert–Arnu or the Gray–King test. A three-digit code number is used to identify a coal; the first digit indicates the class of the coal, the second digit indicates the group, and the third digit indicates the subgroup.

In assessing the suitability of a coal for a particular purpose, the above classification of coal types must be used with caution. The heterogeneous nature of the wide range of plant materials and minerals that were the genesis of coal guarantees an almost unlimited range of chemical constituents within the various types of coal, and these constituents determine the coal's reactivity under specific conditions.

Table 19.3 International classification of coals by type (Courtesy of Bureau of Mines, US Department of the Interior)

Groups (determined by caking properties)			Code numbers												Subgroups (determined by coking properties)		
	Alternative group parameters															Alternative subgroup parameters	
Group number	Free-swelling index (crucible-swelling number)	Roga Index	The first figure of the code number indicates the class of the coal, determined by volatile-matter content up to 33% V.M. and by calorific parameter above 33% V.M. The second figure indicates the group of coal, determined by caking properties. The third figure indicates the subgroup, determined by coking properties												Subgroup number	Dilatometer	Gray–King
3	>4	>45							435	535	635				5	>140	>G_8
							334		434	534	634				4	>50–140	G_5–G_8
							333		433	533	633	733			3	>0–50	G_1–G_4
							332a	332b	432	532	632	732	832		2	≤0	E–G
2	2 ½–4	>20–45					323		423	523	623	723	823		3	>0–50	G_1–G_4
							322		422	522	622	722	822		2	≤0	E–G

Classes (determined by volatile matter up to 33% V.M. and by calorific parameter above 33% V.M.)																	

[a] Gross calorific value on moist, ash-free basis (30°C, 96% relative humidity) BTU/lb. Note: (1) Where the ash content of coal is too high to allow classification according to the present systems, it must be reduced by laboratory flow-and-sink method (or any other appropriate means). The specific gravity selected for flotation should allow a maximum yield of coal with 5–10% of ash. (2) 332a. . . >14–16% V.M., 332b. . . >16–20% V.M.

Coal Structure

From the above discussion, it should be clear that there is no such thing as pure coal. Because of variations in the organic and inorganic material that went into the formation of the coal, each seam will be different. Furthermore, there will be significant differences from point to point in the same seam. Composition and structure can vary dramatically between coals of different ranks or even between coals of the same rank. However, some structural features are common to all coals [4].

In general, at a molecular level, coals are composed of aromatic and hydroaromatic building blocks with a variety of substituent groups and some cross-linking between adjacent units [5]. Some of these units are not strictly planar because of the presence of heteroatoms (oxygen, nitrogen, or sulfur) and hydroaromatic portions. Graphite consists of parallel, mutually oriented layers of carbon atoms separated by a distance of 0.335 μm. The parallel stacking of layers in coal is similar but lacks mutual orientation between the layers, and the average spacing between layers is somewhat larger in coal than in graphite.

Low-rank coals are composed of small layers that are more or less randomly oriented and connected by cross-links. Thus, the structure is highly porous. Medium-rank coking coals show a greater degree of orientation and a greater tendency toward parallel stacking. These coals have fewer cross-links and fewer pores than lignites. High-rank coals (primarily anthracites) show a growth in the individual layers, a marked increase in the degree of orientation, and the development of a new type of pore that is elongated and parallel to the layers. These coals are the result of the highest degree of coalification.

The identification of the constituents of a complex mixture, such as coal, by molecular type may proceed in a variety of ways but generally consists of three types of analyses: chemical, spectroscopic, and physical. Mathematical formulas have been developed that use the properties measured by these techniques to derive structural parameters. Several good reviews on this subject are available [6, 7].

Coal Composition and Analyses

Coal is composed of carbon, hydrogen, oxygen, nitrogen, sulfur, chlorine, other elements in trace amounts, and mineral matter. The percentage of these elements varies considerably, depending on rank and even within coals of the same rank. For coals of different ranks, the largest variation in composition occurs in the carbon and hydrogen contents, while for coals of the same rank, sulfur and mineral matter exhibit the greatest variation.

The two most common coal analyses are the proximate analysis and the ultimate analysis. In addition, there are a number of miscellaneous analyses. Many of these tests are empirical, requiring strict adherence to specified conditions. In the United States, the American Society for Testing and Materials (ASTM) standardizes these methods. International standards are developed by the International Organization for Standardization (ISO).

A proximate analysis includes the determination of moisture, ash, volatile matter, and fixed carbon (by difference). The proximate analysis, together with total sulfur and heating value, is usually sufficient to characterize coal burned for process heating and steam generation. An ultimate analysis includes the determination of carbon, hydrogen, nitrogen, total sulfur, chlorine (sometimes), ash, and oxygen (by difference). Other analyses that may be conducted include not only standard tests, such as heating value, free-swelling index, and ash composition, but also special tests to determine trace elements, mineral phases, maceral types, surface properties, conversion potential, and plastic properties.

Standard analyses are described in ASTM and Bureau of Mines publications, but nonstandard methods must be acquired from publications dealing with the specific area of interest. For example, the plastic properties of coal, which are important considerations in many process designs, can be characterized by various techniques, each having its own advantages and disadvantages (Table 19.4).

Figure 19.3 shows typical heats of combustion, and Fig. 19.4 shows typical proximate analyses (reported on an ash-free basis) of various coal ranks. Analyses listed by coal bed, county, and state can be found in a number of publications, such as the data bank developed by the US Department of Energy and the Pennsylvania State University Coal Bank, Bureau of Mines bulletins, Illinois State Geological Survey circulars, and the Argonne National Laboratory Coal Data Base (for a limited number of coal samples).

The heating value (usually reported in MJ/kg or, in the US, in BTU/lb; MJ/kg = (BTU/lb)/429.92) given in Fig. 19.3 is the higher-heating value (HHV), also referred to as the gross heating value. This quantity is defined as the heat produced by combustion of a unit quantity of coal at a constant volume, under specified conditions, with all water produced being condensed. The lower heating value (LHV), also referred to as the net heating value, is calculated from the HHV by deducting 2.40 MJ for each kilogram of water originally present or formed during combustion. The heating value can be estimated from a number of formulas based on the ultimate analysis for carbon (C), hydrogen (H), oxygen (O), and sulfur (S). Some correlations include additional parameters.

Nitrogen and sulfur are the two primary heteroatoms in coal and tend to form environmental pollutants when coal is

Table 19.4 Summary of various techniques to characterize the plastic properties of coal

	Description	Advantages	Disadvantages
Free-swelling index/Gray–King	Visual comparison of cokes carbonized under well-defined conditions, with standard conditions	Inexpensive, rapid, reproducible	Lack of flexibility; transition phenomena from coals to coke not known
Hot-stage microscopy	Morphological changes observed by optical microscopy	Appropriate to supply the changes in macerals when heated	Provides qualitative information "subjective"
Foxwell/gas flow method	Measures the resistance of the gas flow through a bed of coal during continuous heating	Indirectly measures the fluidity of the plastic mass by the pressure differences between the inlet and outlet ports	Requires highly purified (oxygen-free) gas to avoid oxidation
Plastometer			
(a) Constant torque	(a) Records the angular velocity of a rotating shaft through a bed of coal as a function of temperature	Measures the changes in fluidity as a function of temperature; quite sensitive for determining extent of oxidation or weathering	Does not provide data on swelling properties, limited heating rates (−3°C/min)
(b) Variable torque	(b) Records the changes in torque required to rotate a cylindrical retort (when coal is carbonized) at constant speed as a function of temperature		
Dilatometer	Expansion, contraction, and volume change on resolidification measured as a function of temperature when heated	Provides data on dilation parameters and transition temperatures; wide range of heating rates (<100°C/min)	Does not provide quantitative information on changes in fluidity of coal

processed. Therefore, the structure of sulfur and nitrogen compounds in coals, their evolution during thermal decomposition, and the distribution of these species in products have been extensively investigated. These studies suggest that nitrogen in coal is almost entirely contained in tightly bound ring structures. The nitrogen-containing structures

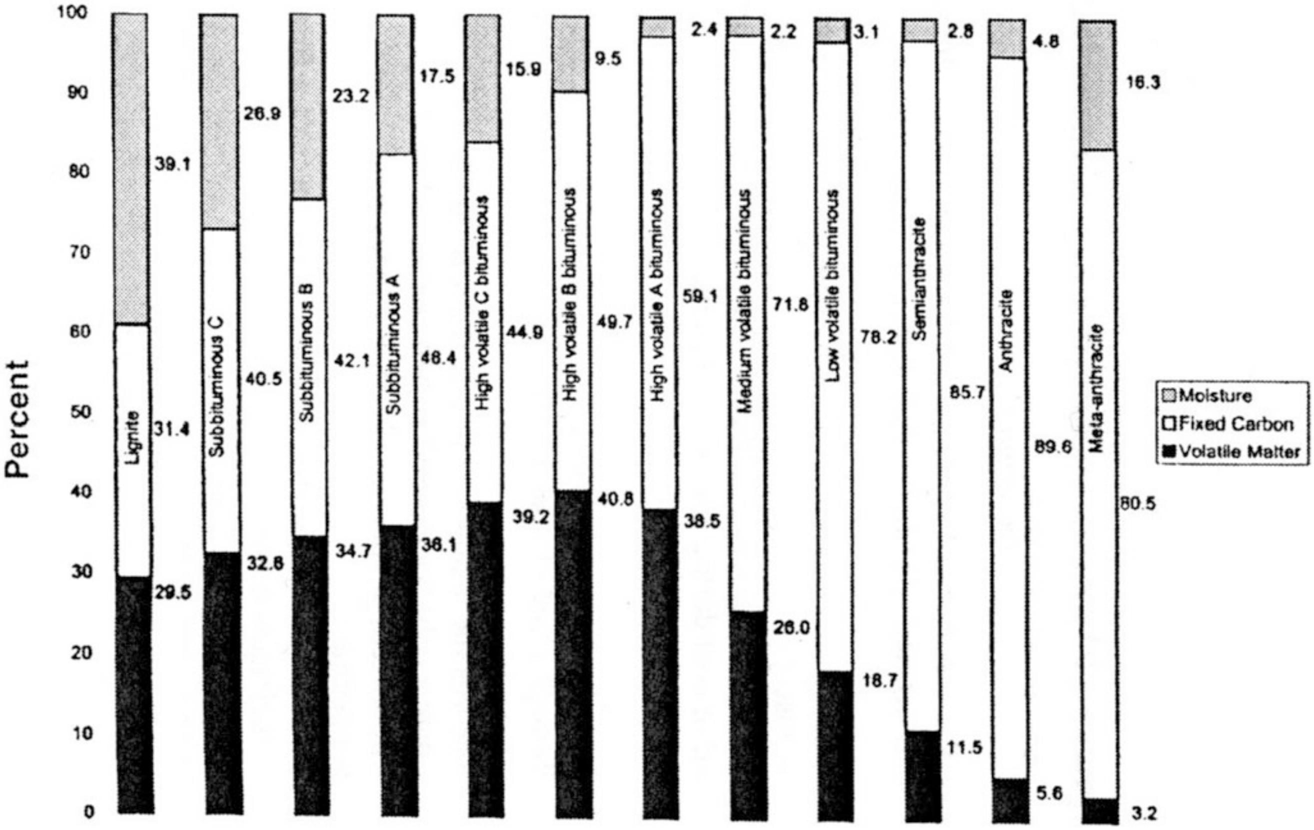

Fig. 19.4 Analysis of US coals selected to represent the various ranks (Courtesy of Bureau of Mines)

evolve from coal without cleavage during pyrolysis. Nitrogen compounds in coal can interfere with synthetic fuels processing owing to the fact that most of these compounds are basic and are strongly adsorbed on the acidic catalysts used, thus poisoning them. Nitrogen present in coal is converted to NO_x during combustion, the extent of the conversion depending on a variety of factors, including oxygen concentration, flame temperature, residence time at temperature, and the degree of fuel–air mixing.

Unlike nitrogen that is almost entirely associated with the organic structure of coal, sulfur is present in both the organic and inorganic constituents. Inorganic sulfur is present in coal in several forms, such as pyrite (FeS_2) and sulfates (small amounts). Organic sulfur is mainly present in ring compounds. Pyrite decomposes at a relatively low temperature (approximately 400°C), producing FeS, H_2S, and organic sulfur compounds. Organic sulfur compounds can be classified into three groups, those with loosely bound sulfur, those with tightly bound sulfur, and an intermediate category. The tightly bound sulfur compounds decompose above 500°C, while the loosely bound sulfur compounds decompose at low temperatures (about 100°C). Some of the tightly bound organic sulfur compounds are formed by incorporating sulfur from pyrite decomposition into ring structures.

Coal Mining and Preparation

Coal mines fall into two general classifications—surface and underground. Production of coal by type of mining for the United States is shown in Fig. 19.1. Most developed countries would use similar techniques.

Surface Mining

Surface mining techniques are used when the coal is present near the surface, and the overlying strata (overburden) are thin enough to permit economic removal. Surface mining techniques include contour mining, strip mining, and auger mining.

Contour mining is used in hilly areas, where the slope of the surface will permit only a narrow bench cut around the side of a hill; the excavation is backfilled immediately after the removal of coal. It is the only method that can be used on slopes of 15° or higher.

Strip mining is used in flat or gently rolling land, predominantly in the Midwest and West, where large, efficient equipment can be used. In this technique, the coal is exposed by removing the overburden. Blast holes are drilled, and

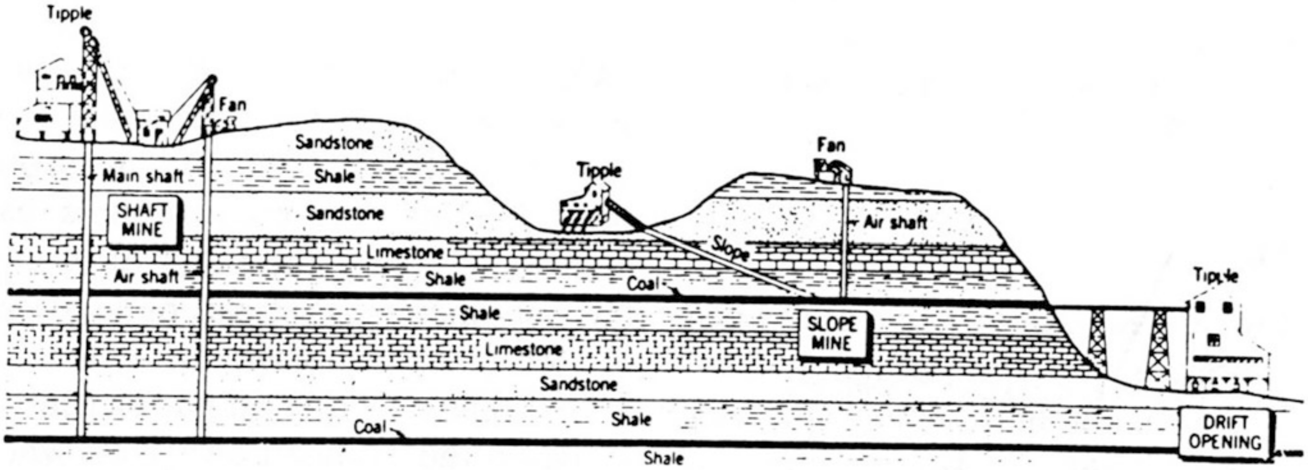

Fig. 19.5 Three types of entrances to underground mines—shaft, slope and drift (Courtesy of Bureau of Mines)

explosives are loaded into these holes to shatter the rock cover; earth-moving equipment is used to remove the soil and the shattered rock. The coal is then collected with power shovels or other coal-digging machines and loaded directly into trucks. When the seam is near the top of a hill, the entire hilltop may be removed to expose the coal. Strip mining can be very efficient, especially in the West, where coal seams can be 30 m thick or more. For example, the Wyodak seam averages nearly 20 m thick.

Auger mining is a supplementary method used to reach coal in stripped areas where the overburden has become too thick to be removed economically. Large augers are operated from the floor of the surface mine and bore horizontally into the coal face to produce some reserves not otherwise minable. This technique is frequently used to supplement coal recovery from contour mining.

Underground Mining

Underground mining is somewhat more labor-intensive than surface mining and is used to remove coal located too deep for surface mining, but here too, machines are used in most instances to dig, load, and haul the coal. Access to the coal seam is through a drift (horizontal passage), a slope, or a shaft (Fig. 19.5), depending on the location of the coal seam.

A drift mine is one that enters a coal seam exposed at the surface on the side of a hill or mountain. The mine follows the coal horizontally. A slope mine is one where an inclined tunnel is driven through the overlying rock to the coal, with the mined coal removed by conveyors or trucks.

A shaft mine is one where a vertical shaft is dug from the surface to reach the coal, which may be at great depth. The coal is then mined by horizontal entry into the seam, with the recovered coal hoisted to the surface through the vertical shaft.

Two general systems are used in underground mines: room-and-pillar mining and longwall mining.

In room-and-pillar mining, coal removal progresses in a nearly horizontal or low-angle direction by opening multiple stopes or rooms, leaving coal pillars to support the vertical load. This system recovers about 50% of the coal and leaves the mined area looking much like a checkerboard. It is used in areas where the overlying roof rock has geologic characteristics that provide good support. This system was used in old mines, where the coal was hand-dug. Two current methods for extracting the coal from the seam are the conventional method, where the coal is undercut and blasted free, and the continuous method, where a machine with a rotating cutter head moves along the coal face to extract the coal instead of blasting it loose. Roof control is the major problem for room-and-pillar mining. Ninety-eight percent of room-and-pillar mining is by the continuous method.

Longwall mining uses a machine that moves back and forth across the face of the coal seam in large rooms to remove up to 100% of the coal along faces of up to 305 m or more across. As coal is removed, the mining machine moves forward, and the roof is allowed to collapse behind. Coal recovery using this method is greater than in room-and-pillar mining, and the method can be used where roof conditions are fair to poor. Strong roof rock, however, can be a problem, since roof collapse is desired in this type of mining. The seam should be over 1.07 m thick to accommodate the large coal cutter or plow that is used, and a large reserve is necessary. The use of longwall mining has increased significantly in the past several years to the point where it accounts for 30–40% of underground production. Despite the increase in the use of longwall mining, subsidence remains a significant problem. Surface structures can suffer significant damage, and wells and streams can be disrupted.

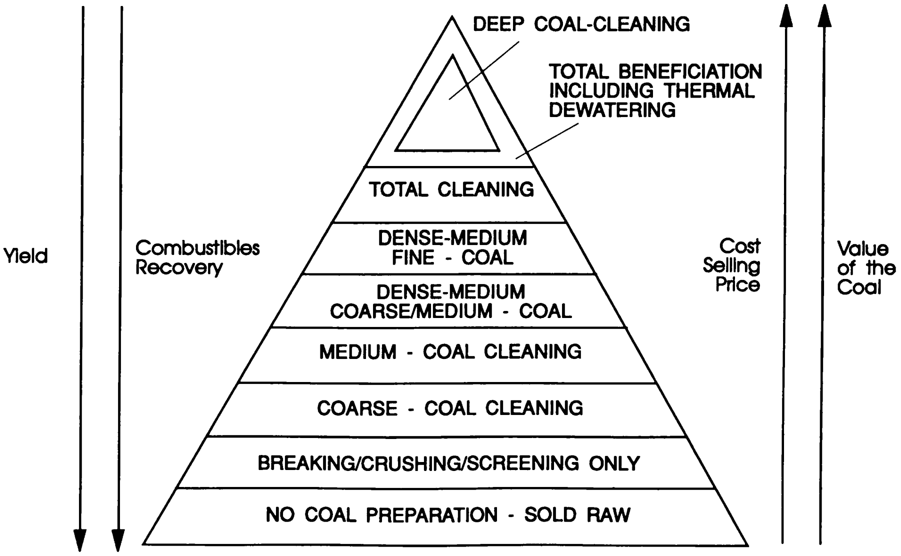

Fig. 19.6 Different levels of coal cleaning and the effect on coal recovery and economics

A modification of this method, using a continuous mining machine on faces up to 46 m long, is known as shortwall mining. It uses the roof support system of self-advancing chocks developed for longwall operations.

Coal Preparation

Coal preparation is a term applied to upgrading coal to make it suitable for a particular use; this includes blending and homogenization, size reduction, and beneficiation or cleaning. It is this last aspect, as well as the degree to which it is required, that most significantly governs the cost of coal preparation. Figure 19.6 shows levels of cleaning in terms of broad categories. Only about one-third of the 3.3 Gt of coal produced worldwide every year is at present cleaned by breaking, crushing, screening, and wet and dry concentrating processes. The purpose of coal cleaning [8, 9] is to remove mineral matter, consisting of rock, slate, pyrite, and other impurities, and to increase the organic content. Coal cleaning typically involves size reduction, particle sizing, cleaning, and dewatering. In general, cleaning processes utilize differences in density or surface properties between the organic and mineral matter in the coal. Depending upon the size of the coal particles being cleaned, cleaning techniques can be divided into three areas: coarse, medium, and fine. The vast majority of the coal cleaned commercially is separated by processes that rely on the density differential of the various components. Technologies that make separations on this basis are particularly effective for treating the coarse to intermediate sizes of coal (i.e., particle sizes ranging from greater than 10 cm to about 0.1–0.5 mm), with efficiency decreasing as particle size decreases. Centrifugal force is often applied to improve separation, particularly for finer particles. Density-based processes are particularly effective in removing pyrite from coal. With very few exceptions, coal cleaning is done using aqueous media. Figure 19.7 shows various coal-cleaning methods and the corresponding size ranges of the coal treated.

The first step in most coal-cleaning operations is size reduction, the main objective being to liberate mineral matter from organic matter. Typically, coal is crushed to 5–10-cm top size, and no grinding is performed. Size reduction equipment ranges from heavy-duty crushers and breakers, capable of crushing lumps up to a meter in size, to coal pulverization equipment, capable of milling coal to a fine powder. Grinding the coal finer liberates more mineral matter, but fine coal is more difficult and expensive to process. The ease with which coal can be ground (coal hardness) is measured in terms of the Hardgrove Grindability Index (HGI) [10]. A high HGI (80) indicates soft, easy to grind coal, and a low HGI (35) indicates difficult-to-grind coal. Details on size reduction can be found in various books on coal preparation [9, 11].

After the coal is crushed, it is generally screened to separate the raw coal into various sizes for cleaning operations. Screening of coal particles above 1.27-cm size usually is carried out dry. Double-deck vibrating screens commonly are used for this purpose. For sizing below 1.27 cm, wet screening is used, employing either high-frequency vibrating screens or the Sieve Bend. Classifying cyclones are used to size coals finer than 100 mesh.

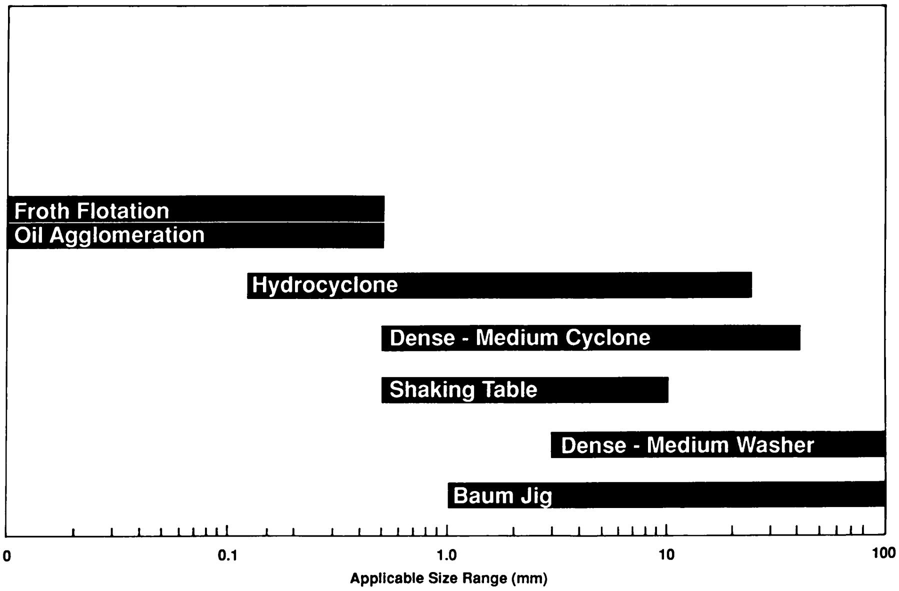

Fig. 19.7 Coal-cleaning equipment in common use in the coal industry with respect to the coal size processed

Coarse-Coal Cleaning

Coarse coal, which is usually the largest weight fraction in the coal feed to the cleaning plant, typically has a size greater than 1.9 cm. Jigging and dense-medium separation are the most frequently used coarse-coal cleaning techniques. In jigging, the separation of coal from mineral matter is accomplished via a fluidized bed created by a pulsating column of water, which produces a stratifying effect on the raw coal. The lighter coal particles rise to the top, overflow at the end of the jig, and are removed as clean product. The denser mineral matter settles and is removed as refuse. Dense-medium separations include processes that clean raw coal by immersing it in a fluid with a density intermediate between the density of clean coal and that of reject mineral matter. Most dense-medium washers use a suspension of fine magnetite in water to achieve a fluid with the desired density. Dense-medium systems are more expensive to install and operate than water-only systems, but their superior performance makes them particularly well suited for cleaning difficult-to-clean coals.

Medium-Coal Cleaning

Medium-size coal, which is usually the second largest weight fraction, includes coal ranging in size from 1.9 cm to 28 mesh (0.5 mm). The principal techniques used for medium-coal cleaning are dense-medium cyclones, hydrocyclones, spirals, and wet concentrating tables. All of these equipment types are widely used in the coal industry, with the dense-medium cyclone being the most efficient and prevalent. In a dense-medium cyclone, a mixture of raw coal and a dense medium (magnetite suspension) enters the cyclone tangentially near the top, producing free-vortex flow. The refuse is discharged through the underflow orifice, and the clean coal is discharged from an axial outlet located at the top of the cyclone. When only water is used in a cyclone for cleaning coal, it is called a hydrocyclone. The spiral separator is usually 2.44–3.05 m in height and consists of a trough going downward in a spiral. The coal slurry is fed in at the top, and, as the slurry follows the spiral down, centrifugal force separates the coal from the denser mineral matter. Wet concentrating tables, also known as shaking tables, work much like the classical miner's pan.

Fine-Coal Cleaning

Coal below 0.5 mm in size, classified as fine coal, typically makes up 5–20% of the feed to the cleaning plant. It is generally processed by methods such as froth flotation, which depend on surface properties. In froth flotation, the fine-coal slurry, to which a small amount of flotation agent (usually fuel oil and a short-chain alcohol, such as methyl isobutylcarbinol) is added, is processed through a flotation cell. In the cell, fine bubbles are generated by using either forced air or suction. The coal, being hydrophobic, attaches to the air bubbles and rises to the top, where it is removed as froth. The refuse, being hydrophilic, remains in the water and is removed from the bottom. The process is effective in recovering high-grade coal at moderate cost.

Conventional mechanical flotation cells have been widely used in the industry for many years and remain the primary means of cleaning coal particles smaller than 100 mesh. These units consist of a number of cells (usually 4–6) connected in series, each cell containing a mechanical agitator and aerator. The feed slurry, pretreated with frother and, usually, collector reagents, passes from one cell to the next with the most floatable coal being recovered in the first cell and the least floatable coal in the last cell.

A newly developed alternative to mechanical flotation cells is column flotation. Column flotation differs from conventional flotation in that columns have a much greater height-to-width ratio and do not require mechanical agitation to induce particle–bubble attachment. Columns are claimed to be more effective than conventional cells for beneficiating finer particles due to better control of bubble size (smaller is better), improved particle–bubble interaction, and froth washing capabilities. There are a number of similar column processes, with each possessing one or more unique technological advances. Among the most significant of these are Microcel™, Kenflote™, Flotaire, and the packed column. The Jameson Cell differs from other columns in that particle–bubble contact is achieved in a downcomer tube, where air and feed mixing occurs in a venturi-type system, rather than in the slurry column itself. The Microcel™ has been applied commercially for the recovery of fines from both freshly mined coal and refuse ponds and has also realized significant applications in the mineral industry.

In addition, improved separation of fine particles has resulted from recent advances in density-based separation techniques. This includes the development of several new water-only devices, such as various concentrating spirals, the Kelsey Jig, the Multi-Gravity Separator, the Falcon Concentrator, and the Knelson Concentrator. The development of advanced ultrafine dense-medium systems, such as Carefree Coal™ and MicroMag, also has the potential to improve cleaning of coal fines. However, none of these processes have yet achieved any significant degree of commercialization.

Oil agglomeration, a process that utilizes oil, or a similar hydrocarbon, to agglomerate coal and leave mineral matter in aqueous suspension, has been tested on pilot and commercial scales. Other processes (high-gradient magnetic and electrostatic cleaning) utilize differences in magnetic and electric charge properties of the mineral matter present in coal. None of these processes have achieved significant commercial success.

Conventional mechanical dewatering devices, such as vibrating screens and vibrating basket centrifuges, are effective in dewatering coarse and medium coal to moisture levels of less than 5%. Vibrating and high-speed vibrating screens are typically used to dewater coal larger than about 0.98 cm. For coal in the 0.98-cm × 30-mesh size range, vibrating basket centrifuges have proven to be highly effective and are widely used throughout industry.

One of the biggest problems in processing fine coal is dewatering and drying. Fine-coal dewatering is one of the most costly operations in the coal-cleaning plant, and, therefore, a significant number of operators bypass this operation by discarding coal fines directly to their waste slurry impoundments. Although these impoundments create a tremendous environmental liability and represent a loss of valuable coal resources, they still are widely used with an estimated 30–50 Mt of coal being added to ponds each year. Abandoned and active ponds in the United States are estimated to contain 2–3 Gt of coal.

Vacuum filtration and screen-bowl centrifuges are the principal unit operations used for mechanical dewatering of fine coal. Pressure filtration (plate and frame filter presses and continuous belt filter presses) is used to a much lesser extent to dewater fine coal and refuse. Sedimentation devices (thickeners, including conventional, high-rate, and multiplate units) are widely used to provide clarified water for recycle back to the plant and to preconcentrate dilute slurries (usually refuse fines) prior to dewatering or disposal. Thickener operation almost always requires the use of flocculants (primarily synthetic polymers or, to a lesser extent, modified starches) to promote particle settling.

The use of screen-bowl centrifuges has increased significantly in popularity to the point where now they are the predominant method for dewatering fine coal. Compared with vacuum filters, these units provide lower operating costs and increased moisture reductions; however, typically 10–15% of the coal entering the unit is lost to the effluent. These units typically produce filter cakes in the range of 15–20% moisture. Solid-bowl centrifuges occasionally are used on very fine coal, where coal losses using screen-bowl centrifuges would be excessive.

The primary form of vacuum filtration is the rotary-disk vacuum filter, which consists of multiple vertical disks, connected by a horizontal hollow shaft, that are partially submerged in open tanks containing the slurry to be dewatered. A vacuum is applied to the portion of the disk that is submerged to draw slurry toward the filter medium supported by the disk to form a filter cake on the surface of the filter as water passes through. As the disk rotates out of the slurry, the filter cake is dried by the continuing vacuum action, and a final product is produced by pressurized air blowback and mechanical scrapers. Flocculating agents may be added to the slurry prior to filtration to improve dewatering performance. These systems typically produce final product moistures in the range of 20–30% depending on the percentage of −200-mesh material in the feed.

Filtration devices that utilize high-pressure forces are capable of reducing moisture in the filter cake to about 20%, but capital and operating costs are high for these devices. Other newly developed techniques that have been tested on a pilot scale include an ultrahigh-g centrifuge, which generates forces up to 4,000 × *g*, and an electro-acoustic technique that utilizes the synergistic effect of electric, ultrasonic, mechanical, and surface chemical forces to remove moisture from the cake.

Chemical Coal Cleaning

Chemical cleaning processes utilize alkali or acid to leach out the impurities present in coal. Chemical methods are effective in removing both organic and pyritic sulfur. For example, the Molten Caustic Leaching Process is quite effective in its ability to remove both organic and pyritic sulfur, mineral matter, and trace elements from coal [12]. The process consists of treating coal with molten caustic (usually a eutectic mixture of sodium and potassium hydroxides) at 350–400°C for up to 4 h. The treated coal is washed with water and dilute acid to give a low-ash, low-sulfur product. The major drawbacks of chemical cleaning processes are economics and the need to use corrosive materials. The optimum coal desulfurization scheme may include both physical and chemical treatment.

Coal Utilization

The vast majority of the coal produced is burned to generate heat and power. The next most important use is for the production of metallurgical coke. Other uses are for the production of synthetic fuels for transportation and energy production, and as a raw material for the production of chemicals [13]. A unique feature of coal utilization is that, with a few exceptions such as Japan and Australia, the use of coal occurs in the country where it is produced (Fig. 19.8) [14]. This section discusses the technologies involved in these uses of coal.

Environmental Concerns Related to Coal Use

As discussed earlier, coal contains many of the elements in the periodic table, at least in trace amounts, and, during processing and/or combustion, these elements or their compounds can be released into the environment. Some of these harmful pollutants that can result from coal use are sulfur and nitrogen oxides, particulates, hydrogen chloride, mercury vapor, and a wide range of trace metals. In addition, most uses of coal result in the production of CO_2 which is considered the most important greenhouse gas from the point of view of the quantity in the atmosphere. At the same time, CO_2 is the feedstock for plant growth—a feature crucial to animal life. While CO_2 receives much attention because of the potential for global warming, there does not seem to be a direct relationship between the content of CO_2 in the atmosphere and the average surface temperature of the earth during the last 60 years (Fig. 19.9). As seen in Fig. 19.9, between 1940 and 1980, the temperature remained essentially constant, while the CO_2 concentration was increasing; then following 1980, the temperature rapidly increased, while the CO_2 concentration followed its steady increase. Thus, during this period, there is no direct relationship between the temperature of the lower atmosphere and the concentration of CO_2. In fact, a projection of the 1910–1950 period temperature increase leads to a projected temperature that is slightly higher than was actually reached.

Table 19.5 Summary of direct combustion coal process (Smoot)

Process type	Description	Extent of coal use in the United States (% of total used)	Commercial use	Scale size (TPD)[a]	Coal types	Coal size
Power station	Commercial electricity production	78–80				
Pulverized	Rapid burning of finely grained goal		Common	1,000–10,000	All	0.01–0.025 mm
Fluidized bed[b]	Well-stirred combustion		Pilot plant	2,000–8,000	All	0.15–0.6 cm
Stoker	Mechanically fed fixed bed		Small	100	Noncaking	1–5 cm
MHD	Combustion energy capture by magnetic fields		Laboratory	800–4,000		
Coal/oil mixture (COM)	Burning coal/oil mixtures in oil furnaces		Demonstration			
Industrial heat/steam	Industrial plant power	8–11				
Pulverized			Small	1–100		
Fluidized bed			Pilot	1–100	Same as above	
Stoker			Common	1–100		
COM			Demonstration	1–100		
Domestic/commercial	Hand-stoked space heating	1		0.005–0.05	Noncaking	3–10 cm
Transportation	Fuel for railroads	0.01–0.02		0.1–1	Noncaking

[a] TPD = t/day

[b] Very adaptable, exhibits high heat transfer in bed as well as low-level pollutant products

Combustion

In the United States, approximately 90% of the coal consumed annually is burned in boilers to generate steam [15–17] to run turbines for electric power production. The burning of coal in small-scale combustion devices for direct heating is more significant outside the United States, so that, on a worldwide basis, about 55% of the coal produced is used for electricity generation.

Combustion Equipment

A summary of the most important direct combustion processes for coal is given in Table 19.5. Options for firing industrial and electric utility boilers are stokers, pulverized-coal-fired burners, and cyclone burners, the choice depending on the kind of coal and the amount of steam needed. Table 19.6 lists the types of coal that can be burned with the various combustion systems. Although good results usually will be obtained with the indicated coal and firing equipment, this table should be used only as a rough guide, and final equipment selection should be based on a sound engineering analysis.

Table 19.6 Suitability of various combustion systems for various coals

Fuel	Under feed	Stokers traveling or chain gate	Spreader	Pulverized-coal burner	Cyclone burner
Anthracite		X		X	
Bituminous					
17–25% volatile	X		X	X	X
23–35% volatile				X	X
Strongly coking	X	X	X	X	X
Weakly coking		X	X	X	X
Lignite		X	X	X	X

Electric utility and large industrial plants favor pulverized-coal-fired and cyclone-fired furnaces because of their inherent capability to effectively burn a range of coal types with varying qualities, their comparatively high availability, their quick response to load changes, and their extremely large steam-generating capacity. Large units can generate as much as 9.5 million pounds of steam per hour at 3,500 psig and 1,000°F. Smaller industrial installations typically favor stoker firing.

Stoker Firing. Stokers have been in operation for more than 150 years and are still used to fire small-capacity boilers, generally for steam production. There are several types of stokers, which are classified by the method of coal feeding and the relative flow directions of the fuel and air. The three main types are underfeed, crossfeed, and overfeed. Both fuel and air flow in the same direction in retort stokers; this arrangement is called underfeed burning. The fuel moves across the air direction in chain- or traveling-grate stokers; this design is called crossfeed burning. The spreader stoker approximates overfeed burning, the incoming fuel moving toward the air. Except for certain types of coal gasifiers, in which lump coal moves downward toward a grate against air (or oxygen and steam) coming through the grate, no conventional combustion system operates purely in the overfeed mode. Table 19.7 gives the approximate capacity range for each type of stoker.

An example of a crossfeed chain-grate stoker being used to heat a fire-tube boiler is given in Fig. 19.10. This stoker consists of an endless track of grate bars that pass over rotating sprockets at each end, similar to a conveyor belt. Coal is fed onto one end of the grate, using a hopper, to a depth of about 5 in. The coal burns as it moves along the grate, and, at the far end of the grate, only ash remains. The ignition of the coal is assisted by radiant heat from a refractory lining.

Table 19.7 Approximate capacity range of stokers

Type	Steam production (1,000 lb/h)	Grate heat release (1,000 BTU/ht/ft^2) (max)
Single retort	5–50	200
Multiple retort	40–300	300
Traveling or chain grate	10–300	300
Spreader	10–300	1,000

Pulverized-Coal Firing. The burner and furnace configurations for the main types of pulverized-coal firing (often called suspension firing) are shown in Fig. 19.11. There are some design variations among various vertical, impact, and horizontal suspension firing systems, but these schematic drawings serve to illustrate the general principles.

Coal-fired boilers are further differentiated by the operating model, either dry-bottom or wet-bottom (slagging), depending on whether the ash leaves the boiler as a solid or as a liquid. Most modern pulverized-coal-fired boilers are of the dry-bottom type, in which the ash is cooled before contacting any surface [18]. Wet-bottom firing provides a more convenient method of ash removal and disposal but has several disadvantages, including less flexibility in fuel selection, higher incidence of fouling and corrosion, and higher levels of NO_2 formation, that have led to its virtual elimination in the United States [19].

The first suspension-fired furnace in the United States was designed like the one shown for vertical firing in Fig. 19.11. Pulverized coal (about 70% through a 200-mesh screen) is transported to the burner with primary air, amounting to about 20% of the total air needed for complete combustion. The balance of the air, known as secondary air, is admitted through openings in the furnace wall. Because a large percentage of the total combustion air is withheld from the fuel stream until it projects well down into the furnace, ignition stability is good. This type of firing is well suited for coals that are difficult to ignite, such as those with less than 15% volatile matter. Although no longer used in central-station power plants, this design, with delayed admission of secondary air, may find favor again if low-volatile chars from various coal-conversion processes become available for burning for heat and power.

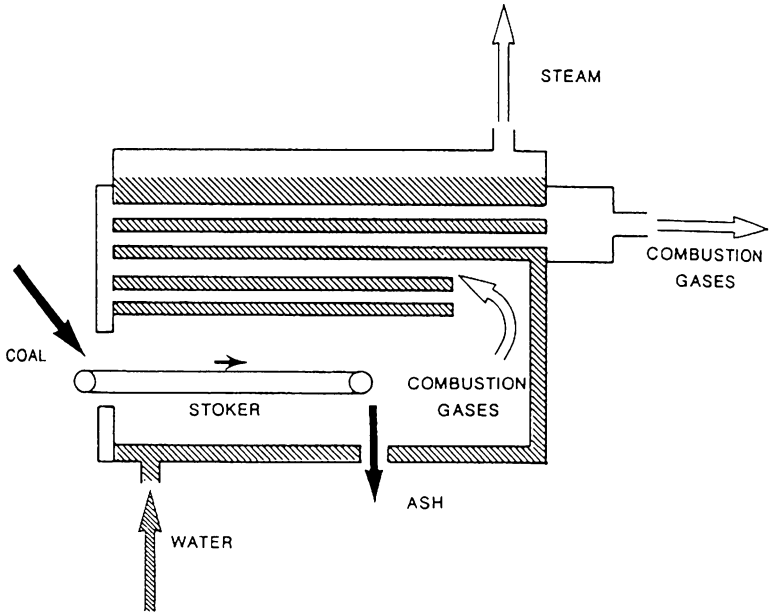

Fig. 19.10 Example of a chain-grate stoker equipped with a fire-tube boiler (reprinted with permission from Schobert [35], Copyright 1987, American Chemical Society)

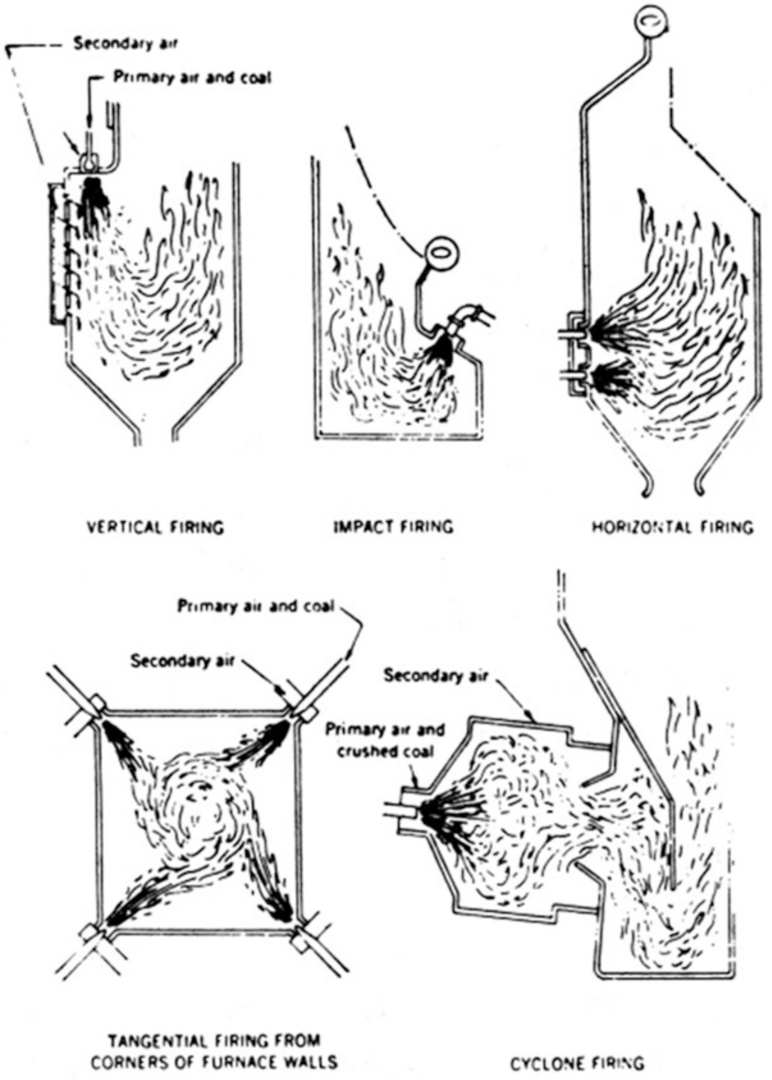

Fig. 19.11 Methods of firing pulverized and crushed coal (Courtesy of Bureau of Mines)

The other types of suspension firing use burners in which the primary air, coal, and secondary air are mixed just before or immediately after entering the furnace. With tangential firing, the burners are arranged in vertical banks at each corner of a square, or nearly square, furnace and directed tangentially toward an imaginary circle in the center of the furnace. This produces a vortex with its axis along the vertical centerline. The burners consist of an arrangement of slots, one above the other, admitting through alternate slots the primary air–fuel mixture and secondary air. The burners can be tilted upward or downward 30° from the horizontal plane, enabling the operator to control superheat and to permit selective utilization furnace heat-adsorbing surfaces. In tangential firing, the turbulence needed for mixing the fuel and air is generated in the furnace instead of in the burners.

The other major type of pulverized-coal-fired boiler is the wall-fired boiler. In wall-fired units, instead of being mounted in the corners, the burners are mounted on the walls of the furnace. They may be mounted on only one wall, or they may be mounted on opposing walls. The burners typically are mounted in a grid pattern.

Cyclone Firing. Cyclone firing is a form of two-stage wet-bottom firing in which the coal is not pulverized, as for suspension firing, but is crushed to 4-mesh size and admitted tangentially with primary air to a water-cooled cylindrical chamber called a cyclone furnace, as shown in Fig. 19.11. The finer particles burn in suspension, while the coarser ones are thrown by centrifugal force to the furnace wall. The wall, having a sticky coating of molten slag, retains the coal particles until they complete combustion. Secondary air, which is admitted tangentially along the top of the furnace, completes the combustion of the coarse particles. Slag drains continuously into the main furnace and through a tap hole into a water-filled slag tank, where it solidifies. The main advantage of cyclone firing is the ability to use larger coal particles. However, being a wet-bottom technique, it suffers from the disadvantages discussed above. In particular, the high temperature required to melt the slag results in high NO_x production.

Fluidized-Bed Combustion (*FBC*). In the past 30 years, FBC has advanced from the laboratory and pilot-plant scale to commercial status. A fluidized-bed combustor consists of a vessel containing a granular material, such as sand, coal ash, or limestone. This bed is fluidized by blowing air up through it. Fuel particles are injected into the bed and burn as they contact the oxygen in the air. Well-balanced air and fuel flow at the burner is needed to get the highest performance from existing and new low-NO_x firing systems. Developments to measure the air and fuel distribution continuously at the burners are the backbone for automated systems which constantly monitor and adjust the stoichiometry at the burners [20]. As ash particles agglomerate, they sink to the bottom of the bed and are removed. Fluidized-bed combustors are very flexible with respect to the fuel that can be burned, and almost any carbonaceous material that can be injected into the bed can be used. Steam tubes are generally immersed in the bed, where the heat-transfer coefficient is high.

Although this technology is not yet widely used in the electric power industry, the potential advantages are clear. (1) The bed temperature is low, about 840°C, which means less formation of NO_x and the retention of some of the sulfur in the ash of certain coals. (Adding dolomite or limestone to the bed greatly improves sulfur retention.) Of equal importance is less volatilization of sodium and potassium in the coal; consequently, there are fewer deposits on, and corrosion of, the furnace, superheater, and reheater tubes. (2) Heat-transfer rates from the fluidized-bed to the immersed heat-transfer surfaces are relatively high, as much as 100 BTU (hr $ft^{2\circ}F$). (3) Temperature control is easier, because rapid mixing in the bed results in a relatively uniform bed temperature. (4) FBC has the capability to burn many kinds of coal and is less sensitive to changes in coal heating value or ash characteristics than other combustion methods. (5) FBC is adaptable to several kinds of power generation cycles (e.g., cogeneration or combined cycle), can operate at atmospheric or elevated pressure, and can use bubbling or circulating beds with in-bed or external heat exchangers. This versatility allows engineers to develop FBC systems that are tailored to specific applications. This can result in significant cost savings when compared with other technologies.

The application of fluidized-bed boilers to electric utility stations should reduce operating costs and increase efficiency compared with conventional pulverized-coal-fired plants of the same capacity equipped with emission controls. The principle of the fluidized-bed combustor is illustrated schematically in Fig. 19.12.

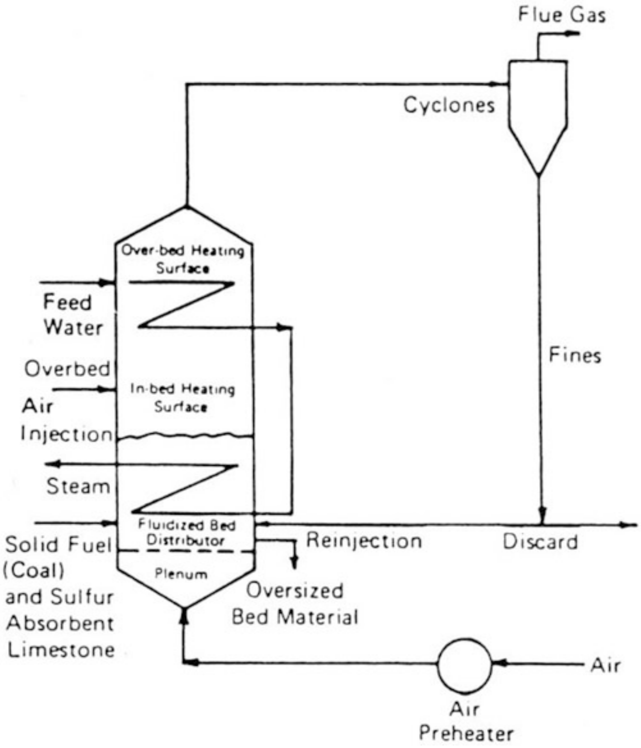

Fig. 19.12 Basic components of a fluidized-bed combustor (Shang YJ, Department of Energy, Morgantown, WV)

Interest is increasing in running units at elevated pressures (6–15 atm) in order to reduce equipment size, lower emissions, reduce sorbent requirements, and increase the thermal efficiency by using a gas turbine in addition to a steam turbine in a combined cycle. There is also a trend away from bubbling beds and toward circulating beds, which use finer solids and higher velocities and are able to use sorbents more efficiently.

Several large demonstrations of FBC technology for electric power generation have proven the viability of this technology. These include the 110-MW(e) atmospheric pressure circulating fluidized-bed boiler at the Colorado-Ute Electric Association's Nucla Station, which began operation in August 1988. In 2002, the JEA utility declared their two atmospheric fluidized-bed systems fully operational to generate 350 MW(e). A second project is the American Electric Power Tidd 70-MW(e) pressurized fluidized-bed combustor/combined-cycle demonstration, which began generating power in December 1990. These projects were partly funded by DOE's Clean Coal Technology program [21].

The Tidd plant utilized a nearly stationary bubbling bed technology (a first-generation technology) with a heat exchanger immersed in the bed to generate steam. The flue gas is utilized in a rugged gas turbine to generate additional electricity. A second-generation technology utilizes a circulating fluid bed that introduces a number of efficiency

Table 19.8 Approximate range of capacities of various types of industrial and utility boilers

Type	Capacity (lb steam/h)	Maximum design pressure (psig)
Fire tube (HRT)	1,000–15,000	250
Water tube		
Straight	15,000–150,000	2,000
Bent, three drum, low head	1,000–35,000	400
Two-drum vertical	1,000–350,000	1,000
Electric utility	Up to 9,000,000	3,500

enhancements. A major efficiency enhancing measure is the integration of a coal gasifier (carbonizer) to produce fuel gas. This fuel gas is combusted and adds to the combustor's flue gas energy fed to the gas turbine. While this adds complexity, it offers opportunity to improve efficiency.

Boiler Types

Industrial and utility boilers are broadly classified as fire tube or water tube. In fire-tube boilers, the hot combustion gases pass through tubes, and heat is transferred to water outside the tubes. Most steam locomotives had this type of boiler. The most common and least expensive boiler of this type is the horizontal return tubular (HRT) boiler. However, because of the design and construction of fire-tube boilers, there is a definite limitation to their size and the pressure that they can tolerate.

Water-tube boilers may be broadly classified as straight-tube and bent-tube types; the latter have several variations in design and are preferred for applications where higher capacities and steam pressures are required. In both types, heat is transferred by radiation or convection to the outside of the tubes, and water flows inside the tubes as a result of thermal circulation, or in the case of certain bent-tube boilers, as the result of forced circulation. A comparatively new version of the forced-circulation, bent-tube boiler for central-station power plants is the "once-through" type. The feed-water passes progressively through the heating, evaporation, and superheater sections; no drum is used for separating steam from unvaporized water as in other boilers, so the ratio of water circulated in the boiler to steam generated is unity. Table 19.8 presents approximate ranges of steam capacity and pressure for the principal types of boilers.

Combustion Going Forward

Unless some means of reducing CO_2 emissions is developed, generating electricity by coal combustion will be declining [22]. Existing US coal plants (over 600) have been listed, and some projections of their future have been made [23, 24]. Geisbrecht and Dipietro [25] have evaluated options for US coal-fired power plants and concluded that while retrofitting or repowering offers hope, the impact will depend on the extent to which efficiency and other cost factors can be collectively upgraded. The average efficiency of all coal power stations in the world currently is around 31%, and this leaves much potential to reduce coal consumption and CO_2 emissions [26]. Roberts and Goudarzi [27] concluded that an 8% improvement in the heat rate could be achieved if all coal generating units could reach the average thermal conversion performance of the 274 most efficient generating units.

Pollution Controls

Coal combustion is drawing increasing scrutiny because of concerns over coal's contribution to several environmental problems: acid rain (from oxides of sulfur and nitrogen), global warming (from CO_2), and particulates and trace elements (from ash) [28]. Despite increasingly stringent environmental regulations, coal is likely to remain in plants in the United States and many other countries [29]. The amount of coal burned is likely to increase steadily in developing countries like China and India. The combustion of coal is also important in a number of eastern European economies, such as Poland. Consequently, there is a strong impetus for developing highly efficient clean coal technologies. Achieving significant reduction of SO_2 and NO_x emissions from coal combustion is a major goal of the 1990 Clean Air Act Amendments. The achievement of these goals has been assisted by a US DOE effort known as the Clean Coal Technology program, which has provided government funding for a range of advanced pre- and post-combustion technologies to mitigate environmental problems.

Emissions of sulfur oxides, nitrogen oxides, and particulates from coal combustion are problems of increasing concern and regulation. Coal combustion contributes about 25% of the particulate matter, 25% of the sulfur oxides, and 5% of the nitrogen oxides emitted to the atmosphere. Much of the particulates are derived from the mineral content of the coal, but some particulates also result from sulfur and nitrogen oxides that react to form various sulfate and nitrate salts. A major concern about particulate matter is that the smallest particles are respirable and may pose a health hazard. Particulate matter is recovered in most power plants by the use of electrostatic precipitators, which have been developed to very high efficiencies (>99%). Other methods of particulate removal include baghouses and cyclone collectors.

An important technology for removal of SO_2 is flue gas desulfurization (FGD), carried out in units known as scrubbers. Most scrubbers contact the flue gas with a slurry of lime or limestone to capture the sulfur oxides and produce a sludge containing calcium sulfite and calcium sulfate. However, disposal of sludge is another environmental problem, and some scrubbers include oxidation to convert all the calcium sulfite to sulfate (gypsum), which can be used for wallboard manufacture. FBC units add a sulfur capture agent, such as limestone, to the bed, and integrated gasification combined cycle (IGCC) systems convert the sulfur in the coal to hydrogen sulfide, which can be removed easily from the fuel gas stream before it is burned.

Most of the NO_x emitted from coal combustion is in the form of nitric oxide (NO). Some of the NO_x originates from oxidation of nitrogen in the coal, and the rest comes from the reaction of nitrogen and oxygen in the combustion air. Consequently, partial control of NO_x can be achieved by changing the conditions of the combustion process. This usually involves the use of staged combustion, in which coal is first burned at fuel-rich conditions. Staged combustion decreases NO_x by lowering both oxygen concentration and temperature during combustion. So-called low-NO_x burners have been developed that can be retrofitted to most utility boilers to reduce NO_x emissions.

Other techniques that have been developed to reduce NO_x emissions involve post-combustion operations, such as reburning, selective noncatalytic reduction (SNCR), and selective catalytic reduction (SCR). In reburning, additional fuel (natural gas, oil, or pulverized coal) is added to the combustion gases downstream of the main combustion to result in fuel-rich, reducing conditions, which convert NO_x into nitrogen and water. Overfire air is then added to complete combustion, but because of the lower temperature, additional NO_x is not formed. In SNCR, ammonia or urea is injected into the furnace to react with NO_x and form N_2. For SNCR to be effective, the flue gas, after urea or ammonia injection, must spend a minimum residence time within a specific temperature range. In SCR, ammonia is injected into the flue gas, which then passes over a catalyst where reduction of NO_x to N_2 occurs. SCR is used extensively in Japan and Germany, and, because of decreasing costs, its use in the United States is steadily increasing. SCR is attractive because it can remove upward of 90% of the NO_x. Fluidized-bed combustors, in which combustion occurs at a lower temperature than in PC-fired furnaces, generally produce less NO_x.

Another pollutant which is coming under increasing scrutiny is mercury [30, 31]. Coal contains trace amounts of mercury (an average of about 0.1 ppm) which, because of its high volatility, is released into the atmosphere when the coal is burned. Approximately 50 t/year of mercury is released by power plants. Although coal cleaning can reduce the mercury content of coal, it will prove difficult to achieve complete removal. Therefore, post-combustion technology is the most probable approach to controlling mercury emissions. Possible technologies include adsorbents and scrubbers. Scrubbers are already used at many power plants to remove SO_2 from the flue gas, and many of these scrubbers have been found to remove a significant fraction of the mercury. One adsorbent that has been used effectively is activated carbon. The EPA is under mandate to develop regulations that may require removal of up to 90% of mercury emissions, and much progress has been made to accomplish this.

Pollution

Finally, the impact of CO_2 on the environment must be taken into account. This involves two issues for coal combustion: capture and sequestration [32]. The cost of carbon capture is not a simple issue, but it appears that carbon capture is less expensive for IGCC than for supercritical power coal (SCPC) plants (Fig. 19.13). The work to define the cost and evaluate the effectiveness of several approaches for sequestration is in its infancy; however, the data generated during decades of using CO_2 for enhanced oil recovery provides an excellent start in this direction [33].

Advances in Combustion Technology

Because of improvements in steam-generating equipment and turbines, remarkable advances have been made in the energy efficiency of electric utility plants. One method of expressing the efficiency of the conversion of coal to electricity is the heat rate, which is the amount of heat energy required to generate 1 kWh of electricity [34]. The heat rate of a modern, well-maintained plant in today is less than 9,000 BTU/kWh, compared with an average value of 17,500 BTU/kWh in 1937 and 10,000 BTU/kWh in 1968. However, the age of US plants causes US plants to have a rating of about 10,000 BTU/kWh. Some new designs project heat rates close to 7,500 BTU/kWh, corresponding to an overall thermal efficiency of 45% [35].

Further improvements in thermal efficiency may be achieved with new power generation systems now being developed. One promising technology is IGCC, in which both a gas turbine and a steam turbine are used to generate electricity. In this concept, the coal is first gasified to produce fuel gas (consisting mainly of CO and H_2, with small amounts of methane and other gases), which is cleaned of H_2S, NH_3, HCl, and particulates and then burned in a gas turbine. The hot exhaust gases from the gas turbine are used to generate steam that drives a steam turbine [36]. An important advantage is that the thermal efficiency of a combined-cycle plant exceeds 40%, whereas that of a conventional pulverized-coal-fired boiler equipped with FGD is

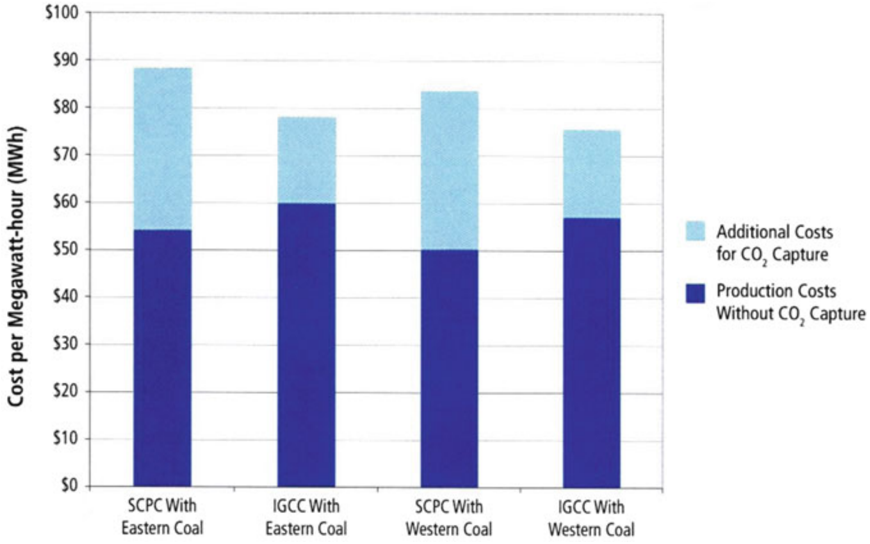

Fig. 19.13 Costs of electricity production from IGCC and SCPC with and without carbon capture technology [32]

about 35%. The development of more advanced gas turbines, capable of operating at higher gas inlet temperatures, will significantly increase the efficiency advantage of combined-cycle plants. IGCC is discussed in more detail later in this chapter in the section "Gasification."

Combined-cycle plants require clean fuel gas for the gas turbine. To maximize efficiency, gas cleanup should be carried out at high temperature. Removing trace amounts of impurities from the gasifier effluent without cooling the gas stream presents a technical challenge. An advantage of combined-cycle plants is that, because of fuel gas volume, pollutant removal equipment can be much smaller. Also, the sulfur and nitrogen are in forms that are more easily removed. Another advantage is the modular nature of combined-cycle plants, which offers flexibility in construction and the ability to add capacity in increments. The feasibility of combined-cycle plants is being demonstrated in two of DOE's Clean Coal Technology programs, the Tampa Electric Company IGCC Project and the Wabash River Coal Gasification Repowering Project. These plants are recognized as being two of the cleanest coal-fired power plants in the world.

The use of coal slurries, either coal–oil mixtures (COM) or coal–water mixtures (CWM), has been the subject of considerable research because of the potential to replace fuel oil in boilers. Recent work has shifted in favor of CWM over COM, as the cost savings for the latter were not enough to offset conversion costs. CWM is typically composed of 60–75% coal, 24–39% water, and 1% chemical additives. The advantages of CWM compared with dry pulverized fuel are the case and safety of handling, transporting (e.g., via pipeline), and injecting the fuel. It is possible that the manufacture of CWM can be integrated into coal beneficiation processes, such as froth flotation. Potential problems from replacing oil with CWM are (1) limited flame stability and turndown, (2) incomplete combustion, and (3) slagging and fouling caused by inorganic constituents. This technology is still in the development stage. Several demonstration projects have been completed or are under way, with the primary focus being on utilization of waste coal fines from coal-cleaning operations.

Chemical Looping

Chemical-looping combustion (CLC), first proposed as a method of improving power plant efficiency, is presently being studied for its potential for carbon capture. Still at an early stage of development [37], it may be used for either combustion [38] or gasification [39]. The concept is simple, but there are many impediments to be overcome before it becomes a commercial process. Two reactors are utilized with the oxidized and reduced solid, the oxygen carrier, being transported between the reactors as illustrated in Fig. 19.14. The fuel is mixed with the oxidized solid in the fuel reactor, where the fuel is oxidized to water and CO or CO_2, depending upon whether the process is combustion or gasification. In the air reactor, the reduced form of the solid that is generated in and transported from the fuel reactor is oxidized to produce CO_2 and water, together with the oxidized form of the catalyst. This process therefore allows CO_2 to be captured by condensing the water, and not from a dilute concentration in nitrogen, as is the case with normal combustion.

There are many problems to overcome. The circulation of the solid as well as the many oxidation–reduction cycles it undergoes can present severe attrition problems as well as significant losses of surface area. The final evaluation of this process is years into the future.

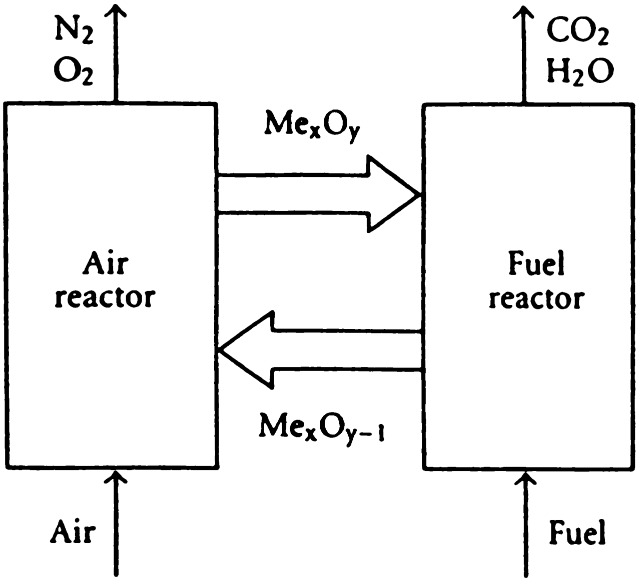

Fig. 19.14 Chemical-looping combustion (CLC)

Coke Production

The production of metals frequently requires the reduction of oxide-containing ores, the most important being production of iron from various iron oxide ores. Carbon in the form of coke is often used as the reducing agent in a blast furnace, which is basically a vertical tubular vessel to the top of which is fed alternate layers of iron ore, coke, and limestone. Coke is the porous residual solid remaining after a coal's volatile matter is released at high temperature. Coal cannot be fed directly at the top of a blast furnace, because it does not have the structural strength to support the column of iron ore and limestone in the furnace while maintaining sufficient porosity for the air blast to pass upward through the furnace.

Not all coals can produce coke that is suitable for use in a blast furnace. The property that distinguishes coking coals is their caking ability. Various tests such as maceral analysis, free-swelling index, and chemical analysis are performed to identify suitable coals. Frequently, to achieve the necessary coal properties to produce a suitable coke, several coals are blended to generate the feed to the coke plant. Commercial cokemaking processes can be divided into two categories: nonrecovery cokemaking and by-product cokemaking.

Combustion Future

A baseline performance and cost estimate for today's fossil energy plants was established [40]. This baseline can be used to benchmark the progress of energy progress. The study provided an accurate and independent assessment of the cost and performance of pulverized-coal (PC) combustion, IGCC and natural gas combined cycles with and without carbon capture and sequestration assuming the plants use the technology available in 2010. They also reviewed the current and future technologies for gasification-based power generation [41].

Nonrecovery Cokemaking

In nonrecovery coke plants, the volatile components released during cokemaking are not recovered, but rather are burned to produce heat for the coke oven and for auxiliary power production. One of the earliest nonrecovery units was the beehive oven, which for many years produced most of the coke used by the iron and steel industry. With these ovens, none of the by-products produced during coking were recovered.

A beehive oven consists of an old-fashioned beehive-shaped brick chamber. It has a charging hole in the top of the dome and a discharging hole in the oven's wall near the bottom. Coal is charged through the opening in the top and spreads over the oven floor. Retained heat from the previous charge is sufficient to start devolatilization. Evolved gases mix with air entering through the discharge door and burn, with the combustion products exiting through the charging port in the top. The heat generated by the burning gases is sufficient to complete the coking process. The finished coke is removed through the discharge door. Because of their low efficiency and pollution problems, beehive ovens are no longer used in the United States.

The general principle of operation of modern nonrecovery coke plants is the same as for the beehive oven, except that the units are designed to prevent the escape of volatile organic compounds (VOCs) and other pollutants to the atmosphere. Coking takes place in large rectangular chambers that are heated from the top by radiant heat transfer and from the bottom by conduction through the floor. Primary air for the combustion of evolved volatiles is introduced through several ports located above the charge level. Combustion gases exit the chamber through downcomers in the oven walls and enter the floor flue, thereby heating the floor of the oven. Combustion gases from all the chambers collect in a common tunnel and exit via a stack that creates a natural draft for the oven. To improve efficiency, a waste heat boiler can be added before the stack to recover waste heat and generate steam for power production.

At the completion of the coking process, the doors of the chamber are opened, and a ram pushes the hot coke (approximately 2,000°F) into a quench car, where it is typically cooled by spraying it with water. The coke is then screened and transported to the blast furnace.

By-Product Coke Production

The majority of coke produced in the United States comes from wet-charge, by-product coke-oven batteries. By-product cokemaking consists of the following operations: (1) selected coals are blended, pulverized, and oiled for bulk density control; (2) the blended coal is charged to a number of slot-type ovens, each oven sharing a common heating flue with the adjacent oven; (3) the coal is carbonized in a reducing atmosphere with the off-gas being collected and sent to the by-product plant for by-product recovery; and (4) the hot coke is discharged, quenched, and shipped to the blast furnace.

After the coke oven is charged with coal, heat is transferred from the heated brick walls to the coal charge. In the temperature range from 375°C to 475°C, the coal decomposes to form a plastic layer near the walls. From 475°C to 600°C, there is marked evolution of aromatic hydrocarbons and tar, followed by resolidification into semicoke. At 600–1,100°C, coke stabilization occurs, characterized by contraction of the coke mass, structural development of coke, and final hydrogen evolution. As time progresses, the plastic phase moves from the walls to the center of the oven. Some gas is trapped in the plastic mass, giving the coke its porous character. When coking is complete, the incandescent coke mass is pushed from the oven and wet or dry quenched prior to being sent to the blast furnace. Modern coke ovens trap the emissions released during coke pushing and quenching, so that air pollution is at a minimum.

By-Product Recovery. Coke-oven gas is released during the coking process. A typical composition for raw coke-oven gas is given in Table 19.9. In addition to the components shown in the table, raw coke-oven gas also contains various chemicals, such as tar vapors, light oil vapors (mainly benzene, toluene, and xylene), naphthalene, ammonia, hydrogen sulfide, and hydrogen cyanide. The by-product plant removes these chemicals so that the gas can be used as fuel. The volatiles emitted during the coking process are recovered as four major by-products: clean coke-oven gas, coal tar, ammonium sulfate, and light oil. The following description represents a typical coke-oven gas cleanup scheme, but considerable variations are possible from plant to plant.

Tar is the first by-product recovered. Hot coke-oven gas at a temperature of about 1,100°C is quenched to about 80°C by contact with an aqueous spray (flushing liquor) in the primary cooler. The cooled gas, along with excess flushing liquor, is collected in the coke-oven battery gas-collecting main. The condensed tars and water are transported to a tar decanter, where the heavier tars are separated out, and the water is recycled to a primary cooler. The gas passes through a compressor, called the exhauster, which sucks the gas from the ovens and provides sufficient pressure to allow the gas to flow through the rest of the by-product train. During cooling of the coke-oven gas, some of the tar forms an aerosol, which is carried along with the gas. Because these tar droplets would contaminate and foul downstream equipment, the tar mist is removed in an electrostatic precipitator. The recovered tar is pumped to the tar decanter.

Table 19.9 Composition of coke-oven gas

Component	Composition (vol. % (dry))
Hydrogen	54
Methane	25
Nitrogen	10
Carbon monoxide	6
Carbon dioxide	3
Higher hydrocarbons (ethane, propane, etc.)	2

Ammonia removal is the next step in the gas cleanup process. A typical approach is to contact the coke-oven gas with a solution of sulfuric acid to form ammonium sulfate, which is then recovered by crystallization, dried, and sold as fertilizer. More modern processes for ammonia removal include the water wash process, in which the coke-oven gas is scrubbed with water that dissolves the ammonia along with the hot blast near the bottom of the blast furnace. The coal reacts with oxygen to form H_2 and CO, which act as reducing agents as they rise through the furnace. As long as sufficient coke is used to preserve bed porosity, a portion of the coke can be displaced by injected coal on a roughly pound per pound basis. Reducing coke requirement not only reduces costs, because coal is cheaper than coke, but also reduces the environmental problems associated with coke production. Furthermore, furnace capacity is increased, because the smaller volume of coke charged means a larger volume of iron ore can be charged.

A wide variety of noncoking coals have been successfully tested for direct injection, ranging from lignite to anthracites. The choice depends on price and availability rather than on attaining the highest injection rates. Among coals of similar cost and availability, important factors are ash, volatile matter, moisture content, and grindability. Also, sulfur and alkali contents should be low. Because ash lowers temperature and affects grindability, ash should be less than 10%. When injecting pulverized coal, volatile matter should be as high as possible, since low-volatile coals tend not to burn completely and contribute particulate matter to the off-gas. Moisture should be minimized, as water adsorbs heat in the blast furnace, causes difficulties during grinding, and can cause plugging problems in storage vessels and injection equipment. In addition to coal, natural gas, oil, and tar are also injected into blast furnaces.

Another approach receiving increased interest is direct reduction of iron ore. In this process, coal is added directly to the smelting vessel to become the source of the reducing gases and thermal energy. Thus, easily crushed and handled, inexpensive noncoking coals of high calorific value can be used. Particle size requirements are variable, but less than 1 mm is most often used, and, in some cases, there is an effort to restrict moisture content to below 6%.

Mild Gasification

Mild gasification is actually a pyrolysis-based process, closely related to coking. It is designed to produce the most profitable slate of alternative fuels and chemicals by decomposing coal at relatively mild conditions of temperature and pressure [42–45]. Mild gasification differs from coking in that in mild gasification, the goal is the production of liquid and gaseous fuels with the accompanying char being the by-product, whereas in coking, the coke is the main product, and the liquids and gases are the by-products. A major problem with this technology is the low quality of the liquid products, which are hydrogen deficient and require expensive upgrading to convert them into gasoline, diesel fuel, and other products. Pyrolysis-based processing for the production of liquids is discussed in more detail later in this chapter under "Pyrolysis-Based Processes" in the section "Coal Liquefaction."

Gasification

Coal was first gasified in England by William Murdock in 1792, and the world's first coal gas company was chartered in England in 1812. Coal gas was first produced in America in 1816 in Baltimore, and by 1850, over 55 commercial coal gasification plants in the United States were generating gas for lighting and heating. During the late 1800s and the early 1900s, a large number of coal gasifiers operated commercially in the United States and Europe to produce industrial and residential fuel gas. In the early 1930s, there were over 11,000 coal gasifiers operating in the United States, consuming about 13 million tons of coal per year and producing 500 million BTU/day of coal gas.

Most of the early gasifiers were moving-bed units, charged with sized coal and blown with steam and air to generate "producer gas" (150 BTU/scf). Operation of the moving-bed gasifiers in a cyclic mode (blowing first with air to heat the coal, followed by contact with steam to produce "water gas") increased the heating value of the product gas to 300 BTU/scf. The heating value of the fuel gas was further increased to about 500 BTU/scf by co-feeding oil with steam in the moving-bed process to produce "carbureted water gas," which contained hydrocarbons in addition to H_2 and CO. Coke-oven gas was also used as "town gas." An early gasification process, still in use today, was that developed by Lurgi. This gasifier operates at elevated pressure and uses oxygen, instead of air, thus increasing the heating value of the product gas.

By the mid-1950s, the availability of inexpensive natural gas and petroleum had led to the abandonment of most coal gasification units. However, even as oil and natural gas use increased, coal gasification plants continued to be built on a limited scale in certain areas of the world, particularly in countries with a limited supply of petroleum.

Extensive process development was carried out in the United States in the late 1940s to mid-1950s, prompted by a concern that natural gas reserves were limited. This work included (1) development of a 100-t/day Texaco entrained-flow gasifier at Morgantown, West Virginia, by Texaco and Olin Matheson; (2) demonstration of a 360-t/day Babcock and Wilcox entrained-flow gasifier at Belle, West Virginia; and (3) development of a 24-t/day Koppers-Totzek entrained-flow gasifier at Louisiana, Missouri. Further work has resulted in the development of several additional gasifiers, including the Shell, Kellogg-Rust Westinghouse (KRW), E-Gas™, British Gas/Lurgi (BGL), Kilngas, and Dow gasifiers. Recent interest in coal gasification has been driven by the potential of IGCC facilities to increase the efficiency of power production and reduce emissions. Development of improved coal gasification processes increases the potential for implementation of coal gasification technology for a variety of applications [46, 47].

In modern gasification systems [47, 48], a bed of coal or other carbonaceous material is blown with a mixture of steam and air or oxygen under pressure to produce a low to medium heating value gas whose main constituents are CO and H_2 with smaller amounts of CO_2, CH_4, and other components. (A mixture of H_2 and CO is called synthesis gas or syngas. Chapter 10 discusses some of the chemicals that can be made from syngas.) Most of the mineral matter (ash) in the feed leaves the bottom of the gasifier either as a dry solid or as a liquid, which solidifies to form an inert glassy slag, suitable for sale or disposal. Only a small fraction of the ash is entrained in the syngas and requires removal downstream. During gasification, sulfur in the feed coal is reduced to H_2S, and nitrogen is reduced to NH_3. These materials, along with HCl and entrained particulates, are removed in the downstream gas cleanup system. A typical gasifier raw gas composition is shown in Table 19.10.

Chemistry of Coal Gasification

The initial step in coal gasification involves grinding and/or pretreatment of the coal to put it into a form suitable for injection into the gasifier. In the gasifier, the coal is heated in the presence of a reactive gas whose composition depends on

Table 19.10 Typical coal gasifier raw gas composition

Component	Concentration (vol. %)
Hydrogen	25–30
Carbon monoxide	30–60
Carbon dioxide	5–15
Water	2–30
Methane	0–5
Hydrogen sulfide	0.2–1
Carbonyl sulfide	0–0.1
Nitrogen	0.5–4
Argon	0.2–1
Ammonia/hydrogen cyanide	0–0.3

Table 19.11 Reactions occurring during coal gasification

	ΔH_r (kcal/gmol)	Name	Number
Pyrolysis reactions			
$CH_x = C + CH_4$		Pyrolysis	(17.1)
$CH_x + H_2 = C + CH_4$		Hydropyrolysis	(17.2)
Gas–solid reactions			
$C + 0.5O_2 = CO$	−26.45	Combustion	(17.3)
$C + O_2 = CO_2$	−94.1	Combustion	(17.4)

$C + CO_2 = 2CO$	41.25	Reserve boudouard	(17.6)
$C + 2H_2 = CH_4$	−17.9	Hydrogasification	(17.7)
Gas–gas reactions			
$CO + H_2O = H_2 + CO_2$	−0.7	Water–gas shift	(17.8)
$CO + 3H_2 = CH_4 + H_2O$	−59.8	Methanation	(17.9)

the product desired. Walker [49] has presented an extensive review of gasification reaction fundamentals. Breault [50] and Shinner [51] have reviewed both the older and newer major processes for gasification.

Reactions occurring during gasification of coal can be divided into three groups: (1) pyrolysis reactions (thermal decomposition of the coal), (2) gasification reactions (gas–solid reactions), and (3) gas–gas reactions. The major reactions taking place are listed in Table 19.11.

The first reaction that occurs is pyrolysis or devolatilization (Reaction (17.1)). Reaction (17.2) represents the conversion of gaseous pyrolysis products into predominantly methane and coke, the extent of this reaction depending upon gasifier design. Gasification is related to pyrolysis/coking in that, when coal is gasified by reacting it at a high temperature with steam and an oxidant (air or oxygen), pyrolysis is the first reaction as the coal is heated to reaction temperature. Depending on the type of gasifier, condensable hydrocarbons may be collected as a by-product or may be completely destroyed.

Combustion reactions, Reactions (17.3) and (17.4), are the fastest gasification reactions and are highly exothermic. The oxygen can come from air, enriched air, or pure oxygen. In practice, the oxidation reactions occur rapidly with essentially complete oxygen consumption, so that most of the reactor volume is utilized for the other reactions listed in Table 19.11. The primary combustion products are CO and CO_2. The equilibrium constants for both Reactions (17.3) and (17.4) are greater than 1 up to 3,500°C, and, as a result, both reactions are essentially irreversible at typical gasifier temperatures. The CO/CO_2 ratio should increase with lower pressure and higher temperature, because pressure does not influence the equilibrium of Reaction (17.4), and Reaction (17.3) is not favored under pressure.

Reactions (17.5)–(17.7) illustrate the gasification of char by reaction with various gases. The carbon–steam Reaction (17.5) is an endothermic reversible reaction. Steam undergoes a side reaction, Reaction (17.8), called the water–gas shift reaction. This reaction, which is very rapid, is catalyzed by various impurities and surfaces. The carbon–CO_2 reaction, Reaction (17.6), is favored at high temperatures and low pressures, whereas the carbon–H_2 reaction, Reaction (17.7), is favored at low temperatures and high pressure. Since only three of Reactions (17.5)–(17.9) are independent, if the equilibrium constants for Reactions (17.6)–(17.8) are known, the equilibrium constants for the other reactions can be calculated.

The reactions in Table 19.11 are useful for examining the effect of changes in gasifier operating conditions on product gas composition. As temperature is increased, endothermic reactions are favored over exothermic reactions, which means that methane production will decrease and CO formation will increase. An increase in pressure favors reactions in which there are fewer moles of products than moles of reactants. Thus, higher pressure favors methane and CO_2 formation. Coal char gasification is generally equilibrium controlled. For design purposes, it is common to consider char as thermodynamically equivalent to graphite, although this is not strictly true.

Even when gasifier operating conditions are known, it is not possible to calculate the composition of the product gas exactly. First, the pyrolysis reactions and those of the pyrolysis products are highly dependent on coal properties and gasifier operating mode and vary significantly from case to case. Second, the thermodynamic equations treat coal char as if it were pure carbon, which is not the case. Finally, the system may not reach equilibrium. Thus, although useful predictions of gas composition can be made, exact calculations are not possible. Nevertheless, knowledge of stoichiometry, equilibrium constants, and reaction rates provides a reasonable basis for the modeling and design of gasification systems.

Pore structure can markedly affect char reactivity. Coals in general are highly porous with a polymodal pore size distribution. Pores normally are classified into macropores (>500 Å in diameter), mesopores (20–500 Å in diameter), and micropores (<20 Å in diameter). Upon pyrolysis, the pores in the coal open up, but the char still contains microporosity. Coal chars in general, and lignitic chars in particular, retain coal's polymodal pore distribution. Surface area of coal chars are in the range 100–800 m^2/g [52]. Most of this surface area and, therefore, most of the active surface reside inside the pores, so accessibility of reactive gases to active sites is very important.

The fundamental reactions occurring during gasification can be described by the Langmuir–Hinshelwood and Rideal–Eley mechanisms. The Langmuir–Hinshelwood mechanism involves three steps: (1) adsorption of the gas onto the solid surface, (2) surface migration/reaction, and (3) desorption of the products from the solid surface. In the Rideal–Eley mechanism, the basic steps are (1) reaction between gas molecules and surface atoms by direct collision and (2) desorption of products.

Because coal chars are highly microporous, most of the gasification reactions take place inside the char particles. Therefore, diffusion of gas into, and products out of, porous particles is required. The overall diffusion process can be described by the following steps: (1) diffusion of the reactant from the bulk gas to the solid surface (film diffusion), (2) diffusion of the reactant from the particle's surface to its interior (internal diffusion), (3) diffusion of the product from the interior to the particle's surface (internal diffusion), and (4) diffusion of the product from the surface to the bulk gas (film diffusion).

If the pore diameter and process conditions are well defined, the rates of internal and film diffusion can be calculated. The temperature dependency of the rate can be presented in the form of an Arrhenius plot, that is, log rate vs. reciprocal of the absolute temperature. Gasification rates can be divided into three zones, depending on whether reaction rate is controlling, diffusion is controlling, or both reaction rate and diffusion are important (Fig. 19.15). To determine the overall gasification rate, it is necessary to model the actual gasifier.

Because of the reducing nature of the product gas, heteroatoms (sulfur, nitrogen, and chlorine) appear in reduced form; that is, sulfur appears as hydrogen sulfide, nitrogen as ammonia, and chlorine as hydrogen chloride. In most cases, these materials are scrubbed from the product gas before it is burned. Ammonia and HCl are very water soluble and are easily removed by a water wash. A number of processes have been developed for H_2S removal; many of these processes are based on absorption in solutions of amines, such as monoethanolamine (MEA).

Types of Coal Gasifiers

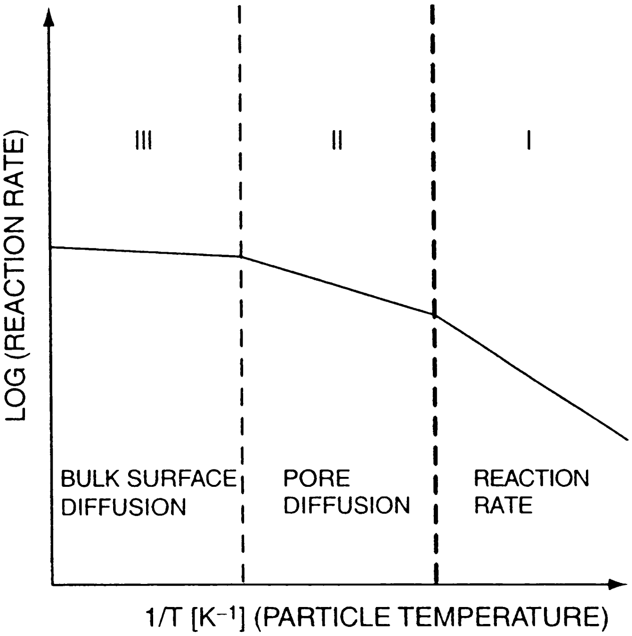

Fig. 19.15 Effective reaction rates in temperature zones

Gasification processes can be separated into three major types: (1) moving-bed (countercurrent flow) reactors, (2) fluidized-bed (back-mixed) reactors, and (3) entrained-flow (not back-mixed) reactors. Figure 19.16 shows the types of gasification reactors together with temperature profiles and locations of feed and product streams. Table 19.12 summarizes the important characteristics of each type of gasifier, and Table 19.13 presents the performance characteristics of selected gasifiers.

Moving-Bed Gasifiers. Moving-bed gasifiers consist of a downward-moving bed of coal contacted by a countercurrent flow of gases moving upward through the bed. In moving down the bed, coal sequentially undergoes dying, devolatilization, gasification, combustion, and ash cooling. Moving-bed gasifiers can be operated at atmospheric pressure or can be pressurized with either air or oxygen as the oxidant, with either dry ash or oxygen as the oxidant, with either dry ash or molten ash removal, and with or without stirrers to prevent agglomeration.

In the drying zone at the top of the bed, the hot upward-flowing gases remove moisture from the coal. As the coal moves down the bed, its temperature increases, and at about 315–480°C, pyrolysis occurs, liberating gases, oils, and tars. As the devolatilized coal (char) further descends, it is gasified by reaction with steam, carbon dioxide, and hydrogen to produce a mixture of carbon monoxide, hydrogen, and methane, containing unreacted steam and carbon dioxide. Below this, char is combusted by reaction with oxygen. The final composition of the gas produced and the rates of reaction are strongly influenced by gasifier temperature and pressure.

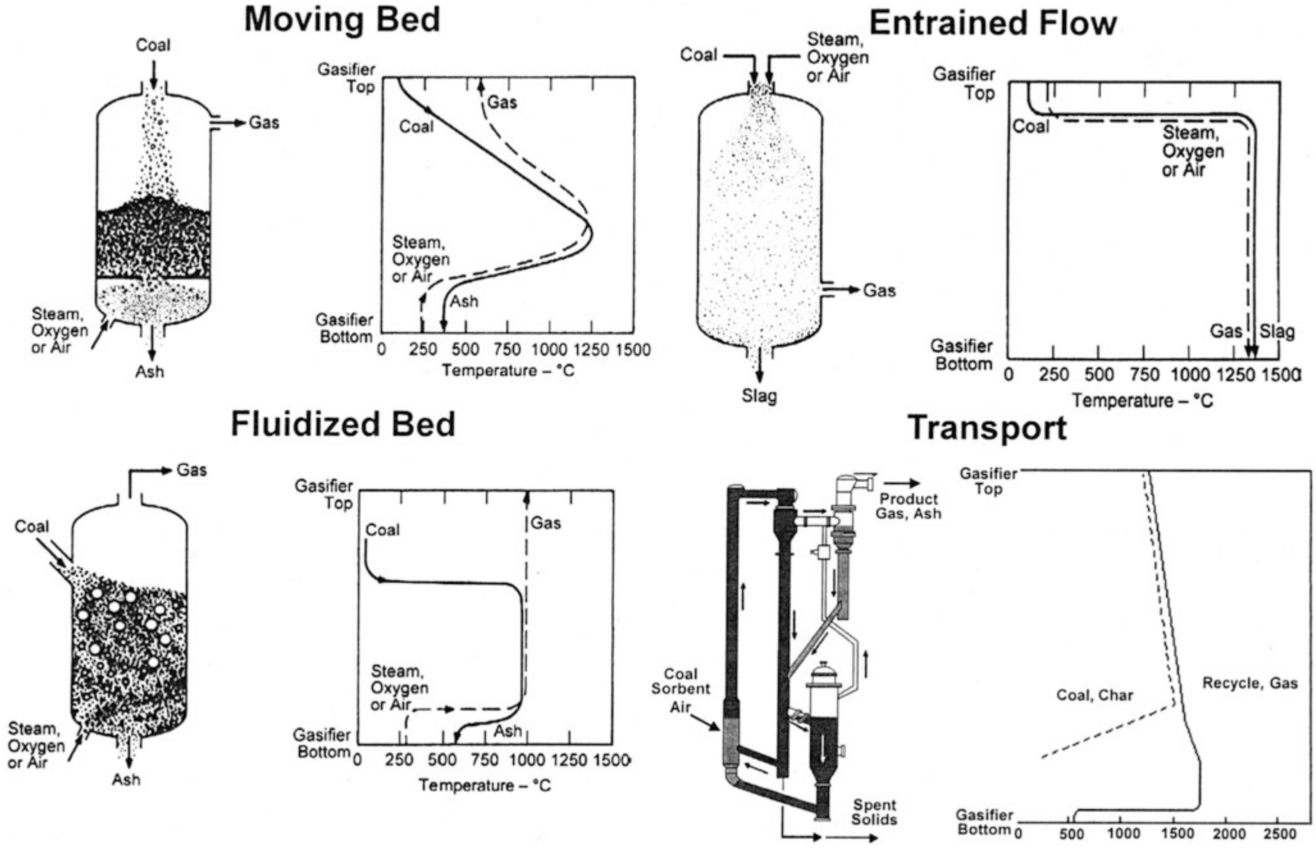

Fig. 19.16 Gasifier configurations

Table 19.12 Features of fixed-bed, fluidized-bed, and entrained-bed gasifiers

Moving bed	Fluidized bed	Entrained bed
Parameters		
Bed of coal descending under the influence of gravity	One or more fluidized-bed zones	Upflow or downflow suspension gasification
Mechanical grates/distributors	Uniform temperature and composition throughout each fluidized zone	High-temperature–high-rate process
	Moderate process response	Fast process response
Discrete zones		
Preheating-drying devolatilization Gasification Combustion		
Advantages		
High carbon conversion efficiency	High degree of process uniformity	Handles all types of coal without pretreatment
Low-ash carryover	Excellent solids/gas contact	Low steam consumption
Lower-temperature operation	Lower residence time than fixed-bed gasifier	Excellent solids–gas contact
Lowest air/oxygen requirement	Higher coal throughput per unit volume of reactor	No tar formation No phenol formation Ability to slag ash High capacity per unit volume of reactor Produces inert slagged ash
Disadvantages		
Sized coal required	Sized coal required	Requires finely crushed coal
Coal fines must be briquetted	Dry coal required for feeding	Small surge capacity requiring close control
Low off-gas temperature	Requires complicated gas distributor	

Table 19.13 Performance characteristics of selected gasifiers

	Illinois No. 6 coal		Pittsburgh No. 8 coal				West Kent coal

Source: Shinner [51]

The ratio of steam to oxygen (air) in the gasifier controls the peak temperature in the combustion zone. If a nonslagging operation is desired, sufficient steam is added to offset exothermic oxidation reactions with endothermic steam–carbon reactions to stay safely below the ash-fusion temperature. Slagging gasifiers operate at a higher temperature, and ash is removed in a molten state and then quenched in a water bath.

Moving-bed gasifiers require sized coal for proper operation; typically, coal between 0.6 and 5 cm in diameter is used. The countercurrent flow of gases and solids leads to high thermal efficiency, with exit gas temperature usually in the range of 260–540°C. The raw product gas contains fines and tar/oil produced during gasification. These materials are removed prior to downstream processing. Figure 19.17 illustrates the mechanical configuration for a Lurgi dry-bottom gasifier.

Fluidized-Bed Gasifiers. In a fluidized-bed gasifier, reactant gases are introduced through a distributor at the bottom of the bed at a velocity sufficient to suspend the feed particles. The result is a bed of highly mixed solids in intimate contact with the gas phase. The agitation leads to a uniform temperature throughout the bed. The high degree of mixing results in reaction rates that are typically higher than those experienced in moving-bed gasifiers, although fluidized-bed gasifiers generally do not achieve as high a thermal efficiency as moving-bed gasifiers.

The exit gas temperature for a fluidized-bed gasifier is higher than that for a moving-bed gasifier. The higher temperature results in further reaction of the pyrolysis products, and, therefore, the product gas contains a much lower concentration of tar/oil. However, particle attrition generally leads to higher levels of fines/dust carryover. Unconverted char and ash are removed as dry solids. Pretreatment is required if strongly caking coals are used.

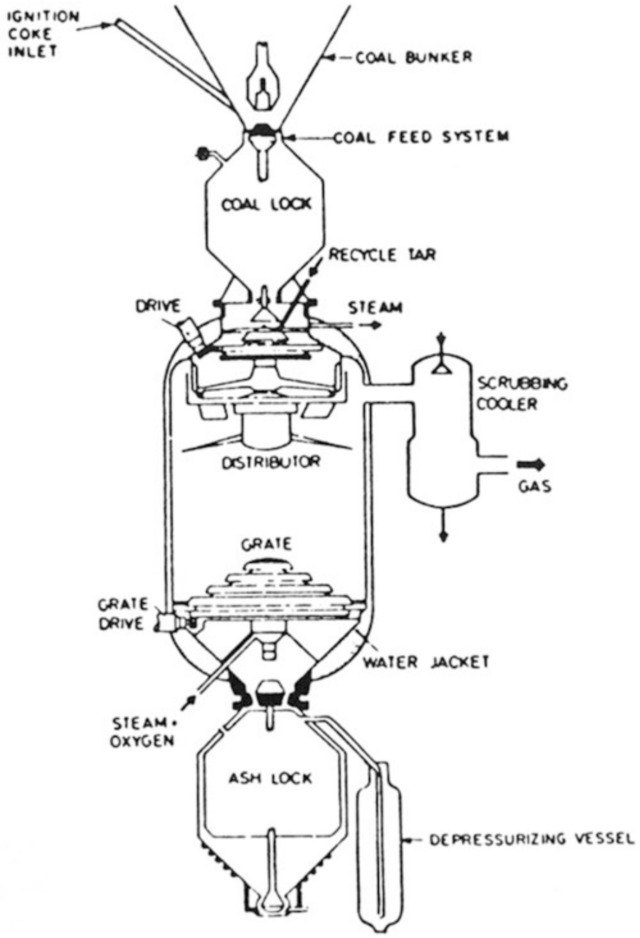

Fig. 19.17 Lurgi dry-bottom gasifier ("Comparative study of coal gasification processes—Koppers-Totzek, Lurgi and Winkler," Koppers Company, Pittsburgh, PA)

Fluidized-bed gasifiers can be operated at atmospheric or higher pressure. Fluidizing gases can be mixtures of steam with either air or oxygen and, in some cases, mixtures of hydrogen with other gases. The KRW gasifier is illustrated in Fig. 19.18.

Entrained-Flow Gasifiers. In an entrained-flow gasifier, a mixture of finely ground coal entrained in a reactant gas

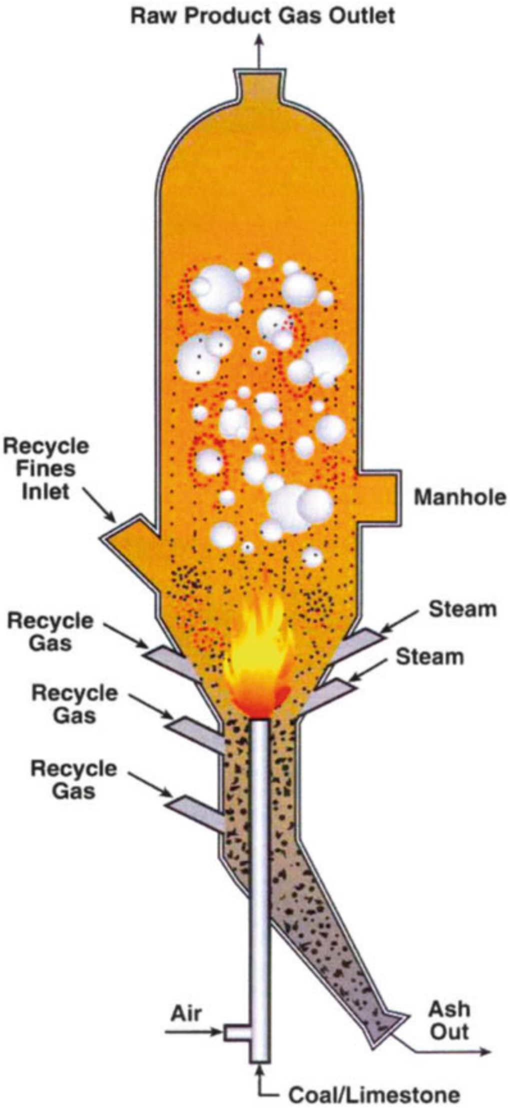

Fig. 19.18 KRW gasifier

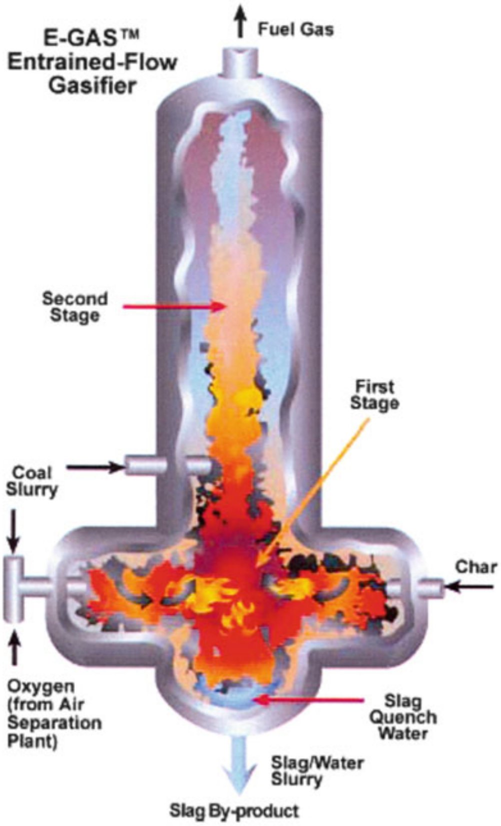

Fig. 19.19 Schematic of E-Gas™ entrained-flow gasifier

flows co-currently through the reactor, with little or no backmixing. This type of gasifier may be either single-stage or two-stage.

In general, high temperatures (1,200–1,760°C) are used to achieve complete gasification of the coal in a mixture with steam and oxygen or air. Because of the high temperatures employed, gasification rates are considerably higher than those achieved with either fixed-bed or fluidized-bed gasifiers. Entrained-flow gasifiers can handle all coals, including strongly caking coals, without pretreatment. The high temperature of operation produces a gas devoid of both methane and tars/oils. In two-stage gasifiers, the incoming coal is first entrained with reactant gases to produce gas; the resultant char is gasified further in a second stage, which may or may not be entrained. As is the case with fluidized-bed gasifiers, a staged operation achieves better overall thermal efficiency without sacrificing higher throughput, because the more reactive incoming coal can be gasified at a lower temperature than the less reactive char. Entrained-flow gasifiers can be operated at atmospheric pressure or pressurized, and ash may be removed either dry or molten. Figure 19.19 illustrates the two-stage entrained-flow E-Gas™ gasifier.

Gasification for Power Generation

High reliability, acceptable capital and operating costs, and minimal environmental impact are requirements for gasification systems proposed for utility applications. Operating costs can be minimized by using a gasifier that is capable of operating on run-of-mine coal, including caking coals and fines. The potential also exists to feed other materials such as petroleum coke, lignite, sewage sludge, refuse-derived fuel (RDF), and biomass to the gasifier. Use of such opportunity fuels can lower electricity costs.

Numerous studies confirm that gasifiers coupled with gas turbine–steam turbine combined cycles represent one of the most promising technologies for future coal-based power

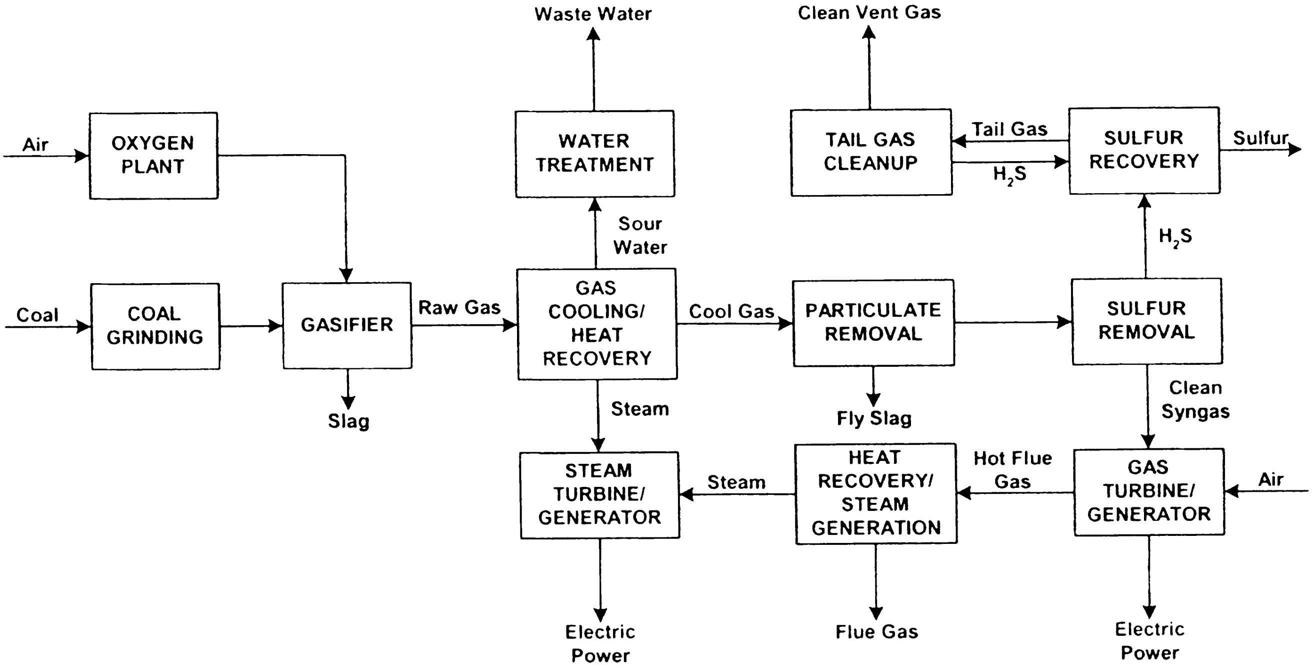

Fig. 19.20 Block flow diagram of a typical integrated gasification combined-cycle power plant

generation systems. IGCC technologies offer the potential for high efficiencies with low pollutant emissions. High efficiencies are achieved in IGCC operation by combining efficient combustion turbines with steam turbine bottoming cycles. The gas turbine converts high-temperature (1,820°C) heat efficiently, while the steam turbine utilizes lower-temperature heat (565°C) in the form of steam generated by recovering heat from the gas turbine exhaust. A typical IGCC facility is illustrated in Fig. 19.20.

A variation on IGCC operation is to combine power generation with chemicals or fuels production, the so-called coproduction option. In this operating mode, part of the syngas produced by the gasifier is used for power production, and part is sent to a Fischer–Tropsch [53], methanol, or similar facility for fuels/chemicals production. The coproduction gasifier facility provides the flexibility to maximize power generation during peak demand while maximizing fuels/chemicals production during off-peak periods. This makes gasification more attractive in the power generation market and allows flexibility in the geographical location of plants based on local grid peak shaving needs. Although not yet commercial, coproduction is being investigated by several energy companies.

A major goal of power production is minimal environmental impact. Because the product gas from IGCC systems is purified before combustion [54], burning this clean fuel results in low pollutant emission levels. Another potential environmental problem is eliminated by designing and operating the gasifier so that tars are not formed. Ash leaving the system is usually in the form of molten slag, which is water quenched to form benign vitreous material suitable for use or disposal. On balance, coal gasification systems are environmentally superior to other alternative coal utilization technologies and can meet rigorous environmental standards for SO_2, NO_x, and particulates. Furthermore, because of their increased efficiency, IGCC plants emit less CO, the major greenhouse gas, per unit of electricity generated.

Description of Selected Gasification Processes

Many different gasifiers have been developed, at least through the demonstration stage, by a variety of organizations, both public and private. However, not all of these gasifiers have achieved commercial success, and improved processes now supercede some technologies that were widely used in the past. In 2007, the GE, Shell, and Lurgi (dry ash) processes accounted for over 90% of the installed coal gasification capacity. It is beyond the scope of this chapter to describe all existing gasifiers. The following processes cover a wide variety of gasifier types and designs.

GE Energy Gasifier (*GEEG*). The GEEG (formerly Texaco Gasification) offers the following design features: a down-fed, pressurized, entrained-flow, slagging reactor; air or oxygen blown; high operating temperature; flexible feedstocks and products; and system coupling for cogeneration. The GEEG is designed to operate at pressures between

20 and 30 atm and temperatures between 1,200 and 1,500°C. Figure 19.21 shows a direct quench gas cooling configuration for the GEEG. The coal is wet ground and mixed with water to make a slurry containing 60–70 wt.% solids. The slurry is mixed with oxygen or air in the gasifier burner. By properly adjusting the oxygen/slurry ratio, gasifier temperature is maintained above the ash-fusion temperature.

The raw product gas is cooled either by direct contact with quench water, as in Fig. 19.21, or by passage through a radiative cooler followed by a convective cooler (Fig. 19.22). The cooled gases go to a scrubber to remove entrained char and ash. The product gas leaving the scrubber contains H_2, CO, CO_2, H_2O, and traces of Ar, N_2, CH_2, H_2S, and COS. Spencer and others have reported on the performance of the GEEG [55–57].

Various products have been prepared in commercial plants employing GEEGs, including H_2, NH_3, fuel gas for electricity generation, and syngas for production of methanol and other oxo products. The direct water quench cooling method is preferred when the desired final product is NH_3 or H_2, as the required shift reactor is easily integrated into the quench train.

Any carbonaceous material that can be processed into a concentrated, pumpable slurry can be gasified in a GEEG. For example, petroleum coke is converted to syngas in a 30-t/day plant in Ube City, Japan, which has been operating since 1982. In 1991, a mixture of coal and sewage sludge was successfully gasified. The ability of the GEEG to handle a wide range of feedstocks without the need for additional equipment or changes in operating procedures ensures flexibility in selecting the least expensive feed alternative while

maintaining high availability and reliability. About 70 GEEGs are operating in 2010.

Shell Gasification Process. Shell's experience with coal gasification started with operation of a 6-t/day pilot plant in Amsterdam. This was followed by a 150-t/day unit in Hamburg, Germany, and a 250–400-t/day unit in Houston, TX. This led to the successful operation of a 2,000-t/day commercial unit.

The Shell gasifier (Fig. 19.23) consists of a pressure vessel containing a gasification chamber whose inner wall consists of closely spaced tubes. The wall temperature is controlled by circulating water through these tubes to generate saturated steam. Coal is ground (90% less than 100 μm) and dried in an inert atmosphere and pneumatically transported to the coal pressurization and feeding system. Coal, oxygen, and steam are injected into the gasifier through pairs of opposed burners. Oxygen purity is typically 95%, but other purities can be used, depending on the application. Gasifier pressure is 20–40 bar, and temperature is above 1,500°C.

Most of the mineral content of the feed coal leaves the gasification zone in the form of molten slag. The high operating temperature ensures that the molten slag flows freely down the tube walls and into a water bath at the bottom of the gasifier, where it solidifies into dense glassy granules that are washed, depressured, and sent to storage or disposal. Greater than 99% carbon conversion is obtained. Because of the high temperature, no hydrocarbons heavier than methane exist in the raw gas. The insulation provided by the molten slag layer minimizes heat loss.

The raw gas leaving the gasifier is quenched with recycled cooled product gas to solidify any entrained slag droplets. The gas then enters a syngas cooler that generates high-pressure steam. The cooled gas flows through filters or cyclones for fly slag removal. The recovered fly slag can be recycled via the coal feed system to enhance gasification efficiency. The syngas goes to a scrubber or removal of remaining solids and water-soluble contaminates and then to an acid gas removal system. Recovered H_2S is converted to elemental sulfur. Overall efficiency (including high-pressure steam production) is very high.

The Shell process can handle a wide variety of coals, varying from lignite to bituminous, in an environmentally acceptable way and produce a high-purity, medium heating value gas for use as a fuel for power generation, as a chemical feedstock, or as a source of hydrogen. As of 2010, 45 plants were operating.

Lurgi Dry Ash Gasifier. The Lurgi Dry Ash Coal Gasification Process (Fig. 19.17) is among the earliest commercially successful gasifiers. The first commercial plant was built in 1936. Since then, numerous plants have been built. In particular, Lurgi gasifiers provide the syngas for the Sasol indirect coal liquefaction (ICL) plants in South Africa (greater than 90 gasifiers) and also for the Dakota Gasification synthetic natural gas plant (14 gasifiers).

Sized coal enters the top of the bed by way of a lock hopper and moves down through the bed. Ash is withdrawn by a rotating grate and is removed from the gasifier through another lock hopper. Steam and oxygen enter the bottom of the gasifier through the grate and react with the coal as the gas moves up through the bed. As the coal passes down through the gasifier vessel, it undergoes in turn drying, devolatilization, pyrolysis, gasification, and combustion. This countercurrent operation results in a temperature drop across the reactor. Temperature in the combustion zone near the bottom is in the range of 600°C, whereas gas temperature leaving the drying and devolatilization zone near the top is typically 125–280°C. The main factor affecting exit temperature is the moisture content of the feed coal. For feed coals high in moisture, such as lignite, the gasifier exit temperature is at the lower end of the range, and for a low-moisture bituminous coal, it is at the upper end.

The raw gas is quenched directly with recycle water to condense the tar it contains. The gasifier vessel is cooled by water jacketing, which generates a portion of the steam that is used in the gasifier. Sufficient steam is injected to keep the temperature at the bottom of the gasifier below the melting

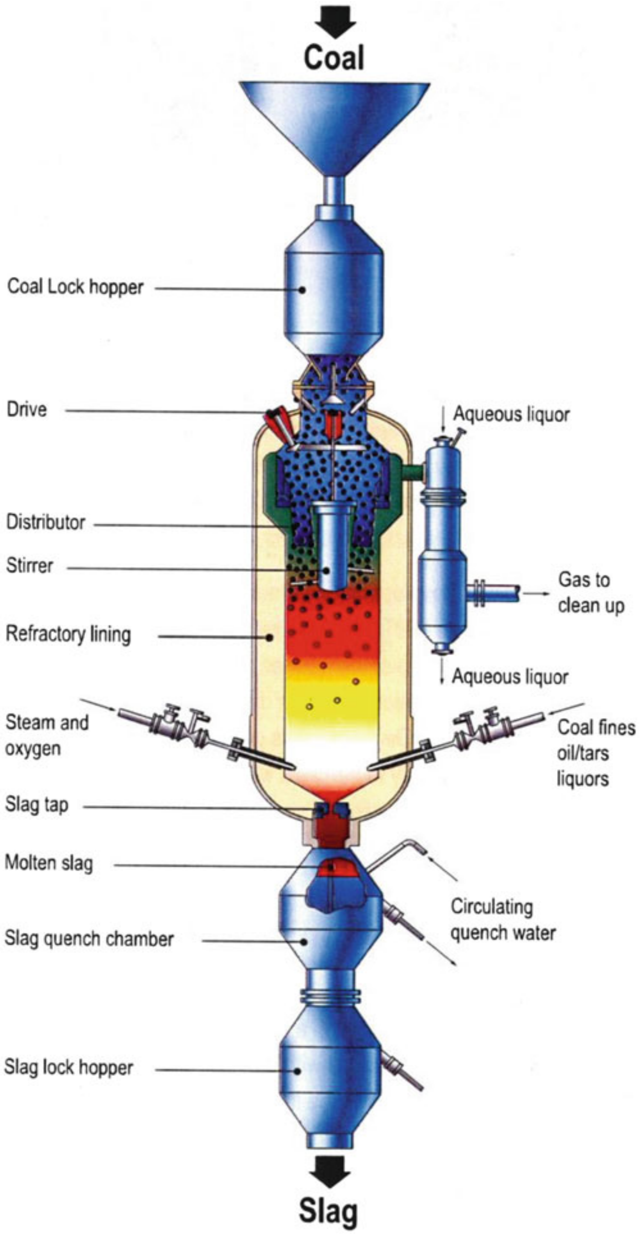

Fig. 19.24 Schematic for a BGL gasifier

temperature of the ash. The quenched gas is sent to cleanup for removal of NH_3, H_2S, and other impurities. After cleanup, the gas has a higher methane and hydrogen content than the gas from other gasifiers. Because of the lower exit temperature, oxygen requirement is reduced. However, recovery and disposal of tar can be a problem, or they can be a source of a variety of chemicals. High-reactivity, low-rank coal with a high ash softening temperature and minimal fines is favored as the feed.

BGL Slagging Gasifier. The BGL slagging gasifier technology (Fig. 19.24) is very similar to the conventional dry ash Lurgi gasifier, the key difference being that the BGL removes ash as molten slag. Advantages of slagging the ash include a significantly lower steam requirement and improved utilization of high-rank coals and coal fines. Slagging operation also eliminates liquid organic by-products by recycling them.

Like the Lurgi dry ash gasifier, the BGL gasifier is a high-pressure, moving-bed, oxygen-blown unit. Coal with a size distribution of 2 × 0 in. (the amount of −¼-in. material allowed depends on the coal's swelling characteristics) and/or briquettes are fed to the top of the bed via a lock hopper system. A rotating internal fuel distributor rakes and levels the top of the bed. The coal is gasified as it passes down through the reactor. Ash is removed from the bottom of the gasifier as molten slag through a slag tap, then quenched in water, and removed by a lock hopper. Oxygen and steam are injected through tuyeres near the bottom of the bed.

As with the Lurgi dry ash gasifier, there is a large temperature difference between the top and bottom, the magnitude of the difference depending mainly of the moisture content of the feed coal. For bituminous coals, this temperature difference is about 540–650°F. The raw gas leaving the gasifier is directly quenched to remove solids and condensable liquids. The solids entrained in the raw product gas, along with hydrocarbon by-products, such as tars and oils, naphtha, and phenols, are recycled to the top of the gasifier and/or reinjected into the gasifier at the tuyeres, where they are gasified. Coal fines can also be fed through the tuyeres, either pneumatically as dried solids or slurried with wastewater.

E-Gas™ Process. The first large-scale experience with the E-Gas™ gasifier (formerly the Destec gasifier) was gained in more than 34,000 h of operation at Louisiana Gasification Technology, Inc., from April 1987 through November 1995. This was followed by construction of an E-Gas™ gasifier at PSI Energy's Wabash River Generating Station in Indiana as part of DOE's Clean Coal Technology program. This plant started operations in 1995 and has the capacity to gasify about 1,000 t/h of bituminous coal.

The E-Gas™ gasifier consists of two stages: an entrained-flow, slagging first stage and a nonslagging second stage, as shown in Fig. 19.19 [58]. The first stage is a horizontal, refractory-lined vessel in which carbonaceous fuel is partially combusted with oxygen at an elevated temperature and pressure (775°C and 27 atm). The gasifier is initially heated with natural gas and then switched to the feed slurry, produced by wet grinding of coal. Oxygen and preheated slurry are fed to two opposed mixing nozzles, one on each end of the horizontal section of the gasifier. The oxygen feed rate is controlled to maintain the gasification temperature above the ash-fusion point. Under gasifier conditions, the feed is almost completely converted to a gas consisting primarily of H_2, CO, CO_2, and H_2O.

Coal ash and any added flux form a molten slag that flows continuously through a tap hole in the floor of the horizontal section into a quench water bath, where the slag solidifies. A continuous removal system transfers the slag to a dewatering bin, where the bulk of the slag settles out. The overflow goes to a settler for removal of the remaining fines. To improve carbon utilization, the fine particles are recycled to the slurry preparation area.

Raw syngas from the gasifier's first stage flows up into the vertical, refractory-lined, second stage, where additional slurry, but no additional oxygen, is injected. The injected fuel undergoes devolatilization and pyrolysis that both cools the syngas (because these reactions are endothermic) and increases its heating value (because of the nature of the products produced). In addition, water reacts with some of the carbon to produce CO and H_2. Unreacted char is carried overhead with the syngas that leaves the gasifier at 565°C.

The hot syngas is cooled to approximately 190°C in the syngas cooler, a vertical fire-tube heat recovery boiler with the hot syngas on the tube side, that generates 110 atm steam. The cooled syngas is sent to the particulate removal system that removes over 99.9% of the particulates. The particulate-free syngas is further cooled and then water scrubbed to remove chlorides and volatile trace metals. The syngas is then cooled to about 5°C before being sent to the acid gas removal system. During cooling, water condenses and dissolves most of the NH_3, along with some CO_2 and H_2S. This water is sent to the sour water treatment unit. The essentially sulfur-free syngas is moisturized and superheated and sent to the combustion turbine.

KRW Fluidized-Bed Gasifier. Development of this process was started by Westinghouse. Later, Kellogg Rust purchased an interest, and the technology was renamed the KRW process (Fig. 19.18). A 15-t/day unit was successfully operated at Waltz Mills, Pennsylvania. Based on this success, a KRW gasifier was included as part of a 100-MW(e) IGCC Clean Coal Technology project near Reno, Nevada. Owing to problems, mainly with the hot gas cleanup system, this unit only operated for short periods of time.

The KRW fluidized-bed gasifier consists of a vertical vessel with a smaller diameter at the bottom than at the top (Fig. 19.18). It is fitted with a central feed tube through which coal, sorbent (limestone), oxidant (air or oxygen), and steam are introduced. Solids are fed through a series of bins, which raise them from atmospheric to gasifier operating pressure. Coal and limestone are then pneumatically transported to the gasifier central feed tube. Oxidant is added to the feed tube, and the streams merge to form a central jet. The coal quickly devolatilizes, and the remaining char and limestone enter the gasifier bed.

Combustion of char and gas occurs within the jet to provide the heat necessary for the endothermic devolatilization, gasification, and desulfurization chemical reactions. Extraction steam from the steam turbine is also fed to the gasifier. CO and H_2 are the major combustible constituents of the product gas. Methane and other hydrocarbons are produced in small quantities during devolatilization of the coal. The gasifier temperature is high enough to crack the tars and oils produced. Because of the reducing atmosphere present during gasification, sulfur in the coal is released as predominantly H_2S. At conditions in the gasifier, limestone is rapidly calcined to form lime that reacts with the H_2S to form CaS. Because chemical equilibrium limits sulfur capture, remaining H_2S in the product gas is captured in a downstream desulfurizer.

As the carbon in the coal is gasified, the particles become enriched in ash. These ash particles tend to agglomerate and, along with dense calcium sulfide/oxide particles, separate from the char bed because of their higher density and different fluidization characteristics. This separation occurs primarily in the region surrounding the central feed tube at the bottom of the gasifier. These solids are cooled in the gasifier annulus by a countercurrent stream of recycle gas. The spent solids (unconverted calcined limestone, sulfide limestone, and ash) leaving the gasifier are transported to the ash collection system, consisting of a series of bins designed to reduce pressure back to atmospheric.

Gas exiting the gasifier flows through a cyclone for removal of entrained solids (char, ash, and sorbent) and then to the product gas cooler, where it is cooled to 540°C while generating 75 atm steam. Solids collected in the cyclone are returned to the gasifier, while the gas goes to sulfur removal before being burned in the gas turbine.

Siemens

The technology was developed originally by Deutsches Brennstoffinstitut in 1975 to gasify brown coal. The technology was acquired in 1991 by the Noell group and operated under other names before Siemens acquired it in 2006. The Siemens gasifier is a dry-feed, pressurized, entrained-flow reactor with the internal gasifier enclosed by a cooling screen (Fig. 19.25 left). The cooling screen consists of a gas-tight membrane that is studded and refractory-lined with a thin layer of silicon carbide. Molten slag cools and solidifies when it contacts the screen, and this layer protects it. Subsequent hot slag flows down the lag coated screen into a water bath where it solidifies to be removed through a lock hopper. For coals with less than 2% ash, the gasification zone is lined with a refractory (Fig. 19.25 right).

This gasifier was used at the Schwarze Pumpe complex in Saxony, Germany, that began commercial operation in 1984. Recently, commercial-scale gasifiers have been installed by Siemens in the US land in China. The company appears to be pursuing a very aggressive campaign in China.

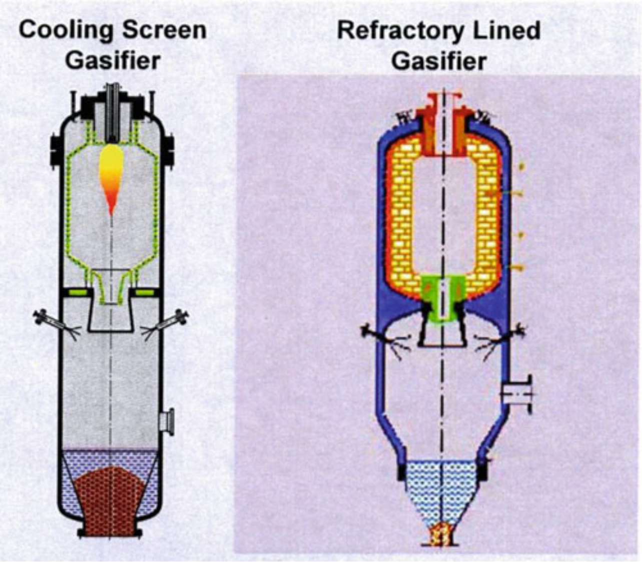

Fig. 19.25 Schematic of the Siemens gasifier for high (>2%) (*left*) and low (<2%) (*right*) ash content coals

Mitsubishi Heavy Industries

The Mitsubishi Heavy Industries (MHI) gasification technology was developed with the goal to maximize the gasifier efficiency (e.g., dry feed using a unique two-stage reactor design) and reduce costs (e.g., air blown to eliminate power consumption and capital cost of an oxygen plant) [59]. A joint venture of several companies and the Japanese government built a 2-t/day PDU and later a 200-t/day pilot plant to test the technology. In 2004, a 1,700-t/day IGCC demonstration plant was built, and the plant started operation in 2007. The MHI gasifier is a pressurized, upflow, entrained-flow slagging reactor with a unique two-state operation, similar to the E-Gas gasifier. Unlike E-Gas, it is a dry-feed operation that uses an internal membrane wall to protect the reactor, similar to the Shell and Siemens designs. MHI's current focus is the utilization of air or enriched air-blown IGCC application.

Compact Gasifier

Pratt & Whitney Rocketdyne has been applying its experience with rocket engines to develop a compact (90% smaller) and cheaper (one-half the cost) gasifier [60]. This gasifier is at an early stage of development.

Other Gasifiers

A number of gasifiers are being introduced for small-scale processes, especially in China. An example of such gasifiers is illustrated by the Synthesis Energy Systems (SES) utilization of the U-Gas technology. Eight 150-t/day U-Gas plants were installed in Shanghai, China, in 1995. Recently, SES has installed two 400-t/day gasifiers in Zaozhuang City, China, and another SES unit is to come on stream in 2011 in China. These SES gasifiers utilize the cheapest coal available, frequently approach 50% ash, and may even exceed this amount. These units are very flexible with a large turndown capability and rapid variation in coal quality.

These smaller gasifiers find wide usage for chemical synthesis, especially for use in a nearby industry. Thus, at this time, China is the scene of widespread activity in gasification and is constructing both small and large gasifiers at a rapid pace.

Underground

The desire to eliminate underground mining and replace it be underground gasification is not new. In 1913, Lenin wrote in Pravda, "Free the miners from going underground by applying underground gasification." During the past 100 years, interest in underground gasification has surged and ebbed [61]. Today, environmental concerns are pushing interest in the topic. The current status of underground coal gasification (UCG) has recently been summarized by Couch [62].

UCG has been practiced in Russia for about 50 years; however, it is possible to operate a process under a communist government under conditions where it would not be practicable under a free market situation. Thus, the Yerostigaz facility in Uzbekistan is the only remaining UCG remaining in the former Soviet Union and Linc Energy now owns more than 90% of this operation. Today, it appears that Linc Energy has demonstrated the first long-term UCG in the Western world. Linc Energy has now opened its fourth syngas generator and is currently developing a Fischer–Tropsch process to utilize the syngas generated by UCG. In South Africa, the electricity supply company Eskom, a state-owned enterprise, is now operating a pilot plant. Sasol and Eskom have joined to develop an environmental impact assessment for UCG in the Mpumalanga coalfields.

Biomass Gasification

One approach to decrease CO_2 emissions is to gasify a coal–biomass mixture [63]. This is not without problems because of their differences in mass and pyrolysis behavior, but its attractiveness to decrease GHG emissions pushes work in this area forward. Thus, the higher reactivity of the biomass leads to pyrolysis at a lower temperature, but this also leads to more tar formation, and it may be necessary to devise methodologies to deal with these tars. The status of US biomass gasification has been reviewed recently [64].

Co-gasification of coal and biomass was demonstrated at the Polk Power Plant in Tampa, Florida, but this was accomplished up to one and a half percent of woody biomass (by weight) being gasified together with a bituminous coal [65]. At the NUON power plant in the Netherlands, they successfully fed a mixture of 30% by weight demolition wood and 79% coal to a Shell dry-feed, high-pressure, entrained gasifier. The wood was reduced to sawdust (1 mm size) and was fed using the existing lock hopper feed system.

Major issues to be defined are the development of high-pressure biomass feed systems, gasifier optimizations for co-gasification at varied biomass feed rates, overcoming hurdles associated with feeding heterogeneous biomass types, design of biomass processing systems, and choice between biomass preprocessing at the plant or at the harvest site [66].

Future of Gasification

It appears that gasification will continue to be utilized at an expanding scale as recent reviews of the US [67] and world [68] programs indicate. In this regard, Collot has recently presented approaches for matching the gasification technology to coal properties. Abadie and Chamorro [69] have provided guidance by providing a market-based approach for the economics of gasification. The Shell, GE, Texaco, High-Temperature Winkler, and E-Gas processes can be classified as high-pressure, oxygen-blown, pulverized-coal, entrained-flow gasifiers having different geometries, operating pressures, and quench mechanisms. A surprising conclusion is that plant availability is the most important factor [70].

Coal Liquefaction

The primary purpose of any coal liquefaction process is to produce a liquid product with an increased hydrogen-to-carbon ratio, a reduced heteroatom (sulfur, nitrogen, and oxygen) content, and a minimal inorganic content. This has been accomplished by a variety of methods, which can generally be grouped into three major categories: pyrolysis, direct liquefaction, and indirect liquefaction. In pyrolysis, coal is heated to generate gases and liquids/tars while leaving a char behind. The liquids/tars are condensed and further treated to produce conventional liquid fuels. A process variation (hydropyrolysis) produces higher-quality products by carrying out the pyrolysis in a hydrogen atmosphere. In DCL, powdered coal is mixed with a solvent and, usually, a catalyst, and heated under pressure in a hydrogen atmosphere to produce gaseous and liquid products. The liquids are separated from ash and unconverted coal and refined to useful fuels. In indirect liquefaction, the coal is first gasified to produce syngas, which is then converted in the presence of a catalyst at an appropriate temperature and pressure to liquid products. Each of these approaches is discussed in more detail below.

Pyrolysis-Based Processes

When coal is heated, it undergoes thermal decomposition, which results in the evolution of gases and liquids/tars from the char that remains. In all coal conversion and utilization processes (including combustion, gasification, and liquefaction), some form of coal pyrolysis occurs. Because coal pyrolysis is an important process for making metallurgical coke, a vast amount of literature exists on the topic. By carefully varying pyrolysis conditions and optionally adding a reactive atmosphere (such as hydrogen), one can optimize production of a desired product (solid, liquid, or gas).

Coal pyrolysis is a very old technique (dating back to the eighteenth century), based on relatively inelegant technology. Most pyrolysis systems in use in the late 1800s and the early 1900s were in Europe and had as their objective the production of smokeless fuel (char) for domestic use. However, within a short time, it was realized that the coal tar fraction contained valuable chemical products. However, as inexpensive petroleum appeared on the scene, interest in coal by-products faded. A detailed review has been published [71].

Interest in pyrolysis was rekindled by the oil embargo of 1973, and emphasis was placed on developing pyrolysis processes that would achieve a maximum yield of liquid products capable of displacing petroleum as a source of distillate fuels. Several processes were developed to the pilot-plant stage in the 1970s, but development was discontinued when oil prices softened in the early 1980s, and none of these processes achieved commercial success.

Pyrolysis conditions determine the extent to which the coal is carbonized and the nature of the liquid and gaseous products. Coal pyrolysis processes are generally classified as low temperature (<700°C), medium temperature (700–900°C), or high temperature (>900°C). A number of reviews on advanced pyrolysis processes are available [72–76]. Two highly developed pyrolysis processes were the COED process, developed by FMC Corporation, which used a series of fluidized beds operating at successively higher temperatures, and the TOSCOAL process, which used a horizontal rotating kiln.

Table 19.14 Summary of effects of process parameters on coal pyrolysis

Heating rate
• A rapid heating rate increases liquid/gas yield and reduced char yield • A rapid heating rate produces poorer quality (lower H/C ratio) tar than that obtained at a slower heating rate [29, 35] • A rapid heating rate (in a reactive gas ‘atmosphere) produces char with increased open structure and reactivity • A rapid heating rate increases the thermoplastic (softening and swelling) behavior of coal • Achieving a rapid heating rate requires a sophisticated (often expensive) system
Temperature
• Low-temperature operation (500–700 °C) improves liquid yield • Temperature affects heteroatom distribution among char, liquid, and gas • At elevated temperatures (>1,300 °C), inorganics are removed as slag • Lower temperatures require a longer residence time for complete reaction
Pressure
Inert gas atmosphere
• Higher pressure operation reduces reactor size (i.e., increases throughput) • Higher pressure reduced tar yield • Coal feeding and product separation are more difficult at high pressure • Higher pressure improves gas–solid heat transfer
H_2 atmosphere
• Improves the yields of liquid and lighter products • Requires a sophisticated pressure control system • May increase undesirable agglomerating properties of coal [81] • H_2 cost must be compared to the increased value of the product
Other atmospheres (H_2O, CO_2, CO, CH_4, CS_2)
• Probably improve liquid–gas yield • Little information available
Vacuum
• Plastic behavior of coal is reduced [48] • Increases liquid/gas yield [48] • Difficult to achieve gas–solid heat transfer (solid–solid heat transfer feasible) • Little information available
Particle size
• Smaller particle size improves gas–liquid yield • Smaller particle size reduced secondary reactions • Grinding cost increases with the reduction in size
Coal rank
• High-volatile A (HVA) bituminous coals produce the largest quantity of tar • Lignites are rich in oxygen functional groups that lead to overall reduction in the calorific value of the product • The type of sulfur (pyritic vs. organic) present influences sulfur distribution among the products

Factors Affecting Coal Pyrolysis

During pyrolysis, the yield of gaseous and liquid products can vary from 25% to 70% by weight, depending on a number of variables, such as coal type, type and composition of the atmosphere present, final pyrolysis temperature, time-temperature path, and pressure. Although certain operating conditions may lead to increased product yield, achieving these conditions may result in increased costs.

Many excellent reviews [7, 77–80] have been published that discuss the factors affecting coal pyrolysis and product composition. In the following sections, major conclusions presented in the literature are discussed (as summarized in Table 19.14).

Temperature and Heating Rate. Coal undergoes many physical and chemical changes when heated gradually from ambient temperatures to approximately 1,000°C. Some changes, such as carbon–carbon bond scission, are observed before the onset of thermal decomposition that occurs above 350°C. When heated to approximately 100°C, physically sorbed moisture is liberated. Heating low-rank coals, such as lignites, that contain appreciable carboxylic functional groups will liberate carbon dioxide by thermal decarboxylation. Over 50% of the carboxylic acid functional groups are lost in the temperature range 100–250°C.

As the temperature of thermal treatment increases to the range 200–400°C, coal produces a number of lower molecular weight organic species (especially aliphatic compounds), which are believed to arise from components that are loosely bound to the more thermally stable part of the coal structure. At a higher temperature (375–700°C, depending on the heating rate), thermal destruction of the coal structure occurs, as reflected by the formation of a variety of hydrocarbons, including methane, other alkanes, polycyclic aromatics, phenols, and nitrogen-containing compounds. In this temperature range, bituminous coals soften and become plastic (thermoplastic) to varying degrees.

At still higher temperatures (600–800°C, depending on the heating rate), the plastic mass undergoes repolymerization, forming semicoke (solid coke containing significant volatile matter). At temperatures exceeding 600°C, semicoke hardens to form coke with the evolution of methane, hydrogen, and traces of carbon oxides. Pyrolysis of coal is essentially complete at approximately 1,000°C. The temperature at which the maximum devolatilization rate occurs depends on the heating rate. For a slow heating rate (about 5°C/s), the maximum rate occurs at around 400°C, whereas for a rapid heating rate (about 10°C/s), the maximum rate might not occur until 900°C [81, 82]. Maintaining the coal at the final temperature for an extended period normally increases the yield of volatile material, because char decomposition is a relatively slow process.

Because pyrolysis reactions do not occur at sharply defined temperatures, the heating rate has a marked effect on the nature and distribution of pyrolysis products, as summarized in Table 19.14. Solomon and coworkers conducted extensive work on the kinetics of coal devolatilization, and many reviews are available [83].

Coal Rank. The type of coal strongly influences pyrolysis behavior. Low-rank coals, such as lignite, contain oxygen functional groups that evolve water and carbon oxides upon pyrolysis. Higher-rank bituminous coals contain less oxygen; consequently, these coals produce significantly less water and carbon oxides when pyrolyzed. The nature of the tar produced is also dependent on coal rank. Bituminous coal tars tend to be more aromatic (and relatively more thermally stable) than the tars generated from lignites. When heated, bituminous coals soften, become plastic, and swell to varying degrees, whereas lower-rank coals generally do not become plastic. However, at a rapid heating rate (about 10°C/min) or elevated pressure, certain lower-rank coals may melt and demonstrate some plastic and swelling characteristics.

Other Factors. Several other factors influence, at least to some extent, the course of the pyrolysis process. These include particle size, bed configuration, pressure/vacuum during pyrolysis, nature of the coal ash, secondary reactions, etc. [84]. It is beyond the scope of this chapter to consider these items, but the interested reader can find additional information in the literature, including reports on pressure effects [45, 85], effect of vacuum [48], effect of inorganics [86], and effect of a reactive atmosphere [48, 87].

Utilization and Characterization of Pyrolysis Products

Efficient utilization of all the products, solid, liquid, and gaseous, is essential if favorable economics for a pyrolysis process are to be achieved. Products may require varying degrees of treatment before they are usable. The stream exiting the pyrolyzer requires separation of gas, liquid, and particulates, similar to the situation for a fixed-bed gasifier (i.e., cold gas cleanup). Possible operations include hot dust removal cyclones, quench/particulate scrubber towers, and venturi scrubbers to remove tar mist. In general, gas stream sulfur removal and wastewater treatment are also required. Finally, environmental factors, such as toxicity [88], carcinogenicity, and mutagenicity of the coal pyrolysis liquids (CPL), need to be considered. For example, the mutagenicity of CPL is strongly dependent on the conditions of pyrolysis (temperature, coal type, and atmosphere during pyrolysis).

Liquid fuels markets tend to have product specifications that do not vary widely. However, the characteristics of CPL can vary greatly, depending on coal type and operating conditions. In general, the H/C atomic ratio for CPL is lower than that for petroleum products, which is in the range 1.8–1.9 for No. 2 fuel oil and 1.7–1.8 for No. 6 fuel oil. In contrast, the H/C ratio for CPL is in the range 0.9–1.5, indicating that CPL is significantly more aromatic (50–70%) than petroleum-derived products.

The uses of CPL can be divided into two broad categories: (1) direct combustion, requiring little or no upgrading, and (2) transportation fuels and chemicals, requiring extensive upgrading. The high aromaticity of CPL indicates that conversion to gasoline is preferred to conversion to diesel fuel. Much of the attention in low-temperature tar processing has been devoted to hydroprocessing techniques, such as hydrotreating and hydrocracking, with the primary objectives of reducing viscosity, reducing polynuclear aromatics, and removing heteroatoms (sulfur, nitrogen, and oxygen) to produce usable fuels and chemicals.

The cost of H_2 is still the primary impediment to tar upgrading. Although the tar fraction can be used as a source for chemicals, such as phenolics, road tars, preservatives, and carbon binders, these uses do not constitute a large enough market to support a major industry. Likewise, the char has a range of potential applications, but the char must provide an economic return for pyrolysis processes to operate profitably. One obvious application is on-site combustion to generate heat for the pyrolysis process. Alternatively, the char can be combusted in an electric power plant. Char could also be gasified to produce hydrogen for use in hydropyrolysis or tar hydrotreatment. Other applications include production of activated carbon and molecular sieves.

Coal Liquefaction

This approach to the conversion of coal to liquids was developed in Germany by Bergius starting in 1913 [89]. It was made possible by the advances in utilizing high-pressure processing that was based on the commercialization of the ammonia synthesis in Germany beginning about 1910. The use of high-pressure processing for DCL continued in Germany during the 1900s.

DCL refers to the process of converting coal to liquid products by mixing ground coal with a recycled process solvent and/or petroleum-derived residual oil (coprocessing). The slurry reacts in a hydrogen atmosphere at 750–850°F (400–450°C) and 1,000–2,500 psig (7–17 MPa). Under these conditions, the coal structure breaks down into a variety of products, some of which are in the gas phase and some soluble in the liquid phase. The highly aromatic products are separated from the ash and unconverted coal by solvent deashing (SDA) or vacuum distillation and upgraded by conventional petroleum refining techniques to gasoline, kerosene, diesel and jet fuels, and other distillate fractions.

The success of any DCL is highly dependent on the type of coal used. Coal rank influences both overall conversion and product distribution. Lower-rank coals have been reported to give both higher and lower conversions than bituminous coals [90], with most evidence supporting the latter. Furthermore, the liquid products from lower-rank coals are generally more volatile and of lower molecular weight [91] than those from bituminous coals.

German organizations demonstrated commercial-scale operation of DCL during World War II, employing the Bergius process, which they had developed. After World War II, the United States constructed a 200-bbl/day DCL plant in Louisiana, Missouri, based on the German technology. This plant was operated by the Bureau of Mines from 1949 to 1954. However, as the extent of petroleum deposits in the Middle East and other locations became apparent and fears of an oil shortage subsided, interest in DCL diminished. For information on the early history of DCL, see Wu and Storch [92], Donath and Hoering [93], Ministry of Fuel and Power [94], and Perry's Chemical Engineering Handbook [95].

The 1973 oil embargo created a new surge of interest in DCL as one of a number of routes to produces petroleum substitutes from indigenous resources. From this renewed effort in the early 1970s, three major DCL processes emerged: Solvent Refined Coal (SRC-I and SRC-II), Exxon Donor Solvent (EDS), and H-Coal. These processes converted coal to liquids in a single reaction stage and, by the late 1970s, had been developed at pilot-plant scale, with designs underway for demonstration plants. However, in the early 1980s, these plants were canceled due to projected unfavorable economics. Interest then shifted to developing a two-stage process, which promised higher yields and better quality product with a concomitant improvement in economics.

Chemistry of Direct Coal Liquefaction

As coal is heated in a suitable solvent, it is rather rapidly (1–5 min) converted into soluble entities that have a high molecular weight and an average elemental composition relatively little changed from that of the moisture- and ash-free (maf) feed coal. As residence time is extended, hydrocracking converts the dissolved entities to lower-boiling liquids with reduced heteroatom content [96]. The exact product slate depends on many factors, including operating conditions, coal properties, and the solvent used. The dissolution reactions produce free radicals, which may undergo retrograde reactions to form insoluble coke or, if there is sufficient hydrogenation activity, be stabilized by reaction with hydrogen atoms. The stabilized free radicals can then undergo hydrocracking reactions to form a wide range of products from methane through heavy oil. Some hydrogen comes from the gas phase, but most is transferred from the solvent. The most effective hydrogen transfer agents (hydrogen donor solvents) are hydroaromatic compounds, which can lose hydrogen and revert to polynuclear aromatics and later to be rehydrogenated to hydroaromatics. The mechanism of these and other DCL reactions is not fully understood, and since every coal molecule is unique, it is unlikely that precise kinetics will ever be possible.

Because of the high concentration of ring structures in coal, coal liquids are highly aromatic, particularly the heavier fractions. This can be a problem, since some polynuclear aromatics are carcinogenic. Even though the carcinogens can be eliminated from the final product by limiting the endpoint of the distillate to about 370°C and recycling heavier components to extinction, care must be taken to prevent exposure of plant workers. Another problem is that the current trend is to limit the aromatics content of transportation fuels for environmental reasons. Therefore, production of specification fuels from coal liquids can require extensive (and potentially expensive) hydroprocessing.

The conversion of coal, measured as the fraction that is soluble, depends upon the coal rank as shown in Fig. 19.26 for subbituminous and lignite coals. For the lower carbon containing coals, it is the lower reactivity of the structure that limits short-time conversion; with increasing reaction time, the higher conversion is obtained. The solid line at about 85 MAF coal represents the coal chosen for the early work by Berguis; he was either well informed or very fortunate in his choice.

One of the great advances made in DCL was the improvement of catalysis and the lowering of the reaction temperature. This led to a very significant reduction in the amount of light gases found in the product slate and therefore an increase in the amount of distillate (Fig. 19.27) [97].

Keogh and Davis [98–100] converted a number of coals at various reaction conditions and came to the conclusion that the production of individual fractions (insoluble, preasphaltenes, etc.) and three lumped parameters (oil plus gases, preasphaltenes plus asphaltenes, and insoluble organic matter) as a function of a severity index, defined in terms of reaction temperature and time, defined a single reaction pathway. From ternary plots of the three lumped parameters, along with plots of individual fractions vs. a severity index, they deduced reaction pathways for a number of coals during either thermal and/or catalyzed pathways. From inspection of the data, they were able to show, for example, that *the addition of a catalyst affects the reaction rate but it does not alter the reaction pathway* (Fig. 19.28). It appears therefore that the catalyst generates the hydrogen donor by adding gaseous hydrogen to aromatic structures which then stabilize radicals generated by the thermal reaction that converts higher to lower molecular weight compounds. The large pilot plants normally did not generate data for a wide range of conversions; however, the reaction pathway defined by Keogh and Davis [99] in small reactors applied to the large pilot-plant data (Fig. 19.29).

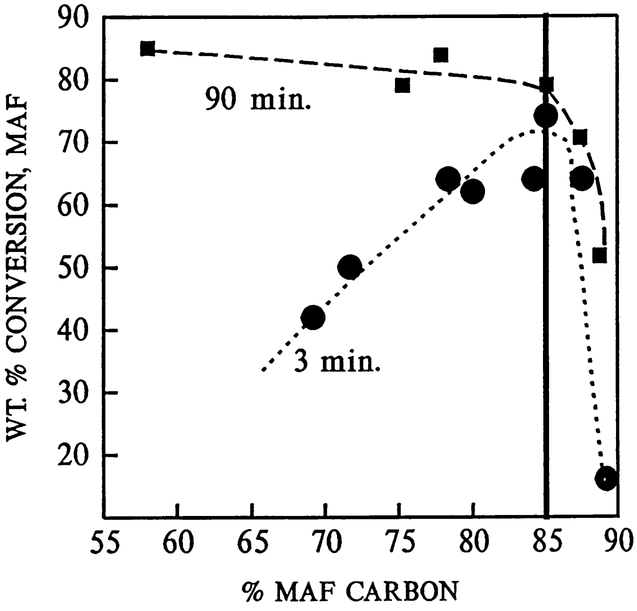

Fig. 19.26 Dependence of coal conversion upon moisture- and ash-free (MAF) carbon content (Adapted from Whitehurst DD, Mitchell TO, Farcasiu M (1980) Coal liquefaction: the chemistry and technology of thermal processes. Academic Press, New York)

The first DCL processes were single-stage processes, in which both coal dissolution and hydrocracking take place in the same reactor. Later, it became apparent that these two steps could not both be optimized at the same operating conditions. This led to the development of a two-stage process, in which a short contact time (SCT) thermal liquefaction reactor was followed by a catalytic and upgrading reactor to optimize conditions for both reactions, thus leading to higher yields, more efficient use of hydrogen, and a better product distribution. Other variations of two-stage processing, such as the integrated two-stage liquefaction (ISTL) process, were developed later. Tables 19.15 and 19.16 present typical compositions and yields, respectively,

of distillates from various DCL processes. Table 19.17 provides a listing of large plants operated in the United States during the 1970–1980s period, and Table 19.18 lists major non-US plants. Table 19.19 presents a typical product distribution obtained at some of these plants.

Solvent Refined Coal (SRC-I and SRC-II)

The Solvent Refined Coal (SRC-I, process began by Spencer Chemical, later acquired by Gulf Oil, in 1962) was designed as a means of deashing coal [101]. It soon became apparent that the cost for the improvement in the quality of the coal that was achieved by the SRC-I process was too large for the process to be viable and SRC-I was abandoned. Gulf Oil continued to operate the Fort Lewis plant in the SRC-II mode which involved recycling the ash that contained iron, a catalyst for the liquefaction process, as well as operating with iron added to the feed. The SRC-II plant operated to provide sufficient SRC for combustion testing in a large power plant; however, the SRC-II had operating difficulties in maintaining an adequate production of recycle solvent. The smaller SRC-I plant at Wilsonville, Alabama, continued to operate and moved on to verify several processes that involved two-stage operations as described below.

Exxon Donor Solvent Process (EDS)

Research on the EDS process began in 1966. Exxon workers investigated a variety of process options before they settled upon a process scheme in which coal is mixed with a recycle

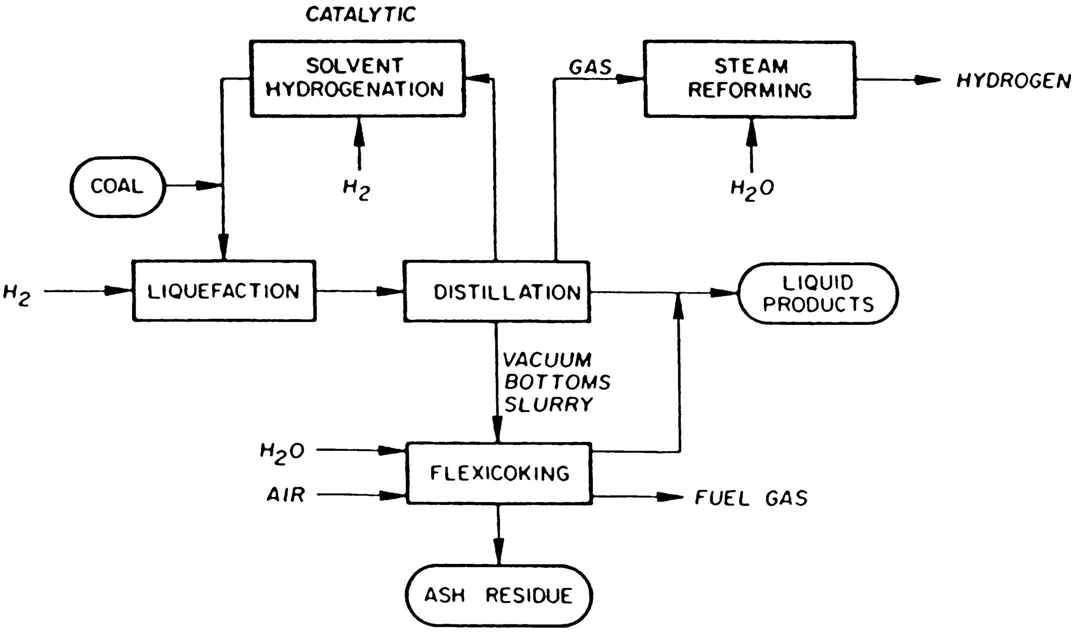

Fig. 19.30 Schematic of Exxon donor solvent process (Courtesy of The Pace Company, Denver, CO)

solvent that has been hydrogenated between passes to the liquefaction reactor and the mixture is then fed to the reactor together with high-pressure hydrogen (see Fig. 19.30). The recycle solvent is hydrogenated in a separate reactor before mixing with the coal. More than 2.6 barrels of a synthetic crude boiling below 525°C are produced from a ton of dry, high-volatile coal feed. The process development advanced to a 250-t/day pilot-plant stage that went into operation in June 1980 and operated during the next 3 years. At a smaller scale, it was demonstrated that the process could be used with a wide range of coals. Even though it was thought that the process was under control, it was learned that this was not the case. In spite of having a staff that was very familiar with operating large-scale refineries, they experienced many unexpected difficulties in operating the coal liquefaction plant. Operation of the plant indicated that there were a number of conditions that had to be overcome, and manageable solutions were found for these operating and mechanical problems. For example, it was learned that there was an optimum level of hydrogen content for the process solvent, and that over hydrogenation could be detrimental. Another important observation was that upon scaling up from the smaller plants to the 250-bbl/day plant, the coal conversion was 5–10% lower than in the smaller units. Radioactive tracer studies showed that the residence time distributions of the reactants change significantly as the reactor diameter was increased. The runs in the large ECLP reactor were terminated in 1983, and the pilot plant was dismantled. After 3 years of operation, it was reported that "the operating staff was now running the plant instead of the plant running the staff" [102].

Initially, the operation of the EDS process resembled the SRC-II process. A later modification of the EDS process utilized vacuum bottoms recycle, and this allowed for the production of a higher distillate yield. This processing scheme allowed for a longer contact time of the heavy, high-boiling bottoms recycle allowed for a higher yield of naphtha [103]. In addition to the longer residence time, the recycle bottoms contained ash which likely provided a catalytic impact [104]. The distillate yield was in the range 2.5–3.0 barrels of liquid per ton of coal.

Exxon continued research at intervals following the closure of the ECLP pilot plant. During this time, they developed the Exxon microcatalytic direct coal liquefaction technology (MCL) [105]. It was announced in 2009 that Accelergy Corp. had obtained a global leasing agreement that would allow them to produce liquid fuels and chemicals from coal resources using the MCL process. In one modification, the solvent hydrogenation could be eliminated because of the activity of the added catalyst, and this increased the thermal efficiency by 7%. In one case, the MCL step is integrated with an existing circulating fluid-bed power plant, and this provides a balanced plant efficiency of 74% (LHV) and produces 5.3 bbl of premium fuels per metric ton of coal [106].

H-Coal Process

The H-Coal process is an extension of the H-Oil process which was designed to upgrade heavy crude under high hydrogen pressure to lower-boiling products [107]. Both processes utilize an ebullated-bed catalytic reactor. A schematic of the H-Coal process with a single stage is illustrated in Fig. 19.31. Research began in 1964 at Hydrocarbon Research, Inc. (HRI, now a part of Headwaters, Inc.), using a bench-scale unit and then progressing to a 200–600-t/day pilot plant at Catlettsburg, Kentucky, that was completed in 1980 and operated through 1983. The time scale for the H-Coal process is typical of the other plants and shows that it would take about 20–30 years from inception to a pilot or commercial plant (Fig. 19.32).

The H-Coal process reactions are carried out at high temperature (ca. 450°C) and intermediate pressure (ca. 150 atm). The dried coal is mixed with a recycle solvent

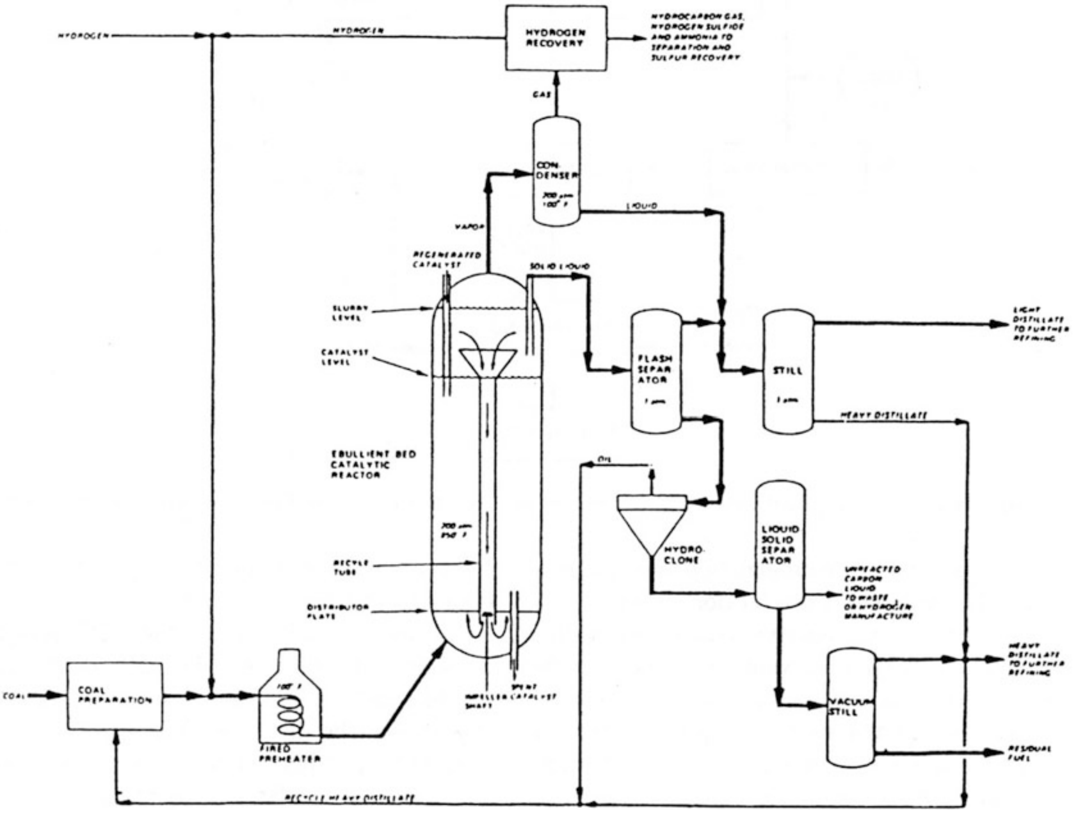

Fig. 19.31 Schematic of H-Coal process (Courtesy of The Pace Company, Denver, CO)

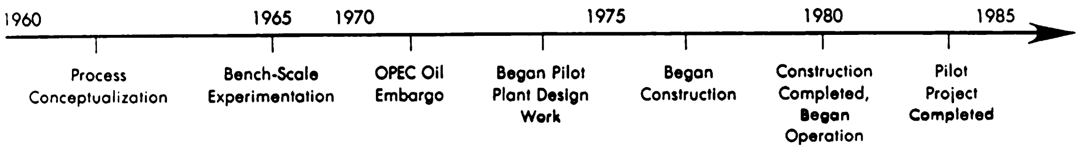

Fig. 19.32 History of development of the H-Coal process

and fed to the bottom of the reactor. In the H-Coal process, the catalyst was a typical hydrotreating catalyst (Co–Mo–alumina) that was maintained in an expanded bed by the upflow of hydrogen and the recycle solvent flow that was provided by an internal pump. The addition of fresh catalyst and the withdrawal of aged catalyst at the bottom of the reactor allowed for the maintenance of a constant catalyst activity allowing for a constant coal-conversion level and constant reactor productivity.

The H-Coal product has a high H/C ratio and a reasonably low heteroatom content. Because of the high temperature, the amounts of light gases that are formed are relatively high compared to the H-Oil process. Typically, between 14,000 and 20,000 standard cubic feet of hydrogen are required for each ton of coal processed. Approximately 3.0–3.5 barrels of liquid product were produced for each ton of coal. The high-volatile bituminous coal was found to be better suited for the process since the lower reactivity of lower-rank coals significantly reduced throughput and distillate yields. Ashland Oil completed the design for a 50,000-bbl/day plant to be located in Western Kentucky, but its construction was canceled due to the low price of petroleum.

German IGOR Process

In Germany, Ruhrkohle AG and Veba Oel AG operated a 200-t/day liquefaction plant that was initially based on the older German process (Deutsche Process, DT). The process was upgraded by adding the Integrated Gross Oil Refining (IGOR) stage and was operated during 1975–1993. The operations were supported by state and/or national government agencies. A 0.2-t/day plant was used in the initial work and was scaled to a 200-t/day plant located at Bottrop. The Bottrop plant utilized a dissolver reactor that contained a “red mud” iron catalyst as well as severe operating conditions (typically 470°C and 300 bar). Liquid yields for the process were in the 50–60% range (maf). A feasibility study for a 50,000-bbl/day plant was carried out, but the decrease in the price of petroleum crude eliminated support for the full-sized plant.

H-Tech

After the shutdown and dismantling of the IGOR/DT plant, key experts of the Kohleoel–Anlage Bottrop (KAB) pilot plant founded h-tech to pool the process know-how in engineering pilot plant, design, and operating plants and to further develop the technology [108]. It is claimed that the KAB process shows the highest conversion levels and liquid yields and thereby the lowest greenhouse gas emissions per barrel of product.

Pyrosol Process

A similar German process (Pyrosol process) for higher ash coals was developed by Saarbergwerke [109]. A 6-t/day pilot plant was operated between 1981 and 1984, but low oil prices prevented the expansion or even continuation of the program. A major difference between the two German processes was that the underflow is processed in a vacuum flash unit in the DT process, whereas in the Pyrosol process, it is carbonized in a hydropyrolysis step.

British Coal Liquid Solvent Extraction

Between 1973 and 1995, the Liquid Solvent Extraction (LSE) process was developed by the British Coal Corporation (Fig. 19.33) [110]. The early work led to the establishment of a 2.5-t/day plant at Point of Aye, North Whales, UK. The coal conversion is carried out in two or more thermal reactors followed by filtration. Following filtration, solvent recovery and hydrogenation is accomplished to produce additional products and recycle solvent. Virtually any coal can be utilized in the process. The process can be operated so only distillable is obtained with total distillate yields of 60–65 (daf), with virtually all boiling below 300°C. Essentially the total effluent from the reactor passed to a filtration drum and the reliable operation of this drum was never accomplished during the work.

Two-Stage Process

As DCL progressed, it was recognized that both coal dissolution and hydrocracking could not be optimized in a single reactor. The use of two reactors could enable the optimization to be made at different reaction conditions. This led to the introduction of a SCT thermal conversion followed by a catalytic upgrading reactor. This combination led to higher yields, more efficient use of hydrogen, and a better product distribution. The development involved both government and industrial organizations and proceeded in an evolutionary manner through a series of steps.

The first approach to separate the two stages was to utilize a SRC-I-type dissolution reactor and to place an upgrading reactor downstream. The operation of these two reactors was not integrated, meaning that the second stage did not contribute solvent to the first stage. Rather than use the typical fixed-bed reactor normally used for hydrotreating, an ebullated-bed reactor was used to avoid the plugging and rapid catalyst deactivation encountered by the fixed-bed reactor at the Cresap, WV plant.

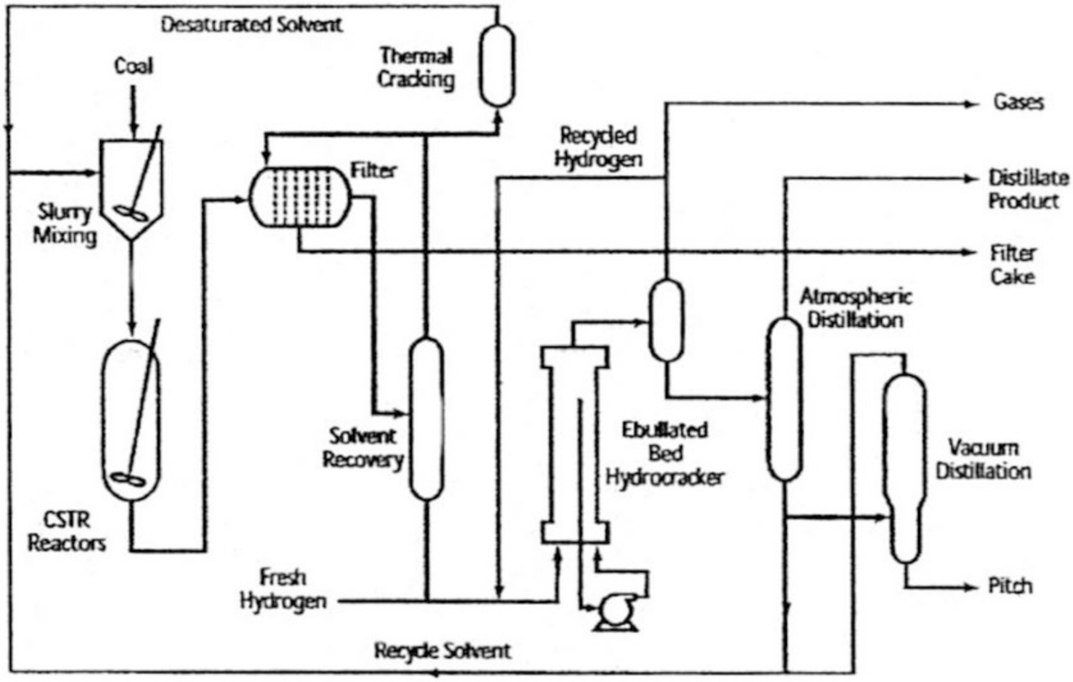

Fig. 19.33 Schematic of the LSE process (DTI, coal liquefaction. Clean coal technology program. Technology status report 010, London, UK, Department of Trade and Industry, 14pp, Oct 1999)

The ISTL process was developed next. In this process, hydrogenated resid is recycled to the first stage to act as solvent. SDA was used to remove ash from the recycled resid. Initially, the SDA was located between the first and second stages, but it was later located after the second stage to become the reconfigured two-stage liquefaction (RISTL). Contrary to expectations, the presence of ash in the second stage did not deactivate the catalyst. As an additional benefit, the product from the two-stage process was easier to upgrade than those from the single-stage process.

The next step in the continuing development was the introduction of the close-coupled integrated two-stage liquefaction (CC-ISTL) where the effluent from the first stage passes directly to the second stage, thereby improving thermal efficiency, reducing the retrograde reactions, eliminating the pressure letdown between reactors, and producing a higher-quality solvent [84, 104, 111–121]. Distillate yields of up to about 65% have been obtained for the conversion of Illinois No. 6 coal for CC-ISTL. A number of variations of the close-coupled process have been tried: thermal first stage/catalytic second stage (T/C CC-ISTL), catalytic ebullated bed for both stages (C/C CC-ISTL), and using a disposable small-particle catalyst rather than the pelleted catalyst.

In the most advanced version of the close-coupled two-stage process, disposable slurry catalysts (usually iron or molybdenum) were added with the coal with an integrated hydrotreated to process the distillate to produce a high distillate yield with a low concentration of heteroatoms.

The US and European units terminated large-scale activities in the early 1990s; following this period, DCL pilot and commercial plants were constructed and operated in the Far East [122].

In Japan, the New Energy and Industrial Technology Development Organization (NEDO) was established in 1980 to conduct activities that focus on research and development that is related to oil-alternative energy, technology for the efficient use of energy and industrial technology. Upon its formation, it assumed responsibility for three liquefaction processes: a solvent extraction process, a direct hydrogenation process, and a solvolysis process. By 1984, they had merged the three activities into a single concept and began the design for a 250-t/day pilot plant that was downsized to 150 t/day by 1988. Many days of testing in a 1-t/day PDU provided information for the design (about a 4-year period) and construction (about a 5-year period) of the pilot plant which was operated for about 3 years. The final NEDO plant has many features of the Exxon EDS process. During the past 10 years, Japanese officials have been working with other Far Eastern countries to move to the commercial stage but have not accomplished this to date. A yield of about 50% light and medium oils was obtained, but these were of poor quality and would need significant upgrading.

In the 1980s, the Japanese and Australians joined to operate a 50-t/day pilot plant for direct brown coal liquefaction in Australia. The coal was from Latrobe Valley in

Victoria and had low-ash content, but the moisture content was in the 55–65% range. Thus, the first step was a dewatering of the slurry followed by liquefaction using a "highly active" iron catalyst. An in-line hydrogenation process produced high-quality distillable oils. Solvent deashing separated ash from heavy oils, with the oils being recycled and the sludge removed for use as a low-grade boiler fuel. The oil yield was 50%, based on daf coal, and subsequent studies using a 0.1-t/day bench-scale plant led to increases in the oil yield as well as its quality and to reduce the amount of catalyst that was needed.

China, with the world's third largest coal reserves but little petroleum, began a massive planning effort for coal liquefaction with many projects in both direct and indirect liquefaction. In 2008, they terminated all of the major plants except for one for direct and one for indirect liquefaction.

The Shenhua Company is the leading Chinese coal producer. They investigated many of the western coal liquefaction operations but decided to develop a Chinese process. Based on results from smaller units, they built a 6-t/day pilot plant in Shanghai, and it has operated since 2004. One train of 20,000–25,000 bbl/day of a commercial plant was constructed and operated in 2009. The unit has two reactors for the coal dissolution and substantial downstream refining and upgrading to finished products. Runs of up to 100 days duration were accomplished with up to 70% of the design capacity being attained [123]. Carbon dioxide sequestration was included in the trial runs. Following the trial runs with the world's largest DCL plant, modifications are being made with start-up expected to occur during 2011.

Direct Coal Liquefaction and the Future

During the 1970s, DCL was the dominant CTL approach. Today, the restriction on the amount of aromatics in gasoline, limitations on sulfur in the fuel, and the difficulty of producing high-quality diesel fuels have almost eliminated the direct pathway from consideration. Only in Japan and China has the direct process continued to be developed, and it appears that the Japanese have downplayed this approach since the 2009 NEDO report does not emphasize their work on the direct CTL approach. However, one should remember that interest in these processes goes through cycles and conditions may soon change so that interest in direct CTL processes is revived [124–126].

Indirect Coal Liquefaction

For indirect coal liquefaction, a synthesis gas (syngas) composed primarily of carbon monoxide and hydrogen is produced in a suitable gasifier by reaction of coal with oxygen and steam. Prior to the synthesis reactor, the syngas is cooled and cleaned, which involves removal of particulates, H_2S, NH_3, and other impurities. Depending upon the catalyst being used, it may be necessary to adjust the H_2/CO ratio of the syngas. The Lurgi gasifiers used at Sasol in South Africa and Great Plains in the United States produce a syngas with a H_2/CO ratio of two or greater and can be employed without water–gas shift to produce the feed for the Fischer–Tropsch or methane synthesis. Most modern coal gasifiers typically produce syngas with a H_2/CO ratio in the range 0.45–1.0, and this must be adjusted upward to about 2.1, the usage ratio to produce the hydrocarbon products. Iron catalysts can be utilized with any syngas below the usage ratio, but a cobalt catalyst does not contain water–gas shift activity, and the feed should be equal to the usage ratio.

Any of the gasifiers mentioned earlier can be used to produce the syngas, and the one used will only impact the subprocesses that need to be placed between the gasifier and the syngas conversion reactor. The feature that defines the indirect coal liquefaction is the technology used to convert the syngas to the syncrude. Today, the Fischer–Tropsch synthesis is the dominant approach to accomplish this synthesis, but the synthesis of methanol, dimethyl ether, etc., can also be used.

Fischer–Tropsch

The Fischer–Tropsch (FT) synthesis was developed in 1925 by the Germans Franz Fischer and Hans Tropsch. The initial commercial processes in Germany were based on cobalt catalysts and utilized fixed-bed reactors. These reactors had a production rate of 15 bbl/day so that a plant would consist of the number of these small reactors that were needed to attain the design capacity of FT products. Because of the exothermosity of the reaction, various fixed-bed reactor designs were tried, but the most widely utilized design consisted of two concentric tubes with the catalyst located between the two tubes and the cooling water/steam located inside the inner tube and outside the outer tube. These reactors were fitted with cooling fins and bundled within a shell in a number needed to produce 15 bbl/day.

Soon after the end of the war, commercial operations were undertaken in the United States and South Africa. The US effort was led by HRI and utilized a fixed-fluid-bed reactor. The US effort was based on cheap natural gas, and the effort was terminated when the price of natural gas rose significantly. In addition to many problems with oxygen production, syngas generation, and syngas cleaning units, the scale-up of the fixed-fluid-bed reactor encountered many problems. The scale-up directly from a 2 to 7 in. laboratory to a commercial-scale reactor caused them to not recognize the formation of large gas bubbles and the much lower conversion that results from this. A circulating bed (HTFT), rather than a fixed-bed, reactor was used in South Africa, and problems were encountered during the initial reaction period. However, government support allowed continued development to overcome the operating problems. Sasol continued operating the HTFT reactors into the 1990s when they introduced a fixed-fluid-bed Sasol Advanced Synthol, SAS, reactor. The major advantages of the SAS reactor led to a rapid switch all of the HTFT reactors to SAS reactors. SAS reactors of 20,000 bbl/day have been placed in operation. In order to maintain the fluid bed, the FT products must remain in the gas phase at the reaction temperature. This requires the SAS reactors to limit the carbon number of the products to about 20–25; to accomplish this, the reactors are operated at high temperatures (300–350°C) and a suitable catalyst formulation. Because the cobalt catalyst produced predominantly methane at these high reaction temperatures, the fluid-bed operations are limited to an iron-based catalyst.

In the 1990s, Sasol brought on-line a 2,500-bbl/day slurry reactor wherein the small solid catalyst particles are suspended in the reactor wax products that are produced. Work using a similar reactor had been conducted in Germany during the 1940–1960 period that utilized an iron catalyst, but this work did not progress beyond the pilot-plant stage. Even so, the German work established much of the theoretical basis for the utilization of a slurry reactor for the Fischer–Tropsch synthesis.

For the slurry reactor, the catalyst particles are suspended in the high-boiling Fischer–Tropsch products; the catalyst slurry enters at the bottom of the reactor and flows upward. The products that are in the gas phase at the reaction temperature exit the reactor with the unconverted syngas through the top of the reactor. The nonvolatile products are removed from the reactor using an internal filter or in an external settling tank; wax removal is one of the challenging aspects of this reactor type. The reactor can be operated essentially in an isothermal mode, and this ensures that all catalyst particles contribute equally to the generation of products. Catalyst addition and withdrawal can be practiced so that a constant productivity can be maintained.

In South Africa, the fixed-bed reactor was also utilized. In the beginning, it was the same as those used in Germany except that the catalyst was iron based rather than cobalt based. These reactors were operated under low-temperature conditions so that waxes were a major product. Normally, these waxes would need to be cracked or hydrocracked to produce transportation fuels. However, the demand for waxes is sufficient for Sasol to process them for a variety of uses, including candles, chewing gum, fruit and vegetable coatings, etc.

The fixed-bed reactor provides for easy separation of the products from the catalyst. Special operating procedures are needed to minimize the uneven temperature along the length of the reactor due to the highly exothermic nature of the reaction. For both reactor types, operating temperature increase is used to offset the gradual deactivation of the catalyst.

Both the circulating and fixed-fluid-bed reactors are capable of nearly isothermal operations. Catalyst addition and withdrawal are easily accomplished with both fluid-bed reactors. Catalyst attrition and degradation due to carbon formation are problems that must be dealt with for the fluid-bed reactors.

Sasol has commercial operating experience with the four types of reactors utilized for Fischer–Tropsch synthesis (Fig. 19.34). Sasol operates with both the iron and cobalt catalysts at the commercial scale. Shell has concentrated on the fixed-bed reactor for their commercial operations that utilize the cobalt catalyst.

In the 1990s, Mossgas (now PetroSA) constructed and brought on-line a 40,000-bbl/day plant that utilized the circulating fluid-bed reactors such as those used by Sasol. During the past few years, PetroSA, working with Statoil, brought on-line and operated a 1,000-bbl/day slurry reactor. Today, this effort has produced the GTL.F1 technology, a combined effort of Statoil, PetroSA, and Lurgi. The PetroSA operation is based on natural gas rather than coal.

In a simple view, the FT synthesis can be viewed as a polymerization reaction in which the monomer is derived from, or is, the CO reactant. Thus, in this simplified model, the polymerization produces a product distribution as shown in Fig. 19.35 (left); in actual practice, the distribution that is obtained is better represented in Fig. 19.35 (right) plot.

The basic products of the FT reaction are paraffins, olefins, and alcohols, and the reactions may be represented as:

Paraffins

$$(2n+1)H_2 + nCO = C_nH_{2n+2} + nH_2O$$

Olefins

$$2nH_2 + nCO = C_nH_{2n} + nH_2O$$

Alcohols

$$2nH_2 + nCO = C_nH_{2n+1}OH + nH_2O$$

The following competing reaction, water–gas shift, may occur; in practice, it occurs to a

$$CO + H_2O = H_2 + CO_2$$

The FT reaction requires a syngas that has a H_2/CO ratio of 2.1–2.2 depending upon the fraction of light hydrocarbons that are produced. Since modern gasifiers produce a syngas with a H_2/CO ratio in the range of 0.5–1.2, water–gas shift or

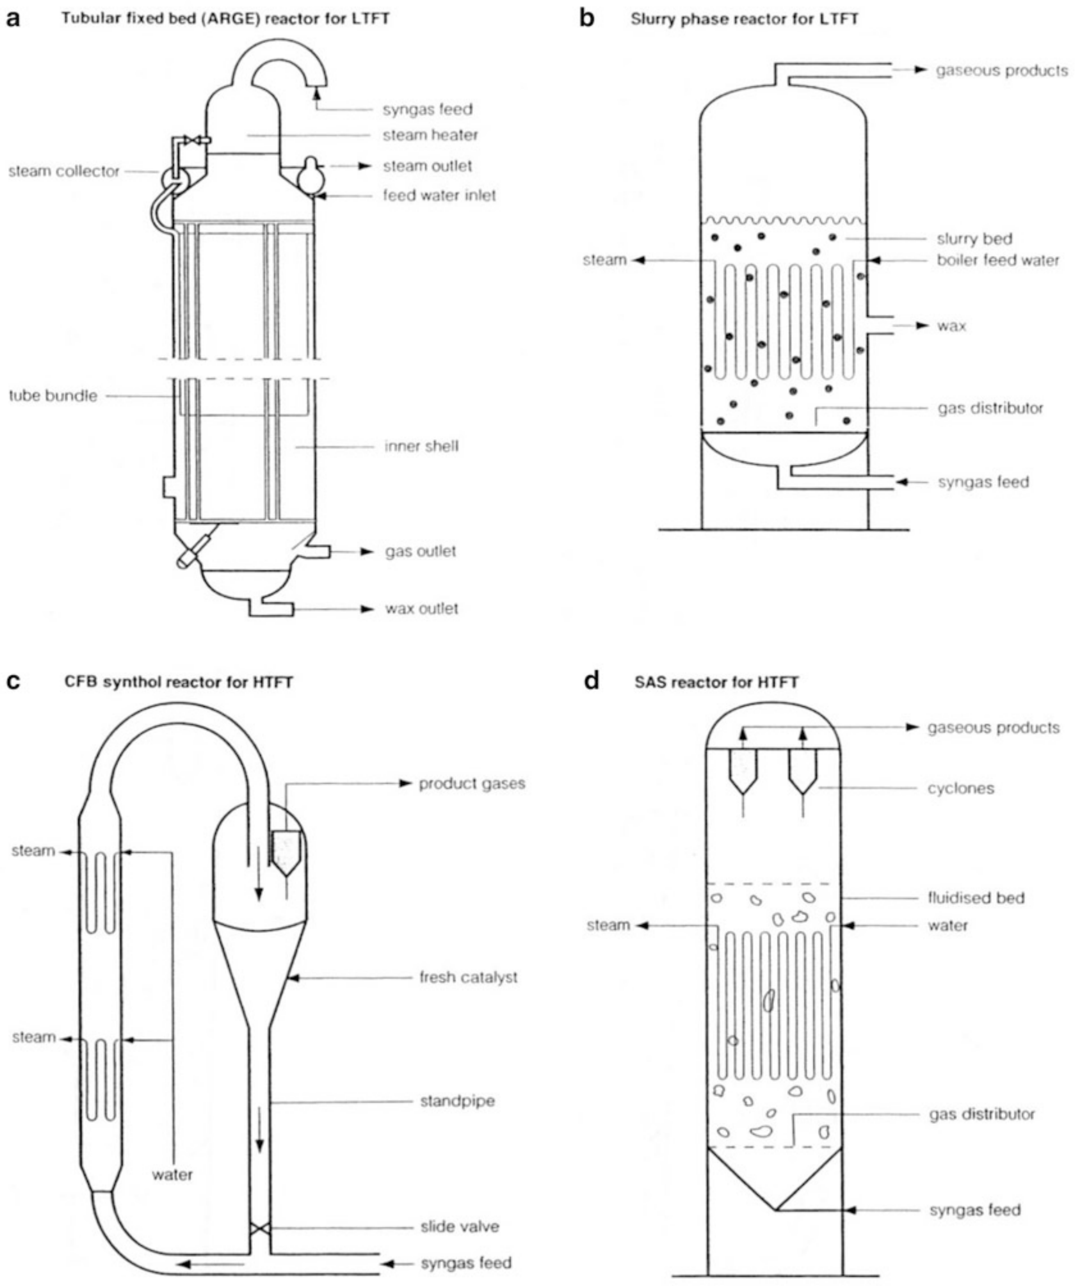

Fig. 19.34 The Sasol FT reactors [147]

another source of hydrogen is required. The near absence of WGS activity for the cobalt catalyst requires an upstream WGS reactor to be utilized with those gasifiers that produce a syngas with a H_2/CO ratio in the 0.5–1.2 range. When an iron catalyst is used, this will not be needed.

The FT synthesis products typically follow an Anderson–Schulz–Flory distribution:

$$W_n = n(1-\alpha)^2\alpha^{n-1}$$

where W_n is the weight fraction of produces with carbon number n, and α is the chain growth probability whose value depends upon the catalyst and operating conditions. When the value of α is zero, only methane is formed, and as the value of α approaches one, the products become predominantly high molecular weight waxes. In logarithmic form, the product distribution becomes

$$\log(W_n/_n) = n\log\alpha + \log[(1-\alpha)^2/\alpha]$$

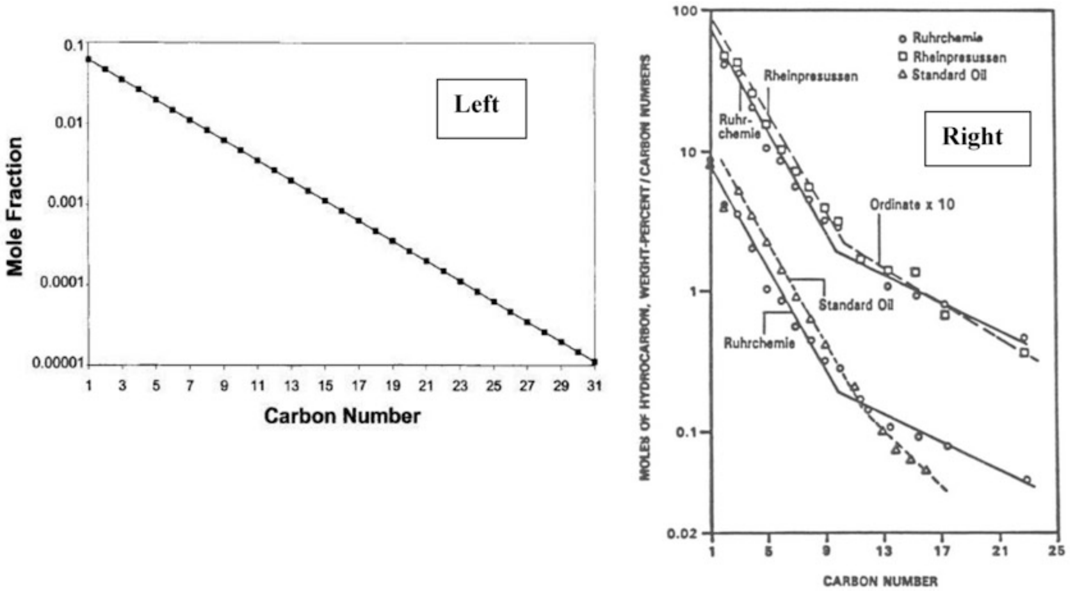

Fig. 19.35 (*Left*) Typical Schulz–Flory plot. (*Right*) Logarithmic plots of moles again carbon number. Hydrocarbons Schwarzheide tests compared with those from fluidized synthesis

A plot of log(W_n/n) vs. n is a straight line with a slope that depends on α (Fig. 19.35 left).

Indirect Coal Liquefaction and the Future

Today, the FT synthesis has replaced the DCL pathway as the preferred route. While Sasol currently is the only commercial coal-based FT operation, it is large and studies are underway that could lead to a doubling of the production from coal (from 150,000 to 300,000 bbl/day). In addition, significant expansion of FT production has occurred, based on natural gas. Thus, Shell/Qatar is expanding by adding 120,000 bbl/day to the current 15,000 bbl/day in Malaysia. Sasol is planning to increase the operation at Sasolburg by 12,000 bbl/day and is at various stages of planning for plants to be located in China, India, and Australia. Thus, it appears that there will be significant growth during the coming years.

Stranded gas and the need to reduce the carbon footprint of fossil fuels offer promise of the need for smaller scale plants. One potential advance that could speed developments in these areas is the introduction of microchannel reactors. In addition to the ability to construct much smaller reactors (a meter length rather than 100), Velocys reports up to at least a tenfold increase in space–time yield using these reactors [127–129].

The technology is practiced in two temperature regions: a high- and low-temperature synthesis. An iron catalyst is used for the high-temperature operation where only a small fraction of the products are higher boiling than the diesel fraction so that downstream processing is essentially limited to a distillation step. Either iron or cobalt can be used for the low-temperature process. An iron catalyst was utilized for the 1950s German slurry reactor investigations and the early Sasol work for their low-temperature slurry reactor. However, today, most of the emphasis is on the cobalt catalyst for both the fixed-bed and the slurry reactors.

In any event, the situation is in a state of flux. A listing was presented for proposed CTL plants in the United States in 2007; an examination of the list at the beginning of 2011 shows that nearly all of these plants have either been canceled or put on hold. The US DOE has caused a baseline technical and economic assessment for FT to be made [130] as well as for coal and biomass for producing FT fuels and electricity [131].

Methanol. Methanol is a water-soluble, low molecular weight alcohol that may be of increasing importance as a low-sulfur fuel, a chemical feedstock, and perhaps as a gasoline additive or an intermediate in gasoline production. The synthesis of methanol is accomplished by the catalytic conversion of synthesis gas containing two moles of hydrogen for each mole of carbon monoxide. Methanol synthesis is widely practiced in industry on a commercial scale. See Chap. 10 for a discussion of methanol manufacture.

Methanol to Gasoline: The Mobil Process. Mobil Research and Development Corporation has developed a process that catalytically dehydrates and polymerizes methanol to produce a high-octane gasoline. The catalyst is one of a family of synthetic zeolites designated ZSM-5 by Mobil. These zeolites

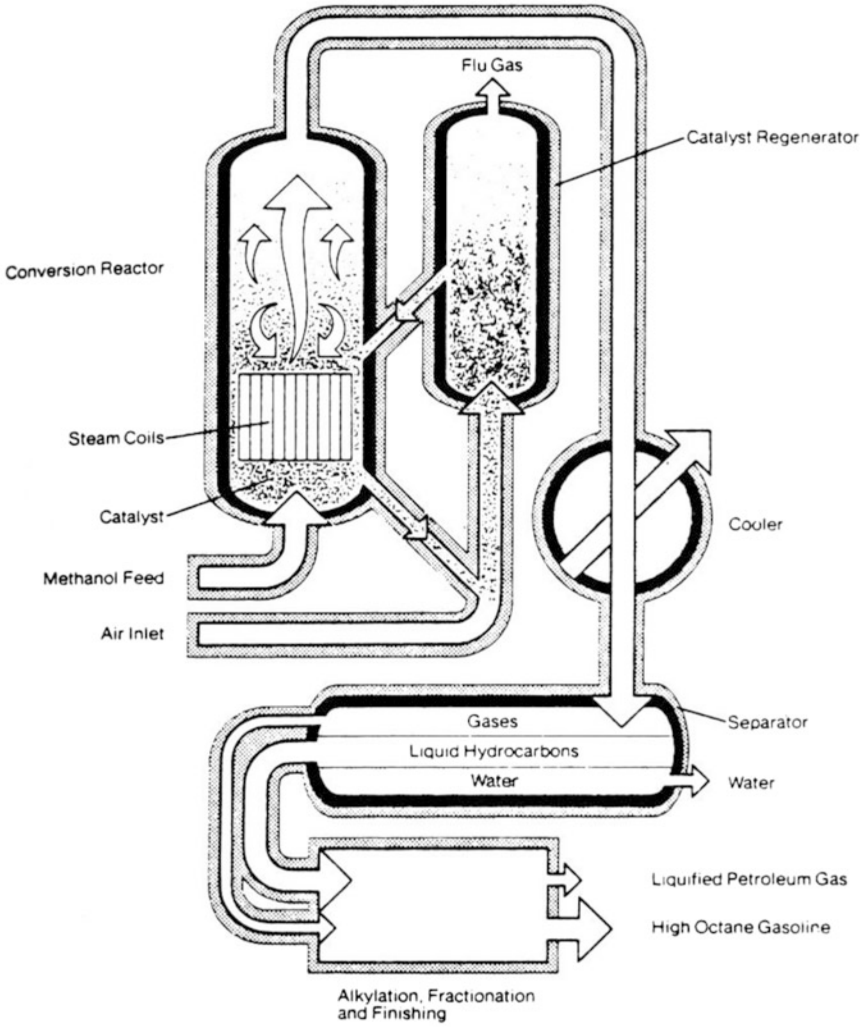

Fig. 19.36 Schematic of Mobil's fluid-bed MTG process, which uses a unique zeolite catalyst to convert methanol to high-octane, unleaded gasoline (Courtesy of The Pace Company, Denver, CO)

have a unique channel structure, and one of these new zeolites converts methanol into a mixture of hydrocarbons corresponding to high-quality gasoline. The mass balance shows 0.44 lb of gasoline and 0.56 lb of water from each pound of methanol; however, the gasoline produced contains 95% of the heating value in the methanol feed.

A schematic diagram of one version of the process is shown in Fig. 19.36. Crude methanol is vaporized at the bottom of the reactor and passes through a dense fluidized bed at 410–415°C and 25 psig. The methanol is converted to hydrocarbons and water. The catalyst is separated from reaction products in a disengager section at the top of the reactor, the reactor effluent is condensed, and the water and hydrocarbon products are separated. To make additional gasoline, propene and butenes can be alkylated with isobutane by conventional petroleum technology (see Chap. 18).

Portions of the powdered catalyst are removed from the reactor, regenerated with air, and returned to the reactor. Small amounts of carbon monoxide, carbon dioxide, and coke are formed as by-products. The process and potential opportunities for the use of MTG to produce fuels from coal have been discussed recently (2008) [132].

The process was operated at the 15,000-bbl/day scale in New Zealand in the 1980s. Multiple fixed-bed reactors were used in the New Zealand operation. The first reactor was used to convert methanol to an equilibrium mixture of methanol, dimethyl ether, and water. This equilibrium mixture is mixed with recycle gas and passed over the ZSM-5 catalyst in a fixed-bed reactor. The first reactor to produce the alcohol, ether, and water mixture releases about 20% of the overall heat of reaction. ExxonMobil claims to have made advances since then that reduce both capital investment and operation expense [133].

Methanol can also be converted to olefins and produce essentially only ethene and propene. While the ZSM-5 catalyst can be adapted for this purpose, usually a less acidic catalyst is utilized, frequently a silicoaluminophosphate (e.g., SAPO-34) [134]. A process (UOP/HYDRO MTO) is

Table 19.20 Crude oil price (Brent) for a profitable DCL project [136]

Market	Crude oil net back price if no carbon capture	Crude oil net back price at CO_2 = 40 \$/tons
China	50–60 \$/bbl	70–80 \$/bbl
United States	75–85 \$/bbl	95–105 \$/bbl
Europe	90–100 \$/bbl	110–120 \$/bbl

described that claims up to 80% ethene/propene and greater than 95% conversion to C_2–C_4 alkenes [135]. The UOP process is at or near the commercial scale.

CTL Summary

The economics for CTL are complex and are very site dependent. This is illustrated by the prices for three locations shown in Table 19.20 for DCL [136]. The outlook should be similar for indirect coal liquefaction. For indirect CTL, the avoidance of CO_2 is relatively low since CO_2 is readily available from the syngas purification step. Based on the cost shown in Table 19.20, projects should be profitable in China and the United States but not in Europe; however, the price in 2011 is not adequate to lead to the initiation of major activities in either country.

The situation with CTL is very unstable. Typical is the case in China. Five years ago, there were many direct and indirect processes at various stages of development. Then, in 2008, the National Development and Reform Commission decided that, apart from two projects operated by the Shenhua Group, none could go ahead before receiving official approval. This was because CTL is "a technology-, talent- and capital-intensive project at an experimental stage with high business risks" [138]. Since Sasol was making significant profits for their CTL operations in South Africa and was involved in a CTL project in China, this decision must have been based on conditions specific to China.

Military needs have provided impetus but little funding for coal to liquids development [138, 139]. The current outlook for CTL has been presented by several groups in recent years [140–147].

Petrochemical Feedstocks

Feedstocks for the petrochemical industry are produced mainly from crude oil (Chap. 18) and natural gas (Chap. 20). About 90% of all organic chemicals are manufactured from just six feedstocks: synthesis gas, ethylene, propylene, butadiene, benzene, and p-xylene, with synthesis gas accounting for over half of these feedstocks. Although a lot of syngas for the manufacture of ammonia, methanol, and other chemicals is produced by steam reforming of natural gas or light oils, as discussed above, syngas can also be produced by coal gasification.

Several sources discuss and evaluate processes for the production of chemicals from coal [148–155]. Most basic chemicals currently produced from oil or natural gas can be produced from coal using demonstrated technology. The broadest range of synthesized products is available by conversion of coal to synthesis gas and utilization of existing processes for production of chemicals, such as ammonia, methanol, and acetyl derivatives. Advances in the chemistry of synthesis gas are rapidly expanding the array of chemicals obtainable from coal by this route [156–162]. Many other chemicals can be separated from the by-products of gasification and pyrolysis processes. In fact, the foundation of the modern chemical industry was built on processes utilizing coal hydrogenation and pyrolysis to obtain a variety of chemicals, including dyes, solvents, fuels, and pharmaceuticals [163]. However, in the 1950s, the wide availability and low cost of crude oil made petroleum-derived materials the preferred source for chemicals production.

Presently (2011), the choice of feedstock for chemicals production depends on complex technical, economic, environmental, and political factors. Clearly, not all chemicals are suitable for production from coal with current technology. Some factors to be considered in the evaluation of the appropriate feedstock for a particular chemical product are (1) the relationship between the carbon/hydrogen ratio in the chemical product and the feedstock, (2) the delivered cost of alternative raw materials, (3) capital costs, (4) environmental protection, and (5) the reliability of supply. Recently, except for special situations, such as that for Sasol in South Africa, the manufacture of chemicals from coal at coal prices relative to the prices of petroleum and natural gas has not been economically attractive.

Chemicals from Coal

The use of coal as a raw material for the production of chemicals started with the discovery of the first coal tar dye by Sir William Perkins in 1856. Prior to that time, the liquid by-products of coking were regarded as wastes. Perkins' discovery revealed that valuable materials could be isolated or made from coal tar and ultimately led to the establishment of the modern chemical industry. Coke ovens rapidly came to be important as sources of chemicals, such as benzene, naphthalene, ammonia, and hydrogen. Coal tar became an important source for aromatic and heterocyclic chemicals for the dye and pharmaceutical industries.

Coke production was formerly the most important demonstrated technology associated with the direct production of chemicals from coal. Industrial chemicals currently obtained in significant amounts as coke by-products include benzene, toluene, xylene, naphthalene, anthracene, phenanthrene, phenol, ammonia, ammonium sulfate, sulfur, and carbon dioxide. The vast majority of aromatics production from coal occurs in Eastern Europe, India, China, and Japan [164].

Chemical by-products from coke manufacture amount to roughly 4% of the coal feed. Although this yield initially supplied adequate quantities of chemicals for developing end uses, the growth of the industry eventually required additional sources of chemicals. The advent of technology for producing calcium carbide and acetylene in 1892 provided a means for conversion of coke to chemical products. Also, this technology stimulated the growth of an independent chemical industry by allowing the manufacture of chemicals to be pursued apart from the manufacture of coke for steel production. More recently, independent production of chemicals from coal has gone through the synthesis gas route.

Chemicals from coal via gasification of coal to synthesis gas as a stand-alone chemical process have been difficult to justify economically because the alternative routes through crude oil or natural gas have been relatively cheap, but that has recently changed. With special circumstances such as large-scale, high final product value, low coal cost, or intangibles such as security of raw material supply, these types of plants have been successfully built and operated on a limited basis. However, as crude oil and natural gas pricing has increased, interest in coal to chemicals has dramatically increased.

Economics of coal gasification plants can often be improved by coproduction of "secondary" chemicals that may be low volume, but high value. This concept of coproduction to improve overall economics is illustrated by the efforts at Dakota Gasification's Great Plains Synfuels plant in North Dakota and at Sasol in South Africa. At Great Plains, the primary product is synthetic natural gas, but other high-value products include naphtha, phenol, fertilizers, krypton–xenon from the air separation plant, and CO_2 exported for enhanced oil recovery. Research and development efforts are ongoing to enable profitable recovery of other by-products. The types of by-products produced depend, in part, on the type of gasification technology employed. Low-temperature gasification such as the Lurgi gasifier used at Dakota Gasification produces more tars and oils that can be separated and refined to other products. Sasol has utilized the tars from gasification and the Fischer–Tropsch products to become a chemical company. At times, chemicals have produced more than half their profits even though chemicals account for less than one-fourth of their production. The high-temperature gasification processes such as GE (formerly Texaco) produce very few chemicals directly other than carbon monoxide, hydrogen, and carbon dioxide.

There is also much interest in coal gasification from power producers to produce electricity from coal more cleanly and efficiently than traditional pulverized-coal steam plants. This concept is commonly referred to as IGCC (integrated gasification combined cycle). Economic justification of stand-alone power plants via IGCC is also difficult due to the high capital cost of these types of plants. There could be significant synergies between power production and chemical coproduction that could improve the economics of both. Power plants bring the large scale necessary for unit cost reductions, but the electricity price in many markets is low and variable (especially in off-peak hours). Chemicals bring a steadier, higher-value demand.

In recent years, several commercial plants have been constructed for conversion of coal to synthesis gas for chemical manufacturing. These include the Eastman Chemical's acetic anhydride plant, the Ube (Japan) ammonia plant, the SAR (Germany) oxo chemicals plant, and several coal to ammonia plants in China (e.g., Weihe, Huainan, and Lunan). The Ube plant and the SAR plant have since converted to lower-cost opportunity fuels (petroleum coke and residues). The Eastman plant is still operating exclusively on coal. Feedstock changes at the other plants illustrate the vulnerability of coal-conversion processes to a changing economic climate. The fact that the Eastman process remains competitive under changing conditions is due to a set of special circumstances that favor a coal-based process. The success of the Eastman chemicals from coal complex demonstrates that synthesis gas from coal is a viable feedstock for some industrial chemicals under certain conditions.

Clearly, the number of chemicals produced from coal-derived synthesis gas can expand as new technologies are developed and favorable economics exist. The most likely such chemicals are those for which processes have been demonstrated but which presently are uneconomic. Relatively small improvements in technology, shifts in feedstock availability and/or cost, decreased capital costs, or political factors could enhance the viability of coal-based processes for the production of methanol, ethanol, and higher alcohols, vinyl acetate, ethylene glycol, carboxylic acids, and light olefins.

New technologies are being developed for the partial oxidation of coal to organic acids, for plasma pyrolysis of coal to produce acetylene and other small molecules [165], and for the manufacture of additional chemicals such as acetaldehyde from synthesis gas [166]. Also, the use of coal tar for the manufacture of high-temperature engineering plastics and bioconversion of coal to aromatics, organic acids, alcohols, and methane [164] have been reported. Innovative strategies are being considered that offer the potential for reduced costs; for example, by co-gasifying coal with waste, waste disposal credits might be obtained.

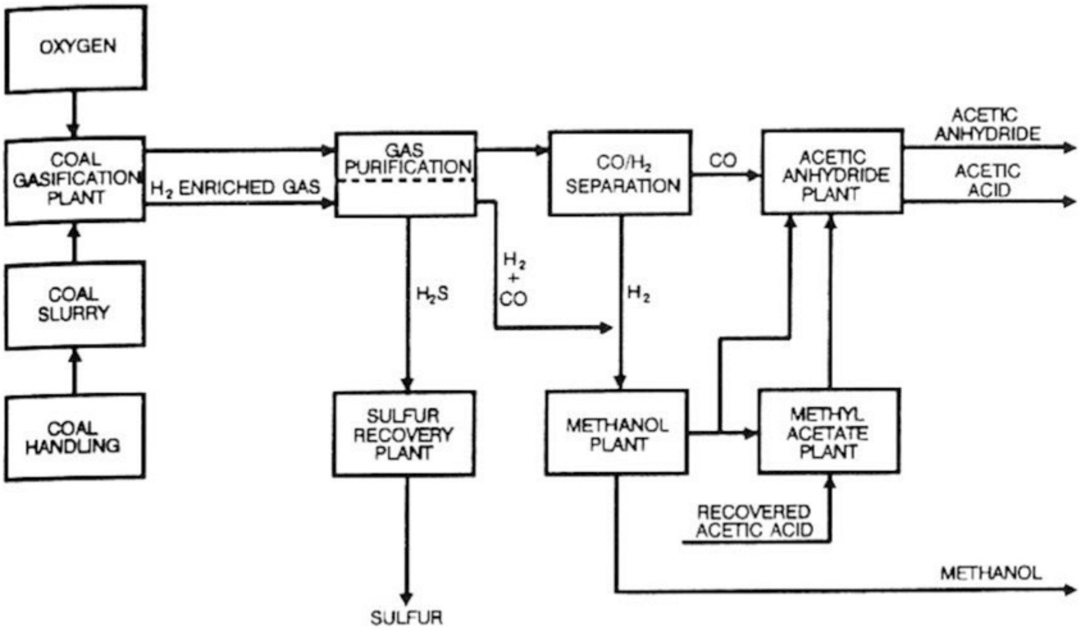

Fig. 19.37 Overall block flow diagram for coal gasification–acetic anhydride complex

Examples of Chemicals Production from Coal

A pioneer US manufacturer to produce a slate of industrial chemicals from coal is Eastman Chemical Company. Commercial facilities include a coal gasification plant for synthesis gas manufacture, raw gas cleanup and separation facilities, a sulfur recovery unit, and chemical plants to produce methanol, methyl acetate, acetic acid, and acetic anhydride. A flow diagram of Eastman's chemicals from coal plant is shown in Fig. 19.37.

A GE quench coal gasifier provides synthesis gas at elevated pressure from local coal. Medium- and low-pressure steams for use elsewhere in the complex are produced by recovering waste heat. After the gasifier product is scrubbed with water to cool the gas and remove ash particles, a portion of the syngas is sent to a water–gas shift reactor to increase its hydrogen content. A Rectisol unit, using a cold methanol wash, then removes hydrogen sulfide and carbon dioxide from the product gas streams. Cryogenic separation in a Linde "cold box" provides a carbon monoxide stream for the acetic anhydride plant and a hydrogen-rich stream for methanol production. The recovered hydrogen sulfide is converted to elemental sulfur in a Claus unit followed by a SCOT tail gas treating unit.

Methanol is produced from carbon monoxide, carbon dioxide, and hydrogen. The proper feed composition is achieved by combining the hydrogen-enriched syngas from the shift reactor and the hydrogen–carbon monoxide stream from the gas separation unit. The feed stream goes to both an energy-efficient, low-pressure, gas-phase, catalytic Lurgi methanol process and an Air Products liquid-phase process. Methanol is reacted with acetic acid to form methyl acetate. In the final step of the process, purified carbon monoxide from the gas separation plant is reacted with methyl acetate to form acetic anhydride. Part of the acetic anhydride is reacted with methanol to coproduce acetic acid. The methyl acetate resulting from this reaction is recarbonylated in the acetic anhydride reactor. The acetic anhydride is used to make various cellulose acetate plastics and fibers and acetate solvents. The reaction produces by-product acetic acid that is recycled to the methyl acetate plant to react with methanol.

Another example of large-scale production of chemicals from coal is the Sasol facility in South Africa. Sasol produces many products from coal-derived syngas, including ethylene, propylene, α-olefins, alcohols, and ketones. They have also increased their production of methanol, synthetic lubricants, detergent alcohols, acrylic acid and acrylates, oxo alcohols, styrene and polystyrene, propylene oxide, and propylene glycol.

Today, the Shenhua Broton Coal Chemical project is a leader in restoring coal as a feedstock for chemicals production, and it will be one of the first new world-scale coals to chemicals project. The methanol plant will be one of the world's largest plants, and the methanol that is produced will be a feedstock for a variety of large-scale chemicals production. Other Chinese plants are converting coal to simple chemicals, and their expansion in this area is very rapid [167–171].

As the above examples illustrate, the potential exists for producing larger quantities of commodity chemicals from coal. Some factors that could facilitate the increased use of coal for this purpose include price increases for petroleum and increased use of coal gasifiers for power production. As IGCC plants are built, there will be an opportunity to incorporate in the plant design the coproduction of high-value chemicals.

Acknowledgment The authors are indebted to the authors of the chapters in previous editions. Without the use and guidance that these afforded us, this section would have been much more difficult.

Natural Gas

20

James D. Idol, Mahmood Moshfeghian, and Arland H. Johannes

Characteristics

Natural gas is a naturally occurring mixture of simple hydrocarbons and nonhydrocarbons that exists as a gas at ordinary pressures and temperatures. In the raw state, as produced from the earth, natural gas consists principally of methane (CH_4) and ethane (C_2H_4), with fractional amounts of propane (C_3H_8), butane (C_4H_{10}), and other hydrocarbons, pentane (C_5H_{12}) and heavier. Occasionally, small traces of light aromatic hydrocarbons such as benzene and toluene may also be present.

The ethane and heavier hydrocarbon components of natural gas are rather easily separated from the gas stream and liquefied under moderate pressure.

Most of these components are separated and recovered because of their added value when they are sold as separate products. Unprocessed natural gas is described as "rich" ("wet") or "lean" ("dry"), depending on the amounts of liquefiable heavier components present in the unprocessed gas. (The dividing line is not specific).

In addition to hydrocarbon components, raw natural gas from some reservoirs may contain varying amounts of nonhydrocarbon contaminants, or diluents, such as hydrogen sulfide (H_2S), carbon dioxide (CO_2), water (H_2O), nitrogen (N_2), and/or helium (He). Natural gas containing the first two of these compounds, hydrogen sulfide and carbon dioxide, is termed "sour" and the contaminants are referred to as "acid" gases. Natural gas that contains low enough concentrations of the acid gases to meet sales specifications is termed "sweet."

Although some natural gas is suitable for use as a fuel as produced, virtually all natural gas undergoes some processing to produce a merchantable gas the composition of which is principally methane and ethane. Water and acid gas components are removed to prevent freezing, corrosion, or other operating problems in transmission or utilization. Diluents that exist in significant quantities usually are removed to improve the combustion and/or heating properties of the gas. Much of the ethane and propane and essentially all of the butanes and heavier hydrocarbons are removed because of their greater value when sold as separate liquid products.

Table 20.1 gives typical raw gas compositions. "Casinghead" gas is typically collected from liquid–gas separators in oil production facilities. Because the separators generally operate at low pressures, the gas from this source tends to be richer in liquefiable hydrocarbons content. "Gas well" gas and "condensate well" gas generally are produced at higher pressure and with little or no accompanying liquid, so their compositions show less liquefiable hydrocarbon content. These characteristics describe "traditional" natural gas or gas from commonly thought of sources. Today gas is available or becoming available from nontraditional sources. This "unconventional gas" tends to have a composition that is much more like the "gas well" gas than "casinghead" gas.

Table 20.2 shows the physical properties of the principal constituents of natural gas as produced. Table 20.3 presents typical specifications for pipeline quality, or "merchantable," natural gas.

The common unit of measurement for natural gas is the "standard" cubic foot in the English system and the "standard" cubic meter in the SI system. Each of these "standards" is expressed at pressures and temperatures commonly used as standard to the system in the geographical area of concern. In the United States, where standards frequently vary from state to state, the cubic foot is frequently expressed in the English system at standard conditions of 14.69 pounds per square inch absolute (psia) and 60° Fahrenheit (60°F),

[a] Extrapolated. Above critical temperature

although there are a number of other "standard" conditions specified by various regulatory and government agencies at various governmental levels. In metric units, the cubic meter is commonly defined as being at one atmosphere of pressure (101.325 kPa) and 15 degree Celsius (15°C).

Another common unit of measurement for natural gas is by use of its heating value, expressed in British thermal units (BTU) per standard cubic foot in the English system, and in Joules (or calories) per unit volume in the metric system. Commercially used natural gas, after processing, yields the equivalent of about 950–1,050 BTU/sft^3. Also used as a unit of measurement is the therm, equivalent to 100,000 BTU, or the nominal heat content of 100 standard cubic feet of lean, processed natural gas.

The most common unit of measurement in the English system is the mscf or thousand (10^3) standard cubic feet. Larger volumes, used to express production or pipeline volumes, are noted as bscf, or billion (10^9) standard cubic feet. Even larger volumes, such as reserve figures, usually are expressed as tcf, or trillion (10^{12}) standard cubic feet.

Occurrence of Natural Gas

Natural gas occurs in a number of different forms, depending primarily on the source: associated gas is gas produced "in association" with crude oil; nonassociated gas is gas produced from a gas well with little or no accompanying liquid;

gas produced in combination with liquid condensate which is much lower in molecular weight and lighter in color than crude oil; and "coal bed methane (CBM)," which is gas produced from relatively shallow (3,000–5,000 ft) formations containing primarily coal but that also contain marketable quantities of high methane content natural gas. Typical compositions for the first three of these categories are shown in Table 20.1. Figure 20.1 is a simplified schematic layout of the flow of natural gas from the producing well through various stages of processing.

Associated gas is found in crude oil reservoirs, either dissolved in the crude oil or in conjunction with crude oil deposits. Dissolved or associated gas provides the driving force or reservoir pressure necessary to produce oil from a reservoir. Dissolved gases are produced from oil wells along with the oil. The gas separates, or is separated from the crude oil at the well head. Such gas also may be called "casinghead gas" or "oil well gas." In the early days of the industry, virtually all the natural gas usefully utilized was associated gas from oil wells. Much of the very large gas reserves of several Persian Gulf countries and the Prudhoe Bay reserves of Alaska are associated gas.

Nonassociated gas occurs in reservoirs separate from those of crude oil. It is commonly referred to as "gas well gas," and contains much less of the heavier, or condensable, hydrocarbons that are found in associated gas.

Recently huge reserves of "nonassociated" or "gas well" gas have been discovered in the Persian Gulf area.

Today, because of the wide demand for natural gas, most utilized gas is nonassociated gas.

The third form in which conventional natural gas reserves occur might be called a single-phase fluid, because it is neither a true gas nor a true liquid. It is not a gas or liquid because no surface boundary exists between gas and liquid. Reservoirs of this type are called "gas condensate" reservoirs, and usually are found in moderately deep formations, have very high pressures, and pose special problems in production and processing.

In recent years gas wells have been drilled at increasing depths. This greatly increases drilling costs and new wells may cost many millions of dollars to drill and bring into production. At least a partial remedy for this has been the rapid development of "CBM" as a major source of natural gas in the United States. The wells are relatively shallow—around 5,000 ft maximum at present—and much less expensive to drill, complete, and bring to onstream production.

In addition, CBM appears to be widely distributed across the lower 48 states of the United States.

Early on the subsurface coal mining industry learned that "swamp gas" or "firedamp" was prevalent in underground coal mines. The gas is largely methane formed from the decay and rotting of carbonaceous materials to ultimately form coal. When pressure is released (as by drilling into the coal seam) the methane-rich gas migrates to the low pressure and is produced. The composition and properties of several CBM streams are shown in Fig. 20.2 [1].

CBM has rapidly gained a major position in the lower 48 states natural gas production. Figure 20.3 [2] shows, by year, the number of producing CBM wells in the lower 48 U.S. states. The total number producing for the year 2000 was almost 14,000, and the total gas production as shown in Fig. 20.4 [2] was almost 1.4 tcf. This works out to an average per well production in the order of 40 mcf per day per well.

Evolution of the U.S. Natural Gas Industry

Although natural gas is the predominant product (98%) of the gas industry today, its utilization evolved out of the production and use of manufactured gas, and its major expansion came about through utilization of early "town gas" systems originally installed to distribute manufactured gas.

Manufactured gases are those obtained by destructive distillation of coal, by the thermal decomposition of oil, or by the reactions of steam passing through a bed of heated coal or coke. Prior to the development of large natural gas reserves, manufactured gas was used widely for illumination in the "gaslight" era of the United States.

Following the discovery of major oil and gas reserves in the early twentieth century, associated gas became plentiful in oil-producing areas, and natural gas began to displace manufactured gas in town systems. However, early natural gas utilization was confined largely to areas at or very near the source of supply because methods and materials for transporting the gas had not yet been developed.

Natural gas is relatively difficult to transport and store and is extremely bulky compared with other forms of energy. At atmospheric pressure, one cubic foot of natural gas contains about two-tenths the energy content of a cubic foot of solid or liquid fuel. This is the primary reason natural gas is transported through pipelines at very high pressures, typically 900–1,000 psia. The development of high tensile strength, thin wall pipe, and modern welding techniques in the mid-1930s permitted the construction of numerous long-distance, high-pressure gas transmission lines from the large and growing gas reserves of the southwestern United States to the major industrial and population centers of the country.

In rapid succession, a number of long-distance pipelines were laid during the period from 1930 to 1940, including three pioneer 1,000-mile lines from areas containing large natural gas reserves in the Southwest to major markets in the North and the Northeast. Spurred by abundant and inexpensive gas reserves, the U.S. natural gas industry expanded rapidly after 1945, and natural gas virtually replaced the more expensive manufactured gas in city distribution systems.

In 1930, marketed production of natural gas totaled 1.9 tcf; following early pipeline expansion, total consumption by 1940 had risen to 2.7 tcf. Then, in the decade between 1940 and 1950, gas consumption more than doubled to 6.3 tcf, and it doubled again to 12.8 tcf by 1960. Marketed production in the United States peaked at 22.7 tcf in 1973, followed by significant declines resulting from conservation efforts. By 1990 the marketed production of natural gas was about 18 tcf per year, and demand was increasing steadily because of the convenience of natural gas and its qualities as an environmentally desirable fuel.

U.S. Marketed Production [3–5]

Natural gas accounts for well over one-half of total U.S. petroleum energy production. Its major market segments are residential and commercial fuels, industrial fuel and chemical feedstock, and electric power generation.

Residential consumption is predominantly for space heating, cooking, and water heating. Commercial use includes space heating and other fuel needs for commercial establishments such as stores, hotels, and restaurants. Industrial use, accounting for about 35% of total gas consumption, includes fuels for manufacturing operations, industrial boiler fuel, and process heat. Oil refineries are major consumers of natural gas for refining operations. In addition, natural gas is the prime feedstock for the manufacture of ammonia fertilizers, methanol, and other basic chemical derivatives. Figure 20.5 is a simplified schematic that shows some of the principal chemical and commercial products derived from natural gas.

Fuel for electric power generation accounts for about 20% of marketed natural gas production. This market segment is extremely price-sensitive and competes directly with fuel oil and coal. Given the current environmental emphasis on reduction of air pollutants, the use of cleaner-burning natural gas is expected to increase significantly in the foreseeable future.

In addition to what is termed “marketed production” for these uses, substantial quantities of natural gas are consumed annually as lease, processing plant and pipeline fuels.

At current production levels, a majority of U.S. petroleum energy production consists of the gaseous fuels natural gas and natural gas liquids. Moreover, since reaching peak production in 1985, U.S. crude oil production has consistently declined while gaseous fuel production has steadily increased. These trends suggest that the U.S. petroleum economy will become even more dependent on the gaseous fuels in the future.

Natural Gas Liquids

Included in the gaseous fuels segment of U.S. petroleum energy production are the natural gas liquids extracted from natural gas as produced and before sale. These natural gas liquids, commonly termed “NGLs,” are ethane, propane, butanes, pentanes, and higher molecular weight hydrocarbons. The recovery and separation of natural gas liquids from raw natural gas is a relatively simple operation, which relies principally on the differences in boiling points and vapor pressures of the various components. (These differences are shown in Table 20.2.) The two most prevalent recovery processes are the absorption process and the cryogenic turbo-expander process. Together, they account for approximately 90% of total U.S. natural gas liquids production. The bulk of U.S. gas liquids is produced as a raw mix stream in some several hundred gas-processing plants located in or near major gas-producing provinces. Typically, the raw mix streams are transported through an extensive pipeline network to large central fractionator complexes where the mixed liquid stream is fractionated into its components ethane, propane, butanes, and pentanes.

The total U.S. recovery of natural gas liquids is about 30–35 barrels per million cubic feet of marketed natural gas. The total NGL supply is supplemented by about 200–250 million barrels per year of refinery production, which equates to about 5% of the total crude oil charge to refineries. Some of the petrochemical products produced from natural gas and NGLs are shown in Fig. 20.5.

Major demand segments for NGLs indicate that around 35–40% of gas liquids, principally ethane and propane, are consumed as cracking feedstocks for ethylene manufacture. Some of the chemical derivatives obtained from ethane and propane are shown in Fig. 20.6.

Traditionally, a major demand for natural gas liquids, mainly butanes and pentanes, has been in the manufacture of motor gasolines. However, the recent phasing out of

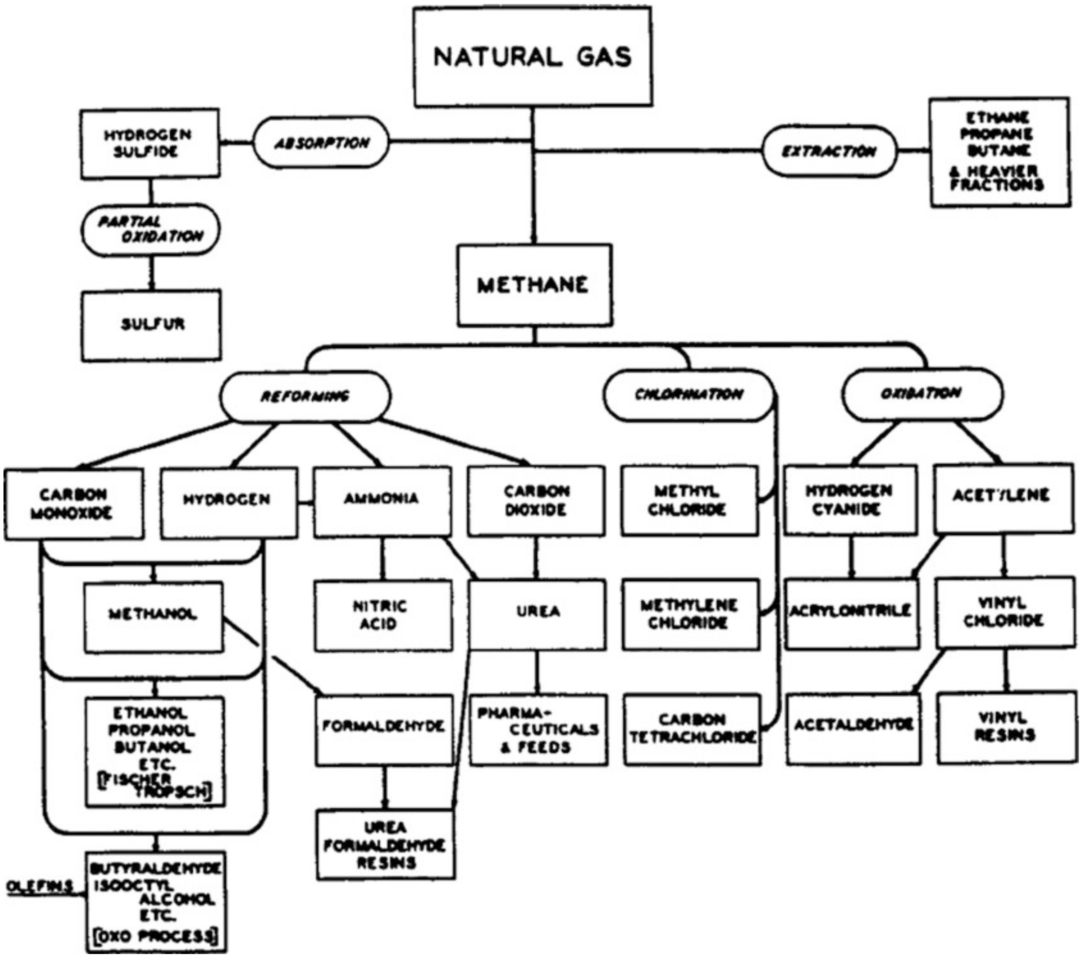

Fig. 20.5 Some petrochemical products derived from natural gas (Crockett and Widgery [35]. Reprinted by permission of the Gas Processors Suppliers Association)

leaded gasoline and the current, ongoing reduction in motor gasoline volatility have drastically reduced demand for butanes and pentanes as gasoline blending stocks. On the other hand, these same measures, enacted to reduce air pollutants from the automobile, have resulted in an increased demand for these products as prime feed stocks for the formulation of clean-burning reformulated gasolines.

A third major market is consumption of propane as both a residential and commercial fuel, principally in rural areas beyond the reach of natural gas distribution systems. Additional major uses indicated in the "other" category of Fig. 20.6 include consumption as internal combustion engine fuels and numerous agricultural uses, such as crop drying.

U.S. Natural Gas Reserves

At any given time proven U.S. natural gas reserves seem to remain at approximately 10 years of indigenous supply at the then current consumption rates. Proven reserves estimates are subject to constant change, either up or down, depending on reservoir operating experience, field extensions resulting from additional drilling, and revised estimates.

Not included in reserves data are undiscovered but probably recoverable reserves in unexplored or unproven provinces. Currently, these probable reserves are estimated by the U.S. Department of Energy at 307–500 tcf, much of which almost certainly will become proven reserves when they become economically feasible.

Whatever the ultimate recoverable reserves may be, current estimates of proven reserves of natural gas comprise about 50% of U.S. proven reserves of total petroleum energy.

Structure of the U.S. Natural Gas Industry

The natural gas industry in the United States is made up of four major segments: production, processing, transmission, and distribution. The industry is physically interconnected by a

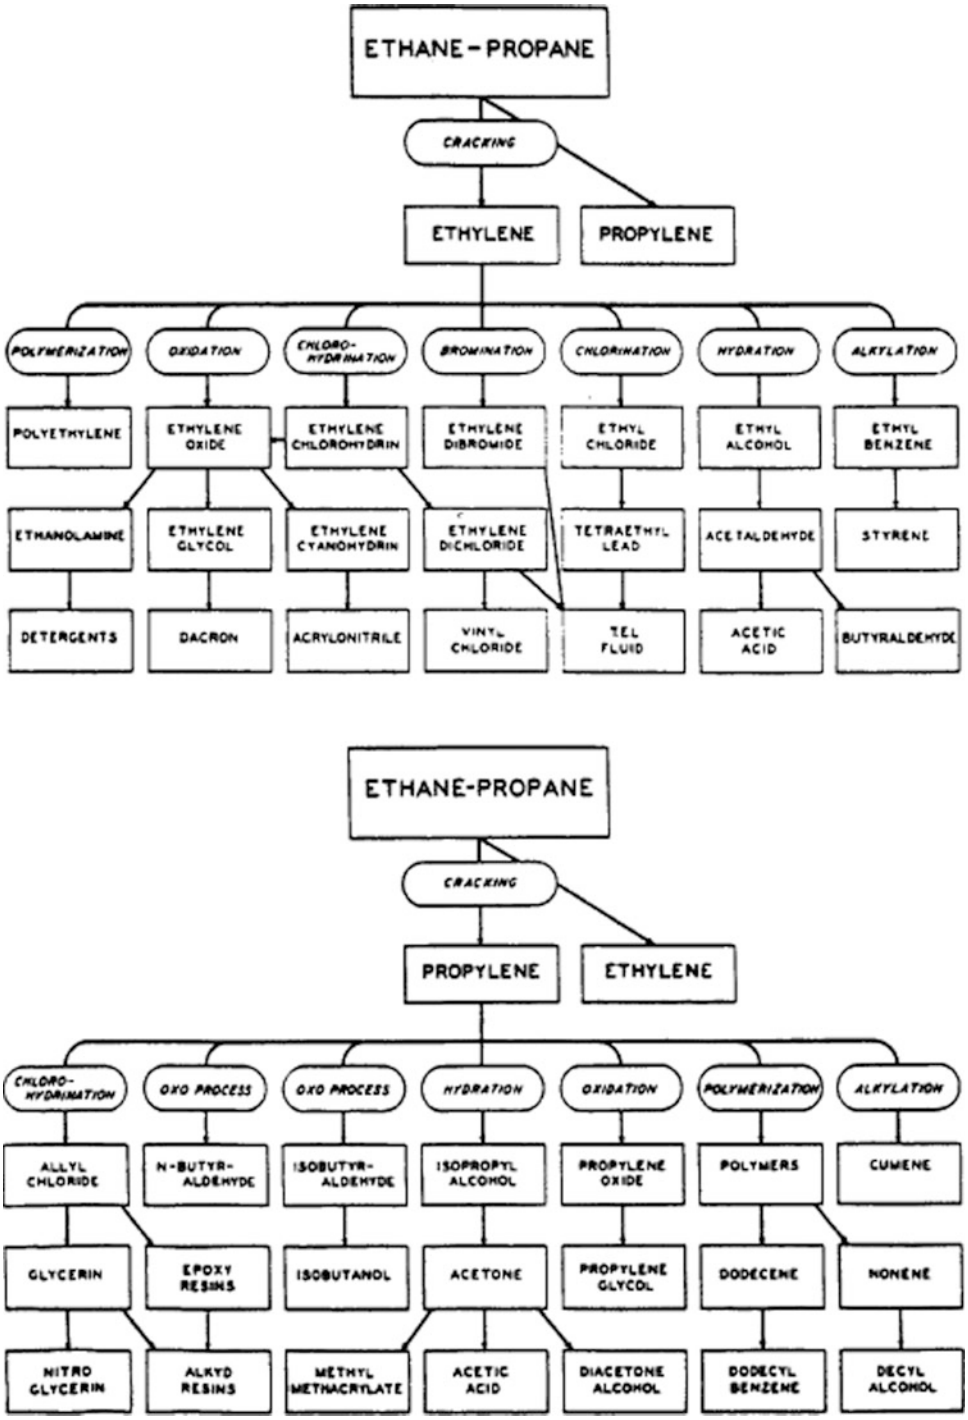

Fig. 20.6 Some products derived from ethane and propane (Crockett and Widgery [35]. Reprinted by permission of the Gas Processors Supplier Association)

pipeline network that extends through the lower 48 states and across international borders into Mexico and Canada.

The production function is a large part of the oil-producing industry, and most of the same firms are dominant in both oil and gas. Exploration and drilling technologies for both oil and gas are essentially identical. Production from both oil well gas and gas well gas is introduced into large field gathering systems for delivery to the processing facilities. A typical gathering system may include 2,000 or more miles of gathering lines connected to 1,000 or more producing wells.

The gas-processing function includes the gathering and delivery of gas streams from a field or fields into a central processing facility. There are currently several hundred gas-processing plants in operation in the United States. In these plants the raw natural gas is dehydrated to remove moisture, treated for removal of contaminants and, if necessary, compressed to pipeline pressure. During treating, most raw gas also is processed for recovery of liquid products, including ethane, propane, butanes, and natural gasoline. These liquid products are then sold separately to be used for petrochemical and gasoline feedstocks and other fuel uses.

The transmission function covers transport of the processed pipeline quality gas from the gas-processing plant to major markets. About two-thirds of U.S. marketed gas production reaches the ultimate consumer through a network of some 250,000 miles of pipelines. Other deliveries may be made directly to industrial consumers or to city distribution systems.

The distribution function receives natural gas from the transmission pipeline at the city gate of the local distribution system and delivers it to the ultimate consumer through a network totaling some 600,000 miles of distribution pipelines.

World Natural Gas

Natural gas, in recent years, has become an international commodity fuel. Current world reserves of natural gas are estimated at about 6,500 tcf [6], the equivalent of about 40% of world petroleum energy reserves. About 35% of these reserves are in remote regions of the Former Soviet Union (FSU) and about 40% are located in the Persian Gulf countries of the Middle East.

The location of these reserves, far from the major populations of consuming countries, suggests that the world natural gas industry is still in a developmental stage and that further extension and expansion can be expected. Gas from the Groeningen field of the Netherlands, from Norway and the North Sea, and from the FSU is flowing by pipeline into industrialized Western Europe. In addition, natural gas is piped from the FSU into Eastern Europe.

Additional international movements of natural gas are in the form of liquefied natural gas (LNG), principally from Northern Africa and the Middle East into Japan, South Korea, and the United States.

It is certain that world use of natural gas will increase dramatically in the near future as industrialized countries replace coal-fired facilities with cleaner-burning natural gas. In addition, a number of countries remote from major markets are in the process of installing world-scale plants for utilization of natural gas and gas liquids for production of fertilizers, methanol, premium gasoline blending stocks, and other basic petrochemical derivatives that will result in higher-value products from natural gas and gas liquids for which there are no local markets.

Already, the gaseous fuels account for approximately 40% of world petroleum energy production and nearly one-half of world petroleum energy reserves. Moreover, the growth of world natural gas consumption is already increasing rapidly.

Despite a world surplus of crude oil capacity for the foreseeable future, it seems certain that the world has entered the “Age of Gaseous Energy,” and that natural gas and gas liquids will continue to move into a position of petroleum energy dominance in the next decade.

Gas-to-Liquids Technology

In contrast to the United States, many oil- and gas-producing areas of the world do not have a well-developed gas distribution system and large numbers of consumers want a clean-burning, environmentally friendly industrial and residential fuel. Also, many of these areas have the potential capability for producing large quantities of natural gas for long periods of time. One way of solving this problem is to market LNG. Atmospheric pressure tankers are the popular choice, and they must operate at or near the atmospheric boiling point of methane, which is ~161.52°C or ~258.74°F. Huge quantities of compression horsepower are required to produce the LNG, and huge quantities of heat are required to gasify the LNG after it has reached port and before it is suitable for consumer use.

Despite these difficulties and obstacles, there are several successful LNG operations in various parts of the world. Japan, which has no petroleum or natural gas reserves, has been particularly active in trying to import LNG and other products. As fuel costs rise, LNG inherently becomes more competitive. Additionally, LNG liquefaction plants are becoming more efficient and cost effective. The combination of these two effects indicate a bright future for tankered LNG.

Before World War II, German scientists developed processes for converting gas primarily formed by burning coal to hydrocarbons and other chemicals with molecular weights in the motor fuel range. Processes using these reactions and catalysts were used for some fuel and chemicals production during World War II. After the hostilities a good share of the Fischer–Tropsch “know-how” and technology was liberated and put within the purview of the U.S. Bureau of Mines. In the early 1950s the South African government made a political decision to produce gasoline and chemicals from their plentiful internal supply of coal and not be dependent on imported petroleum. This led to the design and construction of multiple integrated chemical–motor fuel plants to serve

Table 20.4 Summarized data for the first three major GTL complexes built

Plant site	Date of commissioning	Design capacity (Mbpd)	F-T unit technology	Investment/daily capacity barrel ($/bbl)
Montunui, New Zealand	1985	14.5	Mobil	102,000

the internal requirements for motor fuel and simultaneously provide a variety of chemicals for both export and internal consumption. Derivatives of the original Fischer–Tropsch and later Sasol processes are currently being used to try to make marketable natural gas discoveries in areas where there is no industrial or home-based demand for clean-burning natural gas fuel.

As crude oil exploration spread to cover more of the globe, discoveries of huge natural gas reserves spread to more inhospitable places and thoughts of plants to produce longchain liquid hydrocarbons became more enticing. In the early 1980s planning for such plants began in earnest and in the space of a few years three separate plants utilizing three different liquidation technologies were well under way. Table 20.4 [7] shows some of the key parameters for the three plants. All the investment numbers are too large for the projects ever to be profitable. Estimates now are that about $50,000 investment per daily capacity barrel is about the maximum the traffic can bear.

Plans for several more liquidation plants had developed but the cost, construction, and operating problems of the first three slowed investor ardor and caused reassessment of the possibilities and goals. Expectations had been that by the mid 1990s a dozen or more plants would be in operation producing more than a million barrels per day of automotive fuel range hydrocarbons. Instead, the New Zealand plant was switched to producing methanol and the other two were continuing to encounter operating problems.

Three second-generation gas-to-liquid (GTL) plants are known currently to be underway. Some details for each are shown in Table 20.5 [8]. Investment per daily capacity barrel is much lower than for the first three. But the total capacity of the three new plants is only 80,000 barrels per day. If GTL technology proves out, it will be at a much more sedate pace than originally envisioned.

Preparing Natural Gas for Transmission and Sale

To make a product suitable for sale, the various contaminants and undesirable constituents contained in the raw gas must be removed. The first step is to separate the gas from any liquids and/or solids. This initial separation usually is carried out in near proximity to the producing well. The separators used depend primarily upon the difference in density between the gas and the liquid for separating the two phases. These separators may be classified as vertical, horizontal, or spherical, depending on their geometry and physical orientation [9].

The liquids produced are sold as oil or condensate, depending upon the type of reservoir from which the product is obtained. The natural gas stream after this first stage of separation contains only gaseous components, though some of these may be liquefied by later processing.

Typical compositions for gas streams at this point are shown in Table 20.1. (The compositions in Table 20.1 are on a water-free basis.) As typically produced, each of the gas streams would be saturated with water vapor. Developing the technology for handling gas streams that contain significant quantities of water vapor was one of the keys necessary to the development of the natural gas industry as it exists today.

In the presence of water, natural gas can, under the proper conditions of temperature and pressure, form hydrates. To the naked eye the hydrates are similar in appearance to snow; and they can result in plugging of pipelines and flow systems. Hydrates can form at temperatures well above the freezing point of water. In the early days of pipelining natural gas under pressure, shutdowns of the lines during the winter months frequently were caused by plugging with hydrates.

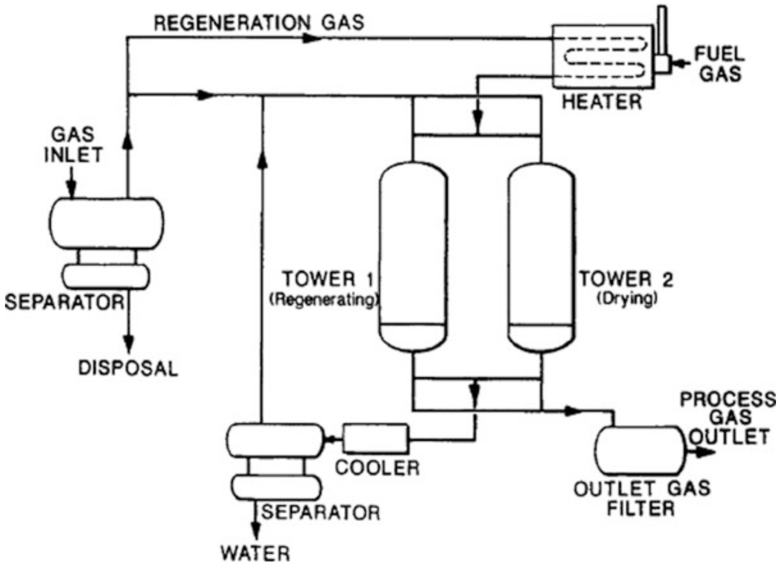

Fig. 20.7 Two-tower adsorption dehydration unit

A hydrate is a type of chemical compound called a clathrate, defined as a solid molecular compound in which one component is trapped in the cavities of cage-like crystals of another component. In the natural gas hydrate, water molecules form the "cage," and hydrocarbon molecules are the trapped component(s).

Hydrate formation can be prevented or avoided in two ways: (1) by dehydration, in which water is removed from the gas stream so that under conditions of processing or transporting, no liquid water will condense; and (2) by inhibition, which involves injecting into the gas stream a component that will dissolve the water and thus interfere with the ability of the water to form hydrates with the gas. Both procedures are widely used in the gas industry.

Of the wide variety of materials that can effectively depress the hydrate-forming tendency of a natural gas, three—methyl alcohol, ethylene glycol, and diethylene glycol—are used almost exclusively. Ethylene glycol ($C_2H_6O_2$) and diethylene glycol ($C_4H_{10}O_3$) are both polyhydroxy alcohols. They are high-boiling-point materials that mix in all proportions with water and both remain predominantly in the liquid phase. At temperatures approaching the freezing point of water, solutions containing more than 50% by weight ethylene glycol (or diethylene glycol) have viscosities approaching 10 cp. This limits their utilization in some low-temperature applications.

Methyl alcohol (CH_3OH) has a much lower boiling point and consequently a much higher vapor pressure than either ethylene or diethylene glycol. Hence procedures used for estimating the amount of methyl alcohol required must take into account the amount of methyl alcohol that vaporizes into the gas phase [10–12]. Although the necessity for vaporization requires the injection of greater quantities of methanol, it does have potential advantages. If the gas phase were cooled in further processing or transmission, one would expect some methanol to condense along with additional water and/or hydrocarbons. This would provide a safety factor for hydrate prevention that does not exist with the glycols.

Dehydration of the gas can be accomplished through the use of either a liquid or a solid desiccant. The solid desiccants most often employed include alumina, silica gel, and molecular sieves. The liquid desiccant most frequently used is triethylene glycol. Any of the solid materials used as desiccants must be regenerated periodically, so there must be at least two adsorption towers if dehydration of the gas is to be continuous. A schematic of a typical two-tower adsorption plant is shown in Fig. 20.7. The adsorbent must be heated to high temperature (about 400°F, 200°C) to remove the water and regenerate the solid desiccant. This usually is accomplished by heating a slip stream of the gas and circulating the heated gas through the off-stream adsorbent bed.

Figure 20.8 shows a schematic flow diagram for a typical triethylene glycol dehydration system. The lean glycol is pumped to the top of an absorber column and flows downward in countercurrent contact with the water–wet gas entering the bottom of the tower.

The absorber may contain either plates or packing. Dehydrated gas leaves the top of the absorber and the glycol diluted by the absorbed water flows from the bottom into a regenerator. After the absorbed water has been fractionated from the triethylene glycol solution, the solution is recirculated to the absorber. The concentration of the glycol leaving the reboiler will be approximately 98.5–98.7% by weight triethylene glycol if the reboiler operates at 400°F (205°C) and one atmosphere pressure.

Normal contract specification for gas to be transmitted through a high-pressure pipeline is a water content of 7 lb of

Fig. 20.8 Glycol dehydration unit

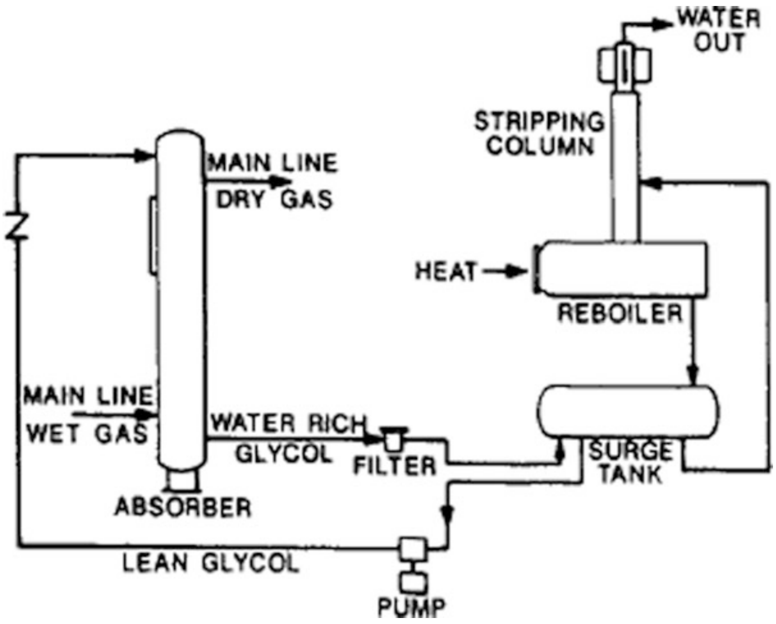

Fig. 20.9 Approximate range of application for compressors (GPSA Data Book, 12th Edition, 2004; Copyright Gas Processors Suppliers Association, and reprinted by permission of the copyright owner)

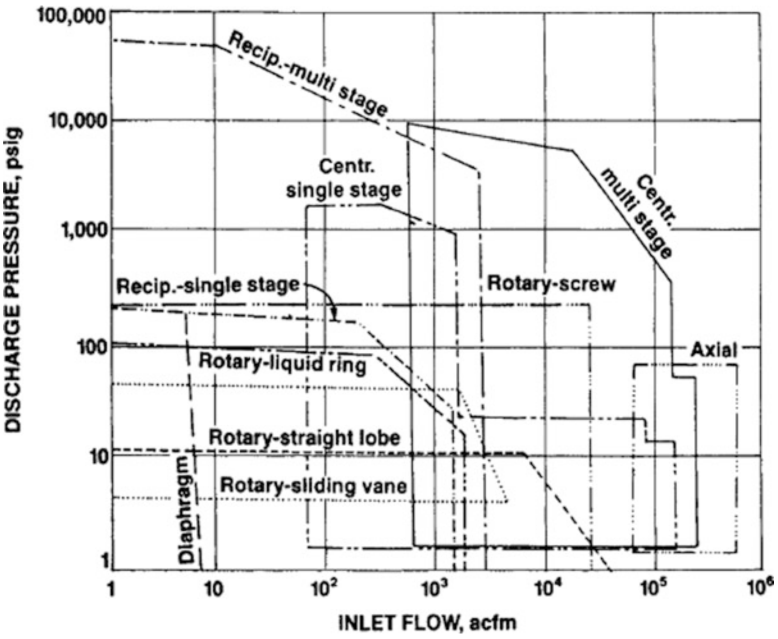

water per million standard cubic feet of natural gas. This is approximately the water content of natural gas in equilibrium with water at the freezing point (32°F) when the gas is under a pressure of 1,000 psia.

The solid desiccants offer much lower water contents for the dehydrated gas. With proper design and operation, molecular sieve dehydrators can satisfactorily prepare gas for total liquefaction at temperatures as low as −263°F (−165°C). Lower outlet water dew points can be obtained with triethylene glycol if the concentration of glycol going to the absorber is increased. This can be accomplished by using a vacuum in the reboiler or by introducing another material into the reboiler to lower the effective partial pressure of the water vapor above the glycol. Proper design and operation of such glycol systems can produce outlet water dew points in the −40°F (−40°C) range, or lower.

Natural gas pipelines normally operate at elevated pressures. In many instances the gas is available at low pressures so must be pumped or compressed to higher pressure. If the volume of the gas stream is small, reciprocating compressors must be used. For larger gas volumes, rotary compressors of various types are available. Figure 20.9 [13] shows pressure and flow rate ranges in which different types of compressors currently available are used.

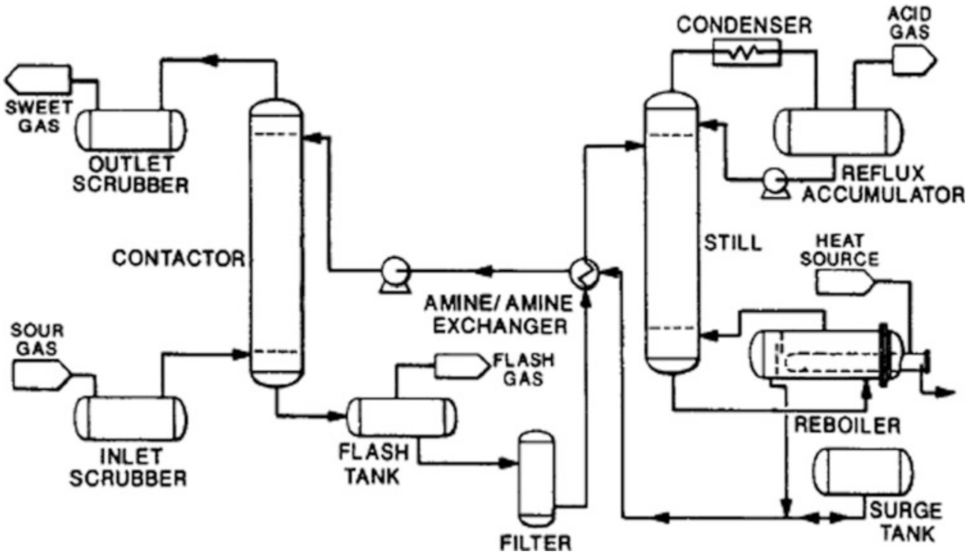

Fig. 20.10 Typical ethanolamine sweetening unit

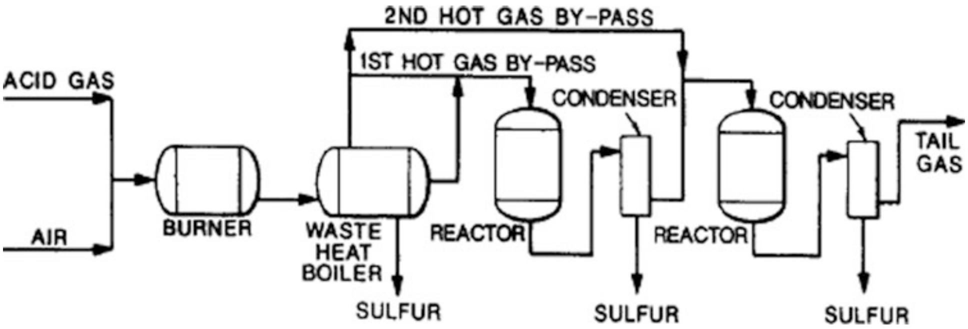

Fig. 20.11 Once-through Claus sulfur unit

If the natural gas stream contains unacceptable quantities of hydrogen sulfide and/or carbon dioxide, they must be removed in order to make the gas suitable for transmission and sale. The details of removal of H_2S and CO_2 from natural gas streams are beyond the scope of this chapter, but excellent discussions are available [13, 14]. There are many different processes available, depending upon the contaminants to be removed and their concentration in both the sour gas available and the sweetened gas to be produced. The dominant treating process is still the use of an alkanolamine. A typical flow diagram for an amine sweetening installation for removal of hydrogen sulfide and carbon dioxide from a natural gas stream is shown in Fig. 20.10 [14].

Environmental restrictions and controls normally will not permit the release of the hydrogen sulfide and/or its incineration to sulfur dioxide. As pointed out by Maddox [14], the least undesirable alternative is conversion of the hydrogen sulfide to sulfur. Again, there are many different processes available, several of which are discussed in the book by Maddox. The dominant method is by use of the Claus process, which involves partial combustion of the hydrogen sulfide to sulfur dioxide and catalytic combination of the hydrogen sulfide and sulfur dioxide to produce sulfur. Detailed discussions of the Claus technology as well as other techniques of converting hydrogen sulfide to sulfur are available [13, 14].

Figure 20.11 is a sketch of a “once-through” Claus process using a hot gas bypass for reheat. Sufficient air is used to burn one-third of the H_2S and all hydrocarbons. Steam usually is generated in the waste heat boiler, where the combustion products are cooled, and sulfur is condensed. The gas must be reheated before introduction to the reactor to prevent sulfur condensation in the reactor bed. Tail gas usually is sent to a tail gas cleanup unit to minimize sulfur emissions.

Processing for Liquids Recovery

The first time that liquids were recovered from a natural gas stream probably happened more by accident than by design. Any time a gas stream from a liquid–gas separator is either cooled or compressed, liquids will form. This simple statement still provides the basis for nearly all hydrocarbon liquid recovery systems from natural gas. Figure 20.12 [15] shows

Fig. 20.12 Liquid hydrocarbon recovery by compression and cooling (*adapted from Huntington* [15])

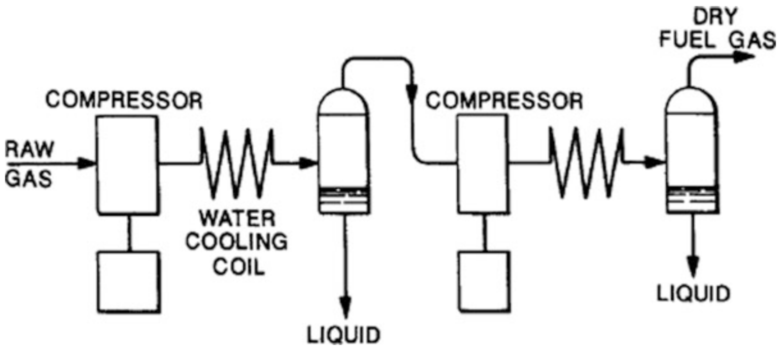

Fig. 20.13 Absorption-stripping unit (*adapted from Huntington* [15])

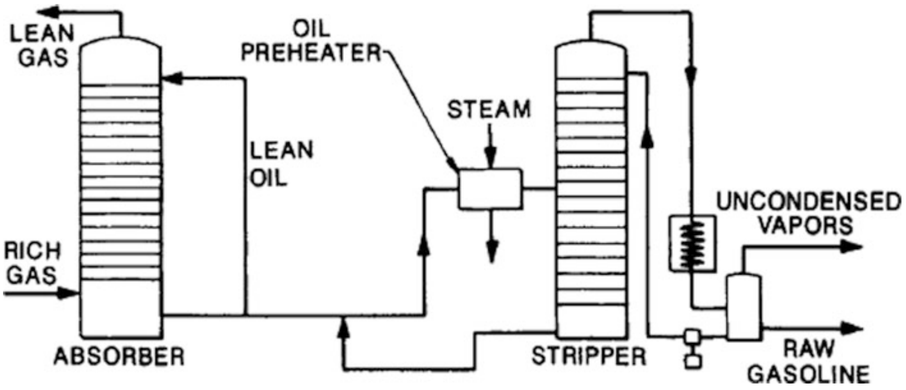

schematically the flow through a simple compression liquids-recovery facility. Replacing the water cooling after the second stage of compression with refrigeration would increase liquids recovery. If the gas had not been dehydrated, there would be danger of hydrate formation at this point unless the water had been removed.

As the natural gas industry developed and expanded, so did the demand for liquids recovered from natural gas. One way of recovering additional liquids is through the use of a heavy absorption oil that has good solubility characteristics for the propane and heavier hydrocarbon components in the gas stream. As in the case of dehydration, the solvent must be regenerated. Figure 20.13 [15] shows the absorption-stripping section of an absorption-type hydrocarbon liquids-recovery facility. The absorbent is circulated to the top of the absorber and flows downward, absorbing liquefiable components from the gas stream. It then is heated in the stripper, with the stripped components being cooled and condensed while the stripped absorption oil is recirculated. The liquid hydrocarbon stream typically would flow through a fractionation train for separation into the individual components or mixtures that could be sold.

Combining refrigeration with oil absorption allowed for additional liquid recoveries and greater economy of operation. Using temperatures as low as −40°F (−40°C), refrigerated oil absorption plants were capable of recovering 70% or more of the propane present in the natural gas stream. Recoveries of the butane and heavier constituents were essentially 100%.

Development of the turbo-expander process allowed the design and construction of plants for recovery of liquid ethane, as well as the heavier hydrocarbon components. The turbo-expander extracts useful work from the gas during expansion from a high pressure to a lower pressure. Because of the work extraction the gas is cooled more than in a simple pressure expansion, and, by means of suitable heat exchange, temperatures as low as −150°F (−100°C) can easily be achieved. The separation at low pressure gives higher relative values of the vapor–liquid equilibrium constant for nitrogen and methane than for ethane and heavier hydrocarbons. The result is that the process shown in Fig. 20.14 [11] can recover as much as 75% or more of the ethane contained in the gas as the demethanized product. In some cases the process will be run to produce a de-ethanized product that contains essentially all the propane in the feed gas.

The liquid product from the facility either can go to on-site fractionation into salable products or, more typically, be introduced into a pipeline and transported to a central fractionation facility near the point of ultimate use for the liquid product.

A New Potential Source for Natural Gas

Under proper conditions of temperature and pressure, water molecules can form ice-like structures in which there are cavities. If small molecules such as methane and nitrogen are present, they can be held in the cavities and there serve to stabilize the crystalline structure. The resulting crystalline structures are called clathrates [16, 17]. Although each crystalline form has a unique composition, there are no chemical bonds per se. Thermodynamically the structures are solid solutions. Although several different hydrate structures are known, the Structure 1 (S-1) hydrate typically dominates in natural gas systems. The general formula for type S-1 hydrates is $8X{\cdot}46H_2O$, where X can be molecules of argon, krypton, xenon, nitrogen, oxygen, hydrogen sulfide, carbon dioxide, methane, ethane, and/or propane. When gas containing more than one component is involved, the hydrate typically will contain more than a single gaseous constituent.

The stability of the hydrate structure depends heavily on the size of the entrapped guest molecules. Ultimately the molecules can become so large (pentane for example) that a stable hydrate cannot form. As noted earlier, many materials can interfere and prevent hydrate formation.

In recent years deposits of methane hydrate have been discovered in all parts of the world. The methane apparently forms in the decomposition of bio mass, primarily in water-containing areas, and the stabilized hydrate accumulates.

The storage of methane as hydrates offers a potentially vast natural gas resource. As to the question of how much hydrate there is right now, there is no definitive answer. However, the worldwide amount of carbon bound in gas hydrates has been *estimated to total twice the amount of carbon to be found in all known fossil fuels originally on Earth*. Additionally, -conventional gas resources appear to be trapped beneath methane hydrate layers in ocean sediments [18].

In the United States, deposits have been confirmed on all areas of the continental shelf and under Alaskan permafrost. Similar deposits have been confirmed in many locations throughout the world. But little is known about the actual size and location of even most hydrates that are presumed to exist.

Estimates of the amount of gas sequestered in hydrates varies markedly. Today, most engineers and scientists estimate that at an absolute minimum there is approximately 100,000 tcf. They also estimate there is a maximum of 270,000,000 tcf, or more.

The numbers for the United States are as follows. The U.S. Geological Survey (USGS) released a report in 1995 evaluating the U.S. hydrate resource base. It categorized estimates by the level of certainty that they exist [19].

- At a level of certainty of 95%, resources ~112,785 tcf
- At a level of certainty of 50%, resources ~276,119 tcf
- At a level of certainty of 5%, resources ~676,110 tcf
- The mean of these estimates ~320,222 tcf

Obviously, hydrates have tremendous potential as a future source for natural gas. The concluding section of this chapter will serve as a summary of what is currently being used and of promising technology for future development.

Methane Conversion Processes

Methane conversion as treated here encompasses chemical transformation only, although in the broadest interpretation purification, compression, and liquefaction operations are sometimes included, especially in relation to methane consumption as a fuel.

Methane is the simplest, most abundant, and geographically most widely distributed hydrocarbon. It therefore receives constantly increasing attention as an alternate energy source to coal and petroleum from both the world fuels industry and from the science and engineering community to broaden its utility and enhance its transportability by energy-efficient conversion to liquid hydrocarbons and functional chemical raw materials.

Apart from combustion as fuel, the largest chemical conversion of methane is steam reforming to synthesis gas (syngas) mixtures of CO and H_2 in ratios varied to fit the particular process. Syngas is the raw material base for methanol and its many derivatives including gasoline range hydrocarbons and methyl-t-butyl ether (MTBE), Fischer–Tropsch hydrocarbons, hydroformylation (oxo reaction) products, formaldehyde, hydrogen source for ammonia, and a further wide spectrum of industrial chemicals [20]. These are regarded as "indirect" methane conversion products since methane is consumed as the raw material for the final plant products and syngas accounts for over 80% of all methane conversion to commercial products.

The industrially important direct methane conversion processes comprise oxidative coupling, reductive coupling including pyrolysis reactions, partial oxidation, halogenation and oxyhalogenation [21], and ammoxidation. Other direct conversions include alkylation, electrophilic substitution, and C–H bond activation over various complex and super acid catalysts [22]. Several of these direct conversion technologies remain to be exploited to achieve their full commercial potentials.

Indirect Conversion via Syngas

Steam reforming of methane—and low-to-middle range hydrocarbons—is widely practiced to generate syngas for a number of basic, high-volume fuel stocks, such as gasoline range and middle distillate hydrocarbons, and also basic industrial chemicals such as methanol and ammonia.

The catalytic reaction of steam with methane at elevated temperatures (300−400 + °C) over various catalysts: copper or nickel/molybdenum oxide/alumina—can be made to yield CO and H_2 in desired ratios. The generalized reaction for hydrocarbons with steam is:

$$C_nH_m + CO + H_2O \rightleftharpoons nCO + [m/2 + n]H_2 \rightleftharpoons CO_2 + H_2$$

With adjustment of the steam/methane ratio, the reactor can produce a synthesis gas with $CO/H_2 = 1/2$, the stoichiometric proportions needed for methanol production. This mixture at approximately 200 atm pressure is fed to the methanol unit where the reaction then proceeds at 350°C. Per pass conversions range from 30 to 50 over the catalyst—typically a supported copper oxide with a zinc, chromium, or manganese oxide promoter: [23]

$$CO + 2H_2 \rightleftharpoons CH_3OH$$

The methanol unit operating regime, process parameters, and sometimes the catalyst may be adjusted to yield a significant coproduction of higher mixed alcohols typically ranging from C_2 to C_6.

Methanol to gasoline units following the Mobil fixed-bed design with a ZSM-5 molecular sieve catalyst are capable of producing high-grade gasoline with an iso-paraffinic hydrocarbon front end and a methlyated aromatic hydrocarbon back end. Dilution with other source alkylate to a lower aromatic content gives a premium grade mid-90s octane gasoline.

Alternatively, high-quality gasoline range distillates are produced directly from syngas via the Fischer–Tropsch synthesis. The product from all the operating units is a mixture of paraffins and olefins having a straight chain structure and molecular weight distribution predicted by the Schulz–Flory–Anderson theory. Isomerization for improved octane rating yields superior automotive fuels. Recent reviews present a position of concern that GTL processes based in syngas intermediate unavoidably entail capital costs exceeding $25,000–30,000 per daily barrel of capacity, and in most cases are not competitive with petroleum-based liquid fuel processes. The 30+ percent consumption of originally contained energy in the methane consumed to power the syngas units—compression and heat costs—must also be reckoned a process driving energy component.

Indirect Conversion via Nonsyngas Intermediates

The oxidative conversion of methane to reactive intermediates such as methyl sulfate has been reported recently [22]. The reaction, catalyzed by Group V and VI metal complexes in concentrated sulfuric acid media, utilizes molecular oxygen (air or industrial gas source) selectively to break and substitute the C–H bond in sequential oxidative scission and sulfate ester formation steps. Methanol may then be generated via hydrolysis with subsequent sulfuric acid recovery. While not yet industrially established as a methanol source for liquid fuels manufacture, this technology provides a methane C–H bond-breaking technique that is restricted to one C–H bond only and conserves much of the CH_3 group energy content that is expended in driving the commercial syngas-based methanol process alternative.

Direct Methane Conversion to Hydrocarbons and Chemical Derivatives

The direct, one-step conversion of methane to higher hydrocarbons and chemical derivatives, after several decades, continues to be intensely researched worldwide as a possible source of liquid fuels and chemical raw materials based on natural gas—independent of petroleum and coal. For clarity and convenience the following "direct conversion" categories [20] are recognized:

- Oxidative coupling to higher hydrocarbons
- Partial oxidation to chemical derivatives

- Pyrolysis or cracking
- Other direct conversion processes

Oxidative Coupling to Higher Hydrocarbons

The catalyzed gas phase reaction of methane with oxygen, wherein a hydrogen atom is abstracted from two methane molecules which are subsequently joined or "coupled" to form ethane with the coincidental formation of gaseous water, was reported [24] in the early 1980s:

$$2CH_4 + \frac{1}{2}O_2 \rightleftharpoons C_2H_6 + H_2O$$

Immediate interest and continuing, increased research by additional investigators has shown that variations in reaction conditions (typically 500–800°C, 1–5 bar, high space velocities) in combination with homo and heterogeneous, fixed and fluid bed catalysts, enables the formation of higher alkanes and olefins reaching to C_6–C_8 chain length, although C_2–C_3 dominates. With optimal methane/oxygen ratio, reaction temperature, and catalyst parameters, further oxydehydrogenation to ethlyene can occur: [25]

$$CH_3 - CH_3 + \frac{1}{2}O_2 \rightleftharpoons CH_2 = CH_2 + H_2O$$

Methane-based commercial production of ethylene via oxidative coupling has been investigated, but to date the lower per pass conversions required for acceptable ethylene selectivities combined with purified oxygen costs make this process noncompetitive with thermal cracking of ethane from natural gas liquids.

Oxidative coupling of methane nonetheless may be basically regarded as a polymerization reaction. Catalyzed oxidative coupling reactions are in commercial use today for high polymer production, for example, conversion of 2,6-dimethylphenol to poly (phenylene oxide) with molecular oxygen. However, the lower C–H bond energy and resulting greater liability of the hydrogen atoms involved in the coupling reaction allow operation in the liquid phase at far lower temperatures (below 100°C).

Methane-coupling reaction conversions and yields less than 25% initially were—and still are—below those acceptable for commercial fuel and chemical feedstock production. But worldwide research and development in more recent years continue to suggest that variations in process parameters, reactor design, and catalyst composition and structure may bridge this gap [26]. Lower reaction temperatures—in the 300–400°C range may be needed. Yields of 90% coupled with hydrocarbon products at 10% methane conversion have been reported at temperatures below 600°C where the activation energy for ethane and ethylene formation is below 90 kcal [27].

The major obstacle to high-yield oxidative methane coupling remains the high energy necessary to dissociate the C–H bond with its 94 kcal bonding energy. The rigorous reaction conditions and temperatures required to accomplish C–H bond scission in the methane molecule are essentially the same as those favoring further oxidation and degradation of the methyl radical or related short-lived highly reactive intermediates to waste products such as CO and CO_2. Research in recent years has identified catalysts, particularly including some based on transition metals, such as iridium and palladium complexes, which are able to dissociate the C–H bond at much lower temperatures, even as low as below 200°C.

Industry experts today suggest conversions of 40–50% and selectivities above 80% based on methane and oxygen as the minimum needed for commercial consideration after fixed and variable costs are added. Nonetheless, methane oxidative coupling holds the most promising combination of process simplicity, product slate versatility and low cost, and worldwide raw material availability not offered now by practiced fuel and chemical feedstock technologies.

An important aspect of direct methane oxidative coupling that merits further attention is optimization of the process to focus on the simplest products of the highest value and which are the easiest to obtain, namely the C-2 and C-3 products. Of these, the C-3 products, now commercially derived from light hydrocarbon and naphtha cracking or refinery streams, propane and particularly propylene, are in increasingly high demand and offer a versatility of existing end uses and potential utility not matched by the higher range C-4 and up aliphatic hydrocarbons, namely

1. Petrochemical raw materials for a multiplicity of plastics, films, fibers, elastomers, and chemical industry intermediates.
2. Specialty (LPG) and commodity automotive fuels–the research octane rating of 115 for propane compels industry interest.
3. High energy content, low vapor pressure (200 psi), and liquid state at ambient temperatures favors low-cost liquid pipeline transportation vs. high-pressure compressed gas—1,000+ psig if methane conversion is done near the production site.

Methane oxidative coupling process simplifications and advances—especially combinations of reactor design and catalyst features, product separation, and recycle economies—are areas marked for technological innovation with accompanying economic opportunity. C-3's handling and transportation advantages compared with remote natural gas, their potential as alternate fuel, and their demand and versatility as chemical feedstocks compared with higher liquid homologues should drive intensive methane-to-C-3's research and development for the next decade. Significant areas of exploration and development [28] will focus on:

1. Reactor design—fixed vs. fluid/moving bed variations.
2. Catalyst discovery research—metal oxides and supports, shape selective and hetero metal substituted molecular sieves, pillared clays, biomimetic, methanotropic and other bio systems; and combinatorial catalytic screening techniques, liquid phase homogeneous systems.
3. Reactor–catalyst combinations with emphasis on porous substrates.
4. Unique absorption–desorption product recovery systems.

Partial Oxidation to Chemical Derivatives

Oxygen-deficient cool flame partial oxidation of methane to methanol and/or formaldehyde has long been known [29], but methane-based selectivities of 71% methanol and 14% formaldehyde at 2% conversions require a recycle ratio of 200 to 1. Higher conversion levels led to flame temperature increase with markedly lower yields. Constraining factors were controlling the reaction stream adiabatic temperature rise within narrow ranges (25°C) to minimize waste product formation, and desirable narrow tube reactor design which raises the reactor pressure to undesirable levels—above 60 bar—and also lowers yields. At 5% conversion, the adiabatic temperature increase was near 250°C.

An alternative approach to partial oxidation of methane is oxyhydrohalogenation—usually oxyhydrochlorination [30]. In this alternative chemistry modification, methane is converted first to methyl chloride in a reactor fed a mixture of HCl, steam, and methane. The intermediately formed methyl chloride then is converted in a second catalytic (zeolite) reactor to low-to-medium range hydrocarbons. The net reaction is:

$$\mathrm{nCH_4 + 2HCl + nO_2 \rightleftharpoons C_nH_{(2n+2)} + Cl_2 + nH_2O}$$

In this process, the strategy of selective chlorination of methane to intermediate methyl chloride in effect provides for much lower temperatures and milder C–H bond-breaking energetic regimes than those so far reported in the higher temperature direct oxidative processes. The lower-temperature, halogen-based stoichiometry further sidesteps the problematic degradative oxidation of the extremely fragile methyl radical and derived intermediate species to waste products (CO and CO_2) experienced in most reported direct oxidative coupling work. This innovative approach has received careful attention as an alternative to the other "direct" oxidative coupling processes. Conversely, the handling, recovery, and recycling of chlorine and hydrogen add complexity and possible cost to the technology.

Pyrolysis or Cracking

Acetylene production via high-temperature gas phase pyrolysis is the method of choice for the production of acetylene in large volume usage. It is essentially confined to on-site dedicated units to avoid the expense and hazards of transporting acetylene long distances by pipeline, truck, or rail. In the classic Wulff process and variations thereon, pure methane is fed to a pipe pyrolysis reactor operating slightly above atmospheric pressure—not more that a few bars—at residence times of a few seconds and temperatures from near 1,000°C to much higher. The reactor effluent after heat exchanger cooling is passed to an absorber where acetylene is solvent scrubbed from the reactor stream comprising the major product hydrogen and unconverted/methane. Following hydrogen separation, methane is recycled. Small amounts of carbon may carry through to the absorber where they are removed from the solvent raffinate after acetylene recovery.

Methane high-temperature, in situ cracking to carbon and easily disposed of gaseous by products is practiced in the carbon/graphite composites industry where additional layerings of amorphous or microstructured carbon deposits are fabricated on preformed scaffolds. These are utilized primarily in the aerospace industry. Thin diamond coatings are also fabricated by the low-vacuum, in situ chemical vapor deposition from methane decomposition.

Other Direct Conversion Processes

Chlorination of methane to methyl chloride, methylene chloride, chloroform, and carbon tetrachloride is practiced industrially worldwide on a large scale. Bromination and iodination are similarly practiced on a smaller scale to prepare the corresponding bromine and iodine derivatives which are important pharmaceutical, synthetic, and fireproofing raw materials.

Methane Ammoxidation

Hydrogen cyanide (HCN) is a widely used high-volume raw and intermediate material in the world chemical industry. For the last several decades it has been increasingly supplied as a by-product of propylene ammoxidation—by which acrylonitrile, a major chemical, plastics fiber, and rubber ingredient, is made. However, transportation of liquid HCN (boiling point 26°C) over significant distances is considered hazardous because of its high toxicity and volatility and on-site production for immediate use is usually desirable. Thus, methane catalytic oxidation with oxygen (air) in the presence of ammonia, or "ammoxidation," the Andrussow process [31], is the long-established most practiced industrial technology for HCN manufacture. The singlestep reaction is straightforward and both conversions and yields are high:

$$CH_4 + NH_3 + \frac{11}{2}O_2 \rightleftharpoons HCN + 3H_2O$$

$$CH_4 + NH_3 + 1\frac{1}{2}O_2 \rightleftharpoons HCN + 3H_2O$$

As can be seen from the above equation, formation of HCN is in reality a *heterobimolecular oxidative coupling* reaction of methane with ammonia. The ammoxidation reactor construction is a simple fixed-bed multitube and the catalyst is usually a platinum or sometimes a Group V or VI metal oxide on a silica or alumina support. The HCN product is recovered by condensation and fractionation. With the reaction simplicity and yield, and widespread availability of starting materials, in situ HCN generation is an ideal industry solution to HCN supply. (See Chap. 29 for more details).

Of coincidental interest, ammoxidation of propylene [32], itself an oxidative coupling product of methane as noted above, is the commercially practiced route to acrylonitrile, which is produced in high conversions and yields:

$$CH_2 = CH - CH_3 + 1\frac{1}{2}O_2 \rightleftharpoons CH_2 = CH - CN + 3H_2O$$

Acrylonitrile is a commodity monomer raw material for many fibers, plastics, rubbers, and chemical intermediates. Economically recoverable quantities of by-product HCN may be produced which are purchased by industrial consumers or, as necessary, disposed of by incineration.

Methane Reductive Nitrilization

Vapor phase co-pyrolysis of methane–ammonia mixtures at temperatures in the 1,200–1,400°C range at modest pressures, the BMA Process [32], is also an industrial source of HCN and is carried out in several international locations where raw material costs are favorable. Another methane reductive nitrilization technology of considerable interest that has been carried out in several facilities internationally, is the Shawinigan fluohmic reactor process. Mixed methane and ammonia gases are reductively co-pyrolized to HCN and hydrogen in a fluidized bed of carbon particles maintained at pyrolytic temperatures in the 1,400°C range. Propane is reported to be a preferred feedstock [33], but methane is sometimes the economic choice. The carbon particle bed temperature is achieved by the transmission of low-voltage electric alternating current from immersed electrodes through and between carbon particles with accompanying interparticle electric arcing. Reaction stoichiometry differs from the Andrussow given the absence of oxygen in the reactant stream, and of water in the reactor effluent stream.

Space restrictions do not allow a complete survey of the countless methane conversion examples available or in the published literature. This overview is intended to highlight those methane conversion technologies which are or have been used industrially and might impact conversion of methane from hydrate deposits.

The authors are firm in their belief that methane conversion(s) hold much greater promise for the future exploitation of huge hydrate reserves than does GTL technology.

A Different View of the Origins of Natural Gas

As an essential transportation and heating fuel, and principal raw material for many process industries the future supply of natural gas is an always critical issue. Because it is more widely geographically distributed than petroleum, maintaining an adequate supply at stable pricing is a national and world economic and societal concern. In concluding this section the authors feel an overview of the status and future outlook for the natural gas supply from the standpoint of methane and light hydrocarbon origins and sourcing is appropriate. Simultaneously, much industry attention is focusing on methane and natural gas hydrates and affordable recovery and production technologies.

The two prevailing concepts on the origin and sources of natural gas and methane, its major constituent, are based on either biological or nonbiological reactions and mechanisms. Both address petroleum and, coincidentally, natural gas because the methane and other light hydrocarbons in natural gas are also constituents of most petroleum as produced. The mounting evidence for nonbiological methane and natural gas is briefly discussed below.

Natural Gas from Biological Origins

The traditional biological concept, still by far the most widely discussed and accepted across the petroleum and gas industries, is based on the widely studied biologically assisted decay and transformation of extensive deposits of vegetable-derived carbohydrate matter—trees, shrubs, etc.—into petroleum hydrocarbons. Deposits of such matter built up over millions of years were captured and compressed at hundreds of kilobars pressure under continuously building sedimentary rock strata in the earth's crust. The theory reconciles how the limestone or sandstone rock burden and at-depth geothermal temperatures combined to provide a favorable environment for indigenous bacterial strains. It then explains how their known metabolic capabilities on carbohydrate substrates accomplished scission of carbohydrate structures, with plausible reaction paths for subsequent recombinant synthesis of hydrocarbons yielding, in combination with subjection to pressure and temperature extremes during geological processes, a variable product plate of kerogen, petroleum, and natural gas, commonly known as "fossil fuels." The concept of a geological region deeper in the earth's crust, i.e., 10–30 km, well below the deepest well bores and where hardy extremophilic bacteria might survive and biocatalyze conversion of methane to higher hydrocarbons has been proposed by Gold [34]. Bacteria from very deep sea volcanic vents which thrive at 130°C and 100 bars pressure are well known. Such conditions exist at ocean depths around the world. They metabolize carbon nitrogen-, oxygen, and sulfur-containing aquatic life to degraded metabolites, and some convert vented mercaptans and H_2S to elemental sulfur and degraded products. Searches are underway to identify strains and higher temperature functionality limits that might oxidatively couple—and thus polymerize—methane to natural gas and petroleum range hydrocarbons.

Natural Gas from Nonbiological Origins

The more recently proposed nonbiological natural gas origin concepts expertly presented and summarized by Gold [34], are based on recognizing that natural gas and petroleum building blocks were constituents of, or derived from, the primordial materials and processes that originally formed planet Earth. Primordial matter and dust in the pre-Earth planetary orbit consisted of H_2 (the most abundant element in the universe) Si, O_2, C, CH_4, C_2H_6, S, and substantial quantities of metals such as Al, Na, K, Ca, Fe, Ni, V, Cr, Mo, radioactive U, Th, and others. Planet Earth formation began about four billion years ago and proceeded through the gradual agglomeration of the planetary orbit materials. As earth mass increased, gravity-driven densification and compaction caused a consequential temperature rise. Metal oxide formation and reduction by hydrogen or carbon (yielding by-product H_2O) led to formation of a dense, semi-solid, mostly metal core. This was followed by the gravitational and density graded formation of the lower and upper mantles (and associated volcanism). The latter was constituted from lighter medium to metals and their oxides, silicious or nonmetal, oxides, sulfate, silicate, and carbonate species. Primordial nitrogen, methane and ethane, light petroleum liquids derived from them, and other volatiles were squeezed out of the more dense lower strata and diffused or otherwise migrated to the crustal strata above. This uppermost earth crust was constituted of basaltic, silica/silicate, sulfate, and carbonate materials via sedimentation processes yielding features including domes, faults, strati graphic traps, and other petroleum and gas reservoir structures, accompanied by magma intrusions, and over- and under-thrusts. The least dense outer crustal materials stabilized gradually into the land masses and oceans. Over time, gravity attracted and captured from the planetary orbit and outer space a gaseous atmosphere with contributions of upward migrating gases from the lower crust and mantles. Earth's depth vs. density gradient and its geotherm or thermal gradient, were established during these events.

Metal and metal oxide catalysts with this capability were reported in the 1980s. Several of these metals occur in widely distributed petroleum samples and are among the above listed as constituents of primordial Earth planetary orbit dust. In the metallic and compounded state some have the ability to catalyze hydrogenation of carbon to kerogen-like high viscosity hydrocarbons. Kerogen, a heavier petroleum-like hydrocarbon mixture occurs in tar sands and porous shales (oil shale). Thus the question of conceivable prehistoric or more recent petroleum from methane generation must be considered.

Natural Gas Release from Lower Crust and Mantle Domains

Methane, the most stable hydrocarbon, and some others, in the absence of oxidants can endure temperatures of 1,000°C and higher. With some mantle and lower crustal rock porosity, gas law behavior would require that during planet earth formation and the long gradient-densification process, most of the primordial methane component (which) escaped oxidation, should have diffused upward to be trapped in the sedimentary crustal reservoirs and likewise for ethane and other light hydrocarbons, with little loss. If this upward migration continued from mantle or lower crustal depths, ca. 300 km, depleted modern natural gas upper crustal reservoirs, given time, should substantially refill. This has been observed in numerous cases, offering convincing support for the nonbiological natural gas concept.

Of particular note is that methane, and natural gas, if from great depths, should contain He from radioactive decay of the very dense uranium and thorium in the lower crust and mantle domains. This has been documented in most of the above instances. Natural gas reservoirs producing gas containing over 5%, sometimes as much as 10%, helium are long known, and they provide this purified gas for many industrial uses and lighter-than-air transportation craft.

Methane and a few other light hydrocarbons, C_2 and C_3 are capable of forming solid clathrate compositions with water. These are literally ice-like structures with methane molecules occupying cavities formed by solid-state hydrogen-bonded H_2O molecules. A ratio of six H_2O units to one CH_4 unit forms the stable methane hydrate at temperatures below 7°C and pressures higher than 50 bars. A typical mostly methane natural gas with about 10% minor components, including ethane, other light hydrocarbons, CO_2 and N_2 forms a stable hydrate at temperatures below 10°C and pressures higher than 21 bars. Such hydrates are often nuisances (and worse) in cold-weather gas pipeline operation, but have great significance to natural gas technology and outlook. Pressure–temperature combinations spanning the above example are common at various ocean depths, and vast gas hydrate deposits exist beneath ocean floors where upwelling natural gas forms hydrate caps with subocean floor seawater and forms very large subterranean free gas reservoirs. The distribution and size of such hydrate deposits offer further persuasive evidence confirming the deep earth gas theory. Analogous in-earth deposits are believed to exist in land sites at temperatures compliant with the geotherm, pressure at depth, and compatible rock structure. Gas reserves in known ocean floor hydrate reservoirs are estimated at 10^{15} kg.

Summary for Methane and Natural Gas Future Sourcing

As for future sourcing, methane generation from biological sources such as coal beds and composted vegetation is well known, industrially exploited, and of particular recent interest as a potentially renewable source. Methane is also an important constituent of numerous petroleum grades that contain hopanoid and optically active hydrocarbons, which are associated with biological and biochemical processes.

Beginning, however, in the 1990s, compelling factors and reasons that support the origin of nonbiologically derived methane have come to worldwide attention. These are rooted in its having been a substantial component of the planetary orbit dust from which the primordial earth mass agglomerated; and that it now appears it is being continuously released from the mantle and lower crustal domains via upward diffusion or other migratory processes to shallow crustal and surface levels. Moreover, methane (with its good thermodynamic stability) and higher hydrocarbons (with somewhat less stability depending on molecular weight and structure) could, with subsequent core and mantle temperature and pressure rise, well have been, and could continue to be, formed within these core and mantle domains by the metal catalyzed combination of primordial hydrogen and carbon.

At least three established major factors strongly reinforce these nonbiological methane scenarios. First is the presence of significant amounts (occasionally up to 10 volume%) helium in widely spread natural gas production sites. Second is the observed gradual refilling of previously depleted natural gas reservoirs by upwelling. Third is the existence of vast methane/natural gas hydrate deposits below ocean floors and land masses, some of which act as caps for larger gaseous methane reservoirs beneath. These gas hydrates are able to form at temperatures above the freezing point of water and at pressures near 5,000–6,000 psi. The estimated worldwide total carbon in these natural gas formations is 10- to 100-fold greater than presently estimated worldwide petroleum reserves.

As a result of these discoveries in recent years, the search for cost-effective production and applicable extraction, drilling, or other recovery technologies is an industry and multinational priority.

The Nuclear Industry

21

Tom Congedo, Edward Lahoda, Regis Matzie, and Keith Task

Introduction

The objective of the nuclear industry is to produce energy in the forms of heat from either fission reactions or radioactive decay and radiation from radioactive decay or by accelerator methods. For fission heat applications, the nuclear fuel has a very high specific energy content that currently has two principal uses, for military explosives and for electricity generation. As higher temperature reactors become more widely available, the high temperature heat (>900°C) will also be useful for making chemicals such as hydrogen. For radiation applications, the emissions from radioactive decay of unstable nuclides are employed in research, medicine, and industry for diagnostic purposes and for chemical reaction initiation. Radioactive decay heat is also employed to generate electricity from thermoelectric generators for low-power applications in space or remote terrestrial locations. Radiation produced from accelerator-based sources is used for geologic investigation (e.g., identifying oil deposits), materials modification, and contrast imaging of dense media (e.g., security inspections in commercial shipping). Fuel from the first atomic pile is shown in Fig. 21.1.

This nuclear technology is based on both the nuclear and the chemical properties of the atom. At the beginning of the twentieth century fewer than 90 chemical elements were known and there was only a dawning awareness of isotopes. Today, largely because of the nuclear industry, thousands of isotopes (or nuclides, depending on the properties of interest) have been identified. Brief definitions of several chemical and nuclear terms are given in Table 21.1.

As with other technology, nuclear technology involves a combination of science and art. However, it is unique because of the development of the atomic bomb that contributed to the ending of World War II. Many people view nuclear technology from the point of view of nuclear weapons and more recently nuclear accidents such as those at Chernobyl and Three Mile Island. This leads to the view that nuclear technology is only useful for explosive applications and that it is only with great care that it can be safely used. In reality, it is difficult to produce nuclear explosions and safe use of nuclear energy is really only a matter of following common-sense rules of behavior no more mysterious than those involved with handling dangerous chemicals or electricity.

This chapter first considers the following subjects.

- The status and outlook of the nuclear industry.
- Nuclear safety.
- The role of nuclear energy in meeting the world's energy needs.
- The nuclear processes on which the nuclear industry is based (Fig. 21.2a).
- The chemical process technologies involved in the fuel cycle for nuclear electric power and chemical process heat generation (Fig. 21.2b).

This is followed by discussions of radioactive waste management and transportation of nuclear materials, and consideration of various applications, such as nuclear power reactors used for the generation of electric power, the use of radioisotopes, and other military and civilian uses of nuclear materials (Fig. 21.2c). The processing of uranium ore, the enrichment of material for use as nuclear fuels, the production of electricity using nuclear fuel and the subsequent handling, storage, and in some cases reprocessing of the radioactively contaminated waste constitute some of the more sophisticated and challenging areas of fundamental and applied chemistry and engineering as well as requiring huge investments on the order of tens of billions of dollars for each stage in the process.

A reference section is provided for those who wish to have more detailed information.

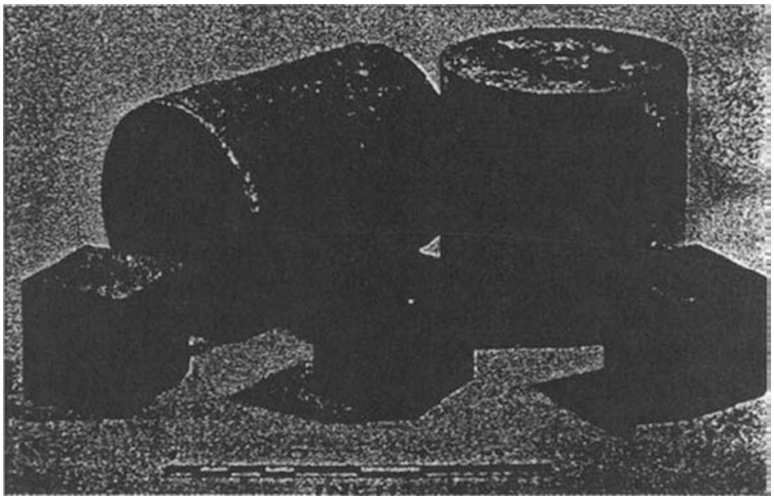

Fig. 21.1 Uranium metal fuel from the first atomic pile. This reactor contained 40 t of uranium oxide along with 6.2 t of uranium metal (ORNL News, 1-01-076)

Table 21.1 Definitions of atoms, chemical elements, isotopes, nuclides, and isomers

Atoms: Elementary particles of matter composed of protons, neutrons, and electrons. In a neutral atom the total number of orbital electrons is equal to the number of protons in the nucleus
Chemical elements: Atoms with unique properties related to their orbital electrons
Fissile: Capable of undergoing nuclear fission initiated by a slow neutron
Fissionable: Requiring a neutron of kinetic energy above a threshold value, to initiate nuclear fission
Isotopes: Atoms of the same chemical element with different masses related to a different number of neutrons in the nucleus
Nuclides: Atoms with unique properties related to the neutrons and protons in the nucleus of the atom
Isomers: Nuclides with the same numbers of protons and neutron but in different energy states
Radioactive decay: The process by which unstable nuclei become more stable
Radioactive half-life: The time during which the decay rate of a radioactive nuclide decreases by a factor of 2

Status and Outlook

Nuclear energy provides products that play vital societal roles:

- As a primary energy source for the production of electricity to meet the world's energy needs without polluting the atmosphere [1]. Currently, it is the only large-scale electrical production process that does not produce greenhouse gases (e.g., CO_2) or other pollutants such as SO_2, NO_x, mercury, or particulates.
- As stable and radioactive nuclides, which contribute significantly to research, medicine, and industry (see Table 21.2 and Fig. 21.2.).
- As radioactive decay heat sources that in conjunction with thermoelectric conversion devices provide low levels (kilowatts) of power for very long times in deep space probes and for remote terrestrial applications such as weather sensors.
- As nuclear explosives and in nuclear-powered submarines and ships, which have contributed to maintaining world peace since World War II, but have since declined in importance.
- Test reactors that are used to generate isotopes, do chemical analyses, and study materials.

Nuclear technology continues to be developed for military applications including nuclear explosives, submarines, and ships. Brief attention is given herein to explosives, primarily in terms of their historical role as a potential means for excavating harbors and canals and in the enhancement of gas and petroleum deposits.

It should also be noted that since the end of the Cold War, official military stockpiles of nuclear (and other) weapons have been diminished, by international agreement. At the same time, acquisition or fabrication of nuclear devices by nongovernmental terrorist groups or individual states has become a matter of increased concern.

Since the discovery of nuclear fission in the late 1930s, this technology has been developed to supply 14% of the world's electricity from 435 nuclear reactors located in 30 countries (2012) [2]. This is an international program regulated by the United Nations International Atomic Energy Agency (IAEA) which, as of 2012, includes 155 member countries. In 2012 there 104 nuclear units in the United States, including 69 pressurized water reactors (PWRs) and 35 boiling water reactors, which together generated 790 billion kWh of electricity, some 20% of the country's total electricity generation [2]. This represented a 217% increase in output since 1980 (see Fig. 21.3).

Fig. 21.2 The nuclear industry

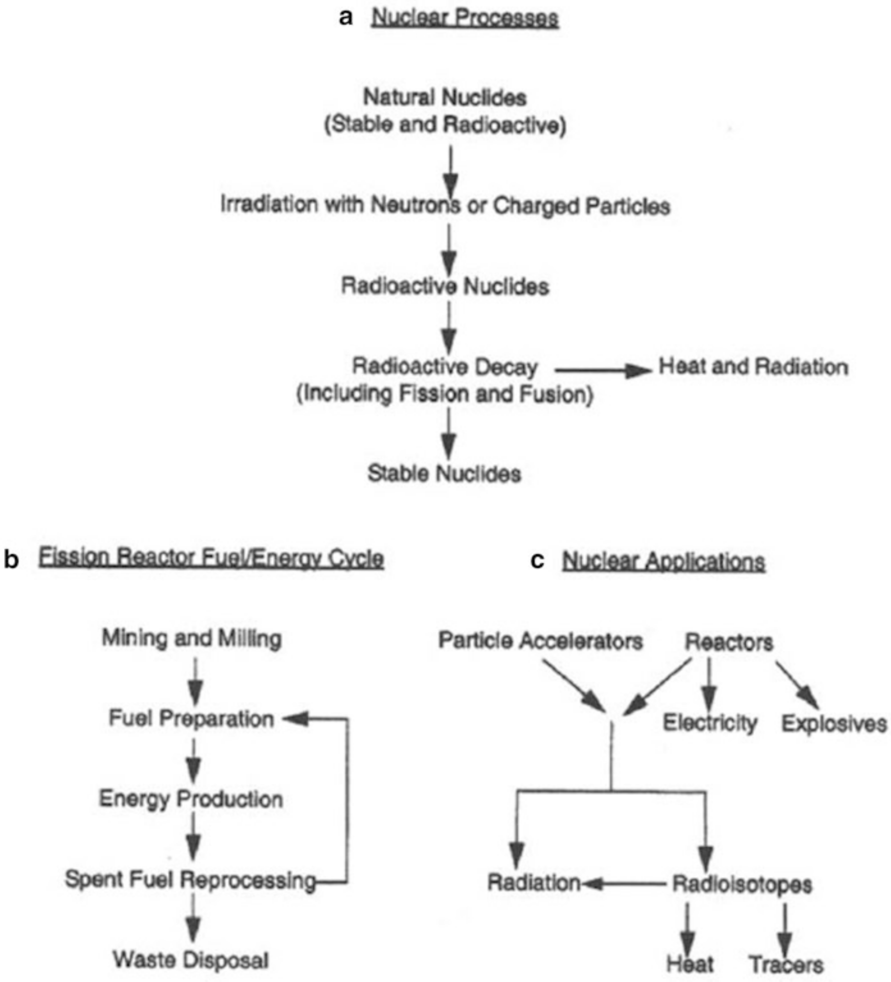

Table 21.2 Nuclear Industry Products (2012)

Civilian	Approximate number
Worldwide electric generating plants	435–433
Ships (icebreakers and transports)	~10
Research reactors	240
Radioisotope applications (tracers, radiation sources, thermal sources)	Millions
Radiation modification of materials (solid-state devices, treated polymers, etc.)	Small (mostly proprietary)
Military	
Weapons	20,000[a]
Submarines, ships (aircraft carriers, cruisers, transports)	~140

[a] Although it is a possibility that up to 10,000 more nuclear warheads may be awaiting dismantling or are in reserve in Russia [3]

The safety record of the nuclear industry has continued to be generally very good, despite the 1987 accident with a nuclear reactor at Chernobyl, in Ukraine, which killed a number of workers, caused the abandonment of adjacent communities and farmland, and resulted in radioactive fallout in neighboring countries. It should be noted that these were the first civilian nuclear fatalities since the beginning of the nuclear power industry [4]. It is generally agreed that this unfortunate occurrence was caused by serious design flaws, and that power reactors in use elsewhere are not subject to similar occurrences. Indeed, a somewhat similar yet also very different accident occurred in the United States in 1979 (Three Mile Island); but because of the reactor's inherent physics feedback mechanisms and its engineered safety features (required in the United States and recommended by the IAEA), there were no injuries and no significant radiation exposure, either to workers or the public [5]. More recently (2011) a tsunami triggered by a major earthquake

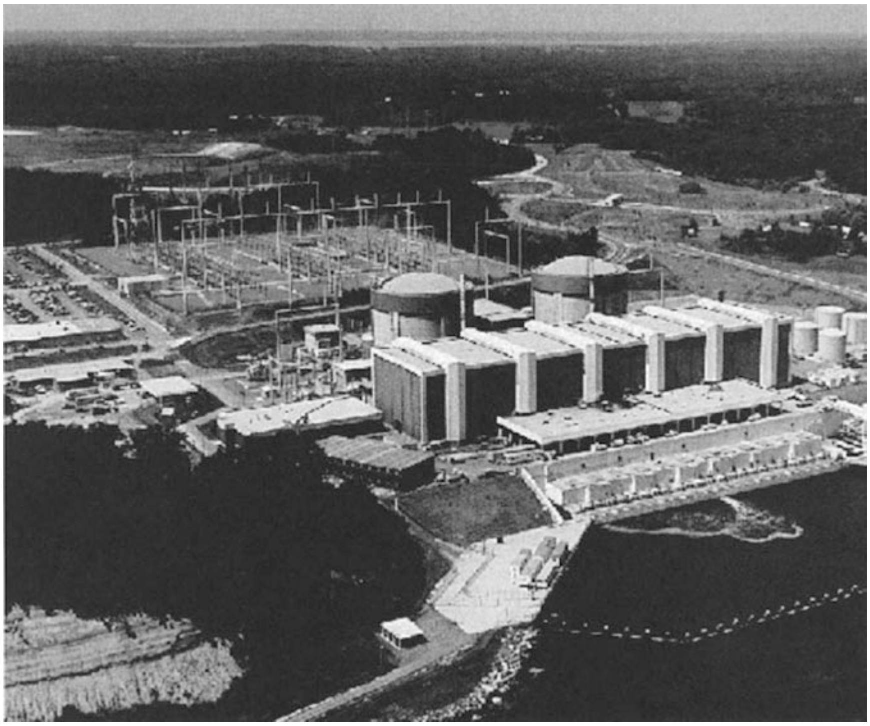

Fig. 21.3 The Calvert Cliffs Plant in Lusby, MD, Baltimore Gas and Electric. Capacity: 1,600 MW(e) from two reactors (Courtesy of EEI-Electric Perspective)

off the coast of Japan disabled the emergency gererators that powered the longterm cooling systems at the Fukushima Nuclear Poner Plant in Japan. Three reactors and some of the spent fuel pools suffered meltdowns and released significant amounts of radioactive material which contaminated large areas of the surrounding country side. Two workers died from non-radiation covles and no willian casualties occured.

Worldwide, aggressive public concern about nuclear safety has been delaying the development of waste disposal facilities for high-level wastes. Current intermediate-level waste facilities in the United States are nearly full, and there has been great difficulty in siting new facilities. It now appears that for many years the interim solution for the storage of spent fuel elements will be above-ground storage facilities at existing reactor sites with appropriate safeguards and security. On the energy side, increased attention to conservation and the ready availability of natural gas in the United States that can be used in low-cost combined cycle electric generating plants reduced the pressure for continued nuclear power development in the later years of the twentieth and the beginning of the twenty-first century. Supplies of natural gas continue to be plentiful and it accounted for about 23% of the energy used in the US in 2010. Due to new shake gas supplies that continue to come on line, prices will likely continue to be low for the foreseeable future, and the percentage of energy from natural gas will continue to increase, mainly from displacing coal use. Because of worldwide concerns regarding climate change and other environmental factors, there is increasing emphasis on reducing the use of all fossil fuels. Nuclear is the only non-fossil technology which is capable of being a significant and economically acceptable electrical power generating option.

Light water reactors (LWRs) and HWRs have been successfully used for electric power generation throughout the world with good operating and safety records. In recent years significant advances in nuclear reactor technology have been realized. A new generation of light and HWRs has been designed and licensed to further reduce the already very low probability of loss-of-coolant accidents such as occurred at Three Mile Island and station blackouts as occured at Fukushima and Chernobyl. In addition, the enrichment level of new fuel for LWRs has been increased, and the average fuel life has thereby been extended from 33,000 to as high as 50,000 MW days/mt, and the typical reactor cycle between shutdowns has been increased from 12 to 18 months. As a result, online times (i.e., capacity factors) have increased to the low 90 percents, providing low-cost as well as reliable electrical power generation.

All the components of the nuclear fission power system are fully operational except for ultimate waste disposal. However, spent fuel is not reprocessed in the United States because there is currently an adequate supply of natural uranium and enrichment services available domestically and from other countries at a lower cost than that of the recovered fissionable material from spent fuel. Also, the United States unilaterally declared a moratorium on reprocessing in the early 1980s in an attempt to reduce the spread of nuclear weapons. Current economics do not favor a return to reprocessing and fuel recycling in the United States it for the foreseeable future.

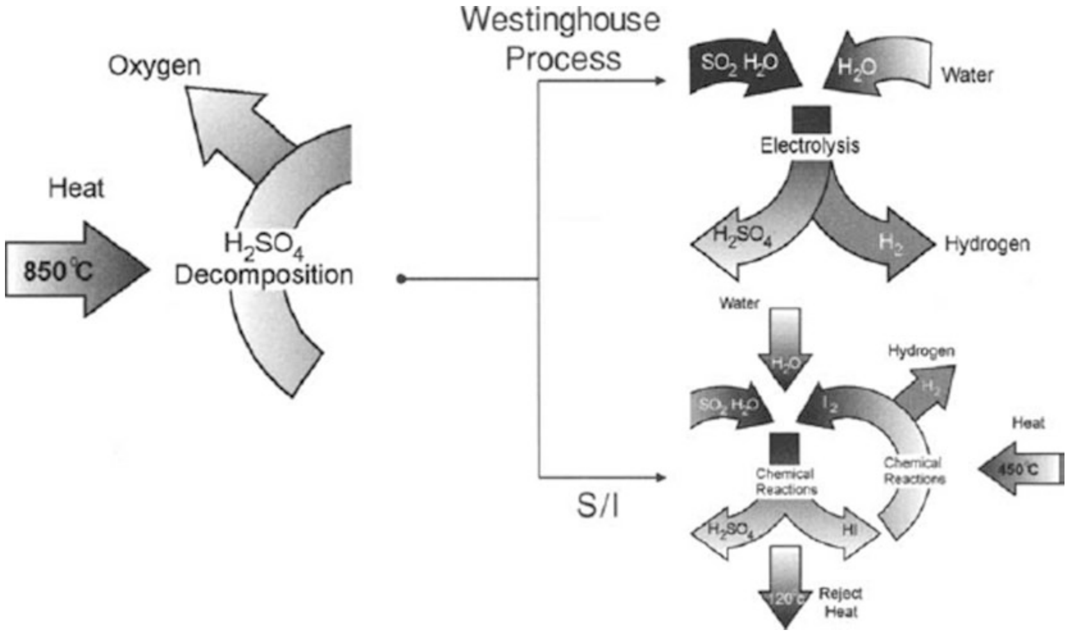

Fig. 21.4 High-temperature processes for generating hydrogen (Nuclear Hydrogen R&D Plan. Final Draft, U.S. Department of Energy, March 2004)

The nuclear industry makes available about 3,000 nuclides, including both the stable and the radioactive nuclides. Approximately 50 radioactive nuclides, along with some stable nuclides that have been isotopically enriched, are essential in research, medical, and industrial applications. Many of these are now produced commercially, but several still are dependent on government facilities. Some, for economic reasons, come from other countries. Radiation processing for sterilization of disposable medical supplies is an important operation using cobalt-60 from Canada. Electron accelerators have replaced radioactive nuclides as radiation sources for polymerizing plastic coatings on wire and paper. Perhaps the greatest disappointment experienced by the industry has been the public opposition to irradiation of food to extend its shelf life. The principal current application of this type is by the Russians, who are using electron accelerators for the deinfestation of wheat, and the use in the United States for treating herbs and spices.

In the continuing research and development of advanced nuclear energy, the liquid metal reactor (LMR), molten salt reactor (MSR), high-temperature gas-cooled reactor (HTGR), and fusion are the major activities. It would now appear that these alternatives will likely increase the cost of electrical energy in comparison with the present LWR/HWR technology based on low-cost uranium ore. HTGRs have been of interest since 2003 when the United States declared its intent to replace the use of oil-based fuels for transportation with hydrogen. Several hydrogen production processes (e.g., the Westinghouse Process and the Sulfur Iodine Process; see Fig. 21.4) have been investigated that utilize high temperature (850–900°C) heat from a reactor to provide a major portion of the energy for making hydrogen. These temperatures are only compatible with HTGRs. The advantage of using these high-temperature processes is the higher overall energy efficiency that is obtainable (see Fig. 21.5). For instance, the Westinghouse Process can achieve overall efficiencies of 33% or greater.

Plant-scale liquid metal (sodium) reactors (2008) have been in operation in France and Russia to establish the engineering technology and to evaluate their role in increasing the efficiency of uranium utilization. France, without a significant primary energy supply, wants to minimize imports of uranium. According to the USEIA web site, the United States imported over 40% of its uranium. In the United States, engineering test LMRs operated for many years and made significant contributions to LMR technology.

Whereas LMRs were first studied to reduce natural uranium requirements to approximately 20 mt/GW year electrical (GWye), development is now centered on reducing plutonium in the waste. However, at this time all such LMRs have been shut down and are being decommissioned. Programs are also underway to use conventional uranium dioxide fuel containing "blended down" highly enriched uranium (HEU) or mixed oxide (MOX) fuel containing oxides of uranium and plutonium in commercial nuclear power reactors in order to dispose of nuclear weapons materials. Other theoretical reactor concepts are also being investigated for disposal of actinides.

It is difficult to assess the progress of fusion research, a significant international research program. Russia, the European Community, China, Japan, and the United States are the principal participants. It is now clear that fusion will be a high-

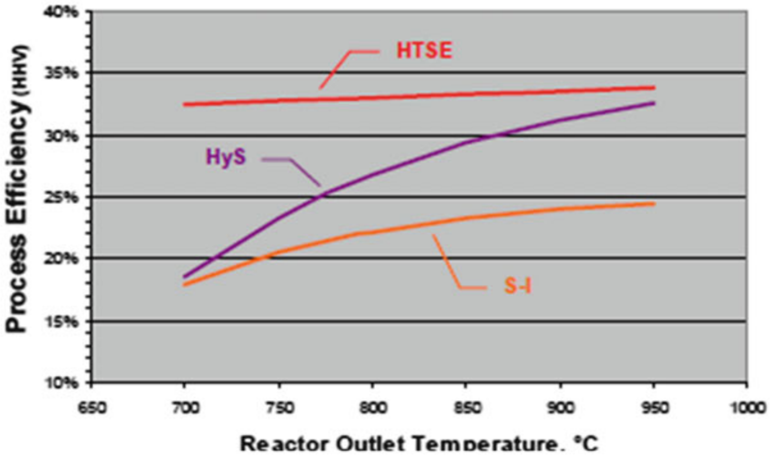

Fig. 21.5 Efficiencies of various H_2 production processes (Charles Bolthrunis et al. (March, 2009) NGNP hydrogen plant alternatives study, NGNP HPS SHAW-HPA, pp. 5–28)

cost source of energy and not economically justified within the foreseeable future. However, it is essential for the major world nations to cooperate responsibly in its development because of the severe technical challenges and high cost of research and development of this technology. The basic research has yet to achieve controlled ignition of the fusion reaction along with energy parity (energy input less than output).

At this time (2012), the outlook for the nuclear industry is difficult to project. France and Korea, countries without domestic energy resources, are continuing to move ahead to establish efficient nuclear systems for electric generation; and although they have a concerned public, their fears regarding waste disposal and proliferation are not overriding their need for electricity. China has embarked on an aggressive nuclear build program, but its projected electricity demand is growing so rapidly that this aggressive program will only result in about 5% of electricity from nuclear in the next 15 years. In Japan and Germany, countries which currently produce a significant amount of electrical power from nuclear, there is movement to eliminate the Nuclear power option.

Recently, a number of countries which had no previous reactors or new construction for a long period of time, have embarked on building new nuclear plants. Included in this list are countries new to nuclear power such as the UAE, as well as established nuclear users such as the US, Canada, UK, and Finland.

Nuclear Safety

Safety first has always been and continues to be the basic policy of the nuclear industry. This includes reactor safety by design as well as activities to discourage the proliferation of nuclear weapons and to prevent sabotage of nuclear facilities. This policy has been successful; the chance of death from a nuclear accident is over a million times less than death from ordinary human activities, and over a thousand times less than death from natural events (see Table 21.3). Safety remains the most challenging responsibility of the nuclear industry.

It is the public's strong perception that all nuclear activities are more dangerous than other accepted risks. Much of this public concern results from the atomic bombs and the government's secret program that produced the bombs. However, even with the early large-scale nuclear operations, there were few nuclear fatalities or life-shortening injuries. After 40 or more years of operation, these facilities were due to be retired; however, there is a strong movement now to extend the life of most operating reactors for another 20 years or more. Meanwhile, considerable operating and safety experience has been gained that may very significantly reduce public concern in the future.

The nuclear safety program originally was based on both established laws regulating all industrial safety and early knowledge of radiation health effects related to radium and X-ray exposure. Since then the safety regulations have been greatly enhanced, and they are present in the Code of Federal Regulations, Title 10, Chapter 1, titled "Nuclear Regulatory Commission" [6]. These regulations strictly control the management, engineering design, and operations of all nuclear activities. In addition the IAEA already detained previouly has established regulations as a reference for all national programs. Each country also has its own regulatory agency. There are two areas of concern in nuclear safety: radiation exposure of the public and of workers resulting from normal and accident conditions; and danger to world peace and order from nuclear weapons proliferation and sabotage.

Table 21.3 Average risk of fatality by various causes in the United States

Accident type	Annual total number*	Individual annual risk**
Total Transportation Accidents	45,832	1 in 4,429

****Calculation based on 100 LWRs operating under United States Nuclear Reugulatory Commission Supervision

Table 21.4 Annual estimated average effective dose equivalent received by a member of the population of the United States (From HP Society University of Michigan site, 1/18/05 [10])

	Average annual effective dose equivalent	
Source	(μSv)	(mrem)
Inhaled (radon and decay products)	2,000	200
Other internally deposited radionuclides	390	39
Terrestrial radiation	280	28
Cosmic radiation	270	27
Cosmogenic radioactivity	10	1
Rounded total from natural sources	3,000	300
Rounded total from artificial sources	600	60
Total	3,600	360

Radiation, like air, has a ubiquitous presence in the human environment. The amount of background radiation that humans are exposed to ranges from 100 to 300 mrem/year depending on their location in the world, and an additional 60 mrem/year comes from other normal sources (medical, consumer products, etc.). The principal natural radiation sources are cosmic rays from outer space, radon from geologic sources, and potassium-40 within the human body (see Table 21.4). The radiation exposure to the public resulting from normal nuclear operations is limited by federal regulation of engineering design and management controls. There is also an overriding requirement that limits the radiation exposure to "as low as reasonably achievable (ALARA)."

The annual radiation exposure of nuclear workers is limited to 5 rem, and the limit for public exposure (not radiation workers) from licensed activities is 100 mrem/year although people living near a nuclear power station are on average only exposed to <1 mrem/year [8]. The government also puts limits on fatality risk levels due to a nuclear accident:

> The risk of an immediate fatality to an average individual in the vicinity of a nuclear power plant that might result from reactor accidents should not exceed 0.1% of the sum of the immediate fatality risks that result from other accidents to which the US population is generally exposed, and the risk of cancer fatalities to the population near a nuclear power plant should not exceed 0.1% of the sum of cancer fatality risks from all other causes [9].

The levels of radiation exposure were first established on the basis of historical data, and since then they have been periodically evaluated by the International Commission on the basis of continuing experience.

In 1975 the United States Energy Research and Development Agency, the forerunner of the United States Department of Energy, sponsored the "Reactor Safety Study," the most thorough hazard analysis ever performed [10] for any technology. It concluded that on the basis of past licensing review practices, the risk from existing light water type power reactors was orders of magnitude less than other commonly accepted hazards. It further concluded that human error would be the expected cause of any accidents that might occur. This study also found that the cost of nuclear power reactor accidents would be several orders of magnitude less than the cost of other natural and human-caused events to which the public is accustomed (see Fig. 21.6).

In the 1950s the Nuclear Safeguards Program was established by the United Nations to administratively reduce the risk of nuclear proliferation. The objective of the Safeguards Program is to prevent the diversion of fissionable material, primarily plutonium, from the reprocessing of spent fuel. A force of onsite inspectors is employed by IAEA in this activity. This program is administered by the IAEA and is generally considered to be successful. Countries join this program voluntarily and do not include their weapons production facilities. India, Pakistan, and North Korea did not choose to join and developed their own nuclear weapons. Two nonmember countries have in the past or are developing nuclear weapons including South Africa and Israel.

In 1980 a study of proliferation control, titled "International Nuclear Fuel Cycle Evaluation," was carried out for President Jimmy Carter of the United States. The United States had called for this study, in which 50 countries

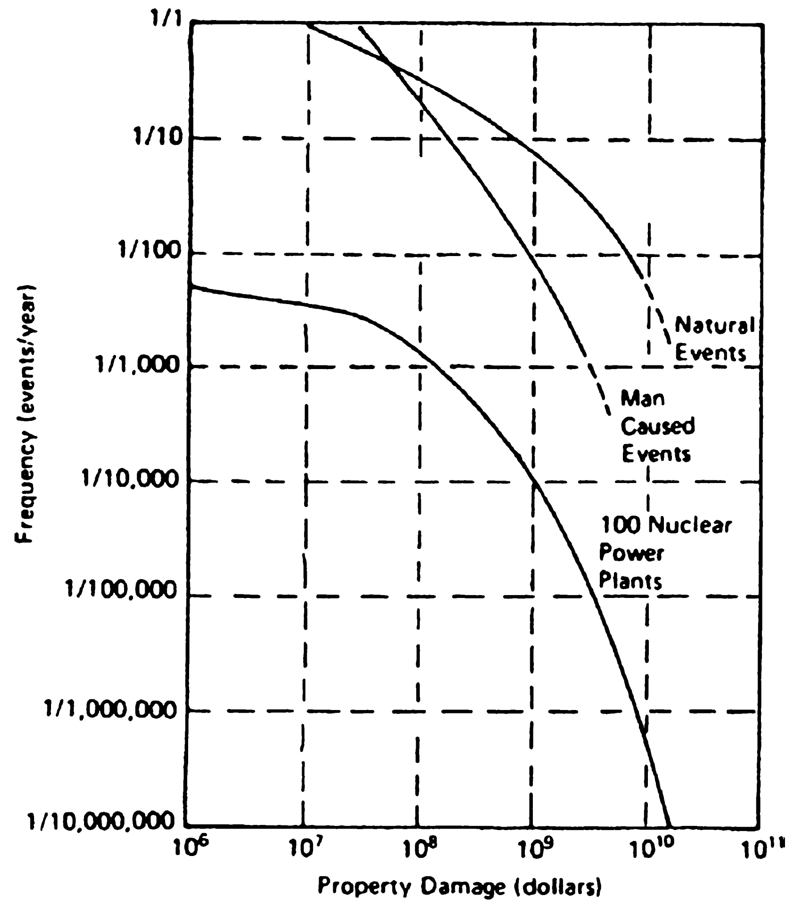

Fig. 21.6 Frequency of property damage due to natural and human-caused events (*Notes*: (1) Property damage due to auto accidents not included. (2) Approximate uncertainties for nuclear events are estimated to be represented by factors of 1/5 and 2 on consequence magnitudes and by factors of 1/5 and 5 on probabilities. (3) For natural and human-caused occurrences the uncertainty in probability of the largest recorded consequence magnitude is estimated to be represented by factors of 1/20 and 5. Smaller magnitudes have less uncertainty)

participated and which required several years to complete. The study concluded that only administrative controls such as those already in place would be effective, and these could only delay really determined nations from diverting nuclear fuel from power reactors to military weapons. By 2003, North Korea became the first example of the subversion of test/commercial nuclear materials for use in weapons.

The Earth's Energy Supply and Use

The earth is provided with two sources of energy, the "capital" resources deposited within the earth during its formation and the "income" resource continuously beamed onto the earth from the sun. Both are essential to human existence.

In the 1950s, global energy analyses were performed by King Hubbard for the US Geologic Survey and by Palmer Putnam for the Atomic Energy Commission. Hubbard's work reported the income energy from the sun to be equivalent to 178,000 million MW (Fig. 21.7). At noon on a cloudless day a square meter of the earth's surface facing the sun receives approximately 1 kW. The income resource also includes a very small contribution, less than 0.02%, from the gravitational forces of the sun, moon, and earth and from the thermal and nuclear sources within the earth. Part of the solar energy appears in the form of water and wind power, wood, alcohol, garbage, cow dung, solar heaters, and photoelectric generators.

Putnam's study, titled "Energy in the Future," was primarily concerned with the capital energy resources. These analyses are continued today by the Energy Information Administration in the US Department of Energy (see Fig. 21.8). The capital resources are the fossil and nuclear fuels present in the crust of the earth. The fossil fuels were created by the interaction of the sun with the terrestrial flora and fauna. This was a very low-yield process that over the 5 billion years the earth has existed captured about 2 days of the solar energy in the form of coal, oil, gas, and other combustibles. The recoverable quantities are difficult to estimate [11–14].

The nuclear fuels were created in the cosmic event that created the universe and were deposited in the earth as it took form. There are two families of nuclear fuels, those for fission (uranium) and those for fusion (protium [^1_1H], deuterium, helium-3, and lithium). Only uranium fission has been developed as a commercial source of nuclear energy.

Fig. 21.8 U.S. energy flow, 2011 (quadrillion Btu) (Annual Energy Review, U.S. Department of Energy 2011)

Although fusion has been developed as a military weapon, the hydrogen bomb, it is premature to include the fusion fuels in the world's inventory of capital energy. The technology for controlled fusion is not available, nor is development of a controlled fusion process expected in the next decade. When available it would increase the capital supply to a level greater than that from all other sources combined [15].

In 1990, the National Academy of Science completed an energy study that concluded that commercial fusion power may be required by the year 2050. By that time 40% of the oil reserves will have been consumed, and current natural gas reserves can supply only about half of the projected needs. Since then, the discovery of additional deposits and improved production methods have met the need for natural gas and decreased prices.

Little use was made of the earth's capital energy until the nineteenth century, and now 5–8% of that resource may have been consumed. Yet even though most of the fossil fuels remain, there are increasing problems with their extraction and distribution and the pollution that is incidental to their use. The demand for energy is increasing as the world continues to industrialize. In 2002, the annual per capita consumption in the United States was 340 million Btus vs.190 million in Russia, 47.7 million in Brazil, and 13.5 million in India. The increasing demand will stem from population growth and increases in the standard of living. It will be accompanied by increased energy use for the extraction of marginal resources and the treatment of wastes before their release into the earth's environment.

Petroleum is and will remain the major source of mobile energy for the next century. However, petroleum production has passed its peak in the United States, and in several decades it may peak in the rest of the world. However, in 2001, approximately 45.8 trillion kWh of energy were consumed worldwide using oil, and projections indicate that this number will increase to approximately 71–74 trillion kWh in 2025, indicating a ~58.3% increase in oil consumption. Also in 2001, the US energy supply from petroleum products was 11.2 trillion kWh, and it is projected that this number will increase to 16.1 trillion kWh, indicating a 43.8% increase [8].

Coal can supply US needs for the next several hundred years, but there is increasing concern regarding pollution from both coal and petroleum. Unfortunately for the developed nations, using pollution-free energy sources such as nuclear and solar will do comparatively little to reduce worldwide atmospheric pollution. The sources of such pollution are worldwide. About 6 billion tons of CO_2 were generated in 1985, and this pollution source is expected to increase to 30 billion t/year by 2060. In the 1980s only 10% of the 6 billion t/year came from the United States. In 2002, this increased to about 5.7 billion tons (Annual Energy Review 2003, DOE) or about 23% of the world's total. In 2002, about 210 million tons of avoided carbon emission was achieved by nuclear (140 million) and renewables (mainly hydro) [16].

The benefits of nuclear power obtainable with the present technology depend on the availability of uranium resources. For example, using the present light water reactor technology, each 1,000-MW reactor requires a few thousand metric tons of uranium during its 60-year operation. Because of limited uranium ore reserves in the United States and the lower cost of uranium from other countries, in the late 1980s about 50% of ore consumed in the United States was imported. This number increased to 64% in 2003. However, US reserves should increase significantly when exploration again becomes profitable. In addition, the energy extracted from the uranium can be significantly increased by reprocessing the spent fuel. If the recovered mixed uranium and plutonium were used in a HRW, there might be as much as a 68% increase in energy generated. A further increase by a factor of 10 might be achieved going to a liquid metal cooled reactor. However, such advanced technology will result in higher electricity cost. In view of the current low cost for natural uranium, storage rather than reprocessing of spent reactor fuel creates a beneficial fission fuel reserve.

Nuclear Processes

The science of the nuclear processes has a long history. Democritus in the fifth century BC started the search for the elementary particle of nature he called the atom. John Dalton, about 1803, related atomic masses to hydrogen, and Mendeleev in 1869 correlated these masses with the atoms´ chemical properties and hypothesized missing elements. Many thought this ended the adventure, but in 1895 Roentgen discovered X-rays, and a year later Becquerel discovered natural radioactivity. A short time thereafter, in 1902, Rutherford and Soddy proposed that radioactivity was related to atomic changes, and in 1905 Einstein equated mass to energy. In 1932 Curie and Joliot discovered artificial radioactivity, and in 1938 Meitner and Frisch recognized that uranium fissioned when bombarded with neutrons. In 1942 Enrico Fermi and Glen Seaborg led development of the first controlled neutron fission reactor to produce plutonium-239 [17].

The nuclear processes of most interest to the nuclear industry are radioactive decay and the transmutation of nuclides. Whereas chemical processes relate to the interactions of orbital electrons of the atom, nuclear processes relate to interactions of neutrons, charged particles, and nuclides with the neutrons and protons in the nucleus of the atom. As noted above, several thousand nuclides and isomers are now known with only 287 of these occurring naturally. More continue to be found. As Mendeleev

Table 21.5 Radioactive decay process examples[a]

	Nuclide			
Decay process	Parent	Daughter[b]	Half-life[a]	Energy (MeV)
Alpha (α, 4/2He)	Pu-238	U-234	89.6y	5.5
Beta (β^-, e)	Cu-64[c]	Zn-64(s)	13 h	0.57
Positron (β+, e)	Cu-64[c]	Ni-64(s)	13 h	0.65
Orbital electron capture (EC, e)	Cu-64[c]	Ni-64(s)	13 h	1.68

Fusion	D/T	He-4(s), n	Prompt	17

[a] Thorium-234 also is radioactive, and the decay process continues through ten more radioactive nuclides before reaching stable lead-210. Decay half-life calculated by $\tau_{1/2} = ((\ell n2(t - t_o))/((\ell n(N/N_o))$ where t = time and N = disintegration/s

[b] Daughters always include gamma rays

[c] Cu-64 has three decay processes (β^- 38%, β^+ 19%, and E, C 43%)

[d] Fission products

(s)Stable nuclides; others are radioactive

invented the chart of the chemical elements, Emilio Segre invented the chart of the nuclides to give order to the nuclear properties and processes [18].

Radioactive Decay

Radioactive decay occurs when an unstable atomic nucleus emits particles and/or energy to achieve a stable state. The nucleus contains neutrons and protons along with the energy that binds them together. Many reactions are involved in radioactive decay (see Table 21.5). These reactions are characterized by the type, energy, and rate of radiation emitted. A different nuclide, which may also be unstable, results from the decay process. This nuclide then will decay with its own unique radiation. Naturally occurring uranium-238 passes through 12 nuclides before reaching a stable end product, lead-210. The types of radiation include:

- Electrons, called beta particles when negatively charged and positrons when positively charged
- Helium ions, called alpha particles
- Electromagnetic energy, called gamma or X-rays, which accompanies almost all other emissions
- Neutrons
- Nuclide ions from fission and fusion

The energy of these emissions covers a wide range of values but is typically 190 million electron volts (MeV) for fission, 17 MeV for fusion, 5 MeV for alphas, 1 MeV for gammas, and 0.5 MeV for betas. The rate of radioactive decay is expressed through the half-life, the time required for the number of atoms of a specific nuclide to decrease by a factor of 2. The half-lives range from less than microseconds to greater than a trillion years.

As radiation is not detected by the human senses, special detection and measurement methods are necessary. The silver halides in photographic film are sensitive to radiation as well as to the electromagnetic energy of visible light; in fact, it was photographic film detection that led to the accidental discovery of radiation. This technique continues to be used, particularly for the study of cosmic irradiation. A closely related method is the use of crystals (sodium iodide and germanium silicide) that emit light when subjected to radiation. This light is measured with photoelectric cells that can be tuned to measure the strength of the radiation. Another popular method measures the discharge of electric condensers in the form of gas-filled ion chambers. The radiation passing through the chamber ionizes the gas and discharges the condenser. Ion chambers are particularly useful for soft alpha and beta radiation measurement. The Geiger counter is an ion chamber with its spontaneous discharge hooked to an audio speaker, whose resulting clicking provides a background noise. All these detection methods have special uses but at the same time a wide range of applications. For each application they are calibrated with radioactive standards that are traceable to national and international reference standards.

Fission

Fission is a relatively simple process. The process is explained in detail very well by Lamarsh [20]. Neutrons at room temperature (termed *thermal*) are captured by a fissile material producing an unstable nuclide which promptly fissions, yielding energy and fission products. (Note that certain nuclei, termed *fissionable*, are caused to fission only by the impingement of an energetic neutron.) The fission products generally include more than two neutrons, and under certain circumstances a fission chain reaction can be sustained. Under special conditions where more than one neutron per fission reaction produces a subsequent fission in the fissile/fissionable material in an uncontrolled manner, a violent explosion can result. However, considerable technical effort is required to hold the material together long enough to obtain a high-yield explosion. In a controlled

nuclear fission process, such as in a nuclear power reactor, only one of the neutrons is captured by other fissile/fissionable nuclei. The remaining neutrons are used to produce more fissile/fissionable material, are absorbed in other components, or leak from the reactor.

Uranium-235. Natural uranium contains 0.711% uranium-235. The nuclear industry is still completely dependent on this single nuclide, which is the only naturally occurring one that can be effectively fissioned with thermal neutrons. A controlled nuclear fission chain reaction was first achieved on December 2, 1942 under the west stands of the football stadium at the University of Chicago. The Chicago event was achieved in an atomic pile, a stacked array of natural uranium bodies in channels of a large graphite block. The graphite was present to reduce the energy of the neutrons to a value where they are most readily captured in U-235 (see Table 21.6.) Approximately 85% of the 200 MeV released in a fission reaction is in the kinetic energy of the fission products and is instantly captured in the uranium in the form of thermal energy. The remaining energy is released in the form of radiation during decay of the radioactive fission products, e.g., strontium-90 and cesium-137. When this radiation is released, it too is largely converted into thermal energy.

The fission neutrons at birth have energies of approximately 1–2 MeV. In a thermal reactor the neutron energy is rapidly reduced through collisions with light nuclei to thermal (~0.02–1 eV), to promote more efficient capture. Besides the nuclear fuel, there are many other materials in the reactor core also competing for the neutrons, including: the moderator (the material used to slow down or thermalize the neutrons), fertile nuclides that produce additional fissile material (discussed in a later section), neutron poisons present in control rods, the coolant, fuel element cladding, and other structural materials.

Neutron poisons, which are nuclides with very high cross-sections for the capture of neutrons but which do not produce any neutrons, are an essential part of the nuclear reactor core. By their addition and withdrawal, the nuclear chain reaction is controlled with a multiplication factor of 1, that is, one fission per fission in the previous generation. To achieve high fuel burnup (utilization) in a pressurized LWR, boron (a poison) is present in the coolant (and in some cases on the fuel pellets) during the early part of each operating cycle. This serves to remove the excess neutrons (and therefore the excess reactivity of the fuel); subsequently, the boron is removed as the fuel is consumed and poisons from the fission products accumulate. This is the primary means of controlling the neutron multiplication throughout the operating cycle. Cadmium and/or boron is placed in control rods for fine tuning such as load-follow operation and reactor shutdown. Gadolinium and boron, which have very high cross-sections for neutron absorption, find use in emergency shutdown of HRWs and as a volumetrically dispersed component within the fuel pellets of some LWRs. Table 21.6 shows cross-sections at thermal energy for the principal fissile materials.

Plutonium-239. Plutonium-239 represents a fortuitous phenomenon. Whereas U-235 is the only significant fissile nuclide in nature, its major isotope, U-238, captures a neutron to produce another fissile nuclide, plutonium-239. A substantial amount of the energy produced during the life of uranium fuel is produced by the conversion of U-238 to Pu-239 which subsequently fissions. This process provides the basis for the nuclear breeding cycle.

Uranium-233. A second fissionable isotope, uranium-233, can be produced from naturally occurring thorium. It does not present an economically attractive option at present because of its dependence on highly enriched U-235 or Pu isotopes to bring the thorium cycle into operation and the large R&D expenditures required to develop the technology (for more information see ref [21]). In addition, U-232 is also generated along with the U-233 whose decay products produce high energy gammas. Fabrication of U-233 based fuel would therefore require extensive amounts of shielding making this fuel significantly less economical than U-235 based fuel.

Fusion

At present the only application for fusion is in thermonuclear military explosives, where the necessary temperature and

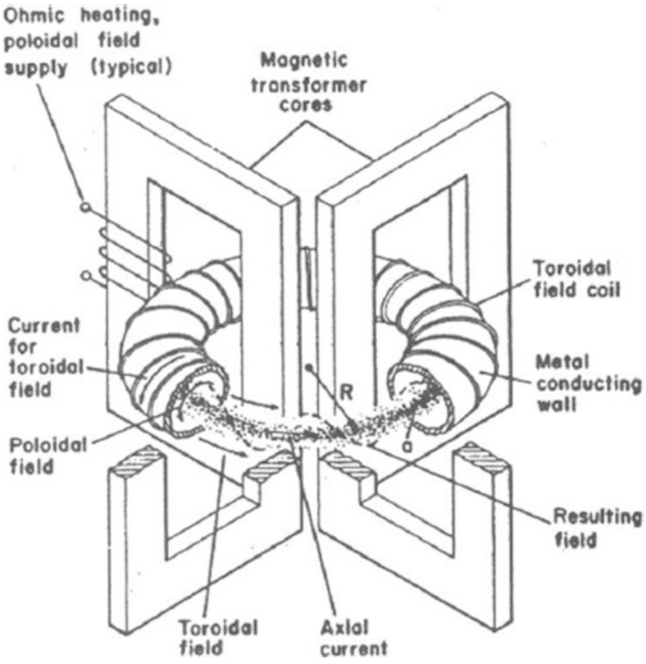

Fig. 21.9 Tokamak fusion reactor (Courtesy of U.S. Department of Energy)

pressure are achieved with a plutonium fission initiator for a very short time. The search for the science and technology needed to make fusion a viable source of energy for commercial electric power generation is the basis for one of the world's most important and challenging R&D efforts. The development of a controlled nuclear fusion reactor could provide a virtually unlimited source of energy. Like fission, fusion eliminates the atmospheric pollution associated with the use of fossil fuels. Also, it could significantly reduce the waste disposal problem of energy-producing processes [21, 22].

In the Tokamak fusion reactor depicted in Fig. 21.9, electric current to the poloidal coils on the primary magnetic transformer generates the axial current in the secondary plasma composed of deuterium and tritium ions. These ions are heated to ignition temperature and then the reaction becomes self-sustaining. The toroidal field coil suspends the plasma away from the metal conducting walls. Contact with the wall would both cool the plasma below ignition temperature and contaminate the plasma with heavy ions. The relevant reactions are given below.

Deuterium-Tritium Fusion

1. ${}^{2}_{1}\mathrm{H} + {}^{3}_{1}\mathrm{H} \rightarrow {}^{4}_{2}\mathrm{He} + {}^{1}_{0}n + 17.6\,\mathrm{MeV}$

It should be noted that this reaction is also used to provide rugged, durable commercial sources of 14 MeV neutrons for oil-well logging and scientific research. Similarly, deuterium–deuterium fusion provides sources of 2.5 MeV neutrons.

Tritium production is accomplished in a fusion reactor blanket (or a fission reactor, as is now done to produce tritium for the weapons program).

2. ${}^{6}_{3}\mathrm{Li} + {}^{1}_{0}n \rightarrow {}^{3}_{1}\mathrm{H} + {}^{4}_{2}\mathrm{He}$
3. ${}^{7}_{3}\mathrm{Li} + {}^{1}_{0}n \rightarrow {}^{3}_{1}\mathrm{H} + {}^{4}_{2}\mathrm{He} + {}^{1}_{0}n$

Protium lithium fusion would produce charged particles (90% of the energy in helium ions) for direct conversion to electricity, but higher temperatures and pressure would need to be achieved.

4. ${}^{1}_{1}\mathrm{H} + {}^{6}_{3}\mathrm{Li} \rightarrow {}^{3}_{2}\mathrm{He} + {}^{4}_{2}\mathrm{He} + 4\ \mathrm{MeV}$
5. ${}^{1}_{1}\mathrm{H} + {}^{7}_{3}\mathrm{Li} \rightarrow {}^{4}_{2}\mathrm{He} + {}^{4}_{2}\mathrm{He} + 17\ \mathrm{MeV}$

Of the several fusion reactions, deuterium-tritium fusion is the most feasible, as it has the lowest ignition temperature, 40 million °K (see Reaction 1). Deuterium comprises 0.15% of naturally occurring hydrogen, whereas tritium is produced by neutron fission of lithium-6 that is irradiated in a blanket surrounding a nuclear reactor core or by the absorption of a neutron by deuterium, for example, in a HRW. Nuclide separation is required to produce the deuterium and possibly the lithium. The tritium would be produced in a surrounding lithium blanket of the fusion reactor to sustain the process (see Reactions 2 and 3). The tritium for hydrogen bombs is produced in nuclear fission reactors using these processes. The alternative fusion reactions use protium and lithium and yield charged helium ions (see Reactions 4 and 5). These would contain 90% of the fusion energy and could be directly converted to electricity, but higher temperatures and pressures would be required.

There are now two approaches to developing a fusion reactor: magnetic containment and inertial confinement. The major effort, magnetic containment, uses the Tokamak concept to compress and heat the reactants in a plasma isolated in a vacuum away from the walls of the reactor. The fuel is injected as pellets and heated with electric ohmic energy to strive for the ignition temperature. Research along this line started in the early 1950s, and in 1968 the Russians discovered the Tokamak principles. (Tokamak is the Russian acronym for "toroidal chamber with magnetic coil.") Massive amounts of electrical energy are required to heat and compress the plasma. Ohmic energy now is supplemented with induction, microwave, and neutral beam techniques. The time of heating has been extended from microseconds to over a minute using these additional methods.

There are two immediate objectives in fusion research, first to achieve ignition self-sustaining burning and then to achieve parity (produce more energy than is required to maintain steady-state operation). In the 1990s the International Energy Agency (IEA) member countries spent approximately \$8.9 billion on fusion R&D. Today (2012), the majority of fusion research is carried out by the European Union (EU), the United States, Russia, China, India, South Korea and Japan. The largest Tokamaks that have been recently studied are the Tokamak Fusion Test Reactor (TFTR) located at Princeton, New Jersey, United States, operated from 1982 to 1997, and the Joint European Torus (JET) located in the United Kingdom (still in operation). JET was first to demonstrate breakeven (output power = input power) in 1997, although ignition had not been achieved as of 2012. However, it was decided by the Soviet Union in the mid 1980s that a next generation Tokamak was needed. In 1992 the Soviet Union, Europe, Japan, and the United States agreed to collectively design an International Thermonuclear Experimental Reactor (ITER). Although the United States pulled out of the collaborative group in the late 1990s, it rejoined in 2003. The cost of the ITER is thought to be about \$12 billion over the 30 year life of the project and its construction would take 10 years. The EU is expected to cover 45% of the project's total cost, with the other six partners—China, India, Japan, South Korea, Russia and the United States—contributing about 9% each [23]. Inertial confinement fusion is an alternative technique that uses lasers to generatic high intensity x-rays to compress a bead containing deutarium and tritium. This technique is being developed at Lowrence Liver more National Laboratory in the US, among others in Japan and the UN. When ignition and parity are finally achieved and understood, spending will need to be substantially increased to establish commercial feasibility. It is now realized that electricity from fusion will be more costly than that from fossil and fission processes. It is only as these resources are depleted that fusion will become economically feasible.

Nuclide Production

Nuclides are produced by capturing a nuclear particle in the nucleus of the target atom, which thus is transmuted to a different atom, one that in most cases is unstable and decays, as discussed in an earlier section [24].

The target atom may be any stable or radioactive atom. In a process termed irradiation, it is bombarded, leading to production of many of the nuclear particles discussed in the previous section. Most often the incident particle is a neutron produced in a nuclear reactor, but frequently it is a charged particle raised to the required energy in an electromagnetic accelerator. The charged particles often are protons but may be deuterons, helium nuclei (He-4 or He-3), or heavier ions [25, 26].

The rate of nuclide production is dependent on the number and the energy of particles bombarding the target, the cross-section of the target and the half-life of the product (see Table 21.7). The decay of these products can be a source of significant amounts of energy, as already discussed.

Table 21.7 Nuclide production process

$A = N\sigma\phi(1 - e^{-\lambda t})$	
Where	
$(1 - e^{-\lambda}t)$	= Saturation factor: for small values of λ, it equals λt; for $t = \tau_{1/2}$, it equals 0.5, the optimum irradiation time
A	= Disintegrations per second; 1 Ci = 3.7 E10 day/s
N	= Number of atoms; Avogrado's number = 6.023E23 atoms/g atomic wt
Σ	= Sorption cross-section; 1 b = 10^{-24} cm^2
Φ	= Irradiation flux, particles/s/cm^2; for electromagnetic accelerators reported in microamperes
Λ	= Decay constant, natural logarithm 2/half-life
T	= Irradiation time, seconds
$\tau_{1/2}$	= Nuclide half-life

1.1	130
2.2	225
5.5	370
2. Pu-239 production (U-238 target at 1E14 s/cm^2, $\sigma = 2.7$ b)	
Grams Pu-239/metric ton target	
1	4,800
2	9,600
3	14,400

[a] These quantities ignore depletion of the products through decay and conversion to other products

Fission Products

The fission process produces radioactive as well as stable nuclides with mass numbers ranging from 72 to 167 and with two broad peaks in the regions of 95 and 138. The masses are identified rather than the specific nuclides because in fission many short-lived nuclides are produced that quickly decay by beta emission to a long-lived or stable member of the mass chain [18, 19].

The yields of selected mass chains that result from fission of U-235 and Pu-239 are shown in Table 21.8. In addition to the fission products with masses roughly half that of U-235, neutrons, tritium, helium, and beryllium are products of ternary fission. There are significant differences in some of the yields from U-235 and Pu-239.

Although the fission products could be recovered as byproducts from the waste from spent nuclear reactor fuel, special-purpose neutron irradiation of HEU (isotopically separated uranium-235) followed by chemical separation is

Table 21.8 Major fission products

Mass	Long-lived nuclides	State	Half-life	Percent yield[a]	
				U-235	Pu-239
72	Zn		46.5 h	0.001	0.001
79	Se	Meta stable	3.92 min	0.044	0.044
		Ground	6.5 E4–6.5 E5 years		
85	Kr	Meta stable	4.48 h	1.3	0.58
		Ground	10.76 years		
90[b]	Sr		28.78 years	5.8	2
99	Mo		2.7476 days	6.1	6.2
102	Pd(s)		1.02% (a/o) abundance	7.7[c]	28.1
103	Rh(s)		100% (a/o) abundance	3	7
124	Xe(s)		0.096% (a/o) abundance	23.7	27.2
131	I		8.0207 days	2.9	3.9
133	I		21 h	6.7	7.0
133	Xe	Meta stable	2.19 days		
		Ground	5.243 days		
137	Cs		30.07 year	6.7	6.6
140	Ba, La		1.678 days	6.2	5.4
167	Dy		6.2 min	0.001	0.001

[a] Because two fission products are emitted for every binary fission, the cumulative yield for the mass chains is 200%

[b] Mass-90 beta decay chain (half-life): Br(2 s), Kr(32 s), Rb(4 m), Sr(29 y), Y(2.6 day), Zn(stable)

[c] This is equivalent to 1.2 kg of palladium/mt of spent fuel burned to 32,000 MWd. One megawatt-day of thermal energy from fission is approximately equivalent to 1 g of fission products

(s) Stable products of the mass chains. Multiple chains contribute to the high yields for palladium and xenon

the normal production method. The major products, molybdenum-99 and iodine-131 with fission yields of 6.1 and 6.7%, respectively, have important medical applications. Mo-99, with a half-life of 2.7 days, is particularly interesting because its short-lived decay product, technetium-99 m with a half-life of 6 h, is the product actually used. To make this short-lived product available, the Mo-99 is sorbed in a silica gel column, and the Tc-99 m is eluted as needed.

During the 1980s, large-scale processing of the defense wastes at Hanford extracted and encapsulated 100 MCi of strontium-90 and cesium-137 to reduce heat generation in the waste storage tanks. Krypton-85 has been recovered from the airborne effluents at the Idaho processing plant.

In addition, development studies have addressed the recovery of stable rhodium, xenon, technetium, and palladium because of their limited availability in nature. For palladium, this would amount to about 40 kg/year from a 1,000 MWe reactor. However, a small amount of palladium-107 (half-life 6E6y) is present that could complicate its use. This is also a problem for technetium, which is 100% technetium-99 with a half-life of 2E5y.

Iodine-135 provides an example of a fission product chain that must specifically be considered in reactor operation. Iodine-135 with a 6.6 h half-life decays to 9.1 h xenon-135, which has a high cross-section for thermal neutrons. When a reactor is shut down, the xenon-135 grows in from its I-135 parent, because it is not being eliminated by neutron irradiation. For high-flux reactors this could lead to a "dead-time" of tens of hours during which the reactor cannot be restarted. These effects are controlled through the adjustment of fixed and dissolved neutron poisons during power changing maneuvers.

Neutron Transmutation Products

The production of neutron transmutation products involves the neutron irradiation of target materials followed by chemical separation. Although this promises high purity with high specific activity, the isotopic composition of the target along with other competing reactions frequently yields a spectrum of isotopes in addition to the desired nuclide.

Plutonium-239 and tritium for use as military explosives are the two major transmutation products. The nuclear process for Pu-239 production is the same as for energy generation, but there are some differences: (a) metallic natural uranium clad with aluminum facilitates later dissolution for plutonium recovery, and the reactor operates at a relatively low temperature because of the aluminum cladding and better heat transfer (due to the metallic natural uranium); (b) the irradiation cycle is limited to a few months to minimize the Pu-239 conversion to Pu-240 and Pu-241; and (c) a carbon or a heavy water moderator is used to increase the neutron efficiency.

More complex is the production of Pu-238 (used for isotopic heat sources) and californium-252 (used in research as a source of fission neutrons). For Pu-238 there are two irradiation cycles: the first starts with natural uranium but maximizes the neptunium-237 yield; then the Np-237 is separated, converted into aluminum-clad oxide targets, and irradiated to Pu-238 in a second cycle. The total process requires double neutron capture.

Californium-252 production was especially challenging, as it involved the sequential capture of 14 neutrons along with the intermediate separation and fabrication of two intermediate targets (americium and curium isotopes) when starting with Pu-239 [27]. This production campaign lasted 10 years, produced about 10 g of Cf-252, and then was terminated. The product was evaluated as a neutron source but had insufficient value to justify continuing production.

Neutron Activation Products

The neutron activation production cycle requires only neutron irradiation without chemical separation. The target and the product are the same chemical element but have different nuclide compositions. The specific radioactivity of the product is a function of the nuclide composition of the target, the neutron flux environment, the irradiation time, and the half-life of the product nuclide, along with the nuclear cross-sections of target and product nuclides.

The major neutron activation product is cobalt-60 with a reasonably long half-life (5.3 years). It is produced by capture of a thermal neutron by cobalt-59, the only naturally occurring isotope of that element. Cobalt-60 emits high-energy beta particles and gamma rays appropriate for radiographic, irradiation, and isotopic power applications. It is an ideal product because naturally occurring cobalt is a relatively stable metal that is uniquely monoisotopic cobalt-59. Furthermore, the target nuclear cross-section is good, and the product cross-section is lower than the target's by a factor of 10. Another factor in cobalt-60s long list of advantages is that the Canadian CANDU family of nuclear power reactors are ideal for production of Co-60.

Other important activation products include molybdenum-99 and iridium-192. However, the Mo-99 is better obtained from fission, as has been previously discussed. The 74-day Ir-192 has a gamma with less energy than Co-60 and is used for radiography of less dense materials.

Charged Particle Transmutation Products

Many radionuclides can be produced in cyclotrons, thus avoiding the use of more costly nuclear reactors. Many research hospitals now have cyclotrons to provide short-lived radionuclides of carbon, nitrogen, oxygen, and fluorine. The longer-lived products are produced commercially or in government laboratories [26, 27, 29]. A list of major isotopes and their uses is shown in Table 21.9.

Table 21.9 Major isotopes and their uses

Isotope	Use
D	D_2O moderator for HWR Fuel in fusion reactions
Li-6	Source for tritium Fuel in fusion reactions
Li-7	Water-cooled reactors use lithium-7 hydroxide as a water conditioner Possible coolant in LMFBR
F-18	Used in nuclear medicine, especially in labeling D-glucose
N-13	Tests done show that when used in ammonia, helps to determine global myocardial blood flow
C-14	Used in carbon dating
N-15 C-13 D-17 O-18	Used as tracer in living beings Using in NMR
B-10	Neutron absorber in nuclear reactors Used in the medical field in neutron-capture therapy
B-11	Can be used in tritium production and in NMR
Na-24	Used to locate pipe leaks
Mg-27	Used to locate pipe leaks
K-42	Can measure exchanged potassium in blood
Cr-51	Used to label red blood cells
Fe-57	Used as a spin isotope in chemistry
Fe-59	Used in blood studies Can be used to determine friction in machinery when used with steel
Co-60	Used in cancer treatment
Ga-67	Used to locate tumors
Kr-81	Used in lung ventilation studies
Tc-99	Used as a tracer in locating brain tumors
I-131	Used as a tracer when studying the thyroid gland
Yb-169	Used during brain scans
U-235	Fuel for most nuclear reactors
Pu-239	Used in nuclear weapons, fast breeder reactors, and MOX fuel reactors
Am-241	Used in smoke detectors

These radionuclides are produced by irradiating targets with beams of hydrogen ions (protons), but frequently deuterium ions (deuterons) are used (see Table 21.10). Some products require beams of helium-4 and helium-3 ions. The typical process involves the capture of the proton with the prompt emission of a neutron. This is called a p,n reaction. However, in other cases there may be protons, alpha particles, or up to five neutrons emitted. The resulting products decay generally by positively charged electron (positron) emission, but also decay by capture of an orbital electron.

To produce the beam of high-energy charged particles, a stream of hydrogen or helium is electrically ionized and accelerated in an oscillating magnetic field that holds the particles in a spiral path within the cyclotron. At the desired

Table 21.10 Nuclide production by charged particles

Typical reaction
${}^{14}_{7}\mathrm{N} + {}^{1}_{1}\mathrm{H} \rightarrow {}^{15}_{8}\mathrm{O} \rightarrow {}^{4}_{2}\mathrm{He} + {}^{11}_{6}\mathrm{C} \overset{20\mathrm{m}}{\rightarrow} \beta^{+} \rightarrow {}^{11}_{5}\mathrm{B}$ (**stable**) This reaction normally is reported as N-14(p,α)C-11. Natural nitrogen gas is bombarded in a cyclotron with a 30-mCi current of 4–13 MeV protons (p). O-15 is produced, but an alpha particle is promptly ejected, producing C-11, the desired product. The yield for a 20-min bombardment is 0.2 Ci
${}^{58}_{28}\mathrm{Ni} + {}^{1}_{1}\mathrm{H} \rightarrow {}^{59}_{29}\mathrm{Cu} - 2{}^{1}_{1}\mathrm{H} + {}^{57}_{27}\mathrm{Co} \underset{270\mathrm{d}}{\overset{\mathrm{EC}}{\rightarrow}} {}^{57}_{26}\mathrm{Fe}$ (stable) Ni-58[p,2p]Co-57. Enriched Ni-58 (enriched in the Oak Ridge Calutron) is plated on a copper heat exchanger, bombarded for 5 h with 1,000 mA of 20 MeV protons. Cu-59 is produced but two protons are promptly ejected producing Co-57, the desired product. The yield for a 14 h bombardment is approximately 28 mCi/mA hour
Other (p,n) processes: Li-7 to Be-7; Fe-56 to Co-56; Cu-65 to Zn-65; Ag-109 to Cd-109
Other processes and products: N-14(d,n)O-15; O-16(p, α) N-13; Ne-20(d, α)F-18

β^{+} represents a positron
EC represents electron capture

energy the particle beam is magnetically deflected to the target. The beam energy can vary from 4 to 800 MeV but is usually less than 30 MeV. The beam current ranges from 3 to 2,500 μA. The target is designed to accommodate the ten to several hundred watts of thermal energy deposited by the beam. Gas and liquid targets are used for the short-lived products to facilitate processing for use. For the long-lived products that require longer irradiation and higher energy flux (up to a kW/cm^2), the target material may be plated on a water-cooled heat exchanger. The target materials in many cases are separated stable nuclides.

The Department of Energy's laboratories have accelerators that provide up to 800 MeV proton beams. Other machines support high-energy physics research but occasionally are used to produce special nuclides such as xenon-127.

Reactor Materials Processing

Reactor materials processing is concerned with preparation of the special materials used in nuclear reactors. This includes the nuclear reactor fuels along with the reactor vessels, plumbing, heat exchangers, coolants, and moderators. All the materials that go into the nuclear reactors are deliberately and thoroughly controlled by standards established by the nuclear industry with the participation of the Nuclear Regulatory Commission and administered by the American National Standards Institute. These materials include the uranium oxide pellets, zirconium cladding, and zirconium or steel fittings of the fuel assemblies, the corrosion–and radiation-resistant steel used for the reactor vessels, and the various corrosion–and erosion-resistant steels for piping, valves, pumps, and heat exchangers. In addition, there are the coolants (water, sodium, and helium), the moderators (water, deuterium, and graphite), and the neutron sorbers (boron, erbium, cadmium, hafnium, and gadolinium). Each of these materials requires intensive processing to achieve safe and reliable operation of the nuclear reactors.

Isotope Enrichment

Isotope enrichment is a major activity of the nuclear industry. The naturally occurring chemical elements are composed of isotopes with varying nuclear properties. By enriching the chemical element in the nuclide with the desirable nuclear property, the performance of the nuclear processes is enhanced. In addition, the sensitivity of isotopic analysis permits the use of enriched chemical elements in place of radioisotopes as tracers in research, medicine, and industry.

The separation of chemical isotopes is based on small differences in their physical and chemical properties. For the lower-mass isotopes, chemical exchange, distillation, and electrolysis have been used. For the higher mass isotopes, techniques based on mass have been used, including jet nozzles, gaseous diffusion, centrifugation, thermal diffusion, and ion activation [29, 30]. A newer method uses lasers that produce coherent light tuned to the specific wavelength of a vibration bond related to the desired isotope in an atom or molecule. This technique is still under development but promises much higher per stage separation factors resulting in lower energy consumption and capital costs. The main issue with this technology is the availability of low capital and operating cost lasers with sufficient wavelength selectivity.

The most universal of these techniques uses the Calutron, an electromagnetic accelerator employing the first arc of a cyclotron (Fig. 21.10). In 1945 it provided the enriched U-235 that was used in an early atomic bomb. Since then it has been used to enrich small quantities of most of the stable isotopes. The separation is achieved by ionizing the feed material and then accelerating the ions through the field of a bending magnet. The differences in mass causes the heavier elements to pass through a larger arc with the ions trapped in carbon pockets located 180° from the feed point. The accelerating voltage and magnetic field are controlled to optimize performance. Separation factors of 10–100 are obtained, but the yields are only 1–10%.

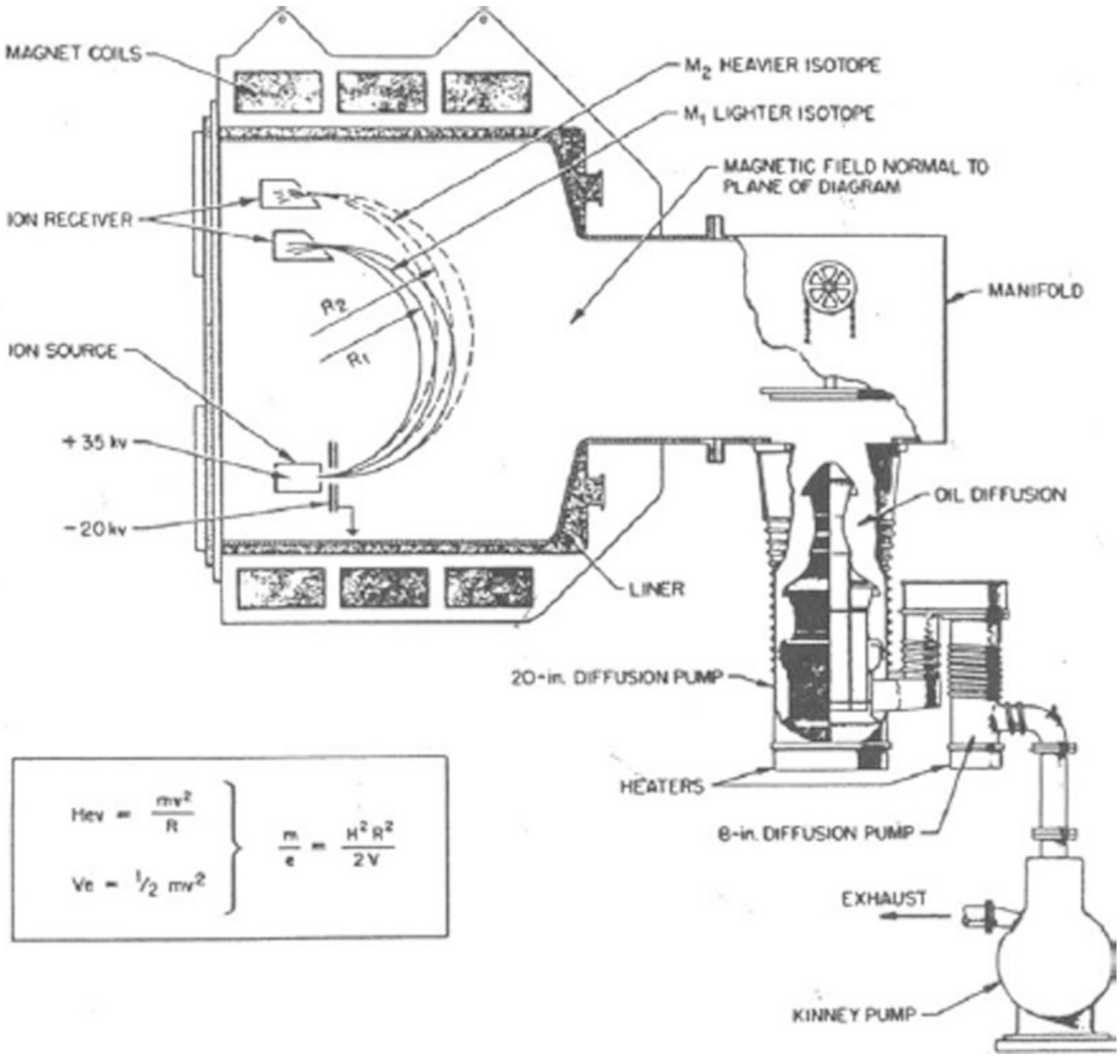

Fig. 21.10 Oak Ridge Calutron for separation of isotopes. The first method to achieve large-scale separation of U-235 and today the source of research quantities of most stable and a few radioactive nuclides (Courtesy of USDOE)

Large-scale production has been applied to enrich U-235, deuterium, boron 10, and lithium-6. The original gaseous diffusion technology has now been replaced by high-speed centrifuges as the principal technology for U-235 and is discussed further as part of the fuel cycle. Dual-temperature chemical exchange processes are used to enrich hydrogen and lithium isotopes. Distillation is used for boron 10.

Several methods can be used to obtain high-purity deuterium for use as a coolant in HRWs. Natural hydrogen contains 0.16% deuterium and is enriched to 10–20% deuterium in pairs of 200 plate columns [31]. The chemical exchange system is hydrogen sulfide gas and water. One column operates at 27°C and the second at 220°C, with the enriched product removed from the bottom of the cold column that flows to the second set of columns. From the second set it goes to distillation and then to electrolysis to yield 99.8% deuterium. The specific enrichments at the crossovers between processes are controlled by energy considerations. Other methods in use are the chemical exchange reaction between liquid ammonia and hydrogen and nitrogen gas using potassium amide as a catalyst. At least two plants are in commercial operation: one in Argentina and one in India.

The chemical exchange system employed for lithium-6 enrichment is lithium amalgam and aqueous lithium hydroxide. It also employs paired dual-temperature columns.

Cryogenic distillation is used to enrich carbon-13, nitrogen-15, oxygen-17, and oxygen-18. Typical of these processes is carbon monoxide distillation, which has a C-13/C-12 separation factor of 1.008 between the vapor and the liquid. The initial 20-m packed column is tapered from 2.5 cm at the boiler to 10 cm at the reflux condenser. This brings the carbon-13 from 1.1 to 12%. In a second column it is brought to 93%.

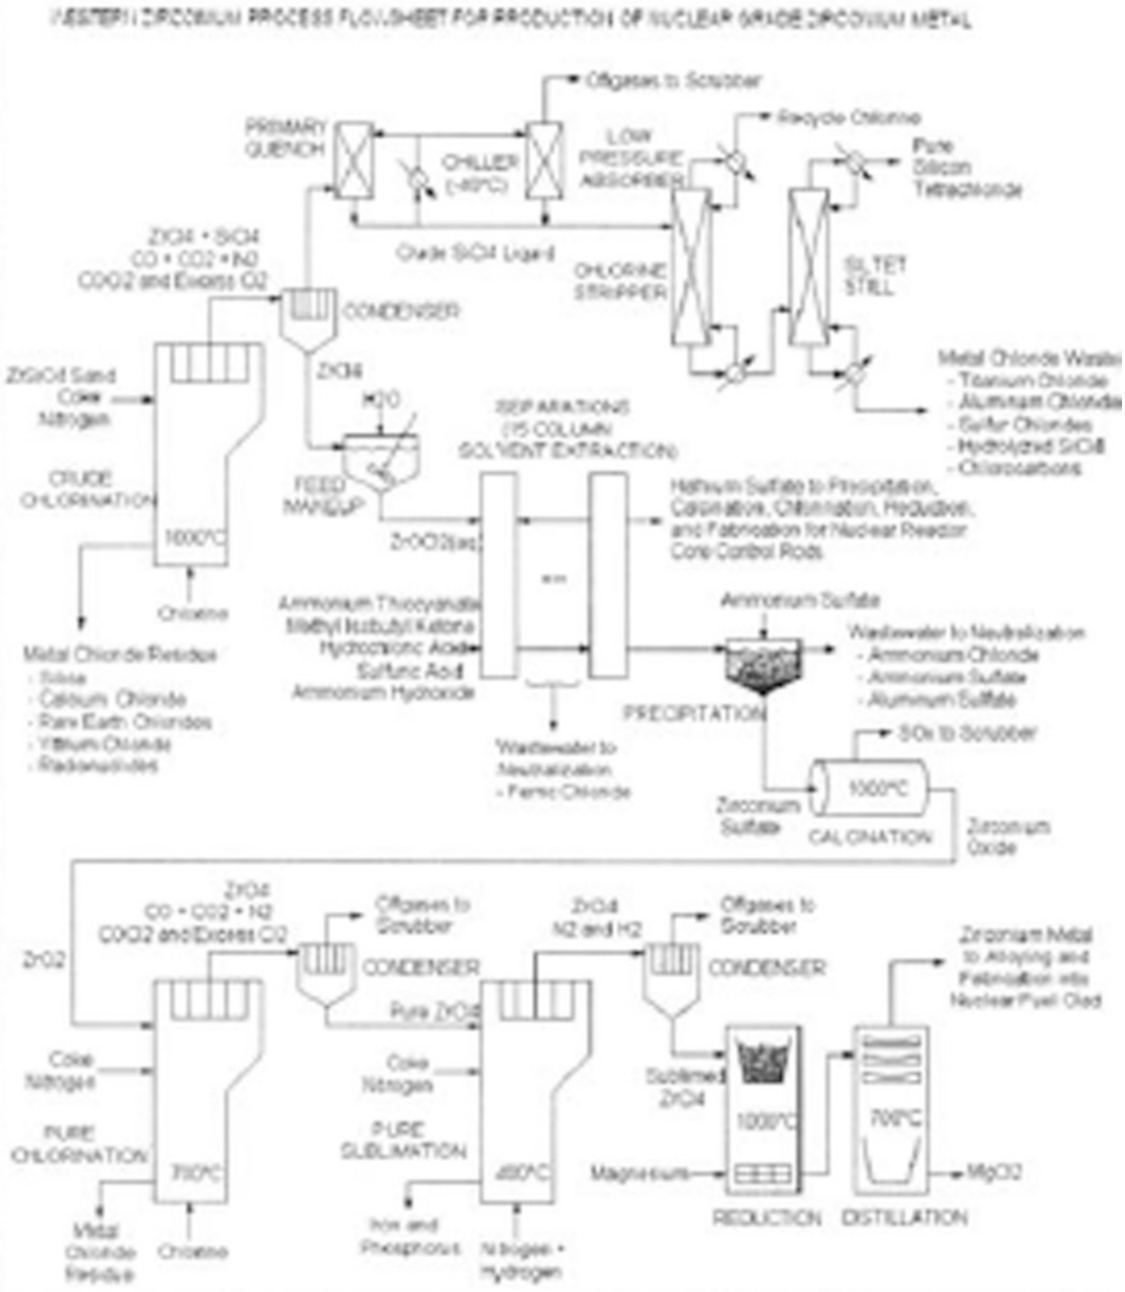

Fig. 21.11 Schematic of Western zirconium plant in Ogden, UT

Zirconium Production

Nuclear-grade zirconium alloys are used for the manufacture of nuclear fuel rod tubes and structural components. Processing begins with zircon sand ($ZrSiO_4$) obtained from Australia, India, or a variety of locations (see Fig. 21.11). Zircon sand is co-milled with coke, and injected into a large fluidized bed reactor (crude chlorination). The reactor is heated to approximately 1,000°C by induction heating of the graphite liner, and the bed is fluidized with chlorine gas. Zircon is converted to zirconium tetrachloride by the following reactions.

$$\begin{aligned} ZrSiO_4 + 4\,Cl_2 + 4\,C &\rightarrow ZrCl4_4 \\ &+ SiCl_4 + 4\,CO; \\ ZrSiO_4 + 4Cl_2 + 2C &\rightarrow ZrCl4_4 \\ &+ SiCl_4 + 2CO_2. \end{aligned}$$

The process gases pass through two stages of condensation, separating low-volatility $ZrCl_4$ product from the remaining offgases. Metal chloride impurities that escape from the chlorinator also condense with the zirconium product. The offgases pass through several stages of cryogenic quenching with liquid $SiCl_4$, recovering $SiCl_4$, Cl_2, and $COCl_2$. Distillation operations then separate silicon tetrachloride from chlorine and phosgene. The latter two species are recycled back to the crude chlorinator, and $SiCl_4$ is purified further by activated charcoal absorption, and sold as a valuable by-product. Remaining offgases are scrubbed with aqueous NaOH to remove traces of chlorine and phosgene, and are then vented; salt solutions resulting from scrubbing operations are sent to evaporation ponds.

The zirconium tetrachloride product must then be purified before reduction to metal. In particular, hafnium must be removed to less than 100 ppm Hf:Zr because of the high neutron absorption cross-section it exhibits, and phosphorus and aluminum must be removed to even lower specifications due to their deleterious metallurgical impact on the final zirconium alloys. The tetrachloride product is first dissolved in water under carefully controlled conditions to produce an acidic $ZrOCl_2$ solution. This solution is complexed with ammonium thiocyanate, and contacted with methylisobutyl ketone (MIBK) solvent in a series of solvent extraction columns. Advantage is taken of the relative solubilities of Zr, Hf, and Fe thiocyanate complexes to accomplish a high degree of separation of hafnium and iron from the zirconium.

Purified zirconyl chloride solution is then reacted sequentially with surfuric acid and ammonium hydroxide to precipitate a complex zirconium oxysulfate. The precipitate is washed, filtered, and stripped to remove traces of MIBK, and then calcined to drive off sulfur and convert the product to ZrO_2. The precipitation process leaves behind most of the aluminum and phosphorus. The hafnium stream leaving solvent extraction is treated similarly, producing a HfO_2 by-product.

Zirconium dioxide is then carbochlorinated a second time (pure chlorination) and converted once again to $ZrCl_4$. This operation is very similar to crude chlorination, but takes place at lower temperature due to more favorable thermodynamics. The purified $ZrCl_4$ product is then reduced to zirconium metal by direct reaction with molten magnesium metal, according to

$$ZrCl_4 + 2\ Mg \rightarrow Zr + 2\ MgCl_2.$$

This reaction (known as Kroll reduction) is carried out in sealed vessels at approximately 1,000°C, producing a mixture of $MgCl_2$ and a porous zirconium metal morphology known as sponge. Because of the large density difference, the molten $MgCl_2$ floats above the sponge; most of it is recovered by mechanical separation, and sold as a high-purity byproduct.

The purified sponge is then crushed, combined with alloying elements, pressed into large cylindrical ingots, and electron-beam-welded into a solid cylinder. This cylinder is then remelted by vacuum arc melting to obtain the proper metallurgical properties. All of these operations must be done with great care to avoid introduction of oxides and nitrides into the final metal product, both of which will result in embrittlement. From here, the ingot is heated, forged, and formed into either flat plate or heavy walled tubing known as Trex (Tube reduced extrusion). The Trex is then extruded and pilgered into the final nuclear fuel to form, and the plate is formed into other structural internal components. A variety of different zirconium alloys are produced, having specific applications for different reactor designs.

The Uranium Fuel Cycle

The uranium fuel cycle for the uranium–plutonium system is a multicomponent system of chemical process operations that begins with mining uranium ore from the earth as the starting material and ends with the radioactive waste products in above-ground or belowground terminal repositories. Some radioactivity is released in the air and water discharged to the environment at concentrations and quantities below those specified by federal regulations. The topics to be considered in this section are mining, milling the ore, uranium fuel preparation, and reprocessing [32, 33]. The following section discusses radioactive waste management.

A similar set of processes has been partially developed for the thorium–uranium system but is not discussed here because it is not expected to be employed in the next several decades. The important feature of the thorium cycle is that it could be used to achieve breeding (to produce more fissionable material than is consumed) in thermal reactors, but nuclear as well as chemical factors have frustrated this development (for more information, see ref. [21]). Thorium based cycles may in the future povide a means of burning very long half-life actinides such as Pu, cm and Am to make a high level Nuclear waste that decays to lower radiatoxicity levels in hundreds rather than thousand on tens of thousands of years.

It should be noted that breeders would not reduce the demand for uranium ore for many decades because several LWR and/or HWR converters (which produce fissionable material, but less than consumption) are required during the run-in of a breeder cycle to equilibrium. The doubling time of a breeder (the time required for the breeder to produce sufficient fissionable material to start up a second breeder reactor) might be a significant part of its operating life. The tritium for the fusion cycle will be made in nuclear

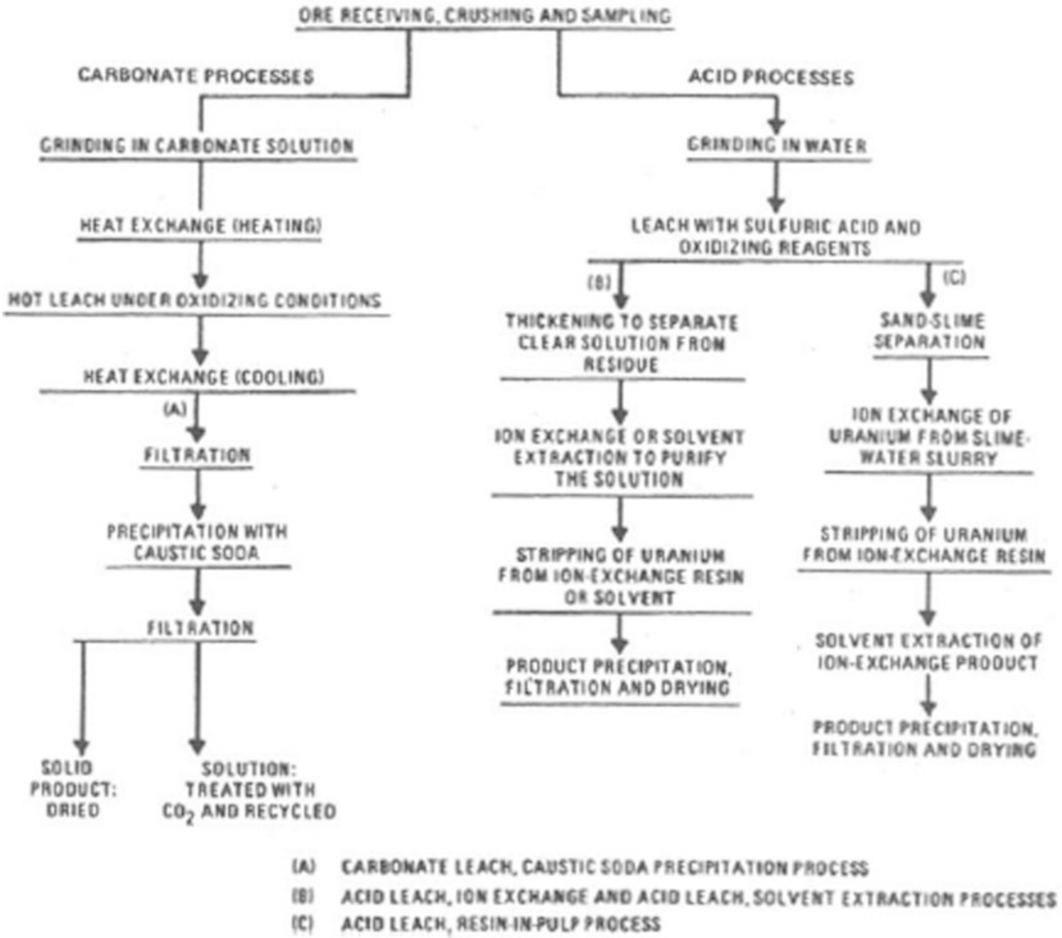

Fig. 21.12 Uranium ore mill processes: (**a**) carbonate leach, caustic precipitation process; (**b**) acid leach, ion exchange and acid leach, solvent extraction processes; (**c**) acid leach, resin-in-pulp process

reactors, as it now is for nuclear weapons. The nuclear industry will always be dependent on a continuing supply of uranium from ore.

Mining

Uranium mines are primarily the open pit type, but there is significant production from deep mines as well as from solution mining. Sometimes uranium is produced as a by-product of mining operations for vanadium, phosphate, copper and gold.

Where uranium ore deposits occur in permeable aquifers with low-permeability geologic formations above and below them, the uranium is extracted by circulating a carbonate leaching solution. The leach solutions are sulfuric acid, ammonium carbonate, or sodium carbonate–bicarbonate along with air, peroxide, or sodium chlorate as the oxidizing agent. Holes are drilled to the bottom of the ore body on a grid pattern, 50–200 ft apart. The holes are cased with screened sections through the ore body. Varying combinations of injection and withdrawal of the leaching agents are applied to recover the uranium. The uranium is recovered from the leaching agent by ion exchange. The leachate is adjusted and recycled.

Milling

In milling, the uranium is leached from the ore, separated from major contaminants, and converted to yellow cake [or sodium diuranate $(Na_2U_2O_7)^-$]. The uranium ores milled in the United States generally contain 0.05–0.2% U_3O_8, with an average of 0.1%. To save transport costs, the mills are located near the mines. There are two major processes, one based on a carbonate leachant and the other on sulfuric acid (see Fig. 21.12.).

Carbonate process. In this process the ores are leached with hot sodium carbonate for 24 h, and sparged with air to

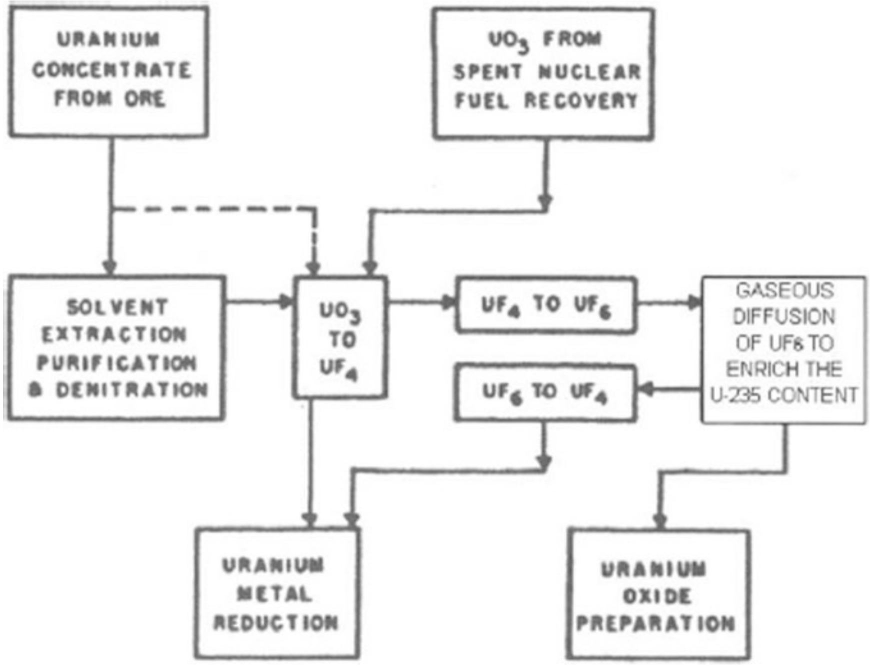

Fig. 21.13 Uranium feed materials flow sheet

provide oxidation. The leachate is cooled in countercurrent heat exchangers, heating the carbonate solution for the next batch. The carbonate leachate is filtered on rotary drums, and the uranium is precipitated with sodium hydroxide and filtered. The filtrate is converted back to carbonate by sparging with carbon dioxide, usually from a boiler flue gas, and recycled. The dried precipitate in the form of sodium diuranate is about 90% U_3O_8. Carbonate leaching is fairly specific for uranium, and the product is fairly low in contaminants.

Sulfuric acid process. In the sulfuric acid process, the pulverized rock is leached for about 8 h with sodium chlorate or manganese dioxide added for oxidation. The leachate passes through a series of thickeners countercurrent to the flow of the wash water. The liquid (leachate) is then separated from the solids using filtration. The acid leachate is not very specific for uranium and therefore goes through ion exchange or solvent extraction for purification. The solvent is a hydrocarbon-diluted 2-diethyl-hexyl phosphoric acid applicable to the recovery of both vanadium and uranium when both are present in the ore. A variation is the RIP (resin-in-pulp) process. After thickening, to avoid the filtration step, the slimecontaining leachate goes into tanks where screen baskets of anion exchange resins, mechanically sloshed up and down, absorb the uranium. After loading, the uranium is stripped from the resin with an acidified chloride or nitrate solution. These product streams are precipitated with sodium hydroxide and the resulting sodium diuranate is dried. An additional cycle of ion exchange may be required to achieve the desired product quality.

Fuel Preparation

There are two general processing routes for making feed for the nuclear fuel manufacturing plants. The primary route is through solvent extraction for purification, denitration to UO_3, and reduction with hydrogen to UO_2, followed by either hydrofluorination to UF_4 and reduction to metal, or fluorination to UF_6 followed by isotopic separation and reduction to UO_2. The other route starts with higher grade yellow cake, skips solvent extraction, and goes directly to hydrofluorination, with distillation of the final hexafluoride added for purification.

Uranium fuel preparation takes the UF_6 and is converted to either (a) aluminum-clad uranium metal for the weapons plutonium production reactors or (b) to Zirconium-clad UO_2 for electricity production in the light and heavy water power reactor (see Fig. 21.13).

Solvent extraction. The yellow cake is dissolved in nitric acid and extracted from this aqueous phase by 5% tributyl phosphate (TBP) in a hydrocarbon diluent. The diluent reduces the density and viscosity of the TBP, enhancing the aqueous/solvent phase separation. The extraction is very specific for uranium, with separation factors of 10^3 to 10^5. The product thus obtained is an aqueous uranyl nitrate solution (Fig. 21.14).

Denitration. The uranyl nitrate solution from solvent extraction is converted to UO_3 by evaporating the solution to a final boiling point of 120–140°C, followed by calcination at 620°C. The product characteristics are dependent on the type of calciner (pot, trough, or fluid bed) and significantly affect the subsequent steps (see Fig. 21.15).

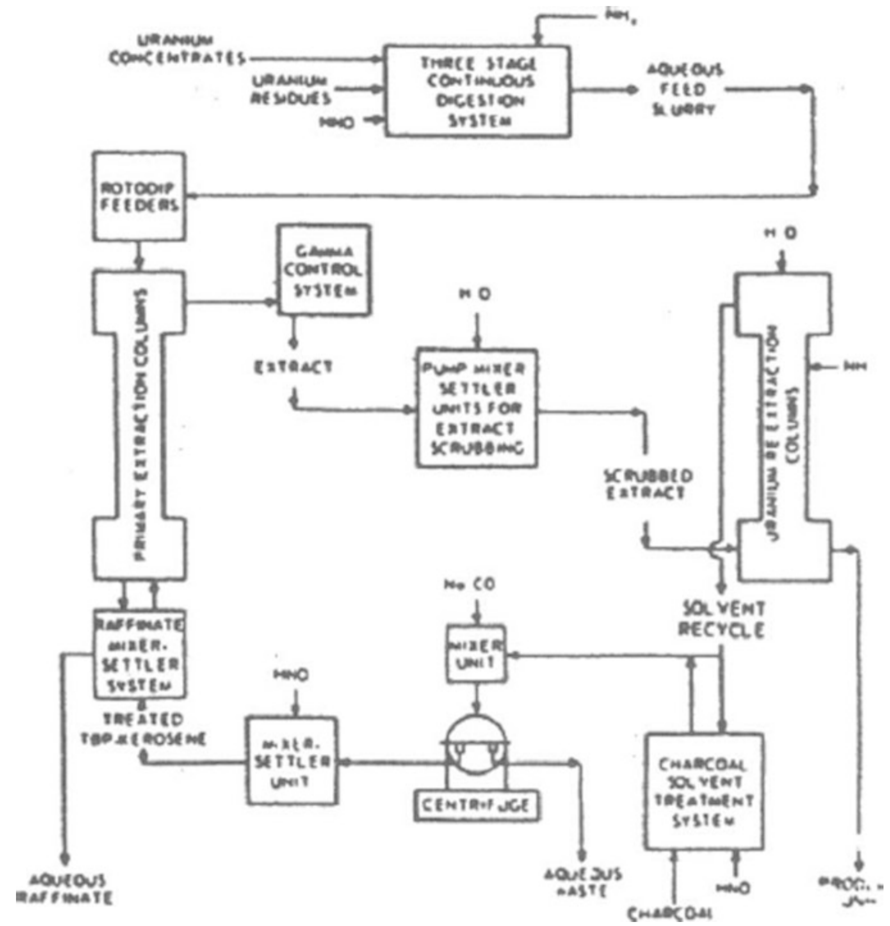

Fig. 21.14 Uranium solvent extraction process for purification of ore concentrate and scrap; slurry feed eliminates clarification cost and losses (Courtesy of USDOE)

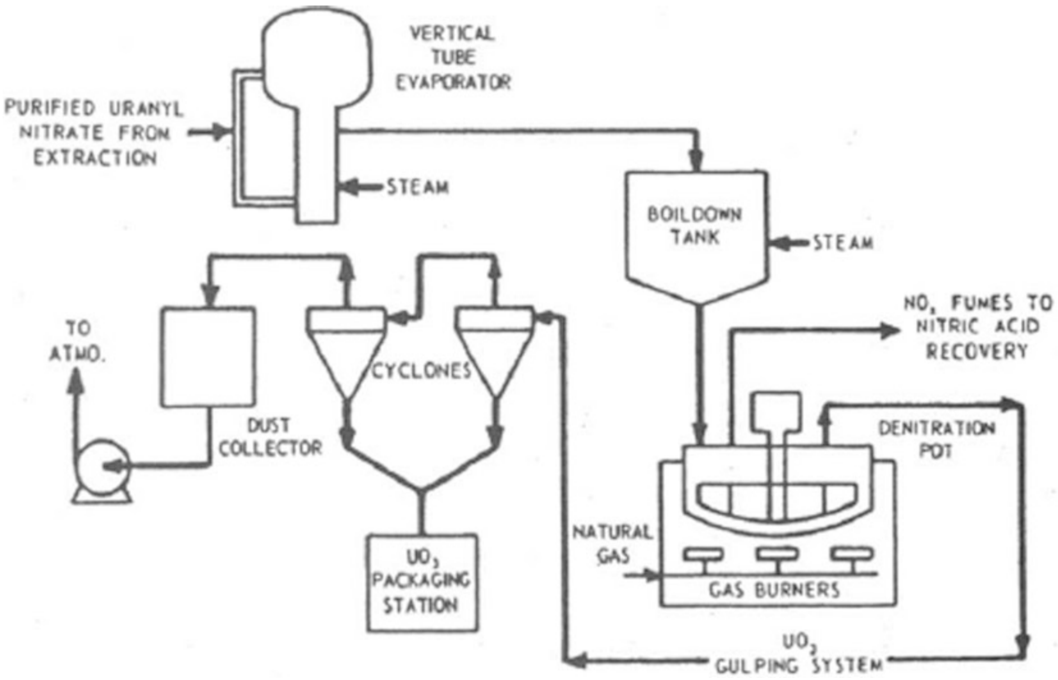

Fig. 21.15 Uranium denigration process prepares UO_3 for conversion to metal and UF_6. A continuous fluid-bed process has been developed (Courtesy of USDOE)

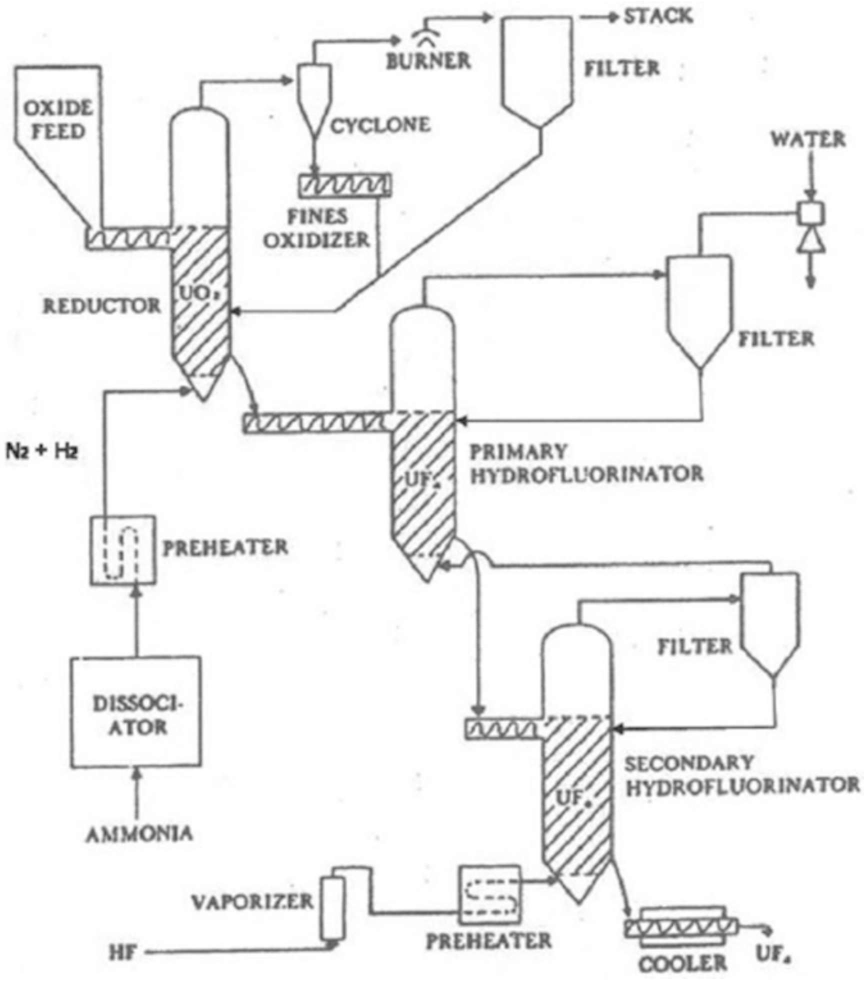

Fig. 21.16 Fluid-bed system for UO_2 conversion to UF_4 (Metropolis process)

Conversion to uranium hexafluoride. The calcined UO_3 is reduced to UO_2 with hydrogen, then converted first to UF_4 with hydrogen fluoride and finally to UF_6 using fluorine. These steps usually are carried out in fluidized bed reactors, but the conversion to UF_4 sometimes is done in a stirred trough reactor [34].

The fluid-bed process at the Honeywell Metropolis Plant uses a series of three sets of fluidized beds (see Fig. 21.16). The first bed is fluidized with hydrogen and reduces the UO_3 to granular UO_2. Then it is hydrofluorinated to a granular UF_4 in a two-stage fluid bed to achieve efficient consumption of the hydrofluoric acid. Finally, in two parallel fluidized bed reactors, the granular UF_4 burns in a fluorine atmosphere to UF_6 vapor. The fluorine is fed in through the ash at the bottom of the reactor to maximize the uranium yield, and then exits through the UF_4 screw feeder to minimize the loss of the high-cost fluorine.

UF_6 purification. Distillation of the UF_6 is required for purification when the yellow cake does not go through solvent extraction. At Metropolis, the molybdenum, vanadium, and other impurities are removed in a pair of columns, one a 120-ft, 100-plate column operating at 200°F and 85 psia to remove the high volatiles and the second a 45-plate column operating at 240°F and 95 psia to remove the low volatiles. The UF_6 is condensed into 10-t (48b) cylinders and delivered to the enrichment plant.

Reduction to metal. Uranium metal is produced by bomb (high-temperature chemical reactor) reduction of UF_4 with magnesium metal. In this process, granular UF_4 is blended with magnesium metal pellets and tamped into a steel reactor lined with the reaction by-product, magnesium fluoride (see Fig. 21.17). After the container is capped, it is placed in a furnace where the temperature is raised to the ignition temperature at which the magnesium and UF_4 react spontaneously. The reaction mass reaches a temperature sufficiently high for the liquid uranium metal to form a puddle within the bomb. This is a very empirical technology, dependent on the control of many physical factors.

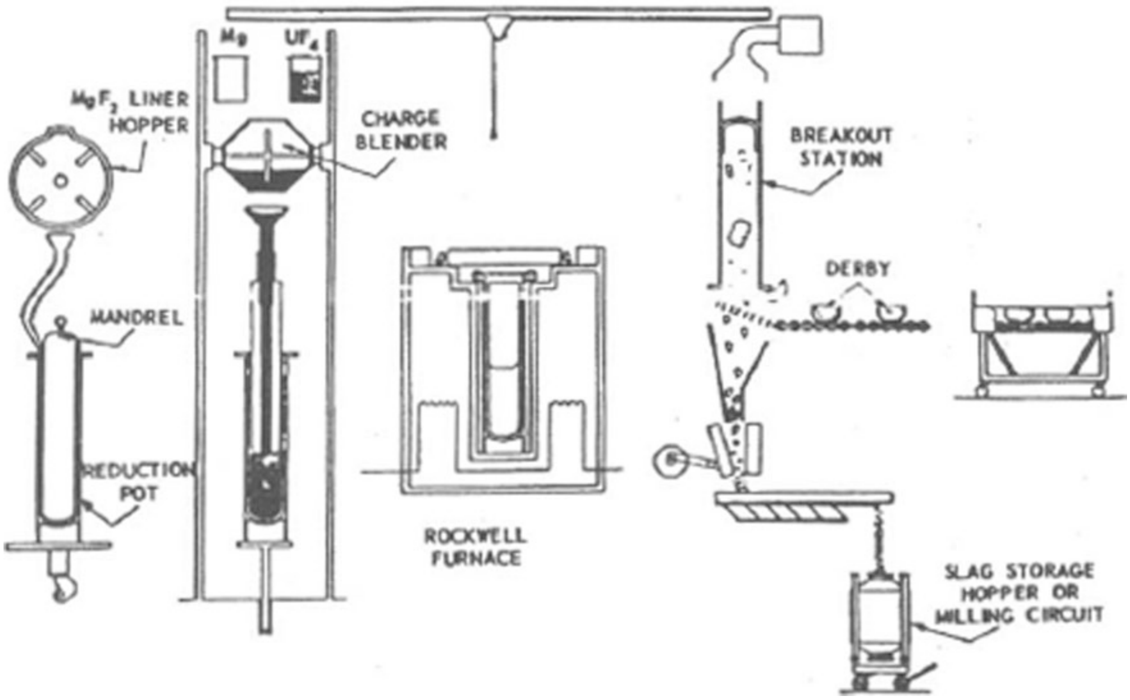

Fig. 21.17 Uranium metal reduction process; a similar process is used for plutonium metal production (Courtesy of USDOE)

Failure to maintain control of the process parameters will produce dispersed uranium shot instead of the desired regulus.

The resulting 350-lb uranium regulus, called the derby, is broken out, remelted in a vacuum furnace, and held at 1,454°C to volatilize and remove the impurities. It then is recast in graphite molds to produce the ingot. This is formed into 1- to 2-in.-diameter rods by extrusion and rolling-mill operations followed by machining and cladding with aluminum. Its primary use is for plutonium production; however, some of the depleted metal is used for shipping-cask shields, military projectiles, and counterweights. The magnesium fluoride by-product is ground and screened to provide material for lining the metal reduction bombs. Excess MgF_2 is disposed of as a low-level waste.

Uranium enrichment. Enrichment of uranium-235, from 0.711% as present in natural uranium, is essential to the economical operation of LWRs where the fuel life is a function of the enrichment. With approximately 4.95% U-235 fuel, the pressurized LWRs produce an average of about 55,000 thermal megawatt-days of energy/metric ton of uranium during the 4.5 years the fuel is in the reactors. In the naval submarine and ship reactors using highly enriched U-235, the fuel life exceeds 10 years. During the original development, gaseous diffusion was selected over electromagnetic separation and thermal diffusion to separate uranium isotopes. Enrichment represents about 15–25% of the production cost (fuel plus operations and maintenance cost) of nuclear-generated electricity. Gas centrifugal separators are now used in newer enrichment plants. Laser technology is now in various stages of development that might reduce this cost by a factor of 4. Separation in the ultra-high-speed centrifuge depends on isotopic mass difference, as does the jet nozzle [35]. The last-named device is a pneumatic cyclone with a high-velocity gas flow induced by a high differential pressure.

Laser-induced separation is being developed, based on differential activation energies of the uranium hexafluorides. This latest enrichment technology uses laser irradiation of the hexafluoride vapor to selectively decompose the U-235 F_6 and precipitate U-235 F_5. This process promises to recover much of the U-235 that remains in the tails from gaseous diffusion plants. Although this process is not yet commercial (as of June 2012), it is very advanced in its development stage. The only process that is currently developing this technique is the SILEX process in Australia. GE is presently testing this process at their Wilmington, NC plant.

Gaseous diffusion. In the gaseous diffusion process, the UF_6 flows through a porous nickel membrane called the barrier.

The heavier U-238 F_6 flows more slowly than the U-235 F_6, and the theoretical separation factor for an equilibrium stage is:

$$\alpha = \sqrt{\frac{{}^{238}\mathrm{UF}_6(352)}{{}^{235}\mathrm{UF}_6(349)}} = 1.0043$$

The optimum conditions require elevated temperature and reduced pressure with a pressure differential across the barrier sufficient to transport half the UF_6 flowing through that stage. However, by varying this flow ratio, the stages are reduced in size as the enrichment of the U-235 is increased. This practice, called tapering, is very important because a large number of stages are required. In the largest stages, axial flow compressors driven by electric motors rated to 3,300 hp transport the UF_6, and 640,000 kg of this material is circulated to produce one separation work unit (SWU).

When it was operating at full capacity, about 150 mt of UF_6 was fed to the plant daily in the process described here. Tapering reduces the time required for the plant to come to equilibrium.

The Department of Energy's gaseous diffusion plant in 1980 had 10,812 stages, consumed 6,000 MW of electric power and 1,350 million gallons of water a day, and took months to come to equilibrium. The building housing the plant had a combined floor area of a square mile. Plans to further expand the plant using gas centrifuges were scrapped in the 1980s when the expected growth of nuclear power was not realized. In addition, other countries and companies, including Russia and URENCO (which services such countries as the United Kingdom, Holland, and Germany), now offer such services [36].

The capacity of processes employing diffusion and mass separation is reported on the basis of the work required, and is expressed as SWUs. (The SWU is a measure of the work required to separate uranium of a given U-235 content into two components, one having a higher and the other a lower U-235 content.) It takes 5.3 SWU to enrich natural uranium to 3.44% U-235 (see Table 21.11). The Department of Energy facility has the capacity of 11.3 million SWU/year, and there is a world capacity of about 60 million SWU/year

Table 21.11 Separation work unit requirements (SWU/kg product)[a]

Uranium hexafluoride conversion to oxide. There are several processes used commercially to make nuclear fuel. A diagram of the conversion and fuel manufacturing process is shown in Fig. 21.18. The oldest is called the ADU process. In this process, the UF_6 is hydrolyzed in water to a UO_2F_2 solution which is mixed with an aqueous ammonia solution to precipitate ammonium diuranate and then calcined in a hydrogen and steam atmosphere to UO_2. Another process is called the AUC process. In this process, UF_6 is injected into a solution of ammonium carbonate to form an uranyl tricarbonate precipitate. This precipitate is then calcined in a fluidized bed using steam and hydrogen to UO_2 powder. In both the ADU and AUC processes, a liquid waste of ammonium fluoride is produced that is treated using lime to produce a calcium fluoride waste and recycle ammonia. Disposal of the calcium fluoride is sometimes difficult depending on how contaminated with uranium it is. In order to get around producing a solid waste that is hard to decontaminate, the IDR process was developed. In this process, UF_6 and steam are combined in a nozzle to form UO_2F_2 powder. This UO_2F_2 powder then drops into a calciner where it is calcined to UO_2 in a hydrogen and steam atmosphere. The advantage of this process is that the waste stream is only HF which can be disposed of (or sold) much more readily than the wastes from either the AUC or ADU processes. This is because the HF can be easily decontaminated (separated from any residual uranium).

The UO_2 powder produced from these conversion processes is then mixed with U_3O_8 recycle material, die lubricants, and other materials and then granulated, pelletized, and fired in a hydrogen furnace to achieve high density (see Fig. 21.18.). Typical densities are >95.5% of the theoretical UO_2 density (10.96 g/cm^3). The pellets are then ground to size in wet centerless griders and inspected for chips, cracks, etc. Rejected pellets and grinder sludge are oxidized in air furnaces at about 400°C to U_3O_8 which is then recycled to the pelleting operation.

As with most industrial operations, uranium-bearing wastes as well as excess uranium scrap is produced during the course of normal operations. Because of the value of the

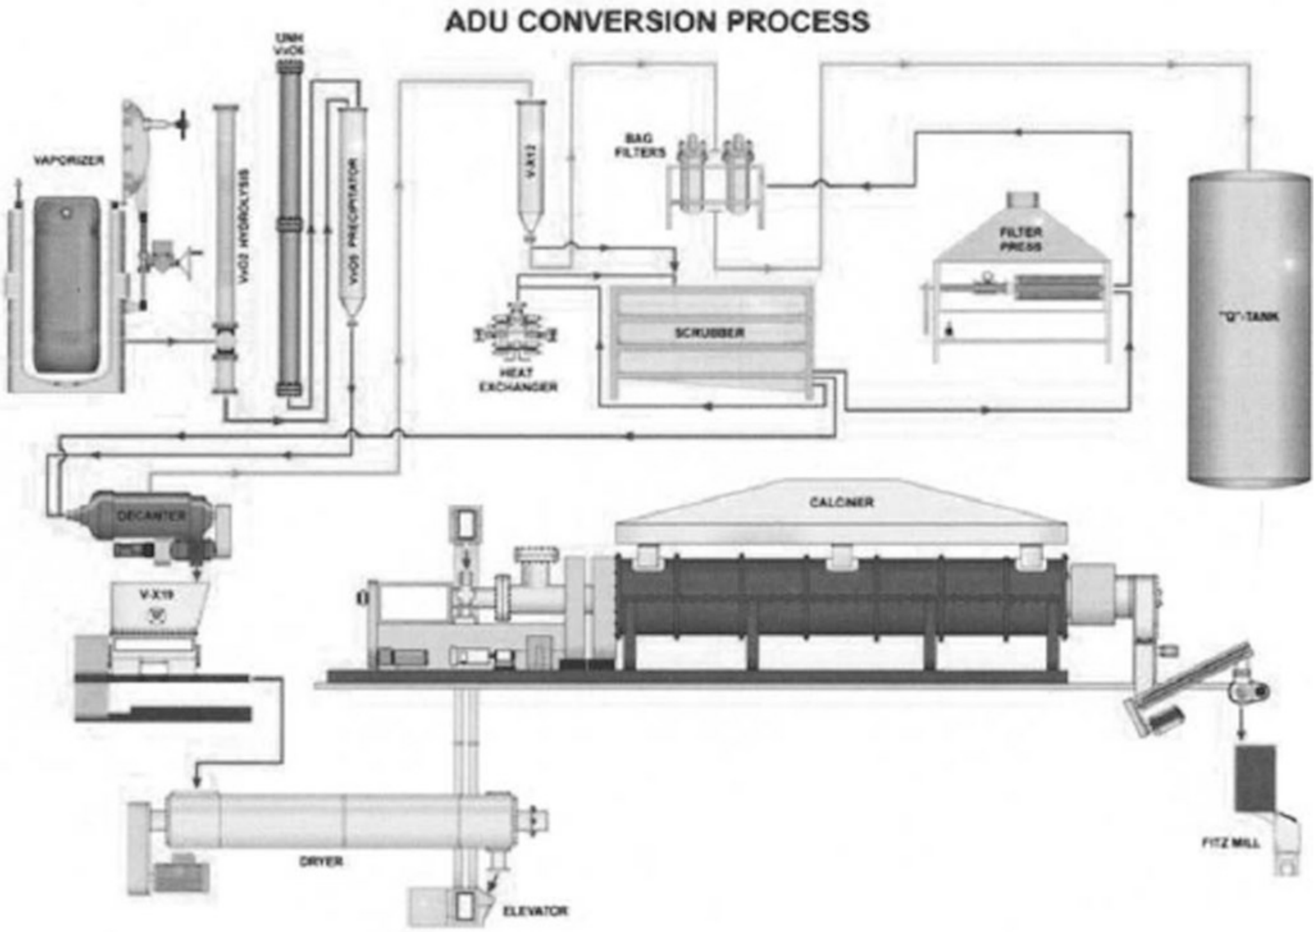

Fig. 21.18 UF_6 conversion to commercial UO_2 nuclear fuel (Courtesy of Westinghouse Electric, LLC, Nuclear Fuels Division)

uranium in this waste and scrap, it is processed to recover the uranium. The scrap and waste is treated with nitric acid to dissolve the uranium. This uranium nitrate solution is then treated using solvent extraction to recover the uranium from the other waste components. The raffinate from this waste is then neutralized with lime to precipitate any metals and then discharged. The resulting uranyl nitrate is processed in either an ADU or AUC process.

The oxide pellets are then ground to size and loaded into zirconium tubing to form fuel rods. There are approximately 80 miles of these rods in a nuclear power reactor. Another method, called the Cezus process, involves dissolving purified (Zr, HF)Cl_4 in $KAlCl_4$, which is then distilled to separate the zirconium from the hafnium. This method has the advantage of not requiring a second chlorination step. However, the compounds are highly corrosive and capital and maintenance cost are high.

Spent Fuel Reprocessing

At this time (2012), it is not know how the used Nucler fuel rods will be treated. An earlier plan of burial in Yucca Mountain (near Las Vegas, NV) was rejected. The spent fuel still contains a large percentage of fissionable material (see Table 21.12 for an example from a 32,000 MW days/t fuel) because the buildup of fission products has effectively poisoned the fuel by capturing too many neutrons. Another option instead of disposal is to reprocess the spent nuclear fuel. Most of the reprocessing to date has been performed for the weapons program. Currently, there are plants in England, France, Russia and India for commercial reprocessing. Japan is building a plant. Reprocessing provides more efficient use of natural uranium for the uranium cycle. Note that reprocessing does not reduce the activity of the fission products in the spent fuel but concentrates it into a high-level waste.

High-level waste reprocessing is the most hazardous operation in the nuclear industry. It is there that the largest quantities of fissionable and radioactive nuclides are handled in aqueous solution. These large-scale operations require both remote control and remote maintenance of the plant to protect the workers from radiation. In addition, the air and water effluents along with the solid refuse must be closely monitored to assure that the public is protected. Finally, the fissionable material requires strict accountability to ensure that it is not diverted to unauthorized uses.

As nuclear safety is a foremost public concern, it is well to note that the operation of the plutonium recovery plants since 1945 has met design specifications. There have been no significant health effects on either the workers or the public. The recovery plants were designed with large underground tanks for interim storage of the aqueous waste. This waste is then processed to an oxide, blended with glass-forming additives, and then melted into a glass mass (log) within a metal canister. The use of glass to encase the high activity waste has been chosen for defense waste in the United States and for defense and commercial waste in the rest of the world. Cement/grout or glass has been picked for stabilizing the mid- and low-activity waste that results from this processing. It is proposed that the canisters containing the high-level waste will then disposed of for the long term (hundreds or thousand to millions of years) deep underground in geologic formations. In the United States, the proposed geologic formation was at Yucca Mountain in Nevada. However, the status of this site as a repository is not known at this time due to political considerations. Other counteries such as the UK, France and Japan have also not yet identified deep geological reposition.

Table 21.12 PWR and BWR fuel burnup (late 1980s)

		Fuel composition (g/mt)		
Fuel burnup (Mwd/mt)		U-235	Pu-239	Pu-241

The main separation process in spent fuel reprocessing is the Purex (plutonium–uranium extraction) process. Fig. 21.19 shows a generalized flow diagram for nuclear fuel recovery via solvent extraction [37]. The solvent is TBP in a hydrocarbon diluent. The process was first used at the Ames Laboratory for uranium purification, then at Oak

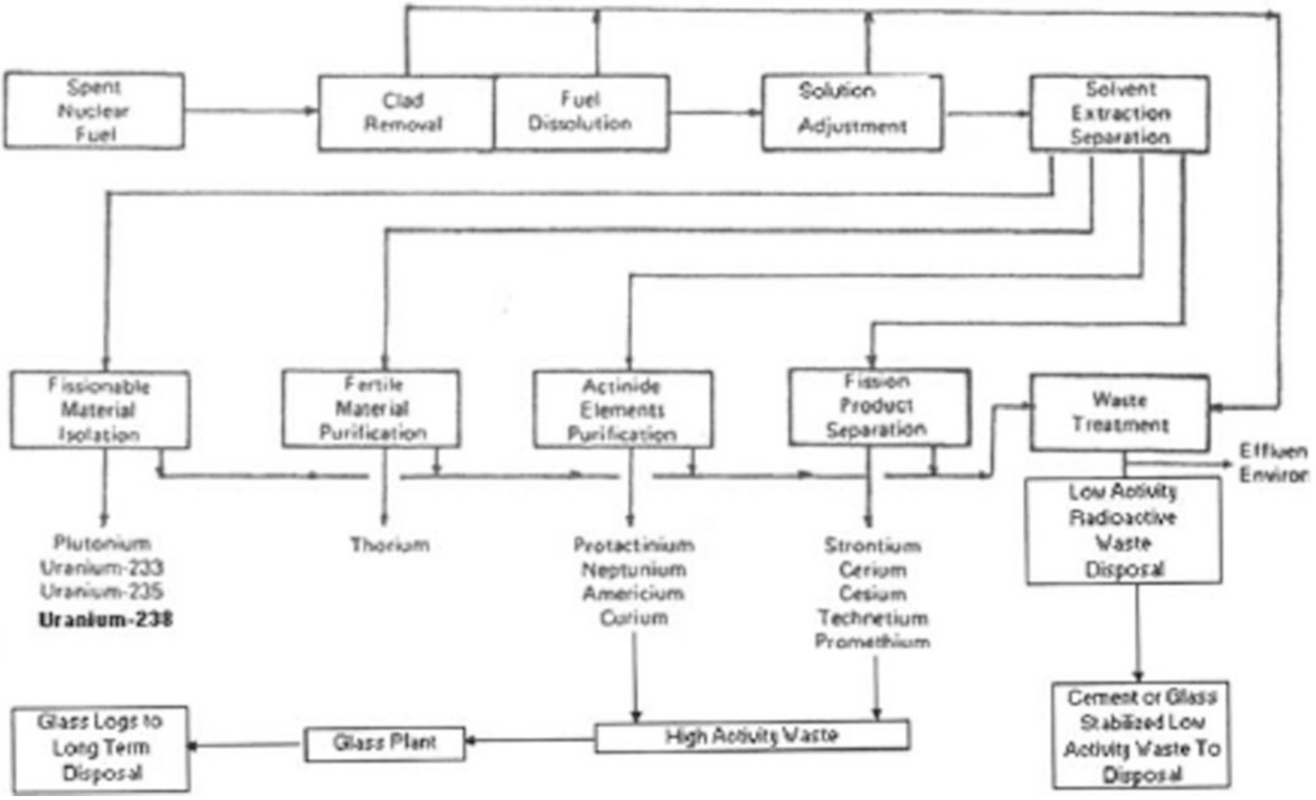

Fig. 21.19 General solvent extraction process for spent fuel recovery

Ridge National Laboratory for spent fuel. Although other processes were used in earlier days, the Purex process, with various modifications, is now used for many chemical separations in the uranium fuel cycle. It first was used on a large scale to recover uranium from the bismuth phosphate waste generated by the original plutonium recovery operation. This technology was shared with the world at the first Atoms for Peace Conference in Geneva in 1955.

A typical Purex process includes the following.

1. Aging the spent fuel to reduce by radioactive decay the 8-day iodine-131 that would be released to the atmospheric during dissolution
2. Shearing the Zircaloy-clad fuel rods into approximately 1 in. lengths so the UO_2 can be dissolved
3. Dissolving the UO_2 in nitric acid
4. Solvent extraction to separate the plutonium, uranium, and fission products
5. Anion exchange to clean up the plutonium
6. Sorption to clean up the uranium

Modifications to this process can be made to effect recovery of neptunium, americium, curium, californium, strontium, cesium, technetium, and other nuclides. The efficient production of specific transuranic products requires consideration of the irradiation cycle in the reactor and separation of intermediate products for further irradiation.

The facilities and equipment are designed for worker and public protection and for accident avoidance. Also, provision is made to allow remote replacement, decontamination, repair, and disposal. The instrumentation used in the process is designed to measure and report all the independent and dependent parameters essential to controlling and monitoring the operation. Management of the defined standard operating procedures, including quality control and quality assurance, is dictated by international standards and safety regulations.

Dissolution. The spent fuel is dissolved in nitric acid to prepare it for solvent extraction. This is a batch process that is made complex by the fuel cladding and radioactivity. A typical fuel assembly for a PWR contains about 250, 0.37-in. zirconium-clad rods 12-ft long containing in total about 1,100 lb of UO_2. The assembled rods are mechanically sheared into 1 to 2 in. lengths and dropped into a perforated basket. This is placed in the dissolver tank where the uranium oxide is dissolved as discussed above. The basket then is removed from the dissolver, and the zirconium hulls and associated hardware therein are dumped into containers, compressed, sealed, and sent to transuranic waste storage. Ultimately, they will go to a disposal facility.

Separation and purification. In the Purex process discussed here, the uranium, plutonium, and fission products are separated by solvent extraction into three different streams (Fig. 21.20). The plutonium stream goes through anion exchange (discussed later) to reduce traces of ruthenium, and the uranium stream goes through silica gel sorption to reduce traces of zirconium. The fission-product stream, which contains the fission products with the transplutonium products, is sent to waste treatment. About 99% of the uranium and plutonium is recovered in separate product streams, and decontamination from fission products by a factor greater than 10^7 is effected [38]. The spent fuel solution from the dissolver, adjusted to 2 M nitric acid, flows into the middle of the first column. From there it flows downward countercurrent to a 5% TBP/95% hydrocarbon solvent, which is introduced into the bottom section. The uranium and plutonium transfer to the solvent, leaving most of the fission products in the acid phase, which pass out the bottom of the column. The U/Pu solvent solution is scrubbed in the top half of the column with 3 M nitric acid to wash out additional fission products.

The valence of the plutonium in the U/Pu solvent stream is reduced from +6 to +4 with hydrazine to lower its extractability, and the stream flows to the middle of the second column, where the plutonium is stripped out of the solvent with mild acid. The uranium passes on in the solvent stream to the third column, where it is washed from the solvent with a weak acid. The fission product stream flowing from the bottom of the first column, containing less than 1% of the U and the Pu, is the high-level waste. It is evaporated to remove most of the acid, and neutralized with sodium hydroxide before going to earth-covered storage tanks in the United States. In Europe, the high-level waste steam is oxidized, mixed with glass formers, and disposed of in glass logs.

The uranium and plutonium streams flow separately through second sets of two columns for re-extraction and stripping for further separation from fission products, according to the scheme shown for Pu in the lower portion of Fig. 21.20. The acid waste streams from the second cycles may be recycled to the first to eliminate the second cycle losses.

Centrifugal contractors or pulsed columns are used for these solvent extraction operations in preference to longer packed columns because the latter would complicate the shielding problem. Longer columns increase the exposure time and therefore the decomposition of the extractant and solvent due to the radiation field. Mixer-settlers also can be used. The solvent is recycled after treatment to remove decomposition products caused by radiation and chemical effects. This treatment may include a combination of distillation with acid and caustic washes.

From the second cycle the plutonium goes through anion exchange for final purification (Fig. 21.21). The principal problem here is due to ruthenium, which is difficult to remove because of its many valence states. The uranium stream goes through silica sorption primarily to remove zirconium, which seems to be carried along as a colloid.

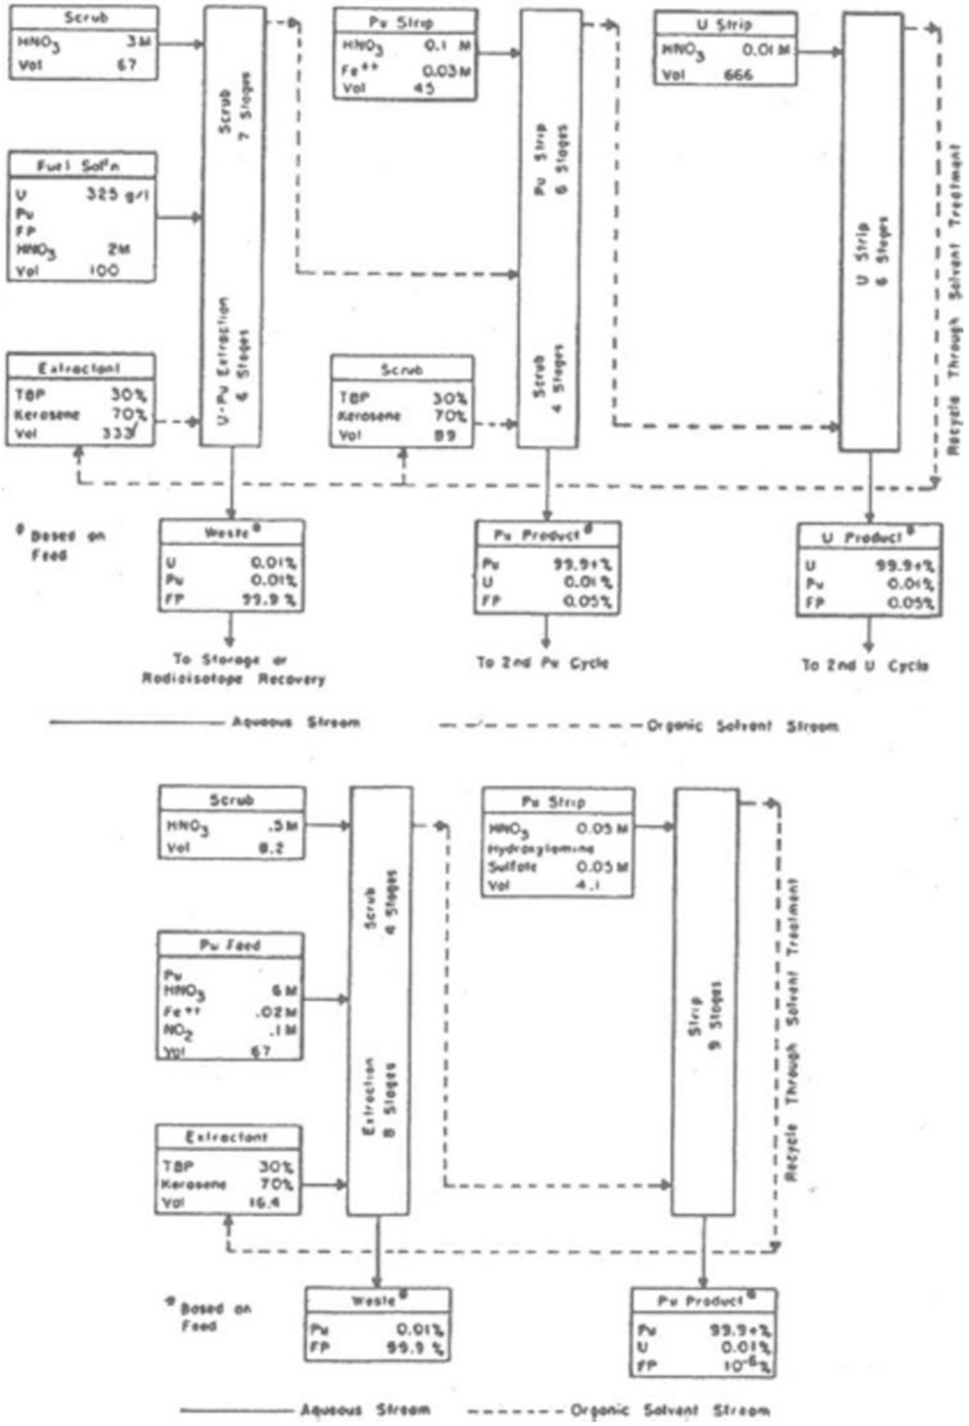

Fig. 21.20 Purex process showing (top) first solvent extraction cycle, and (bottom) second plutonium solvent extraction cycle

The process is installed in buildings called canyons, where there are rows of concrete shielded cells serviced by overhead gantry cranes for remote replacement and servicing of valves, pumps, piping, and other equipment. Penetrations through the cell walls are offset to prevent radiation from streaming through. Some equipment is located in cells equipped with windows, TV cameras, and manipulators. Cells for remote repair of the equipment may be similarly equipped.

It is occasionally necessary for personnel to enter some of these facilities. This requires considerable time for decontamination and placement of local shielding. The operations that will be performed are carefully planned and rehearsed in order to get the entry over with as swiftly as possible. A special group of employees, the health physicists, are responsible for radiation safety throughout the plant, and they provide close monitoring of these entries.

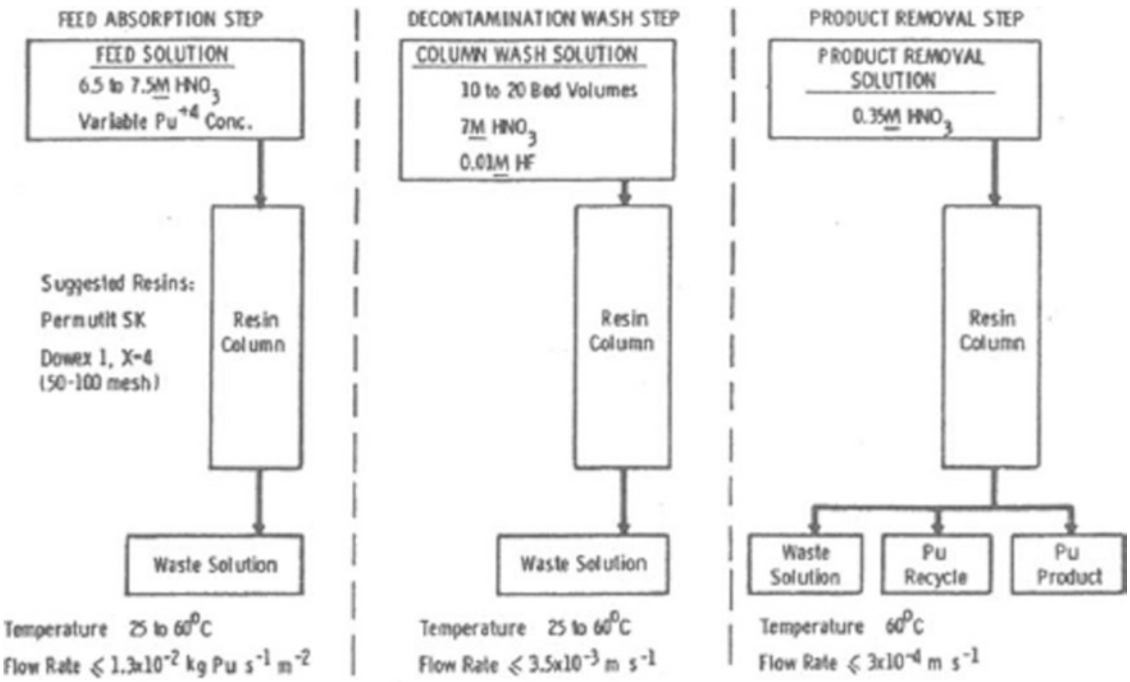

Fig. 21.21 Plutonium ion exchange flow sheet

Another unique consideration is the prevention of nuclear criticality, i.e., the start of a chain reaction leading to a self-sustaining nuclear reaction within the cells. In the dissolver and first cycle, criticality is prevented by the presence of the uranium-238, which absorbs neutrons. Later in the process, where the plutonium is separated from the uranium, criticality is prevented by proper design of the vessels and piping. This includes the cell floor and sumps, where materials would collect in case of leakage from the equipment. To prevent criticality, the vessels are limited in either diameter or thickness. Vessels and piping are placed in arrangements designed to avoid a critical array. In addition to design considerations, the risk of criticality can be lowered by limiting the amount of total fissile material in any given vessel, and when possible, by choosing a medium which is not an appropriate moderator for fission.

In one modification of the Purex process, the plutonium is not separated from the uranium. In this version, the first cycle has only two columns instead of three. In addition to reducing the criticality risk, this modification reduces the risk of unauthorized diversion of the plutonium.

Radioactive Waste Management

Radioactive waste management involves the treatment, storage, and disposal of liquid, airborne, and solid effluents from the nuclear industry's operations, along with those from other activities that employ the radioactive products. Its strategy involves four approaches: limit generation, delay and decay, concentrate and contain, and dilute and disperse. Combinations of all four of these usually are employed to manage each waste stream [39].

There are three types of nuclear wastes, based on their radionuclide characteristics:

- Uranium-contaminated waste, principally from mining, (the "Tails" (Non-Uranium containing minerals contain radium and radon as uranium decay products)) milling, and enrichment [40]. Under some circumstances uranium's 15-h radon decay product requires additional control. The uranium tails from enrichment generally are not included in waste tabulations because in time they may be incorporated as a fertile material in breeding.
- Plutonium-contaminated waste, principally from weapons materials processsing. There are two classes of plutonium wastes: the transuranic, containing mostly plutonium and other transuranics, and the high-level wastes that contain significant heat-generating products, strontium, and cesium.
- Other radionuclide-contaminated waste, generally called low-level waste, as generated in the reactor and fuel cycle, as well as in the radionuclide applications (see Tables 21.13 and 21.14.).

Limiting the generation of waste is the first and most important consideration in managing radioactive wastes. The Purex process was developed to eliminate the solids additions to the -high-level wastes in earlier technology. Improved housekeeping procedures have greatly reduced the low-level and transuranic wastes generated in the power plants, defense plants, and laboratories. Delay and decay is frequently an

important strategy because much of the radioactivity in nuclear reactors and accelerators is very short-lived, a few minutes to a few days. Concentrating and containing is the objective of the treatment activities for the longer-lived radioactivity. The concentrate and contain strategy generally involves converting the airborne, liquid, and solid waste to stable solids in corrosion-resistant containers for storage and for transport to and emplacement in carefully selected disposal sites.

Finally, both dilution and dispersion of large volumes of air and water effluents containing very low quantities of radioactivity generally are necessary. The concentration of radioactivity in these effluents is controlled by federal and international regulations, and such effluents are continuously monitored before release to the environment from the waste treatment and other activities. In a particular operation, the regulations may be reflected by a set of actions that are triggered by successively higher levels of radioactivity.

The first action, where correction by the plant operator is called for, occurs at a small fraction of the permissible level. A somewhat higher level of radioactivity requires both operator action and regulatory notification. The next higher level requires regulatory participation, and if the final level is reached, the operation must be shut down.

Liquid Waste Treatment

Liquid waste treatment is primarily concerned with conversion of an aqueous solution to a solid form suitable for storage and disposal. Evaporation is the most effective process and achieves decontamination factors for the evaporate of 100–100,000 per cycle.

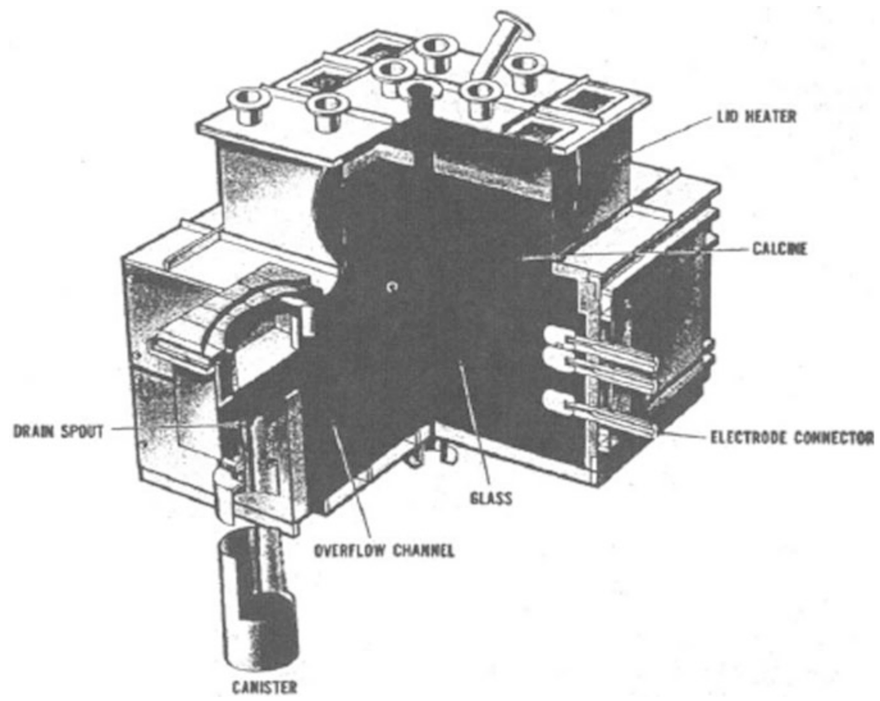

Fig. 21.22 Slurry-fed vitrification furnace converts aqueous high-level waste into a boro-aluminum silicate glass form (Courtesy of USDOE)

Ion exchange and scavenging precipitation can be employed at a lower cost than that of evaporation when decontamination factors of 5–100 are adequate.

As an example, in the US defense establishment most of the radioactivity from plutonium production is found in the liquid high-level waste from the first cycle of the Purex process. This liquid is neutralized with sodium hydroxide and stored in earth-shielded tanks. There a sludge settles out that contains most of the radioactivity. The residual liquor is partially evaporated to decrease the volume of the waste, and sodium nitrite crystallizes on top of the sludge. In a process to be used at the Savannah River plant, the sodium liquor fraction, containing most of the cesium fission product, is pumped from the tank and treated using solvent extraction. The concentrated cesium and strontium stream is then combined with the sludge that was slurried from the tank and washed to remove the salt liquor. The resulting mixture is then mixed with a pulverized glass frit and converted to a boro-aluminum silica glass in a vitrification furnace, cast in a canister, and sealed (see Fig. 21.22). This high-level waste form is then sent to a high-level repository. The sodium nitrate and the residual liquor will be combined with cement and other components to make a “Saltcrete” for long-term disposal in above-ground storage vaults.

Airborne Waste Treatment

The largest volume of radioactive waste is made up of the ventilation air from processes, plants, and laboratories. However, the quantity of radioactivity is relatively low. It generally occurs in a particulate form readily removed by dry filters. A special class of paper filters developed for this purpose (HEPA or high efficiency particulate air) removes 99.97% of 0.3-μm particles. These filters frequently are preceded by scrubbers, sorbers, and roughing filters to extend the life of the paper filter.

A notable exception to the above is the airborne effluent from spent nuclear fuel reprocessing and from tritium production. In this case, iodine-131 volatilizes from fuel reprocessing and must be removed by passing the airborne effluent through a silver catalyst bed, which provides a decontamination factor of about 100,000. Prior to reprocessing, the spent fuel is stored for a sufficient time for decay of the 8-day iodine-131, usually 10 half-lives, to make this treatment adequate. The processing effluent also carries increased levels of krypton-85, xenon and tritium, gases, and solid radioactive particulates. The particulates are removed by filtration, but the other substances generally can be released. In tritium production, cold traps and sorbers are used to remove tritium from the airborne effluents.

Solid Waste Treatment

The solid wastes from nuclear operations include the concentrates from liquid and airborne treatment along with paper, clothing, lab glassware, and scrap equipment. The transuranic and low-level wastes both receive the same but separate treatment. In plutonium operations the first step frequently is monitoring to separate the transuranic from the low-level wastes. Some of these are incinerated to reduce their volume, but this process produces additional airborne and liquid waste. Physical compaction frequently is more useful. Equipment items, including large reactor components, are decontaminated by using a series of acid, chelating, and caustic washes. Finally, the solids may be incorporated in asphalt or concrete to reduce their leachability and then are drummed. Most of these solid wastes go to low-level disposal.

From power reactors with no reprocessing, the high-level waste consists of assemblies of zirconium-clad spent fuel rods to be packaged in stainless steel canisters. If the spent fuel is reprocessed, then the high-level waste will be converted to a silicate glass form similar to that from defense operations. The uranium and plutonium content in the waste, and also possibly the strontium-90 and cesium-137, would be reduced by 90–99%. The nuclides are useful, and their removal reduces the waste disposal problem in several ways: it reduces the toxicity and heat load of the waste and also reduces the incentive for future generations to undertake the very costly recovery of what may become valuable energy-producing resources.

Storage of Spent Fuel

Spent fuel originally was originally supposed to be stored at each nuclear power reactor in water pools designed to accommodate a 5-year inventory on the assumption it would be reprocessed later. However, reprocessing did not develop, and there has been a delay in identifying the ultimate repository. The storage pools were reracked to increase their capacity, and now the older reactors also are installing dry storage capacity to accommodate the life of the reactor, approximately 60 or even 80 years, as power plant license extensions are granted [41].

The federal government was committed to begin accepting spent fuel in the late 1990s and was planning to provide away-from-reactor storage that would have included a fuel rod consolidation facility. The nuclear utilities have been assessed at 0.001/kWh electric that is expected to pay for disposal of their high-level spent fuel wastes. As is usual for all new nuclear operations, the site and the schedule for this facility was dependent on public acceptance. Because this public acceptance was not forthcoming, the political support was not available in the US Congress to make a decision on an ultimate final burial site for high-level waste. While many options have been considered (see Table 21.15), as of 2012, no site has been selected.

Table 21.15 Conceptual methods for radioactive waste disposal

Terrestrial	Shallow land burial Deep geological vaults Continental sites Island sites Caves Deep hole Sub seabed Ice cap Hydrofracturing In situ rock melting
Extraterrestrial	Solar orbit–space shuttle Moon crater–rocket/soft lander Solar escape–electric cannon
Transmutation	Fission reactors Fusion reactors Electromagnetic accelerators

It appears that the repository capacity for high-level wastes will be heat-limited to 1 kW/acre. This is equivalent to 1 t of fuel after storage for 10 years. This can be increased to about 2 tons od fuel if the uranium and the plutonium were removed, and considerably less than that if the strontium and the cesium also were removed. Although reprocessing would reduce the transuranic content by a factor of 10–50, this amount would be an insignificant fraction of the transuranic hazard in the waste.

The most restrictive of the current regulations require this waste to be contained for about 10,000 years. Intensive international R&D has been conducted, along with extensive geologic surveys by responsible scientists. A 1990 National Academy of Sciences study concluded that this requirement is beyond the possibility of proof. Extensive experimental work has been carried out, and perhaps the most interesting study is related to a group of natural nuclear reactors found by the French in Gabon, Africa. During the Neolithic time, where uranium was being deposited in a swamp, the developing ore body repeatedly achieved criticality. This occurred over a period of centuries at a series of interconnected sites. It appears that the long-lived products were closely held within the ore body. Unfortunately, the translation of this information to other geologic environments poses many uncertainties.

In 1989 a deep mined repository, The Waste Isolation Pilot Plant, was opened in a bedded salt formation near Carlsbad, New Mexico. The site has been receiving transuranic wastes since and has now disposed hundreds of tons.

Low-Level Waste Disposal

The solidified low-level radioactive wastes for which ultimate disposal must be provided fall into two broad categories: the uranium-containing wastes from milling and the front end of the fuel cycle, including enrichment; and the radionuclides from the nuclear reactors and spent fuel operations, together with the radionuclides from applications in research, medicine, and other industries [42].

The proposed technology for disposing of the second category of wastes consists of near-surface burial for low-level wastes after stabilization in cement.

Mill wastes. Agreement has been reached with the public regarding mill waste, and disposal of the accumulated backlog is nearly complete via monitored surface repositories. The uranium-containing wastes from milling are mounded and covered with earth. This earth cover prevents erosion and delays escape of the 14-h half-life radon gas, the gaseous decay product of uranium, long enough to significantly reduce released levels. They also reduce rainwater teaching and dispersion of the radium daughter decay product. These mill waste repositories are located near the mines and mills and are not a very different hazard from the original naturally occurring uranium deposits [43, 44]. The depleted uranium from the enrichment operations is stored in cylinders as uranium hexafluoride for possible future use in the uranium–plutonium breeding cycle. Other uranium-containing wastes from enrichment and fuel fabrication go to the low-level repositories.

Low-level wastes. Low-level wastes presently are being entombed in near-surface, earth-covered trenches. These trenches are designed to minimize the inflow of water and drain to a sump that is constantly monitored. Treatment facilities are maintained to process drainage that exceeds licensed levels of radioactivity for release in the groundwater.

One of the major repositories for commercial low-level waste is near Barnwell, South Carolina and is nearing its capacity. Other repositories around the country were closed when full or when required to be closed by state regulatory action. The major repository for very low-level or incidental nuclear waste is near Salt Lake City, UT and there is another located in Texas. There have been no health effects or releases of radioactivity exceeding licensed limits from these low-level repositories. The schedule for opening additional low-level repositories has been delayed for several years by the same type of public opposition encountered by proposals relating to treatment and disposal of municipal and other wastes.

Transportation of Nuclear Materials

The transport of nuclear materials reflects many years of experience based on millions of shipments. These shipments range from microcuries in liquid and gaseous forms in glass vials carefully packaged in sealed cans inside cardboard boxes to megacurie quantities contained in spent fuel packaged in hundred-ton shipping casks. They are shipped by both private and public carriers, by car, bus, truck, railroad, airplane, barge, and ship.

During these years there have been many incidents involving all forms of transportation, both commercial and military, and a few of these events resulted in some contamination of facilities. However, there have been no health effects to any individual transport worker or the general public.

Shipments of radioactive materials, originated by many different shippers throughout the world, are controlled by an established code of national and international regulations. Although most nuclear operations relate to a localized population, transport potentially affects large numbers of people. Many communities have attempted unsuccessfully to prohibit nuclear transport through their jurisdiction. Some, notably New York City, have succeeded.

Shipments of spent nuclear fuel constitute the largest quantity of nuclear materials being transported. These shipments involve 50-t truck casks with the capacity for one to several fuel assemblies. Rail and ship casks weighing about 100 t carry many assemblies. The design of these casks provides:

1. Radiation shielding to limit radiation to the workers and the public
2. Passive cooling for the heat-generating spent fuel, up to several kW per assembly
3. Assured containment in the event of the maximum accident

Current casks are designed to handle 5-year were aged spent fuel that travels by truck, rail, and ship. There are frequent ocean shipments from Japan to England and considerable rail shipment in Europe. Most of the spent fuel shipments in the United States are by truck. No cask failure has been experienced in any accident to date.

The transport of plutonium wastes to the transuranic and high-level repositories will represent a major increase in the quantities of radioactive materials shipped; therefore an extensive demographic study has been made to examine potential exposures of the public and to select routes to minimize such exposure [45, 46].

New casks are being developed to maximize the efficiency of the longer-aged spent fuel shipments and to reduce the exposure of the workers involved in loading and unloading the casks. There are expected to be two families of casks; those transporting the spent fuel from the reactors to a temporary storage facility, primarily truck casks; and those transporting the spent fuel from the storage facility to the repository, primarily rail casks. Another set of casks is being developed for the high-level defense waste glass at the Hanford and Savannah River facilities, and the commercial high-level waste at West Valley, NY.

The Nuclear Reactor

Development of the commercial nuclear power industry for electricity generation began in the early 1950s. The first commercial electric power was produced using a LWR at Shippingport, PA in 1957. By the 1970s, large numbers of power reactors had come online. In the United States all but one were LWRs, but in Canada the preference was for heavy water reactors (HWRs). There were many gas-cooled graphite reactors (GCRs) in England, France, and Russia and one in the United States. France and Russia had the first operating liquid metal fast breeder reactors (LMFBRs) operating, with several engineering test reactors in the United States. The characteristics of typical units are presented in Table 21.16. Nuclear reactors can be classified in several ways:

- *Burners* vs. *breeder*s: Burners depend on uranium from ore but may recycle the residual fissionable material from the spent fuel to reduce the ore requirement. Breeders produce more fissionable material than they consume by converting either uranium-238 into plutonium-239 or thorium-232 into uranium-233. The breeders depend on the plutonium-239 or uranium-233 from the burners to bring them into equilibrium, and this may take 30 years.
- *Choice of neutron moderator-light water (protium), heavy water (deuterium), liquid sodium or lead or molten salts, or solid (graphite)*: Except in the case of graphite, the moderator also serves as the coolant. In the case of a graphite moderator, gas (He or CO_2) or sometime water is used as a coolant.
- *Neutron energy (thermal* vs. *fast)*: The liquid metal/salt reactor operates with fast neutrons to breed using the uranium cycle. The water and graphite reactors operate with thermalized neutrons to more effectively burn the fissile material.
- *Pressurized* vs. *boiling LWRs*: The PWR transfers its energy from the fuel to an intermediate heat exchanger to generate the steam that drives the turbine. The boiling reactor generates steam within the reactor that goes directly to the turbine.

The LWR, CANDU, and graphite reactors are the major producers of electricity from nuclear energy. When compared on the basis of cost, reliability, and safety, they are competitive. The PWR is the most widely used LWR (267), but there are also many BWR's in use (84). In 2010 there were 51 CANDU's and other heavy water moderated reactors operating in the world, including Canada, where they were developed with several in other countries as well. In addition, there are 33 other types of reactors, including sodium cooled, and graphite-moderated (Nuclear News, 1th Annual Reference Issue, March 2012).

When PWRs and CANDUs are compared on the basis of uranium utilization, the CANDU requires 19% less uranium from ore on a per kWh basis (see Table 21.17). As there is now an abundance of low-cost uranium from ore and enrichment service, the electric utilities continue to favor the PWR

and BWR types. Operating experience with graphite reactors in England, France, and Russia also has been generally satisfactory. However, the graphite moderator represents a large inventory of combustible material, which contributed significantly to the severity of the Chernobyl and windscale accidents. Further development of the high-temperature, gas-cooled, graphite-moderated reactor is being considered for the advanced Generation IV reactors to be deployed from 2015 and beyond. Due to its much higher operating temperature (~900°C), this type of reactor can be used to provide process heat for a variety of industries.

A new family of advanced nuclear reactors has been designed by the PWR, BWR, and CANDU suppliers, which are now (2012) being licensed and built in Finland (1), China (4) and the US (4). It is the industry's objective to use proven technology to provide reactors that are simpler and less costly to build than older designs. These reactors would have wider safety margins through the increased use of passive safety systems, relying more on reactor design and less on operator action and outside power and water resources to prevent accidents. They would be made less complex by drastically reducing the number of components necessary for operation. This design also would facilitate plant construction by requiring less concrete, fewer valves and pumps, and less piping. Most likely the future will see introduction of modular built systems that will be prefabricated at the factory. Safety considerations always will be paramount [47, 48].

Light Water Reactors

Pressurized water reactor. The PWR contains three coolant systems: the primary system, which removes heat from the reactor and partially controls nuclear criticality; the secondary system, which transfers the heat from the primary system via the steam generator to the turbine-driven electrical generator; and the service water system (the heat sink), which dumps the residual coolant energy from the turbine condenser to the environment. The service water is recirculated from a river, lake, ocean, or cooling tower. In the primary system (Fig. 21.23), dissolved boron is present to control

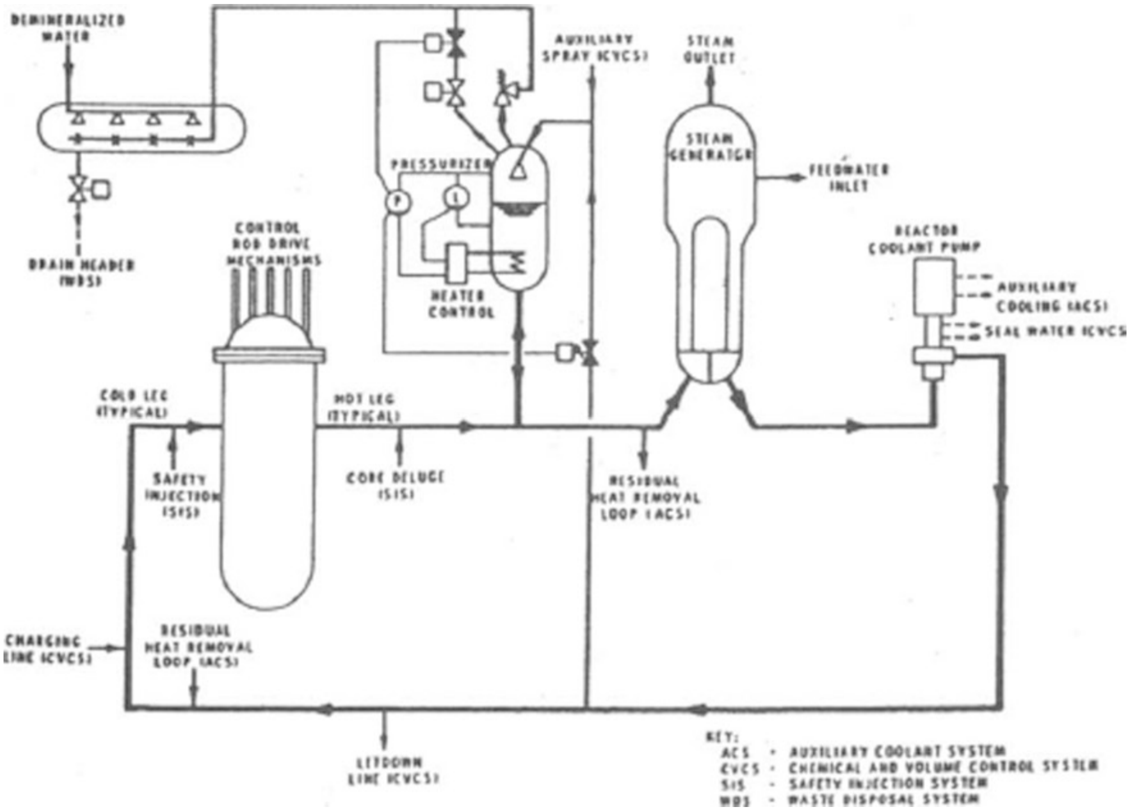

Fig. 21.23 Pressurized water reactor (PWR) for power generation (Courtesy of USDOE)

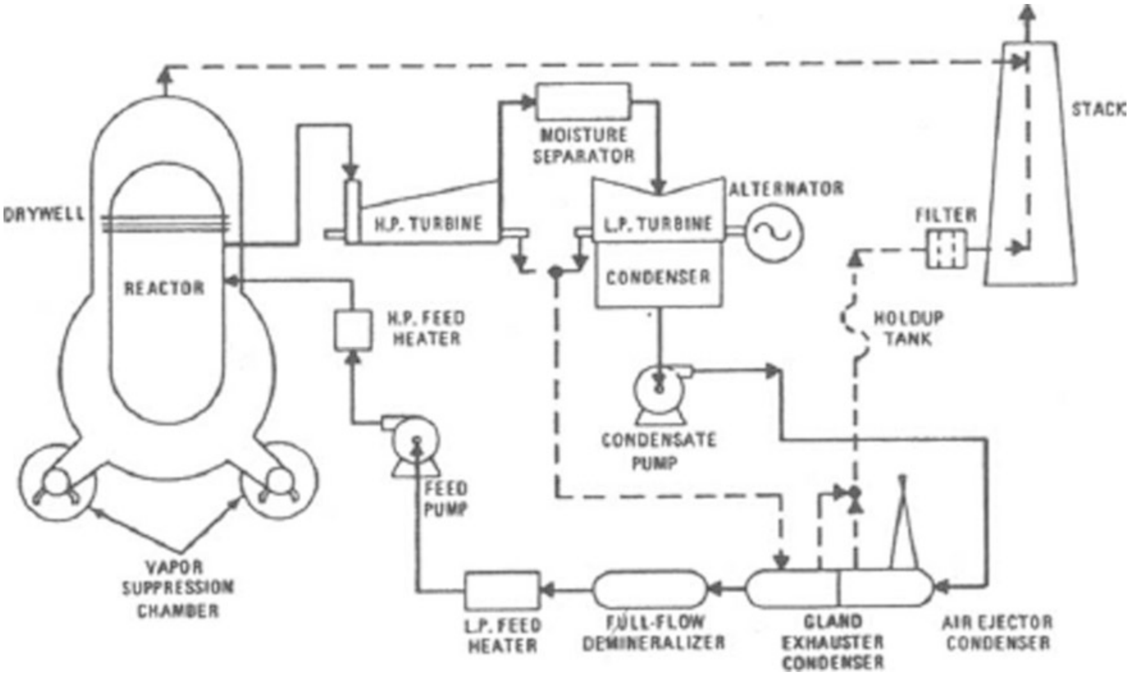

Fig. 21.24 Boiling water reactor (BWR) for power generation (Courtesy of USDOE)

nuclear criticality. Fixed-bed ion exchange units are used to maintain the water quality in both the primary and the secondary systems. The chemical and volume control system reduces boron concentration during the power cycle to compensate for fuel burnup. These operations are carried out continuously through bypass systems [49].A more complete view of the current technology is presented in Table 21.16.

Boiling water reactor. In the BWR, steam is generated in the reactor and goes directly to the turbine (Fig. 21.24). Although the BWR eliminates the intermediate heat exchanger, it places the steam turbine in a radioactive environment. In the primary system, there are full-flow ion exchange units treating about 30,000 gal of water/min, which serves two objectives: removal of radioactivity resulting from neutron-activated corrosion products and fuel cladding leaks; and corrosion protection of the reactor, fuel, and turbine from possible leakage of service water to the primary coolant from the turbine condenser.

In the following paragraphs, three important aspects of LWRs are discussed: fuel elements, the primary coolant system, and reactor containment. They each play an important role in providing multiple barriers that prevent radioactive fuel and fission products from being released to the environment.

Fuel elements. The fuel element is designed to provide the primary containment for the radioactive fuel and fission products over the three- to six-year operating life of the PWR and BWR fuel. In addition, without significant problems, it has provided the containment of the spent fuel after discharge from the reactors for more than 50 years under water in the storage pools at some of the reactors. At some of the older reactors it is now being packaged in stainless steel canisters and placed in dry storage vaults at the reactor site [50].

The quality of the reactor coolant depends on the integrity of about 80–110 miles of 0.0225 inch thich wall Zirconium alloy tubing operating at temperatures up to 350°C containing uranium oxide pellets. The PWR fuel assembly, which is about 14 ft long, is made up of up to about 264 fuel pins (Fig. 21.25). A typical PWR contains about 110 mt of fuel charged with up to 4.95% U-235. The economics of the fuel cycle require this degree of enrichment to achieve a reasonably long operating life and high energy yield from each assembly. Because these nuclear power stations represent a significant part of the total power system capacity of the United States (about 20% in 2012), frequent shutdowns are undesirable. With the increased experience and expectation of a once-through fuel cycle, the enrichment has been increased to raise the energy yield to an average of 50,000 MW days/metric ton and to extend the time between refueling shutdowns to 18 months or longer. This reduces the amount of replacement power needed during shutdowns, which generally comes from the older, more costly, fossil-fuel-powered plants or must be purchased from outside the system. Approximately one-third of the fuel is replaced in the core of the reactor during each refueling shutdown.

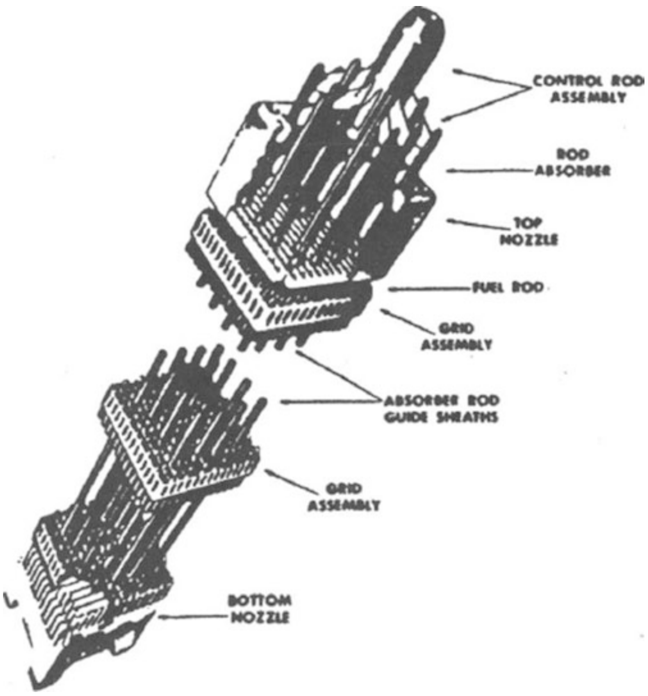

Fig. 21.25 Cutaway of PWR fuel element with the control rod cluster assembly. Element contains about 1,200 lb UO_2 in up to about 264 rods (Courtesy of USDOE)

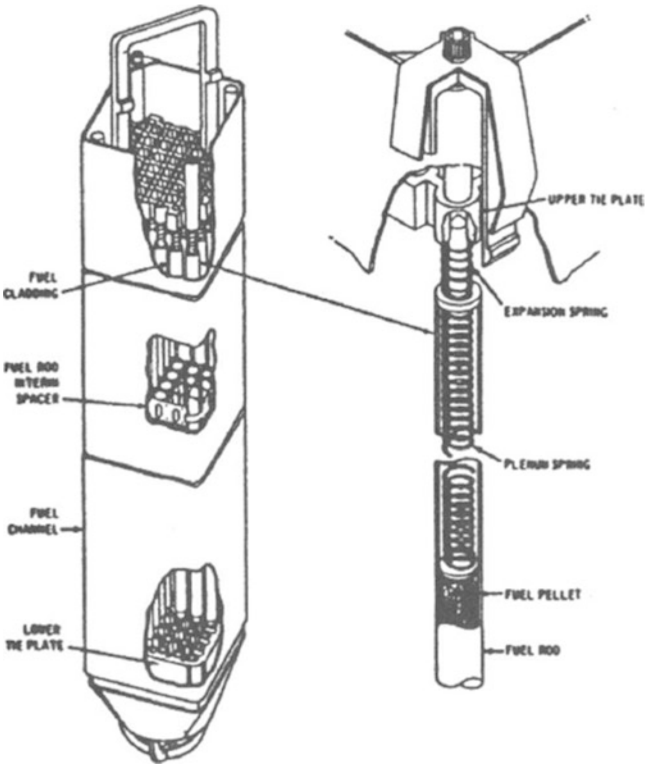

Fig. 21.26 Cutaway of BWR fuel element containing 488 lb UO_2 in 49 rods (Courtesy of USDOE)

In order to improve fuel cycle economics and protect the reactor vessel from radiation-induced embrittlement, partially burned fuel is often loaded in the core periphery. Appropriate placement of the new fuel and shuffling of other partially burned fuel ensures satisfactorily flat power distributions.

A 1,000 MWe BWR core contains about 165 t of UO_2, which is charged up to 4.95% U-235 (Fig. 21.26). Here the integrity of the 0.032 inch thick wall fuel cladding (Fig. 21.26) is even more important than in the PWR because the steam is generated in the reactor core and goes directly to the turbine. This has proved to be a feasible design and eliminates the PWR expense of replacing steam generators.

Two engineering system demonstrations were performed to reduce the uranium-from-ore requirements of LWRs: recycle of the plutonium and conversion to the thorium–uranium cycle to achieve thermal breeding. The demonstration phase of the plutonium recycle development was carried out in seven power reactors. Several LWRs originally were started up on the thorium–uranium cycle, and a light water breeder reactor core using the thorium cycle was tested in the Shippingport reactor. Although these tests did not resolve all the technology questions, no major problems were uncovered. In the United States, plans for fuel recycling and the use of the thorium cycle have been postponed because of the low cost of uranium from ore as well as the perceived danger of diversion of the fissionable materials.

Primary coolant system. Nuclear technology faces challenges on most of the frontiers of engineering, with design and fabrication of the primary coolant system being one of the greatest. The reactor vessel and associated piping and heat exchangers comprise the second barrier to prevent the release of radioactive materials from the fuel to the environment. The steel for the reactor vessels must meet metallurgical standards developed for them to withstand the temperature and pressure cycles as well as neutron irradiation, which in time reduces the ductility of the metal. Carbides and phosphides precipitated in the grain boundaries prevent slippage along the crystal planes. The design criteria for optimum performance require operating pressures of 1,050 psia for BWRs and 2,250 psia for PWRs. Typical dimensions for vessels serving 1,000 MWe stations range from 21 ft in diameter by 70 ft in height for BWRs, to 14 by 42 ft for PWRs, with vessel weights of 782 and 459 t, respectively. These vessels are shop-fabricated, and their transport to the reactor site tests the ingenuity of the carriers [51, 52].

As anticipated, there have been occasional equipment failures involving reactors, but the safety systems have been sufficiently redundant so that one or more have always worked. Even in the Three Mile Island accident in 1979, the safety systems worked as designed. Much of the damage resulted from operator actions to override the safety systems.

As concluded in the Reactor Safety Report, the limitations of the operator created and then seriously aggravated the Three Mile Island incident. Nevertheless, the features of the containment system prevented significant exposure to the plant personnel or any off-site individual, this despite failure of the barriers provided by the fuel cladding and the primary coolant system.

LWR tests-to-failure had been performed to evaluate accident scenarios involving loss-of-coolant accident (LOCA) events such as occurred in the Three Mile Island incident. The power burst tests in a 20 MW PWR have created fuel failures and defined the initiating conditions. The LOCA tests with a 50 MW PWR have demonstrated recovery from catastrophic major feedwater and steam line breaks without fuel damage.

Advanced reactors such as the Westinghouse AP600, AP1000, and General Electric ESBWR have been developed that produce the same amount of power but with many fewer components. These reactors will have increased reliability and greater safety due to the reduced component count that reduces both the cost and the number of points at which failures can occur. In addition, these newer reactor designs are designed to be passively safe. That is, active involvement by the reactor operators is not required to maintain the reactor in a safe state. These types of designs were developed to allow time for reasoned decisions to be made in case of an accident or major equipment failure while still keeping the reactor in a safe state.

CANDU Heavy Water Reactor

This Canadian reactor design originally utilized (1) natural uranium as the fuel, thus avoiding the necessity for uranium enrichment, and (2) heavy water as both coolant and moderator, to maximize neutron utilization. Current designs plan to use slightly enriched fuel and light water as a coolant. In addition to electrical power, this reactor can efficiently produce cobalt-60, which has commercial markets for product irradiation. Each reactor can produce 30–50 MCi annually, and in 1999, the catalog price was $1.20/Ci. The CANDU requires 18% less uranium from ore than the LWR once-through cycles need. The spent fuel contains 0.23% U-235, roughly equivalent to the tails from the gaseous diffusion enrichment operation. It also contains 0.27% fissionable plutonium. The average residence time of a fuel is about 1 year, with approximately 0.3% replaced each day. This requires refueling during operation. The CANDU fuel bundles contain 37 Zircaloy-clad UO slugs, a less complex design than that of LWR assemblies. Many alternative fuel cycles are being considered for the CANDU to further decrease the requirements of uranium from ore, but they will require enrichment or reprocessing [53].

Liquid Metal Fast Breeder Reactor

The salient features of the liquid metal fast breeder reactor include a fuel doubling time of 10–30 years, along with a high coolant temperature for more efficient energy conversion and low operating pressure through the use of liquid sodium or lead as the coolant. Operation of the reactor with fast neutrons increases the neutron multiplication factor for the mixed uranium–plutonium oxide fuel. The power density in the LMFBR is about five times greater than that in the LWR cores; so the reactor vessel is much smaller. This core is surrounded with radial and axial blankets of fertile material. These blanket regions, which capture the leakage neutrons, must be used to achieve breeding, which consists of the production of fissile material from fertile material. Finally, the use of the uranium–plutonium fuel cycle makes optimum use of the plutonium produced in the LWRs.

All major nuclear countries have participated in LMFBR demonstration plants, ranging from about 200–500 MWe. In the United States, the Experimental Breeder Reactor I (EBR I), the starting point of this program, went critical in 1951. LMFBRs were operated in the United States, England, France, Japan, and Russia. In France, the Phenix, a 590 MW/230 MWe reactor, was operated starting in 1973, and the Super Phenix, a 1,200 MWe reactor, first generated power in 1987 and was in commercial operation. The EBR I, Phenix and Super Phenix have all been shut down. In the former Soviet Union, the BN-350 MWe reactor produced power and steam heat for Shevchenko on the shore of the Caspian Sea from 1973 to 1999; and another reactor, the BN-600, has been operating since 1980. In the United States, the 400 MW Fast Flux Test Facility started operation in 1980 to test fuels and materials. The objectives of this program were satisfied in 1989, and it was shut down.

During the 1980s, the Argonne National Laboratory was developing a metal-fueled LMFBR in contrast to the oxide-fueled version described above. The principal advantage of the metal fuel was to be the ease of recycle using electrometallurgical technology. The program was called the Integral Fast Reactor with emphasis on high burnup instead of breeding, possibly 185,000 MW-days/metric ton vs. 50,000 for the present-day PWRs (Fig. 21.27) Early work with metal fuel showed that it expanded because of the presence of the xenon and ruptured the cladding. The fuel rods have been redesigned to accommodate this phenomenon. Finally, each reactor site would have its own reprocessing unit, and this would greatly reduce concern about proliferation. Cost estimates indicate that the cost of the electricity generated would exceed to that from LWR and HWR systems. Much work remains to be done to confirm all these attractive indications [54]. However, the high cost of reprocessing, the fast reactor and fuel manufacture as well as the safely and maintenace issues associated with

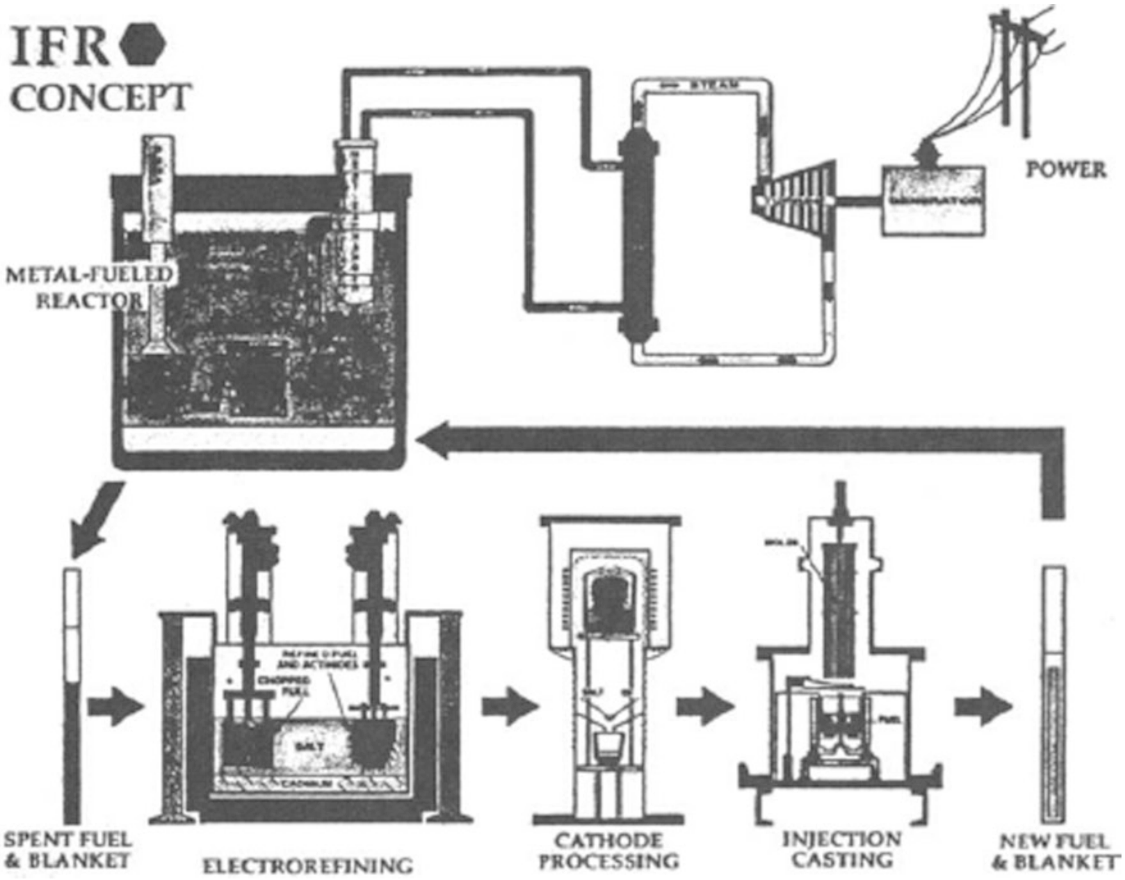

Fig. 21.27 Schematic of integral fast reactor and fuel cycle concept (IFR) (Courtesy of USDOE)

molten sodium metal make this technology commercially unacceptable for electrical production.

Other Nuclear Reactors

Many other nuclear reactors have been developed for research, engineering development, nuclide production, and mobile power. Most noteworthy are the nuclear propulsion systems for naval applications. In the United States, the PWR technology for electric power generation is an outgrowth of the nuclear naval development program. The first nuclear submarine, the *Nautilus*, was commissioned in 1954. Today there are more than 100 nuclear submarines, along with a number of aircraft carriers and other surface vessels. Other nuclear propulsion systems have been studied for arctic tractor trains, aircraft, and rockets for space propulsion, but these studies were terminated before completion owing to insufficient benefit or other funding priorities and environmental concerns. Recently, nuclear reactor development was started again to provide power on orbiting space stations in connection with the United States Strategic Defense Initiative program and for propulsion as part of the NASA manned and unmaned planetary explorer programs [55]. As part of this activity, a "space" reactor was purchased from the Russians who have been employing them for many years.

The remaining classes of nuclear reactors range from zero-power, subcritical neutron sources for university training to large-scale reactor systems for plutonium-239 production. Portable reactors have provided heat, power, and water to US bases in Alaska, Antarctica, and Panama. Private industry has operated various test reactors for reactor studies and radioisotope production.

Radiation Processing

Next to the generation of electric power, radiation processing is potentially the most important commercial application of nuclear energy. Radiation processes have been developed for treating food and medical supplies to inhibit growth of bacteria, viruses, fungi, and insects, and for polymerization of plastics and rubber. They take the place of thermal and chemical treatment to achieve these objectives.

Radiation also is an important tool in the medical treatment of cancer. However, what may be one of its most important applications, extending the storage life of foods, has been seriously delayed by public concern, in spite of extensive tests showing that irradiated foods meet all international safety standards. Currently, the United States irradiates spices for the main purpose of bug removal.

In early radiation processing work, cobalt-60 was the principal source of radiation, but now it has been displaced by machine-produced electrons wherever possible. Cobalt-60 is commercially available from the Canadian CANDU power reactors.

Commercial information regarding the application of machine-produced electrons is closely held, but the following are a few examples of their use:

1. Low-energy electrons, up to 0.5 MeV, are in general use to polymerize thin plastic sheeting and coatings. Fixed beams up to 2.5 m wide irradiate 0.4-mm-thick products with 10 kiloGray (kGy) at 1,600 m/h.
2. Electrons with energies up to 5 MeV are widely used in scanned beam machines. The typical scan width is 1–2 m when applied to the polymerization of thicker materials. These machines also are being used for irradiating grain and chicken feed. The Russians are treating 200 t/h of grain with a dose of 0.4 kGy, and the Israelis treat chicken feed with 3.8 kGy at 15 t/h. In both cases the flowing-bed depth is about 6 mm.
3. A 5-kW beam of 7 MeV electrons is delivering a 3 kGy dose to flat cakes of deep frozen cakes of chicken meat at a rate of 50 t/day; disposable medical supplies are being treated at the rate of 100 m^3/day [56].

Radioisotope Applications

The tremendous release of energy from nuclear reactions makes possible a unique family of applications for long-lived radioisotopes that are important to health, science, and industry. Whereas fission and fusion occur almost instantaneously, other radioactive decay processes occur in times ranging from a few minutes to thousands of years. The general areas of application may be grouped into irradiation, thermal energy generation, and tracer applications [57].

Radiation Sources

Radiation from radioactive nuclides is used to detect changes in density or other characteristics of materials, to promote chemical, physical, or biological changes, and to provide a source of thermal energy. Some radioactive materials find use in industry, research, and medicine as tracers for physical, chemical, and biological processes [58].

The very important radioisotope cobalt-60 has a 5-year half-life and emits 1.17 and 1.33 MeV gamma rays. Co-60 is made by irradiating naturally occurring Co-59 with neutrons in a reactor. It is the major radioisotope in a number of applications including the following.

1. Destruction of malignant tumors.
2. Sterilization of prepackaged medical supplies, particularly those that are heat-sensitive or can be contaminated by chemical agents.
3. Food irradiation to extend shelf life.
4. Radiographing metals to determine weld quality (Iridium-192, with a 0.3 MeV gamma ray, provides better definition than Co-60 in some cases but has a shorter half-life.).
5. Polymerization of coatings on electrical conductors and paper and monomers impregnated into wood and concrete (Machine radiation generally is preferred in applications involving thin materials.).
6. Density measurements for level controllers in silos and other vessels bearing solids.

There also are many applications for alpha and beta radiation sources, including:

1. Polonium-210 alpha activation of beryllium to yield neutrons that in turn are used to start up nuclear reactors.
2. Plutonium-238 activation of beryllium to produce neutrons for logging drill holes to detect hydrogenous materials in geologic formations.
3. Strontium-90 beta sources to measure the thickness of paper in paper manufacture and also to discharge static electricity by ionizing the air in high-speed printing operations.

Radioisotope Thermoelectric Generators

These devices (radioisotope thermoelectric generators, RTGs) provide reliable long-life sources of electrical energy. The thermal energy required to drive the thermoelectric element is provided by a long-lived radionuclide. The electricity is generated by passing the thermal energy through the thermoelectric element from the heat source at one end (the hot foot) to a heat sink at the other end (the cold foot). Germanium silicide is now the thermoelectric material of choice; because of its higher thermal stability, it can be driven with larger temperature differentials. Lead telluride is more efficient per degree of temperature difference but has lower thermal stability [59].

Plutonium-238 is the most important heat source; it is an alpha emitter whose radioactive decay energy is easily absorbed and converted into thermal energy. It also is easily shielded. In addition, its long half-life, 90 years, makes possible hundred-watt power sources with a design life exceeding 10 years. Although solar cells generally comprise the

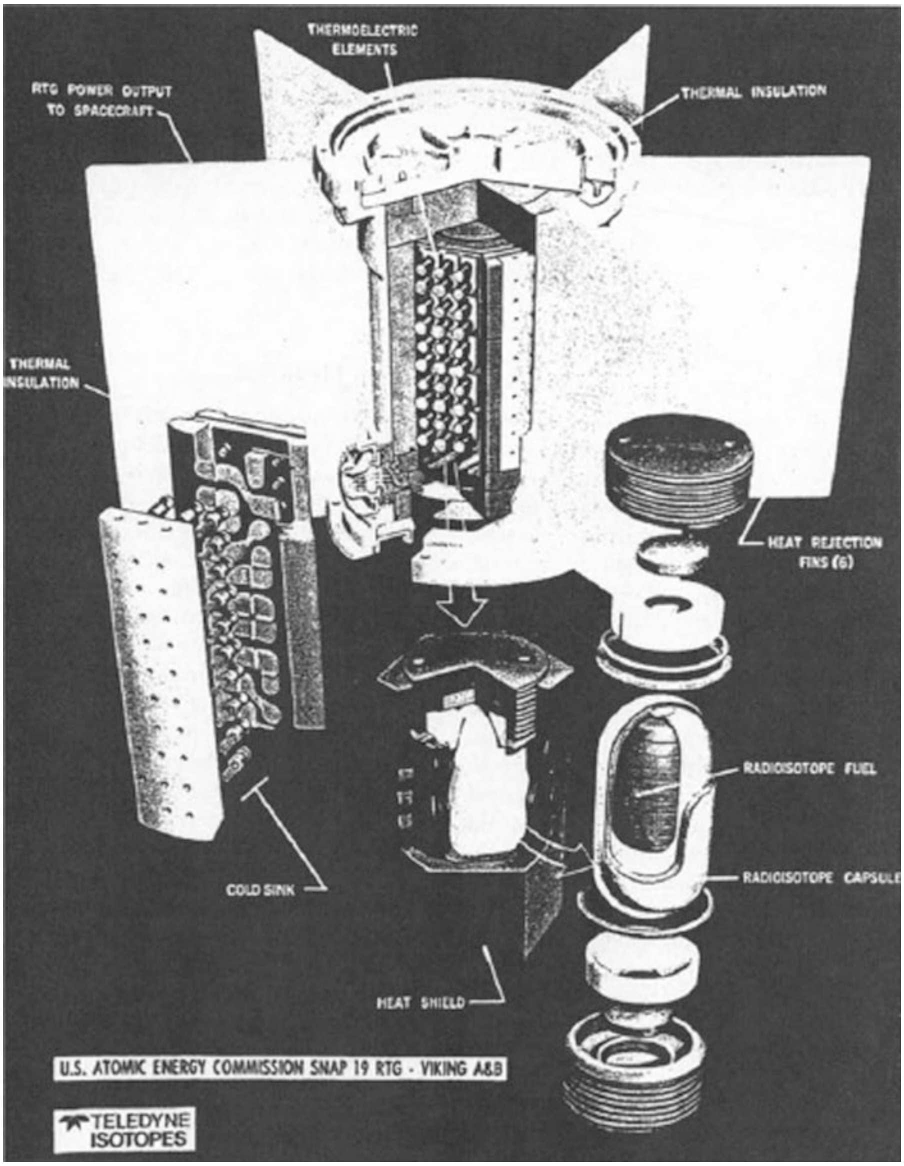

Fig. 21.28 The multi-hundred-watt electric generator. Three units on Voyager generated 475 W from the decay heat of plutonium-238 acting on thermoelectric couples (Courtesy of USDOE)

technology of choice to power extraterrestrial missions, a Pu-238 RTG was used for the Apollo moon landings. Such devices are used when the mission path is shielded from the sun, and they continue to be used for deep-space missions (see Fig. 21.28).

Terrestrial RTGs have also been developed and are commercially available. A beta emitter, 30-year strontium-90, has been the major radionuclide used for terrestrial applications. Although beta particles (negative electrons) are easily sorbed and converted to thermal energy, the sorption process is accompanied by the emission of X-rays that require shielding. This necessitates a heavy device, about 300 lb for a 5-W source. Because strontium-90 is a fission product, the supply now is limited to 100 MCi recovered in the 1960s from the Hanford defense waste. This is equivalent to about 10 kW of electrical energy, assuming a 5% conversion efficiency.

Tracers

The radiation emitted from decay of single atoms can be easily measured. Thus, small amounts of radioisotopes can be incorporated into systems to study, for example, chemical reactions and the flow of fluids through complex systems such as organs of the human body. They also can be used in more mundane applications such as locating leaks in buried piping. Many organic compounds tagged with carbon-14 in specific positions are commercially available.

Because C-14 with a half-life of 5,700 years occurs in nature, it can be used to determine the age of carbon-containing artifacts. The basis for such determinations is the loss of C-14 that was trapped in the artifact (animal, human, fired pottery, etc.). The related art and science of carbon dating are fairly complex and thus subject to significant uncertainties.

Table 21.18 Radionuclides used in nuclear medicine

For organ function and tumor visualization

Cobalt-60	Cesium-137
Radium-226	Iodine-131

Nuclear Medicine

Nuclear medicine is one part of nuclear utilization readily accepted by the public. However, there is strong opposition to the siting of the low-level waste repositories needed for disposal of the wastes that result from the practice of nuclear medicine.

The medical applications of nuclear technology range from in vitro and in vivo injections for diagnostic tests to cobalt radiation for cancer therapy. A new medical specialty was created, a family of compact cyclotrons was developed to provide short-lived nuclides, and a sizable industry evolved to produce technetium. Until the nuclear industry was created, technetium had been missing from the chart of chemical elements because the half-life of the most stable member was too short, 21,000 years. Technetium and several other nuclides of importance here are discussed elsewhere in the chapter in connection with their production (see Table 21.18) [60, 61].

The two principal applications of nuclear medicine are for radiation treatment of tumors and for visualizing organ functions and tumors. These nuclear-medical procedures supplement other medical treatment and diagnostic procedures, and are available in most hospitals throughout the industrialized countries and in the major hospitals in other countries.

Synthetic Nitrogen Products

22

Gary R. Maxwell

Nitrogen products are among the most important chemicals produced in the world today. The largest quantities are used as fertilizers, but nitrogen products also find very important uses in the manufacture of nylon and acrylic fibers, methacrylate and other plastics, foamed insulation and plastics, metal plating, gold mining, animal feed supplements, and herbicides.

Nitrogen

Characteristics

Nitrogen is colorless, odorless, and slightly lighter than air with a density of 0.967 (air = 1.0). Some people consider nitrogen to be one of the most dangerous gases. This is because a person in an atmosphere of nitrogen can lose consciousness without any warning symptoms in as little as 20 s. Death can follow in 3–4 min. One deep breath of 100% nitrogen can be fatal because nitrogen will displace carbon dioxide in the body completely. In the absence of a carbon dioxide signal to the brain, breathing stops.

No one should work in or enter atmospheres containing less than 19.5% oxygen, unless equipped with a self-contained breathing apparatus or a breathing air mask. This is also true of rescue personnel who can be overcome by the same oxygen-deficient atmosphere as the initial victim [1].

The properties of nitrogen are listed in Table 22.1.

Although the ability of nitrogen to easily unite with other elements is quite limited, it does form some interesting compounds. When nitrogen combines with certain elements, it produces dyes that rival the rainbow in the brilliance of their colors. With other elements, nitrogen forms drugs such as morphine, quinine, and acetanilid that ease pain and combat diseases. With other compounds, nitrogen forms some of our most powerful explosives such as nitroglycerin and guncotton. Nitrogen can also be used to make some very deadly compounds such as ptomaines. Some nitrogen compounds provide pleasant-tasting flavors and sweet perfumes, and others are so vile in taste and odor that they are beyond description. In nitric acid, we find nitrogen in a strong acid, whereas in ammonium hydroxide, we have it in a well-known base [2].

Nitrogen Production Processes

Economical fixation of nitrogen from the atmosphere has been a never-ending quest. It has been a difficult task because elemental nitrogen is comparatively unreactive. It only combines with most elements under high pressure and/or high temperature. As a result, industry meets its demand for high-purity nitrogen by obtaining most of it from liquid air (see reference 1 and Chap. 27).

Nitrogen production via PSA (pressure swing absorption) is based on the principle that nitrogen and oxygen have different absorption rates on carbon molecular sieves (CMS). Some of the nitrogen production processes that use this technology are described in [3–7].

Nitrogen Fixation

Nature uses nitrogen fixation to combine free nitrogen with other elements. Nodules on the roots of many plants contain bacteria that extract nitrogen from the air and convert it into soluble nitrates that fertilize the soil. Most nitrogen products are based on nitrogen oxides and ammonia, as described on the following pages.

Nitrogen Oxides

The five oxides of nitrogen are [2]: nitrous oxide (N_2O), nitrogen dioxide (NO_2), nitric oxide (NO), nitrogen

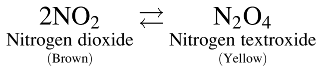
pentoxide (N_2O_5), and nitrogen trioxide (N_2O_3). Nitrogen trioxide and nitrogen pentoxide are the anhydrides of nitrous acid and of nitric acid.

Nitrous oxide (laughing gas) is a colorless gas. Since the 1840s, the major use of nitrous oxide has been as an anesthetic, especially by dentists. It is also used as a propellant in some aerosol cans, in atomic absorption spectrophotometry, in cryosurgery, and in racecar engines to provide extra power and acceleration.

Nitric oxide is a colorless gas that is insoluble in water. The most noticeable chemical characteristic of nitric oxide is the ease with which it combines with oxygen to form nitrogen dioxide. Its major use is in the industrial preparation of nitric acid.

In the late 1980s, nitric oxide (NO) was discovered as a product of enzymatic synthesis in mammals. And in 1998, the Nobel Prize in Physiology was awarded to the scientist that discovered the role of NO as a biological messenger. Nitric oxide uses range from its role as a critical endogenous regulator of blood flow and thrombosis to a principal neurotransmitter mediating erectile function to a major pathophysiological mediator of inflammation and host defense. These major discoveries have stimulated research into a vast array of fields. The Nitric Oxide Society has been formed to coordinate meetings, and they also publish a research journal. More information is available at http://www.apnet.com/no.

Nitrogen dioxide is a red-brown gas that is very soluble in water. It has an unpleasant odor and is quite poisonous. When nitrogen dioxide is cooled, its brown color fades to a pale yellow.



$$\underset{\substack{\text{Nitrogen dioxide}\\ \text{(Brown)}}}{2NO_2} \rightleftarrows \underset{\substack{\text{Nitrogen textroxide}\\ \text{(Yellow)}}}{N_2O_4}$$

The importance of nitrogen dioxide lies in the fact that it combines readily with water to form nitric acid.

$$3NO_2 + H_2O \rightarrow 2HNO_3 + NO$$

This is the final step in the synthetic production of nitric acid. Nitrogen dioxide also acts as an oxidizing agent in the manufacture of sulfuric acid.

Nitrous oxide production technology can be licensed from the Sanghi Organization in Worli, India (http://www.sanghioverseas.com). Their technology is based on heating ammonium nitrate to 250°C and then purifying the resulting gas stream.

Research continues on the formation of nitrogen oxides. The high-temperature fixation of nitrogen as oxides remains an environmental problem rather than a commercially attractive process, as large quantities of nitrogen oxides are produced by fixation in high-temperature combustion processes such as power plants, automobile engines, and home furnaces. The US EPA promulgated regulations in 2000 (NO_x SIP Call) that require several states in the Eastern United States to reduce their NO_x emissions by a combined total of 35–40% by 2005 (see http://www.epa.gov/ttn/otag).

Ammonia

Ammonia was prepared by the alchemists by distilling leather scraps, hoof, horns, and other animal refuse. Because they found that the best ammonia was obtained by distilling deer antlers, the alchemists called ammonia "spirits of hartshorn" [2]. Nature forms ammonia by decomposition of proteins. The odor of ammonia can often be detected around manure piles and other decaying organic matter.

A process for synthesizing ammonia from nitrogen and hydrogen, using high temperatures and pressures and an iron-containing catalyst, was invented by Fritz Haber at

BASF in 1908 [3]. In 1909, C. Bosch of BASF built a pilot plant using an osmium-based catalyst, and in 1913, a larger plant was built in Germany [8–13]. The chemistry for this process is

$$N_2 + 3H_2 \rightleftarrows 2NH_3$$

In 1883, the Mond gas process produced ammonia by gasifying coal at a relatively low temperature by using a mixture of air and steam [3]. It was invented primarily to produce ammonia that was needed for the Solvay process that makes sodium carbonate [14, 15].

Some other processes that have been used to make ammonia are

- The Casale ammonia process in Switzerland in 1921 [3, 11, 16].
- The high-pressure Claude–Casale ammonia synthesis process in the 1920s [3, 11, 17, 18].
- The Fauser process in Italy in 1924 [11].
- The Mont Cenis process that was similar to the Haber–Bosch process except that it used coke-oven gas [3]. It was started up in The Netherlands in 1929 [19, 20].
- The Braun process is a variation on the classic ammonia synthesis process in which the synthesis gas is purified cryogenically [3]. It has been widely used since the mid-1960s [21].
- The AMV process for making ammonia was invented by ICI and announced in 1982 [3]. It is described in [22–24].
- The LCA (*L*eading *C*oncept *A*mmonia) is essentially a simplified form of the standard ammonia synthesis process that is more suitable for smaller plants. It is described in [3, 14, 25, 26].
- The BYAS (*B*ypass *A*mmonia *S*ynthesis) process can be used for economical expansion of existing ammonia synthesis plants. It is described in [3].
- The KAAP (*K*ellogg *A*dvanced *A*mmonia *P*rocess) process is the first high-pressure ammonia synthesis process that makes ammonia from nitrogen and hydrogen without the aid of an iron-containing catalyst [3]. It is described in [27–30].

Ammonia and some of its salts and derivatives are used as fertilizers. Ammonia also is a very important building block for many other chemical commodities as shown in Fig. 22.1.

Nitrogen Consumption

The demand for nitrogen in a chemically fixed form (as opposed to elemental nitrogen gas) drives a huge international industry that encompasses the production of many nitrogen products. Nitrogen products had a total annual commercial value on the order of $50 billion in 1996. The cornerstone of this industry is ammonia. Virtually all ammonia is produced in anhydrous form via the Haber process. Anhydrous ammonia is the basic raw material in the manufacture of fertilizers, livestock feeds, commercial and military explosives, polymer intermediates, and miscellaneous chemicals [31].

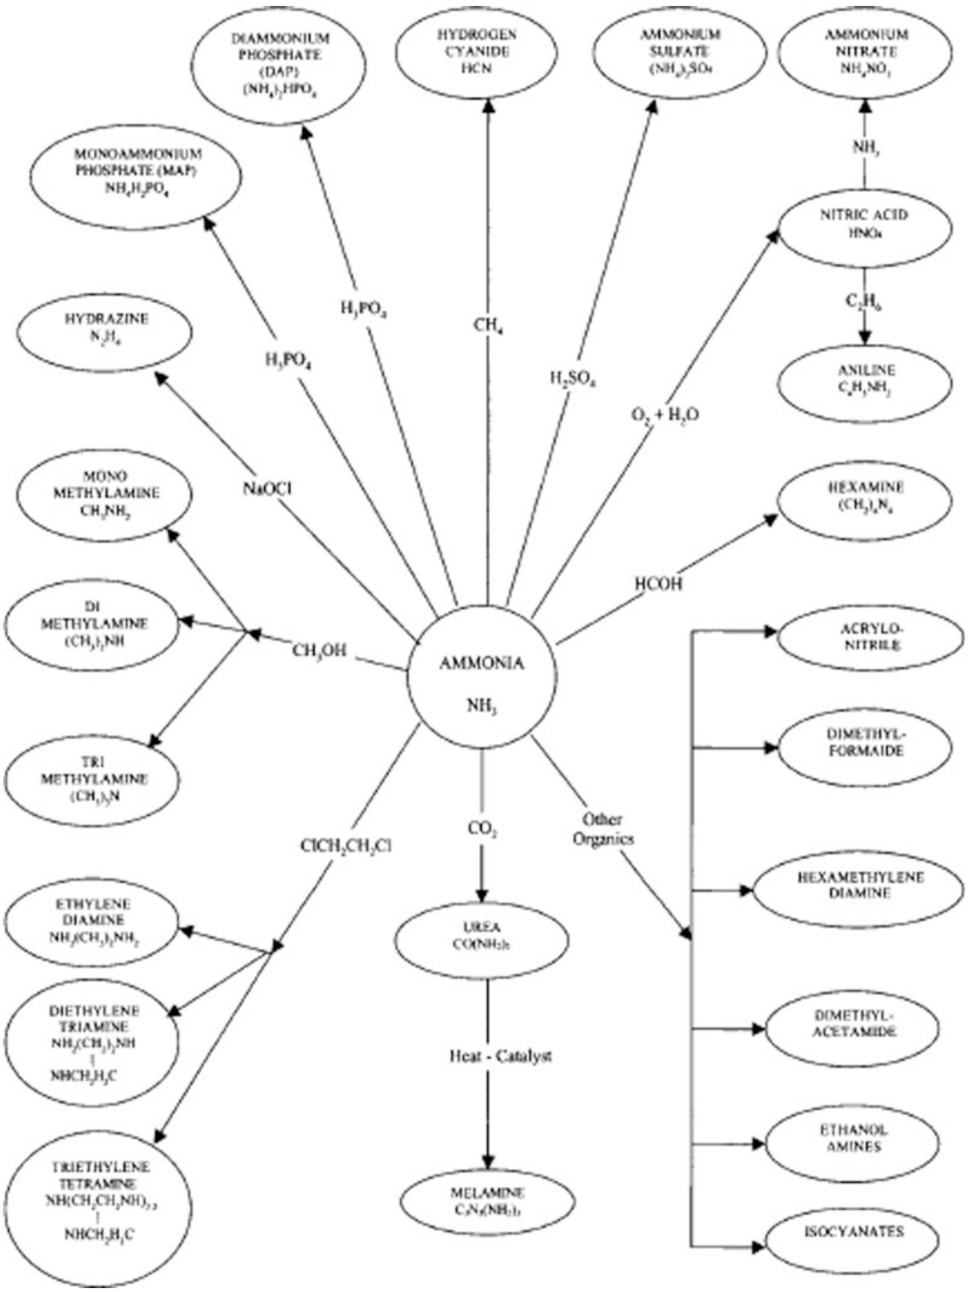
On a worldwide basis, nitrogen fertilizer consumption accounts for more than 85% of the total nitrogen industry. In the United States, with its significant industrial markets, fertilizer use accounts for only approximately 80% of total nitrogen consumption [31]. About 97% of nitrogen fertilizers are derived from synthetically produced ammonia. The rest are produced as by-product ammonium sulfate from caprolactam processes, acrylonitrile (ACRN) processes, metal refining operations, and small quantities of natural nitrates, especially from Chile [31]. Ammonia is the starting material for six primary nitrogen fertilizer products: urea, ammonium nitrate, ammonium phosphates, ammonium sulfate, nitric acid, and nitrogen solutions [32].

Up through the 1960s, the development of the nitrogen industry took place in the developed countries of Western Europe, North America, and Japan. However, in the 1970s and early 1980s, the construction of new plants shifted to the gas-rich countries of the Caribbean and Middle East. Additional plants were also built in some large consuming countries such as China, India, Indonesia, and Pakistan. At the same time, many plant closures occurred in Western Europe and Japan. Western European share fell from 20% in 1980/1981 to 11% in 1997/1998. In 1980/1981, the developing countries accounted for 31% of nitrogen fertilizer production. By 1997/1998, their share had increased to 55% [32] (see Fig. 22.2). The main regions that produced nitrogen fertilizers in 1997/1998 are summarized in Table 22.2. Although at least 60 countries produce urea, over one-third of the world's production is in just two countries: China and India [32].

World ammonia capacity increased by nearly 14% from 1984 to 1996, and capacity for urea, the primary downstream nitrogen product, increased by 45%. The increases were due primarily to (1) a desire by some major importing countries to become more self-sufficient and (2) the construction of export-oriented capacity in the Middle East and in the former Soviet Union (FSU). Ammonium nitrate capacity declined by 2% from 1984 to 1996, and ammonium sulfate capacity declined by 8% [31]. Ammonium phosphate capacity increased by 9% during this time.

In the future, developing nations are expected to continue to account for most of the increases in ammonia and urea capacity. Ammonia capacity is expected to increase by about 13.5 million tons and urea capacity by about 15 million tons between 1999 and 2004. The availability of relatively low-cost feedstock (usually natural gas) will be a major determinant as to where this new capacity is installed [31, 33].

Fig. 22.1 Synthetic nitrogen products



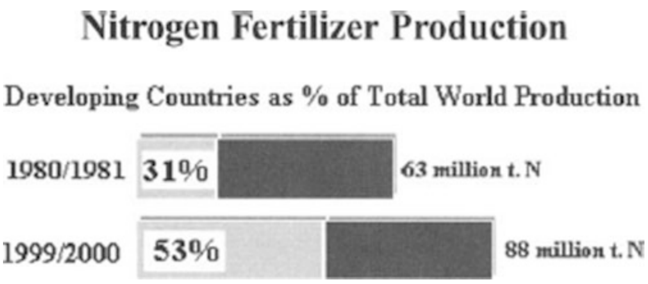


Fig. 22.2 Nitrogen fertilizer production 1980/1981 and 1999/2000 [32] (Reproduced by permission of the International Fertilizer Industry Association, IFA)

The apparent consumption of ammonia increased by about 15% between 1984 and 1996, and the apparent consumption of urea increased by about 54%. The developing countries are largely responsible for the increased consumption.

In 2002, urea accounted for almost 61% of worldwide consumption of the four major downstream nitrogen products. World urea consumption is forecast to increase at an average annual rate of 2.4% between 1999 and 2004. Only ammonium phosphate consumption, at 4.3% per year, is expected to grow more rapidly [31, 32].

Although world fertilizer consumption grew substantially between 1984 and 1996, it actually peaked at 79.6 million

Table 22.2 Main producing regions for nitrogen fertilizers

Region	% of world production
China	23
North America	18
South Asia	15
Western Europe	11
Former Soviet Union (FSU)	10
Other countries	7
Central Europe	5
Middle East	5
Indonesia and Japan	4
Mexico and the Caribbean	2

tons of nitrogen in 1989 and declined through 1994 because of a sharp drop in fertilizer consumption in Eastern Europe, the FSU, and Western Europe. Total world nitrogen fertilizer consumption resumed its long-term upward growth trend in 1995, and substantial growth is expected [31]. Japan is one of the few countries where the use of slow-release fertilizers is developing on field crops, especially in crops grown in paddies [32].

Estimates of world industrial nitrogen consumption by region show that the four largest markets in 1984 were North America, socialist Asia, Western Europe, and the FSU [31]. By 1996, South Asia had replaced the FSU as one of the four largest markets.

Trade is an important component of the world nitrogen industry, and trade in each of the nitrogen products analyzed (ammonia, urea, ammonium nitrate, ammonium sulfate, and ammonium phosphates) increased substantially between 1986 and 1998. The percentage of production that is traded internationally varies from 10% for ammonia up to 40% for ammonium phosphates [31].

Environmental Issues

Since 1980, the nitrogen industry has made major improvements in environmental controls to reduce atmospheric emissions and liquid effluents.

The primary pollution problem in nitric acid manufacture is the abatement of nitrogen oxides (NO_x) in tail gases. In the United States, gaseous emissions from newly constructed nitric acid plants must be limited to 1.5 kg of NO_x/ton of nitric acid (100% basis) produced, with a maximum stack opacity of 10%. Modern acid towers, with extended sections, can reduce NO_x emissions to less than 200 ppm [31].

The most important environmental concern about the use of nitrogen fertilizers is the loss of nitrogen to groundwater. This is having a significant impact on the use of nitrogen fertilizers, particularly in Western Europe. There is a lesser but still significant concern about nitrate levels in groundwater in the United States. Other than this runoff aspect, which most seriously affects ammonium nitrate, no serious environmental concerns exist with the use of the major nitrogen products as fertilizer materials [31].

Environmental issues play an important role in the ammonium sulfate industry. This is because a significant portion of the world's ammonium sulfate production is the direct result of the necessity to remove sulfur dioxide from stack gases at various metal smelting and refining operations in order to conform to government regulations on sulfur dioxide emissions. A large potential source of additional by-product ammonium sulfate production is sulfur dioxide recovery from coal-fired electrical generating stations. It is estimated that a 500-MW plant that is burning 3.5% sulfur coal could generate 250,000 tons of ammonium sulfate per year [31]. This is equivalent to ~7% of the total worldwide ammonium sulfate production in 2000.

Ammonia Production

Because no economical nitrogen fixation process that starts with nitrogen oxides has been discovered, ammonia has developed into the most important building block for synthetic nitrogen products. Anhydrous ammonia is produced in about 80 countries [32].

In the USA, only 80% of the ammonia is used to make fertilizers. Chemical intermediates (such as acrylonitrile and caprolactam) account for 19% of the ammonia use, and the remaining 1% is used in pulp and paper, metals, and refrigeration applications [34].

Worldwide ammonia capacity grew from 119 million tons in 1980 to a peak of 141 million tons in 1989 [32]. Ammonia demand grew at a rate of 3.2% per year from 1993 to 1998, but the growth rate is expected to slow to 0.5% per year from 1998 to 2002 [34]. US capacity declined in the 1970s, and it continued to decline during the 1990s by 5–10% to about 13 million tons/year. During the 1990s, US ammonia capacity was between 13 and 14 million tons/year with operating rates over 95%. The US capacity is forecast to reach 15 million tons/year by 2002, and worldwide ammonia capacity is forecast to grow at over 2% per year and exceed 140 million tons/year by 2002 [31].

By 2002, 30% of North American ammonia production was curtailed, and in 2004, four more plants were shut down. Although periodic downtimes of plants are not uncommon, the combination of import competition that depressed prices and very high feedstock costs in many industrialized countries has resulted in shutdowns of high-cost plants which resulted in a decline in world capacity [35–37].

In 1998, most of the ammonia production capacity was located in the regions shown in Table 22.3 [32, 36].

Table 22.3 Ammonia capacity by region (thousands of metric tons *N*)

	1987		1998	1999		2005

About 90% of world ammonia production is processed or used in the countries where it is produced. The remaining 10% of production enters international trade. The major net exporters in 1997 were Russia and Ukraine (43% of world exports), Trinidad (22%), and the Middle East (13%). The major net importers were the United States (43% of world imports) and Western Europe (26%) [32].

In the mid-1990s, the ammonia industry accounted for about 5% of worldwide natural gas consumption. For economic and environmental reasons, natural gas is the feedstock of choice. However, processes for ammonia production can use a wide range of energy sources. For example, 60% of China's nitrogen fertilizer production is currently based on coal. At present, natural gas is the most economic feedstock for the production of ammonia as shown in Table 22.4 [38].

All commercial ammonia manufacturing processes are based on the synthesis of ammonia from nitrogen and hydrogen. Thus, the many processes are differentiated by the method of producing the hydrogen and nitrogen for the synthesis. Preparation of nitrogen can be by separation from air in a standard "air" plant. Or air can be fed to the ammonia unit where the oxygen is used to burn a portion of the hydrocarbon feed, leaving the nitrogen for ammonia synthesis. The latter is the dominant type. Most of the hydrogen for ammonia manufacture is prepared from hydrocarbon feeds.

Some physical properties of ammonia and densities of aqueous solutions of ammonia are given in Tables 22.5 and 22.6, respectively.

[a] Anhydrous ammonia

Hydrogen Production

Ammonia production is the single largest consumer of hydrogen for use in chemical manufacture. Hydrogen production is typically integrated into the overall plant design, so most ammonia producers regard themselves as consumers of natural gas (or another feedstock) rather than hydrogen.

Table 22.6 Densities of aqueous ammonia at 15°C

Ammonia (wt.%)	Density (g/L)
8	0.970
16	0.947
32	0.889
50	0.832
75	0.733
100	0.618

Worldwide, a few ammonia plants have been located near by-product sources of hydrogen. In the United States, Coastal Refining & Marketing, Inc. brought a new ammonia plant onstream in late 1997 in Freeport, Texas, using purchased pipeline hydrogen. Air Liquide America purifies 45 million SCF/day of by-product hydrogen from Dow Chemical Company for pipeline delivery to Coastal's Freeport facility. In 2002, this was the only US ammonia plant using purchased hydrogen [39]. Hydrogen requirements in the main world regions are shown in [39, 40], and more details are given in Chap. 27.

To help meet increased hydrogen requirements, a methodology has been developed for assessment of hydrogen sources that is based on an analogy with the problem of process heat recovery. A hydrogen surplus diagram allows the engineer to find the "hydrogen pinch" and to set targets for hydrogen recovery, hydrogen plant production, and import requirements. This method also gives insights into the effective use of hydrogen purification units. It has been shown that a purification unit should not be placed below the hydrogen pinch. Purifying gas above the pinch may have some benefits, but placing the purifier across the pinch is the best option [41].

Hydrogen pinch technology has been applied commercially by several companies including AspenTech, BP-Amoco, Engineers India, Exxon, ICI, Linnhoff-March, M. W. Kellogg, and UOP [42, 43].

Hydrogen is a nontoxic, colorless, odorless, and tasteless gas. It is the lightest and most abundant element (making up over 90% of the atoms in our universe), but it is present at only extremely low levels (0.1 ppm) as a pure element in the earth's atmosphere. More than 50% of the atoms in our environment are hydrogen.

Hydrogen is present in fossil fuels and water in sufficient amounts that it can be produced from these sources on a large scale by several different methods: (1) petrochemical processes, (2) coal-based chemical processes, and (3) electrochemical processes (electrolysis).

In Table 22.7, the percentage of hydrogen production is broken down by type of manufacturing process [44].

In the petrochemical processes, both natural gas and crude oil fractions can be converted into synthesis gas using two basically different methods [44]:

Table 22.7 World hydrogen production and type of manufacturing process (in %) [44]

Process	1974	1984	1988
Cracking of crude oil	48	77	80
Cracking of natural gas	30		
Coal and coke gasification	16	18	16

Oxygen-coal-steam	1.0
Oxygen-fuel oil-steam	1.0
Propane-steam	1.33
Methane-oxygen	1.7
Oil-steam	2.1
Petroleum ether-steam	2.4
Methane-steam	3.0–5.0

- With the allothermal steam reforming method, catalytic cracking takes place in the presence of water vapor. The necessary heat is supplied from external sources.
- With the autothermal cracking process, heat for the thermal cracking is supplied by partial combustion of the feed. Water is used and carbon dioxide (CO_2) may be recycled to attain a desired CO/H_2 ratio.

The processes for the manufacture of synthesis gas were originally based on the gasification of coke from hard coal and low-temperature coke from brown coal by means of air and steam. After World War II, the easy-to-handle liquid and gaseous fossil fuels—oil and natural gas—were also employed as feedstocks. Their value lies in their high hydrogen content that produces higher molar ratios of hydrogen (H_2) to carbon monoxide (CO) in the synthesis gas (see Table 22.8). By using excess steam in the reforming of methane, the H_2-to-CO molar ratio can be as high as 5.0 (see Table 22.8).

Selection of a process for hydrogen manufacture from hydrocarbons and coal therefore depends on the raw material and its cost, the scale of operation, the purity of the synthesis gas to be produced, the pressure level of the natural gas feed, and the number and type of downstream processes that will consume the carbon monoxide and hydrogen.

Hydrogen is also manufactured industrially by direct electrolysis of H_2O, HF, and 22–25% hydrochloric acid (HCl). However, the hydrogen produced by electrolysis accounts for a small percentage of the total H_2 production (see Table 22.7). In contrast to the steam reforming of

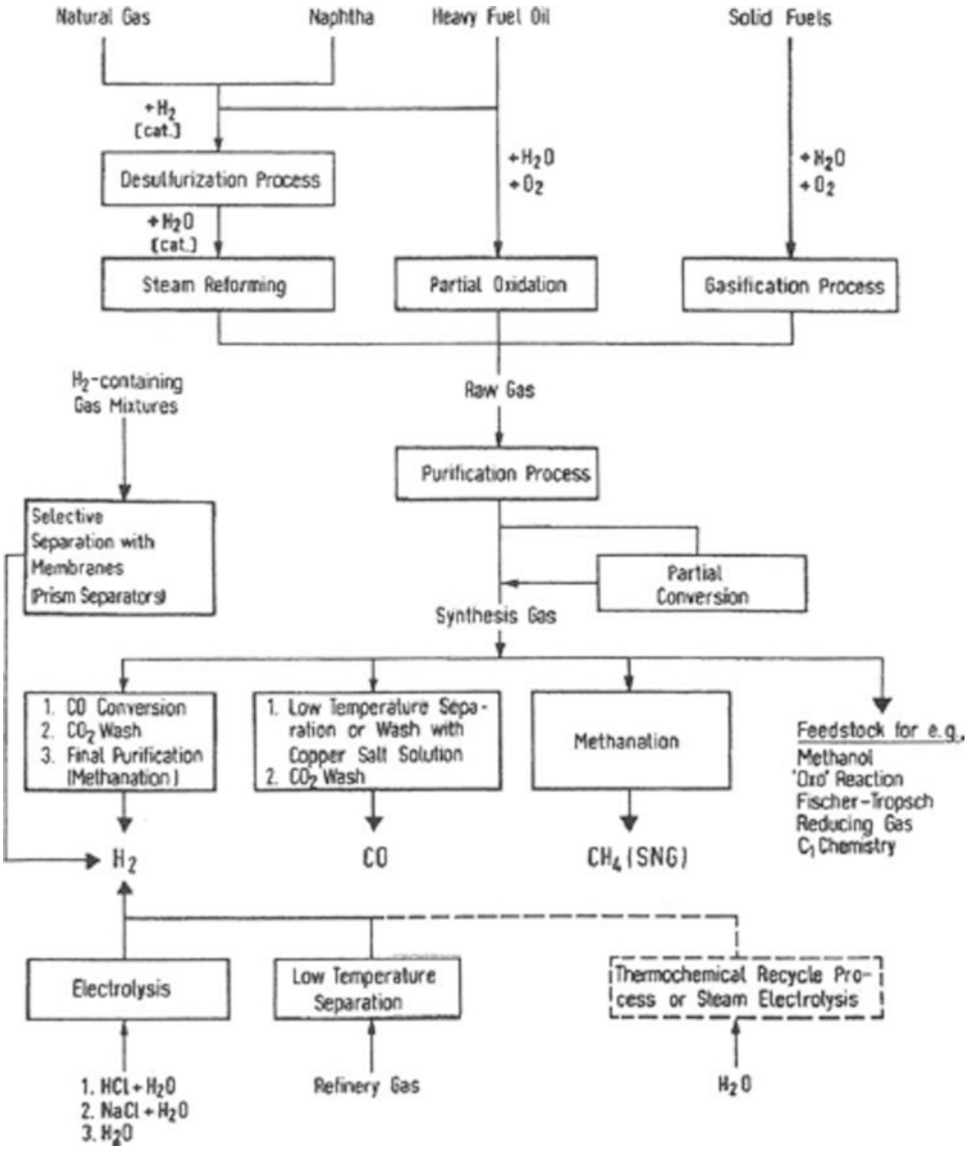

Fig. 22.3 Hydrogen manufacturing process steps [44] (Copyright by VCH Publishers and reproduced by permission of the copyright owner)

hydrocarbons, the hydrogen from electrolysis is very pure (>99 vol.%) which eliminates the costly purification steps.

Manufacturing Processes

Hydrogen is manufactured by four principal processes (see Table 22.7 and Fig. 22.3): steam reforming of natural gas, partial combustion of natural gas or oil with pure oxygen, gasification of coal or coke with air (or oxygen) and steam, and recovery of by-product hydrogen from petroleum refinery gases or other cracking operations. Small amounts of hydrogen also are manufactured by electrolysis. These processes are discussed in more detail in the following sections.

Reforming. Reforming is a general name for the reaction of a hydrocarbon, such as methane, with water and/or carbon dioxide, to produce a mixture of carbon monoxide and hydrogen. The different reforming processes can be divided into the following types [38]:

- Conventional steam reforming with a fired primary reformer and stoichiometric air secondary reforming (stoichiometric H/N ratio)
- Steam reforming with mild conditions in a fired primary reformer and excess air secondary reforming (under-stoichiometric H/N ratio)
- Heat exchange autothermal reforming (ATR), with a process gas heated steam reformer (heat exchange reformer) and a separate secondary reformer, or in a combined autothermal reformer, using excess or enriched air (under-stoichiometric or stoichiometric H/N ratio)

The typical steps in the reforming process and how they tie into ammonia production are shown in Fig. 22.4.

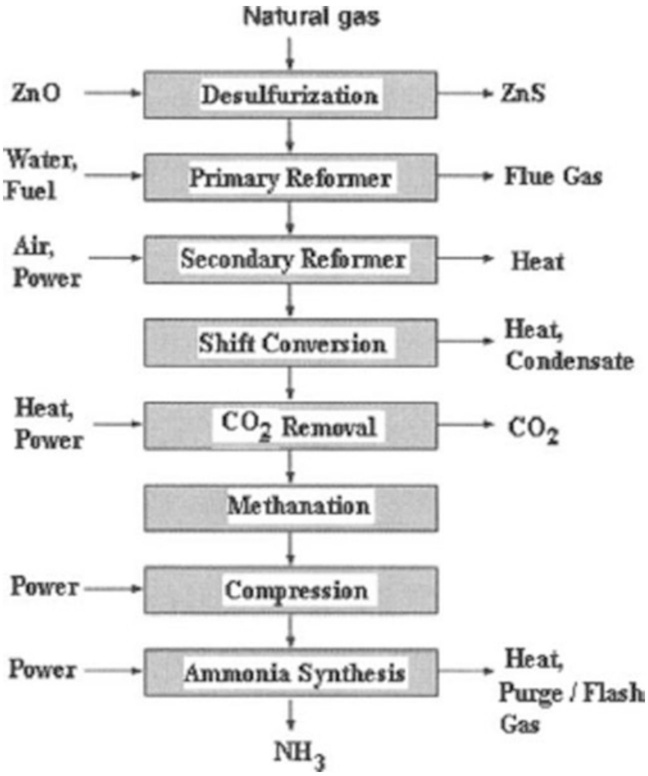

Fig. 22.4 Block diagram of the steam/air reforming process [38] (Used by permission of European Fertilizer Manufacturers Association)

If water is used, the process is called steam reforming or steam cracking. The reforming reaction (22.1) is endothermic and requires a catalyst [3].

$$CH_4 + H_2O \rightleftarrows 3H_2 + CO \quad \Delta H = +49 \text{ kcal/mol or } 205 \text{ kJ/mol} \tag{22.1}$$

Other reactions that proceed at the same time as the reforming reaction are [44]

$$CO + H_2O \rightleftarrows H_2 + CO_2 \quad \Delta H = -10 \text{ kcal/mol or } 42 \text{ kJ/mol} \tag{22.2a}$$

(The Homogenous Water–Gas Reaction or Water–Gas Shift)

$$CH_4 \rightleftarrows 2H_2 + C \quad \Delta H = +17.9 \text{ kcal/mol or } 75 \text{ kJ/mol} \tag{22.3}$$

$$2CO \rightleftarrows CO_2 + C \tag{22.4}$$

Boudouard reaction

$$\Delta H = -41.4 \text{ kcal/mol or } 173 \text{ kJ/mol}$$

The equilibrium composition of the synthesis gas depends on the steam-to-gas ratio entering the reactor, the reaction temperature, the reaction pressure, and the quantity of inerts in the reaction mixture. To avoid carbon formation as indicated by (22.3) and (22.4), the steam-to-gas ratio must be kept high enough to favor the reforming reaction (22.1) and the water–gas shift reaction (22.2a) over the reactions that form carbon.

In 2003, Synetix, a subsidiary of Johnson Matthey, offered for license a large-scale steam reforming process. In this process, hydrocarbon feeds with boiling points up to 200°C can be treated. The process consists of three steps: feed pretreatment, catalytic reforming, and reforming of residual methane. The advantage of the Synetix process is that no soot forms, even with liquid crude oil fractions as feed. This makes catalyst regeneration unnecessary [44]. Because of these advantages, the Synetix technology is used in over 400 reformers in over 30 countries. When North Sea gas and other natural gas reserves around the world were developed, the use of naphtha as a feedstock declined and the need for this technology was reduced.

Feed Pretreatment

The catalysts used in the steam reforming process are poisoned by trace components in the hydrocarbon feed—particularly sulfur, chlorine, and metal compounds. The best way to remove sulfur compounds is to convert the organic sulfur species to H_2S over a hydrodesulfurization catalyst. The next step is sulfur removal with an absorbent. The same catalyst can usually convert any organochloride species to give HCl and also act as an absorbent for most problematic metal species. A second absorbent is used for chloride removal [45].

Prereformer

A prereformer partially completes the steam reforming reactions upstream of the main steam reformer at a much lower temperature by using a more active catalyst. One advantage in new plant designs is that the conventional steam reformer furnace can be smaller [45]. All the ethane, the heavier hydrocarbons, and some of the methane are decomposed endothermically and at temperatures below those in the main reformer. The product gas from the prereformer is an equilibrium mixture of hydrogen, methane, steam, and carbon oxides. The prereformer can reduce fuel consumption by up to 10% and increase throughput by up to 15% [46].

Another advantage is that a prereformer may be preferred in flowsheets for processing heavier feedstocks.

The prereformer converts heavier hydrocarbons to methane before they are fed to the steam reformer. This allows the steam reformer to be designed for methane service. The prereforming catalysts are very sensitive to poisons. Therefore, a good feed purification section is essential [45].

Reformers

Steam reforming refers to the endothermic catalytic conversion of light hydrocarbons in the presence of steam. Catalytic reforming takes place across a nickel catalyst that is packed in tubes in a fired furnace (the "primary reformer") and in the refractory-lined chamber reactor (the "secondary reformer"). This is where hot process air is added to introduce nitrogen into the process. Typical reaction conditions in the primary reformer are 700–830°C and 15–40 bar. Additional details about the primary reformer can be found in [44]. A portion of the primary reformer discharge gas is burned in the secondary reformer with added air or oxygen to give a gas mixture at a temperature of over 1,200°C. Almost all of the methane reacts with steam at this temperature. The methane concentration depends upon the pressure, the temperature, and the quantity of nitrogen and steam present [44].

Reformer Catalysts

The secondary reformer catalyst does not need to be as active as that in the primary reformer. The usual nickel concentration is about 15% in the secondary reformer and 25% in the primary reformer catalyst.

The steam reforming catalyst selection depends on furnace design, feedstock types, and the operating conditions. The main categories of catalyst are for (1) light-duty reforming, (2) intermediate-duty reforming, and (3) heavy-duty reforming. The light-duty catalysts are for natural gas, refinery off-gas, and preformed feeds [45].

Intermediate-duty catalysts are for feeds with a significant content of components from ethanes up to liquid petroleum gas (LPG). Heavy-duty catalysts are primarily for naphtha feeds that have even more tendency for carbon deposition [45].

Silica and silica-bearing materials cannot be used with the shift catalyst. This is because the silica volatilizes and migrates from the hotter zone to lower-temperature zones downstream. Usually it deposits on the waste heat boiler tubes after the secondary reformer.

Normally, the nickel oxide is reduced to nickel and water by the hydrogen that is produced in the operation. In some cases, the reduced nickel can be reoxidized to nickel oxide when large amounts of steam and small amounts of H_2 are present [47]:

$$\mathrm{Ni} + \mathrm{H_2O} \rightleftarrows \mathrm{NiO} + \mathrm{H_2} \tag{22.5}$$

The addition of H_2 to the natural gas feed keeps the nickel in the reduced state, which makes it more active. Also, the hydrogen will retard the formation of nickel sulfide and prevent or minimize poisoning of the catalyst:

$$\mathrm{NiS} + \mathrm{H_2} \rightleftarrows \mathrm{Ni} + \mathrm{H_2S} \tag{22.6}$$

Carbon can also reduce the effectiveness of the catalyst. When conditions are favorable for the following reactions, carbon will deposit on the catalyst:

$$\begin{gathered}\mathrm{CH_4} \rightleftarrows 2\mathrm{H_2} + \mathrm{C} \\ \Delta H = +17.9\ \text{kcal/mol or } 75\ \text{kJ/mol}\end{gathered} \tag{22.3}$$

$$\begin{gathered}2\mathrm{CO} \rightleftarrows \mathrm{CO_2} + \mathrm{C} \\ \Delta H = -41.4\ \text{kcal/mol or } 173\ \text{kJ/mol}\end{gathered} \tag{22.4}$$

Thus, if insufficient steam is present, carbon will be deposited on the catalyst and reduce its effectiveness. Carbon will gasify with steam at 800°C or higher in the reformer:

$$\begin{gathered}\mathrm{C} + \mathrm{H_2O} \rightleftarrows \mathrm{H_2} + \mathrm{CO} \\ \Delta H = +28\ \text{kcal/mol or } 119\ \text{kJ/mol}\end{gathered} \tag{22.2b}$$

Reformer operation and changes in operating rate should always be carried out in a way that ensures sufficient steam is over the catalyst. Thus, if the feed rate is to be increased, the steam rate should be increased first. Conversely, if the feed rate is to be decreased, the natural gas rate should be decreased first.

Reformer Materials of Construction

The primary reformer is a steam–hydrocarbon reforming tubular furnace that is typically externally fired at 25–35 bar and 780–820°C on the process side. From the 1950s through the 1960s, SS 304, SS 310, SS 347, HK 40 alloy, and HP 25/35 modified alloys were used as tube materials. However, these materials developed various operating problems as rates increased and longer service lives were needed for economical operation [48].

HP microalloys were developed during the 1990s. The microalloys enhanced carburization resistance and improved high-temperature creep–rupture resistance [48].

For reformer outlet manifolds, the normal metallurgy choice is a wrought type of Alloy 800 H. Hot reformed-gas transfer lines are usually refractory-lined with an interior of Alloy 800 sheathing [48].

In the secondary reformer, air is added to the process stream at operating conditions of 28–30 bar and 955–1,025°C. The refractory-lined vessel has an outer shell of a low-alloy steel containing 0.5 month. Metal dusting occurs in the secondary reformer outlet sections. With hot gases containing a high CO content, carbon will diffuse into the Fe–Cr–Ni alloy. This phenomenon can lead to local mechanical fracturing of surface layers and failures by pitting [48].

Materials such as SS 304 and Alloy 800 are very susceptible to metal dusting in the range of 500–800°C. Besides temperature, carbon activity (the CO/CO_2 ratio in the gas) and CO partial pressure also affect metal dusting. Severe attacks occur when the carbon activity is in the range of 3–10. Recirculating CO_2 into the primary reformer along with feedstock can maintain a low CO/CO_2 ratio and avoid the severity of this attack. By maintaining a high steam-to-hydrogen ratio in the gas, the metal dusting can also be minimized [48].

Hydrogen embrittlement is another important corrosion problem that is encountered in reformed-gas pipelines. The Nelson curves list the operating limits that should be followed to avoid decarburization and fissuring of steel in hydrogen service [48].

Waste Heat Recovery

The waste heat recovery system is associated with flue gas from the reformer furnace and process gas from the secondary reformer. It generates high-pressure steam in specially designed boilers. Proper material selections and stringent water quality control are two proactive loss-prevention methods [48].

Hydrogen Production Costs and Capital Costs

The theoretical energy requirement per mole of hydrogen produced for the overall steam reforming process is 40.75 kJ/mol of hydrogen [49]. The capital cost for a 60 million SCF/day hydrogen plant, based on steam methane reforming technology, is US$ 1.00 to US$ 1.50 per SCF of hydrogen/day [50].

The cost for making hydrogen by steam reforming of natural gas depends primarily on the cost of natural gas. Several sources estimate the hydrogen production cost, excluding capital charges (in US$ per million BTU of H_2), to be 150% of the natural gas cost (in US$ per million BTU) [50–52].

Other Reforming Processes

The RKN process uses steam reforming to make hydrogen from hydrocarbon gases. This process was developed by Haldor Topsøe in the 1960s. By 1974, 24 plants based on this technology were operating [53].

The SMART (*S*team *M*ethane *A*dvanced *R*eformer *T*echnology) process makes hydrogen by the steam reforming of methane, and it houses the catalyst in a proprietary heat exchanger. The process was developed by Mannesmann KTI in 1996, and the first installation was started up in Maryland in 1998 [53].

The ATR (*a*utothermal *r*eforming) process makes CO-enriched syngas. It combines partial oxidation with adiabatic steam reforming. It was developed in the late 1950s for ammonia and methanol synthesis and then further developed in the 1990s by Haldor Topsøe [53].

The CAR (*c*ombined *a*utothermal *r*eforming) process is used to make syngas from light hydrocarbons, and the heat is provided by partial oxidation in a section of the reactor. It was developed by Uhde and commercialized in Slovakia in 1991 [53].

The KRES (*K*ellogg *r*eforming *e*xchanger *s*ystem) is a reforming process that provides syngas to the KAAP process. The KAAP process is a high-pressure process that makes ammonia from its elements and does not use an iron-containing catalyst. MW Kellogg developed the process in 1990, and Ocelot Ammonia installed the first plant in British Columbia, in 1994 [53]. Another KRES plant started up in 2003 at an NH_3 plant owned by Liaotong in Liaoning Province, China [54].

The *H*aldor *T*opsøe *c*onvection *r*eformer (HTCR) is a relatively small piece of equipment that combines the radiant and waste heat sections of the conventional reformer. It uses PSA to make 99.9% hydrogen purity. It is best for small- and medium-sized hydrogen plants (500–10,000 Nm^3/h) [55].

Reliability and Revamps

Some of the revisions to conventional reforming are listed below.

Decreased Firing in the Primary Reformer. Decreased heat supply in the primary reformer means that the process outlet temperature is lowered to about 700°C, the firing efficiency increases, and the size and cost of the primary reformer are reduced. The milder operating conditions prolong catalyst life, catalyst tube life, and outlet header service life [38].

Increased Process Air Supply to the Secondary Reformer. Decreased heat supply in the primary reformer means that increased internal firing is necessary to achieve approximately the same degree of total reforming. A somewhat higher methane slip (and thus a lower secondary reformer outlet temperature) is acceptable and preferable in this type of process. This is because methane is removed in the final purification [38].

The process air requirement is about 50% higher than in the conventional process. This means increased compression capacity and energy. The process air compressor is usually driven by a gas turbine with the exhaust gas from the turbine being used as combustion air in the primary reformer. Some excess steam is available for export when using a gas turbine [38].

Reformer. Where an increase of 10–50% of existing steam reforming capacity is required, revamping is often more cost effective than a new plant or the purchase of hydrogen over the fence. In most revamps, the reaction area is only slightly affected by operating rate, and existing reactors are often able to operate at increased rate. Existing heat exchangers are often adequate as capacity is increased. However, air coolers in a CO_2 removal unit often need to be modified by adding surface area or increasing fan horsepower [56].

Separation equipment tends to have fixed limits and can be costly to change. However, more capacity can often be obtained by changing column internals or the solvent composition [56].

Radiant Section. Changes in the radiant section can be difficult to justify based on capacity alone. However, if the radiant tubes are near the end of their useful life, an upgrade to this section may provide more capacity. Changes in metallurgy since the mid-1970s have allowed changes in radiant section operating conditions.

Time period	Tube material	Operating pressure (psig)	Operating temperature (°F/°C)
1970s	HK 40	300	1,450/790
1980s	HP	325	1,550/845
1990s	Microalloy	450	1,575/855

The microalloy tubes allow increased flux rates and higher reformer outlet temperatures. This in turn can make it possible to reduce the steam-to-carbon ratio, while the hydrogen purity remains the same [56].

Convection Section. The effects on the reformer of increased gas flow and temperature are multiplied in the convection section because additional load is placed on convection coils, fans, and the steam system. These areas commonly limit the operating rate of the reformer. The tube supports also need to be considered because they are exposed to hot flue gas without the cooling effect of process fluids [56].

One of the most effective reformer modifications is to use heat from the convection section to preheat radiant section feed. This will reduce radiant section heat load, reduce radiant section firing rate, and potentially unload other areas such as steam generation. This option has been used to increase capacity by 10% without increasing the arch temperature in the radiant section [56].

Combustion Air Preheat. Combustion air preheat reduces the flue gas flow through the furnace which unloads the fans and the entire convection section. The best known option is to use heat exchange with flue gas. For new units, this can have the advantage of very high efficiency because the heat sink is ambient air. Another option is the use of steam to preheat air. This option was used to obtain a 12% increase in capacity at the same fuel firing rate and combustion air flow. A third option is to use circulating boiler feedwater to preheat the air [56].

Heat Exchange Autothermal Reforming. A new development in the late 1980s was heat exchange autothermal reforming. In this process, the heat content of the secondary reformer gas is used in a primary reformer with a new design. This reformer is a gas-heated, heat exchange reformer rather than the conventional fired furnace design. Surplus air or oxygen-enriched air is required in the secondary reformer to meet the heat balance in this autothermal concept [38].

Emissions to the atmosphere are reduced significantly by eliminating the flue gas from the primary reformer. NO_x emissions may be reduced by 50% or more compared to conventional steam. The level of NO_x reductions depends on the extent of auxiliary combustion in the plant [38].

Two processes of this kind are in operation, and some others are at the pilot stage. As of 1999, single-train capacities have been limited to 1,000 tons/day or less [38], and four plants had been installed that use Synetix gas-heated reformer (GHR) technology [57].

Synetix developed a modified design of the GHR known as the advanced GHR or AGHR. BHP Petroleum of Australia became the first operator of an AGHR in 1998. The key difference in the AGHR is that it uses a single-pass tube arrangement, whereas the GHR uses a bayonet tube reformer. Based on the experience at BHP Petroleum, the AGHR design results in a reformer that is lower in cost, easier to operate, easier to fabricate, and allows scale-up to capacities in excess of current world-scale throughputs (see Fig. 22.5) [57].

A hydrogen plant based on steam reforming with PSA was installed in Venezuela at the Compagnia Hidrogeno de Paraguana (CHP) plant to supply hydrogen to a refinery. The plant produces 50 million SCFD of hydrogen at 99.5% purity and 400 psig. The plant is a joint venture between BOC and Foster Wheeler and was started up in September 1997. This plant uses 4% less in total fuel for firing and has an installed cost that is approximately 23% below that of other plants of the same size [58].

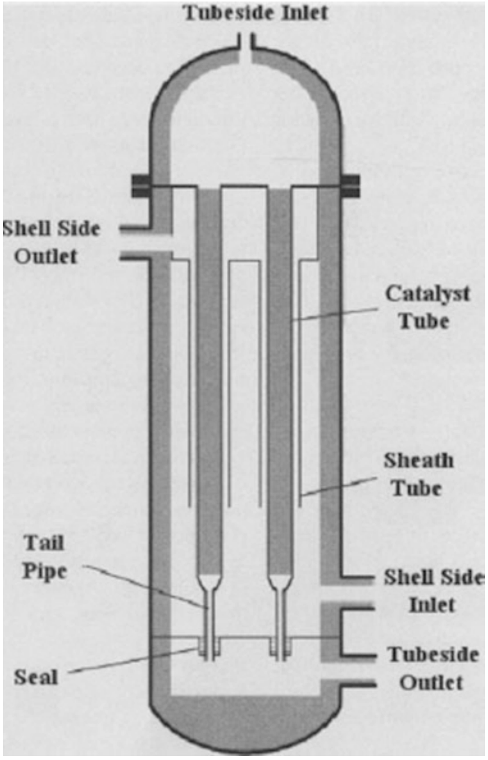

Fig. 22.5 Advanced Gas Heated Reformer (AGHR) from Synetix (Reproduced by permission of Johnson Matthey Catalyst. Copyright Johnson Matthey PLC)

Small-Scale Reforming

Small-scale reforming systems are being pursued by a number of companies developing fuel cell electrical generation systems for home and automotive fuel cell applications. Before these systems become affordable and simple enough to be used as home electrical system components, they may be cost effective for industrial hydrogen supply systems [59].

Small-scale reforming systems are relatively complex because they need fuel and air-feed systems, the reformer, a hydrogen purification system, and various cooling and water processing ancillary systems to make it all work. The systems also have to employ a specific hydrocarbon that is available at a reasonable cost at a customer's location. These systems probably work best for customers with hydrogen consumption rates in the 1,500–10,000 SCF/h range. They are most cost effective when employed to produce hydrogen with a 99.9% or lower assay. As of 2007, small-scale reforming systems have not been commercialized. But they are in the advanced development stage [59].

Technology Suppliers

Companies that provide technology to produce hydrogen via steam reforming are in the United States, Europe, and Japan. Many of these companies are listed in [39].

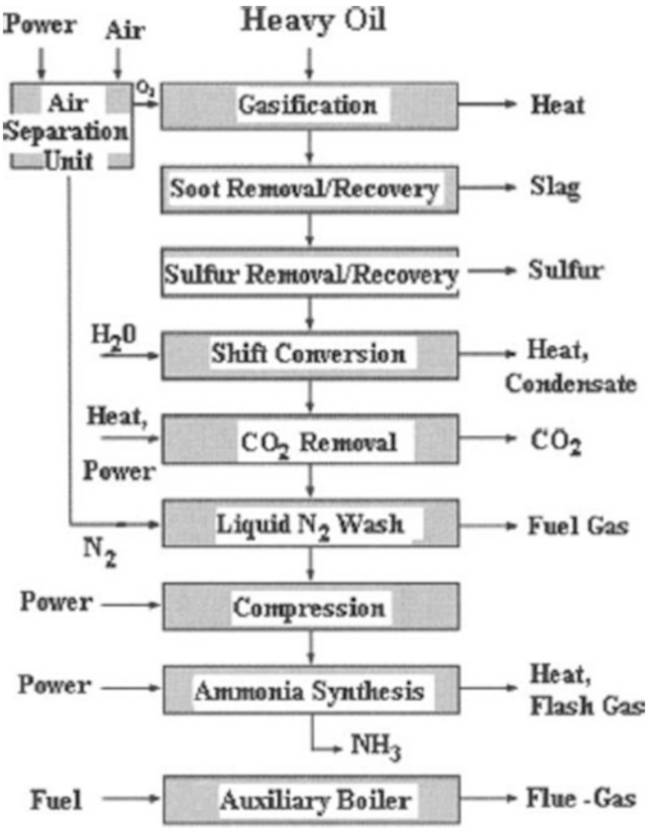

Fig. 22.6 Block diagram of partial oxidation process [38] (Used by permission of the European Fertilizer Manufacturers Association)

Partial Oxidation. Noncatalytic partial oxidation processes (see Fig. 22.6) react hydrocarbons with gaseous oxygen at very high temperatures in a refractory-lined, pressurized reactor to produce synthesis gas. Although the process can handle a wide range of feedstocks, it was developed mainly to utilize the low-value "bottom of the barrel" and waste feedstocks that typically have high-sulfur and high-metal contents [39].

Synthesis gas manufacture by partial oxidation or autothermal cracking of crude oil fractions was developed by BASF/Lurgi, Texaco and Hydrocarbon Research. Heat for the thermal cracking is supplied by partial combustion of the feed in the presence of water. Recycled CO_2 may also be added to the combustion to attain a desired CO/H_2 ratio. Shell developed a modified version (which does not use a catalyst) that is referred to as the gasification process [44].

As illustrated in Table 22.8, the H_2-to-CO molar ratio in the synthesis gas product stream depends on the raw materials and the operating conditions. By burning natural gas with a limited quantity of oxygen, a synthesis gas that has an H_2-to-CO molar ratio of approximately 2:1 can be produced:

$$CH_4 + \frac{1}{2}O_2 \rightarrow 2H_2 + CO \qquad (22.7)$$

Table 22.9 Product gas compositions from various feeds by partial combustion (percent by volume—dry)

Feedstocks and gas components	Nat. gas	Light naphtha	Heavy fuel oil	Vacuum resid.	Propane asphalt	Coal
Hydrogen	61.80	52.09	46.74	44.80	43.69	34.39
Carbon monoxide	33.75	42.59	48.14	49.52	50.09	44.22
Carbon dioxide	3.10	4.88	3.80	4.16	4.45	18.64
Methane	1.00	0.30	0.30	0.30	0.30	0.38
N_2 + A	0.27	0.13	0.23	0.18	0.30	0.68
H_2S	–	0.01	0.76	1.00	1.12	1.46
COS	–	–	0.03	0.04	0.05	0.10
NH_3	–	–	–	–	0.13	–
H_2/CO mol/mol	1.83	1.22	0.97	0.09	0.87	0.78

If steam is introduced into the reaction, the H_2-to-CO molar ratio can be increased to over 2.0. This reaction is exothermic and can reach temperatures of 1,200–1,500°C [60]. Typical operating costs are shown in [39].

If fuel oil or crude oil is used as the raw material in partial combustion, care must be taken to provide for the removal of sulfur compounds and ash-containing materials in the crude oil (see Fig. 22.6). With crude-oil or fuel-oil partial combustion, the carbon content is much greater than in the case of natural gas, and special design considerations are necessary to produce a satisfactory gas.

Typical gas compositions from the partial combustion of various fuels are given in Table 22.9. The nitrogen that is needed to produce the desired H_2/N_2 ratio for ammonia production is usually introduced later in the processing sequence.

Partial Oxidation Processes

The Multipurpose Gasification (MPG) process uses partial oxidation with oxygen to generate synthesis gas from different hydrocarbon feeds. These feeds include natural gas, tars, and other coal gasification residues, refinery residues, asphalts, coal and coke slurries, and chemical wastes. MPG is an updated development based on technology that Lurgi acquired in 1997 from SVZ [61].

The MPG process preheats a gaseous feedstock with hot raw gas and an optional fired preheater. Preheat level and installation of the fired heater are determined by energy and cost optimization, which is based on the relative values of feed, fuel gas, and oxygen. Feed gas and oxygen enter the reactor with a minor amount of steam via the gas burner. Gasification occurs in a refractory-lined reactor at temperatures between 1,200 °C and 1,400°C [61].

The noncatalytic partial oxidation of hydrocarbons by the Shell gasification process (SGP) takes place in a refractory-lined reactor that uses a specially designed burner. The oxidant is preheated and then mixed with steam before it is fed to the burner. The feedstock gasification conditions range from 1,200°C to 1,400°C at a pressure of 50–70 bar, depending on the feedstock [62, 63].

The THGP (*T*exaco *H*ydrogen *G*eneration *P*rocess) makes pure, high-pressure hydrogen from various gaseous and light hydrocarbons. This process can be licensed from the Texaco Development Corporation [3, 64].

Technology Suppliers

The companies that license partial oxidation technology can be found in the United States and Europe. Some of these companies are listed in [39].

Coal and Coke Gasification. In coal gasification, the exothermic partial combustion of carbon and the endothermic water gas formation represent the actual gasification reactions [44]:

$$C + O_2 \rightleftarrows 2CO \quad \Delta H = -60\ \text{kcal/mol or 246 kJ/mol} \\ \text{Partial combustion} \tag{22.8}$$

$$C + H_2O \rightleftarrows H_2 + CO \quad \Delta H = +28\ \text{kcal/mol or 119 kJ/mol} \\ \text{Heterogeneous water gas reaction} \tag{22.2b}$$

Some other important reactions are

$$C + CO_2 \rightleftarrows 2CO \quad \Delta H = +38\ \text{kcal/mol or 162 kJ/mol} \\ \text{Boudouard reaction} \tag{22.9}$$

$$CO + H_2O \rightleftarrows H_2 + CO_2 \quad \Delta H = -10\,\text{kcal/mol or 42 kJ/mol} \\ \text{Homogeneous water gas reaction (water gas shift)} \tag{22.2a}$$

$$C + 2H_2 \rightleftarrows CH_4 \quad \Delta H = -2\,\text{kcal/mol or }87\,\text{kJ/mol} \tag{22.10}$$

Hydrogenative gasification

$$CO + 3H_2 \rightleftarrows H_2O + CH_4 \quad \Delta H = -49\,\text{kcal/mol or }206\,\text{kJ/mol} \tag{22.11}$$

Methanation

Gasification processes can be characterized by the type of coal used and by the coal's physical and chemical properties [44]. Some processes use external heating and others use self-heating. The reactors may be fixed bed, fluidized bed, or entrained bed. The coal gasification processes are described in more detail under "Coal Technology" (Chap. 19).

Sasol (*S*uid-*A*frikaans *S*intetiese *O*lie) in South Africa has one of the largest coal gasification production operations in the world with the three plants [3]. One plant produces only chemicals and the other plants produce both liquid fuels and chemical feedstocks from coal. In 1994, Sasol's total ammonia capacity was over 500,000 tons/year [65].

One of the first coal gasification plants in the United States was the Great Plains Synfuels plant that is operated by Dakota Gasification in Beulah, ND. This plant consumes over 5.5 million tons of coal per year and produces over 54 billion SCF (1.4 billion Nm^3) of natural gas, 365,000 tons/year of ammonia, 24 million gal of liquid nitrogen per year (68 million kg or 150 million lb) plus several other chemicals [66] (see http://www.dakota.com for more details).

In 2000, Farmland Industries in Kansas started up a petroleum coke gasification plant to make ammonia. The plant uses Texaco's process to make 1,000 tons/day of ammonia [67, 68]. In 2004, Rentech purchased an 830-tons-per-day ammonia plant in Illinois and plans to convert it from natural gas to coal feedstock. Startup of the conversion is expected in 2007 [69].

By-product Hydrogen. Large volumes of by-product hydrogen are generated from a variety of production processes. Some of these processes are listed in [39]. Some of the processes that can be used to obtain purified hydrogen are summarized below.

The HyTex (*H*ydrogen *T*exaco) process makes pure hydrogen from waste gases in oil refineries in a three-step process [3]. The process was developed by Texaco and announced in 1991. The first commercial unit started up in Anacortes, WA, in 1993.

Platforming operations make a gas that contains as much as 90–95% hydrogen. This gas is usually purified by low-temperature fractionation or washing with liquid nitrogen.

Kvaerner Oil & Gas, Norway, has introduced a process for manufacturing carbon black that generates substantial quantities of by-product hydrogen. In 1998, the process was installed in Montreal, Québec (Canada), to produce 20,000 tons of carbon black and 50 million Nm^3/year (5.2 million SCF/day) of hydrogen. The process appears to be economic only when the carbon black can also be sold as an end product [39].

Air Products and Chemicals, Inc. has been selected to supply a hydrocarbon and nitrogen recovery system for a new polyethylene manufacturing plant in Baytown, TX. The plant will be owned by Chevron Phillips Chemical Company and Solvay Polymers, Inc. The recovery system uses partial condensation in conjunction with Air Products' PSA technology to recover hydrocarbons in the polyolefin plants and recycle nitrogen with a purity of greater than 99% [70].

A few ammonia plants have been located where a hydrogen off-gas stream is available from a nearby methanol or ethylene operation (e.g., Canadian plants at Kitimat, BC, and Joffre, AB). The capital cost of such a plant is about 50% of the cost of a conventional plant of similar capacity because only the synthesis portion of the plant is required. However, by-product carbon dioxide is not produced, and downstream urea production is therefore not possible [71].

Electrolysis. Electrolytic hydrogen production yields the highest-purity hydrogen (up to 99.999%), benefits from widespread raw materials availability (electricity and water), boasts simple system architecture, and can be scaled economically to serve applications ranging from the smallest hydrogen uses to the larger-volume uses. The main disadvantage of water electrolysis is that electricity is an expensive "fuel." As a result, the technology generally is practical only for systems with hydrogen requirements of 2,000 SCF/h and less [59].

By 2002, several manufacturers had introduced advanced water electrolysis systems that are standardized, compact in size, need minimal operator intervention, and require little maintenance. New cell designs, materials of construction, standardized designs, and manufacturing techniques have enabled manufacturers to decrease the fixed costs of electrolysis technology. In addition, these new systems operate automatically and require very little maintenance [59, 72].

Developing regions are the largest market for electrolysis systems. Electrolysis currently accounts for a very small portion of the hydrogen generated in developed countries that have a commercial hydrogen infrastructure. However, electrolysis can be economic for small-scale generation in areas with inexpensive electricity, and a few plants still produce hydrogen for small-volume ammonia production [36]. In 1997, Messer-MG Industries announced two hydrogen gas plants based on water electrolysis in the United States. In Canada, a portion of the capacity installed at HydrogenAl's merchant hydrogen plant in Québec is based on electrolytic cells [39]. Some of the companies that offer electrolysis technology are listed in [39].

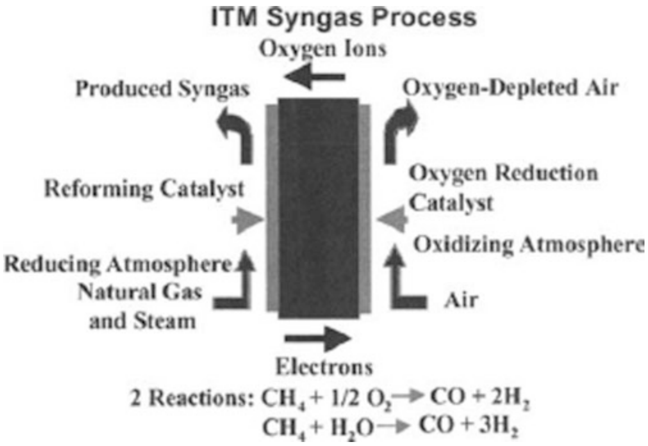

Fig. 22.7 ITM syngas process

Other Processes [3]. The Hypro process makes hydrogen by catalytically decomposing hydrocarbons to carbon and hydrogen. The carbon is burned to provide the heat for the reaction. This process was developed by UOP.

The Lane process makes hydrogen by passing steam over sponge iron at approximately 650°C. The iron is converted to magnetite.

The MRH (*m*ethanol *r*eformer *h*ydrogen) process for generating hydrogen from methanol and separating it by PSA was developed by the Marutani CPE Company.

The Proximol process makes hydrogen by reforming methanol. This technology is offered by Lurgi.

The SBA-HT (*S*ociété *B*elge de l' *A*zote–*H*aldor *T*opsøe) process is a combination of both steam reforming and partial oxidation. The process converts LPG to syngas that is rich in hydrogen. This process was operated in France and Belgium in the 1960s.

New Developments. Several research organizations are developing low-cost methods of hydrogen production. Much of this work is sponsored by the US Department of Energy. Some of the research programs can be found in [73].

The ITM Syngas process involves the direct conversion of methane to synthesis gas (see Fig. 22.7). The process utilizes a mixed, conducting ceramic membrane and partial oxidation to produce the synthesis gas [39]. The goal of this advanced reformer technology is to reduce the cost of hydrogen production by over 25% [73, 74].

Two projects were announced in the late 1990s to develop the ITM process and another related technology. Air Products will lead an 8-year, US$ 90 million research project that is supposed to culminate in the construction in 2005 of a 500 million SCFD ITM process development unit [39]. A separate Oxygen Transport Membrane (OTM) Syngas alliance was formed in 1997 to develop ceramic membrane technology for conversion of natural gas to synthesis gas [75].

Another process is the CO_2-free production of hydrogen via thermocatalytic decomposition of hydrocarbon fuels. The process involves a single-step decomposition of hydrocarbons over carbon catalysts in an air- and water-free environment. Preliminary assessments of the process indicated that hydrogen could be produced at a cost of US$ 5.00 per million BTU (if carbon sold at US$ 100/ton). This production cost is less than that for a steam reforming process coupled with CO_2 sequestration [49].

Some additional new developments in hydrogen production are summarized below.

NGK Insulators of Japan received US Patent 5,741,474 in 1998 for a process for production of high-purity hydrogen. This process is a combination of reforming, partial oxidation, and membrane separation.

Northwest Power Systems obtained US Patent 5,997,594 in 1999 for a steam reformer with internal hydrogen purification.

BP and Kvaerner process are finalizing the demonstration of their compact reformer technology in 2001. This technology involves the integration of combustion, heat transfer, and catalytic reaction within a simple tubular module [76].

Battelle Pacific Northwest National Laboratories are developing microreactors that produce synthesis gas. These reactors can be mass-produced to yield efficient, compact, and cost-effective systems [77].

A related effort is FORSiM (*f*ast *o*xidation *r*eaction in *S*i-technology-based *m*icroreactors) which is funded by the Dutch Technology Foundation and is a cooperative venture between the University of Twente and the Technical University of Eindhoven. The objective of this work is to build and operate the first microreactor for catalytic partial oxidation for small-scale and on-demand hydrogen production [77].

Initial Purification of Synthesis Gas

Synthesis gas from the gasification of fossil fuels is contaminated by several gaseous compounds that would affect its further use in different ways. The purification steps depend on the type of syngas process and the feedstock. Table 22.9 illustrates how the synthesis gas stream can vary with different feedstocks. Figure 22.8 illustrates the different process steps that may occur before ammonia synthesis takes place [78].

If sulfur is present as H_2S or COS, it is a poison for many catalysts and will partly or completely inhibit the catalyst activity [44]. Carbon monoxide (CO) and carbon dioxide (CO_2) can poison the ammonia synthesis catalyst, so both of these compounds must be removed [38].

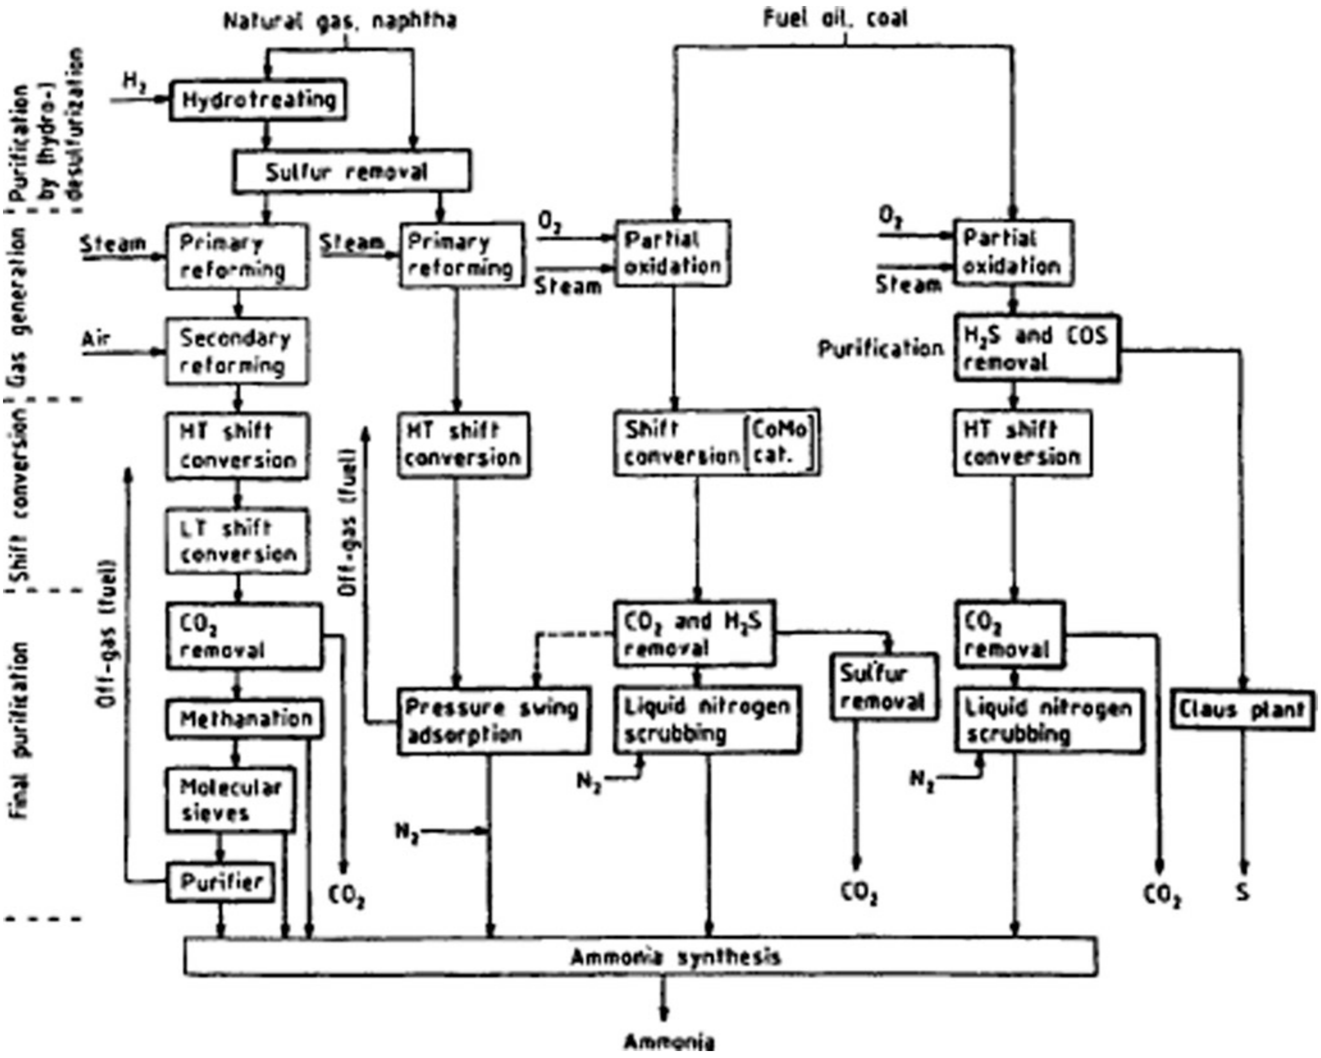

Fig. 22.8 Alternative process steps for generation and purification of synthesis gas (Courtesy of Wiley-VCH. Bakemeier H, Huberich T et al (1985) Ammonia. In: Ullmann's encyclopedia of industrial chemistry, 5th edn, vol A2. VCH Verlagsgesellschaft, Weinheim, pp 143–242)

Table 22.10 Hydrogen recovery technology characteristics [39, 184]

Characteristic	Membrane	Absorption	Cryogenics
Hydrogen purity, %	<95	99.9+	95–99
Hydrogen recovery, %	<90	75–90	90–98
Hydrogen product pressure	<Feed pressure	Feed pressure	Variable
By-products available	No	No	Yes
Feed pressure, psig	250–1,800		250–500

After the sulfur is removed, most traditional ammonia processes have employed the purification steps that are shown in Figs. 22.4 and 22.6. However, ammonia plants have been built that use hydrogen purification via PSA, membrane separation with polymeric membranes, and cryogenic separation. PSA achieves the greatest product purities (about 99.999% pure hydrogen), but it is capital-intensive. Polymeric membranes are the least capital-intensive, but they achieve the lowest purity (about 96–98%). In 1998, PSA was considered the standard process for high-purity hydrogen recovery from raw synthesis gas. It has replaced the traditional steps of the shift conversion of carbon monoxide followed by carbon dioxide removal by absorption and then final purification by methanation. Characteristics of these three purification technologies are outlined in Table 22.10 [39].

Purification with PSA and Polymeric Membranes. The PSA process is based on the selective adsorption of gaseous compounds on a fixed bed of solid adsorbent in a series of identical adsorption beds. The adsorbent is an active carbon or a carbon molecular sieve. Each bed undergoes a repetitive cycle of adsorption and regeneration steps [79, 80]. PSA provides the hydrogen at about the same pressure as the feed, but recoveries are typically lower than from other technologies [51].

The first purification plant that used PSA was developed by Union Carbide Corporation (UCC) and was built at the Yokkaichi Plant of Mitsubishi Petrochemical Industries in 1971 [5]. The process is now licensed by UOP, and more than 400 units were operating worldwide in 1992 [3].

The HYSEC process was developed by Mitsubishi Kakoki K. and Kansai Coke & Chemicals. It has basically the same PSA unit as the UCC process. After the main PSA beds, trace amounts of remaining oxygen are removed by a Deoxo catalytic converter followed by a zeolitic dehumidifier [5].

The LO-FIN (*L*ast *O*ut–*F*irst *I*n) includes a unique gas-retaining vessel that preserves the concentration gradient in one stream before using it to repressurize another bed. This process was jointly developed by Toyo Engineering and Essex Corporation [5].

The Sumitomo-BF PSA process uses CMS as the selective adsorbent [5].

Monsanto and Ube (Japan) developed membrane processes for purification of hydrogen gas mixtures. This process is based on the selective diffusion of hydrogen through semipermeable membranes in the form of hollow fibers. The Monsanto PRISM® separator process (owned by Air Products as of 2004) uses a polysulfone fiber, whereas Ube uses an aromatic polyimide fiber [44].

Conventional polymeric hydrogen separation membranes yield hydrogen at low pressure. Air Products has demonstrated a carbon membrane on an alumina support that removes hydrocarbons from hydrogen/hydrocarbon mixtures and leaves the hydrogen at high pressure [39].

For ultra-high-purity hydrogen (up to 99.9999% pure), high-pressure gas passes over heated palladium membranes. Johnson Matthey is believed to be the leading supplier of these membranes. In 1996, Generex (Tryon, NC) licensed newly developed palladium membrane technology from Los Alamos National Laboratories. In 1998, Wah Chang, an Allegheny Teledyne Company, purchased all patents and rights to the hydrogen metal membrane technology that Bend Research developed [39].

US Patent 6,183,542 was issued in 2001 for a palladium membrane process. This process provides an apparatus that can handle high flow rates of gas while using a minimal amount of hydrogen-permeable material.

Proton Energy Systems (Rocky Hill, CT) received US Patent 6,168,705 in 2001 for an electrochemical gas purifier system that can purify and simultaneously compress hydrogen from a dirty gas stream without relying on moving parts. Final hydrogen gas pressures can exceed 2,000 psig.

The companies that supply PSA and membrane separation systems are listed in [39].

Carbon Monoxide Shift. The water–gas shift conversion or the carbon monoxide shift reaction is one of the traditional purification steps that are found in many ammonia plants. The CO must be removed because it acts as a poison to the catalyst that is used in ammonia synthesis.

The carbon monoxide shift removes most of the CO from the synthesis gas and also produces more hydrogen:

$$\mathrm{CO} + \mathrm{H_2O} \rightleftarrows \mathrm{H_2} + \mathrm{CO_2} \quad \Delta\mathrm{H} = -10\,\mathrm{kcal/mol\ or\ 42\,kJ/mol}$$
$$\text{Homogenous water gas reaction (water gas shift)} \tag{22.2a}$$

The "shift" from CO to CO_2 occurs in two steps. In the high-temperature shift (HTS) conversion, the synthesis gas is passed through a bed of iron oxide/chromium oxide catalyst at around 400°C. The CO content of the gas is reduced to about 3% (on a dry-gas basis). Additional details about the HTS step are given in [38, 45].

The gas from the HTS is cooled to increase the conversion, and then it is passed through the low-temperature shift (LTS) converter. The LTS converter is filled with copper oxide/zinc oxide–based catalyst and operates at about 200–220°C. The residual CO content is about 0.2–0.4% (on a dry-gas basis) [38].

In some plants, the two shift reactions are combined in a medium-temperature shift conversion. When the feed gas is not desulfurized, the CO conversion is called sour–gas shift, and a sulfur-resistant catalyst is used [81–86].

Removal of Sulfur Compounds and Carbon Dioxide. If sulfur is present as H_2S or COS or if CO_2 is present, any of these compounds will be a poison for many catalysts and will partly or completely inhibit catalyst activity.

The point at which sulfur removal is employed depends on the synthesis gas process that is used. Table 22.11 lists many of the processes that are available [44].

The Amine Guard is a corrosion inhibitor that was developed by Union Carbide. It is added to the monoethanolamine (MEA) solvent and allows MEA concentration to be increased. The higher MEA concentration leads to a lower circulation flow rate and a lower energy demand during regeneration [78].

As shown in Figs. 22.4, 22.6, and 22.8, the CO_2 removal step is normally after the shift conversion step. The process gas from the LTS converter contains mainly hydrogen, nitrogen, CO_2, and excess process steam. The gas is cooled, and most of the excess steam is condensed before it enters the CO_2 removal system. This condensate normally contains

Table 22.11 Processes for removal of carbon dioxide and sulfur compounds from synthesis gas

Process name	Key chemical(s)
The Alkazid process	Alkali salts of amino acids (*N*-methylaminopropionic acid)
The aMDEA process	Activated methyl diethanolamine
The Benfield process	Hot potassium carbonate
The Carsol process	Potassium carbonate
The Catacarb process	Hot potassium carbonate
The Fluor Solvent process	Propylene carbonate
The Giammarco-Vetrocoke process	Potassium carbonate with arsenite
The Hi Pure process	Two-stage hot potassium carbonate washing
The Purisol process from Lurgi	*N*-Methyl-2-pyrrolidone (NMP)
The Rectisol process	Low temperature methanol
The Selexol process	Dimethyl ethers of polyethylene glycol
The Shell Sulfinol process	Di-isopropanolamine dissolved in sulfolane and water
Pressurized washing	Monoethanolamine (MEA) or diglycolamine

1,500–2,000 ppm of ammonia and 800–1,200 ppm of methanol. Therefore, it should be stripped or recycled.

The heat that is released during the cooling/condensation can be used to regenerate CO_2 scrubbing solution, to drive an absorption refrigeration unit, or to preheat boiler feedwater. The amount of heat released depends on the process steam-to-carbon ratio (see Tables 22.8 and 22.9). If all this low-level heat is used for CO_2 removal or absorption refrigeration, then high-level heat has to be used for the feedwater system. An energy-efficient process should therefore have a CO_2 removal system with a low-heat demand [38].

The CO_2 is removed in either a chemical, a hybrid, or a physical absorption process. Residual CO_2 contents are usually in the range of 50–1,000 ppmv, depending on the type and design of the removal unit. The physical absorption processes may be designed for zero heat consumption. But for comparison with the chemical processes, the mechanical energy requirements have to be considered [38].

Alkazid Process

The Alkazid process removes sulfur compounds from gas streams. All the sulfur compounds are first catalytically hydrogenated to hydrogen sulfide (H_2S) using a cobalt/molybdena catalyst. The H_2S is then absorbed in an aqueous solution of a potassium salt of either methylamino propionic acid ("Alkazid M") or dimethylamino acetic acid ("Alkazid DIK"). This solution is heated to regenerate the hydrogen sulfide as a concentrate. This concentrate is then treated by the Claus process to recover the sulfur [3].

aMDEA Process

The aMDEA (*a*ctivated *m*ethyl*d*iethanolamine) process removes CO_2, H_2S, and trace sulfur compounds from natural gas and syngas via a pressurized wash with activated diethanolamine. This process was developed by BASF, and in 2002, it was used in more than 140 plants [3].

Benfield Process

The Benfield (*B*enson and *F*ield) process removes carbon dioxide, H_2S, and other acid gases from industrial gas streams by scrubbing with hot aqueous potassium carbonate that contains activators. The chemical reactions are [3, 44]

$$K_2CO_3 + CO_2 + H_2O \rightleftarrows KHCO_3 \quad (22.13)$$

$$K_2CO_3 + H_2S \rightleftarrows KHS + KHCO_3 \quad (22.14)$$

Process details are given in [48, 87]. The process was invented in 1952 and is now licensed by UOP. More than 700 plants were operating in 2000 [3].

Catacarb Process

The Catacarb (*cata*lyzed removal of *carb*on dioxide) process removes carbon dioxide and hydrogen sulfide from gas streams by adsorption in a hot potassium carbonate solution that contains a proprietary catalyst. The process was developed and licensed by Eickmeyer and Associates based on work at the US Bureau of Mines in the 1950s. More than 100 plants were operating in 1997 [3].

Fluor Solvent Process

The Fluor Solvent process removes CO_2 from natural gas and various industrial gas streams by dissolving the CO_2 in a propylene carbonate solvent [3]. Additional details are given in [88, 89]. The process was invented in 1958 by the Fluor Corporation and can be licensed from Fluor Daniel. By 1985, 13 plants were operating [3].

Giammarco-Vetrocoke Process

Two processes are known by the Giammarco-Vetrocoke name. Both processes use an aqueous solution of sodium or potassium carbonate and arsenite to absorb acid gases. Some variations of the process use glycine instead of arsenite to activate the potassium carbonate solution. In one process, the solution is used to extract carbon dioxide from natural gas or synthesis gas. In the other, hydrogen sulfide is extracted from coke-oven or synthesis gas and yields elemental sulfur from a complex sequence of reactions. In 1992, more than 200 plants were operating [3, 90].

Hi Pure Process

The Hi Pure process is a variation of the Benfield process. It uses two stages of scrubbing by hot potassium carbonate solution to reduce the CO_2 content of gases to very low levels [3].

Purisol Process

The Purisol process removes H_2S from gases by selective absorption in *N*-methyl-2-pyrrolidone (NMP). It was developed and licensed by Lurgi, particularly for desulfurizing waste gases from IGCC (*i*ntegrated *g*asification *c*ombined *c*ycle) coal gasification plants. However, the technology might be applied to some synthesis gas processes. In 1996, seven Purisol units were either in operation or under construction [3].

Rectisol Process

The Rectisol process was originally developed to remove sulfur and acid gas compounds from gas mixtures that are produced from the partial oxidation of hydrocarbons. It is based on pressurized washing with low-temperature methanol, which results in the physical absorption of the sulfur compounds in the methanol. The process was originally developed in 1951 by Lurgi for the SASOL coal gasification plant in South Africa. The process was further developed by Linde and is now offered for licensing by both companies for the removal of CO_2, H_2S, HCN, C_6H_6 (benzene), and gum-forming hydrocarbons from syngas and fuel gas. In 2003, over 70 units were in operation or under construction [3].

Selexol Process

The Selexol process removes acid gases from hydrocarbon gas streams by selective absorption in polyethylene glycol dimethyl ether (DMPEG). It absorbs H_2S, CO_2, COS, and mercaptans. The process has been used to remove carbon dioxide from syngas, natural gas, and coal gas. The process was developed by Allied Chemical in the 1960s and is now offered for license by UOP. Over 55 units were operating in 2002 [3].

Shell Sulfinol Process

The Shell Sulfinol process removes H_2S, CO_2, COS, and organic sulfur compounds from natural gas by scrubbing with di-isopropanolamine dissolved in a mixture of sulfolane ($C_4H_8SO_2$) and water. It was developed in the 1960s by Shell. In 1997, over 200 commercial units were operating or under construction [3].

Pressure Washing with Monoethanolamine

In this process, a 15–30% solution of MEA in water is used to absorb the CO_2 under pressure. The solution is then regenerated by heating it in a stripper to release the CO_2. This process is characterized by good CO_2 absorption properties at low pressure. However, high regeneration energy consumption limits its use.

If the Amine Guard corrosion inhibitor is used, the MEA concentration in the circulating solution can be increased to 30% from a normal 20%. Hence, the circulating rate can be decreased by 33%, and the heat requirements are decreased by 43% [91]. The Amine Guard technology is licensed by UPO [92].

Retrofits of CO_2 Removal System

In a CO_2 removal system that uses wet scrubbing, the existing towers are the major limit to more capacity because they are expensive to replace. In an amine system, absorption increases as amine concentration increases. But a higher amine concentration requires (1) more filtration to clean the solution and (2) the addition of corrosion inhibitors. Another option is to change from MEA to methyl diethanolamine (MDEA) [56].

In a potassium carbonate system, different additives can be used to increase the CO_2 absorption rate. In any wet scrubbing system, a change from random to structured packing can lead to higher solvent circulation rates and improved mass transfer [56].

Final Purification of Synthesis Gas

Before the synthesis gas enters the ammonia synthesis loop, essentially all of the oxygen compounds must be completely removed to (1) avoid poisoning the ammonia synthesis catalyst and (2) keep CO_2 from forming carbamates and ammonium carbonate in the synthesis loop. It is also advantageous to remove the inert gases (methane, argon, etc.) to achieve a higher synthesis conversion per pass [78].

Methanation. In a steam reforming process that includes CO shift conversion and CO_2 removal, the synthesis gas still contains 0.1–0.2 mol.% CO and 100–1,000 ppmv of CO_2. The following reactions are the simplest method for eliminating these small concentrations of oxygen compounds:

$$\begin{aligned} &CO + 3H_2 \rightleftarrows H_2O + CH_4 \\ &\quad \Delta H = -49.27\,\text{kcal/mol or } 206\,\text{kJ/mol} \end{aligned} \tag{22.11}$$

$$\begin{aligned} &CO_2 + 4H_2 \rightleftarrows 2H_2O + CH_4 \\ &\quad \Delta H = -39.44\,\text{kcal/mol or } 165\,\text{kJ/mol} \\ &\quad \text{Methanation} \end{aligned} \tag{22.12}$$

The normal methanation operating temperature is 250–300°C, and a large excess of hydrogen is present. The equilibrium lies far to the right side of the above reactions, so the CO and CO_2 impurities can be reduced to about 5 ppm [45]. Additional catalyst and process details are given in [55, 78, 93, 94].

Cryogenic Purification. In the cryogenic purifier, all the methane and the excess nitrogen are removed from the synthesis gas as well as a part of the argon. The cooling is produced by depressurization, and no external refrigeration is needed. The purified syngas is then practically free of all impurities, except for a small amount of argon. The cryogenic unit also receives the purge from the ammonia synthesis section and delivers an off-gas for fuel. The combination of higher conversion per pass and reduced purge flow results in a more efficient process [38]. The KBR Purifier is an example of this process [95]. Fifteen KBR Purifier plants have been built since 1966. These plants range in capacity from 680 to 1,750 tons/day, and as of 2001, all 15 plants are still operating [95].

Dehydration. If the makeup gas to the ammonia synthesis loop is absolutely free of catalyst poisons, such as H_2O and CO_2, it can flow directly to the ammonia synthesis converter. This leads to the most favorable arrangement from a minimum energy point of view. This can be accomplished by allowing the gas that leaves the methanation step to pass through beds of molecular sieves to remove water and CO_2 [78].

Liquid Nitrogen Wash. In many partial oxidation syngas processes, liquid nitrogen scrubbing is used to remove the carbon monoxide that remains after the shift conversion step. The CO content may be as high as 3–5% in plants that have only an HTS conversion. The liquid nitrogen wash (1) delivers a gas to the ammonia synthesis loop that is free of all impurities (including inert gases) and (2) adds all or part of the nitrogen that is required for ammonia synthesis. The nitrogen is obtained from the air-separation plant that provides the oxygen for the partial oxidation process (see Fig. 22.6) [78].

Adjust Hydrogen-to-Nitrogen Ratio. The optimum ammonia synthesis reaction rate depends on several factors including pressure, temperature, H_2-to-N_2 molar ratio, and catalyst activity. Therefore, the H_2-to-N_2 molar ratio is adjusted to suit the requirements in ammonia synthesis. This adjustment occurs before the compression step.

Compression

Ammonia synthesis is normally carried out at a pressure that is higher than that for synthesis gas preparation. Therefore, the purified synthesis gas to the ammonia synthesis loop must be compressed to a higher pressure [78].

Due to several major developments in ammonia process technology, ammonia plants with 1,000–1,500 tons/day capacities have become the industry standard for new plant construction. In 2001, plants as large as 2,000 tons/day have become common. These plants have much lower production costs than the earlier generation of smaller plants mainly because steam-driven, centrifugal compressors are used rather than electrically driven, reciprocating compressors [36, 78].

Ammonia Synthesis

The ammonia synthesis reaction is [78]

$$\begin{aligned} &N_2 + 3H_2 \rightleftarrows 2NH_3 \\ &\quad \Delta H_{298} = -45.72\,\text{kJ/mol or } 11.04\,\text{kcal/mol} \end{aligned} \tag{22.15}$$

The reaction normally takes place on an iron catalyst. The reaction pressure is in the range of 100–250 bar, and temperatures are in the range of 350–550°C. At the usual commercial converter operating conditions, the conversion achieved per pass is 20–30% [38]. In most commercial ammonia plants, the Haber recycle loop process is still used to give substantially complete conversion of the synthesis gas. In this process, the ammonia is separated from the recycle gas by cooling and condensation. Next, the unconverted synthesis gas is supplemented with fresh makeup gas and returned as feed to the ammonia synthesis converter [78].

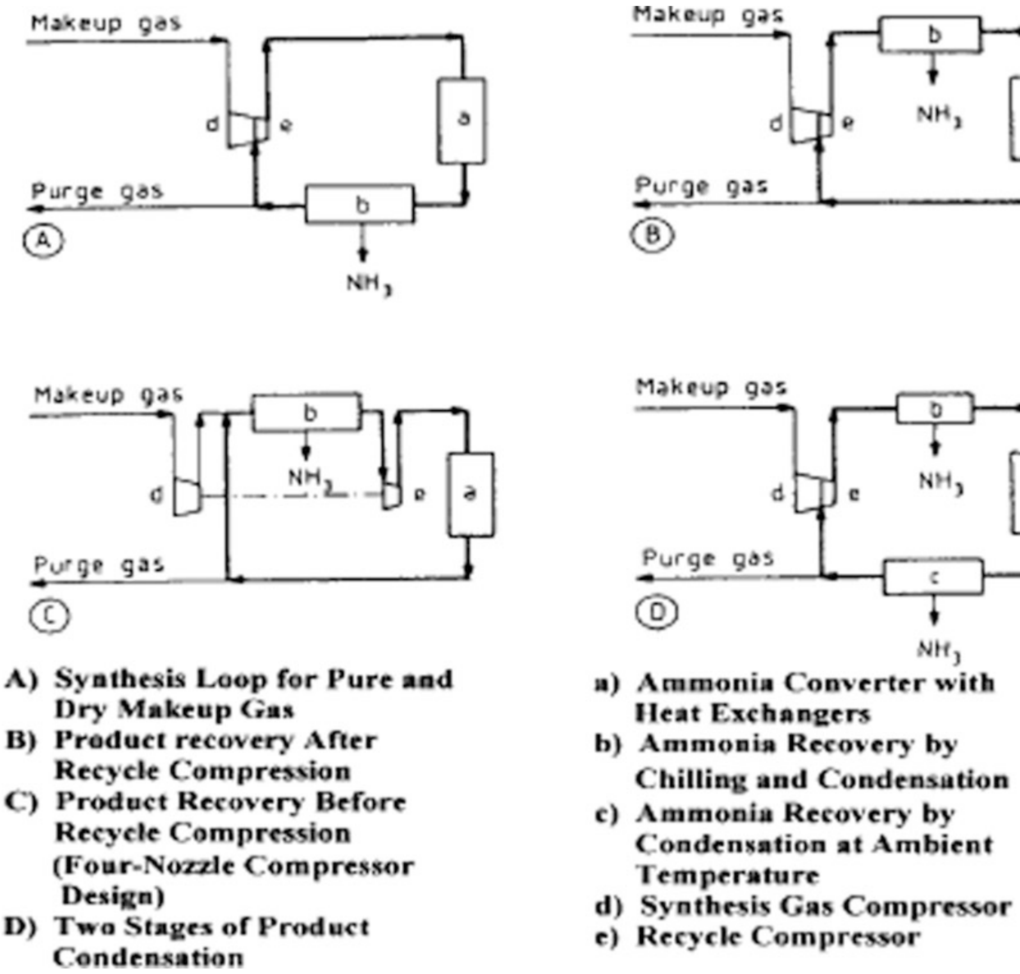

Fig. 22.9 Schematic flow diagrams of typical ammonia synthesis loops [78] (Courtesy of Wiley-VCH. Bakemeier H, Huberich T et al (1985) Ammonia. In: Ullmann's encyclopedia of industrial chemistry, 5th edn, vol A2. VCH Verlagsgesellschaft, Weinheim, pp 143–242)

Synthesis loop arrangements differ with respect to (1) the points in the loop at which the makeup gas is delivered, (2) where the ammonia is taken out, and (3) where the purge gas is taken out [38] (see Fig. 22.9). The best arrangement is shown in Fig. 22.9a. After the gas leaves the ammonia synthesis converter, ammonia is condensed/removed by cooling and the recycle gas is returned to the recycle compressor. This represents the most favorable arrangement from a minimum energy point of view. It results in the lowest ammonia content at the entrance to the converter and the highest ammonia concentration for condensation [78]. The advantages and disadvantages of the other arrangements in Fig. 22.9 are described in [78].

Conventional reforming with methanation as the final purification step produces a synthesis gas that contains inerts (CH_4 and argon) in quantities that do not dissolve in the condensed ammonia. Most of the inerts are removed by taking a purge stream out of the synthesis loop. The size of this purge stream controls the level of inerts in the loop at about 10–15%. The purge gas is scrubbed with water to remove ammonia, and then it can be used as fuel or sent to hydrogen recovery. The best point at which to take the loop purge is discussed in [38].

Reaction Rate

Knowledge of the macrokinetics is important for solving the industrial problem of designing ammonia synthesis reactors, for determining the optimal operating conditions, and for computer control of ammonia plants. Some of the considerations are as follows: high pressure promotes a high rate of ammonia formation, high ammonia concentration in the synthesis gas (recycle gas) restricts ammonia formation (see Fig. 22.10), the rate of formation initially increases with rising temperature but then goes through a maximum as the system approaches thermodynamic equilibrium (see Fig. 22.11), and with lower temperatures, the maximum rate shifts to a lower hydrogen–nitrogen ratio (see Fig. 22.12) [78].

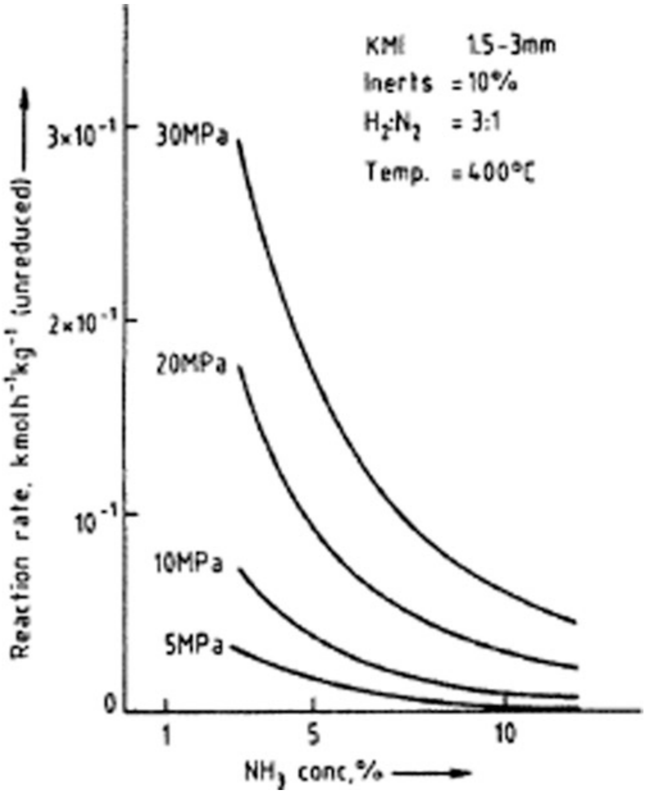

Fig. 22.10 Reaction rate for NH_3 synthesis. Dependence on the ammonia concentration at various pressures (Courtesy of Wiley-VCH. Bakemeier H, Huberich T et al (1985) Ammonia. In: Ullmann's encyclopedia of industrial chemistry, 5th edn, vol A2. VCH Verlagsgesellschaft, Weinheim, pp 143–242)

In 2001, Hyprotech and Synetix announced an ammonia plant simulation that can be used for modeling, online monitoring, and optimization of the plant. The simulation includes Synetix reactor models, customized thermodynamic data, and information to simulate the performance of a range of catalysts. The reactor models in the simulation include primary and secondary reformers, high-temperature shift converter, low-temperature shift converter, methanator, and ammonia synthesis converter [96].

Catalysts

When ammonia is made from natural gas using the steam reforming process, several reaction stages are needed and catalysts are key to the economic operation of each stage. The chemistry of the process and the basic materials that make up the catalysts are shown in Fig. 22.13 [45].

For a given operating pressure and a desired production rate, the catalyst determines (1) the operating temperature range, (2) recycle gas flow, and (3) refrigeration requirements. It also indirectly influences the makeup gas purity requirements [78].

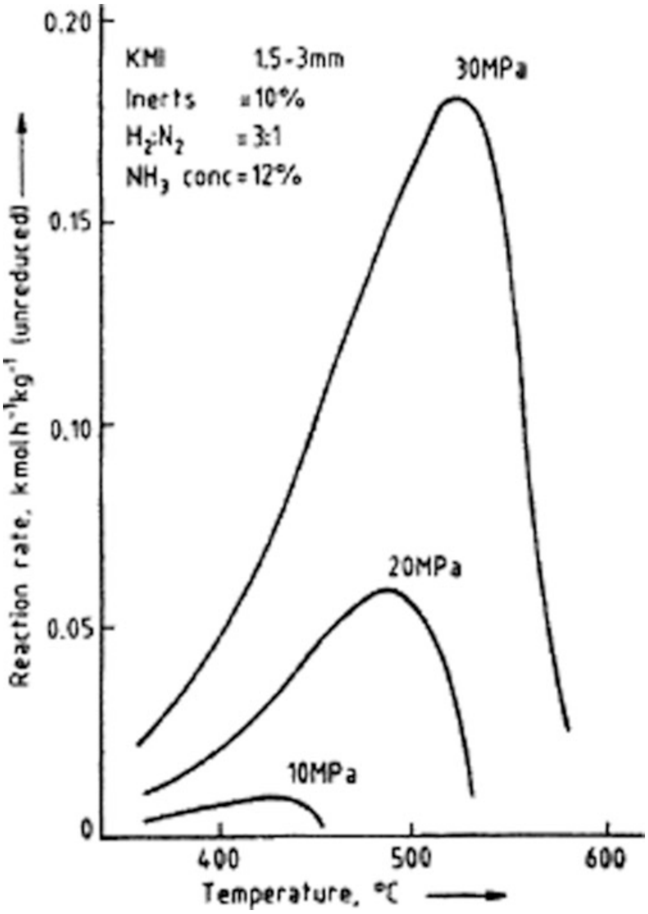

Fig. 22.11 Reaction rate for NH_3 synthesis. Dependence on the temperature at various pressures (Courtesy of Wiley-VCH. Bakemeier H, Huberich T et al (1985) Ammonia. In: Ullmann's encyclopedia of industrial chemistry, 5th edn, vol A2. VCH Verlagsgesellschaft, Weinheim, pp 143–242)

Industrial catalysts for ammonia synthesis must satisfy the following requirements: (1) high catalyst activity at the lowest possible reaction temperatures, (2) the highest possible insensitivity to oxygen- and chlorine-containing catalyst poisons, (3) long life, and (4) mechanical strength.

The choice of particle size and shape of commercial ammonia catalysts is determined mainly by the catalyst performance and the pressure drop. From the standpoint of space–time yield, it is desirable to use the finest possible particle, which is about 1–2 mm [78].

For processes operating at pressures of 25–45 MPa (250–450 bar) and space velocities of 8,000–20,000 m^3/m^3 h (STP), a grain size of 6–10 mm is preferred. (Space velocity is defined as the number of reactor volumes of feed—at specified conditions—that can be treated in unit time.) Larger granulations (8–15 or 14–20 mm) are used only in plants where the lowest possible pressure drop is essential because of very high gas velocities. In catalyst zones in which the ammonia formation rate is so high that

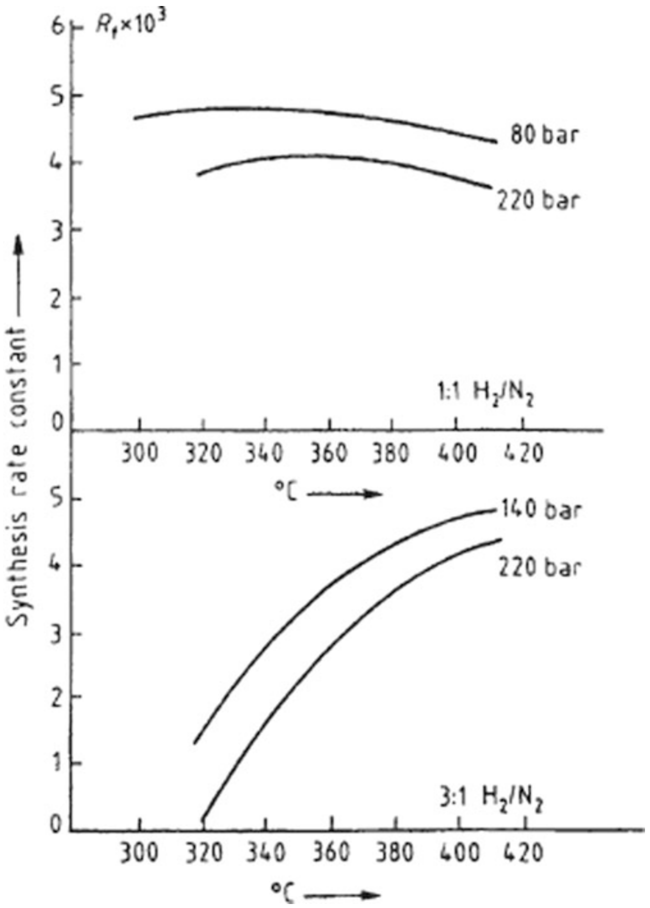

Fig. 22.12 Ammonia synthesis rate constant dependence on hydrogen–nitrogen ratio (Courtesy of Wiley-VCH. Bakemeier H, Huberich T et al (1985) Ammonia. In: Ullmann's encyclopedia of industrial chemistry, 5th edn, vol A2. VCH Verlagsgesellschaft, Weinheim, pp 143–242)

the allowable temperature limits are exceeded, it may be advantageous as well to use coarse particles for suppressing the reaction [78]. Some of the poisons of ammonia catalysts are discussed in [78].

The activity of damaged catalysts may be almost completely restored by reduction with clean synthesis gas at a relatively low temperature. It has also been found that the degree of poisoning rises as the partial pressure ratio, p_{H_2O}/p_{H_2}, increases and the degree of poisoning falls with increasing temperature [78].

Energy Efficiency

Due to increased feedstock costs, some new ammonia plant designs use fuel more efficiently, but their capital cost may be higher. The recovery of hydrogen and ammonia from the synthesis purge gas by a cryogenic unit or a membrane system results in an ammonia capacity increase of about 5% [36].

Substantial improvements have been made in the energy efficiency of CO_2 removal systems. The first large-scale ammonia plants in the 1960s typically used MEA as a solvent. Energy input was over 50,000 kcal/kg mol of CO_2 removed. In 2001, plants use improved solvents and designs that can reduce the energy input to about 10,000 kcal/kg mol of CO_2 removed [36].

A typical world-scale plant that was built in the 1970s consumed about 42 billion BTU of natural gas per ton of ammonia produced. Retrofitting such a plant to improve fuel efficiency can reduce gas consumption to about 36 million BTU/ton. Ammonia plants that were built in the late 1990s use only about 30 million BTU/ton of ammonia, are easier to

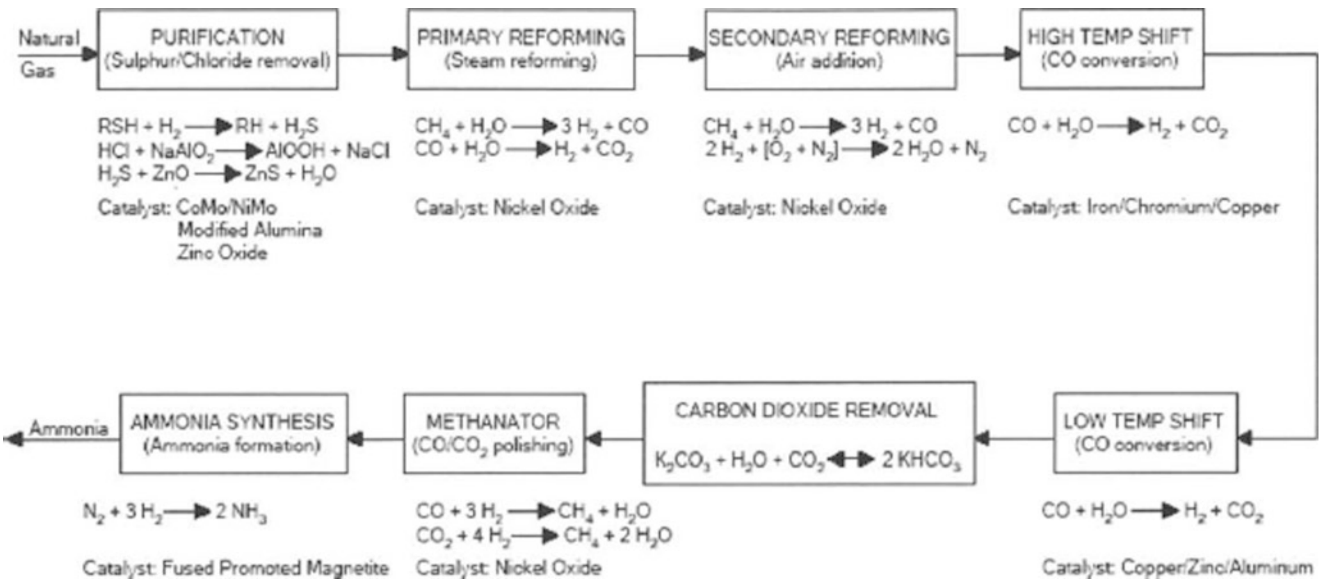

Fig. 22.13 Basic catalyses materials and chemistry of the ammonia process (Copyright Johnson Matthey plc. Reproduced by permission of Johnson Matthey plc)

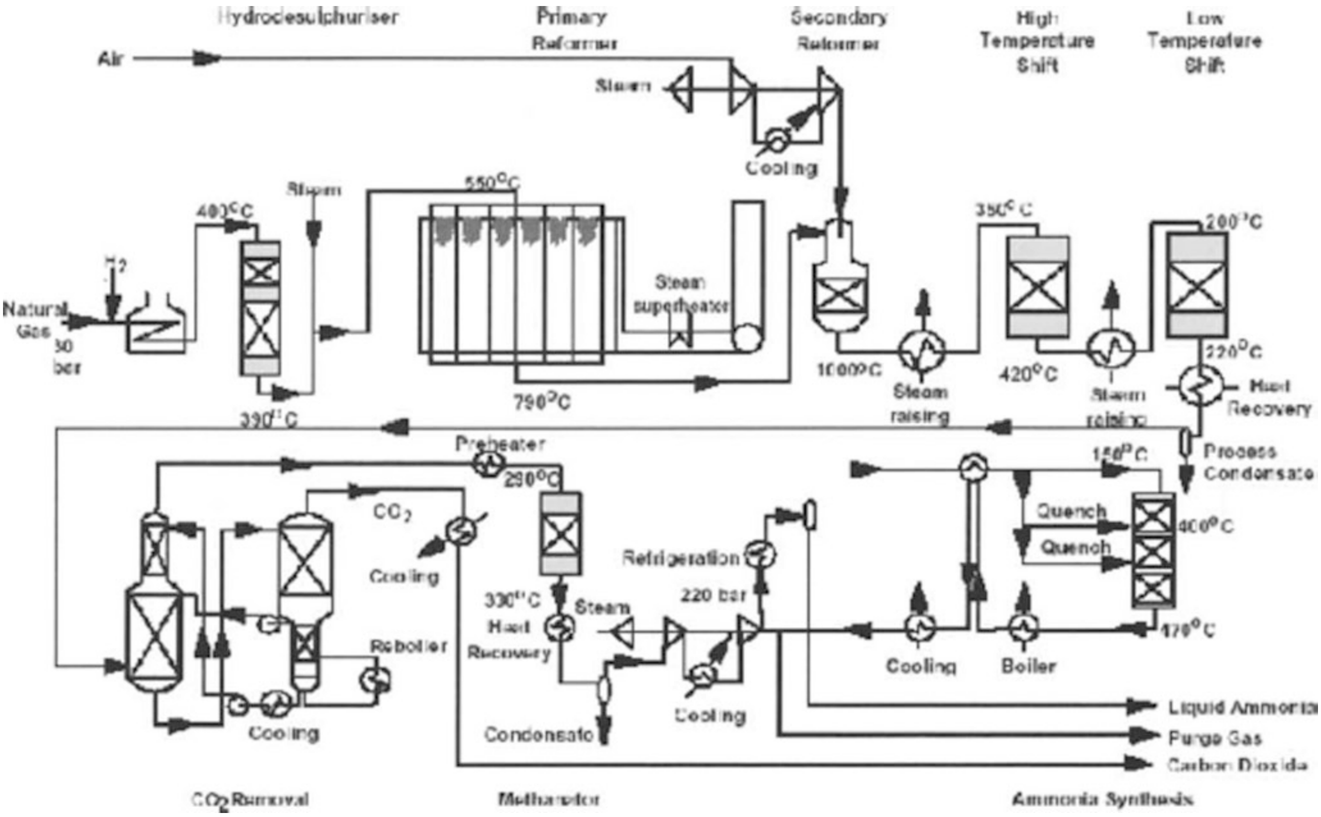

Fig. 22.14 Simplified ammonia flowsheet (Copyright Johnson Mattey plc. Reproduced by permission of Johnson Mathey plc)

operate, and have slightly lower conversion costs. Some new plants also recover more than 1 million BTU/ton by generating electricity from waste heat [36].

Ammonia Plant Design

A simplified flowsheet for an ammonia plant that processes natural gas via steam reforming is shown in Fig. 22.14. A block diagram of this same plant is shown in Fig. 22.15. This diagram lists typical stream compositions, typical operating conditions, catalyst types (recommended by Synetix), and catalyst volumes.

The KAAP*plus*™ (*K*ellogg *B*rown & *R*oot *A*dvanced *A*mmonia *P*rocess *plus*) is an ammonia process design made up of commercially proven technologies: KBR Reforming Exchanger System (KRES), KBR Purifier, and KBR Advanced Ammonia Process (KAAP) for synthesis. This process uses a ruthenium-based catalyst that is 20 times more active than the iron-based catalysts and improves synthesis efficiency. This is because synthesis pressure is lowered from a typical pressure of 150 bar (2,175 psig) to 90 bar (1,305 psig) [36, 95, 97]. Capital cost savings of 3–8% are achieved with KAAP*plus*™ [95].

Haldor Topsøe's ammonia synthesis technology is based on the S-200 ammonia converter. This is a two-bed radial flow converter with indirect cooling between the beds. This converter concept has been used extensively to upgrade existing converters (Topsøe or other designs) in modification projects to achieve higher capacity (up to 20%) and/or better energy efficiency [98].

Other companies that offer ammonia process technology are Linde [99, 100], ICI [23, 24], Ammonia Casale [101–104], and Uhde [105].

Ammonia Separation

The removal of ammonia product is accomplished via mechanical refrigeration or absorption/distillation. The choice is made by examining the fixed and operating costs. Typically, refrigeration is more economical at synthesis pressures of 100 atm (1,470 psia) or more. At lower pressures, absorption/distillation is usually favored [106].

Ammonia Synthesis

If the synthesis gas contains traces of carbon oxides, ammonium carbamate will form upon mixing with the ammonia in the recirculating gas from the synthesis loop. The carbamate will clog and/or corrode downstream equipment. To avoid

	Volume %	Volume %	Volume %	Volume %	Volume %	MUG Volume %	Loop Volume %

this condition, the carbon oxide levels in fresh makeup gas should be less than 5 ppm [48].

Many ammonia synthesis converters are subject to nitriding and hydrogen embrittlement. The internal catalyst baskets are made of SS 321 material [48]. The nitriding effect is more pronounced in low-alloy steels above 450°C. Austinic steels with a high nickel content offer considerably more resistance. Alloys of the Cr–Ni–Mo type are usually used for the gas side. Atomic hydrogen is absorbed in the metal by diffusion. The subsequent reaction with carbon in the steel results in blistering and cracking from decarburization [48].

Large-Capacity Ammonia Plants

In 2002, the design and construction of ammonia plants with capacities of 3,000 tons/day or more were underway. These large-capacity plants will be at least 50% larger than the largest plants that were operating in 2002. The benefit of bigger plants is to realize economy of scale. Doubling the size of a single-train plant has the potential to reduce the capital-related cost of production by about 20% [107].

The companies that are developing large-capacity plants are KBR [107], Haldor Topsøe [107, 108], Uhde [107, 109], plus Lurgi and Ammonia Casale [110].

Ammonia Production Costs

Ammonia production costs are very dependent on feedstock cost, which is normally natural gas. Natural gas prices can vary significantly from region to region and by the cycles in the world energy market. Typical ammonia production costs are listed in [36]. The natural gas cost makes up 70% to over 85% of the cash production costs as the natural gas cost varies from $2.00 per million BTU up to $6.00 per million BTU. In general the ammonia cash production costs in $ per ton are a factor of 40–50 times the natural gas price in US dollars per million BTU.

Uses of Ammonia

Anhydrous ammonia was produced in about 80 countries in 2001. About 85% is used for nitrogen fertilizer production, including about 4% that is directly applied to the fields [32, 111]. In the United States, the distribution of ammonia use differs slightly from the worldwide uses. In the United States, only 80% of the ammonia is used to make fertilizers. Chemical intermediates account for 19% of the ammonia use, and the remaining 1% is used in pulp and paper, metals, and refrigeration applications [34].

Chemical Production and Other Uses

The uses of ammonia are listed below:

- *Acrylonitrile.* ACRN is used in the production of acrylic fibers and various resins. ACRN is produced by the catalytic oxidation of propylene and ammonia. About 0.48 ton of ammonia is needed to make 1 ton of ACRN [36].
- *Caprolactam.* Caprolactam is used principally in the production of nylon-6 fibers. In the production of caprolactam, ammonia is used to maintain a reaction pH of 7 in one step, and in another step, it is used to neutralize sulfuric acid. Both of these steps result in the production of a low-grade ammonium sulfate fertilizer. In the classical process, 5 kg of $(NH_4)_2SO_4$ is produced per kilogram of caprolactam. In 1992, about 33% of the worldwide caprolactam capacity was based on DSM's caprolactam process that only produces 1.8 kg of $(NH_4)_2SO_4$ per kg of caprolactam [44].
- *Miscellaneous Amines and Nitriles.* A small but significant amount of ammonia is consumed in the production of various amines and nitriles [36].
- *Metallurgy.* In this application, ammonia is cracked to produce a "dissociated ammonia" that consists of 75% hydrogen and 25% nitrogen. Dissociated ammonia is used in a number of metal treatment processes [36].
- *Refrigeration.* Anhydrous ammonia is used as a refrigerant in industrial, closed-circuit refrigeration systems. Ammonia's high latent heat, low vapor density, chemical stability, and low iron corrosivity promote its use. Ammonia is used in large industrial systems (rather than halocarbon refrigerants) because ammonia absorbs about six times as much heat per unit weight and energy costs of operation are substantially lower [36].
- *Pulp and Paper.* In the production of ammonia-based sulfite pulp, the amount of ammonia used per ton of pulp varies from mill to mill. The industry average is 125 lb of ammonia per ton of sulfite pulp. Ammonia is also used for stack gas scrubbing and wastewater treatment [36].
- *Phosphate Ore Flotation.* A small amount of ammonia is used as a modifying reagent in the froth flotation of phosphate ores.
- *Household Cleaners.* Household ammonia, liquid window cleaners, liquid all-purpose cleaners, and various other household cleaning products constitute this small market for ammonia. Ammonia is also used to make surfactants that go into liquid dishwashing detergents [36].
- *Air Pollution Control.* A number of processes use ammonia for scrubbing sulfur oxides (SO_x) and/or nitrogen oxides (NO_x) from industrial and electrical power plant stack gases [36].
- *Uranium Concentrate Production.* Ammonia is used to precipitate the final uranium concentrate salt (yellowcake) prior to drying or calcination. It is generally economically preferred over sodium hydroxide or hydrogen peroxide [36].
- *Water Purification.* Ammonia is combined with chlorine to purify some municipal and industrial water supplies [36].
- *Waste Treatment.* Small amounts of ammonia are added when needed as the nitrogen source for the bacteria in industrial and municipal biological waste treatment systems. Other industrial plants use minor amounts of ammonia to neutralize acid in plant wastes [36].
- *Duplicating Processes.* Ammonia is used as a process chemical in photographic copy machines [36].
- *Fabric Treatment.* Permanent-press, 100% cotton fabrics are produced via a licensed process involving mercerization in a bath of liquid anhydrous ammonia. This Sanfor-Set process was commercialized in 1975 [36].
- *Semiconductor Industry.* High-purity ammonia (99.99995%) is used in gallium nitride (GaN) manufacturing processes to provide high brightness blue and white LEDs (light emitting diodes), in high-performance optoelectronics (such as liquid crystal displays and flat panel displays), and in high-power electronic devices (such as lasers and laser diodes).

Distribution and Storage

Ammonia Toxicity

Ammonia is a strong local irritant, and the primary target organ is the pulmonary system. Ammonia or ammonium hydroxide can penetrate the cornea rapidly and lead to damage of the iris, cataract, and glaucoma. Oral ingestion of aqueous ammonia can corrode the mucous membranes of the oral cavity, and constrictions of the esophagus may result [78].

Ammonia is not considered to be carcinogenic nor is it mutagenic. The effects of different ammonia concentrations are summarized in Table 22.12 [78].

Ammonia Quality

Most industrial uses of ammonia require a higher-purity level of product than agricultural uses. Typical ammonia specifications are shown in Table 22.13 [78].

Commercial grade is produced by ammonia synthesis, while refrigeration grade is normally made from industrial raw ammonia by distillation. For ammonia shipped or pipelined in the United States, water content must be at least 0.2 wt.% to inhibit stress corrosion cracking of the carbon steel [36].

Various concentrations and purities of aqueous ammonia are on the market. The typical concentration is 25–30% ammonia, and the iron content is less than 10 ppm. If the ammonia content is above 25%, it must be shipped in a pressure vessel because of its elevated vapor pressure [78].

Distribution and Storage

Ammonia production requires storage facilities to smooth over fluctuations in production, usage, and shipments. Ammonia is stored and distributed to point of use almost exclusively as a liquid [78].

Three methods have been used for storing liquid ammonia [78]:

- Pressure storage at ambient temperature in spherical or cylindrical pressure vessels having capacities up to about 1,500 tons
- Atmospheric storage at −33°C in insulated cylindrical tanks for up to about 50,000 tons per vessel
- Reduced pressure storage at about 0°C, usually in insulated, spherical pressure vessels for quantities up to about 2,500 tons per sphere

Table 22.12 Health effects of different ammonia concentrations

Ammonia concentration (ppm)	Health effect[a]
5	Threshold detection limit
50	Easily perceived
50–72	No significant impairment to respiration
100	Irritation to nose and throat
	Burning sensation in eyes
200	Headache and nausea
250–500	Rapid heart beating
700	Immediate onset of burning sensations in the eyes
1,000	Immediate coughing

[a] The TLV has been set at 25 ppm (17 mg/m^3) as an 8 h time-weighted average (TWA) with a short-term exposure limit (STEL) of 35 ppm (24 mg/m^3)

Ammonia is delivered in small containers, tank trucks, tank cars, barges, and via pipeline. The most common small containers are cylindrical steel bottles and pressurized flasks that contain about 20–200 kg and polyethylene canisters and metal casks [78]. Trucks have ammonia capacities up to 100 m^3, whereas jumbo rail cars hold up to 150 m^3. Liquid ammonia shipments by barge constitute a larger volume than by road or rail. Additional guidelines about ammonia shipments are given in [36, 78].

Several ammonia pipeline systems were built in the United States in the 1960s. Their construction resulted from the construction of large plants near the sources of natural gas and from developing a large market for liquid anhydrous ammonia in direct fertilization. Pipelines are the lowest cost method to move ammonia over the long distances between the producers along the Gulf Coast and the consumers in the upper Midwest. Some pipelines are up to 3,000-km long and up to 10 in. in diameter [78].

An integrated pipeline system has not been developed in Europe. Only a few pipelines with lengths of less than 50 km have been installed. However, in the FSU, a 2,424-km-long pipeline is in use [78].

Ammonia Price

Direct sales by basic producers are generally at wholesale prices. Basic producers also sell to distributors and jobbers for resale to end users buying smaller quantities. Distributors of ammonia to industrial end users have their own storage facilities, packaging plants, and distribution networks. They are able to supply end users that buy in less than truckload quantities (a minimum of 1,000–2,000 lb or 450–910 kg) or in cylinders or bottles [36].

Another important aspect of the ammonia business is seasonality. The major end use for anhydrous ammonia is as a direct application fertilizer. The application season, particularly in Canada and the Northern United States, is limited and significant storage capability is needed. As a result, it is normal to expect a plant to produce a downstream nitrogen product (such as urea) that is easier to store and

Table 22.13 Ammonia quality specifications

	Commercial grade		Refrigeration grade	
	USA	Germany	USA	Germany

[b] The noncondensable gases dissolved in ammonia are H_2, N_2, CH_4, and Ar. Their amounts depend on the methods of synthesis and storage. The inerts amount to about 50 mL/kg for atmospheric storage

handle and does not have such a limited application season. Industrial markets are normally nonseasonal [36].

Long-term fixed-price contracts are not considered workable due to the volatility in the market and the uncertainty regarding future natural gas prices. The normal long-term contract simply guarantees continuity of supply and calls for prices to be negotiated every 3–6 months [36]. Historical prices are listed in [36].

Nitric Acid

Nitric acid is a strongly acidic, corrosive liquid that is produced by the oxidation of ammonia and subsequent reaction of the oxidation products with water. Pure nitric acid is colorless. The characteristic yellow-brown color generally associated with concentrated solutions is due to dissolved nitrogen dioxide [112].

Nitric acid is an active compound, and its salts are found in all fertile soils. The alchemists obtained nitric acid by heating alum and copper sulfate with nitrate in a retort. Owing to its powerful corrosive action, they named it aqua fortis or "strong water" [2].

Being a powerful oxidizing agent, nitric acid reacts violently with many organic materials, and the reactions may be explosive. As a general rule, oxidizing reactions occur primarily with the concentrated acid and favor the formation of nitrogen dioxide (NO_2). The acidic properties tend to dominate the dilute acid, and this results in the preferential formation of nitrogen oxide (NO) [38].

Nitric acid reacts with all metals except the precious metal series and certain alloys. Although chromium, iron, and aluminum readily dissolve in dilute nitric acid, the concentrated acid forms a metal oxide layer that protects the metal from further oxidation [38].

Physical Properties

Pure anhydrous nitric acid (100%) is a colorless liquid that solidifies at −41.6°C to form white crystals. It boils at 84.1°C. When it boils in light, a partial decomposition occurs with the formation of NO_2 via the following reaction:

$$HNO_3 \rightleftarrows H_2O + 2NO_2 + \frac{1}{2}O_2 \qquad (22.15)$$

Anhydrous nitric acid should be stored below 0°C to avoid decomposition. The nitrogen dioxide remains dissolved in the nitric acid and creates a yellow color at room temperature and a red color at higher temperatures. The pure acid tends to give off white fumes when exposed to air; however, acid with dissolved nitrogen dioxide gives off reddish-brown vapors which leads to the common name "red fuming acid" [38].

Nitric acid is miscible with water, and distillation results in an azeotrope with a concentration of 68.4% HNO_3 and a boiling temperature of 121.9°C at atmospheric pressure. Two solid hydrates are known the monohydrate ($HNO_3 \bullet H_2O$) and the trihydrate ($HNO_3 \bullet 3H_2O$) [38].

Nitrogen oxides are soluble in nitric acid, and this property influences all the physical characteristics that depend on the concentration of the oxides. This mainly includes the vapor pressure above the liquid and the boiling temperature as well as the color. "Red fuming nitric acid" is a term that, according to *Sax's Dangerous Properties of Industrial Materials*, applies to nitric acid that contains more than 17% NO_2 and has a density of more than 1.48 g/cm [4, 38]. White fuming nitric acid usually contains 90–99% by weight HNO_3, from 0 to 2% by weight dissolved NO_2, and up to 10% by weight water.

The TLV for nitric acid has been set at 2 ppm as an 8-h time-weighted average (TWA) with a short-term exposure limit (STEL) of 4 ppm.

Some properties of nitric acid are given in Tables 22.14 and 22.15.

Processes

The Birdeland–Eyde or Arc process made nitric acid by passing air through an electric arc, forming nitric oxide, oxidizing NO with air, and absorbing the resulting oxides of nitrogen in water. The reactions are

$$N_2 + O_2 \rightarrow 2NO \qquad (22.16)$$

$$2NO + O_2 \rightarrow 2NO_2 \qquad (22.17)$$

$$2NO_2 + H_2O \rightarrow HNO_2 + HNO_3 \qquad (22.18)$$

$$3HNO_2 \rightarrow HNO_3 + 2NO + H_2O \qquad (22.19)$$

The process was operated in Norway from 1905 to 1930, and it was first used in the United States in 1917 [3]. It used hydroelectric power but was made obsolete by the ammonia oxidation process.

The Ostwald process is the basis for the modern processes that make nitric acid by the catalytic oxidation of ammonia. It was discovered in 1900 by Wilhelm Ostwald, a German physical chemist. The process was used by Germany during World War I to make explosives after the Allied blockade cut off the supply of nitrites from Chile and other places [113].

Some of the processes that have been based on the Ostwald process are

- The CNA (*c*oncentrated *n*itric *a*cid) process is a general name for processes that make nitric acid more concentrated than the 70% made in conventional processes.
- The CONIA process makes nitric acid simultaneously at two different concentrations.
- The DSN (*d*irect *s*trong *n*itric) process is a general name for processes that concentrate nitric acid from the 50 to 70% range up to the 98% range.
- The HOKO process also makes nitric acid simultaneously at two different concentrations.
- The Hycon process makes nitric acid at a range of concentrations. It was developed in 1968 and patented (US Patent 3,542,510) by the Chemical Construction Corporation.
- The SABAR (*s*trong *a*cid *b*y *a*zeotropic *r*ectification) process makes nitric acid by the atmospheric oxidation of ammonia. Davy McKee developed the process and built plants based on this technology from 1974 to 1986.

Chemistry. In the Ostwald process, ammonia is catalytically oxidized. The key steps in the process are (1) oxidation of ammonia to nitric oxide (NO), (2) oxidation of NO to nitrogen dioxide (NO_2), and (3) absorption of NO_2 in water to produce nitric acid. Overall, the principal reactions may be summarized as follows [112, 114].

Ammonia reacts with air on platinum/rhodium alloy catalysts in the oxidation section of nitric acid plants:

$$\begin{gathered} 4NH_3 + 5O_2 \rightarrow 4NO + 6H_2O \\ \Delta H_{298} = -54\,\text{kcal/mol}\ (-226\,\text{kJ/mol}) \end{gathered} \tag{22.20}$$

Simultaneously N_2O, N_2, and H_2O are formed in side reactions according to (22.21) and (22.22):

$$\begin{gathered} 4NH_3 + 3O_2 \rightarrow 2N_2 + 6H_2O \\ \Delta H_{298} = -75.8\,\text{kcal/mol}\ (-317\,\text{kJ/mol}) \end{gathered} \tag{22.21}$$

$$4NH_3 + 4O_2 \rightarrow 2N_2O + 6H_2O \tag{22.22}$$

Some of the process energy recovery options are discussed in [114]. The yield of nitric oxide in (22.20) depends on pressure and temperature as indicated in Table 22.16 [114].

The space velocity in the ammonia oxidation reactor should be kept high to maximize yield and avoid

Table 22.16 Effect of reaction pressure and temperature on nitric oxide yield

Pressure (bar)	Temperature (°C)	Nitric oxide yield (%)
Below 1.7	810–850	97
1.7–6.5	850–900	96
Above 6.5	900–940	95

Table 22.17 Effect of reactor residence time on nitric oxide yield

Reactor residence time (s)	Nitric oxide yield, percent NH_3 oxidized
0.28	82.1
0.11	85.7
0.061	90.2
0.023	91.8

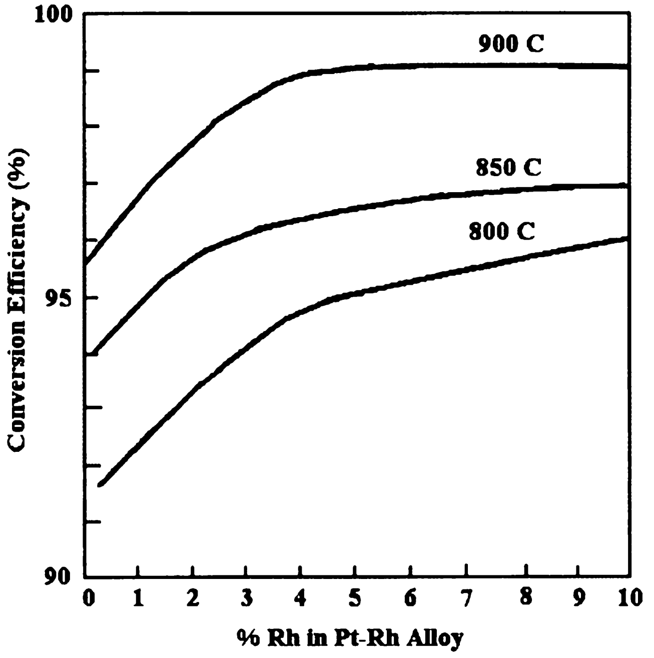

Fig. 22.16 Effect of rhodium content on catalyst efficiency

decomposition of ammonia in the feed gas. Another potential yield loss is shown in (22.23):

$$4NH_3 + 3NO_2 \rightarrow \frac{7}{2}N_2 + 6H_2O \qquad (22.23)$$

The effect of reactor residence time on nitric oxide yield is shown in Table 22.17 [115].

NO is oxidized to NO_2 as the combustion gases are cooled, but some side reactions (such as (22.24) and (22.25)) may also occur.

$$\begin{array}{c} 2NO + O_2 \rightarrow 2NO_2 \\ \Delta H_{298} = -13.6\,\text{kcal/mol}\ (-57\,\text{kJ/mol}) \end{array} \qquad (22.17)$$

$$4NO \rightarrow 2N_2O + O_2 \qquad (22.24)$$

$$\begin{array}{c} 2NO_2 \rightleftarrows N_2O_4 \\ \Delta H_{298} = -6.8\,\text{kcal/mol}\ (-28.6\,\text{kJ/mol}) \end{array} \qquad (22.25)$$

For the reaction in (22.17), secondary air is added to the gas mixture obtained from the ammonia oxidation to increase the oxygen content to such a level that the waste gas leaving the plant has an oxygen content between 2 and 4% by volume. The rate of reaction is proportional to pressure cubed (see (22.26)), and the volume or size of equipment needed to oxidize the nitric oxide is inversely proportional to pressure cubed:

$$d(P_{NO})/dt = -k(P_{NO})^2(P_{O_2}) \qquad (22.26)$$

The absorption reaction (22.27) is exothermic, and continuous cooling is required within the absorber:

$$\begin{array}{c} 3NO_2 + H_2O \rightarrow NO + 2HNO_3 \\ \Delta H_{298} = -6.8\ \text{kcal/mol}\ (-28.6\ \text{kJ/mol}) \end{array} \qquad (22.27)$$

The nitric acid produced in the absorber contains dissolved nitrogen oxides and is then bleached by the secondary air.

The overall reaction is

$$\begin{array}{c} NH_3 + 2O_2 \rightarrow HNO_3 + H_2O \\ \Delta H = -98.7\ \text{kcal/mol} \end{array} \qquad (22.28)$$

Several process variations are described in [112].

Catalysts. The catalyst typically consists of several woven or knitted wire gauze sheets with a composition of about 90% platinum, 5% rhodium, and 5% palladium. The primary functions of rhodium are to add mechanical strength to the gauze and to improve yield. The palladium is present to replace a portion of the more expensive rhodium [112]. Figure 22.16 shows that conversion efficiency does not improve if more than 5% rhodium is present in the catalyst [116].

Catalyst life depends on several variables. High-pressure oxidation operations (which also operate at higher temperatures, per Table 22.16) require more frequent catalyst regeneration. The presence of trace amounts of iron, calcium, MoS_2 (lubricants), and phosphorus in the ammonia feed has been shown to shorten catalyst life. Deposits of iron oxides tend to catalyze the conversion of ammonia and oxygen to nitrogen and water, rather than to nitric oxide. These effects, as well as poor ammonia–air mixing and poor gas distribution across the catalyst, may reduce the yield by up to 10% [112, 114].

Some weight loss due to catalyst erosion and vaporization occurs and is more pronounced at the higher converter temperatures that are employed in the higher-pressure processes. Lost catalyst is usually recovered by "getter" systems that use palladium alloy gauzes and recover 60–80% of the lost catalyst. The "getter" gauze is placed as close to the platinum catalyst pack as possible so that the catalyst components can be recovered while they are in the vapor form. Although pure palladium is the most effective "getter," it becomes too brittle, so a palladium alloy is used. Additional catalyst is recovered during periodic cleaning of the ammonia oxidation reactor and during cleaning of downstream heat exchangers [112, 114].

When the catalyst pack no longer provides the desired reaction rates or product composition, new sheets of catalyst may be added to the old sheets. Or the old sheets may be replaced by a set of new sheets, and the old sheets sent back to the supplier to be refurbished. If any catalyst that is lost from the gauze is trapped in the downstream filter or recovered during equipment cleaning, it is also returned to be reprocessed [112].

US Patent 6,073,467 was issued in 2000 for a three-dimensional, knitted, noble metal gauze for nitric acid production. This catalyst design claims to provide elevated product yields and longer catalyst service life with the small noble metal losses.

Operating Pressure. All nitric acid plants are based on the same basic chemical operations: oxidation of ammonia with air to give nitric oxide, oxidation of the nitric oxide to nitrogen dioxide, and absorption in water to give a solution of nitric acid. The efficiency of the first step is favored by low pressure, whereas that of the second step is favored by high pressure. Therefore, both single-pressure and dual-pressure nitric plants are operating [114].

In the single-pressure plant, the oxidation and absorption steps take place at essentially the same pressure. In dual-pressure plants, absorption takes place at a higher pressure than the oxidation stage. The oxidation and absorption steps can be classified as [114]: low pressure (below 1.7 bar), medium pressure (between 1.7 and 6.5 bar), and high pressure (between 6.5 and 13 bar).

The main unit operations in nitric acid plants are [114] ammonia evaporation, ammonia filtration, air filtration, air compression, air/ammonia mixing, catalytic reaction of ammonia and air, energy recovery by steam generation and/or gas reheating, gas cooling, dual pressure only →NO_x compression, absorption with nitric acid production, and tail gas energy recovery.

Most new plants built in the 1990s have a dual-pressure design. Ammonia oxidation is operated at a medium pressure, and absorption is operated at a high pressure. High-pressure systems offer the advantage of lower capital costs (as much as 30% lower than some lower-pressure processes) and are preferred in the United States for this reason. Relative disadvantages are higher catalyst loss and lower ammonia conversion. Lower-pressure oxidation designs have the best efficiencies in ammonia conversion and catalyst conservation. These plants have been preferred in Europe and other areas where ammonia has been relatively expensive and where allowable payout times have been longer [112].

The single-pressure design (see Fig. 22.17) is generally used in smaller plants or in larger plants where minimization of capital is a critical design consideration. Ammonia oxidation and absorption of NO_2 occur at the same relative pressure. This reduces the complexity and capital cost compared to the dual-pressure plant. However, efficiency may be lower in both the front and back ends of the plant. Single-pressure plants can be designed to operate at low to medium pressure to favor the ammonia oxidation reaction, at high pressure to favor the absorption reactions, or at any operating pressure in between [117].

The dual-pressure design (see Fig. 22.18) is generally use in larger plants or in mid-size plants where higher utility/raw material costs dictate a minimization of operating expense. Ammonia oxidation occurs at low or medium pressure. The result is an increase in efficiency of the ammonia oxidation reaction and lower catalyst loss. Absorption of NO_2 occurs at high pressure to maximize the partial pressure of the gas reactants. A nitrous gas compressor boosts the pressure from the front end of the process (ammonia oxidation) to the back end (absorption) [112].

In Table 22.18, the raw material and utility consumption figures are given for both single- and dual-pressure processes [117].

One type of NO_x abatement system, the DCN (*D*estruction by *C*atalysis of NO_x) reactor, is shown in Fig. 22.19 [117].

Concentration of Nitric Acid. Most production of CNAs (i.e., greater than the azeotrope of 68.4%) is based on weak-acid hydration via extractive distillation with a drying agent. Common drying agents are sulfuric acid and magnesium nitrate [112, 118].

A process exists that can directly produce CNA from dehydrated and concentrated nitrogen dioxide, weak acid, and oxygen. Generally the process operates at high pressure and follows these chemical reactions [112]:

$$2NO_2 \rightleftarrows N_2O_4 \tag{22.25}$$

$$N_2O_4 + H_2O + \frac{1}{2}O_2 \rightarrow 2HNO_3 \tag{22.28}$$

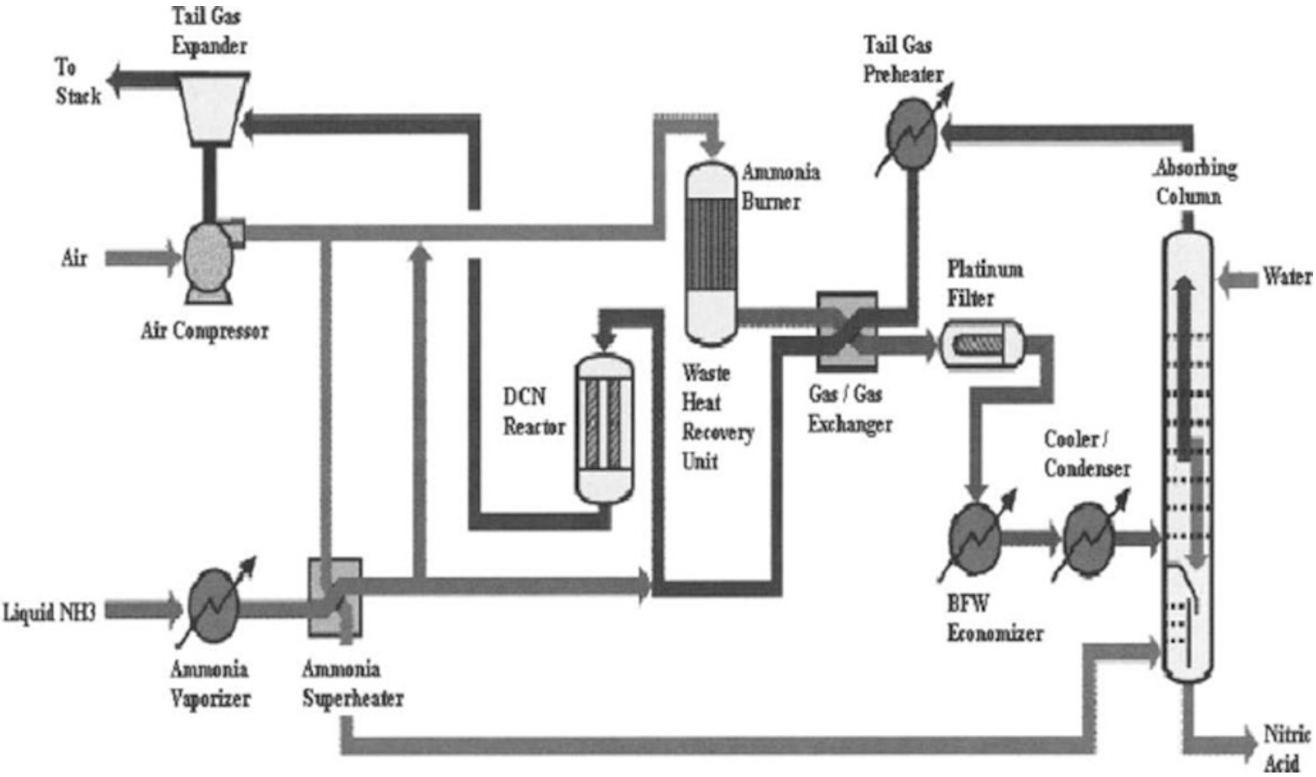

Fig. 22.17 Single-pressure nitric acid plant (Reproduced by permission of Monsanto Enviro-Chem Systems, Inc.)

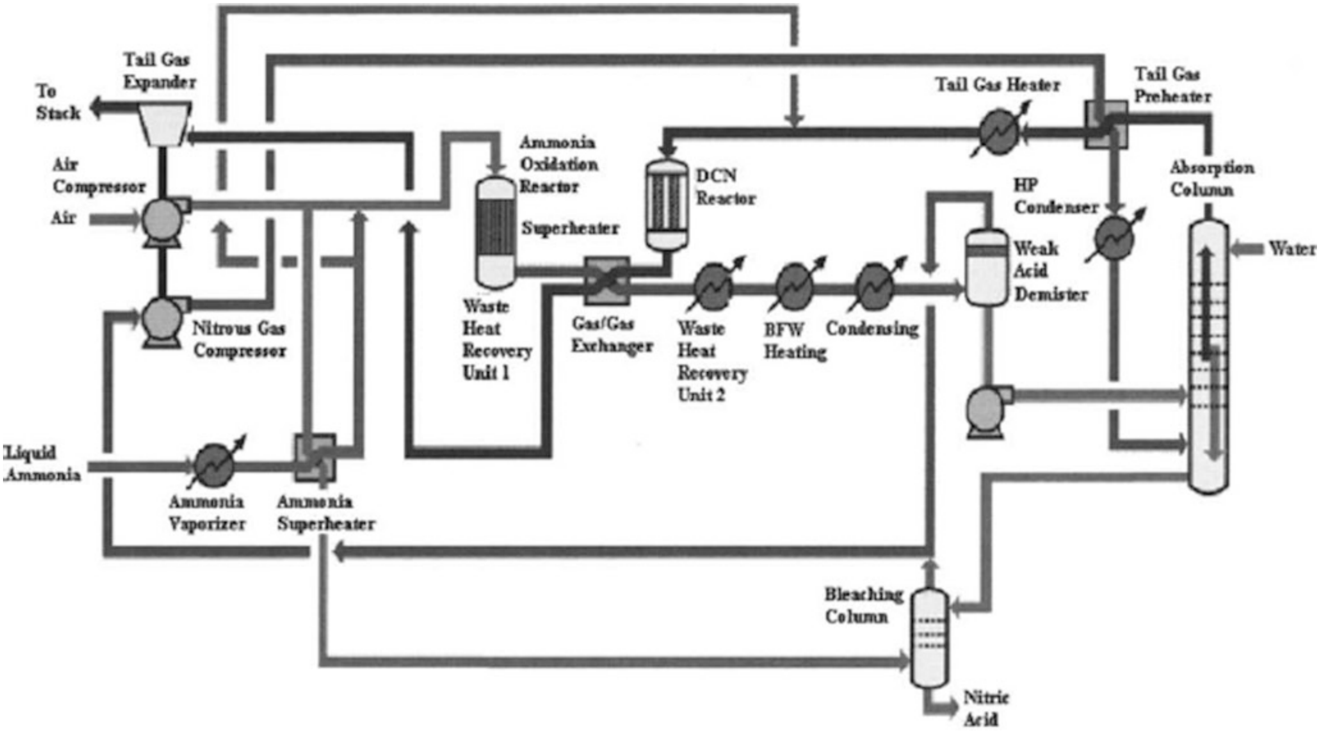

Fig. 22.18 Dual-pressure nitric acid plant (Reproduced by permission of Monsento Enviro-Chem System, Inc.)

Few US plants employ this method for production of concentrated acid. Most production of concentrated HNO_3 (i.e., concentrations above the azeotrope) is based on weak-acid dehydration via distillation with a drying agent. The most common dehydrators have been concentrated sulfuric acid and magnesium nitrite [112].

Table 22.18 Raw material and utility consumptions in different nitric acid plant designs

	H&H	M&M	M&H

[a] Includes catalytic NO_x abatement to 200 ppmv and average ammonia conversion efficiency over the entire gauze run length

[b] Described as net of platinum recovery systems

[c] Add 25 kW for HVAC, lighting and instrumentation

[d] Steam conditions are 42 kg/cm^2 g and 400°C

[e] Steam conditions are saturated at 3.5 kg/cm^2 g

[f] At 11°C temperature rise and 2.5 kg/cm^2 pressure allowance

An example of the dehydration process is the Kvaerner Chemetics process that uses concentrated sulfuric acid to eliminate the azeotrope and enable colorless, strong nitric acid up to 99% to be distilled from the mixed acids. The residual acid leaving the bottom of the processing tower is approximately 70% sulfuric acid [119].

Alternative methods of integrated concentration have been developed that do not require separate dehydrating agents. These processes differ from the direct process in that weak acid reacts with concentrated nitrogen dioxide to produce an acid that is sufficiently superazeotropic that distillation into concentrated acid is economically feasible. The weaker azeotropic acid may be recycled for concentration or used as it is [112]. The magnesium nitrate process is described in [120].

Uhde developed another process for the 98–99% that uses oxygen but no dehydrating agents. The NO from ammonia oxidation is converted to NO_2 by highly concentrated HNO_3. The NO_2 is cooled while it is physically absorbed in chilled, highly CNA. Then the NO_2 is separated from the CNA in a distillation column and liquefied by refrigeration. The liquid NO_2 is dimerized in a $N_2O_4/HNO_3/H_2O$ mixture that reacts with supplemental oxygen at a pressure of about 720 psi to form highly CNA. The acid that leaves the reactor contains about 20% dissolved N_2O_4, which is separated in a distillation column

and returned to the reactor. The CNA product is bleached and sent to storage, and a portion is recycled to the absorber.

Stabilizers. Over a period of time, CNAs tend to decompose according to (22.29), and pressure will build up in storage vessels:

$$HNO_3 \rightarrow 4NO_2 + H_2O + O_2 \qquad (22.29)$$

Because nitric acid is also very corrosive, some stabilizers and/or corrosion inhibitors are used.

Corrosion of aluminum by red fuming nitric acid is reduced by adding 4% by weight of hydrogen fluoride. Decomposition of concentrated acid is reduced by such substances as quaternary ammonium compounds, organic sulfonium compounds [121].

Pollution Abatement. The primary pollution problem in nitric acid plants is the abatement of NO_x in tail gases. The processes that have been developed to reduce emissions at existing and new plants can be classified into four general categories: absorption, adsorption, selective catalytic reduction, and nonselective catalytic reduction [112, 120].

The main environmental factor that affects nitric acid process selection is the concentration of NO_x in the tail gas. In the United States, gaseous emissions from newly constructed nitric acid plants are limited to 1.5 kg NO_x/ton of nitric acid produced with a maximum opacity of 10%. In Western Europe, NO_x emissions are limited by EU regulations to 200 ppm [112].

Absorption abatement refers to modifications that involve the addition of increased absorption capacity or optimization of the existing absorption system [112].

Adsorption abatement uses acid-resistant molecular sieves to absorb the NO_x from the tail gas. The adsorbent is periodically regenerated and the NO_x recovered, converted to NO_2, and recycled for recovery as nitric acid [112].

Selective catalytic reduction is normally used in new nitric acid plants. In this process, ammonia reacts with nitric oxide and nitrogen dioxide but to a lesser extent with oxygen to selectively reduce the NO_x compounds to N_2 [114, 120] as shown below:

$$6NO + 4NH_3 \rightarrow 5N_2 + 6H_2O \qquad (22.30)$$

$$6NO_2 + 8NH_3 \rightarrow 7N_2 + 12H_2O \qquad (22.31)$$

$$3O_2 + 4NH_3 \rightarrow 2N_2 + 6H_2O \qquad (22.32)$$

Nonselective abatement uses a catalyst and fuel (usually a gaseous hydrocarbon) to reduce nitrogen oxides to nitrogen and combust any remaining free oxygen in the tail gas. This process consumes significantly more fuel than a selective reduction system, but the energy from burning the fuel is mostly retrieved as power in an expander [120].

The gas at the outlet of the absorber may vary within the following limits during stable operation: NO_x = 100–3,500 ppmv, N_2O = 300–3,500 ppmv, O_2 = 1.5–4% by volume, H_2O = 0.3–2% by volume, flow = 3,100–3,400 Nm^3/ton of HNO_3.

The minimum emission levels achieved in 2001 without added pollution abatement are

- Medium-pressure absorption: 1,000–2,000 ppmv
- High-pressure absorption: 100–200 ppmv

Whereas a dual-pressure plant or a high-pressure, single-pressure plant (with high-pressure absorption) may give acceptable emission levels, the medium-pressure absorption plant must be followed by an abatement system [114].

Monsanto Enviro-Chem offers NO_x abatement technology that is licensed from Rhodia of France. It includes a high-efficiency absorption (HEA) section for extended absorption and a catalytic reduction section (SCR) for catalytic destruction of NO_x (i.e., the DCN technology) [117]. Additional process details are given in [117]. The operating conditions for the steps in the Monsanto technology are compared in Table 22.19.

Production. An estimated 65% of the worldwide nitric acid production is used to make ammonium nitrate (AN) for use in fertilizers. Other AN uses (mainly explosives) account for about 15% of the market. The balance is consumed in a variety of non-AN industrial applications. The production of AN fertilizers and most industrial explosives require acid concentrations less than the azeotropic concentration of 68.4%.

World nitric acid production in 1999 is estimated to be 53 million tons/year. Captive use consumes most of the production, and the merchant market probably involves only about 10% of the total [112].

World demand for nitric acid will continue to be largely dependent upon demand for solid ammonium nitrate fertilizer and nitrogen fertilizer solutions that incorporate ammonium nitrate. Since the 1980s, urea has been replacing solid ammonium nitrate as a fertilizer. This has been partially offset by increased use of AN in explosives, polyurethane foams, declined by about 5% between 1987 and 1999, but it is projected to increase marginally by 2005. The major producing regions are Western Europe and the United Eastern Europe [112, 120].

Nitric acid is sold commercially in various concentrations that are expressed in degrees Baumé (Be) which is an alternate specific or fuming nitric acid (95% or more HNO_3/NO_2) are available [112, 120].

Storage and Distribution. Nitric acid is normally stored in flat-bottomed, roofed tanks that are made from low-carbon, austenitic acid are transported in tank cars and by truck. Stainless steel is necessary for concentrations up to 80–85%. Stronger solutions are less corrosive and may be stored in aluminum.

In the United States, the Department of Transportation (DOT) defines three categories of nitric acid: nonfuming, more than 70 wt.% acid; nonfuming, less than 70 wt.% acid; and red fuming nitric acid. All must be labeled “corrosive.”

Nitric acid is subject to self-decomposition, depending on the concentration and temperature. The general rule is that the higher the concentration or the temperature, the faster the decomposition rate. Nitric acid must be transported from the manufacturer to the user in the summer months [114].

Uses of Nitric Acid

Some of the major uses of nitric acid are

- *Ammonium nitrate (AN)*: Production for fertilizers and explosives.
- *Adipic acid*: Nitric acid oxidizes cyclohexanone–cyclohexanol mixtures to adipic acid, which goes into nylon 6,6, other resins, and plasticizers.
- *Nitrobenzene*: Nitrobenzene is made by the direct nitration of benzene with nitric/sulfuric acid mixtures.
- *Toluene diisocyanate (TDI)*: TDI (2,4- and 2,6 isomers) are produced from toluene diamine derived from dinitrotoluene, which is produced by the nitration of toluene with nitric/sulfuric acid mixtures. TDI is used mainly in
- *Potassium nitrate*: Production for tobacco fertilizer and industrial markets.
- *Sodium nitrate*: Production for fertilizers, explosives, and as a heat transfer medium.

Some of the other uses of nitric acid are as follows: other metal nitrates, in the steel industry, in the electronics industry, to make nitrochlorobenzene; cellulose nitrate, in several nitrate paraffins (e.g., nitromethane, nitroethane, and nitropropane), in nonmilitary explosives, to digest crude uranium concentrates, in mixed fertilizers, and in CNA.

Ammonium Nitrate

Ammonium nitrate (AN) was first prepared in the sixteenth century. Its early industrial development was primarily for use in explosives. However, after 1940, its use as a fertilizer exploiter developed rapidly. It is made by the reaction of gaseous ammonia with aqueous nitric acid:

$$\begin{aligned} &HNO_3(l) + NH_3(g) \rightarrow NH_4NO_3(aq) \\ &\Delta H = +26\ \text{kcal/g mol} \end{aligned} \tag{22.33}$$

The resulting AN solution may be handled in various ways [122]. It can be stored as a solution used in downstream plants or sold as a solution, it can be formed into solid AN by prilling or granulation, or it can be mixed with a solid filler. The most common filler is calcium carbonate in the form of ground limestone, dolomite, or by-product calcium carbonate. This product is known as calcium ammonium nitrate (CAN) and can be prilled or granulated.

Processes

As shown in Fig. 22.20 [123], the typical AN production process has three main unit operations: neutralization, evaporation, and solidification (prilling and granulation) [122, 124]. Additional details about AN production are given in [125].

Neutralization. The exothermic neutralization of nitric acid with ammonia gas produces AN solution and steam. The nitric acid is commonly preheated if the available concentration of nitric acid is in the lower end of the 50–70% range [122].

Neutralization can be performed in a single stage or in two stages. A two-stage neutralizer operates with a low pH in the first stage and a neutral pH in the second stage.

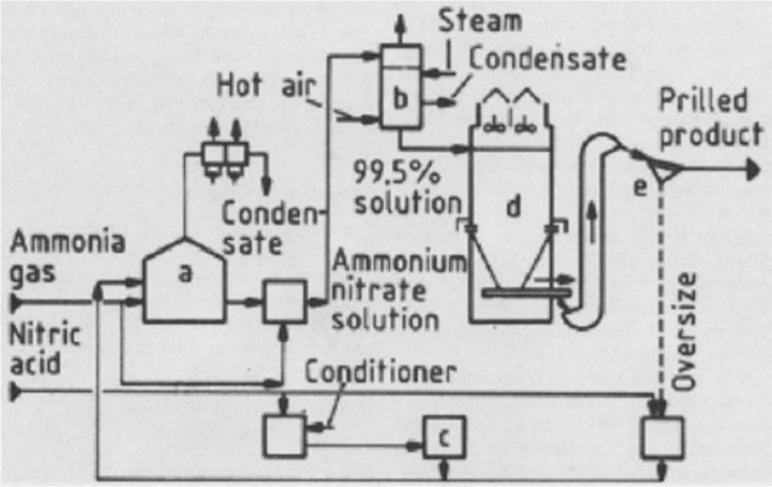

Fig. 22.20 Ammonium nitrate process sketch (Courtesy of Wiley-VCH [123])

In most neutralizers, the pressure, temperature, and concentration are linked by the boiling point characteristics of AN solutions with only two of these variables being independent [122].

Neutralizers may be free-boiling vessels, circulating systems, or pipe reactors. The water in the nitric acid is evaporated by the heat of reaction (550–620 BTU/lb of AN, depending on the acid strength). At least ten different types and designs of neutralizers are used in Europe. The factors that influence the choice of neutralizer design are described in [122]. Different neutralizer designs are discussed in [123, 126, 127].

Steam Purification. The steam that leaves the neutralizer can be purified, or it can be condensed and then purified. Some steam purification techniques are described in [122]. The steam may be used in the evaporator, be used to preheat and evaporate ammonia, or be used to preheat the nitric acid [122].

Evaporation. The evaporator is normally needed to remove water from the AN solution. It must produce a solution with the required concentration at a temperature that avoids crystallization. The acceptable water content is normally below 1% for a prilled product and up to 8% for the feed to some granulation processes. Evaporators in commercial use include circulatory systems, shell and tube heat exchangers, and falling film-type evaporators [122].

Prilling. Prilling refers to the formation of granules by the solidification of droplets of AN. The AN solution is concentrated to 96–99% at a pH above 4.5 to form a "melt." The melt may be mixed with an additive or nucleating agent that stabilizes the prills against temperature cycling through the crystal transition phases. Then the melt is transported to the top of the prilling tower and sprayed through a system of fixed orifices or dropped through a rotating perforated bucket into a rising air stream. The droplets crystallize into hard spherical "prills" that are dried, cooled, and sized for shipment. If CAN is made, ground calcium carbonate (limestone or dolomite) is added to the melt prior to the formation of the droplets [122, 124, 128].

SASOL in South Africa produces a porous, prilled ammonium nitrate (PPAN) that finds its widest application in a mix with fuel oil. This mixture is used as an explosive and is commonly known as ANFO (*a*mmonium *n*itrate–*f*uel *o*il). Additional details about PPAN are given in [129].

Granulation. Granulation refers to techniques using processes such as agglomeration, accretion, or crushing to make a granular fertilizer. In contrast to the prilling technique, granulation requires a more complicated plant, and a variety of equipment is used: rotating pans and drums, fluidized beds, and other equipment. Granular products can be made in a wider choice of particle sizes than prills [122].

The AN is added in the granulator as a spray of hot concentrated solution. No further drying of the granules will normally be required. The granules are screened, and the fines and crushed oversize returned to the granulator [122].

Typical CAN granulators include drums and pugmills. The calcium carbonate may be mixed with the AN solution before granulation or in the granulator itself. Granules from this process will normally require drying in a fluidized bed or rotary drier [122].

Air Abatement Equipment. Emissions from the prilling and granulation sections of AN and CAN plants can be treated by a range of abatement equipment. Particulate material from some granulation plants is relatively coarse in particle size, whereas the prill tower emissions contain very fine particles.

Candle filters are normally required for prill tower emissions. They can abate particulate emissions down to 15 mg/m^3 of air. For coarser material, dry devices such as bag filters or dry cyclones are used. Particulate emissions can have higher concentrations, perhaps up to a range of 30–50 mg/m^3, but the recovered material is a solid that can more readily be recycled.

Production

Production of fertilizer grade AN is concentrated mainly in Europe and North America. In 2001, US production was 7.1 million tons, which was 18% lower than the peak production in 1998. US plants were operating at 70% of nameplate capacity in 2001 [128]. International trade amounts to about 4 million tons (on a nitrogen equivalent basis) per year. Additional information can be found in Chap. 24.

Some of the physical and chemical properties of ammonium nitrate are given in Table 22.20 [122].

Table 22.20 Ammonium nitrate physical and chemical properties

Property	
Appearance	White or off-white granules or prills
Odor	Odorless
pH (10 g/100 mL)	>4.5
Melting point	160–170°C (depending on moisture content)
Decomposition point	>210°C
Molecular weight	80.05
Solubility in water	
0°C	118.3 g/100 g
20°C	190.0 g/100 g
80°C	576.0 g/100 g
Bulk density	830–1,100 kg/m^3
Nitrogen content	35% (100% ammonium nitrate)

Storage and Distribution. Solid AN in packages must be stored in a general warehouse that has been approved for AN duty. Bulk AN and CAN must be protected from moisture as both products are hygroscopic. Large bulk warehouses may be air-conditioned due to the local climate. Some additives can also reduce the water uptake. The anticaking agents may be used that are internal to the finished particle or applied as a coating [122, 128].

AN solution must be stored at a temperature above the crystallizing temperature of the solution. Gaseous ammonia is normally added in small quantities to maintain the solution at the correct pH because AN solutions lose ammonia during storage [122]. Steps should also be taken to avoid contamination by decomposition catalysts such as chlorides and organic materials.

Ammonium nitrate decomposes in two ways. Controlled decomposition with careful heating is the commercial process for producing nitrous oxide:

$$\begin{aligned} &\mathrm{NH_4NO_3} \xrightarrow{200-260^\circ} \mathrm{C\,N_2O + H_2O} \\ &\Delta \mathrm{H} = -6.7\ \mathrm{kcal/g\,mol} \end{aligned} \tag{22.34}$$

Explosive decomposition by heating or by explosive shock is the basis for its use as an explosive:

$$\begin{aligned} &\mathrm{2NH_4NO_3 \rightarrow 2N_2 + 4H_2O + O_2} \\ &\Delta \mathrm{H} = -28.2\ \mathrm{kcal/g\,mol} \end{aligned} \tag{22.35}$$

The oxygen that is released in (22.35) can be used to more than triple the explosive effects by mixing an organic, such as fuel oil, with AN. This mixture, known as ANFO, is much cheaper and much safer to handle than dynamite:

$$\begin{aligned} &\mathrm{3NH_4NO_3 + (CH_2)_{\mathit{n}} \rightarrow 3N_2 + 7H_2O + CO_2} \\ &\Delta \mathrm{H} = -102.5\ \mathrm{kcal/g\,mol} \end{aligned} \tag{22.36}$$

Urea

Urea was discovered in 1773, and it was first synthesized from ammonia and cyanic acid in 1828 [130]. In the early 1900s, urea was produced on an industrial scale by the hydration of cyanamide, which was obtained from calcium cyanamide [131]:

$$\mathrm{CaCN_2 + H_2O + CO_2 \rightarrow CaCO_3 + CNNH_3} \tag{22.37}$$

$$\mathrm{CNNH_3 + H_2O \rightarrow CO(NH_2)_2} \tag{22.38}$$

After development of the ammonia process by Haber and Bosch in 1913, the production of urea from ammonia and CO_2 developed rapidly. In 2001, urea is prepared on an industrial scale exclusively by this method [131].

$$\underset{\text{Ammonia}}{\mathrm{2NH_3}} + \underset{\text{Carbon dioxide}}{\mathrm{CO_2}} \rightleftarrows \underset{\text{Ammonium carbamate}}{\mathrm{NH_2COONH_4}} \tag{22.39}$$

$$\underset{\text{Ammonium carbamate}}{\mathrm{NH_2COONH_4}} \rightleftarrows \underset{\text{Urea}}{\mathrm{CO(NH_2)_2}} + \underset{\text{Water}}{\mathrm{H_2O}} \tag{22.40}$$

Reaction (22.39) is fast and exothermic and essentially goes to completion under the high-pressure reaction conditions. Reaction (22.40) is slower, is endothermic, and does not go to completion. The conversion (on a CO_2 basis) is usually 50–80%. The conversion increases with increasing temperature and NH_3/CO_2 ratio. It decreases with increasing H_2O/CO_2 ratio [132].

Table 22.21 Physical properties of urea [130]

Chemical formula	NH_2CONH_2
Molecular weight	60.06
Freezing/melting point	132.6°C

Density, d_4 [17]	1.3230 g/cm^3
Heat of solution in water	+251 J/g (60 cal/g)
Bulk density	0.74 g/cm^3
Specific heat, J/(kg K)	
0°C	1.439
50°C	1.661
100°C	1.887
150°C	2.109

Properties of saturated aqueous solutions of urea

Temperature (°C)	Solubility in water (g/100 g solution)	Density (g/cm^3)	Viscosity (mPa s = cP)	Water vapor pressure (kPa)
0	41.0	1.120	2.63	0.53
20	51.6	1.147	1.96	1.73
40	62.2	1.167	1.72	5.33
60	72.2	1.184	1.72	12.00
80	80.6	1.198	1.93	21.33
100	88.3	1.210	2.35	29.33
120	95.5	1.221	2.93	18.00
130	99.2	1.226	3.25	0.93

When urea melt is subjected to heat, some biuret is formed:

$$\underset{\text{Urea}}{2CO(NH_2)_2} \rightleftarrows \underset{\text{Biuret}}{NH_2CONHCONH_2} + \underset{\text{Ammonia}}{NH_3} \qquad (22.41)$$

Biuret is undesirable for some industrial and fertilizer applications. Prilled urea normally contains more biuret (0.8–1.5%) than granular urea because prilled urea goes through an extra evaporation step.

Urea is an odorless white solid that contains 46.65% nitrogen. It is not flammable, but it will melt and decompose in a fire to give off ammonia. When it is dissolved in water, it hydrolyzes very slowly to ammonium carbamate and eventually decomposes to ammonia and carbon dioxide. Some of the other properties of urea are given in Table 22.21 [130, 132].

Processes

In 2001, most new urea plants are licensed by Snamprogetti (SNAM), Stamicarbon (STAC), or Toyo. SNAM utilizes thermal stripping, whereas STAC and Toyo use CO_2 stripping. At the end of 1996, about 70 SNAM plants, 125 STAC, and 7 Toyo plants had been built. STAC will design plants for over 3,000 tons/day; SNAM designs plants for about 2,800 tons/day; and Toyo designs plants for about 2,300 tons/day as single-train units [130].

Because urea is made from ammonia and carbon dioxide, all urea plants are located adjacent to or in close proximity to an ammonia plant. Figure 22.21 [133] shows an example of an ammonia plant and a urea plant that are part of the same complex.

The SNAM process, the synthesis section of the STAC process, and the synthesis section of the Toyo ACES (*a*dvanced *p*rocess for *c*ost and *e*nergy *s*aving) process are described in [130, 132]. An updated version of the STAC process, Urea 2000plus, is offered by DSM (STAC's parent company) [130, 132].

The *i*sobaric *d*ouble-*r*ecycle (IDR) urea process was developed by Montedison. In this process, most of the unconverted material leaving the reactor is separated by heating and stripping at synthesis pressure using two strippers in series. The unconverted ammonia, CO_2, and carbamate in the urea solution are recycled to the synthesis loop [130, 132].

The *H*eat *R*ecycle *U*rea *P*rocess (HRUP) was developed by Urea Technologies in the 1970s and is offered by Monsanto Enviro-Chem. This process is described in [132, 134]. Several urea-producing reactors have been updated with Casale high-efficiency trays. These trays increase conversion, which increases plant capacity and reduces energy use [102].

Prilling. A prilling plant is shown in Fig. 22.22 and is described in [130, 132].

Granulation. Almost all new plants that make granules use the Hydro-Agri process, which can be built to make over 3,000 tons/day. The basic principle of the process involves the spraying of the melt onto recycled seed particles or prills circulating in the granulator. The process is described in more detail in [130–132].

Another process is the C&I Girdler drum system, but it cannot compete in today's market because of capacity restrictions. Toyo has developed a spouting-fluid-bed technology, and by 1996, three plants were in operation. STAC will also license a fluid-bed plant that is similar to the Hydro-Agri design [130].

Production

The ammonia cost makes up 62 to over 70% of the cash production costs of urea as the natural gas cost varies from $2.00 per million BTU up to $6.00 per million BTU. In general urea cash production costs in dollars per ton are a factor of 1.4–1.6 times the ammonia price in US dollars per ton [135] (see [32, 136, 137] for details about urea production).

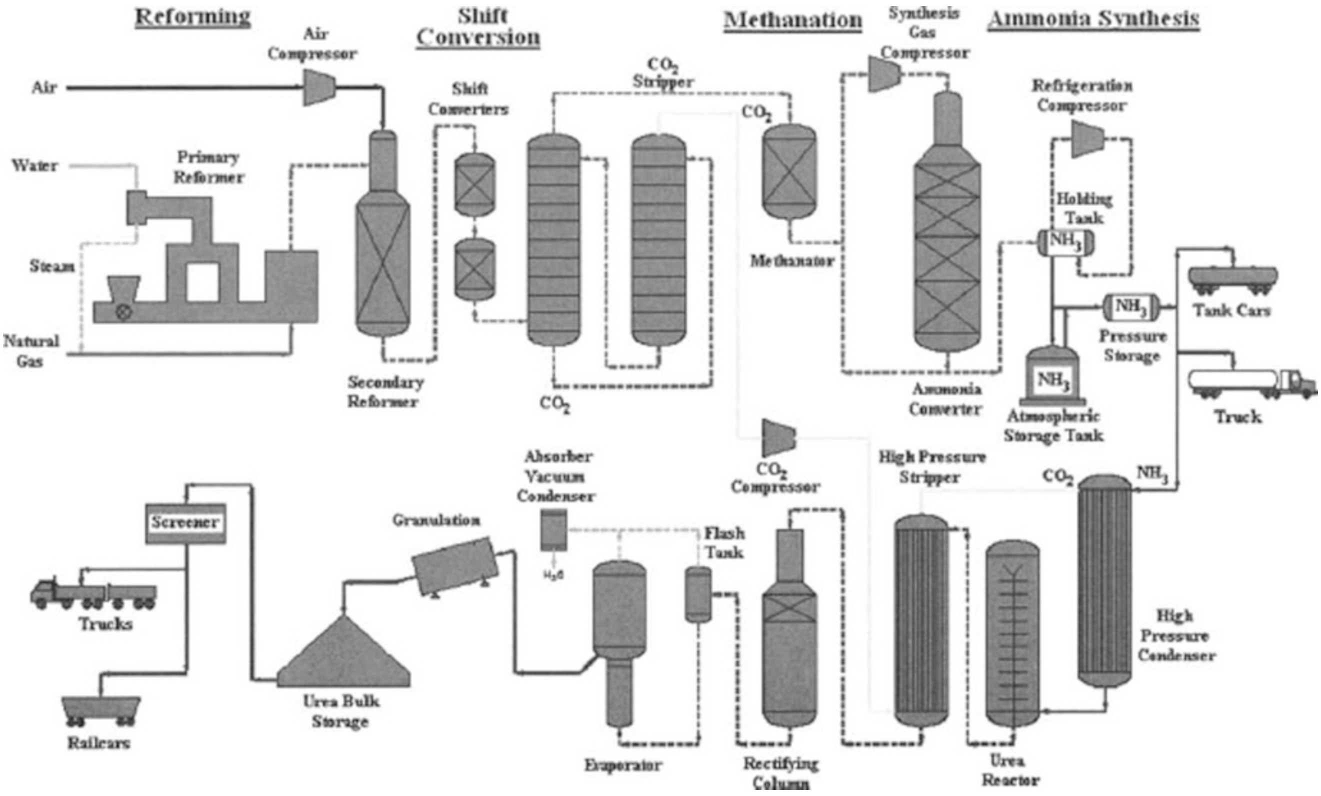

Fig. 22.21 Agrium's Carseland nitrogen operations: ammonia and urea production (Agrium Carseland Nitrogen Operation, Carseland Alberta, Canada, 3/01. Image may not be duplicated or reproduced without the written permission of Agrium)

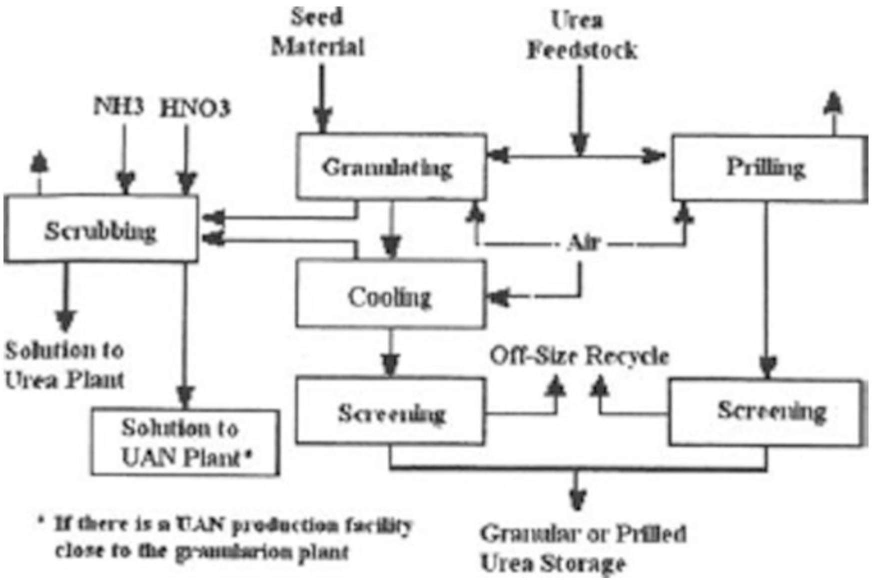

Fig. 22.22 Block diagram for urea granulation and prilling processes [132] (Reproduced by permission of European Fertilizer Manufacturers Association)

Storage and Distribution

Urea may be supplied as a solid or in a solution, and solid urea is classified as granular or prilled products. Prilled products have less desirable qualities than granules and are usually marginally cheaper than granulated product [131].

The majority of urea is designated as fertilizer grade. Technical grade does not contain any additives. Low-biuret grade contains less than 0.3% biuret and is used on citrus crops. Feed grade is fed directly to cattle. It is free of additives and is supplied as microprills with a diameter of about 0.5 mm. Slow-release grades use coatings and additives to increase the amount of nitrogen absorbed by crops. Urea supergranules have diameters up to 15 mm and are used in wetland rice and forest fertilization [131].

The shift from bagged to bulk transport and storage of prilled and granulated urea has called for warehouse designs in which large quantities of urea can be stored in bulk. Caking and subsequent product degradation at unloading are the result of water absorption. To avoid these problems, the warehouse should be airtight and thoroughly insulated. The caking can also be reduced by adding small amounts of formaldehyde (up to 0.6 wt.%) to the urea melt or by adding surfactants to the solid product [131].

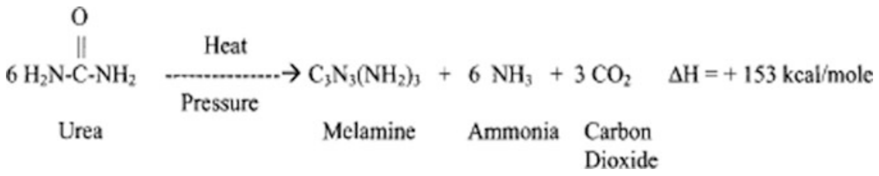
Processes

Melamine can be produced from urea, dicyandiamide, or hydrogen cyanide, but in 2001, all commercial-scale production is based on urea [138].

Melamine is produced from urea by either a high- or a low-pressure process, and either process can consist of one or two stages. The net reaction is [138]

The reactions in the two-stage process are shown in (22.43) and (22.44). The products are quenched with water or an aqueous mother liquor. This stream is then processed by filtration, in centrifuges, or by crystallization [138].

In a typical high-pressure process such as the one licensed by Eurotecnica (see Fig. 22.23 and http://www.eurotecnica.it/melamine.htm), the reaction is carried out in the liquid phase (without a catalyst) at 90–150 bar and 380–450°C.

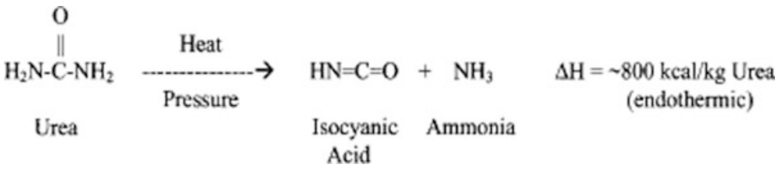


$$\underset{\text{Urea}}{6\,H_2N\text{-}\overset{\overset{O}{\|}}{C}\text{-}NH_2} \xrightarrow[\text{Pressure}]{\text{Heat}} \underset{\text{Melamine}}{C_3N_3(NH_2)_3} + \underset{\text{Ammonia}}{6\ NH_3} + \underset{\text{Carbon Dioxide}}{3\ CO_2} \quad \Delta H = +153\ \text{kcal/mole} \tag{22.42}$$

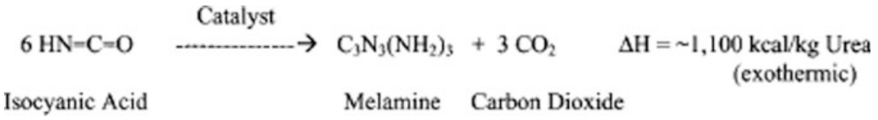
Uses

Urea is used in [135] liquid and solid fertilizers, urea-formaldehyde resins that make adhesives and binders mostly for wood products, livestock feeds, melamine for resins, and NO_x control for boilers and furnaces.

Under these conditions, urea forms cyanuric acid which then reacts with ammonia to form melamine. The first step is the same as (22.43), and the second step is shown in (22.45) and (22.46) [44, 138]:



$$\underset{\text{Urea}}{H_2N\text{-}\overset{\overset{O}{\|}}{C}\text{-}NH_2} \xrightarrow[\text{Pressure}]{\text{Heat}} \underset{\text{Isocyanic Acid}}{HN{=}C{=}O} + \underset{\text{Ammonia}}{NH_3} \quad \Delta H = \sim 800\ \text{kcal/kg Urea (endothermic)} \tag{22.43}$$



$$\underset{\text{Isocyanic Acid}}{6\ HN{=}C{=}O} \xrightarrow{\text{Catalyst}} \underset{\text{Melamine}}{C_3N_3(NH_2)_3} + \underset{\text{Carbon Dioxide}}{3\ CO_2} \quad \Delta H = \sim 1{,}100\ \text{kcal/kg Urea (exothermic)} \tag{22.44}$$

Melamine

Melamine is characterized by its three amino ($-NH_2$) groups and by its 66.6% nitrogen content. Its chemical formula can be written as $C_3H_6N_6$ or $C_3N_3(NH_2)_3$. It was first prepared in 1834, but it was not until 1937 that it was produced commercially.

Some of the properties of melamine are listed in Table 22.22 [138].

$$\underset{\text{Isocyanic acid}}{3HN = C = O} \rightarrow \underset{\text{Cyanuric acid}}{C_3N_3(OH)_3} \tag{22.45}$$

$$\underset{\text{Cyanuric acid}}{C_3N_3(OH)_3} + \underset{\text{Ammonia}}{3NH_3} \rightarrow \underset{\text{Melamine}}{C_3N_3(NH_2)_3} + 3H_2O \tag{22.46}$$

In a typical low-pressure process, the reaction is carried out in the vapor phase at 1–10 bar and 350–400°C. This process

Melamine structure	
uses a catalyst such as modified aluminum oxide or alumino-silicate. Under these conditions, urea forms isocyanic acid as shown in (22.43). On the catalyst, the isocyanic acid is converted to cyanamide or carbodiimide which is subsequently converted to melamine (see (22.47) and (22.48)) [44, 138]:

$$\underset{\text{Isocyanic Acid}}{2\,HN{=}C{=}O} \rightarrow \left(\underset{\text{Carbodiimide}}{HN{=}C{=}NH} \quad \text{or} \quad \underset{\text{Cyanamide}}{H_2N{=}C{\equiv}N}\right) + \underset{\text{Carbon Dioxide}}{CO_2} \tag{22.47}$$

$$\left(\underset{\text{Carbodiimide}}{HN{=}C{=}NH} \quad \text{or} \quad \underset{\text{Cyanamide}}{H_2N{=}C{\equiv}N}\right) \rightarrow \underset{\text{Melamine}}{C_3N_3(NH_2)_3} + \underset{\text{Carbon Dioxide}}{CO_2} \tag{22.48}$$

Carbon dioxide and ammonia are obtained as by-products in both the low- and high-pressure processes and are usually recycled to the urea process to improve process economics. With recycling, about 1.5 lb of urea is used to produce 1 lb of melamine which corresponds to a yield of 95% (compared to a yield of only 49% without recycle) [138].

DSM Melamine started up a new 30,000-tons/year melamine plant in 2004 and reached design capacity in 2006. This plant will use the high-pressure shortened liquid-phase (SLP) process developed by DSM. The SLP process is expected to increase efficiency by 25% and have the same costs as a 100,000-tons/year production facility. The new process requires only three or four processing steps, in contrast to the ten steps in conventional processes [139].

The major melamine process technologies and the suppliers of these technologies are listed in [138].

Production

In 2001, worldwide capacity was 1.1 million tons/year [140]. In 1998, Western Europe accounted for 35% of world capacity, followed by Asia (excluding Japan) with 24%, and both the United States and Japan with 16% each [138]. Demand for melamine is heavily influenced by construction and auto manufacture [138].

Uses

Melamine is supplied in bags, carlots, and truckloads. Some of the melamine uses are surface coatings, laminates, paper treating, molding compounds, textile treating, wood adhesives, and other uses such as ceiling tiles, tire cord, flame retardants, and many other small-volume applications [138, 141].

Aliphatic Amines

Amines are derivatives of ammonia in which the hydrogen atoms in the ammonia have been displaced by monovalent hydrocarbon radicals. Depending on the number of hydrogen atoms displaced, amines are classified as primary (RNH_2), secondary (R_2NH), or tertiary (R_3H). The amines can be categorized further according to the type of hydrocarbon radicals that substitute for the hydrogen atoms: aliphatic (saturated or unsaturated), aromatic, heterocyclic, alicyclic, or any combination of these.

Imines are one group of compounds that are similar to amines. Imines contain an ammonia molecule in which two hydrogen atoms are displaced by bivalent hydrocarbon radicals ($R = NH$). Another group of compounds that are similar to amines is nitriles. In nitriles, all the hydrogen atoms in ammonia are displaced by a trivalent hydrocarbon radical ($RC \equiv H$).

Methylamines

Methylamines are colorless liquids that are volatile at normal atmospheric conditions. They have threshold odor limits of less than 10 ppm, and at low concentrations, they have a fishy smell. At high concentrations, they smell like ammonia. The physical properties are given in Tables 22.23 and 22.24.

Conventional Processes. The reaction of an alcohol with ammonia provides the most common commercial routes to

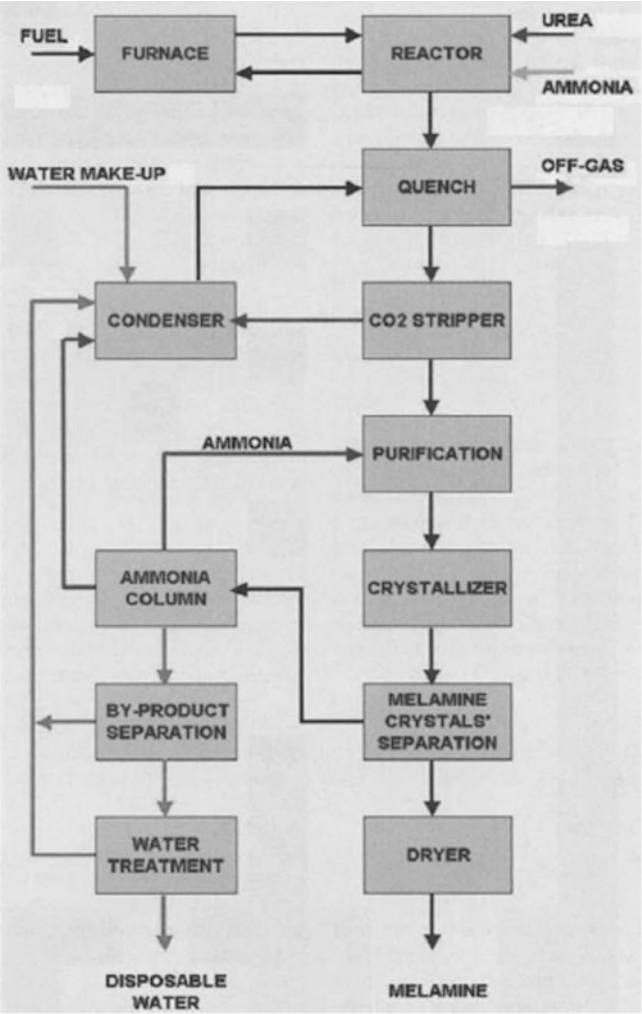

Fig. 22.23 Eurotecnica high-pressure melamine process (Reproduced by permission of Eurotecnica)

alkylamines. Capacities of many plants depend on the product mix of mono/di/tri products as well as the variety of amines (ethyl, propyl, and butyl) [142].

In alcohol amination, methanol and excess ammonia react at 350–500°C and 15–30 bar in the presence of aluminum oxide, silicate, or phosphate catalysts according to the following reactions [44]:

$$NH_3 + CH_3OH \xrightarrow{Cat} CH_3NH_2 + H_2O \quad \Delta H = -5.358 \text{ kcal/mol} \tag{22.49}$$

$$CH_3NH_2 + CH_3OH \xrightarrow{Cat} (CH_3)_2NH + H_2O \quad \Delta H = -9.598 \text{ kcal/mol} \tag{22.50}$$

$$(CH_3)_2NH + CH_3OH \xrightarrow{Cat} (CH_3)_3N + H_2O \quad \Delta H = -14.098 \text{ kcal/mol} \tag{22.51}$$

Reactions (22.49), (22.50), and (22.51) are known as the alkylation reactions. They are exothermic and highly irreversible, except for (22.51). Reactions (22.52), (22.53), and

(22.54) are known as disproportionation reactions. They are reversible and are endothermic. The alkylation reactions dictate the rate of consumption of methanol and are somewhat faster than the disproportionation rates that govern the selectivity of the three amines. Guidelines for optimizing the reactions are discussed in [44, 142].

Figure 22.24 shows a typical methylamine process diagram [143]. The raw material and utility use are summarized in Table 22.25 [24].

Although companies can produce a range of C_2 to C_6 amines on a campaign basis in a higher-alkylamine plant, methylamine plants are usually designed and dedicated solely for production of a given chain-length product. The methylamine plants also use a different catalyst from that in a higher-amine plant [142].

Mitsubishi Rayon has operated a process since 1984 in which the equilibrium of methylamine formation is shifted to make more dimethylamine by use of an acid zeolite catalyst. The product stream contains 7 mol.% MMA, 86 mol.% DMA, and 7 mol.% TMA, and the investment as well as the operating costs are lower than the conventional Leonard process that is used by most companies. Because DMA has the highest sales volume, the process might be appealing.

Aldehyde–Amine and Ketamine Hydrogenation Process. Imines can be addition of ammonia to a carbonyl compound, and the imines are hydrogenated to make amines per (22.55) [142]:

$$RCHO + NH_3 \rightarrow RCH = NHH_2RCH_2NH_2 \qquad (22.55)$$

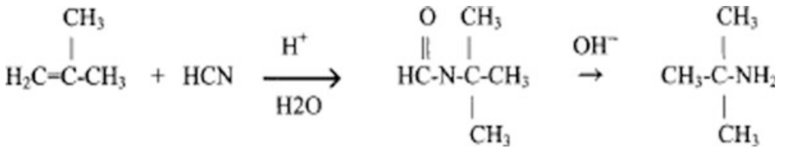
Nitrile Reduction. The choice of catalyst and variations of the temperature, pressure, and concentration of ammonia can control the product mix of amines from hydrogenation of a nitrile. The reaction is shown in (22.56):

$$RC{\equiv}N + H_2 \rightarrow RCH_2NH_2 + (RCH_2)_2NH_2 + (RCH_2)_3N \qquad (22.56)$$

A large excess of ammonia suppresses formation of di- and trialkylamines. Reference [142] describes the process in more detail.

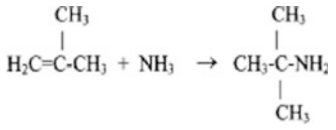
Other Alkyl Amines

Ritter Reaction. Mitsubishi Rayon and Sumitomo Chemical in Japan make *t*-butylamine (22.57). Average yields are about 85% based on isobutylene. Rohm and Haas in the United States make *t*-octylamine from hydrogen cyanide and diisobutylene by a similar route [142].



$$H_2C{=}\overset{\overset{\displaystyle CH_3}{|}}{C}{-}CH_3 + HCN \xrightarrow[H2O]{H^+} H\overset{\overset{\displaystyle O}{\|}}{C}{-}N{-}\underset{\underset{\displaystyle CH_3}{|}}{\overset{\overset{\displaystyle CH_3}{|}}{C}}{-}CH_3 \xrightarrow{OH^-} CH_3{-}\underset{\underset{\displaystyle CH_3}{|}}{\overset{\overset{\displaystyle CH_3}{|}}{C}}{-}NH_2 \qquad (22.57)$$

Direct Amination. Direct amination of olefins is a special case and has been successfully developed for only a few amines. BASF has developed a process for the direct amination of isobutylene to yield *t*-butylamine solutions (see (22.58)) and has operated a commercial plant in Western Europe since 1993 [142].



$$H_2C{=}\overset{\overset{\displaystyle CH_3}{|}}{C}{-}CH_3 + NH_3 \rightarrow CH_3{-}\underset{\underset{\displaystyle CH_3}{|}}{\overset{\overset{\displaystyle CH_3}{|}}{C}}{-}NH_2 \qquad (22.58)$$

Hydrogenation of Anilines. A manufacturing process that is specific for cyclohexylamines is the catalytic hydrogenation of anilines or phenols in the presence of ammonia. Process details are given in [142].

Manufacturing Costs. Manufacturing costs for alkylamines depend on the specific amine and the process. Reference [142] gives the estimated production costs for two different processes.

Production

Methylamines are commonly sold as anhydrous gases or as 25, 40, 50, and 60% aqueous. The other alkylamines are

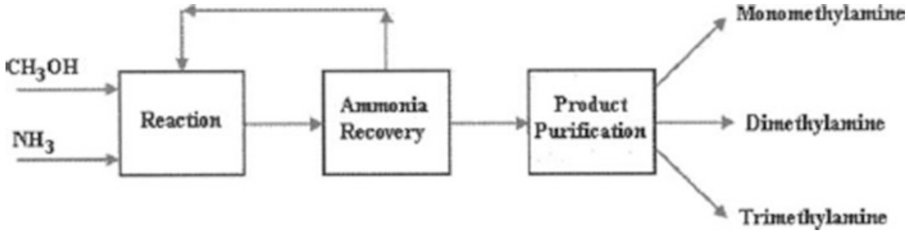


Fig. 22.24 Typical methylamines process

Table 22.25 Methylamine production: raw material and utility use (ton per ton of product leaving the reactor)

	MMA	DMA	TMA
Methanol	1.053	1.451	1.660

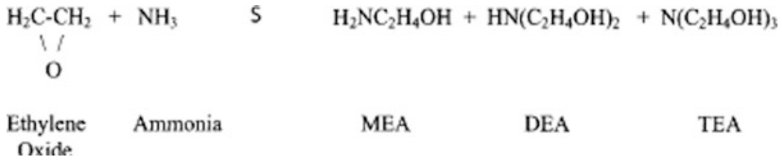
usually sold on a 100% basis although some are also marketed as aqueous solutions. In 1997, MMA and TMA prices increased to \$0.73 per lb, and DMA went up to \$0.77 per lb. Since that time, market prices have declined somewhat as methanol prices have receded [142, 144]. From 1995 to 2003, the price of cyclohexylamine has varied from a low of \$0.70 per lb to a high of \$1.35 per lb. High benzene prices have increased the price of aniline and are putting pressure on cyclohexylamine prices [145].



$$H_2C\text{-}CH_2 + NH_3 \quad \text{S} \quad H_2NC_2H_4OH + HN(C_2H_4OH)_2 + N(C_2H_4OH)_3 \tag{22.59}$$

Methylamine growth should remain strong as applications in the largest market segments are growing two to three times quicker than GNP [146]. However, worldwide growth in alkylamines should average a modest 2–3% annually from 2005 to 2009 [142]. From 1998 to 2003, cyclohexylamine production has been constant at 15.5 million lb/year [145].

In the United States, growth is expected to increase at 3.3% per year between 2003 and 2006 [144].

The major world producers of methylamines include BASF, Air Products, DuPont, and UCB. The major producers of C_2 to C_6 alkylamines include Air Products, BASF, and Celanese [142].

The largest consumer of alkylamines are the United States, followed by Western Europe (at ~70% of the United States consumption) and Japan (at ~25% of the United States consumption) [142].

Uses

The three methylamines are important intermediates for the manufacture of solvents, insecticides, herbicides, pharmaceuticals, and detergents. DMA is the most important due to its use in the manufacture of *N*,*N*-dimethyl-formamide and *N*,*N*-dimethylacetamide, which find wide application as solvents [44, 142].

Methyl methacrylate (MMA) ranks second in terms of demand. It is mainly used to make dimethyl urea and *N*-methylpyrrolidone, as well as for methyltaurine, which is employed in CO_2 washes or as a raw material for detergents [44, 142].

TMA plays only a minor role. It is used in the manufacture of choline chloride, quaternary salts, and epichlorohydrin [44, 142].

Some of the other alkyl amines and their uses are

- Ethylamines: Pesticides and catalysts
- Propylamines: Herbicides, detergents, catalysts
- Butylamines: Pesticides, plasticizers, insecticides, catalysts, herbicides
- Cyclohexylamines: Corrosion inhibitors, catalysts, antibiotics, herbicides, cyclamate sweeteners in Asia

Ethanolamines and Secondary Products

The main use of ethanolamines (EOA) is for the manufacture of detergents by reaction with fatty acids. The principal secondary products of EOAs are morpholine, ethylenimine, and ethylenediamine (EDA).

EOAs are corrosive and will attack some plastics and rubbers. They are a moderate fire hazard. MEA and TEA are clear viscous liquids with a mild ammonia-like odor. DEA is crystalline or a viscous liquid. All are soluble in

Table 22.26 Effect of excess ammonia on ethanolamine selectivity [44]

	Selectivity ratios

water and ethanol. Vapor is irritating to the eyes, skin, and respiratory tract, and depression of the central nervous system can occur. They can also be absorbed by the skin in toxic amounts [147].

Ethanolamine Process

Ethylene oxide reacts exothermically with 20–30% aqueous ammonia at 60–150°C and 30–150 bar in a tubular reactor to form the three possible EOAs (monoethanolamine: MEA, diethanolamine: DEA, and triethanolamine: TEA) with high selectivity.

The composition of the reaction product stream can be influenced by temperature and pressure. Higher ratios of excess ammonia lead to a higher MEA content as shown in Table 22.26. The high triethanolamine content that results from an equimolar mixture of reactants indicates that the primary reaction with ammonia is slower than the secondary reactions [44].

A typical EOA flowsheet is shown in Fig. 22.25 [143]. Nippon Shokubai has developed technology that uses a zeolite catalyst that suppresses the formation of TEA and produces more MEA and DEA [147]. Another process flowsheet is described in [148] along with detailed process conditions.

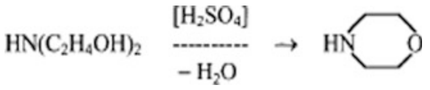
Himtek Engineering in St. Petersburg, Russia, offers EOA technology that operates at 40–70°C and 15–35 atm. The ammonia and part of the MEA are recycled. Three vacuum stills are used to separate the three products. This technology is described in Russian patents No. 2,141,475 and No. 2,063,955 [149].

Production. All EOA plants make a mixture of products. The most important is MEA, which accounts for about half of total production. It is followed by DEA with 30–35% of production. In 2001, Ineos was the largest global producer followed by BASF and Huntsman. EOA demand is growing between 4 and 6% annually with MEA and DEA growth rates substantially exceeding that for TEA. In 2001, EOA supply exceeded demand, and the oversupply situation continued through 2002 with startups of more new plants. About 50% of EOA capacity is in the Americas, more than 30% is in Europe, and the balance is in the Pacific Rim and the Middle East. Table 22.27 summarizes world consumption and growth rates for EOA [35, 147].

Uses. EOA production is consumed in the following areas: detergents (32%), ethyleneamines (20%), gas purification (17%), metal cleaning (10%), herbicide intermediates (10%), textiles (5%), and miscellaneous (6%) [150]. The specific uses of MEA, DEA, and TEA are listed in [151].

Secondary Products of Ethanolamine

Morpholine. Morpholine is a solvent and intermediate for optical brighteners and rubber chemicals. In one process, it is obtained from DEA by dehydration with 70% H_2SO_4 to close the ring:

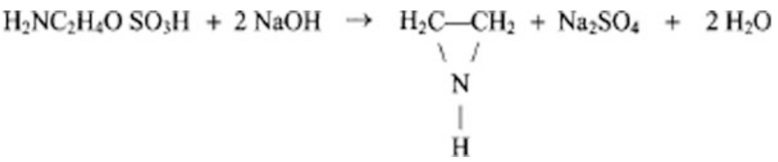


(22.60)

In the United States, a newer production route is used in which diethylene glycol, ammonia, and hydrogen react at 150–400°C and 30–400 bar over a catalyst containing Ni, Cu, Cr, or Co to give morpholine [44].

Ethylenimine. Ethylenimine can be made from MEA via a two-step process that BASF and Hoechst developed [44]:

$$H_2NC_2H_4OH + H_2SO_4 \rightarrow H_2NC_2H_4OSO_3H + H_2O \qquad (22.61)$$



$$H_2NC_2H_4O\,SO_3H + 2\,NaOH \rightarrow H_2C{-}CH_2\,(NH) + Na_2SO_4 + 2\,H_2O \qquad (22.62)$$

Dow makes ethylenimine by reacting 1,2-dichloroethane (EDC) with ammonia in the presence of CaO at about 100°C:

Fig. 22.25 Typical ethanolamine (EOA) process

$$ClC_2H_4Cl + CaO + NH_3 \rightarrow H_2C{-}CH_2(NH) + CaCl_2 + H_2O \qquad (22.63)$$

Most ethylenimine is converted into polyethylenimine, a processing aid in the paper industry. It also serves as a reaction intermediate when ureas are formed with isocyanates [44].

Ethylenediamine. Commercial EDA is produced by two different routes:

- From EDC and ammonia by Cl/NH_2 substitution
- From MEA and ammonia by OH/NH_2 substitution

The reaction in the first process is shown below, and the process details are given in [44]:

$$\begin{aligned} ClC_2H_4Cl + 2NH_3 \rightarrow\; & NH_2C_2H_4NH_2 \\ & + \text{Higher amines} + NH_4Cl \\ & + \text{Amine clorides} \end{aligned} \qquad (22.64)$$

In 1969, BASF developed a process to make EDA by the reaction of MEA and ammonia [44]:

$$NH_2C_2H_4OH + NH_3 \xrightarrow[H_2]{Ni} NH_2C_2H_4NH_2 + H_2O \qquad (22.65)$$

The properties of EDA and some of the higher amines are given in Table 22.28.

Ethylenediamine Production

In 1999, the EDA capacity in the United States was 390 million lb/year of ethyleneamines. Demand was expected to grow from 310 million lb/year in 1998 to 370 million lb/year in 2003. These estimates include exports that average 70–80 million lb/year and imports that total about 10–12 million lb/year. From 1989 to 1998, growth averaged 4% per year, but it is expected to slow to 3% per year through 2003 [152]. Prices are kept confidential, but the 2001 US EDA price is estimated to be \$0.80–\$0.85 per lb [145].

Ethylenediamine Uses

EDAs are used in the following products: lube oil and fuel additives (20%), chelating agents (16%), wet-strength resins (15%), epoxy curing agents and polyamides (13%), surfactants (10%), oil field chemicals (7%), and miscellaneous (19%).

Hexamethylenetetramine (Hexamine)

Hexamine was first prepared in 1859. It is a white crystalline powder with a slight amine odor. It is soluble in water, alcohol, and chloroform, but it is insoluble in ether. However, the aqueous solutions exhibit inverse solubility, i.e., less hexamine dissolves as the temperature increases. The hydrate, $(CH_2)_6N_4{\cdot}6H_2O$, can be crystallized from the aqueous solution at temperatures below 14°C. Additional properties are listed in Table 22.29.

Hexamine Processes

Hexamine is made by the liquid-phase reaction of ammonia and formaldehyde:

$$\begin{gathered} 4NH_3 + 6HCHO \rightarrow (CH_2)_6N_4 + H_2O \\ \Delta H = -55 \text{ kcal/mol Hexamine} \end{gathered} \qquad (22.66)$$

Process details are given in [153, 154].

Production. Production has declined from 48 million lb in 1995 to 32 million lb in 2001. The decline is mainly due to a

decline in the use of phenolic resins that contain hexamine [154]. Hexamine is produced as a granular and free-flowing powder as well as a 42.5% solution. The solution is shipped in tank trucks, railcars, and drums. Solids are packed in bags, fiber drums, and super sacks. Hexamine is sensitive to moisture. Therefore, it should be stored in an atmosphere with a relative humidity below 60% [155].

Uses. Hexamine is used as a stabilizer and surface treatment in numerous applications and industries. Specific applications are described in [156].

Hydrazine

Hydrazine, $NH_2–NH_2$, is the simplest diamine. Anhydrous hydrazine was first prepared in 1894. In 1953, Arch Hydrazine (formerly Olin Chemical) pioneered US production of hydrazine to fuel the first Titan rocket.

Hydrazine is a clear, hygroscopic fuming liquid with the odor of ammonia. It is a mild base that is miscible in polar solvents such as water, ammonia, amines, and alcohols. Additional properties are shown in Table 22.30 [157].

Processes

Five processes are available for the commercial production of hydrazine: the Raschig process, the Raschig/Olin process, the Hoffmann (urea) process, Bayer ketazine process, and the peroxide process from Produits Chimiques Ugine Kuhlmann (of France).

Raschig Process. The Raschig process was discovered in 1907 and then modified into the Olin process. The chemical reactions take place in the liquid phase and involve three steps:

$$NaOH + Cl_2 \rightarrow NaOCl + HCl \tag{22.67}$$

$$NH_3 + NaOCl \rightarrow NH_2Cl + NaOH \tag{22.68}$$

$$NH_2Cl + NH_3 + NaOH \rightarrow NH_2 - NH_2 \cdot H_2O + NaCl \tag{22.69}$$

Hydrazine is produced in the hydrated form with 1 mol of water added. Although a significant fraction of hydrazine is used as the hydrate, numerous applications (such as rocket propulsion) require anhydrous hydrazine. Because of the azeotrope at 68% hydrazine, reactive distillation or extractive distillation must be used to produce pure hydrazine.

Additional process details are given in [158]. The Raschig process is shown in Fig. 22.26.

The Raschig process can also be used to react amines with chloramine to make mono-substituted or unsymmetrical disubstituted hydrazines:

$$NH_2Cl + RNH_2 \rightarrow RNHNH_2 \tag{22.70}$$

$$NH_2Cl + R_2NH \rightarrow R_2NNH_2 \qquad (22.71)$$

Raschig/Olin Process. The Raschig/Olin process is used to make anhydrous hydrazine. In this process, (22.67), (22.68), and (22.69) also occur. However, the refining area has a different design from the Raschig process. Additional details are given in [158].

The refining area has five steps: ammonia removal, NaCl concentration and removal, hydrazine–water distillation to reach azeotropic concentration, extractive distillation with aniline to break the azeotrope and distillation to separate hydrazine from aniline. Sometimes 50% caustic replaces aniline in the extractive distillation. If ultra-pure hydrazine is needed, freeze crystallization is used to remove the supernatant fluid. Assays between 99.5 and 99.99% have been achieved.

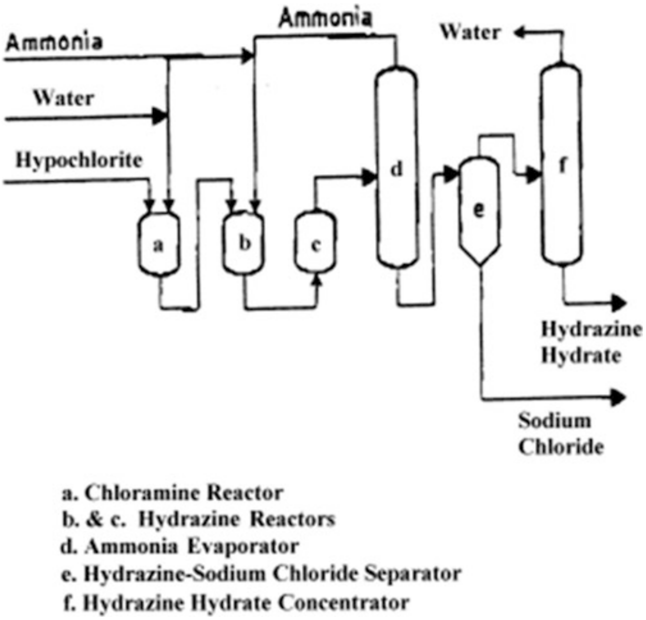

Fig. 22.26 Raschig process for hydrazine production (Courtesy of Wiley-VCH [158])

The overall yield based on chlorine is 65%. The combined yield for (22.67) and (22.68) is about 95%, whereas the yield for (22.69) is 70%. Japanese patent SHO-62-83308 claims to increase hydrazine yield by almost 10% by high-frequency heating immediately after the reactants are mixed in (22.68). A sketch of the Raschig/Olin process is shown in Fig. 22.27 [158].

Hoffman (Urea) Process. The overall reaction for the Hoffman process is

$$\underset{\text{Urea}}{CO(NH_2)_2} + \underset{\text{Hypochlorite}}{NaOCl} + 2NaOH \rightarrow \underset{\text{Hydrazine}}{NH_2 - NH_2} + NaCl + Na_2CO_3 + H_2O \qquad (22.72)$$

Process details are given in [158].

This process was not being operated in 2001 although it has operated commercially in the past. Compared with the standard Raschig process, it was the most economical method for low production levels. However, rapid growth in plant size made it obsolete [158].

Bayer Ketazine Process. The Bayer ketazine process is based on the reaction of chloramine with ammonia in the presence of acetone at pH 12–14. NaOCl, acetone, and a

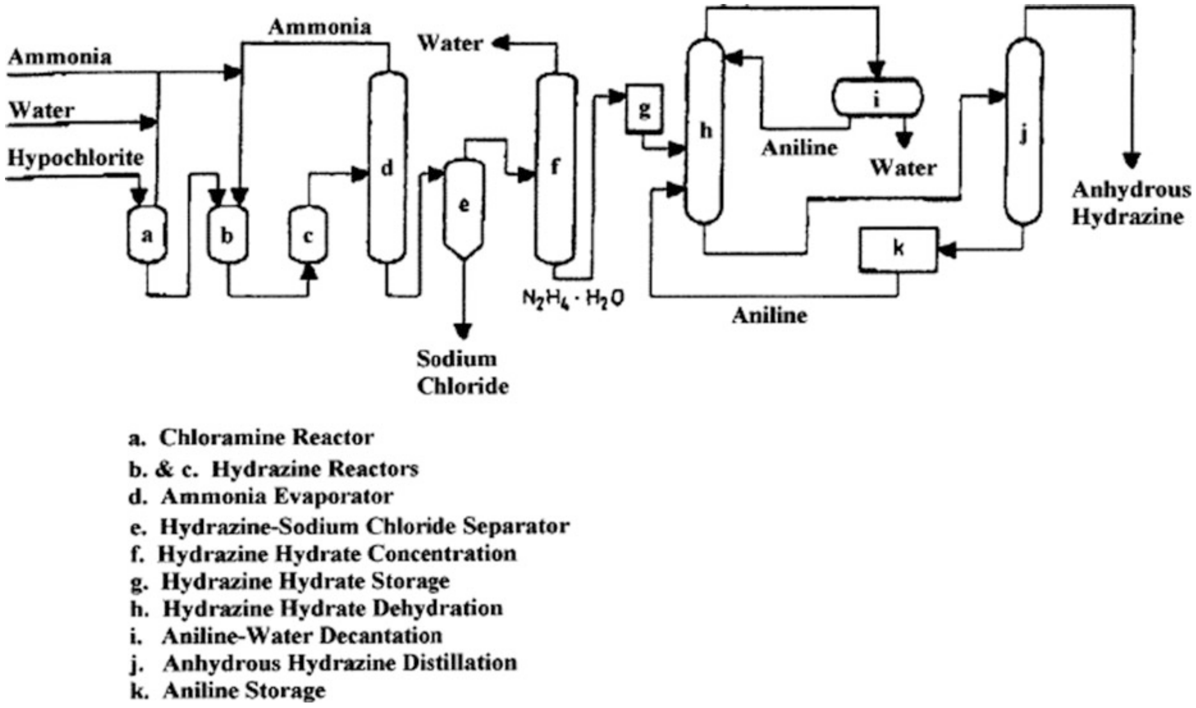

Fig. 22.27 Raschig/Olin process for hydrazine production (Courtesy of Wiley-VCH [158])

20% aqueous solution of ammonia (at a mole ratio of 1:2:20, respectively) are fed to a reactor at 35°C and 200 kPa to make the aqueous dimethyl ketazine solution. Excess ammonia and acetone are removed in a series of columns and recycled to the reactor. The ketazine solution is distilled to make a hydrazine hydrate containing 64% hydrazine [158].

Peroxide Process. This process (see Fig. 22.28) was invented by PCUK and is operated by AtoFina in France. The reaction is carried out in the presence of methyl ethyl ketone (MEK) at atmospheric pressure and 50°C. The molar ratio in the feed of hydrogen peroxide (H_2O_2), MEK, and NH_3 is 1:2:4. Additional process details are given in [158].

Production. Hydrazine is marketed as anhydrous hydrazine, as the monohydrate (64% hydrazine), and as a 54.5% aqueous solution (85% hydrazine monohydrate). The largest US producers of hydrazine based on a 2000 report [159] are Arch Chemical (23 million lb/year), Bayer (17 million lb/year), and Fairmont Chemical (1 million lb/year).

About 29 million lb is sold in the United States, and the manufacturers retain about 7 million lb for internal use. The space industry uses only 5% of all hydrazine produced in the United States [159]. Total capacity in the western world in 1988 was estimated to be about 130 million lb/year [158].

The permissible exposure limit (PEL) for hydrazine hydrate on an 8-h TWA is 0.1 ppm. The ammonia-like

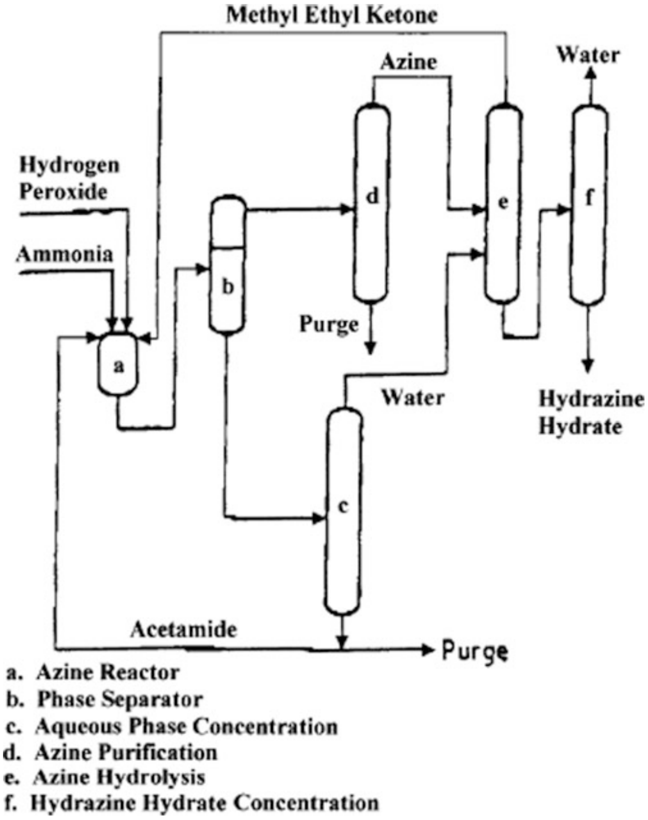

Fig. 22.28 Peroxide process for hydrazine production [158] (Courtesy of Wiley-VCH [158])

odor of hydrazine hydrate normally cannot be detected until the concentration is above 3–5 ppm [157].

Uses. Hydrazine is used directly as an oxygen scavenger and as an energy source. Hydrazine is consumed in the following applications: blowing agents (33%), pesticides (32%), water treatment (18%), and miscellaneous (17%) [160].

Hydrogen Cyanide

HCN is a colorless liquid. However, some iron cyanides are blue (prussian blue), and their presence as a slight contaminant usually gives HCN a bluish tint that led to the German name Blausäure—blue acid. Selected physical properties of hydrogen cyanide are shown in Table 22.31.

Safety

Many people can detect hydrogen cyanide by odor or taste sensation at a concentration of 1 ppm in air, whereas most people can detect 5 ppm. OSHA has set 4.7 ppm as the maximum, average safe exposure limit for a 15-min period. Exposure to 20 ppm of HCN in air causes slight warning symptoms after several hours; 50 ppm causes disturbances within an hour; 100 ppm is dangerous for exposures of 30–60 min; and 300 ppm can be rapidly fatal unless prompt, effective first aid is administered. A small concentration of cyanide always exists in a person's body, and the body has a mechanism to continuously remove small amounts of cyanide [161].

HCN may also present some processing hazards. HCN undergoes an exothermic polymerization at a pH of 5–11 to form solid black compounds. This polymerization can become explosively violent, especially if it is confined. To avoid polymerization, stored HCN should contain less than 1.0 wt.% water; it should be kept cool; and it should be inhibited with sulfuric, phosphoric, or acetic acid [161].

Explosively violent hydrolysis can occur if an excess of a strong acid (H_2SO_4, HNO_3, or HCl) is added to HCN. The reaction is fastest at or near stoichiometric ratios, e.g., 1–2 mol H_2SO_4 per mol HCN, and can cause severe equipment damage if confined [161].

An important environmental issue is the fate of cyanide. HCN, if spilled, evaporates quite readily. That which does not evaporate is soon decomposed or rendered nonhazardous by complexing with iron in the soil, by biological oxidation, or by degradation from photolysis [161]. Several methods for treatment and disposal of cyanide compounds are described in [161, 162].

Manufacture

Six processes are presently of economic significance: the Andrussow process is currently the principal HCN manufacturing process in the world, the BMA process is practiced by two companies and provides high yield and selectivity by using a complex reaction system, the Fluohmic process is of interest in locations where electricity is inexpensive, the formamide process is useful for sites with inexpensive carbon monoxide, the BP (British Petroleum) ACRN process produces HCN as a by-product, and the methanol process.

Andrussow Process. The Andrussow process was patented in Germany by Dr. L. Andrussow in 1933. Its main advantages are low converter investment, low maintenance costs, and

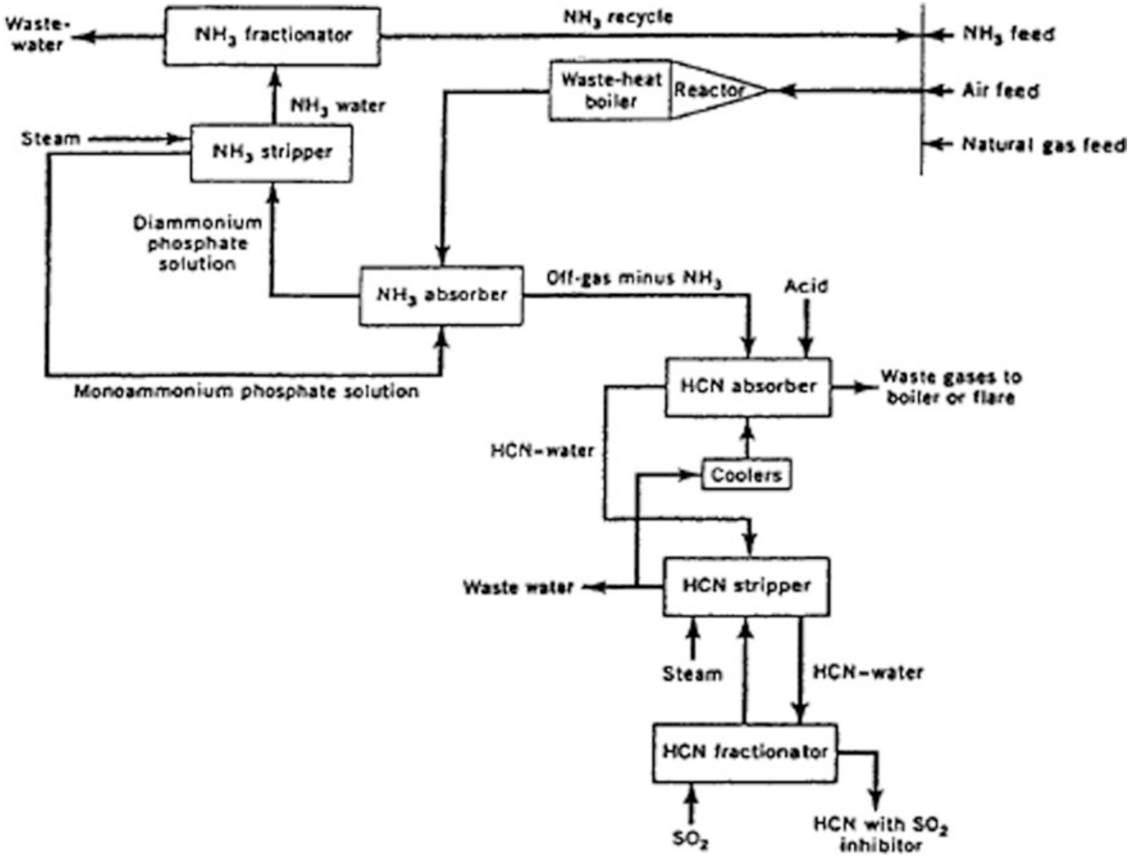

Fig. 22.29 Andrussow HCN process with ammonia removal [161] (Copyright by Wiley and reproduced by permission of copyright owner)

high natural gas yields. The Andrussow process produces HCN by the reaction of ammonia, air, and natural gas at 1,000–1,200°C in the presence of a platinum/rhodium catalyst. The reaction is

$$NH_3 + CH_4 + 1.5O_2[Pt/Rh]1,200°C HCN + 3H_2O \quad \Delta H = -115.2 \text{ kcal/mol HCN} \tag{22.73}$$

More reaction details are given in [161]. The heat of reaction is recovered in the waste heat boiler to generate about 5 lb of steam per lb of HCN produced.

The precious metal catalyst is usually 90% platinum and 10% rhodium in gauze form. The catalyst life can range from 4,000 h to as much as 10,000 h. A catalyst pack is usually replaced because it has been contaminated by minor impurities in the feed gases. Very little catalyst metal is consumed or lost during the life of a catalyst.

The reaction takes place under fuel-rich conditions to maintain a nonflammable feed mixture. Typical feed composition is 13–15% ammonia, 11–13% methane, and 72–76% air on a volumetric basis. Control of feed composition is essential to guard against deflagrations as well as to maximize the yield. The yield from methane is approximately 60% of theoretical.

The reactions in the Andrussow process are more complex than that shown in (22.72) [163]. Most of the heat required for HCN formation is supplied by combustion of methane. This results in an overall reaction that is exothermic [161]. The converter off-gas typically has the following molar composition: HCN = 6–12%, NH_3 = 1.5–3%, H_2 = 7–11%, N_2 = 50–55%, H_2O = 20–25%, CO = 3–4%, CO_2 = 0.3%, and CH_4 = 0.1%.

Two processes can be used to remove NH_3 from the converter off-gases. Figure 22.29 shows a process that recovers unreacted ammonia for recycle to the converter, and the process in Fig. 22.30 uses sulfuric acid to produce ammonium sulfate as a by-product. Ammonium sulfate can create a disposal problem, but the recycle system is capital and energy intensive. Ammonia must be removed from the off-gas before HCN can be recovered because the ammonia promotes polymerization of the HCN [161]. Additional process details are given in [161].

BMA Process. The BMA (Blausäure–Methan–Ammoniak, or HCN–methane–ammonia) process was developed by Degussa around 1949. In the process, ammonia reacts with

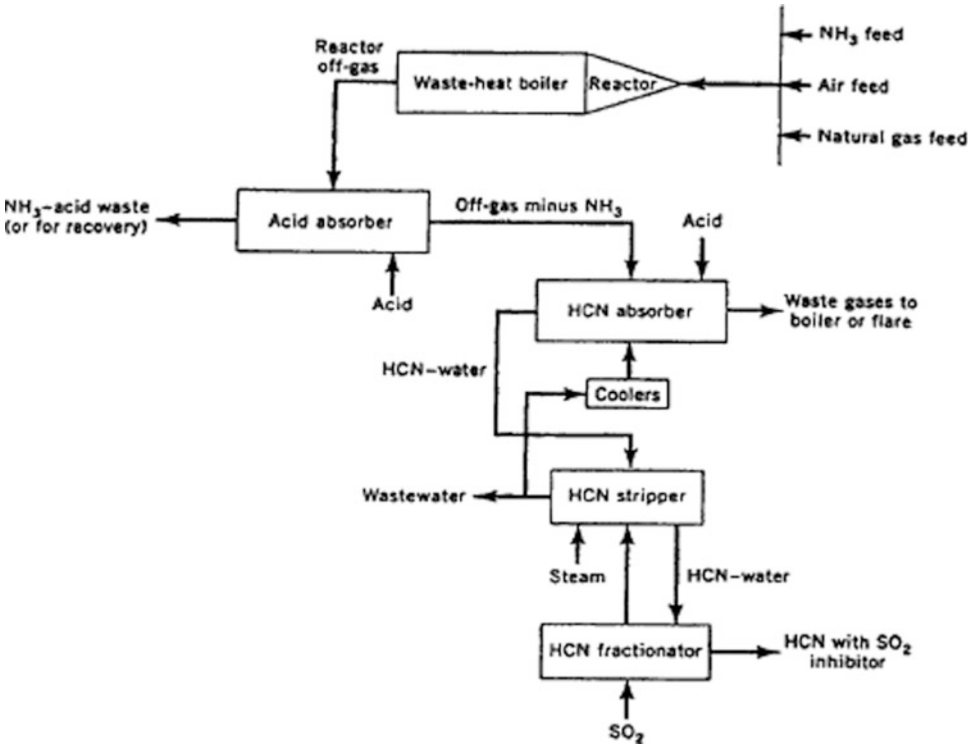

Fig. 22.30 Andrussow HCN process with ammonia removal [161] (Copyright by Wiley and reproduced by permission of copyright owner)

methane in the absence of oxygen in a gas-fired tubular reactor. US patent 5,785, 942 describes the BMA process and improvements that were made during the mid-1990s. The reaction is [44]

$$NH_3 + CH_4 \xrightarrow[\text{[Pt/Ru]}]{1{,}300^\circ C} HCN + 3H_2$$
$$\Delta H = +60 \text{ kcal/mol HCN} \qquad (22.74)$$

In a reactor that is similar to a reformer, the reaction occurs in tubes that are heated externally to supply the endothermic heat of reaction [161]. Sintered corundum (α-Al_2O_3) tubes with an internal layer of platinum/ruthenium catalyst are normally used. To achieve adequate heat transfer, the tubes may be only 3/4 in. in diameter and 6 $^1/2$ ft long. Selectivities of 90–91% for methane and 83–84% for ammonia are reached at 1,200–1,300°C reaction temperatures.

A typical converter is made up of multiple furnaces, each of which contains eight to ten reactors. Each reactor contains 10–30 tubes with a catalyst lining. Catalyst life is approximately 10,000 h [161].

The converter off-gas typically has the following molar composition: $HCN = 20$–23%, $NH_3 = 2$–3%, $H_2 = 70$–72%, $N_2 = 0.5$–1%, and $CH_4 = 1$–2.4%.

The unreacted ammonia is removed from the reactor off-gas by scrubbing with sulfuric acid to make ammonium sulfate. Just as with the Andrussow process, ammonia must be removed from the off-gas before HCN can be recovered because the ammonia promotes polymerization of the HCN. After ammonia is removed from the converter off-gases, the remaining gas stream is processed in a way similar to the Andrussow process [161].

In the BMA process, the gas that leaves the HCN absorber has the following molar composition: $H_2 = 96\%$, N_2 and $O_2 = 1.5\%$, and $CH_4 = 2.5\%$. The vent gas is used either as a chemical feedstock or as fuel gas in the HCN furnaces.

The advantages of the BMA process are high ammonia yields, high natural gas yields, and the useful hydrogen in the vent gas. But the high investment and high maintenance costs for the converter are the disadvantages. The complexity of the reaction system also makes the process less attractive for large-scale production [161]. In 2003, the BMA process was in use at four plants [164].

Fluohmic Process. The Fluohmic process was developed around 1960 by Shawinigan Chemicals of Canada. This process involves the reaction of ammonia with hydrocarbons (usually propane or butane) in an electrically heated, fluidized bed of coke. The reaction is

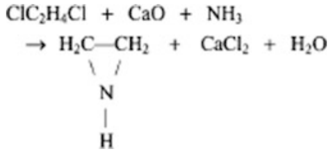
$$3NH_3 + C_3H_8 \xrightarrow{1{,}370^\circ C} 3HCN + 7H_2$$
$$\Delta H = +151 \text{ kcal/mol HCN} \qquad (22.75)$$

The fluidized bed is heated at 1,350–1,650°C by passing an electric current between carbon electrodes immersed in the bed. The performance of the reaction system is reported to be

	Conversion (mol. %)	Yields	
		mol.%	lb/lb HCN
C_3H_8	88	88–90	0.60–0.62
NH_3	86	86–90	0.70–0.73

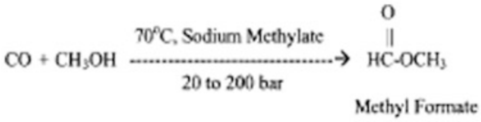
The reactor off-gas typically has the following molar composition: HCN = 25%, NH_3 = 0.25%, H_2 = 72%, and N_2 = 3%. The HCN is separated from the off-gas for refining, and the hydrogen leaves the system as a by-product together with a small amount of nitrogen and unreacted ammonia. The high electrical consumption (~3 kWh/lb HCN) makes the process attractive only in locations where the cost of electricity is extremely low. In 2003, the Fluohmic process was used in Spain, Australia, and South Africa.

Formamide Process. The formamide process was developed by several companies, but in 2001, it was only used by BASF. The process involves the following steps [44]: (1) methyl formate synthesis, (2) formamide synthesis, and (3) HCN formation/dehydration.



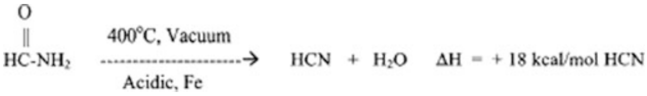
(22.76)

With excess methanol, the conversion to methyl formate is 95% with nearly 100% selectivity.



$$CO + CH_3OH \xrightarrow[\text{20 to 200 bar}]{\text{70°C, Sodium Methylate}} \underset{\text{Methyl Formate}}{\overset{\overset{O}{\|}}{HC}\text{-}OCH_3} \tag{22.77}$$

The conversion of ammonia is 60–85%



$$\overset{\overset{O}{\|}}{HC}\text{-}NH_2 \xrightarrow[\text{Acidic, Fe}]{\text{400°C, Vacuum}} HCN + H_2O \quad \Delta H = +18 \text{ kcal/mol HCN} \tag{22.78}$$

The overall performance of the reaction system is

	Yield	Consumption
	mol.%	lb/lb HCN
CH_3OH	–	0.20–0.30
NH_3	79–90	0.70–0.80
CO	52–94	1.10–2.00

The reactor off-gas contains 60–70% HCN.

BASF has obtained European patent 1,110,913, which describes HCN production from gaseous formamide in a fluidized bed. Elements of the commercialized formamide process are included in a MMA process that Mitsubishi Gas Chemical started up in 1997. The formamide is obtained by reacting hydroxyisobutyramide with methyl formate. Therefore, the external requirements for HCN are reduced to the replacement of yield losses [164]. The process is described in US patent 6,075,162, and the catalyst is described in European patent 1,086,744.

Methanol Process. HCN is produced when methanol reacts with ammonia and oxygen in the presence of an oxide catalyst that contains iron, antimony, phosphorous, and vanadium. The reaction occurs in the vapor phase in a fluidized-bed reactor. The process and the catalyst are described in patents that were issued to Nitto Chemical (now Mitsubishi Rayon) during the late 1990s (European patent 864,532; Japanese patents 10-167,721, 10-251,012, 11-043,323; US patent 5,976,482).

In 2003, Mitsubishi Rayon is believed to operate a commercial-scale, methanol-based HCN process and has offered to license the technology to other companies. The technology might provide a low-cost way to convert an ACRN plant to HCN-only production. However, methanol is a higher-cost source of carbon compared to natural gas, so the methanol process probably has a higher operating cost than the Andrussow process.

ACRN Process. The Standard Oil Company of Ohio (now BP Amoco) commercialized in 1960 a fluidized-bed process in which the catalytic oxidation of a mixture of propylene and ammonia produces ACRN. INEOS purchased the ACRN business from BP in 2005 by-products, from this reaction are HCN and acetonitrile. The yields of HCN depend on the process conditions and on the catalyst system [164]. The reactions are

$$\underset{\text{Propylene}}{CH_2 = CHCH_3} + NH_3 + \tfrac{3}{2}O_2 \rightarrow \underset{\text{Acrylonitrile}}{CH_2 = CHCN} + 3H_2O \tag{22.79}$$

$$\underset{\text{Propylene}}{CH_2 = CHCH_3} + \tfrac{3}{2}NH_3 + \tfrac{3}{2}O_2 \rightarrow \tfrac{3}{2}\underset{\text{Acetonitrile}}{CH_3CN} + 3H_2O \tag{22.80}$$

$$CH_2 = CHCH_3 + 3NH_3 + 3O_3 \rightarrow 3HCN + 6H_2O \tag{22.81}$$

Depending on the type of ACRN process and the operating conditions, about 10–24 lb HCN is obtained per 100 lb of ACRN [44]. US patent 5,840,648 describes a catalyst that permits more HCN production.

During the 1990s, several patents were issued (European patent 878,464, US patent 5,288,473, and US patent 6,204,407) in relation to the addition of methanol to the feed stream of an ACRN plant to increase HCN production.

BP and Asahi are developing processes for the ammoxidation of propane to produce ACRN. This process is believed to yield a lower level of HCN than the optimized oxidation of propylene [164]. In 2007, Asahi started up a propane process in Tongsuh, South Korea.

Other HCN Processes. Some alternate HCN processes that have been studied in the 1990s were

- Production of HCN from acetonitrile (see Japanese patent 10,167,721)
- Production of HCN by use of a corona (German patent 1,054,982)
- Production of HCN by use of microwave heating (US patents 5,393,393; 5,470,541; and 5,529,669)4.

None of these processes are believed to be used in commercial production in 2004.

Production

In 1999, a total of 34 companies were operating 47 HCN production facilities in the United States, Western Europe, and Japan. Capacity in these three regions was about 3.6 billion pounds (1.6 million tons). Direct production accounts for 75% of total capacity, and the balance is coproduct from ACRN production. Worldwide capacity is about 1.8 million tons [164].

Between 1994 and 1999, HCN consumption increased about 2.2% per year. Consumption is expected to increase at around 2.8% per year from 1999 to 2004 [164]. In the United States, production is expected to grow at a rate of 2.4% per year from 1.7 billion pounds in 2003 to 1.87 billion pounds in 2007 [165].

Uses

HCN is usually consumed at its production site, and some consumers without on-site HCN production capability are believed to be developing plans to eliminate HCN shipments. For example, BASF in the United Kingdom produces by-product HCN in an ACRN plant and ships HCN railcars to Ineos. This HCN is used to produce acetone cyanohydrin (ACH) in a MMA plant. To eliminate these shipments, BASF and Ineos plan to (1) install an ACH plant on the BASF plant site and (2) transfer the ACH to Ineos via a 9-km pipeline [166].

ACRN plants are highly dependent on the actions of the acrylic fiber industry, the major outlet for ACRN. As a result, HCN consumers may have to operate at reduced rates if an adequate supply of HCN is not being produced by the ACRN plant. In the early years of the new century, many consumers of HCN from ACRN plants evaluated options that would give them a more consistent supply of HCN. Some ACRN plants were shut down during this time, and market conditions plus company finances will determine whether any of these plants will be restarted.

Some of the uses of HCN are

- Adiponitrile (ADN). ADN is made when HCN reacts with butadiene. It is a key ingredient in production of nylon.
- Acetone cyanohydrin (ACH). ACH is made when HCN reacts with acetone. It is a key ingredient in many MMA plants. MMA is used to make acrylic sheeting and related products.
- Sodium cyanide (NaCN). NaCN is made when HCN reacts with sodium hydroxide (NaOH). NaCN is used in precious metals (gold and silver) extraction, metal plating, and some chemical production processes.
- Methionine. Methionine is an essential amino acid that is used in animal feed. The key ingredients are HCN or NaCN, methyl mercaptan, acrolein, and NH_4HCO_3.
- Cyanuric chloride (CYC). CYC is made when HCN reacts with chlorine and is then rearranged into a ring compound. It is used to make herbicides, pharmaceuticals, and explosives.
- Chelating agents. Chelating agents are made when HCN reacts with formaldehyde and amines to make aminocarboxylic acids, which are then saponified to produce the acid salts. Their major uses are in soaps, water treating agents, and various cleaning agents.
- Other uses include ferrocyanides (for blue jeans), acrylates, lactic acid, pharmaceuticals, and specialty chemicals.

In 2004, HCN was consumed in the following applications: ADN (for nylon 6/6): 50%, ACH (for MMA): 28%, methionine: 7%, sodium cyanide: 6%, cyanuric chloride: 3%, chelating agents: 2%, and miscellaneous (including nitrilotriacetic acid and salts): 4% [165].

Table 22.32 lists the HCN consumption for different products.

Aniline

Aniline was first produced in 1826 by the dry distillation of indigo, the oldest known vat dye. Fritsche also obtained aniline from indigo by heating it with potash (K_2O). Hofmann obtained aniline by reduction of nitrobenzene in 1843. Aniline is a colorless, oily, flammable liquid that is slightly soluble in cold water and infinitely soluble in alcohol and ether. Its physical properties are summarized in Table 22.33.

Processes

The aniline processes that are currently in use include (1) hydrogenation of nitrobenzene, (2) nitrobenzene reduction

Table 22.32 Consumption of hydrogen cyanide by major region, 1999 (thousands of ton)

Product	United States	Western Europe	Japan	Total
Adiponitrile	340	127	–	467
Acetone cyanohydrin	206	152	50	408
Sodium cyanide	72	55	16	143
Methionine and analogues	37	32	4	73
Cyanuric chloride	20	20	1	41
Chelating agents	18	11	–	29
Other	35	13	13	61
Totals	*728*	*410*	*84*	*1,222*

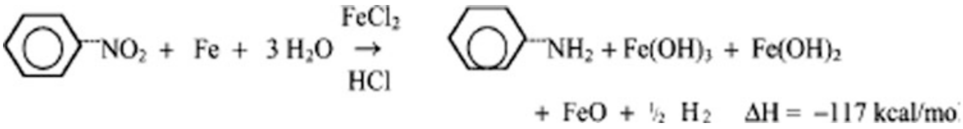
with iron filings, and (3) ammonolysis of phenol. Almost 97% of the nitrobenzene produced in the United States is converted to aniline between the hydrogenation process and the iron filings process [167].

Hydrogenation of Nitrobenzene. The primary aniline production process in the world is the hydrogenation of nitrobenzene. BASF, DuPont, ChemFirst, and Rubicon use this process in the United States. This technology is also used by all Western European aniline producers and all but one Japanese aniline producer.

This process would have been replaced much earlier by more economical reduction methods if it had not been possible to obtain valuable iron oxide pigments from the iron oxide sludge. However, the increasing demand for aniline has far surpassed the market for iron pigments, so this process is no longer preferred [44].

Ammonolysis of Phenol. Aniline can also be produced when phenol is subjected to gas-phase ammonolysis at 200 bar and 425°C.

This is the Halcon/Scientific Design process. The chemistry is

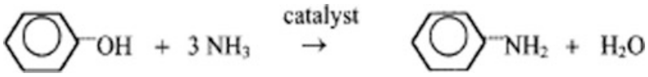


(22.82)

The catalytic gas-phase hydrogenation processes for nitrobenzene can be carried out using a fixed-bed or a fluidized-bed reactor. Details of both processes are given in [44]. A typical process diagram is shown in Fig. 22.31.

Nitrobenzene Reduction with Iron Filings. The older Bechamp method for iron oxide pigment production gives aniline as a coproduct and is operated by Bayer in West Virginia. Nitrobenzene is reduced by reaction with iron filings in the presence of a hydrochloric acid catalyst. The iron is oxidized to the ferrous or ferric state, and the coproduct aniline is separated. The yield is 90–95% of theoretical. The reactions are represented as follows [168]:

$$2\,Fe(OH)_3 + Fe(OH)_2 \rightarrow Fe_3O_4 + H_2O \quad (22.83)$$



(22.85)

The catalysts are $Al_2O_3{\cdot}SiO_2$ (possibly as zeolites) and oxide mixtures of Mg, B, Al, and Ti. These can be combined with additional co-catalysts such as Ce, V, or W. With a large excess of ammonia, the selectivity to aniline is 87–90% at a phenol conversion of 98%. The by-products are diphenylamine and carbazole. This technology is used at one plant in Ohio and at another plant in Japan. The economics of this process are favorable if low-cost phenol is available and high-purity aniline is desired. Capital costs are low because benzene nitration is avoided. A typical process sketch along with a material balance is shown in Fig. 22.32.

(22.84)

Table 22.33 Physical properties of aniline

Property	Value
Molecular weight	93.12
Boiling point, °C	
101.3 kPa (760 mmHg)	184.4
4.4 kPa (33 mmHg)	92
1.2 kPa (9 mmHg)	71
Melting point, °C	−6.15
Density, *d*	
At 20/4°C	1.02173
At 20/20°C	1.022
Viscosity at 20°C, mPa s (= cP)	4.423–4.435
Dissociation constant, *pK*	
At 20°C	4.60
At 60°C	8.88
Enthalpy of dissociation, kJ/mol (kcal/mol)	21.7 (5.19)
Heat of combustion, kJ/mol (kcal/mol)	3,389.72 (810.55)
Specific heat, 20–25°C	0.518
Latent heat of vaporization, J/g (cal/g)	476.3 (113.9)
Flash point (closed-cup), °C	76
Autoignition temperature, °C	615
Flammable limits in air (% by volume)	
LEL	1.3
UEL	11.0
Vapor density (air = 1)	3.22
Solubility (g in 100 g water @ 20°C)	3.5
Odor threshold, ppm	1.1

Uses. MDI (4,4′-methylenebis phenylisocyanate) accounted for almost 85% of the worldwide demand for aniline in 2000. MDI is used primarily to make rigid polyurethane foam and polyurethane elastomers. MDI growth is expected to be 6.0–8.0% per year during the first 10 years of the new century as its use continues to increase in the construction industry (the largest user of rigid polyurethane foam) and the auto industry (the largest user of reaction–injection molding plastics) [168, 169].

Other aniline uses and the percent of worldwide aniline production that goes into these uses are rubber-processing chemicals (9%), dyes and pigments (2%), agricultural chemicals (3%), specialty fibers (1%), and miscellaneous, such as explosives, epoxy curing agents, and pharmaceuticals (1%) [168, 169].

Production. MDI has been the driving force behind the recovery of the aniline business since 1982 when the industry had a capacity utilization rate of less than 50%. By 1996, capacity utilization had approached 95% in some regions [168].

Aniline production is concentrated in the United States, Western Europe, and Japan where aniline capacity is over 1.8 million tons/year [168]. Aniline's global production capacity in 1999 was 2.9 million tons, and demand in 2000 was estimated to be 2.68 million tons/year [170, 171].

Aniline pricing tends to track benzene pricing. In general the aniline price will move 1.2 cents/lb for each 10 cents/gal movement in benzene price. Between 1995 and 2001, the aniline sales prices varied from US$ 0.35 per lb to US$ 0.40 per lb [169].

The OSHA PEL for aniline is 5 ppm for an 8-h TWA.

Other Compounds

Several other nitrogen compounds are commercially important, including

- Hexamethylenediamine which is used primarily in the manufacture of nylon
- Dimethylformamide, a versatile solvent for organic and inorganic compounds and an important reaction medium for ionic and nonionic compounds
- Dimethylacetamide, an important industrial solvent for polyacrylonitrile, vinyl resins, cellulose derivatives, styrene polymers, and linear polyesters
- Isocyanates, important materials in the production of foams, resins, and rubbers
- Calcium cyanamide, which is used as a fertilizer, herbicide, insecticide, a steel-making additive, and an ore-processing material. It can also be used to make thiourea, guanidine, and ferrocyanides [172]
- Methyl methacrylate, which is used in plastic glass, resins, and paint [173–175]
- Acrylamide, which is used in water treatment chemicals, paper, and resins [176–178]
- Caprolactam, which is used to make nylon 6 [179–181]
- Acrylonitrile, which is used in many different acrylic fibers [182, 183]

Phosphorus and Phosphates

Glenn A. Gruber

Introduction

Phosphates, compounds of the element phosphorous, are produced from relatively abundant supplies of phosphate rock.

The major use of phosphate is to supply phosphorous, one of the three essential plant foods—nitrogen, phosphorus, and potassium. Phosphate rock extraction from its ore, and its subsequent conversion into fertilizer materials and industrial chemicals, is a relatively mature art. Single superphosphate, a mixture of monocalcium monohydrate and gypsum formed by the reaction of sulfuric acid with phosphate rock, has been used as a fertilizer since the mid-1800s. Phosphoric acid, derived by the treatment of phosphate rock with sulfuric acid so as to produce gypsum in a separable form, was manufactured in many locations by batch and countercurrent decantation methods in the 1920s.

Phosphoric acid produced by the later process is called the "wet process acid" to distinguish it from "furnace phosphoric acid," which is produced by hydrating the phosphorous pentoxide formed by burning elemental phosphorous in air. The "wet" processes utilized for the bulk of today's phosphoric acid and fertilizer production trace their origins to the early 1930s [1].

Higher-purity industrial and food-grade phosphates, until recently, were most often derived from furnace processes. New plants recover purified phosphoric acid suitable for food-grade uses from relatively impure wet process acid, using solvent extraction technology.

Phosphate Rock

Naturally occurring mineral products having sufficient phosphate content to be of commercial value are classified as phosphate rock. The grade or phosphate content of these products has been traditionally reported as percent $Ca_3(PO_4)_2$, which is referred to as bone phosphate of lime (BPL), tricalcium phosphate (TCP), or triphosphate of lime (TPL). Stoichiometric factors relating traditional rock analysis to other commonly used analytical terms are 100% BPL = 45.77% P_2O_5 = 19.96% P.

International trade of phosphate rock is based on dry metric tons, whereas US domestic shipments are reported as short tons, on a dry or as is moisture basis. Specifications for purchased rock may address grade, particle size, moisture content, and chemical impurities such as CaO, MgO, SiO_2, Al_2O_3, Fe_2O_3, F, Cl, Na_2O, and K_2O. The content of organic material and heavy metals is also of importance.

The treatments by which phosphate rock is commonly converted to fertilizers and chemicals are summarized in Fig. 23.1.

Minerals

The most common and widely distributed phosphate minerals are the apatite group, with the general formula $Ca_{10}(PO_4)_6(X)_2$. The apatite is designated as fluorapatite, hydroxyapatite, or chlorapatite, when X = F, OH, or Cl, respectively. The most abundant sedimentary apatite is carbonate fluorapatite (francolite). Relative to pure fluorapatite, francolite is characterized by the substitution of Na and Mg for Ca and of carbonate and fluoride for phosphate. An empirical formula for francolite is given below and the chemical compositions of the end members of the fluorapatite–francolite series, as quantified by McClellan [2], are given in Table 23.1.

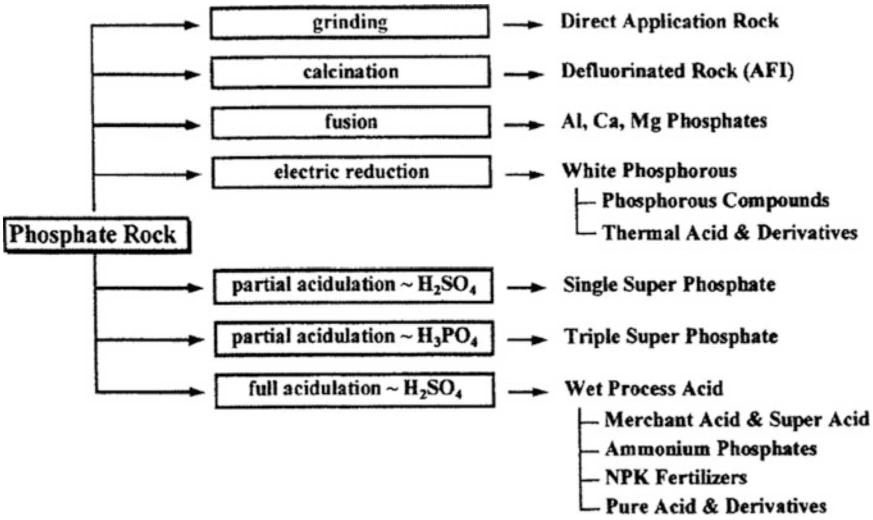

Fig. 23.1 Phosphate rock treatments and end products

Table 23.1 Composition of the fluorapatite–francolite end series

Constituent	Fluorapatite	Francolite
%CaO	55.60	55.40
%P_2O_5	42.20	34.00
%CO_2	–	6.30
%F	3.77	5.04
%Na_2O	–	1.40
%MgO	–	0.70

Source: McClellan [2].

Francolite

$$(\mathrm{Ca}_{10-a-b}\mathrm{Na}_a\mathrm{Mg}_b\mathrm{PO}_4)_{6-x}(\mathrm{CO}_3)_x\mathrm{F}_{0.4x}\mathrm{F}_2$$

Van Kauwenberg [3] has described the mineralogy and alteration of phosphate ores in Florida. Mineralogical composition varies by particle size. Francolite and then quartz are the most abundant minerals for plus 20-mesh particles (pebble), while the reverse is true for particles in the 20–200-mesh fraction (flotation feed). In the −200-mesh size fraction (clay waste) quartz, francolite, wavellite, crandallite, goethite, dolomite, and a variety of clay minerals such as smectite, kaolinite, illite, and palygorskite occur.

Resources and Ores

Naturally occurring phosphates exist, or originated, as accessory minerals in igneous rocks. Prolonged weathering gradually converts the water-insoluble apatite into dissolved compounds that accumulate in the world's oceans. Sedimentary marine deposits (phosphorites) are formed when phosphorous compounds are precipitated by chemical or biological reactions. Bernardi [4] describes secondary enrichment as an important aspect in the formation of sedimentary deposits.

McKelvey [5] reported that the earth's crust contains an average of 0.27% P_2O_5, most of which occurs as apatite species. Sedimentary rocks, which predominate at the earth's surface, host the majority of commercial phosphate deposits discovered to date. Igneous rocks, which make up about 95% of the earth's crust, contain few phosphate deposits of commercial value. Guano deposits formed from the droppings of sea birds or bats are of minor importance, as are guano-related deposits. Northolt [6, 7] describes known phosphate deposits in the world, and estimates that identified phosphate resources in North America total more than 35 billion metric tons.

Resources are typically quantified as in situ tons of phosphatic material, without regard for economic criteria. However, it is preferable to quantify phosphate reserves as tons of phosphate rock recoverable according to specified economic, chemical, and regulatory criteria [8]. The definition of phosphate reserves therefore requires an integrated program of geological exploration, laboratory testing, and classification using applicable criteria.

Significant commercial deposits of sedimentary phosphate ore occur in the United States, the Former Soviet Union, Morocco, China, Jordan, and Tunisia, and lesser deposits are mined in many other countries. Although phosphorite ores generally are classified as having siliceous or carbonate gangue minerals, soluble salts, and organic material are also of concern. The phosphate content of the ores, depending on conditions of deposition and secondary enrichment, ranges from 10% to more than 70% BPL. The recovery of byproducts from phosphorite ores is uncommon; however, uranium has been extracted commercially from phosphoric acid.

The types of igneous rock in which commercial deposits of apatite have been found are nepheline–seyenite and carbonatites. The apatite deposits in Russia's Kola

Fig. 23.2 Loading trucks with phosphate ore in Jordan

Peninsula are associated with nepheline–seyenite. Carbonatite deposits that are mined for their phosphate content include Siilinjarvi in Finland, Jacupiranga and Araxa in Brazil, Phalaborwa in South Africa, and Kapuskasing in Canada. By-product recovery from igneous phosphate ores is common. Nepheline ($NaAlSiO_4$) is recovered from the Russian ore, calcite from the Finnish ore, copper concentrate and baddelyite (ZrO_2) from the South African ore, and barite from Brazilian ore. A minor percentage of the world's phosphate rock production is recovered from guano-related phosphate deposits.

Mining

Phosphate ores are extracted from deep deposits by underground mining methods and from shallow deposits by surface mining methods. Underground mining tends to be more costly and therefore less common for phosphate deposits than surface mining. Because 1 t of phosphate rock has only about 10% of the commercial value of 1 oz of gold, low-cost mining is imperative.

Sedimentary phosphate deposits are exploited by underground mining in China, Mexico, Morocco, and Tunisia. Generally, the flat laying ore is most economically extracted by room-and-pillar mining or long-wall mining. Ore from deep sections of the igneous phosphate deposits in Russia's Kola Peninsula is mined by a block caving technique.

Many shallow deposits have unconsolidated ore covered by unconsolidated overburden. Large electric walking draglines are ideally suited for such deposits, as evidenced by their use at large capacity phosphate mines in the southeastern USA, Morocco, Jordan, Senegal, and Togo. Other deposits have over burden and ore that may be partially or fully consolidated. For these deposits, ripping or drilling and blasting are required to fragment the overburden and ore to the extent that they can be excavated. Power shovels, backhoes, and wheeled loaders are also commonly used for excavation. Figure 23.2 shows a hydraulic shovel loading phosphate ore into a haul truck in Jordan.

Bucketwheel excavators are used for overburden removal at phosphate mines in eastern North Carolina, Senegal, and Togo. One mine in central Florida has used cutter head dredges for both overburden removal and ore excavation.

The method of transporting ore from the mine to the beneficiation plant depends on ore characteristics, mining methods, and local infrastructure. Railroad transport has been practiced in Russia and Iraq. Haul trucks and belt conveyors are commonly used in China, Jordan, Mexico, Morocco, Russia, Syria, Tunisia, and the western United States. Slurry pipelines of 18–22 in. diameter, operating at less than 100 psig, are used exclusively in central Florida, north Florida, and eastern North Carolina. The pipelines may be extended up to 10 miles or more, by installing a series of centrifugal slurry pumps at 4,000 ft intervals.

A typical Florida phosphate mining scheme, utilizing a dragline and slurry pipeline, is illustrated in Fig. 23.3. The dragline first exposes the phosphate ore (matrix) by stripping and casting the overburden into the adjacent mined area. The matrix is then dug by the dragline and placed in a slurry pit, where it is gunned with high-pressure water. Gunning the matrix, as shown in Fig. 23.4, transforms the unconsolidated ore into a slurry which is pumped to the beneficiation plant.

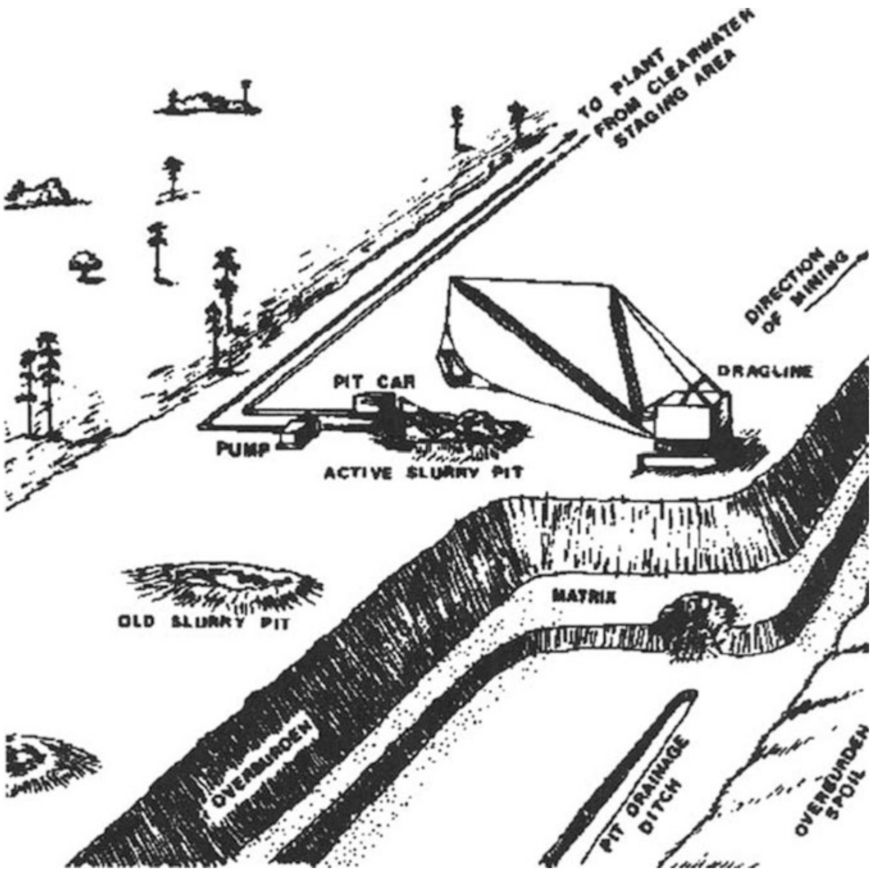

Fig. 23.3 Typical Florida phosphate mine

Fig. 23.4 Gunning phosphate rock in a Florida mine

Beneficiation

Beneficiation, also known as mineral dressing or ore processing, may involve a variety of operations such as size reduction, size separation, mineral separation, dewatering, and thermal processing. Almost all phosphate ores require beneficiation to meet commercial specifications concerning particle size, moisture content, or chemical analyses.

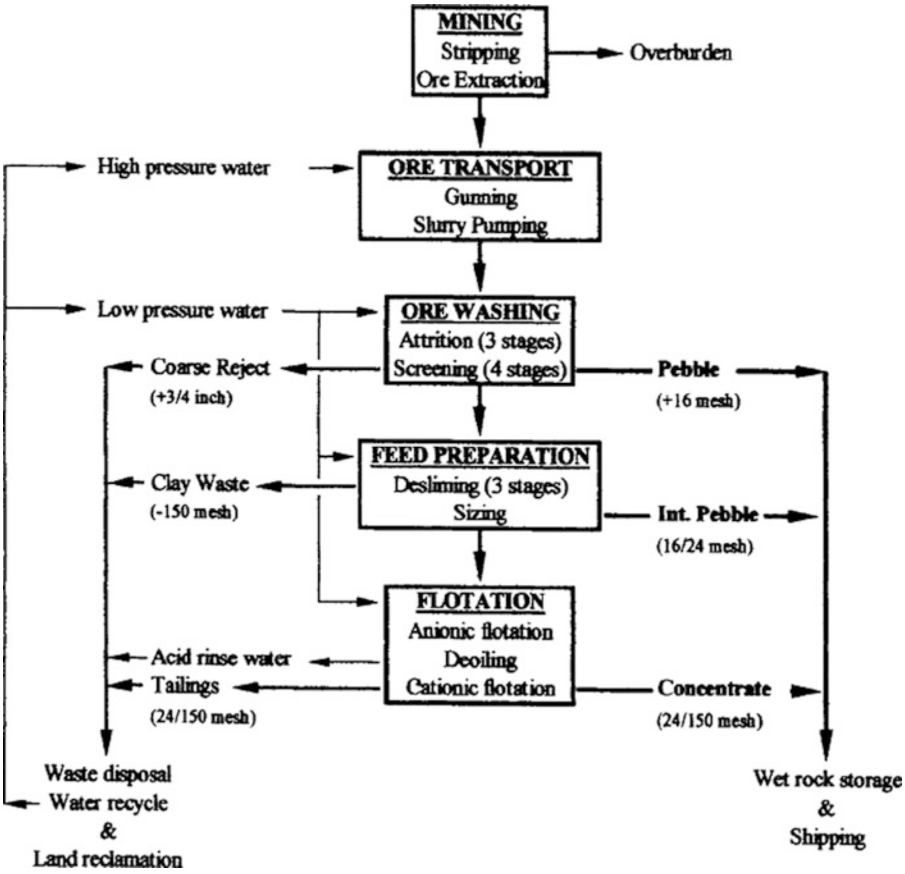

Fig. 23.5 Unconsolidated sedimentary ore beneficiation flow diagram

The usual first beneficiation operation is size reduction, which may be achieved by crushing, grinding, or disaggregating by scrubbing and washing. Particle size reduction liberates mineral species so that they can be separated. Size separation usually follows size reduction. When gangue minerals are more indurated than the phosphate, it is often practical to reject coarse waste material by wet or dry screening. Similarly, when gangue minerals are microcrystalline or softer than the phosphate, fine waste material may be rejected by wet or dry classification. Soluble chlorides, when present, must be removed from phosphate rock by washing with fresh water followed by dewatering.

Gangue minerals frequently have the same particle size as the phosphate mineral grains, and techniques such as heavy media separation, magnetic separation, or froth flotation are required. Heavy media separation is an appropriate process when liberation occurs at 16 mesh or coarser, and the phosphate mineral has a significantly higher density than the gangue (dolomite, calcite, quartz, shale). Low-intensity magnetic separation will remove highly magnetic minerals, such as magnetite [9], from phosphate. High-intensity magnetic separation will remove ankerite [10] and other paramagnetic iron-bearing minerals [11] from phosphate. Froth flotation is the most widely practiced operation for recovering phosphate rock from fines (−20 mesh). Variations of this process are used commercially to separate phosphate from barite, calcite, dolomite, feldspars, nepheline, phlogopite, and quartz. Flotation plants have been constructed and operated in Brazil, Canada, China, Finland, Jordan, Mexico, Russia, Senegal, South Africa, and the United States. Dolomite flotation from phosphate is of increasing interest. In the United States, one commercial plant has a dolomite flotation circuit [12], and other dolomite flotation processes have been demonstrated by pilot plant testing of Florida low-grade pebble [13].

Electrostatic removal of quartz from apatite is technically feasible although it is impractical and costly [14].

A generic scheme for mining and beneficiating central Florida phosphate ore is presented in Fig. 23.5 as a block flow diagram.

Liberation of phosphate from the gangue occurs during ore transport and washing. First, a low-cost product, called pebble, is recovered by screening the ore at about 16 mesh. Secondly, a low-grade product (intermediate pebble) is recovered by sizing the flotation feed at about 24 mesh. Clays are removed from the flotation feed by three or more stages of desliming with hydrocyclones. Finally, a more expensive but higher grade concentrate is obtained by a two-stage flotation process. A rougher phosphate concentrate is recovered by direct flotation with anionic reagents.

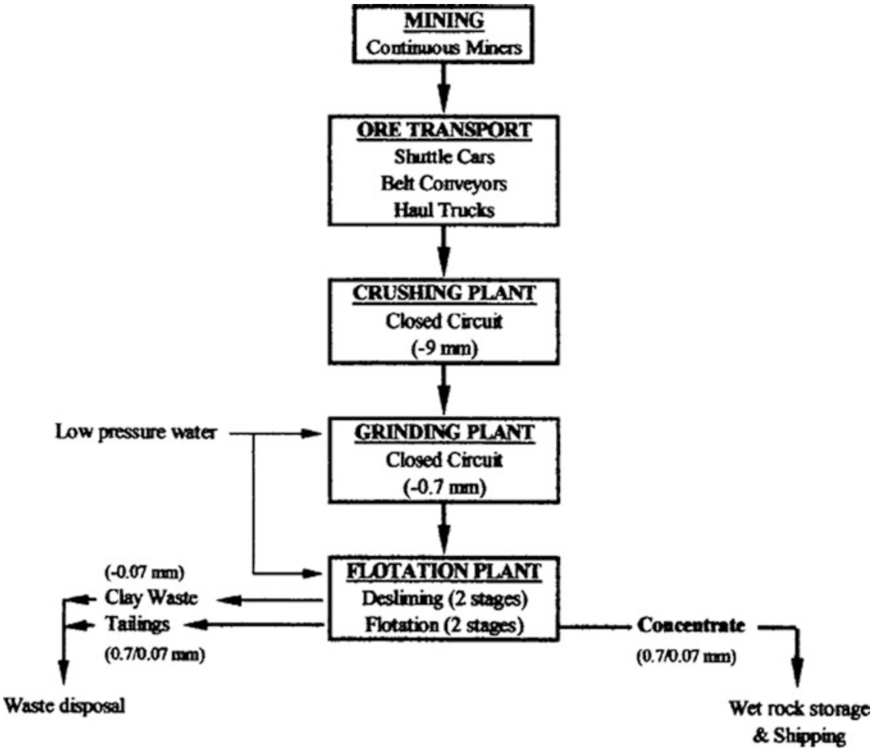

Fig. 23.6 Consolidated sedimentary ore beneficiation flow diagram

After deoiling with sulfuric acid and rinsing with water, the rougher concentrate is conditioned with cationic reagents and subjected to inverse flotation. The phosphate rock product, comprised of pebble, intermediate pebble, and flotation concentrate, dispatched to a chemical plant for conversion to phosphoric acid.

The initial beneficiation steps for consolidated phosphate ores generally differ from those of unconsolidated ores. Figure 23.6 depicts the flow diagram for the San Juan de la Costa phosphate mine in Mexico. The high-grade ore, slightly more than 1 m in thickness, is extracted by room-and-pillar mining. Continuous miners rip ore from the mining face and load shuttle cars, which transfer the ore to feeder-breakers and belt conveyor systems. Outside the mine, ore is loaded into haul trucks and transported to the beneficiation plant. Liberation of the phosphate is accomplished by crushing to 9 mm followed by grinding to 0.7 mm. Following grinding, the ore is deslimed, attrition scrubbed, and deslimed a second time to remove clays and carbonate minerals from the flotation feed. The feed is conditioned with anionic reagents and subjected to rougher and cleaner direct flotation using sea water. The concentrate is washed with fresh water to remove sea salt prior to use in the chemical plant.

Figure 23.7 presents a simplified mid-1980s flow diagram for the Siilinjarvi phosphate beneficiation plant in Finland. The low-grade igneous ore to this plant is carefully blended to avoid changes in plant feed characteristics. Liberation of phosphate is achieved by rod milling followed by closed circuit ball milling.

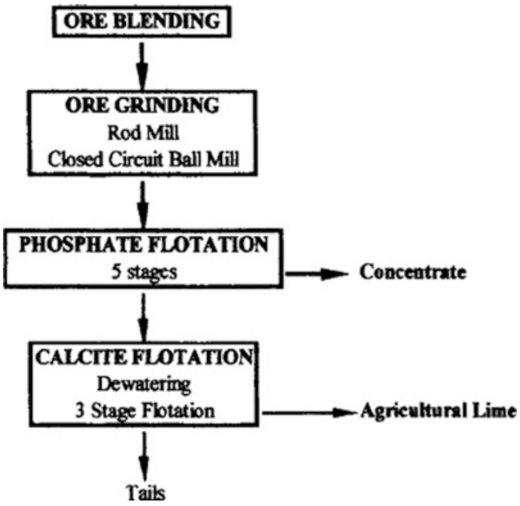

Fig. 23.7 Igneous ore beneficiation flow diagram

The ground ore is conditioned without desliming, at pH 11, using an amphoteric flotation reagent. A phosphate concentrate is recovered by five stages of direct flotation. The tailings from phosphate flotation are dewatered, conditioned with anionic reagents, and subjected to three stages of direct flotation to recover calcite, which is used as agricultural lime.

Table 23.2 Phosphate rock value (United States marketable production)

Crop (year)	Total value (billion $)	Unit value ($/metric ton)

Production and Value

The dollar value of marketable phosphate rock produced in the United States since 1975 is summarized in Table 23.2. The statistics apply to crop year (July 1 to June 31) and represent current dollars. The unit value of phosphate rock did not keep up with inflation and consequently the production capacity of US phosphate mines that were depleted in the last 30 years has not been replaced on a one-for-one basis. During the 2006–2009 period the international price for exported phosphate rock peaked at about $400 per metric ton and then declined to about $100 per metric ton.

The global demand for food stimulated increased fertilizer usage and consequently increased phosphate rock consumption through 1990. Table 23.3 shows that global phosphate rock production decreased from 1990 to 2000 and then recently exceeded the 1990 level. Although phosphate rock production in the United States declined by about 50% over the last 30 years, the United States remains a major producer. China's commitment to become self sufficient in phosphate rock is evidenced by the 50-million metric ton increase ion production since 1980. China has now replaced the United States as the leading producer of phosphate rock.

Many countries use indigenous phosphate rock as a source of phosphorous for industrial chemicals and fertilizers. Few countries are self-sufficient and supplemental sources of phosphate rock are essential. The cost of imported phosphate rock is markedly influenced by freight, and therefore the low-cost producer is not necessarily the low-cost supplier.

Since 1980, United States went from the major exporter to a net importer of phosphate rock. The phosphate rock is converted in the United States to high analysis of granular fertilizers, some of which are exported. Morocco has been the major exporter of phosphate rock for several years.

Chemical Processing of Phosphate Rock

Phosphate rock is converted into usable chemicals by two methods. In the first, the rock is charged to an electric furnace with silica and coke to produce elemental phosphorus. The phosphorus then is converted into phosphoric acid and other compounds. In the second, the phosphate rock is reacted with sulfuric acid in a medium of phosphoric acid and calcium sulfate crystals to form dilute, impure phosphoric acid, the acid is separated and used to make fertilizers. This is known as the wet process method [15].

The wet process is further divided into two subprocesses based on the type of calcium sulfate crystal produced. The dihydrate process wherein gypsum ($CaSO_4$•2H2O) is produced has been the dominant process, but processes making hemihydrate ($CaSO_4$•1/2H_2O) have become more important over the past decade.

Thermal Process for Phosphorus and Phosphoric Acid

The furnace or thermal process is shown in Fig. 23.8. The approximate reaction is:

$$Ca_3(PO_4)_2 + 6SiO_2 + 10C \rightarrow 6CaSiO_3 + P_4 + 10CO$$

The phosphorus leaves the furnace as a vapor and is condensed by direct contact with water. Phosphoric acid of high purity is made by burning phosphorus with air and hydrating the resulting P_2O_5 with water, according to the reaction:

$$P_4{+}5O_2{+}6H_2O \rightarrow H_3PO_4$$

If even less water is used for hydration, a product known as polyphosphoric acid results. Ordinary phosphoric acid is a solution of the monomer, H_3PO_4, in water, and is called orthophosphoric acid. If a molecule of water is removed between two orthophosphate molecules, the dimer, pyrophosphoric acid, $H_4P_2O_7$, is formed. Similarly, the trimer and higher polymers can be made. Superphosphoric acid is a mixture of orthophosphoric acid and polyphosphoric acid and is now made from wet process acid as described later in this chapter.

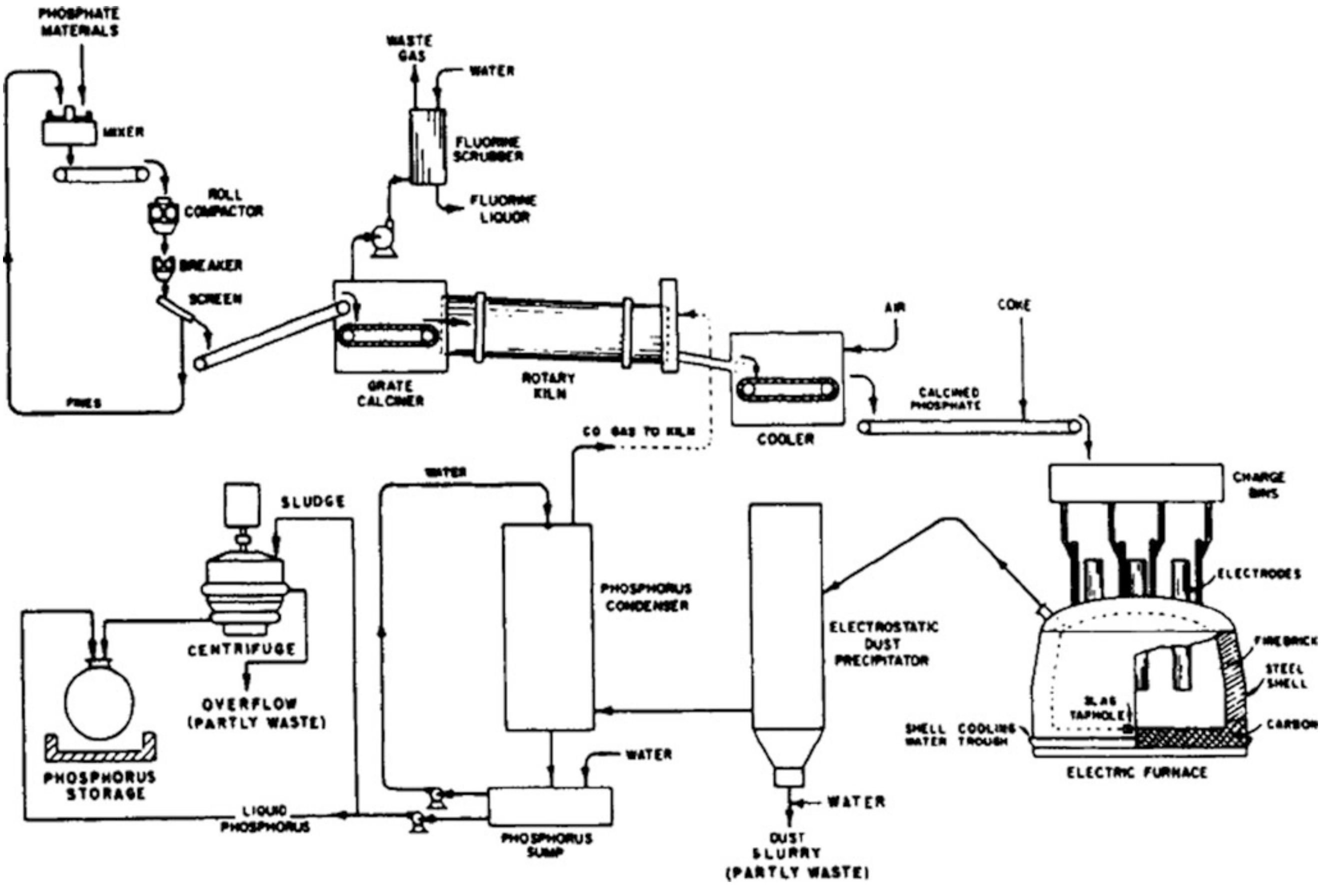

Fig. 23.8 Electric furnace process for production of elemental phosphorus

In 1990, there were about eight plants in operation, some with multiple furnaces, in the United States. By 2000–2001, only one plant remained. New emission standards, high capital and operating costs, and competitive lower-cost wet acid purification technology have spelled doom for most of the furnace plants. A more thorough discussion of electric furnace processing is to be found in the ninth edition of this *Handbook*.

Industrial Phosphates

Furnace phosphorus currently produced in the United States is consumed to make compounds such as phosphorus pentoxide, phosphoric trichloride, and phosphorus pentasulfide, which find use in the preparation of drying agents, plasticizers, oil additives, fire retardants, and insecticides. These products are derived from phosphorus and, therefore, cannot be made from purified wet process acid so there is a continuing demand for a small amount of thermal product. However, for orthophosphoric acid use, the purified wet process acid is cheaper [16]. This has now replaced furnace acid in soft drinks, candy, baked goods, and various other food products. It is also used for pickling metals.

The cheapest and most important salts of purified phosphoric acid are the sodium salts, made by reacting the acid with sodium carbonate or sodium hydroxide. Sodium phosphates may be classified in a general way as (1) orthophosphates, (2) crystalline condensed phosphates, and (3) glassy condensed phosphates.

Three sodium orthophosphates can be prepared, depending on whether one, two, or three hydrogen atoms are replaced by sodium.

Monosodium phosphate is formed in the following reaction:

$$2H_3PO_4 + Na_2CO_3 \rightarrow 2NaH_2PO_4 + H_2O + CO_2$$

Sodium carbonate is also used to make disodium phosphate, Na_2HPO_4, but sodium hydroxide must be used to replace the third hydrogen in trisodium phosphate, Na_3HPO_4. The orthophosphates have a wide range of uses in industry.

Condensed phosphates are made by eliminating water from orthophosphates. The most important compound is sodium tripolyphosphate (STPP), made according to the following reaction:

$$2Na_2HPO_4 + NaH_2PO_4 \xrightarrow{-H_2O} Na_5P_3O_{10}$$

The most important use of STPP is as a builder in detergents. However, legislative restrictions on the use of phosphorus compounds in household detergents have caused a Worldwide flattening of consumption.

Glassy condensed phosphates are represented by sodium hexametaphosphate, in which the O:P ratio is 3:1. There can be considerable variation in the Na_2O to P_2O_5 ratio.

The principal use of the condensed phosphates is to sequester metallic ions in water. They form water-soluble complexes with the metals and prevent metallic compounds from precipitating to cause discoloration, scale, and sludges.

Wet Process Phosphoric Acid

In the wet process, phosphate rock is reacted in a slurry of phosphoric acid and calcium sulfate crystals containing a controlled quantity of sulfuric acid. The simplified reactions for the dihydrate process is as follows:

$$Ca_3(PO_4)_2 + 3H_2SO_4 \rightarrow 3CaSO_4 \cdot 2H_2O + 2H_3PO_4$$

Until 1969, virtually all wet process acid was made at maximum strengths of 26–32% P_2O_5, separating the calcium sulfate as gypsum containing two molecules of water. Since 1969, a substantial number of commercial hemihydrate process plants have been built in various modes. In the hemihydrate process, reaction conditions are higher in temperature and phosphoric acid strength so that the stable solid phase is calcium sulfate with one-half molecule of water.

The hemihydrate process may be a single-stage process, known as HH, in which the hemihydrate solids are the waste product, or the process can have a second step in which the hemihydrate is recrystallized to gypsum, known as hemi-dihydrate (HDH). In the hemihydrate process, acid strengths of 38% P_2O_5 to about 42% P_2O_5 normally are produced although strengths up to 50% can be produced under somewhat more difficult circumstances requiring more filter area.

The neutralization reaction of the above equation is conducted in one or more strongly agitated reaction vessels, whether in a gypsum or in a hemihydrate mode. The system is highly exothermic and the slurry is maintained at 80–85°C for dihydrate processing, 95–100°C for hemihydrate, by evaporative or air cooling. During the reaction of phosphate rock with sulfuric acid, fluorine is evolved and must be scrubbed from the vent gas.

Table 23.4 Annual production of phosphoric acid by region (1,000 mt P_2O_5)

Region	2000	2003	2006	2008
West Europe	1,275	1,117	948	818

Source: ifa, World Phosphoric Acid (PA) statistics

Table 23.4 lists the production of phosphoric acid in the recent past, and shows the substantial changes in location of P_2O_5 production over the last decade. The East and West Europe fertilizer industry was in a steep decline by 1999. North Africa and the Middle East are continuing to expand based on their huge reserves of high-grade phosphate. China, with substantial deposits, has now begun to develop these, as evidenced by the significant increase in the production of phosphate rock and phosphoric acid since the year 2000.

Dihydrate Process

The conventional dihydrate process, as operated over the last 70 years, was first demonstrated by the Dorr Company in the Cominco plant at Trail, British Columbia, in 1931 [1]. The principles discovered at that time for making an acid strength of up to 32% P_2O_5 and a highly filterable gypsum crystal are still used today. The salient features of the process included maintaining H_2SO_4 content in the digestion acid of about 2.0–3.0%. Reaction slurry was recycled at a ratio of 10–15:1 relative to the volume of product slurry sent to the filter. The relatively higher recirculation of seed gypsum than had previously been practiced, together with control of the free sulfate, resulted in product acid well above the previous 22% P_2O_5 possible with batch and countercurrent decantation systems.

If the sulfate in the solution is allowed to exceed certain limits, depending on rock reactivity and particle size, the rock becomes coated with gypsum, and the reaction becomes uncontrollable. If the sulfate level is too low, the precipitated gypsum filters poorly and contains excessive quantities of crystallized (solid solution) P_2O_5, leading to excessive P_2O_5 losses. Over the years, the process has evolved to employ increased slurry recirculation and different reactor configurations, In addition, several different filter designs are available.

Table 23.5 Phosphoric acid plants, worldwide dihydrate process, 2009

Process	Number of lines 450 MTPD or larger
Prayon	20–25
Rhone Poulenc	10–15
Nissan H	7
Jacobs/Dorr–Oliver	8
Badger–Isothermal	6

The principal dihydrate processes in use as of 2,000 are shown in Table 23.5. During the decade 1990–2000, many of the smaller plants and even some larger than 450 t per day P_2O_5 plants have been shut down due to environmental or market conditions. This has resulted in more production in Morocco, Jordan, and India, and less in Europe. Most of the world's phosphoric acid is produced by the dihydrate method, but there is likely to be increased production by the hemihydrate method because of advantages in some situations. The dihydrate processes listed have been modified over the years so that many slightly different configurations of the same process may exist.

The unique feature of each process is the reactor system configuration. The reactor or reactors normally provide from 2 to 6 h detention for the gypsum slurry. This is about 0.8–2.5 m^3 of reactor volume per ton of P_2O_5 per day, meaning relatively large vessels totaling 1,500 m^3 to over 2,000 m^3 in size for large plants. The individual reactor systems are described briefly below.

The objective of the reaction system is to produce a highly filterable gypsum crystal that washes well, and that also contains a minimum amount of insoluble P_2O_5. The filter ability of the gypsum slurry depends on the reactor configuration and on the rock source. Highly filterable gypsum slurries are produced from Florida, Togo, and Senegal phosphates. These rocks may provide more than double the P_2O_5 from a given filter when compared with gypsum produced from other sources. However, because phosphate rock is costly to transport, the use of local, less treatable phosphates can be quite economical. Table 23.6 lists the approximate filtration design rates for these groups of commercially available phosphate rock.

The advantages of the dihydrate process vs. the various, newer hemihydrate configurations are as follows.

Table 23.6 Filtration design rates for phosphoric acid produced from various rock sources

Rock source	Tons P_2O_5 produced per m^2 active area
Togo	
Florida	7.5–9.0
Senegal	
Morocco Khouribga	
Western U.S.	4.5–7.0
Kola (USSR)	
North Carolina	
Morocco Safi	
Algeria	2.5–5.0
Tunisia	

1. The water balance permits the use of wet rock slurry feed. This eliminates the cost of drying the rock and the dust nuisance. This is the principal benefit that has deterred most Florida producers from using the hemi routes. Because gypsum has two moles of water of hydration vs. one half mole for hemihydrate, and because product acid strength is 26–28% P_2O_5 normally, the ground phosphate feed slurry can be as low as 65% solids for the dihydrate process. This still leaves enough makeup water for adequate washing of the gypsum. For hemihydrate processes the maximum moisture is generally considered to be about 15–18% in the feed rock. Such a low moisture would call for a dewatering step for ground Florida pebble rock. Producers in Florida have thus far chosen not to go this route because of the difficulty and expense of dewatering.
2. Dihydrate gypsum, in the case of most phosphates, filters at relatively higher P_2O_5 throughput rates than hemihydrate, comparing dihydrate filter performance at 28% P_2O_5 and hemihydrate at 42% P_2O_5.
3. Dihydrate plants are proven at huge outputs, in excess of 2,000 mt per day P_2O_5, thus offering economies of scale.
4. A vast amount of operating data and experience exists on a wide variety of phosphate rocks for the dihydrate mode.
5. Capital costs for the dihydrate system can be less than for the two-stage hemi processes even when evaporation and rock grinding are considered, because of the larger reaction vessels and two stages of filtration in the hemi process.
6. The yield across the filter for the dihy drate process, generally about 96% of the P_2O_5 fed, is about 3–4% above the single-stage hemi processes.
7. Dihydrate process maintenance costs are substantially less than those for hemi processes due to less severe process conditions. The on-stream factor is also higher for the average dihydrate facility.

Major Dihydrate Processes

Prayon process. The Prayon process [17] has evolved from the cascade system first used by the Dorr Company in the 1930s. Instead of round, steel vessels with rubber and brick lining, Prayon developed a multicompartmented reinforced concrete vessel, rectangular in shape, lined with a membrane and carbon brick in the early 1960s. The construction has proved to be exceedingly durable. A similar concrete construction is used by Jacobs and by Rhone Poulenc.

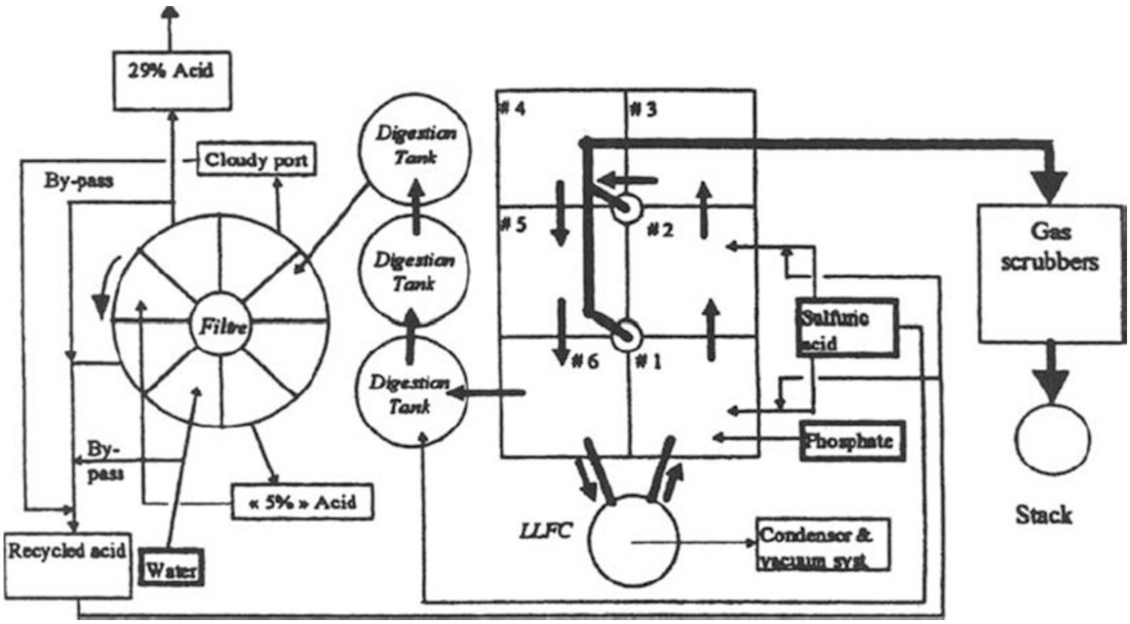

Fig. 23.9 Prayon Mark IV reaction and filtration system

A diagram of the Prayon Mark IV reactor configuration is shown in Fig. 23.9. The Prayon process uses vacuum cooling, a low-level vacuum chamber through which reaction slurry is circulated to maintain a reactor temperature of 80–85°C. There are numerous installations of large Prayon plants in the United States, although the center of process technology is Belgium.

Prayon also offers the Prayon–Central Glass process, a name derived from its Japanese origins. In this process, gypsum is crystallized in a dihydrate mode in the first stage. After separation of most of the P_2O_5 from the slurry by centrifugation or filtration, the gypsum is recrystallized to hemihydrate employing the sulfuric acid ultimately required in the first stage. The recrystallized hemi is quite low in P_2O_5 and impurities suitable for by-product wallboard and plaster, and is readily washed in a second stage of filtration, followed by an agglomeration step that results in a semi-granular by-product. This process has allowed the Engis, Belgium, plant to continue operation by converting all of its gypsum to a saleable product. The Prayon Mark III and Mark IV dihydrate processes are used in Florida and Louisiana in some eight lines operating between 1,350 and 2,000 t per day P_2O_5, and in one revamped plant in Jordan.

Speichim–Rhone Poulenc process. Most of Rhone Poulenc's existing plants are of a single stirred vessel configuration. However, a two-vessel arrangement, the Diplo system, [18] has been offered and retrofitted into several of the previous single reactor plants.

The original Rhone Poulenc Single Tank system is an exceedingly simple plant. It is air-cooled by passing a flow of air over slurry splashers, and does not have a filter feed tank, the slurry simply overflowing the reactor to a vertical pipe on top of the filter feed pump. The newer Diplo system is said to offer a better yield, higher P_2O_5 product acid strength, and a more filterable gypsum by providing a better concentration gradient for gypsum growth.

Rhone Poulenc installations are located in France, Belgium, Morocco, Senegal, Brazil, and China.

Nissan H process. In this process, the rock attack is done under conditions favoring the formation of an unstable hemihydrate. The slurry then is cooled and seeded to recrystallize to gypsum at high sulfate levels, producing a gypsum low in co-precipitated P_2O_5. Yields in the 97–98% range are reported. The process, in operation since the 1960s, has been favored in many instances where the phosphogypsum can be used for wallboard or other building materials. Major installations are located in Japan and Morocco. A large plant at Pernis, Netherlands, has been closed and it appears that Nissan no longer offers phosphoric acid technology.

Jacobs process. Jacobs Engineering acquired the Dorrco process technology in 1974 and has carried on the annular reactor design begun by Dorr in the early 1960s. The reactor configuration is a compromise between a multicompartment system, as used in the earlier Dorr–Oliver cascade system and in the compartmented Prayon reactor, and the true single stirred vessel used by Rhone–Poulenc and Badger.

In the Jacobs system, the annulus of a large concrete tank is fitted with a series of agitators. There is baffling, but there are no walls between the agitators. High slurry recirculation

Fig. 23.10 Oswal phosphoric acid plant during construction—May 1999—Paradeep, Orissa, India

rates are achieved by a combination of back-mixing and slurry pumping. Vacuum cooling normally is used. The Jacobs plants include a 1,500 t per day plant in Tampa, Florida, a 900 tons per day facility at Paradeep, India, and several smaller units. Figure 23.10 shows the Oswal Fertilizers and Chemicals construction site of the world's largest phosphoric acid plant [19–21] 2,650 mt per day P_2O_5 also at Paradeep, Orissa, in mid-1999. Figure 23.11 is a diagram of the reactor itself. Starting in the center foreground of the photo and moving clockwise, the large building, partially roofed, holds five 110 m two-belt filters, next is the wet grinding and screening structure. The concrete reactor tank, having 4,350 m^3 of slurry volume, is shown prior to the installation of the agitators. The three small cylindrical vessels are slurry vacuum coolers. Six evaporators with fluosilicic acid recovery are pictured next. The large tanks are for acid storage and clarification, and finally, on the far right, the cooling tower foundations. Slurry flow is clockwise around the annulus, into the center compartment, then to the long narrow vacuum cooler feed compartment. The cooled slurry flows to the cooler seal compartment opposite the feed compartment. The bulk of the slurry recycles to the annular reactor with the net flow proceeding to the filter feed tank. In principal, the flow pattern is similar to the Prayon reactor system shown in Fig. 23.9. The ground phosphate rock is mixed with recycled cool slurry in the first position of the annulus followed by the addition of sulfuric acid diluted in a mixing tee with weak phosphoric acid from the filter.

Isothermal process. The Badger–Raytheon reactor is a draft tube mixer within a vacuum vessel [22]. All reactants are added to this vessel, which is under vacuum, and cooling and rock digestion are achieved simultaneously.

There are three lines in Florida, two in Mexico, and two in the Western United States. The system has low energy consumption, but lacks flexibility in that it works best with finely ground rock. It has also exhibited some difficulty in handling the high organic Mexican phosphate.

Hemihydrate Processes for Phosphoric Acid

Methods for making higher strength P_2O_5 acid have been known for a long time. The basic hemihydrate–dihydrate process shown in the Hydro Fertilizer flowsheet, Fig. 23.12, is similar to the initial process attempted in 1931 at the Cominco plant at Trail, BC. The hemihydrate—dihydrate process failed there, mostly because of inadequate filters, but the Dorr dihydrate process did emerge successfully.

The first large hemi plant of more modern times was the Kemira hemi-dihydrate two-stage plant at Siilinjarvi, Finland, which started operation in 1969, using the Dorr HYS process. After about 4 years of operation at 250 mt per day P_2O_5, its rated design, the plant was expanded but operated in the dihydrate mode. In the hemihydrate mode, filtration and recrystallization problems had plagued the plant, which operated on Kola rock.

Hemihydrate processes are available for new facilities and also for the retrofitting of existing dihydrate plants. Several conversions to higher-strength acid have been made, where the steam saved in evaporation can replace fuel. Plants that make super-phosphoric acid, or where

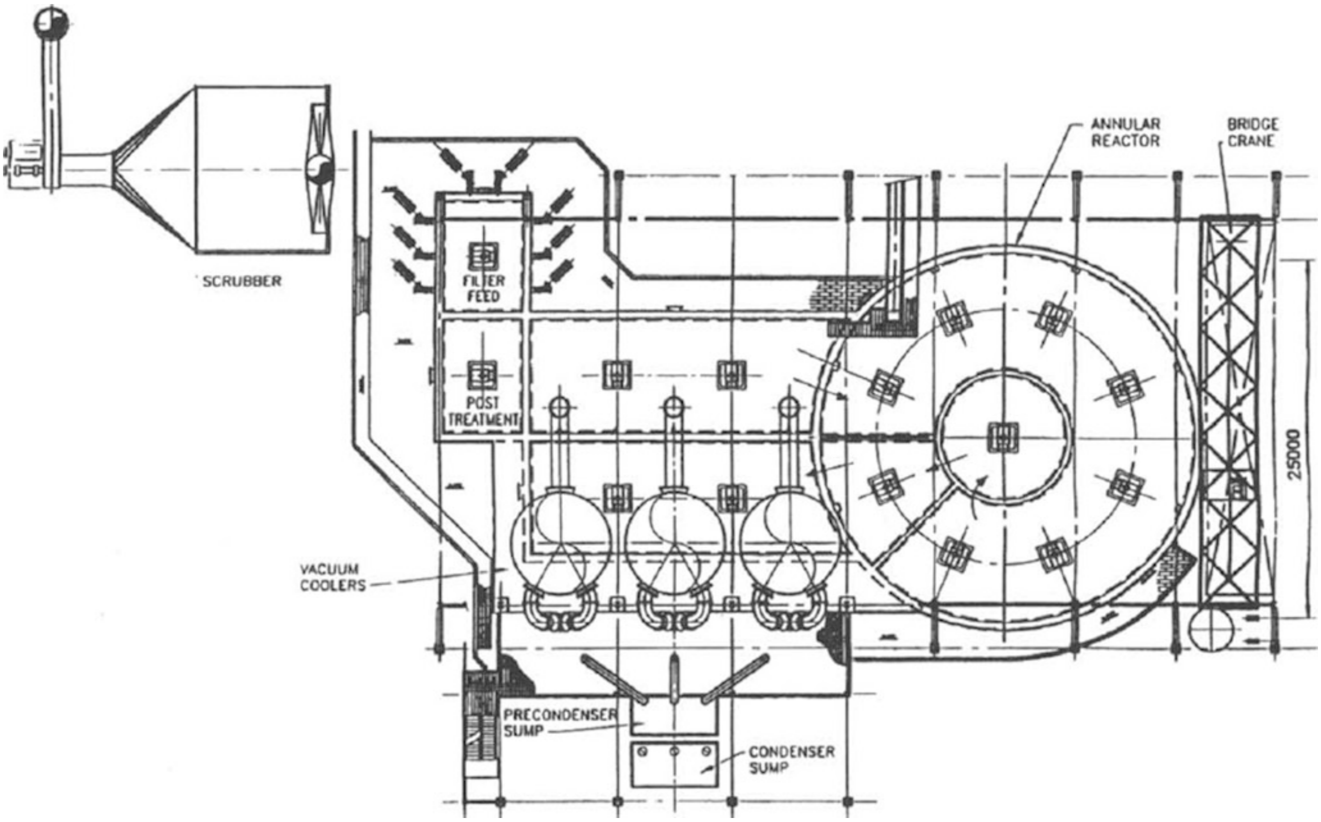

Fig. 23.11 Jacobson reaction system, 2500 tons per day P_2O_5

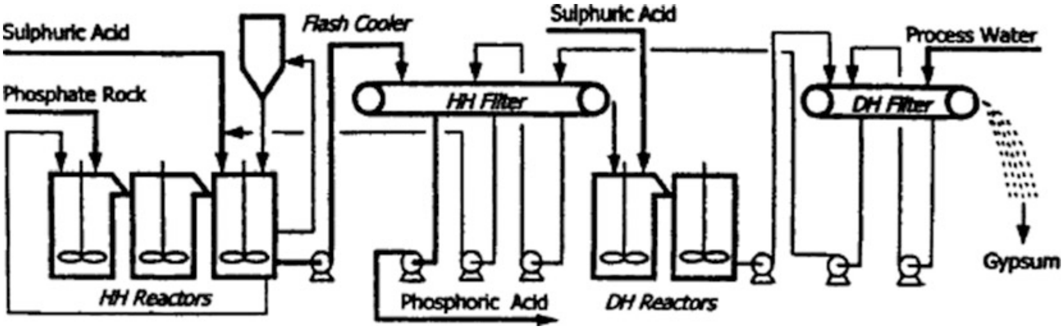

Fig. 23.12 Hydro fertilizer technology hemihydrate process

sulfuric acid plant steam is not available, are likely targets for conversion.

The single-stage hemi process is similar to the front end of the HDH process (see Fig. 23.13). However, in this case, the hemi is sent to waste without deliberate recrystallization after washing. Yields for the single-stage process are generally below the yields of the dihydrate process, whereas yields for the two-stage HDH process are very high; see Table 23.7.

Table 23.8 lists the major hemihydrate plants operating in 2000. Many of the smaller facilities on the ninth edition list have been shut down. However, two major single-stage hemi plants have recently started operation. The Indo-Jordan facility has been particularly successful operating at full capacity from the initial startup, and up to 1,000 t per day P_2O_5 on two 80-m^2 Eimco belt filters.

The WMC plant [23, 24] extends proven hemi capacity to 1,500 t per day P_2O_5, but the plant has had to contend with a highly abrasive, low-grade rock, 23.5% P_2O_5 with over 35% SiO_2. In addition, the PCS (Occidental) single-stage hemi plant, in operation since the early 1980s, has been termed by some as one of the best phosphoric acid plants in the world. Also, the conversion at Arcadian has met the test of time.

Fig. 23.13 Hydro fertilizer technology hemihydrate process

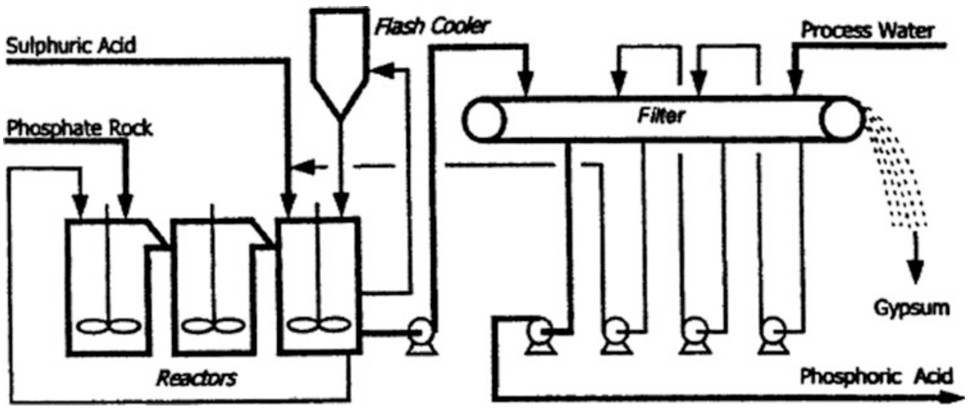

Table 23.7 Range of P_2O_5 yield through filtration as % of P_2O_5

Phosphate acid process	
Hemi-dihydrate	98–99
Conventional dihydrate	95–97
Single-stage hemi	91–94

The advantages of the hemihydrate processes compared with the conventional dihydrate processes are:

1. Energy savings due to higher product acid strength.
2. Higher P_2O_5 recovery and lower H_2SO_4 consumption for the two-stage process.
3. Lower capital cost for the single-stage process.
4. Hemi-hydrate recrystallized gypsum that is relatively pure, 0.2–0.4% total P_2O_5. This makes it more suitable for a cement additive or in wallboard.
5. Less rock grinding required.

Energy savings in phosphoric acid. As has just been noted, the hemi processes provide energy savings due to the reduced steam consumption for evaporation. This steam, even though of low-pressure, 2.0–3.0 kg/cm^2, has significant value for the cogeneration of power. In some cases, the hemi process also saves rock-grinding power. On the other hand, dihydrate processes have the ability to use wet rock slurries and to absorb, in the process, more contaminated water resulting from rainfall collected off the waste gypsum stacks. The latter advantage may be important to maintaining a zero water balance and eliminating costly effluent treatment. The use of wet grinding and slurry feeding eliminates the fuel and electricity consumed in drying the rock.

Another energy-saving option is the use of hot water instead of steam for evaporation. This is an alternative, energy-wise, to the higher-strength hemi processes. Hot water normally is available from the heat of absorption of the sulfuric acid plant. Strengths of 40–42% P_2O_5 can readily be achieved. A few commercial installations exist in Europe. A more expensive alternative is offered in the HRS sulfuric acid process by Monsanto, which converts the absorption heat to low-pressure steam.

Unit Operations

In addition to the reaction step discussed above, there are a number of other unit operations used in producing wet process phosphoric acid.

Calcination. Phosphate rock normally is used as a dry rock or in slurry form. However, in some cases, particularly where the raw phosphate is high in carbonaceous matter or it is desirable to have a clean acid, the rock is calcined. Also, in a few cases, the phosphate rock is calcined, the product slaked, and free lime separated as a beneficiation step. Calcination is energy intensive and produces a less reactive rock and, in some cases, a less filterable gypsum. Therefore, the use of calcination is diminishing, and is being replaced by a wet oxidation step to produce green acid [16]. In separating calcium carbonate, flotation, where it is successful, is favored over calcination because of its lower cost.

Rock grinding. Until 1973, most phosphate was ground dry in roller or ball mills. In that year, Agrico, at South Pierce, Florida, converted one of its dry mills to wet slurry grinding and proved that the plant water balance could manage the rock at a 65–68% solids slurry. Since that time, most US installations have converted to wet grinding.

Relatively fine phosphates, such as Kola, North Florida, Senegal, and Togo, can be processed unground as dry concentrates or as dewatered beneficiated product with 12–18% moisture. In the hemi processes, somewhat coarser feed, -20 mesh, may be tolerated. For dihydrate, it is desirable to feed from 1.5% + 35 mesh (Tyler) to about 8% + 35 mesh.

Filtration. The separation of phosphogypsum or hemihydrate from its mother liquor has always been a difficult operation. The process has been subject to the formation of calcium sulfate, sodium fluosilicate, and other types of scale that clog the cloth and necessitate periodic filter washing. Filter cloth wear is severe, requiring cloth changes as often, in some cases, as 2 or 3 weeks apart.

Table 23.8 Major hemihydrate installations (2000)

Owner	Location	Year in operation	Process	Product acid strength	Rock	Capacity P_2O_5 (million tons per day)

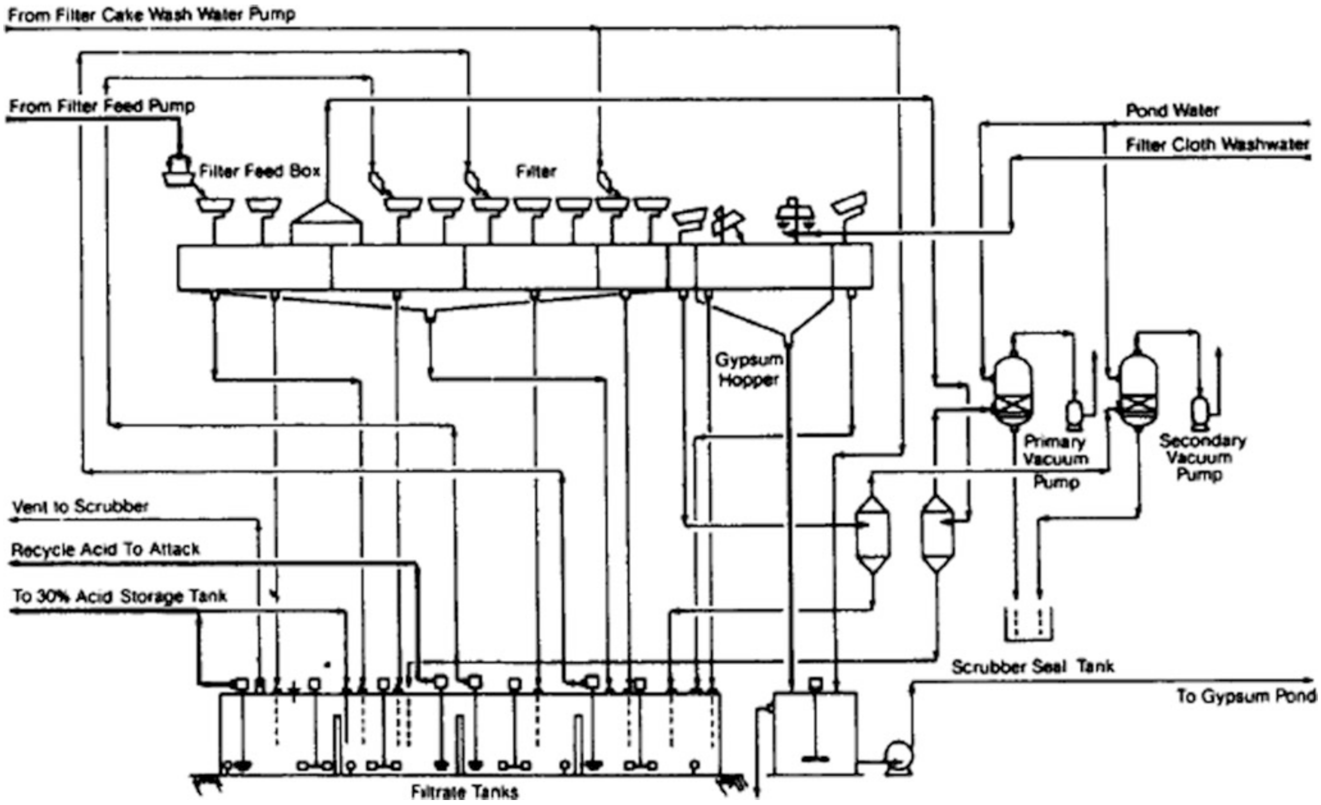

Fig. 23.14 Flow diagram of filtration section of a wet process phosphoric acid plant (Prayon process, courtesy Davy Mckee Corp.)

Three types of filters have predominated over the past 20 years, the most widely used being the Bird–Prayon tilting pan filter shown in Fig. 23.14. The Ucego, a table filter with a peripheral side wall belt that leaves the filter to permit cake sluicing, has been popular worldwide since the late 1960s. In the late 1970s and the 1980s, belt filters became more readily accepted. The belt filter has been used on phosphoric acid since the 1940s and 1950s, but in the past it was plagued by mechanical problems and materials failures.

During the last decade, many successful belt filter installations have been made by Eimco, Filtres Philippe, Delkor, and Gaudfrin. Even in hemi service at Namhae, Indo-Jordan, and WMC, operating at 95°C or above, the belt filters appear to be successful. Because of their long narrow configuration, the belt filter is well suited as a supplemental filter and three have been installed in Florida for this purpose.

The filtration step is a countercurrent washing using two or three washes. Usually the final wash is a contaminated

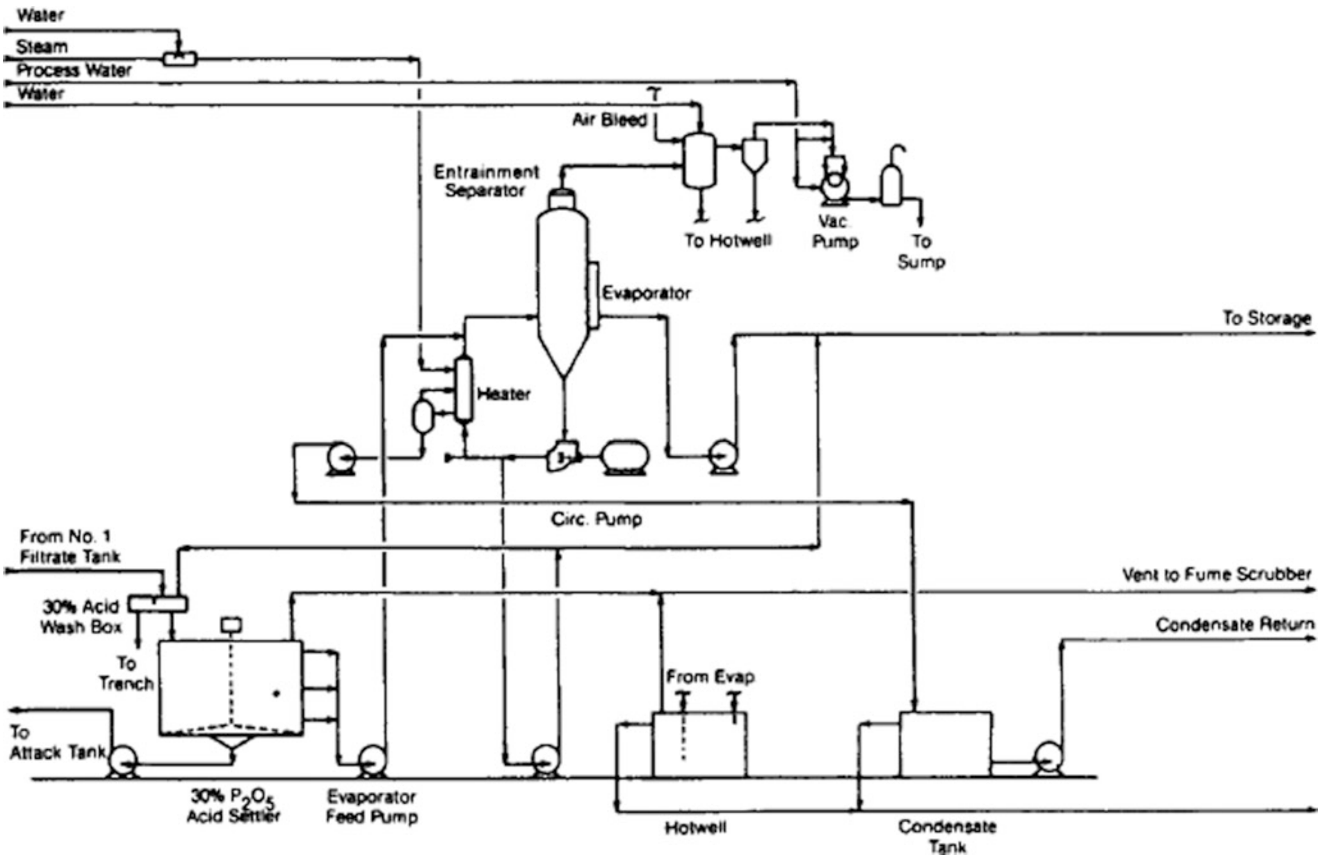

Fig. 23.15 Flow diagram of evaporation section of a wet process phosphoric acid plant (courtesy Davy Mckee Corp)

pond water or a cooling loop water, thus providing for, in most cases, a zero effluent plant.

Sizes of the Bird–Prayon and Ucego filter can be very large, over 200 m^2 of active surface area, allowing rates up to 1,600–2,000 mt per day P_2O_5. Belt filters are, so far, 110 m^2 or less; however, they are relatively inexpensive because little alloy steel is used, and normally two belt filters would be less in first cost than one large tilting pan or table filter.

Evaporation. Phosphoric acid is used for downstream products mostly at 28% P_2O_5, 40% P_2O_5, and 54% P_2O_5. Many plants also make clarified merchant grade acid (MGA), which, at 52–54% P_2O_5, is a world traded product.

Evaporation normally is done under vacuum using forced circulation via an axial flow pump. Vacuum can be accomplished by steam ejectors, vacuum pumps, or with condenser water using an entraining condenser downleg. Heat exchangers normally have been shell and a tube, with graphite tubes in the United States. French practice has been to use carbon block exchangers, but these tend to scale more and are no longer in favor in many areas. Some newer shell and tube exchangers have been Sanicro 28 or Hastelloy G3 or G30. A flow sheet is shown in Fig. 23.15.

Typical analyses of wet process phosphoric acid made from North Carolina calcined concentrate are shown in Table 23.9.

Table 23.9 Typical analyses, wet process phosphoric acid made from North Carolina calcined concentrate

	Weight percentage

Sp.g, at 75 °F	1.68	2.0

[a] About 36 % of the total P_2O_5 is present as polyphosphates (courtesy Texasgulf.Inc.)

Superphosphoric Acid

Solution fertilizers have become very popular in the United States. The principal source of P_2O_5 for these fertilizers is wet process Superphosphoric acid containing about 70% P_2O_5 where 35% or more of the P_2O_5 is present in the polyphosphoric form. When this acid is ammoniated and diluted, the iron, aluminum, and magnesium compounds naturally present remain in solution, sequestered by the polyphosphates. Clear solutions result, and there is no clogging of the sprays used for applying the fertilizer. When ordinary phosphoric acid is neutralized with ammonia, heavy sludges form, and the resulting solution is difficult to store and apply.

Superphosphoric acid is made by the additional concentration of clarified phosphoric acid in vacuum evaporators of the falling-film or forced-circulation type. High-pressure steam or Dowtherm vapor is used for heating. Corrosion is a problem, so the equipment is made from high alloy stainless steels. The acid is shipped in special insulated tank cars to the solution fertilizer plants, which are located close to the farm areas they serve. Organic matter contributes to sludge problems in making solution fertilizers; therefore, calcination of the phosphate rock used for making the acid is advantageous. Organics also may be removed by oxidation with nitric acid or ammonium nitrate [16], and several SPA producers have gone to such treatment to improve their product quality.

Wet Process Acid By-Products

Phosphogypsum

About 5 t of gypsum on a dry basis are made for each ton of P_2O_5 produced in a wet process phosphoric plant. This material usually is disposed of as a waste, by impounding it in old mine pits, stacking it in huge piles, or, in some cases, discharging it into very large rivers or river mouths. Phosphogypsum is sold to farmers in California for control of salt buildup in irrigated soils; a small quantity is sold to peanut farmers in the southeastern United States. However, there has been concern about the utilization of gypsum because of its low-level radioactivity in some instances. In addition, it contains fluosilicates and P_2O_5 so that utilization in building products, such as wallboard and blocks, has been limited to Europe and Japan, where natural gypsum is more costly than manufactured gypsum. In these cases, the phosphogypsum generally comes from a hemihydrate process producing a slightly purer form than natural gypsum.

Regeneration of SO_2 from gypsum has been done via the Krupp–OSW process, the most important facility formerly being the Fedmis plant in South Africa, which made about 300 t per day H_2SO_4 and a similar amount of cement. Apparently, because of the high cost of cement and sulfur in this remote location, the plant was not economically viable and shut down in the late 1980s. Because of the present low cost of sulfur and its future abundance as a result of the removal of sulfur from sour natural gas and because of SO_2 removal processes in power generation, interest in sulfur recovery from phosphogypsum has waned.

The Florida Institute of Phosphate Research (FIPR) has studied phosphogypsum utilization at length, but the U.S. Environmental Protection Agency has prohibited its movement from its stacks (piles) because of its low level radiation. The FIPR hopes to show that its use in road building subsurfaces and as an additive to enhance digestion of municipal waste in land fills can be accomplished without harm to the public now or in the future [25, 26].

Fluorine Recovery

Phosphate rock contains about 3.5% fluorine, some of which is recovered as a byproduct in manufacturing wet process phosphoric acid. During acidulation, the fluorine is released as hydrofluoric acid, HF, which reacts with the silica present as an impurity in the rock to form fluosilicic acid, H_2SiF_6. Some of the fluorine is lost with the gypsum as sodium or potassium fluosilicates, and some remains dissolved in the filter acid. When the acid is concentrated, much of the fluorine in the feed is boiled off, appearing as HF and silicon tetrafluoride, SiF_4, in the vapors.

Fluorine is recovered at the evaporator station by scrubbing the vapors leaving the flash chamber. The vapors pass through an entrainment separator to remove fine droplets of phosphoric acid and then into a spray tower where they are scrubbed with a weak solution of fluosilicic acid according to the reaction:

$$2HF + SiF_4 \rightarrow H_2SiF_6$$

Part of the circulating solution is continuously withdrawn as a 20–25% aqueous solution of H_2SiF_6. The solution is shipped in rubber-lined tank cars and is used for fluoridation of drinking water, the preparation of fluosilicates, and production of AlF_3. These salts find use in ceramics, pesticides, wood preservatives, concrete hardeners, and aluminum production.

Uranium Recovery from Wet Process Phosphoric Acid

Uranium recovery was briefly described in the ninth edition. Since 1990, all uranium recovery contracts have expired in the United States and the recovery facilities moth-balled or scrapped. There is no indication that the situation will change in the near future, because the reduced price of uranium no longer makes its recovery from phosphoric acid economical.

Animal Feed Supplements

Calcium phosphates for use in animal and poultry feeds are made from both furnace and wet process phosphoric acids. Dicalcium phosphate, $CaHPO_4$, containing 18.5% P, and

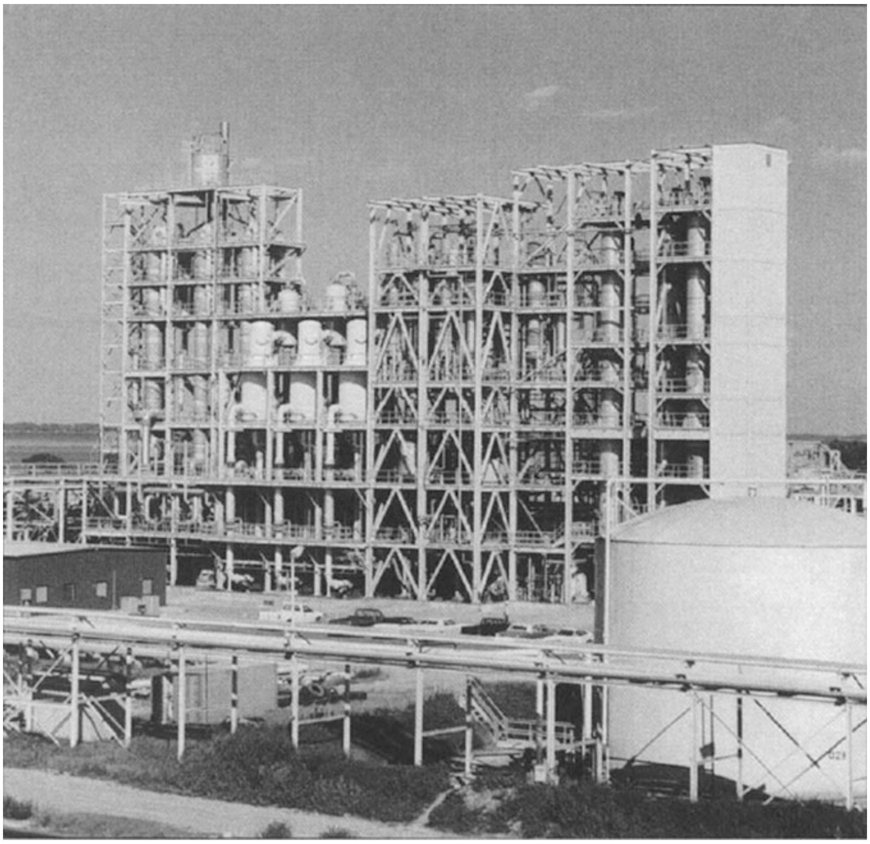

Fig. 23.16 Purifried phosphoric acid plant for P.A. Partnership, Aurora, NC (courtesy P.A. Partnership and Jacobs Engineering)

mono calcium phosphate, Ca $(H_2PO_4)_2 \cdot H_2O$, containing 21.0% P, are made in large tonnages. Both grades are prepared by reacting phosphoric acid with pulverized lime stone in a pug mixer. The limestone must be quite pure, and the phosphoric acid must have a low fluorine content, below 100 P to 1.0°F. If 54% P_2O_5 wet process phosphoric acid is used, it is defluorinated first by adding diatomaceous earth and then sparging the acid with steam. An alternate method is to use wet process superphosphoric acid, which has a low fluorine content. The superphosphoric acid is hydrolyzed by diluting it with water and heating. The pug mixer product is a fine granule, −12 mesh, which is dried and shipped in bulk to feed-mixing plants.

Purified Phosphoric Acid

Currently only one furnace acid plant remains in operation in the United States to supply elemental phosphorus and a few uses that cannot be satisfied by purified wet acid produced from wet process acid.

Wet process phosphoric acid made from calcined rock is preferred feed stock because it is devoid of the soluble organics and sludges present in acid made from sedimentary phosphates. However, calcination is expensive so that some plants are willing to go through laborious clarification to avoid it.

Clear acid is fed to a column or a battery of mixer-settlers and extracted with a solvent such a butyl alcohol or tributyl phosphate. Generally, about three-fourths of the phosphoric acid transfers to the organic phase, leaving the impurities in the raffinate, which is sent to a fertilizer unit to recover its P_2O_5. The yield of cleaned acid can be increased by adding another mineral acid such as sulfuric acid or hydrochloric acid to the extraction step.

After washing, the phosphoric acid is stripped from the solvent with water, and the solvent is returned to the extraction section. The phosphoric acid now is quite dilute and still contains small amounts of impurities. The acid then is concentrated, and the impurities are removed by steam stripping and the addition of reagents and adsorbents followed by filtration. The exact details of the process vary, depending upon the process technology, which is proprietary, the impurities present in the feed acid, and the solvent used. Purified wet phosphoric acid is suitable for both industrial and food-grade use, although food-grade requires another level of purification over industrial or technical grade acid.

There are now several purified acid plants in the United States. Figure 23.16 is a photo of the PCS plant at Aurora, NC. That plant was expanded by adding a third train in 2001 and a fourth train in 2006. The Rhone-Poulenc purification plant at Geismar, LA continues in operation. There are also plants in Morocco, Belgium, Japan, and Israel.

Environmental Aspects

As implied earlier in this chapter, gypsum disposal is a problem that generally has defied an inexpensive solution. As a waste material, it is relatively benign, but P_2O_5, sulfate, fluorine, low-level radioactivity, and other contaminants, including some heavy metals in small quantities, can leach from waste stacks into the nearby groundwater. In Florida, the underlying layers of limestone afford some protection, but the EPA will require future stacks be lined with a membrane to prevent seepage. The "gypsum dilemma" has loomed as an increasing problem over the last decade [25–27].

Although dumping of waste gypsum slurries into the ocean still is practiced in some locations outside the United States, and harmful effects are generally difficult to quantify, there is continuing pressure from environmental groups to cease dumping into rivers and the seas.

Gaseous emission from phosphoric acid plants can be scrubbed with cool contaminated recycle cooling water to relatively low emission levels. However, to minimize cooling tower or cooling pond emission, fluorine recovery often is necessary on those streams that have a significant fluorine content.

Fertilizers and Food Production

24

Amit H. Roy

Introduction

Fertilizers provide plants with the nutrients they need for their growth and development. Plants live, grow, and reproduce by taking up water and nutrients, carbon dioxide from the air, and energy from the sun. Apart from carbon, hydrogen, and oxygen, which collectively make up 90–95% of the dry matter of all plants, other nutrients needed by plants come essentially from the media in which they grow—essentially in the soil. The other nutrients are subdivided into primary nutrients (nitrogen, phosphorus, and potassium) and secondary nutrients (calcium, magnesium, and sulfur). In addition, plants also need other nutrients in much smaller amounts, and they are referred to as micronutrients (boron, chlorine, copper, iron, manganese, molybdenum, and zinc).

To maintain soil fertility and productivity and prevent land degradation, nutrients taken up by crops must be replenished through the application of fertilizers. The use of fertilizer results in many benefits to producers, consumers, and the environment, starting with increased agricultural outputs (mainly food and fiber) to contributing to soil organic matter maintenance, water-holding capacity, biological nitrogen fixation, soil erosion control, other physical and chemical properties, and less extensive land use. These benefits contribute to increased agricultural growth and agribusiness activities, which are catalysts for broadly based economic growth and development in most developed and developing economies; agriculture's links to the nonfarm economy generate considerable employment, income, and growth in the rest of the economy.

A commercial fertilizer is a material that contains at least one of the plant nutrients in chemical form that, when applied to the soil, is soluble in the soil solution phase and assimilable or "available" by plant roots. Most often, this implies chemical forms that are water soluble. However, in the case of phosphorus, solubility in special reagent solutions (citric acid, neutral ammonium citrate, or alkaline ammonium citrate) often is used as a guide for availability to plants. In the case of nitrogen, slow solubility in water may be more desirable from an environmental and efficiency standpoint than easy solubility.

Fertilizer products are customarily designated by a series of numbers separated by dashes. This set of numbers is called "grade" of the fertilizer product. Each of the numbers indicates the amount of a nutrient that the manufacturers guarantee is contained in the fertilizer product. This number includes only the amount of nutrient found by accepted analytical procedures, thereby excluding any nutrient present in a form that is deemed to be unavailable for plant nutrition. The content of each nutrient, expressed as a percentage of total weight, is the guaranteed minimum rather than actual, which is usually slightly higher.

Usually, three numbers are used when giving the grade fertilizer product, and these three numbers always refer in order to the content of the primary nutrients: nitrogen, phosphorus, and potassium. If other nutrients are present, their content can also be indicated in the grade of the fertilizer product; each extra number is followed by the chemical symbol of the nutrient it represents. Many countries indicate the content of phosphorus and potassium not in the elemental form but in the oxide form, P_2O_5 and K_2O. Thus, a fertilizer product with a grade of 12–6–22– 2MgO is guaranteed by the manufacturer to contain: 12% N, 6% P_2O_5, 22% K_2O, and 2% MgO.

The beginning of our dependence on inorganic fertilizer can be traced back to the nineteenth century when Justus von Liebig articulated the theoretical foundations of crop production and when John Bennett Lawes began producing fertilizers containing phosphorus [1]. However, only since the 1960s when global starvation became a real possibility have fertilizers assumed a predominant role in increasing agricultural productivity. Fertilizer was an integral part of

technological trinity—seed, water, and fertilizer—responsible for bringing about the "Green Revolution" that helped many densely populated countries, including India, China, and Indonesia, achieve food self-sufficiency in a short span of 20–25 years.

Since the 1960s, global cereal production has more than doubled, increasing from 866 million metric tons (mt) in 1961 to nearly 2,433 million mt in 2010, with developing countries accounting for nearly 60% of the increase (Fig. 24.1). Most of the increased cereal production in South Asia was through higher yields, but increases in sub-Saharan Africa were mostly through area expansion (Fig. 24.2). It is estimated that fertilizers accounted for 56% of the rise in average yields per hectare and about 30% of the total increase in production. Consequently, cereal production closely parallels fertilizer use in developing countries (Fig. 24.3). The only exception is sub-Saharan Africa where per capita food production has decreased since the 1970s. This decline can be attributed to several factors, including low soil fertility, agroclimatic conditions,

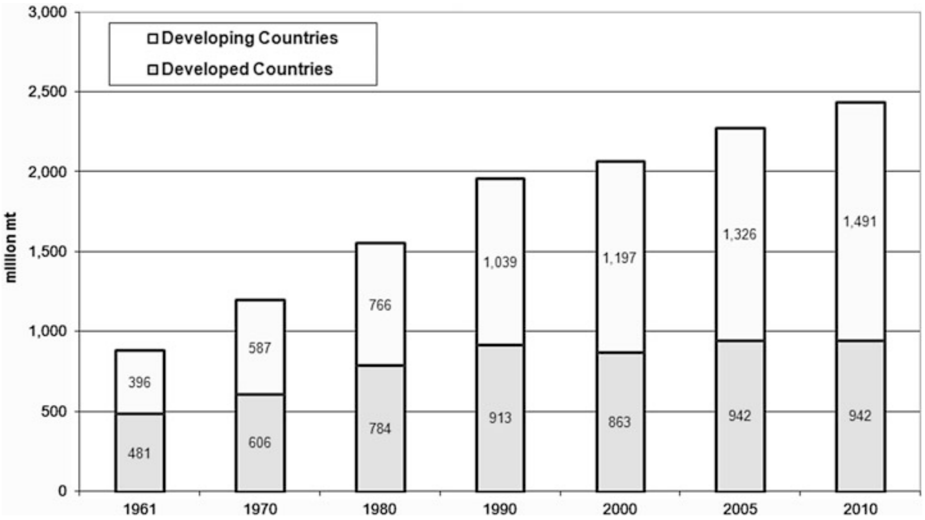

Fig. 24.1 Cereal production in developed and developing countries, 1961–2010

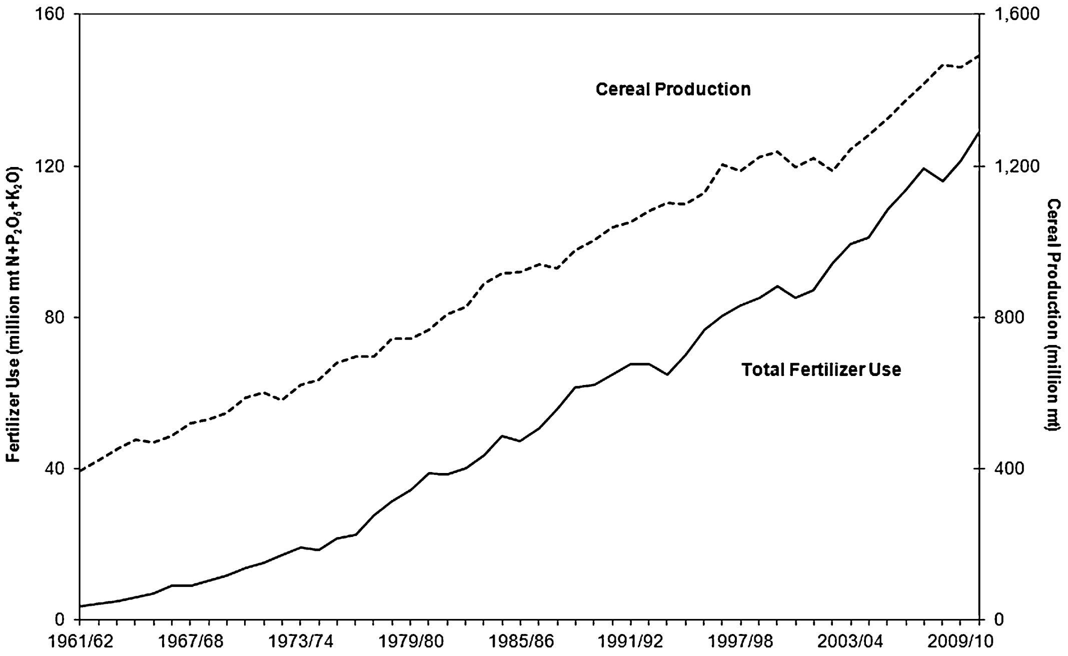

Fig. 24.3 Developing countries: total cereal production and total fertilizer use, 1961/1962–2010/2011

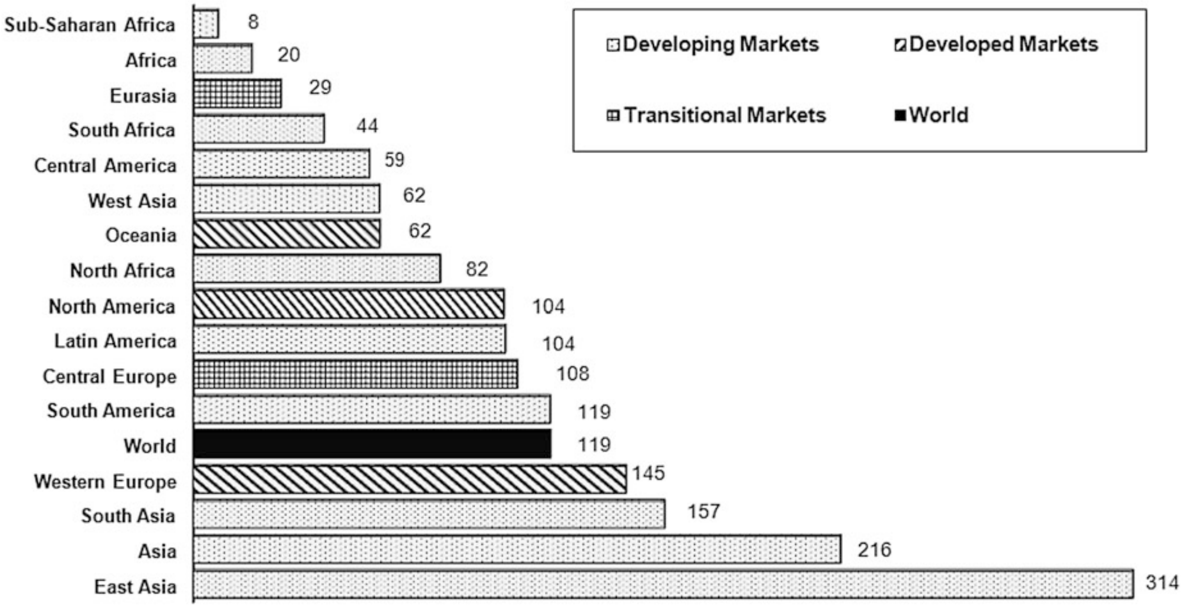

Fig. 24.4 Per hectare fertilizer use by regions and markets, 2010 (kg/ha)

and low fertilizer use. Compared with a world average of 119 kg of nutrients per hectare, sub-Saharan Africa uses only 8 kg of nutrients per hectare, resulting in a significant mining of inherent nutrients from soils that are already low in nutrient status (Figs. 24.4 and 24.5).

Growth in the future demand for food and feed will be influenced by changes in a number of forces, but mainly by growth in population, income levels and economic development, and changes in the food preferences of consumers. Although the United Nations recently adjusted downward its estimates of population growth, still during the next 20 years approximately 75 million people will be added to the world's population each year, increasing it from about 6.8 billion in 2010 to over 9.2 billion by 2050 (Fig. 24.6). Much of this increase will occur in the cities of the developing world, which will account for most of the increased

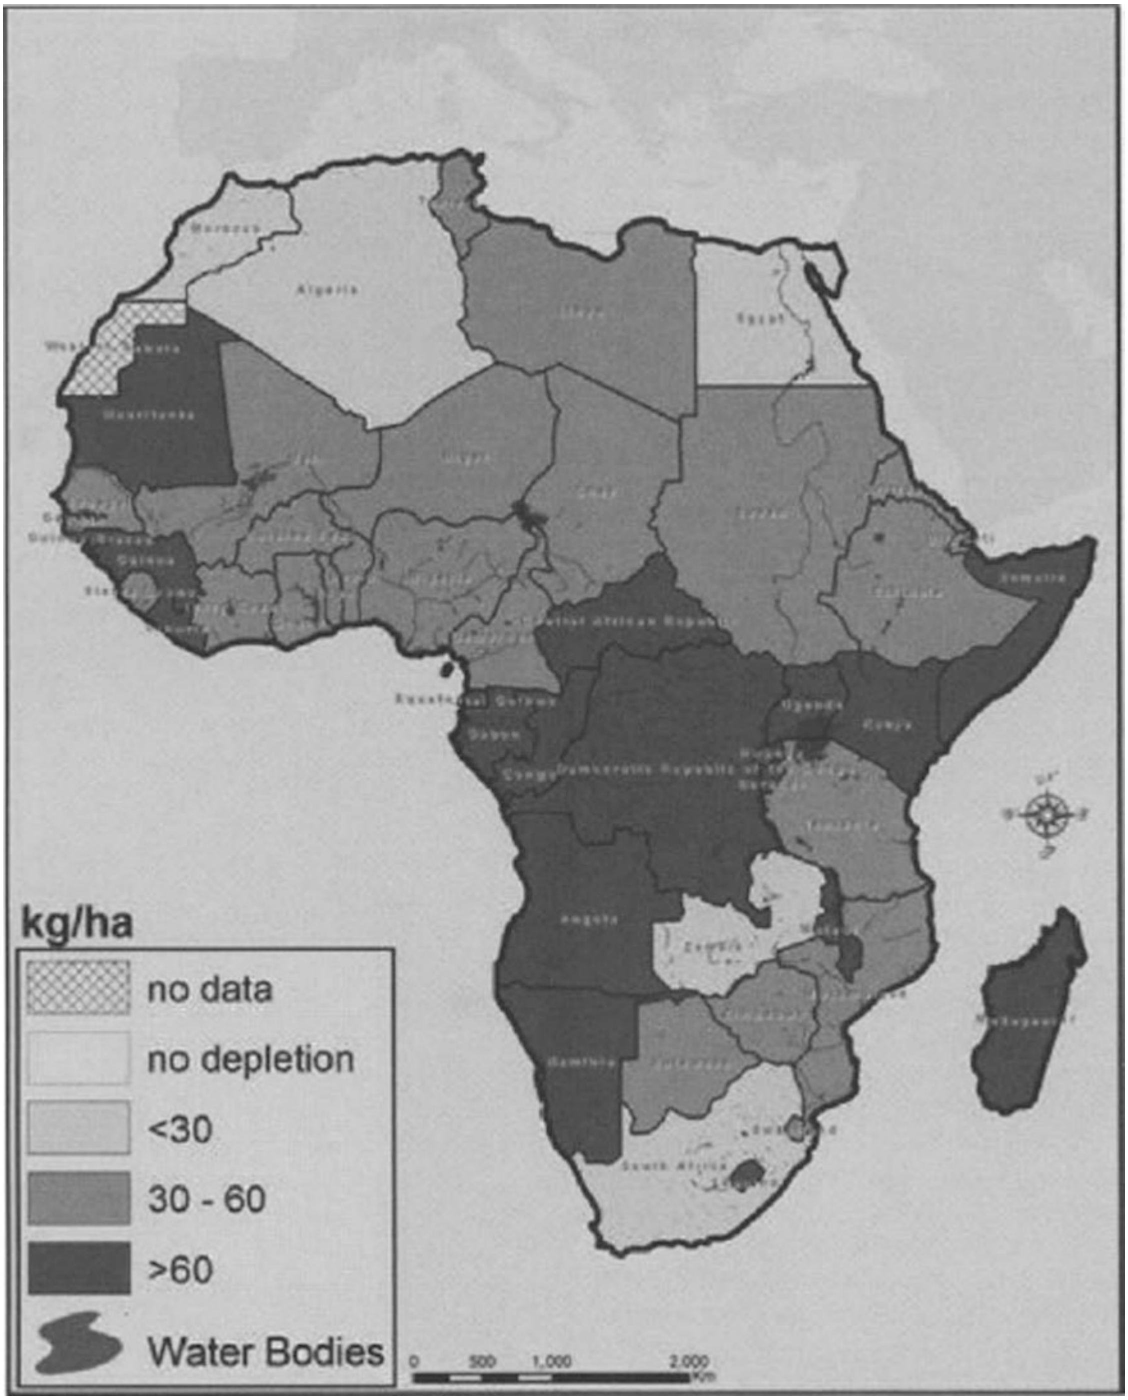

Fig. 24.5 Average nutrient depletion (NPK) in Africa for 2004

demand for food, including meat products. The recent drive toward renewable energy sources, particularly biofuels, will also increase demand. Enthusiasm for biofuels is because of dramatically higher energy prices, geopolitical tensions, and uncertainties about future availability and access to petroleum. Also, farmers must produce more crops from existing farmland if forests and wildlife habitats are to survive. This will require increased crop yields through use of improved seeds and fertilizer. This increased fertilizer use has to be balanced against the environmental and human health concern stemming from intensive fertilizer applications, particularly in industrialized countries.

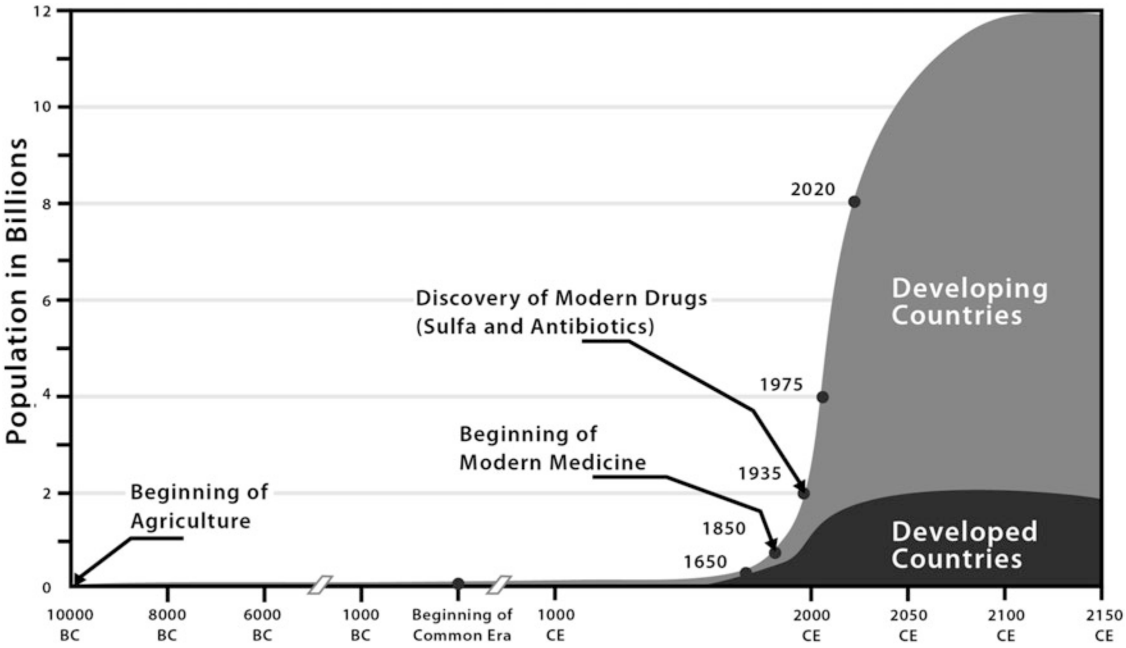

Fig. 24.6 World population projection

Overview of the Fertilizer Industry

Since medieval times, farmers have realized the need to maintain the productivity of soil to achieve improved crop yields. Until the last 200–300 years, however, the approach was highly empirical; only by accident or by trial and error was it found that applications to the soil of various organic wastes or naturally occurring mineral substances such as manure, compost, fish, ashes, saltpeter, and other substances would sometimes increase yields or apparently restore productivity to fields that were considered "worn out."

As more and more chemical elements were identified, scientists became interested in determining the amounts and relative importance of various elements in plants. The German scientist Liebig clarified the value of elements derived from the soil in plant nutrition and stressed the necessity of replacing those elements to maintain soil fertility. He usually is credited with initiating the fertilizer industry. Liebig recognized the value of nitrogen but believed that all plants could get nitrogen from the air, a concept that unfortunately is not true. He envisioned a fertilizer industry with nutrients such as phosphate, lime, magnesia, and potash prepared in chemical factories. In 1840 Liebig published a recommendation that pulverized animal bones be treated with sulfuric acid to make the phosphate more readily available to plants. This practice was accepted, and the production of fertilizers by chemical processing thus began.

Natural organic materials and various chemical by-products represented a large proportion of the total world fertilizer supply until about the middle of the twentieth century; in the later years of the century, however, the dependence shifted almost entirely to synthesized or chemically processed materials. Only by this means has it been possible to keep up with increasing populations, increased farm acreage, and increased plant food needs of new and improved crop varieties. Today, the fertilizer industry utilizes many facets of highly sophisticated chemistry and engineering in the manufacture of fertilizers, and in pollution control, including disposal of waste products. The procuring and handling of raw materials and the distribution and marketing of products also involve the latest technology and many innovations. In addition, the agronomic aspects of fertilizer usage engage the efforts of many individuals and organizations worldwide. The development and introduction of "high-yielding" varieties of seed required more concentrated and efficient fertilizers. Many organizations and private companies worldwide have carried out extensive research and development R&D on improving fertilizer production, developing new products, and increasing efficiency of usage. The most notable among them include the U.S. Tennessee Valley Authority, the International Fertilizer Development Center, and the Rothemstadt Experiment Station.

The fertilizer industry is a large-volume producer, one that falls within the basic industrial structure of a country. The magnitude of this industry is apparent from Fig. 24.7, which shows the yearly global consumption of primary plant nutrients (N, P_2O_5, and K_2O) since 1970/1971. For 2010/2011 the total consumption of N, P_2O_5, and K_2O was

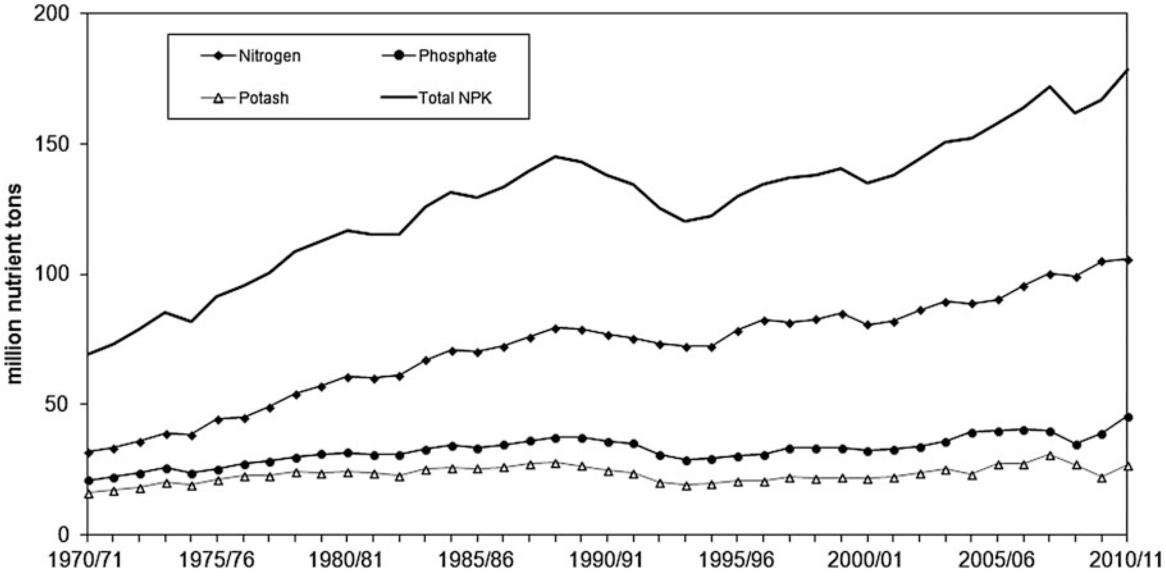

Fig. 24.7 World: nitrogen, phosphate, potash, and total NPK consumption, 1970/1971–2010/2011

178.4 million mt. Of this amount, China, the United States, and India consumed 57.4 million mt, 19.7 million mt, and 28.1 million mt, respectively. Collectively, these three countries accounted for about 50% of the world consumption. Assuming an average nutrient content of all fertilizers for that period of about 40% shows that some 358 million mt of fertilizers was produced and handled by the industry during that year [2]. In general, the industry includes a number of "basic producers" each of which typically concentrates on producing large amounts of single-nutrient or high-nutrient fertilizer products, usually at locations near raw materials. Numerous other components of the industry concentrate on locating close to local farmers and distributing the basic products either in the form received from basic producers or after various secondary-processing operations such as granulation, blending, or conversion to fluids. In the United States, fluid mixtures account for more than 20% of the total fertilizer sales. To a lesser extent, fluid mixtures have been introduced into Europe, North America, and South America. Fluid mixtures are used on high-value crops in some middle eastern countries, particularly Israel, where efficient use of water is as important as the efficient use of plant nutrients.

Raw Materials for Fertilizer Production

The primary raw materials for nitrogen fertilizers are natural gas, naphtha, fuel oil, and coal. The manufacturing of phosphate fertilizers most often requires phosphate rock. Naturally occurring potassium salts form the basis of the production of most potash fertilizers.

Natural gas, naphtha, fuel oil, and sulfur have fairly definable specifications. In contrast, phosphate rock and coal are products that can vary significantly in composition and other characteristics. These variations can affect the processes used to upgrade the "as-mined" ores or the processes for manufacture of fertilizers from beneficiated products. Potash ores also vary greatly in composition depending on origin; however, the end products of mining, beneficiation, and processing generally have relatively constant compositions.

Adequacy of requisite raw materials is the most obvious concern when facing a substantial increase in future demand. Two separate yet intertwined issues in the case of fertilizers are: sufficiency of raw materials and availability of energy to convert them into final products. Potassium is of least concern among the three primary nutrients. Not only is this element abundantly present in the earth's crust, but also it can be found in conveniently concentrated deposits in both deeply buried and near-surface sediments. Potassium deposits in descending order of known reserves are in North America (Canada and the United States), Germany, Russia, Belarus, Brazil, Israel, and Jordan. Even the most conservative reserve base estimates indicate a reserve on the order of 500 years at the level of the late 1990s production [3]. Mining, crushing, and beneficiation of potassium usually amount to about 10 gigajoules (GJ)/t of the nutrient, energy demand comparable with that required in making cement.

Phosphate rock is a finite nonrenewable resource. There is no substitute for phosphorus. Phosphate deposits are known from every continent of the world with the exception of Antarctica. Recently published total world phosphate rock reserves range from 60 billion tons of producible concentrate [4] to 65 billion tons of undifferentiated phosphate rock. Total world phosphate rock resources may range from 290 billion tons to 460 billion tons of phosphate rock at varying P_2O_5 grades [4]. Phosphate deposits are not evenly distributed around the globe. The most abundant known reserves, in descending order of abundance, are located in Morocco, China, the United States, Jordan, and Russia. At the current rates of extraction, these reserves can support the current rate of use for 300–400 years. Of course, in the future based mainly on requirements due to population growth, increased demand for phosphorus-based products will require increased rates of phosphate rock production and the rate of depletion of known reserves may increase. This time horizon can be extended by exploiting by both known, incompletely explored, and yet unknown phosphate deposits at higher costs. Conservation and efficient use of this valuable natural resource and recycling of P has received and will continue to receive more emphasis in the future.

Nitrogen fertilizers via ammonia synthesis account for more than 90% of the world's nitrogen fertilizers. Nitrogen supply for ammonia synthesis is truly inexhaustible since the atmosphere contains 3.8 quadrillion tons of the element. Various feedstocks can be used to obtain hydrogen, and during the last several decades the focus has been to improve the energy efficiency of ammonia synthesis. Natural gas is the preferred feedstock and the best natural gas-based plants now use less than 33 GJ/t N. The global mean, which is affected by more energy-intensive reforming of heavier hydrocarbons (naphtha and fuel oil) and coal, is now between 49 and 55 GJ/t N, roughly half of the level prevailing during the early 1950s.

Even if all of the energy needed to fix the fertilizer nitrogen were to come from natural gas, it would still be less than 7% of the recent annual global consumption of the fuel and less than 2% of all energy derived from fossil fuels [5]. Clearly, there is little reason to be concerned about either the current needs or the future supplies of energy for producing nitrogenous fertilizers via the ammonia synthesis route. Moreover, there is no doubt that higher absolute energy needs for nitrogen fertilizers will be partially offset by improved efficiency of ammonia synthesis and by higher efficiencies of fertilizer use. Because today's low-income countries will experience much faster growth of energy needs in sectors other than the fertilizer industry, the share of global fossil fuel consumption for ammonia synthesis by the middle of the twenty-first century may be only marginally higher than it is today.

Global natural gas resources are considered abundant. Generally, proven reserves of natural gas are considered those quantities that geological and engineering data indicate can be recovered with reasonable certainty in the future from known reservoirs under presently existing operating and economic conditions. Total world proved reserves were 187.49 trillion cubic meters at the end of 2009 [6]. The reserve to production ratio (R/P ratio) was increased at the end of 2009 to 62.8. That is, the amount of proven reserves divided by the production that year indicates the amount of years of reserves remaining at that rate. It should be noted that gar reserves have increased over the last 20 years from 122.4 trillion cubic meters in 1989 to the present figure of 187.49 trillion cubic meters. Similar to many other natural resources, natural gas reserves are a dynamic quantity determined by exploration activity, technology, and economics. In absence of natural gas, naphtha or fuel oil, ammonia synthesis could be accomplished (albeit more costly) by tapping the worlds coal resources or by using a variety of biomass feed stocks.

Nitrogen Fertilizers

Nitrogen is a component of amino acids that make up proteins; chlorophyll (the molecule that captures the sun's energy); enzymes; and the genetic material, nucleic acids. Therefore, this nutrient is required in large amounts by all plants and forms one of three primary nutrients. Although nitrogen is available in abundance (79% by volume) in the earth's atmosphere, only a very limited number of plant varieties, chiefly legumes, can utilize this nitrogen directly from the air. For most plants, including such important cereal crops as rice, wheat, and corn, the nitrogen must be in a chemical form dissolved in the soil solution. Atmospheric phenomena, including lightning discharge, convert nitrogen to nitrogen oxides, which then is absorbed in rain water and enters the soil. However, this contribution is quite small and the resultant nitrogen content of soils is normally very low (less than 0.3%). Continuous cropping without replenishment quickly depletes the soil of this important nutrient.

Until about the early 1950s, the more widely accepted method of supplying nitrogen was through the application of manures/organic waste and the use of crop rotation. Crop rotation entailed growth of a nitrogen-fixing legume crop such as peas, clover, or alfalfa, which then was plowed into the soil to provide nitrogen for a subsequent non-legume crop, for example wheat and corn. This method gives the added bonus of improving soil organic matter status. Such a crop rotation is relatively inefficient with regards to land usage and labor requirement. Modern, high-yield agriculture cannot, under most conditions, be sustained by such a system. Nevertheless, the use of crop rotation is being promoted in many countries of sub-Saharan Africa, particularly landlocked countries where natural soil fertility is very low and the price of fertilizers relatively high.

Natural Organics

Animal and human wastes have long been used as fertilizers, especially in Europe and Asia, particularly China. Even some American Indians are said to have planted a dead fish in each corn hill to increase yields. Such materials contain small percentages of nitrogen and other plant nutrients that are assimilable by plants. Today, the use of raw sewage on crops persists in Asia and Europe, but volumewise is not of great significance. In the United States and most European countries, the use of raw sewage is not considered acceptable, but some municipal sewage plants employ special sterilization, heavy metals removal, and drying processes that yield acceptable fertilizers of low nitrogen content. The volume of such output is small, however. Other organic materials traditionally employed as fertilizers of usable nitrogen content include guano (deposits of accumulated bird droppings), fish meal, and packinghouse wastes including bone meal and dried blood. However, the cumulative importance of all such natural nitrogen sources in modern agriculture is minor. Less than 1% of the total fertilizer nitrogen now used comes from such sources. These products for the most part are not chemically altered prior to use. Processing is mainly physical in nature to improve handling and distribution properties.

Nitrogen Fertilizers from Synthetic Ammonia

The development of a practical ammonia synthesis process in the early years of the twentieth century was a profound scientific achievement of great social significance in view of the subsequent dependence of the world on fertilizer for support of its growing population.

Both the historical background and detailed technical descriptions of modern ammonia synthesis processes are covered in Chap. 22. These processes are all refinements of the original one conceived and developed by Fritz Haber and Carl Bosch in Germany during the period 1904–1913. Basically, a gaseous mixture of nitrogen and hydrogen, in proper proportions to form ammonia, is compressed to very high pressure in the presence of an activated iron catalyst. Ammonia forms and is removed by cooling and condensation. The nitrogen feed is obtained from air by any of several routes that remove the oxygen. Likewise, there are several routes by which hydrogen feed is obtained, most of which involve decomposition of water by reaction with a carbon source such as natural gas, naphtha, or coke. The preparation and the purification of the synthesis gas and the synthesis itself are highly sophisticated modern processes that require great skill and know-how in design, construction, and operation of plants.

There are many processing routes by which synthetic ammonia subsequently finds its way into finished fertilizers. The major routes are outlined graphically in Fig. 24.8 and are discussed in some detail below.

Anhydrous Ammonia. Anhydrous ammonia, without further processing, is an excellent nitrogen fertilizer when properly injected in gaseous form below the surface of many soils. Such direct injection first came into farm use in the early 1940s and rapidly became accepted. Anhydrous ammonia is an important nitrogen fertilizer in the United States, Canada, Denmark, and Mexico, but in some other countries, for various reasons it is a relatively minor nitrogen source [3].

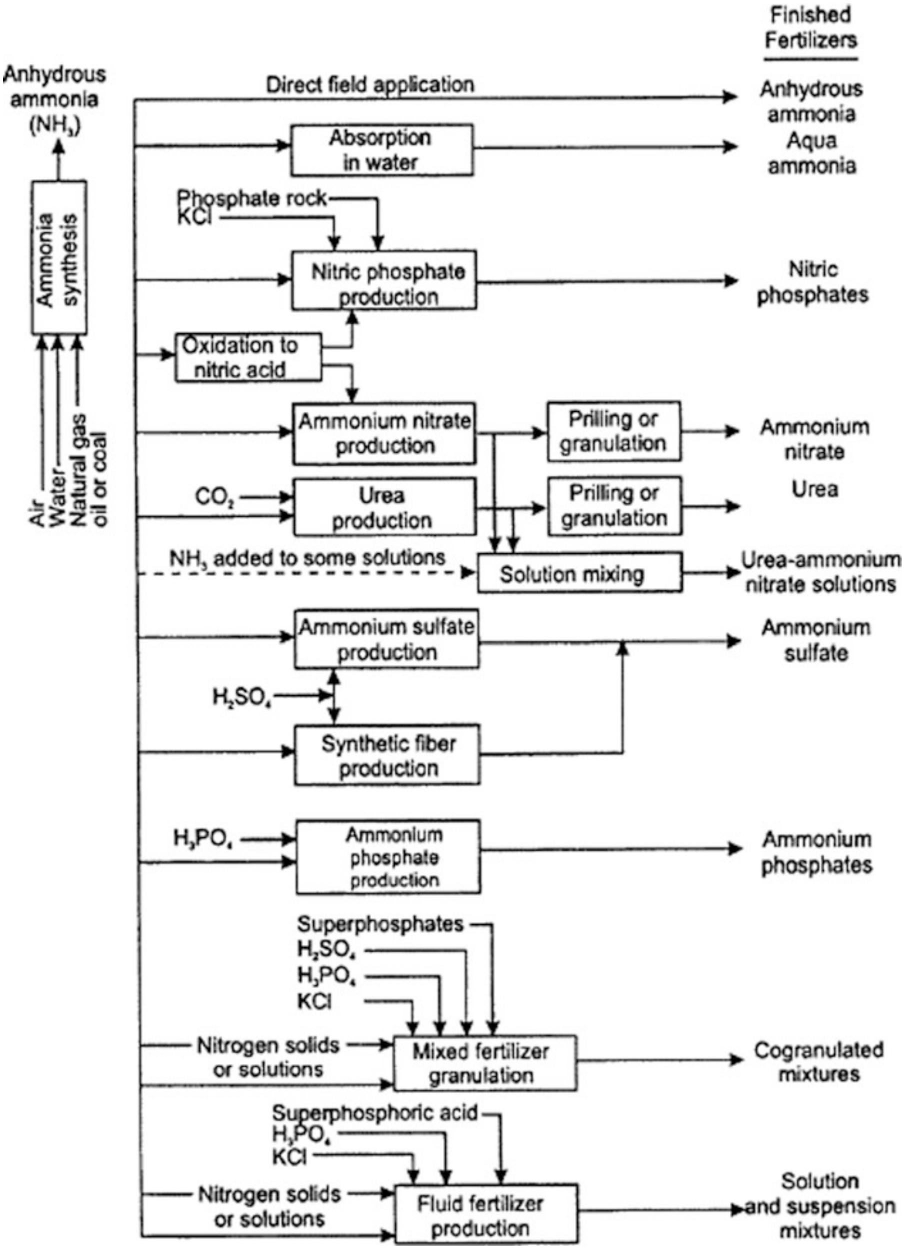
Anhydrous ammonia injection is popular for economic reasons. Ammonia is naturally the cheapest form of fixed nitrogen at the point of production because no further processing is required. Also, the nitrogen content of anhydrous ammonia (82.4% N) is almost twice that of the next most concentrated nitrogen fertilizer (urea: 46% N); this high nitrogen content reduces shipping and handling weight proportionally.

From production to field application, ammonia is handled in liquefied form. Because ammonia is a gas at normal atmospheric pressure and temperatures, its maintenance in liquid form requires either pressurization or refrigeration. Although such handling requires specialized equipment and considerable safety precautions, there are advantages and economies inherent in the handling of a fluid rather than a solid [3].

In order to maintain ammonia in liquid form at atmospheric pressure, it is necessary to refrigerate it to at least −33°C. In storage and handling without refrigeration, rather high pressures must be contained when atmospheric temperatures reach high levels. For example, a pressure of 19 kg/cm^2, which for safety reasons has been set as the upper limit allowable for storage vessels at retail locations, will maintain the liquid form only up to a temperature of 46°C. Safety pop-off valves are set to vent ammonia at higher pressures.

Facilities for handling liquid ammonia from points of production to points of use are highly developed in the United States. A considerable amount of ammonia is moved hundreds of miles through interstate pipelines. Major pipelines run from points of production in Texas, Oklahoma, and Louisiana oil fields all the way to the intensively farmed mid-western area of the United States. Storage at the points of production and at large terminals sometimes is in pressurized vessels (spheres), but more often it is at atmospheric pressure in large, insulated, refrigerated vessels. Refrigeration is effected simply by allowing vaporization of some of the contained ammonia, compressing the resulting vapor, and recondensing it in a water-cooled condenser. Barges with similar self-sustaining refrigeration systems commonly move large amounts of anhydrous ammonia on rivers and on the high seas. Also, specially designed railroad tank cars ranging in capacity from 24 to 73 tons are used widely for ammonia transport. These cars typically are

Fig. 24.8 Major routes of synthetic ammonia into finished fertilizers *(Courtesy TVA)*



nonrefrigerated, instead depending on pressure retention to maintain the liquid form. Large pressurized tank-trucks also are used. At retail depots in farming areas, storage normally is in pressure vessels, often with some compressor capability to recondense vapor and to facilitate transfers. Movement of ammonia to farm fields is via wheeled pressure tanks known as “nurse” tanks. Application equipment, usually tractor-drawn, is equipped with pressure tanks that are filled by transfer from nurse tanks.

Because anhydrous ammonia is gaseous at atmospheric conditions, for fertilizer use it must be injected below the surface of the soil to ensure absorption by the soil solution. Most applicators are equipped with a metering system and a series of soil-penetrating “knives”; the metered ammonia is piped through tubing down the trailing edge of each knife to a single opening at the deepest extremity. A penetration of 15–25 cm is typical. Retention of ammonia in the soil is best when abundant soil moisture is present.

Aqua Ammonia. Ammonia in a simple water solution is popular as a nitrogen fertilizer in some locations, but overall it claims less than 1% of the total nitrogen fertilizer market. This product is made from anhydrous ammonia in units referred to as “converters.” These units simply provide cooling as ammonia and water are combined in metered proportions. Aqua ammonia normally contains 20% nitrogen (24% NH_3). Its chief advantage over anhydrous ammonia is its low vapor pressure; this allows handling in nonpressure equipment, which simplifies design and reduces safety hazards. The chief disadvantage of aqua ammonia as a fertilizer is its relatively low nitrogen content, which limits its shipping range and increases field handling requirements. As with anhydrous ammonia, the preferred application method is knifing below the soil surface to limit volatilization loss; however, a relatively shallow injection depth of only 7–13 cm can be used.

Ammonium Nitrate and Urea. Almost half of the total global fertilizer nitrogen application is as ammonium nitrate or urea, in either solid or solution form, although many countries are restricting the availability of ammonium nitrate because of its potential use by terrorists to make bombs. The history and the technology of ammonium nitrate and urea production from synthetic ammonia are covered in detail in Chap. 29. The production of nitric acid from synthetic ammonia, which is a prerequisite to the production of ammonium nitrate, also is covered completely in Chap. 29. The production plants for all these materials are, like synthetic ammonia plants, highly sophisticated, involving all facets of modern engineering.

The production processes for both ammonium nitrate and urea yield their products first in the form of saturated solutions. Typical ammonium nitrate solution concentration is 75–85% (26–30% N) at 40–75°C, and typical urea solution concentration is about 75% (34% N) at 93°C. To produce the solid forms of these products, the solutions first must be concentrated to extremely low water contents (1–2%) and then fed to prilling or granulation equipment. The resultant solid products that range in size between 2 and 4 mm are highly acceptable to farmers as high-nitrogen fertilizers and to "bulk blenders" as nitrogen sources in the formulation of dry-blend mixed fertilizers, as will be described later. The nitrogen content of solid ammonium nitrate is 34%, and that of urea is 46%.

The concentration and the solidification of ammonium nitrate and urea solutions to form solid fertilizers require considerable expenditure of energy and processing expense; so it is attractive to use the solutions in the formulation of liquid fertilizers, without processing them into solid form. However, neither ammonium nitrate nor urea alone is sufficiently soluble at ambient temperatures to be attractive for direct use as liquid fertilizer. With either compound alone, a solution with a salting-out temperature of 0°C would contain only about 18% nitrogen. Fortunately, however, the joint solubility of the two compounds in water is much more favorable than this; so the liquid nitrogen solutions marketed for fertilizer use almost invariably are joint solutions of ammonium nitrate and urea. Typical commercial solutions contain 28–32% nitrogen, with compositions and characteristics as shown in Table 24.1.

Table 24.1 Physical and chemical characteristics of urea–ammonium nitrate nonpressure nitrogen solutions

Grade, % N	*28*	*30*	*32*
Composition by weight			
Ammonium nitrate, %	40.1	42.2	43.3
Urea, %	30.0	32.7	35.4
Water, %	29.9	25.1	20.3
Specific gravity, 15.6°C	1.283	1.303	1.32
Salt-out temperature, °C	−18	−10	−2

Source: Fertilizer Manual, United Nations Industrial Development Organization and International Fertilizer Development Center, Kluwer Academic Publishers, Dordrecht, The Netherlands, 1998

The high-volume use of these solutions is a result of their economy of production and the safety and convenience of their handling and application. The use of nonpressure equipment and surface application (in contrast to knifing) is normal. Nitrogen solutions of other compositions also are prepared commercially, but are used primarily as intermediates in the preparation of solid fertilizers. Such solutions usually consist of various combinations of water, ammonia, ammonium nitrate, and/or urea. Because of the content of free ammonia, most of these solutions require pressurized handling.

Ammonium Sulfate. Although an excellent nitrogen–sulfur fertilizer with good physical properties, ammonium sulfate is now outranked economically by ammonium nitrate and urea. The chief reasons for the unpopularity of ammonium sulfate are its relatively low nitrogen content (21%) and its relatively low solubility in liquid fertilizers. At most U.S. locations, it is uneconomical to produce ammonium sulfate from synthetic ammonia and virgin sulfuric acid. As a result, most of the ammonium sulfate available for fertilizer use is a by-product of other processes. A larger source now is by-product ammonium sulfate solution from the production of caprolactum and acrylonitrile, which are synthetic fiber intermediates. This by-product solution normally is fed to steam-heated evaporator–crystallizers to yield the solid ammonium sulfate. Additional production of by-product ammonium sulfate is obtained from "spent" sulfuric acid, by reaction with synthetic ammonia. In this case, the production of ammonium sulfate is a method of disposing of acid that already has been partially spent in other processes. Some ammonium sulfate is produced by scrubbing ammonia-containing coke-oven effluent gas with sulfuric acid. This production is discussed later.

By-product ammonium sulfate produced by any of the above-mentioned methods is usually in the form of crystals that are 90% or less than 1 mm in size, and thus are much smaller than the size preferred for present-day finished fertilizers. This small size is not undesirable if the material is to be used as feed to a fertilizer granulation plant, but it is undesirable for bulk blending (dry mixing) or direct field application. It is possible to produce suitably large crystals, but only at the expense of greatly reducing crystallizer capacity. Both compaction and granulation processes have been employed with some success on a limited scale to convert the small-crystal material to a larger-size product [7].

Ammonia in Multinutrient Fertilizers. All the ammonia-based fertilizers discussed thus far contain only one of the three major plant nutrients, namely nitrogen. Referring again to Fig. 24.8, one may see that ammonia is the source of fertilizer nitrogen also, either directly or via nitrogen solids or solutions, in multinutrient fertilizers. These are fertilizers that contain two or three of the major plant nutrients—nitrogen, phosphorus, and potassium. Ammonium phosphates, both mono- and di-, are phosphate fertilizer products that also carry nitrogen. (These are discussed later as major suppliers of phosphate.) As suppliers of nitrogen, the ammonium phosphates and other multinutrient solid and fluid fertilizers collectively furnish about 20% of global fertilizer nitrogen. (Production of these fertilizers is also described later.) The source of their nitrogen is, in all cases, ammonia and/or ammonia-based solids or solutions. Nitric phosphates are suppliers of nitrogen through their content of nitric acid and ammonia. They are not presently produced or used to any significant extent in the United States but are produced in Europe and some other locations. (Their production too is discussed briefly later).

Miscellaneous Low-Volume Nitrogen Fertilizers

Mineral Nitrogen. The only nitrogen-containing mineral that is mined commercially for fertilizer use is saltpeter (sodium nitrate, $NaNO_3$). An impure form of sodium nitrate known as "coliche" is found in large, rocklike deposits in a relatively dry desert area of Chile, and these deposits have long been mined to provide natural sodium nitrate for the fertilizer market. The ore is blasted from open mines, sized, and leached with water in vats. Evaporation of the resultant solution yields the commercial crystalline fertilizer product known widely as "Chilean nitrate," "nitrate of soda," or among some farmers simply "sody." Its nitrogen content is 16%. This product first was imported and marketed in the United States in 1830, so it is one of the oldest fertilizers on the American market. Sodium nitrate now, however, is a relatively insignificant component of the world's nitrogen fertilizer market, having been supplanted by synthetic nitrogen compounds.

By-product Ammonia. Coke, an essential ingredient in the smelting of iron ore and in some other metallurgical processes, is produced by the heating of coal in an essentially oxygen-free atmosphere. This heating volatilizes numerous hydrocarbon components of the coal and results in decomposition of some of these compounds. The nitrogen content of coals normally is about 1%, and approximately half of this is volatilized as ammonia gas in the coking process. Recovery of this ammonia has long been effected by passing the coke-oven effluent gas through scrubber–crystallizers containing sulfuric acid. The resultant crystalline by-product, ammonium sulfate, is an excellent fertilizer source of both nitrogen and the secondary plant nutrient sulfur. The nominal nitrogen content of the product is 20%, and the sulfur content is 24%. Prior to the introduction of synthetic ammonia production processes (1913–1925), coke-oven ammonia was a major source of fertilizer nitrogen; however, its production was very small when compared with today's demand for fertilizer nitrogen. Today, ammonia production from coke ovens, although still carried out, is insignificant in volume compared with that from ammonia synthesis processes.

Phosphate Fertilizers

Phosphorus intake is essential to the metabolism of both plants and animals. In the case of plants, the entire uptake is from the soil solution via root absorption. Absorption occurs only when the phosphorus is present in the soil solution in the form of $H_2PO_4^-$, HPO_4^{2-}, or PO_4^{3-} ions [8]. Furthermore, a large proportion of the soil phosphorus is present in chemical forms that are not "available" (assimilable), or are only very slowly available, to crops. Cropping of native soils without phosphate fertilization soon depletes the supply of phosphorus and renders the soil barren. In times before fertilizers became readily available, it was not uncommon to "wear out" a farm by repeated cropping. Crop rotation, which was mentioned earlier as a useful method of converting atmospheric nitrogen to available soil nitrogen, is ineffective as a means of phosphorus fertilization. In fact, the nitrogen-converting legumes generally are voracious consumers of phosphate.

Modern, high-yield agriculture is dependent on regular fertilization with phosphorus compounds that are either immediately soluble in the soil solution or become soluble at a rate sufficient to supply the crop. A factor to contend with in phosphate fertilization is soil "fixation" of phosphorus; that is, the characteristic of many soils to convert at least a portion of applied phosphate to chemical forms that are unavailable to plants. The fixation tendency varies with soil type, and generally is highest in soils of high clay content. The overall result of fixation is that considerably more phosphate must be applied as fertilizer than is removed with crops.

Natural Organic Phosphate Fertilizers

In animal metabolism, phosphorus concentrates in the bones and, in the case of Crustacea, in the shells. Manures and human wastes, previously mentioned as effective but low-volume sources of fertilizer nitrogen, are much less efficient sources of phosphorus than of nitrogen. The phosphorus content of such products is normally only 1.3–3.0%, which is only 25–50% as great as their nitrogen content. Bird droppings, including chicken manure and guano deposits, are somewhat higher in phosphorus content (7% P), but are available in only relatively insignificant amounts overall.

Raw animal bones normally contain 8–10% phosphorus (20–25% P_2O_5); thus they are a relatively rich source. The commercial grinding of bones for fertilizer use began in Europe in the early nineteenth century [9]. The practice persists today in the production of bone meal, but only in very low volume, chiefly to furnish slowly available nutrients for greenhouse and house plants. In about 1830, it was found that pretreatment of bone meal with dilute sulfuric acid greatly enhanced the "availability" of the phosphorus to plants, and the practice became common. The initiation of this practice now is regarded to have had considerable historic significance as the apparent beginning of the chemical fertilizer industry. The supply of bones being very limited, it soon was found (about 1840) that a similar acid treatment of mined phosphate ore rendered the phosphorus "available" as a fertilizer. Thus was born the still important "superphosphate" industry, and the supplanting of the very limited organic phosphorus sources by widely available mineral sources was begun.

Today, organic sources of fertilizer phosphorus account for less than 1% of total worldwide consumption.

Fertilizers from Mineral Phosphates

Essentially all fertilizer phosphorus now is derived from mined ores. (The occurrence, mineral characteristics, mining, and beneficiation of major phosphate ores were described in some detail in Chap. 23.) Worldwide, about 85% of the mined phosphate eventually finds its way into fertilizer [3]. As mentioned earlier, the most conservative estimates indicate a sufficiency for hundreds of years at expected consumption levels. Supply problems of the immediate future will relate chiefly to exhaustion of the better ores, with the result that ores of lower grades and higher impurity contents will have to be processed.

Major routes of mineral phosphate (phosphate rock) into finished fertilizers are outlined in Fig. 24.9 and are discussed below. It is obvious from the figure that although phosphate rock is used directly in several major fertilizer production processes (single superphosphate (SSP), nitric phosphates), most important processes require that the rock phosphate first be converted to phosphoric acid (H_3PO_4). Phosphoric acid production, then, is a very significant component of the phosphate fertilizer industry. The processes used for the production of fertilizer-grade phosphoric acid are known collectively as "wet" processes, and involve, initially, dissolution of the rock in sulfuric acid. (The highly specialized technology of wet-process acid production was discussed in Chap. 23).

Single Superphosphate. In 1842, Lawes in England followed up on the pioneering work of Liebig and received a patent on the use of sulfuric acid in reaction with raw phosphate material to produce "superphosphate" fertilizer. The industry grew slowly, and in 1862 about 150,000 tons of what later would be referred to as "ordinary" (OSP) or "normal" (NSP) or "single" (SSP) superphosphate (16–18% P_2O_5) was produced in England. By 1870, there were 70 SSP plants in the United Kingdom and 7 in the Charleston, South Carolina, area of the United States [10]. In 1888, commercial shipment of phosphate rock from Florida was initiated, and a major mining industry followed in that state, which continues today. As late as 1955, SSP supplied over 60% of the world's phosphate fertilization and was the major phosphate fertilizer in the United States. Rock from Florida or South Carolina was shipped throughout the country to local SSP production facilities. These facilities usually included the capability of blending the SSP with nitrogen and potash materials and bagging the resultant mixtures.

In recent years the production of SSP, to a large extent, has given way to the production of the higher-analysis "triple superphosphate (TSP)" and ammonium phosphates. SSP retains greater importance in some countries. For example, SSP remains popular in Australia, at least in part because its sulfur content is particularly needed there.

SSP is the simplest, as well as the oldest, of manufactured phosphate fertilizers. Its manufacture consists of reacting pulverized phosphate rock with sulfuric acid in comparatively simple equipment, followed by sufficient aging (curing) to complete the reaction and improve the physical condition. The acid rock reaction converts the water-insoluble apatite structure of the rock to soluble monocalcium phosphate. When produced from high-grade rock of 30–32% P_2O_5 content, SSP contains about 20% available P_2O_5; the product made in earlier years from lower-grade rocks contained only 14–18% P_2O_5. SSP can be used for direct application, for bulk blending, or in the production of granular NPK fertilizers. If the product is to be used for direct application or bulk blending, it usually is granulated to improve handling properties.

The main equipment for manufacturing SSP consists of a mixer to bring together sulfuric acid and phosphate rock,

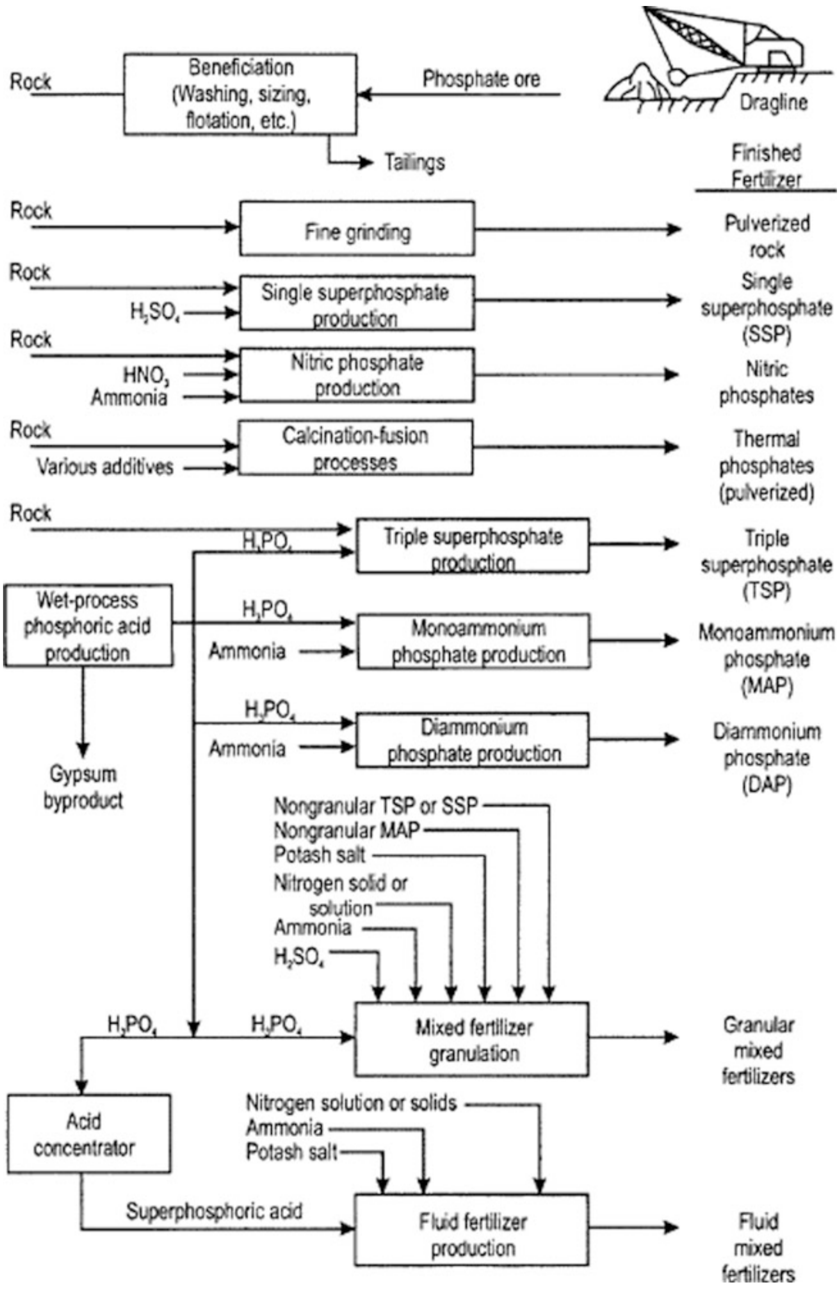


Fig. 24.9 Major routes of mineral phosphate into finished fertilizers *(Courtesy TVA)*

followed by a den, and if granulation is used, some suitable type of equipment for granulation with steam or water. Early plants used batch-type mixers for acid–rock mixing, but these mixers mostly have been replaced by continuous types. Several types of continuous mixers have been employed; of these, the lowest-cost, simplest, and apparently most satisfactory one is the TVA cone mixer, which has no moving parts. Mixing is accomplished by the swirling action of the acid. Short, single-shaft or double-shaft pug mills also are used for continuous mixing. The mixers discharge into a den, the purpose of which is to allow time for the acid–rock reaction to progress and the physical condition to reach a dry, friable state. The dens can be of either the batch or the continuous type. A slat-conveyor continuous den, commonly referred to as a Broadfield den, is used in many continuous systems [11]. A diagram of a typical SSP plant employing a cone mixer and a continuous den (slat-conveyor) is shown in Fig. 24.10. The reaction of phosphate rock with sulfuric acid to produce SSP can be approximated in chemical stoichiometric terms.

However, in general practice the proportioning usually is based on a simpler relationship of about 0.6 kg of sulfuric acid (100% H_2SO_4 basis) per kilogram of phosphate rock (30–32% P_2O_5). The phosphate rock usually is pulverized to

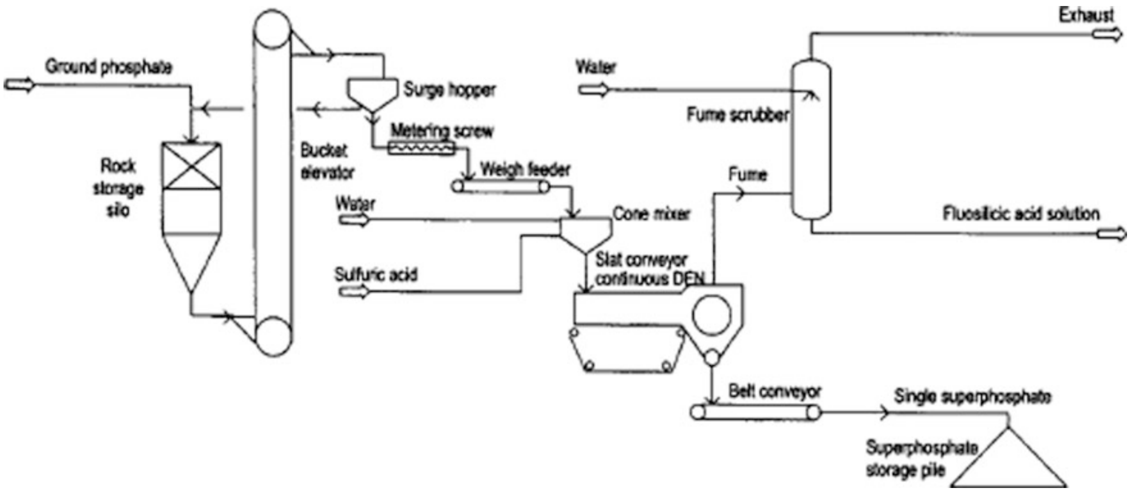

Fig. 24.10 Continuous process for manufacture of single superphosphate *(Source: Fertilizer Manual)*

about 90% smaller than 0.15 mm and 70% smaller than 0.075 mm.

Gases that are released while the superphosphate is solidifying (setting) cause the mass in the den to become porous and friable so that it can be "cut" (disintegrated) and handled readily. SSP made from typical rock will "set" in 40–50 min in a continuous den, whereas the set time in a batch den is 1.5–2 h. The superphosphate usually is held in storage piles (cured) for 4–6 weeks in order to obtain better handling properties and to allow the chemical reactions to continue. The usual grade of SSP made from Florida rock is 20% available P_2O_5. A typical analysis is shown below:

Analysis, % by Weight

P_2O_5								
Total	Available	H_2O Soluble	CaO	Free Acid	SO_4	F	R_2O_3	MgO
20.2	19.8	18.0	28.1	3.7	29.7	1.6	1.6	0.15

Because of the low phosphate analysis of SSP (20% P_2O_5), economics favor shipping the rock (32% P_2O_5) to local plants and producing the superphosphate there. A majority of the producers use the locally produced SSP in formulations for granular NPK fertilizers made in an ammoniation–granulation process. The maximum amount of SSP possible is used in the NPK formulations because usually it is the lowest-cost form of P_2O_5; however, because of the relatively low P_2O_5 content of SSP, not much can be used in high-analysis NPK formulations. SSP will readily absorb about 6 kg of ammonia per 20 kg of P_2O_5 during the ammoniation–granulation process. Production of granular SSP can be carried out by starting with either cured or ex-den SSP. The SSP is fed to a rotary drum or pan granulator along with a water spray and/or steam. The granulator is followed by a dryer and screening (sizing) system. Fines and crushed oversize material are fed back to the granulator.

Triple Superphosphate. TSP is made by acidulation of phosphate rock with phosphoric acid, using equipment and processes similar to those for SSP. As in SSP production, the acid–rock reaction converts the water-insoluble apatite structure of the rock to water-soluble monocalcium phosphate. TSP, with its relatively high P_2O_5 content of 45–46%, did not appear on the scene in any appreciable quantity until wet-process phosphoric acid (see Chap. 23) was produced commercially. TVA carried out demonstration-scale production of TSP in the late 1930s by using electric-furnace phosphoric acid. Extensive agronomic testing and market development, through the use of large tonnages of this TSP by farmers and fertilizer manufacturers in TVA demonstration programs, led to the rapid acceptance of TSP. Producers of phosphate rock in the United States and other countries moved into production of wet-process acid and TSP. Logistics favored production of the higher-analysis TSP (46% P_2O_5 vs. 32% P_2O_5 in phosphate rock) near the source of the phosphate rock, and shipment of the TSP to distribution facilities or blending plants near the markets. Today, most producers of TSP are located adjacent to phosphate mining operations in Florida, Morocco, and Tunisia. Since its introduction, TSP has steadily displaced SSP in the marketplace.

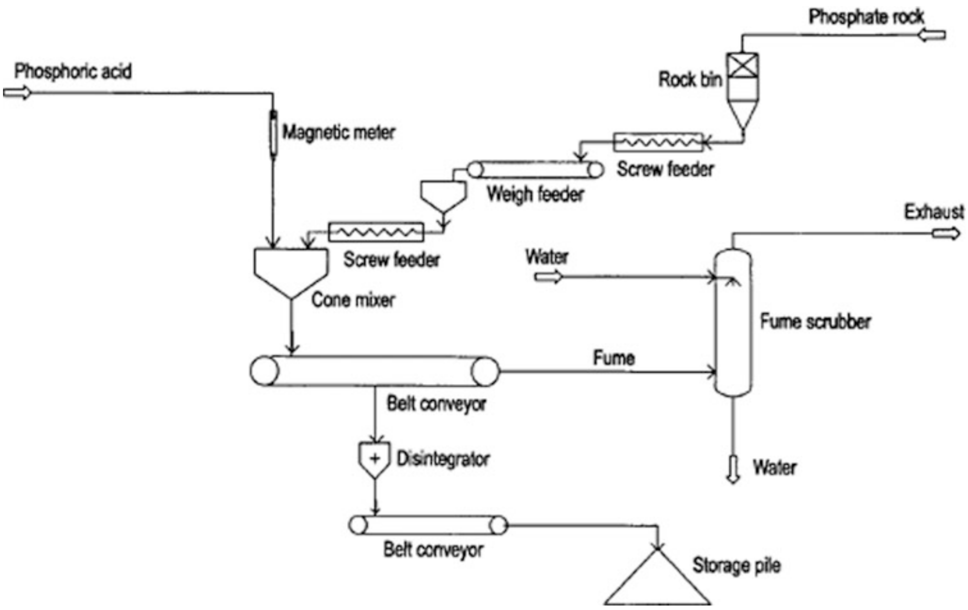

Fig. 24.11 Continuous system for manufacture of nongranular triple superphosphate *(Source: Fertilizer Manual)*

The cone mixer has been used almost universally in the production of nongranular TSP. Because the "set time" for TSP is only 14–20 min, as compared with 40–50 min for SSP, a simple, cupped conveyor belt usually is used to hold the acidulate until the TSP solidifies; this is instead of the slat-type den used for SSP. With a belt about 1.5 m wide and 30 m long, the production rate usually is 40–50 tons/h. A flow diagram for TSP production by the cone mixer-"wet-belt" system is shown in Fig. 24.11.

Proportioning for TSP typically is 2.4–2.5 kg of P_2O_5 from acid for each kg of P_2O_5 from rock. Nongranular TSP usually is cured 4–6 weeks prior to shipment or used at the site. Typical chemical analysis of TSP made with Florida rock is shown below:

Analysis, % by Weight

P_2O_5									
Total	Available	H_2O Soluble	Free Acid	CaO	R_2O_3	MgO	F	H_2O
46.9	46.3	42.0	3.4	19.3	3.1	0.5	2.7	4.5

The use of TSP in granular NPK fertilizer formulations, together with or in place of SSP, has allowed the production of higher-analysis grades of granular NPK fertilizers, such as 13–13–13 instead of 10–10–10. The TSP can readily be ammoniated using 3.5 kg of ammonia per 20 kg of P_2O_5 during the granulation process.

TSP is produced in large quantities in granular form for use in direct application and for use in bulk blends. In some processes cured or ex-den TSP, like SSP, is granulated in a rotary drum or pan granulator using steam and water to promote granulation [3]. A slurry-type granulation process, as outlined in Fig. 24.12, is now the process of choice of major producers of TSP. Pulverized phosphate rock is treated with wet-process phosphoric acid in a two-stage reaction system, and the slurry is sprayed into a pug mill or rotary drum where it is layered on recycled undersize and crushed oversize at a ratio of 1 kg/5–12 kg of recycle. Product granules (45% P_2O_5) are quite spherical and dense. The lower grade of the granular product, as compared with that of cured nongranular TSP, results from the need to decrease the acidulation ratio from the usual 2.45 kg of acid P_2O_5 per kilogram of rock P_2O_5 to about 2.25 in order to control the free-acid content and to minimize stickiness. For production rates higher than about 25 tons/h, a rotary drum usually is used instead of a pug mill.

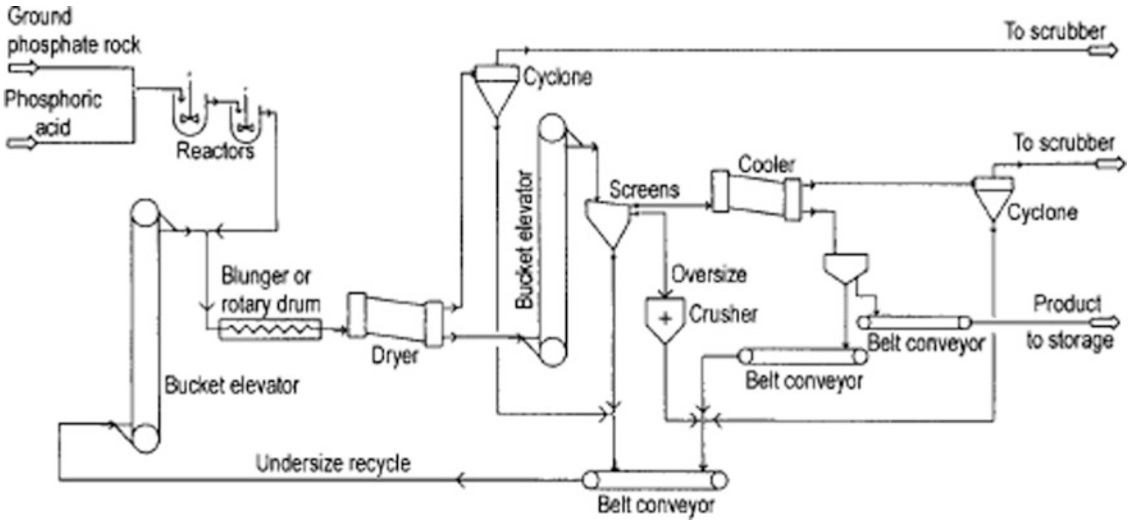

Fig. 24.12 Slurry process for the manufacture of granular triple superphosphate *(Source: Fertilizer Manual)*

Nitric Phosphate. Fertilizers that are referred to as nitric phosphate or nitrophosphate are produced by acidulation of phosphate rock with nitric acid or with mixtures of nitric and sulfuric or phosphoric acids. The primary advantage of nitric phosphate processes is that no sulfur or less sulfur is required as compared with superphosphates or ammonium phosphates; this is particularly important during a shortage of sulfur, or in locations where sulfur must be shipped long distances. A variety of processes and equipment have been used in Europe since the late 1930s [3, 12]. Also there are a number of plants in Central and South America and in Asia. The production of nitric phosphates is complex. Simple substitution of nitric acid in a superphosphate-type acid–rock reaction is not feasible because (1) decomposition of the nitric acid would occur and cause noxious fumes and loss of nitrogen and (2) the product would be extremely hygroscopic and unstable.

One process modification that overcomes these difficulties uses only nitric acid for acidulation; the extraction slurry is cooled to crystallize calcium nitrate, which then is removed by centrifugation. This process is referred to as the Odda process. The calcium nitrate by-product is either sold as a fertilizer or converted to coproduct ammonium nitrate. The extraction slurry, with its lowered calcium content, then is ammoniated and granulated. Various process modifications utilize a rotary drum, pug mill, or spray drum (Spherodizer) for granulation of the slurry. NPK nitric phosphate grades also have been produced by a prilling process in a few European plants. In earlier years, a main disadvantage of nitric phosphate processes was the low water solubility of phosphate in the products, as the main phosphatic constituent was dicalcium phosphate. The use of supplemental phosphoric acid, or "deep cooling" by refrigeration to remove a higher proportion of calcium nitrate in the Odda-type processes, now allows water solubility of 60% or higher. The remaining 40% of the phosphate, although water-insoluble, is almost completely citrate-soluble, and this is "available" as plant nutrient. Popular grades of nitric phosphates include 14–14–14, 22–11–11, 20–20–0, and 16–13–0.

Diammonium Phosphate (DAP). Ammonium phosphates did not come on the fertilizer scene in significant quantities until the early 1960s; however, they have rapidly become the leading form of phosphate fertilizer in the world. Almost all new phosphate fertilizer complexes built in recent years, and those planned, are for the production of ammonium phosphate as the major product. In 1960, world production of ammonium phosphates was equivalent to only 0.5 million mt of P_2O_5. By 1990 it was up to 15.4 million mt and by 1999 it has reached 16.7 million mt. Ammonium phosphates now provide two-thirds of total world phosphate fertilization.

Prior to the late 1940s, DAP $(NH_4)_2HPO_4$ was considered to be too unstable for use as a fertilizer. However, at about that time, exploratory work by TVA indicated otherwise. The first demonstration-scale DAP made by TVA for fertilizer use was a monocrystal product made by ammoniation of pure electric-furnace acid in a vacuum crystallizer [13]. Demonstration programs showed this material to be stable and to be an excellent high-analysis fertilizer. Small amounts of similar product were produced by others using electric-furnace acid and by-product ammonia. However, general acceptance of DAP by the fertilizer industry was not possible until procedures could be developed to produce it from wet-process phosphoric acid instead of the relatively expensive electric-furnace acid. This occurred in 1960–1961 with the development and patenting of the "TVA process" for production of granular 18–46–0 grade DAP from wet-

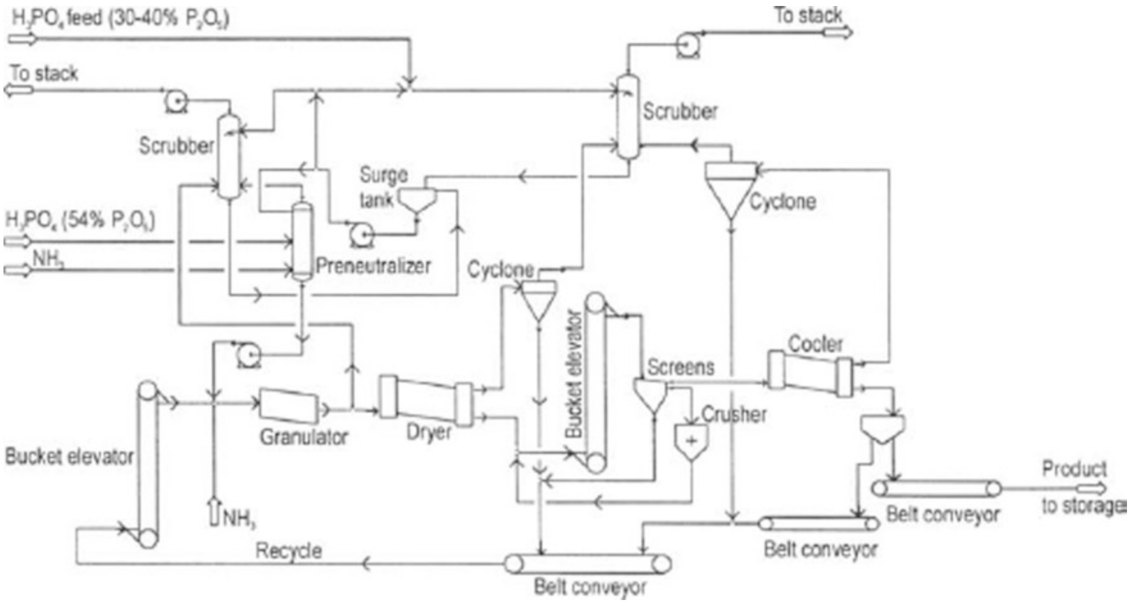

Fig. 24.13 TVA process for production of granular diammonium phosphate *(Source; Fertilizer Manual)*

process acid [14, 15]. This relatively simple process was rapidly adopted by the industry, and remains the basic process for production of this major phosphate fertilizer. Many granular DAP plants have production capacities of about 50 tons/h, with some going as high as 70–100 tons/h.

The flow diagram of a typical granular DAP production unit of the TVA type that has become standard in the industries is shown in Fig. 24.13. Wet-process phosphoric acid of about 40% P_2O_5 content (often a mixture of 54% P_2O_5 acid and acid from the scrubbing circuit of 28–30% P_2O_5 content) is fed to a preneutralizer vessel. Anhydrous ammonia is sparged into this preneutralizer through open-end pipes that project through the walls. A key feature of the process is that this neutralization of the acid is carried to a closely controlled NH_3:H_3PO_4 mole ratio of about 1.4. Ammoniation to this degree provides maximum solubility of ammonium phosphate, as is shown by the solubility curve of Fig. 24.14. The heat of the ammoniation reaction evaporates considerable water, with the result that the water content of the slurry is reduced to only 16–20%. The slurry still is fluid and pumpable because of the high solubility at a 1.4 mole ratio.

The preneutralizer slurry is pumped at a controlled rate to a rotary-drum, ammoniator–granulator; there it is distributed onto a rolling bed of recycled solids. The most commonly used metering system for the preneutralized slurry is a variable-speed centrifugal pump with automatic control from a magnetic flowmeter. Some plants have had success with a magnetic flowmeter and automatic control valve of a special ball type.

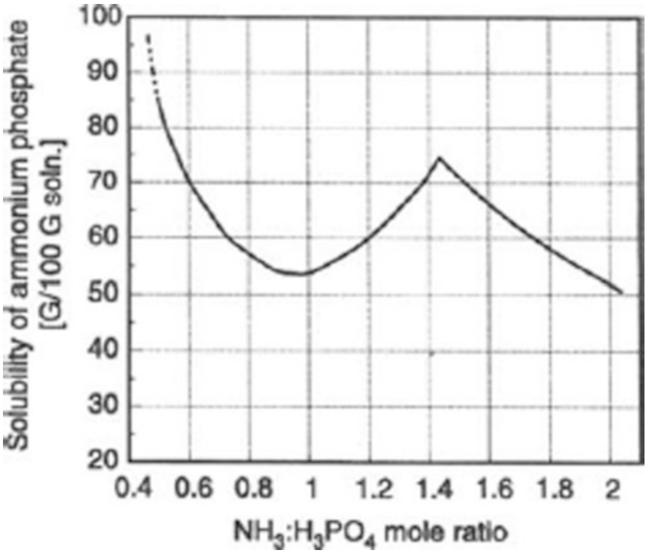

Fig. 24.14 Effect of NH_3: H_3PO_4 mole ratio on solubility of ammonium phosphate at 75 °C *(Source: Fertilizer Manual)*

Ammonia is sparged beneath the bed in the rotary drum to ammoniate the slurry further to near the theoretical DAP ratio of 2.0; the usual finishing NH_3:H_3PO_4 mole ratio is 1.85–1.94. Metallic phosphate impurities such as iron, aluminum, and calcium phosphates account for most of the deviation from theoretical. This ammoniation in the granulator drastically decreases ammonium phosphate solubility (Fig. 24.14), and thus promotes solidification and granulation. Ammonia absorption is not 100% complete in either the preneutralizer or the granulator. However, the unabsorbed ammonia is recovered in a scrubbing circuit containing phosphoric acid of about 30% P_2O_5 content. Solid recycle to the granulator drum consists of undersize from screening of dried product plus some crushed, dry product and oversize. These combined materials are recycled at a rate of 5–7 kg per kilogram of product, and variation of this recycle rate is the primary method of controlling granulation efficiency. Product discharged from the granulator is dried with moderate heat to a 180–190°F product temperature. Higher drying temperatures must be avoided because of a relatively low melting point for DAP. Most plants screen hot and cool only the product fraction because the material is not too sticky for recycle without cooling. Rotary coolers or fluidized-bed-type coolers are used. The product, with a moisture content of 1.5–2%, does not require a conditioner. It has excellent storage and handling properties in bags or in bulk. It has been shown that the iron and aluminum phosphate impurities in the product are present in a gel-like structure that favorably hardens the granules and increases their resistance to moisture [16]. The critical relative humidity of DAP made from wet-process acid is about 70%; thus it is relatively nonhygroscopic.

Construction materials other than mild steel are required only for the acid lines, the preneutralizer, the slurry handling system, and the scrubbing circuits. Type 316 L stainless steel or rubber- and brick-lined mild steel is used for the preneutralizer. Type 316 L stainless is used also for the slurry pumps and piping. Fiberglass-reinforced polyester plastic and high-density polyvinyl chloride are sometimes used for wet-process acid pipes and for scrubbers. Scrubbers also may be constructed of rubber-lined mild steel.

Monoammonium Phosphate (MAP). “DAP,” and the grade designation “18–46–0” have become extremely familiar terms in the world fertilizer industry. However, substantial interest has developed also in fertilizer use of MAP, $NH_4H_2PO_4$. Agronomically, MAP is favored where soils are mainly alkaline, for example in Canada, Egypt, and Pakistan. From an economic standpoint, the relatively high P_2O_5 contents of typical MAP grades (11–52–0 to 10–54–0) make them attractive where the primary interest is in producing and shipping phosphate; the MAPs provide a higher P_2O_5 payload than does DAP.

TVA developed two comparatively minor modifications of the granular DAP process to allow production of granular MAP [17]. In one method, the acid is ammoniated to an NH_3:H_3PO_4, mole ratio of only about 0.6 in the preneutralizer and then to about 1.0 in the granulator drum. The 0.6 ratio is, like the 1.4 used in DAP production, a high-solubility point in the ammonium phosphate system (Fig. 24.14); the subsequent ammoniation to 1.0 in the granulator decreases solubility and thus promotes granulation. In the other procedure, which has been preferred by the industry, acid in the preneutralizer is ammoniated to the high-solubility NH_3:H_3PO_4 ratio of about 1.4, as in DAP production; then additional wet-process acid is distributed onto the bed in the granulator to adjust back to the low-solubility MAP mole ratio of about 1.0. With either modification, the remainder of the process is the same as for DAP, except that, because of the higher temperature stability of MAP, a higher drying temperature can be used to increase the production rate for MAP.

Starting in about 1968, simple processes were developed for the production of nongranular (sometimes called powdered) MAP. Chief developers were Fisons and Scottish Agricultural Industries (SAI) in the United Kingdom, Swift in the United States, and Nissan in Japan. These processes involve variations in the simple reaction of wet-process acid with ammonia followed by spray-type drying with air. On the basis of this work, a number of comparatively low-cost units for production of nongranular MAP have been built commercially, including plants in the United Kingdom, the Netherlands, Japan, Australia, Spain, the United States, Brazil, and Iran. This intermediate usually is shipped to other plants, where it then is used in the production of NPK solid or fluid fertilizers. Thus far, however, the nongranular MAP has not attained the popularity that was predicted for it in the mid-1970s.

Miscellaneous Low-Volume Phosphate Fertilizers

Phosphate Rock for Direct Application. Application of finely pulverized raw phosphate rock directly to the soil has been utilized almost from the beginning of fertilization practice. Although such direct use eliminates the need for most processing, there are major drawbacks. The ores are of low phosphorus content in comparison with most manufactured fertilizers, which increases shipping cost. Also, the very fine grinds that are required to encourage solubility are difficult to handle and to apply. The major drawback, however, is agronomic. The agronomic effectiveness of raw rock depends upon the origin and the chemical and mineralogical nature of the particular rock, the pH and other characteristics of the soil, and the crop produced. Researchers at TVA and IFDC have characterized phosphate rocks from a large number of sources as to their reactivity [3, 18]. In general, phosphate rock of sedimentary origin is more reactive than igneous source. Phosphate rock from North Carolina (U.S.), Sechura (Peru), and Gafsa (Tunisia) are at the top, and are about equal in reactivity and suitability for direct application. Other phosphate rocks that are reasonably reactive and are marketed for this purpose include some types from Morocco, Israel, Algeria, and a few other locations. In 2002, less than 1.0 million mt of phosphate rock was used for direct application.

Defluorinated Phosphate Rock. There is substantial production of defluorinated phosphate rock for fertilizer use in Japan (about 100,000 mt/year). Ground, high-grade rock is mixed with small proportions of sodium carbonate or sulfate and wet-process acid. The mixture is calcined at a temperature of 1,350°C in an oil-fired rotary kiln 45.0 m in length and 2.7 m in diameter. The product contains 38–42% P_2O_5 of which more than 90% is soluble in neutral ammonium nitrate solution and is an effective fertilizer on acid soils. During the production of defluorinated phosphate rock, substantially all fluorine is driven off. Sodium bifluoride ($NaHF_2$) is recovered as a by-product. A similar product is made in the United States, but it is mainly used for animal feed supplement.

Calcined Aluminum Phosphate. Ores consisting mainly of hydrated aluminum phosphate minerals are useful for direct application after thermal treatment (calcination) at a controlled temperature. Calcination removes the combined water and destroys the crystallinity of the phosphate minerals, thereby improving the reactivity of the phosphate [3].

At present, only two aluminum phosphate ores are known to be used for direct application after thermal treatment. One such ore is found near Thies, in Senegal. The “as-mined” ore contains about 29% P_2O_5 on a dry basis; after calcination it contains over 34% P_2O_5. The calcined product is ground to about 95% smaller than 0.15 mm and marketed for direct application under the trade name “Phosphal.” About 75% of the P_2O_5 is soluble in alkaline ammonium citrate, and the product is effective as superphosphate in calcareous, neutral, and acid soils. The product is used in France, Senegal, and some nearby countries.

A similar ore occurs in the upper stratum (“C-grade”) of the phosphate deposit on Christmas Island. The C-grade ore contains about 25% P_2O_5 dry basis. Calcination is carried out in a fluidized bed, operated in the range of 400–600°C. The maximum solubility in alkaline ammonium citrate solution is about 70%.

Partially Acidulated Phosphate Rock (PAPR). Not all phosphate rock is suitable for direct application and may require the addition of a more soluble form of phosphate. An alternative is partial acidulation to render its P_2O_5 more available. The PAPR process depends on treating ground phosphate rock with only a portion of the stoichiometric value of acid, for example 50% PAPR [19]. The amount of water-soluble phosphate in PAPR varies according to the degree of acidulation. The crop response to the product is often quite similar to fully acidulated products such as SSP or TSP.

Sulfuric and phosphoric acids are the most common acids used for partial acidulation. Possibilities exist for using three processes: a conventional run-of-pile process followed by granulation, IFDC-developed singlestep acidulation and granulation, and a slurry granulation TSP-type process.

Enriched Superphosphate. This product, which is also referred to as “double” superphosphate, is essentially a mixture of SSP and TSP, usually made by acidulation of phosphate rock with a mixture of sulfuric and phosphoric acids. The desired concentration of mixed acid can be obtained by mixing concentrated sulfuric acid (93 or 98% H_2SO_4) with dilute phosphoric acid (30%) thus avoiding the need for concentrating the latter. Production processes and equipment are about the same as for SSP [20].

Theoretically, any grade between SSP and TSP can be produced, but the usual range is 25–35% P_2O_5. The product is useful in sulfur-deficient areas where SSP would supply more sulfur than necessary. Only a small amount of enriched superphosphate is produced and used in Australia.

Basic Slag. This is also known as Thomas slag and is a by-product of the steel industry. Iron made from high-phosphorus ore is converted to steel in a Thomas converter by oxidation in contact with a basic (high CaO) slag. Sometimes phosphate rock is deliberately added to the blast furnace charge to increase the phosphorus content of the iron thereby increasing the P_2O_5 content of the slag. A typical range of composition of high-grade basic slag is:

The calcium magnesium phosphate (CMP) is found to be more effective than superphosphate when used on acid soils. The product has a liming value equivalent to 0.5–0.7 ton of calcium carbonate per ton of material. The magnesium oxide and soil-soluble silica is available to growing plants.

Rhenania Phosphate. Rhenania phosphate is another thermally produced phosphate fertilizer. It is made by calcining a mixture of phosphate rock, sodium carbonate, and silica in

While the present market for basic slag is quite small, it is primarily produced and used in Western Europe where high-phosphorus iron ore occurs.

Fused Calcium Magnesium Phosphate. In a process developed by TVA, a mixture of phosphate rock and olivine or serpentine (magnesium silicate) is fused in an electric furnace [21]. The molten product is quenched with water and used in a finely divided state as a fertilizer. The product, a CMP glass, contains about 20% P_2O_5 and 15% MgO. Over 90% of the product is soluble in citric acid.

The theoretical compositions of some magnesium-containing minerals that can be used to produce CMP are:

Olivine	$(Mg,Fe)_2SiO_4$
Serpentine	$Mg_3H_4Si_2O_9$
Garnierite	$(Mg,Ni)H_2SiO_4$
Magnesite	$MgCO_3$

Although small compared with soluble phosphates, CMP is used in Japan, China, Korea, Taiwan, and South Africa.

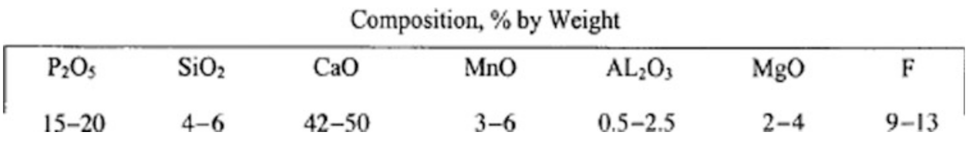
The reason for the decline in production and use is the relatively high (850 kW h/ton of product) energy requirements.

A rotary kiln at 1,250°C [3]. Enough sodium carbonate is used to form the compound $CaNaPO_4$ and enough silica to form Ca_2SiO_4 with excess calcium. Typical charge proportions are one part sodium carbonate to three parts of phosphate rock and enough silica to raise the SiO_2 content of the product to about 10%. The overall reaction in producing Rhenania phosphate is assumed to be:

$$\begin{aligned} &Ca_{10}F_2(PO_4)_6 + 4Na_2CO_3 + 2SiO_2 \\ &\quad \rightarrow 6CaNaPO_4 + 2Ca_2SiO_4 + 2NaF + 4CO_2 \end{aligned}$$

Any grade of phosphate rock can be used, but since the grade of the product is determined by the grade of the rock, a high grade is preferred.

A typical product contains 28–30% P_2O_5, nearly all soluble in neutral or alkaline ammonium citrate solution. The product is applied in a powdered form or granulated with potash salts. Some grades are produced containing magnesium or boron, which are added during granulation as kieserite or borax, respectively.



Composition, % by Weight

P_2O_5	SiO_2	CaO	MnO	AL_2O_3	MgO	F
15–20	4–6	42–50	3–6	0.5–2.5	2–4	9–13

Potassium Salts

The element potassium has been recognized to be beneficial to plant growth since J.R. Glauber.

In the Netherlands first proposed, in the middle of the seventeenth century, that saltpeter (KNO_3) was the "principle" of vegetation. This salt, derived from the leaching of coral soils, was thus the first chemical compound intentionally applied to crops to satisfy their nutrient needs. Justus von Leibig had established the essentiality of the element for plant growth in his pioneering work published in 1840. The potassium or potash chemical industry dates from the year 1861, following the discovery by German chemists of a process for recovery of KCl (muriate of potash) from rubbish salts, the residues remaining from the extraction of sodium chloride (NaCl).

The term "potash" generally refers to potassium chloride, but it is also used to designate other potassium compounds that may be qualified by the words muriate of potash, sulfate of potash, etc.

The functions of potassium in the plant are manifold. This element serves to activate or catalyze a host of enzyme actions, to facilitate the transport of nutrients and assimilates in the xylem and phloem, to maintain the structural integrity of the plant cell, to regulate turgor pressure, to mediate the fixation of nitrogen in leguminous plant species, and to protect plants to some degree from certain plant diseases.

Potassium is a relatively abundant element in the earth's crust, ranking seventh in concentration. It is widely distributed geographically and is commonly found in association with sodium compounds. The feldspars, muscovite (white mica), granite, and gneiss are rich sources; but because they are siliceous and refractory, they are difficult and costly to convert to forms suitable for use as fertilizers. The common potassium minerals are listed in Table 24.2.

The name potash derives from an early production method in which potassium carbonate, leached from wood ashes, was crystallized by evaporating the leachate in large iron pots. The salt potassium chloride (muriate of potash or

Table 24.2 Common K minerals

Mineral	Formula	K content (g/kg)	K_2O content (g/kg)
Sylvite	KCl	524.4	631.7
Carnalite	$KCl{\cdot}MgCl_2{\cdot}6H_2O$	140.7	169.5
Kainite	$KCl{\cdot}MgSO_4{\cdot}3H_2O$	157.1	189.2
Langbeinite	$K_2SO_4{\cdot}2MgSO_4$	188.5	227.0
Leonite	$K_2SO_4{\cdot}MgSO_4{\cdot}4H_2O$	213.3	256.9
Schoenite	$K_2SO_4{\cdot}MgSO_4{\cdot}6H_2O$	194.2	233.9
Polyhalite	$K_2SO_4{\cdot}MgSO_4{\cdot}2CaSO_4{\cdot}2H_2O$	129.7	156.2

Source: Stewart, J. A., in *Potassium in Agriculture*, R. D. Munson (Ed.), p. 83, ASA-CSSA-SSSA, 1985

KCl) is now the major source of the element (95%); other important salts are potassium sulfate (sulfate of potash, K_2SO_4), potassium magnesium sulfates of varying K/Mg ratios, and potassium nitrate (KNO_3).

The potash industry is based on very large deposits of water-soluble potassium minerals resulting from the evaporation of shallow seas or natural brine lakes over a geological time span. These evaporates normally are located at depth in the earth's mantle. Ironically, the best deposits are found in areas quite remote from the more productive agricultural regions, which thus are the areas most in need of this element. Typically, the deposits are to be found in horizontal tabular bodies or beds and may occur at depths up to 2,100 m or more. The beds may be only a few centimeters to a few meters thick, but commercial production is limited to strata that are at least 1 m thick. As with hard-rock mining, the potash-bearing ores are extracted or harvested with continuous mining machines and brought to the surface through vertical shafts. Where the ores occur below a depth of about 1,100 m, or where the beds exhibit geological anomalies (e.g., folding), the potash is dissolved in a brine solution and pumped to the surface for recovery using solution-mining techniques.

Potassium Minerals

The ore zone or stratum typically contains potassium or potassium–magnesium minerals along with halite (sodium chloride). Muriate of potash is refined from sylvinite ore, a mechanical mixture of potassium chloride (KCl) and sodium chloride (NaCl). Because the latter salt is injurious to most crop plants, the KCl (sylvite) must be separated from the NaCl (halite).

For coarse-grained ores, physical methods employing froth flotation and/or heavy-media methods are employed to achieve separation. The heavy medium may consist of, for example, pulverized magnetite in a brine solution. The specific gravity of the medium is adjusted so that it falls between that of KCl (1.99 g/cm^3) and that of NaCl (2.17 g/cm^3).

When the crushed ore is placed in this medium, the potassium values are floated off, and the contaminating sodium values sink and are drawn off and rejected from the bottom of the flotation vessel. Entrapped magnetite from both the product and waste streams is easily recovered magnetically and returned to the flotation vessel.

In froth flotation the crushed ore, which has been scrubbed to remove contaminating clay particles, first is treated with an aliphatic amine acetate and a froth-promoting alcohol. The water-repellant amine acetate is attracted preferentially to the sylvite particles. In a subsequent step, the ore or pulp is maintained in suspension, and the coated sylvite particles are attracted to and entrained on the rising air bubbles generated by the flotation agitator. They rise to the surface and are collected by hydraulic and mechanical means. The potassium-depleted pulp is then discarded. The sylvite or muriate is collected, centrifuged to remove the hydraulic medium, dried, screened, into various particle size ranges, and sent to storage.

Potassium–Magnesium Minerals

Other important sources of potassium for fertilizer use are the double salts kainite ($KCl{\cdot}MgSO_4{\cdot}3H_2O$) and langbeinite ($K_2SO{\cdot}2MgSO_4$). The former is recovered from potash mines in Germany and Sicily; the latter is recovered and processed from mines in New Mexico (U.S.). These minerals supply important quantities of both magnesium and sulfur as well as potassium, and all are essential nutrients for plant growth. Kainite has a theoretical composition of 15.99% K (19.26% K_2O), 9.94% Mg, and 13.11% S, and langbeinite contains 18.85% K (22.7% K_2O), 11.71% Mg, and 23.18% S.

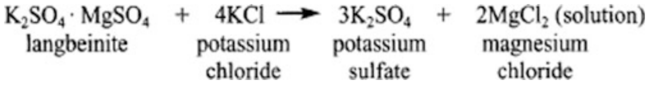
In the processing of langbeinite, the contaminating chlorides (NaCl, KCl) are removed by extracting the crushed ore with water. Centrifugation, drying, and screening follow to prepare the product in various size grades for the market. Where the mixed ore contains recoverable quantities as KCl as well as langbeinite, froth flotation and heavy-media methods may be employed to recover both potassium-containing salts.

Potassium Sulfate

Sulfate of potash (K_2SO_4), unlike the earlier-discussed potash salts, does not occur as natural deposits. It can be recovered by fractional crystallization from such natural brines as those of the Great Salt Lake in Utah and Searles Lake in California. Here separation and recovery are achieved by solar evaporation in shallow ponds. These processes can be utilized only where a suitable brine source is available, and where solar evaporation rates are high.

A much more important source of K_2SO_4 is the product resulting from either a controlled decomposition reaction of a complex sulfate salt, reaction of the salt with KCl, or both. Thus, kainite ($KCl{\cdot}MgSO_4{\cdot}3H_2O$) may be reacted with water in a two-step reaction, first to form schoenite ($K_2SO_4{\cdot}MgSO_4{\cdot}6H_2O$), with the schoenite then reacted with KCl to form K_2SO_4.

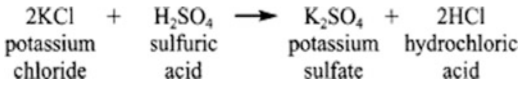
Langbeinite likewise is reacted with KCl to form sulfate of potash, according to the following reaction:



$$\underset{\text{langbeinite}}{K_2SO_4 \cdot MgSO_4} + \underset{\text{potassium chloride}}{4KCl} \longrightarrow \underset{\text{potassium sulfate}}{3K_2SO_4} + \underset{\text{magnesium chloride}}{2MgCl_2\ (\text{solution})}$$

Approximately 50% of world K_2SO_4 production is derived from the reaction of KCl with either kainite or langbeinite.

For those producers who do not have access to such suitable sulfate salts to serve as the sulfate donor, the so-called Mannheim process, in which sulfuric acid is reacted with KCl, may be utilized. The following reaction unfortunately generates the corrosive substance hydrochloric acid as a coproduct:



$$\underset{\text{potassium chloride}}{2KCl} + \underset{\text{sulfuric acid}}{H_2SO_4} \longrightarrow \underset{\text{potassium sulfate}}{K_2SO_4} + \underset{\text{hydrochloric acid}}{2HCl}$$

Potassium sulfate, though relatively costly to produce, is a preferred source of potassium for some vegetable and fruit crops and tobacco—crops that are sensitive to the chloride forms.

Potassium Nitrate

The third most widely used potassium salt in agriculture is potassium nitrate (KNO_3). An ore containing sodium nitrate, potassium nitrate, some chlorides, and sulfates is mined in Chile. The ore is leached and part of the sodium nitrate is crystallized and removed.

The salt is produced in small amounts commercially in the United States, Israel, and Norway by the reaction of KCl with nitric acid. Though the salt is an attractive fertilizer material containing the two essential nutrients, nitrogen and potassium, in plant-available form, it is expensive to produce and thus enjoys only a limited market.

Potassium Phosphates

Potassium phosphates are excellent fertilizers, and their very high analysis is an advantage that has stimulated much research in an effort to find an economical production process. However, no process has been developed that is economical enough to result in widespread production; therefore, present use is limited to special purposes for which the high cost can be justified.

At present, most of the potassium phosphates used in fertilizers are produced from potassium hydroxide or carbonate and phosphoric acid and are used in liquids for foliar application or other specialty uses.

Some of the potassium phosphates are:

	Approximate grade	
Monopotassium phosphate	KH_2PO_4	0–52–35
Dipotassium phosphate	K_2HPO_4	0–40–54
Tetrapotassium pyrophosphate	$K_4P_2O_7$	0–43–57
Potassium metaphosphate	KPO_3	0–60–40

In addition, a potassium polyphosphate solution of 0–26–27 grade has been produced from superphosphoric acid and potassium hydroxide; it contains a mixture of ortho, pyro, and higher polyphosphates.

Another process that received attention involves the use of concentrated sulfuric acid to treat potassium chloride to produce potassium bisulfate: [22, 23]

$$KCL + H_2SO_4 \rightarrow KHSO_4 + HCL$$

The hydrogen chloride is recovered as a dry gas and can be used for certain oxychlorination reactions or other industrial purposes for which elemental chlorine is now used. The potassium bisulfate is used, with more sulfuric acid, to make monopotassium phosphate and phosphoric acid. A simplified equation, representing phosphate rock as tricalcium phosphate, is:

$$\begin{aligned} &KHSO_4 + 2H_2SO_4 + Ca_3(PO_4)_2 + 6H_2O \\ &\quad \rightarrow 3CaSO_4 \cdot 2H_2O + KH_2PO_4 + H_3PO_4 \end{aligned}$$

After removal of the gypsum by filtration, the mixture of phosphoric acid and monopotassium phosphate can be ammoniated to produce a chloride-free NPK fertilizer such as 8–48–16, or monopotassium phosphate can be separated from the phosphoric acid by precipitation in methanol solution and marketed separately. If desired, the monopotassium phosphate can be converted to a pyroorpolyphosphate by pyrolysis.

The obvious advantage of the process is the recovery of HCl in a useful form. Another advantage is that a standard wet-process phosphoric acid plant can be adapted with a minor change. Numerous other processes for making potassium phosphate from KCl have been proposed, patented, or developed on a commercial scale, but none is known to be in commercial use for fertilizer purposes.

Compound Fertilizers

The preceding sections of this chapter have described the production of nitrogen fertilizers, phosphate fertilizers, and potash fertilizers from basic raw materials. These fertilizers, without further processing, are referred to as “straight materials.” Worldwide, in 2009/2010 (Fig. 24.15), straight materials accounted for about 213 million mt—about 55% of the total production. The remaining 45% was in the form of “mixed” fertilizers, that is, fertilizers that contain more than one of the major plant nutrients nitrogen, phosphorus, and potassium. Application of nitrogen fertilizer as straight material is much more prevalent than phosphate fertilizer. The reasons for these patterns are both agronomic and economic.

Agronomically, large applications of nitrogen alone—for example, in the rice production and “side dressing” of

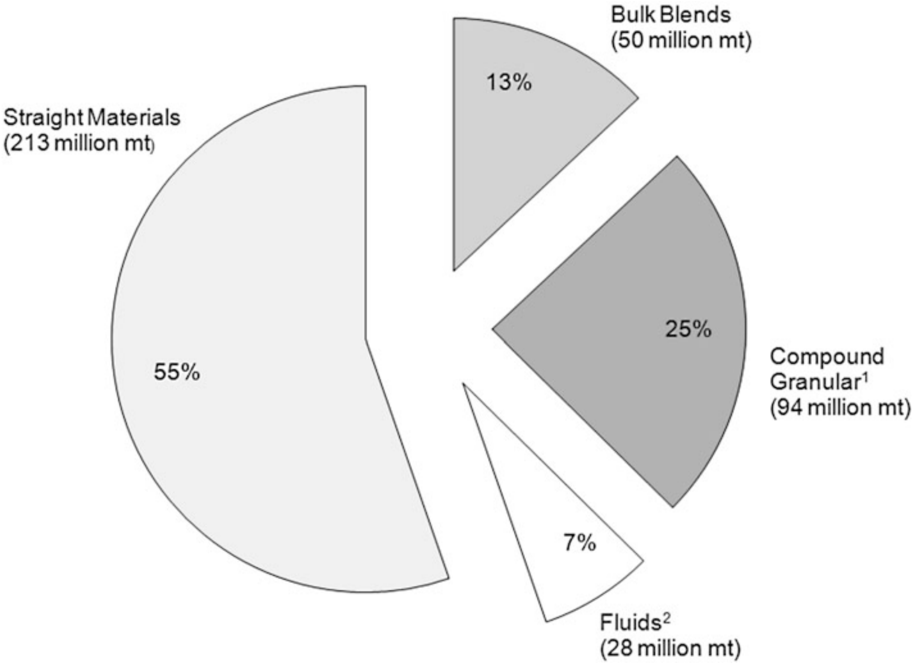


Fig. 24.15 Estimated world production of fertilizers by product type. (1) Steam/water, chemical (including ammonium phosphate), and compacted granular products. (2) Single- and multiple-nutrient fluids, including anhydrous ammonia. (3) As reported by IFA, nutrient production (2009/2010 reporting year) amounted to 163.7 million mt ($N + P_2O_5 + K_2O$). Product mt were calculated by multiplying 2.35 times the nutrient. *Source*: Derived from IFA and IFDC data files

corn—often are of considerable importance. For phosphate, there usually is no similar agronomic need for single-nutrient application; so application in mixtures, with the resultant elimination of multiple handling, is preferred. In the United States and Europe, with highly mechanized farming practices, the present trend is toward "precision" agriculture, which involves variable rates of application of nutrients at different locations in the same field based on the nutrient status. This method of application requires straight fertilizers rather than compounds [24].

Mixed fertilizers can be divided, by physical characteristics and production methods, into the following categories, all of which will be discussed in some detail:

- Nongranular mixtures
- Compound granulars
- Bulk blends
- Fluid mixtures

Nongranular Mixtures

Until about 1950, essentially all the mixed fertilizers available to farmers were of the nongranular type. Production was by simple batch weighing and blending of available nitrogen, phosphorus, and potassium ingredients, usually in locations that were convenient with respect to rail or water receipt of raw materials and out-shipment of bagged mixtures to dealers in farm areas. The source of phosphate almost invariably was nongranular SSP produced at the mixing location from in-shipped phosphate rock and locally produced sulfuric acid. In-shipment of elemental sulfur was required to produce the acid, usually by the now obsolescent "chamber" process. The major nitrogen ingredient used in the mixtures was fine-crystal by-product ammonium sulfate, and the potash source was nongranular potassium chloride. In some plants the superphosphate was "ammoniated" by reaction with ammonia solution, either in a separate operation before mixing with the other ingredients or during the mixing operation. Such ammoniation was beneficial in reducing the corrosiveness (acidity) of the superphosphate and in improving its physical condition. The ammonia also provided nitrogen at relatively low cost, but the amount that could be absorbed by the superphosphate was limited. Organic materials often were included in the mixtures as nutrient sources, bulking agents, or physical conditioners. Materials used included fish meal, packinghouse wastes, dried blood, tobacco stems, cottonseed hulls, and others. Mineral materials such as kaolin clay, diatomaceous earth, and vermiculite sometimes were included as conditioners. Batch-type drum mixers of 1- to 3-ton capacity were used with the ammonia solution piped directly into the mixer. Mixture grades were low by present-day standards, and storage and handling properties of these nongranular mixtures were generally poor. Caking problems, in particular, were considerable. Production of this type of fertilizer now persists in only a very few locations.

Compound Granulars

Continuous Ammoniator–Granulator Process. Following the close of World War II in 1945, farmer demands developed for much increased quantities of fertilizer and for products with better handling properties. Granulation, which provides an increase in particle size and the elimination of fines, was a promising avenue for the physical improvement that was pursued by researchers in both the United States and Europe. A milestone in this movement to granulation was the development, patenting, and demonstration by TVA, in 1954, of a continuous rotary-drum granulation process for mixed fertilizers [25, 26].

The rotary-drum granulator in this process is essentially the same as was pictured for the DAP granulation process. In early versions of the process, feed to the drum of SSP consisted of (1) crushed oversize product and fines, (2) nongranular SSP, (3) nongranular potassium chloride, (4) ammonium sulfate crystals, (5) sulfuric acid, and (6) anhydrous ammonia or an ammonia-containing nitrogen solution. The acid and the ammonia or ammoniating solution were sparged under the rolling bed of solids in the drum with a sparger arrangement, as shown in Fig. 24.16. With the proper balance of liquid and solid feeds, granulation occurs as a result of the rolling action in the action in the drum, and it is completed, with hardening, in a rotary-drum dryer.

This process was rapidly and widely adopted by mixed-fertilizer producers throughout the United States and later adopted by producers in Europe, Latin America, and Asia.

The process was particularly attractive because: (1) the raw materials were essentially the same as materials that were already available at most batch-type nongranular plants, (2) higher proportions of relatively cheap anhydrous ammonia or nitrogen solution could be used, (3) continuous-type processing allowed higher production rates, and (4) product physical properties were much improved as a result of granulation. Today, the same basic process, but with numerous modifications, is used in most mixed-fertilizer granulation plants. However, the number of plants has dwindled in favor of bulk blending and fluid fertilizers. One early modification to the process was the addition of phosphoric acid as a feed material, either along with or in place of sulfuric acid. Other feed materials used in some variations include TSP, MAP, ammonium nitrate, and urea. The use of urea has become more attractive in compound fertilizer production in Asia because higher grades can be achieved. The molten urea or concentrated urea solution is sprayed onto the bed of materials in the granulator and the wet product requires gentle drying. Most urea-based compound fertilizers are more hygroscopic, requiring dehumidified bulk storage facilities before the product is bagged [27].

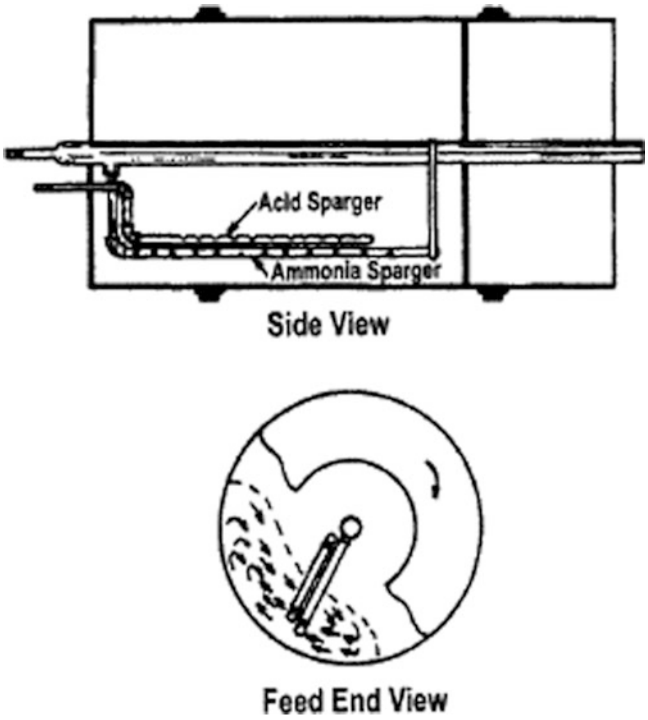

Fig. 24.16 Sparger location under rolling bed in TVA-type ammoniator-granulator *(Courtesy TVA)*

Use of Preneutralizer (Slurry Granulation). A major improvement to the basic TVA granulation process was the incorporation in most plants of a preneutralizer vessel for prereaction of phosphoric acid with ammonia. The procedure, as applied to the production of DAP, was described earlier and was pictured in Fig. 24.13. As in the DAP process, the preneutralizer used in the production of mixed fertilizers is operated at an NH_3:H_3PO_4 mole ratio of about 1.4 to give maximum ammonium phosphate solubility and thus maximum fluidity of the slurry pumped to the granulator. Subsequent further addition of ammonia in the granulator sharply decreases solubility and thus promotes solidification and hardening of granules. As in ammonium phosphate production, the iron and aluminum impurities normally present in wet-process phosphoric acid contribute significantly to the hardening of granules during ammoniation [17]. Sulfuric acid, when used, is fed directly to the granulation drum, not to the preneutralizer. The use of the preneutralizer allows the inclusion of higher proportions of acid in formulations. Also, better use is made of the heat of the ammonia–acid reaction for the evaporation of water, with resultant savings in dryer fuel.

Use of a Pipe Reactor (Melt Granulation). A more recent development that has been adopted in most U.S. granulation plants involves the substitution of a pipe reactor or a pipe-cross reactor for the preneutralizer vessel as the locale for the ammonia–acid reaction [28–32].

A simple pipe reactor differs from the pipe-cross reactor in that only one acid inlet port, usually for phosphoric acid, is provided.

The salient feature of the pipe reactor and pipe-cross reactor systems is that the heat of the ammonia–acid reaction

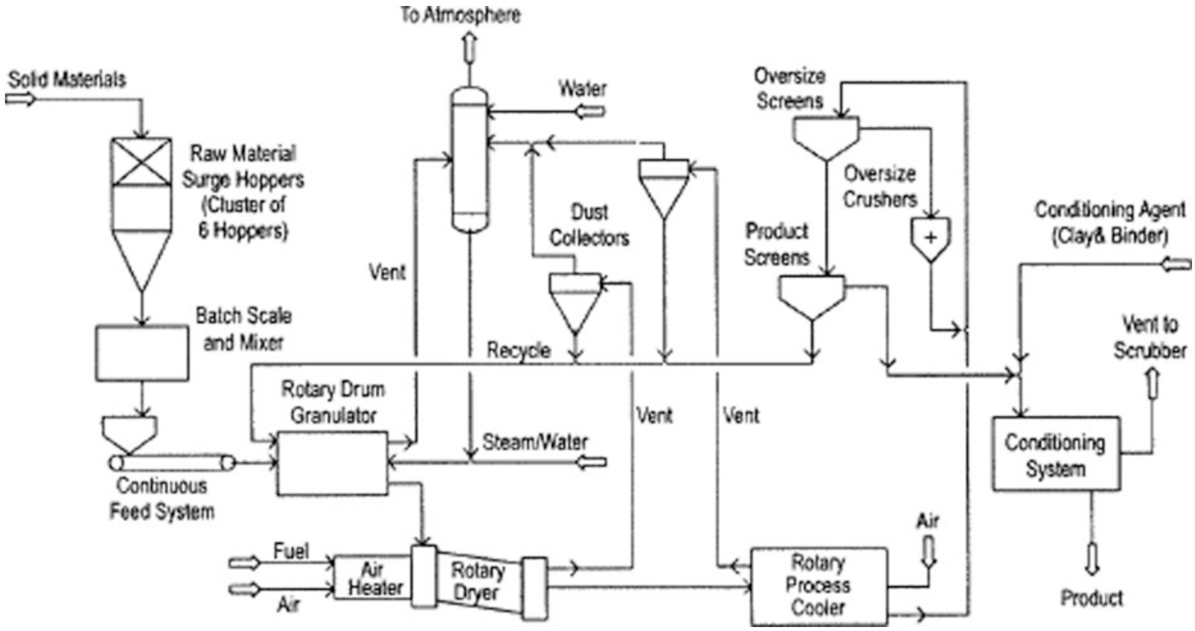

Fig. 24.17 Typical NPK fertilizer granulation plant using steam and/or water *(Source: Fertilizer Manual)*

is confined to the pipe and is efficiently utilized there to vaporize essentially all the moisture in the feed acid. The resultant steam exits the pipe discharge end in the granulator and is swept away in an air stream. The ammonium phosphate melt, which is of very low moisture content, also exits the pipe and is discharged onto the rolling bed of dry solids in the granulator. This melt serves as the binder for granule formation. The reaction temperature in the pipe reactor usually is held below 150°C to avoid a buildup of troublesome scale in the pipe. In view of this temperature limitation, there is little or no conversion of the phosphorus to polyphosphate forms. By allowing the pipe temperature to rise to about 200°C or higher, polyphosphate can be formed without scaling, but this mode of operation seldom is used in mixed-fertilizer granulation. TVA has used such high pipe temperatures to produce 11–57–0 and 28–28–0 grade ammonium polyphosphate granules in which 15–25% of the P_2O_5 is in polyphosphate form [28]. The physical properties of these products are exceptionally good, and the polyphosphate content makes them particularly suitable for dissolution to form fluid fertilizers. Because of the very low moisture content of the pipe reactor melts, even at the lower operating temperatures, the normally expensive drying of finished granular product usually is not needed: passage of the product through a cooler with an air sweep is sufficient for final drying. This results in a major fuel saving, which is a very significant economic advantage.

Steam Granulation. A simple method for granulating dry mixtures of fertilizer materials was developed in Europe in the early 1950s and still is employed there to some extent. In this procedure, which is pictured in Fig. 24.17, the feed materials are finely ground to ensure their incorporation in the granules. A dry mixture is made and then is moistened in a rotary drum or pan-type granulator with either water spray or steam, or both. This added moisture forms a salt solution by partial dissolution of the mixture ingredients. The granules form because of the plasticity and rolling action in the granulator. Initially, these granules are very soft; but, with further rolling and drying in a subsequent drying operation, salt bridging imparts the required granule hardness. In contrast to the TVA ammoniation–granulation process, the steam granulation process usually causes no significant reaction between mixture ingredients. In Europe, this feature is of considerable significance when superphosphate is used as a feed material. Ammoniation of superphosphate, which occurs in the TVA ammoniation–granulation process, converts part of the water-soluble P_2O_5 content of the superphosphate to water-insoluble but citrate-soluble forms that are beginning to be accepted as marketable phosphate fertilizer in some European countries. The citrate-soluble forms are accepted as effective, marketable phosphate forms in the United States.

Compaction Granulation. This process involves the use of mechanical force to form granules (dense particles) from finely divided solid materials [7]. In this process (Fig. 24.18) the fine materials are weighed and, depending on the desired grade, thoroughly mixed. The mixture is then continuously fed to a pressure-roll compaction machine

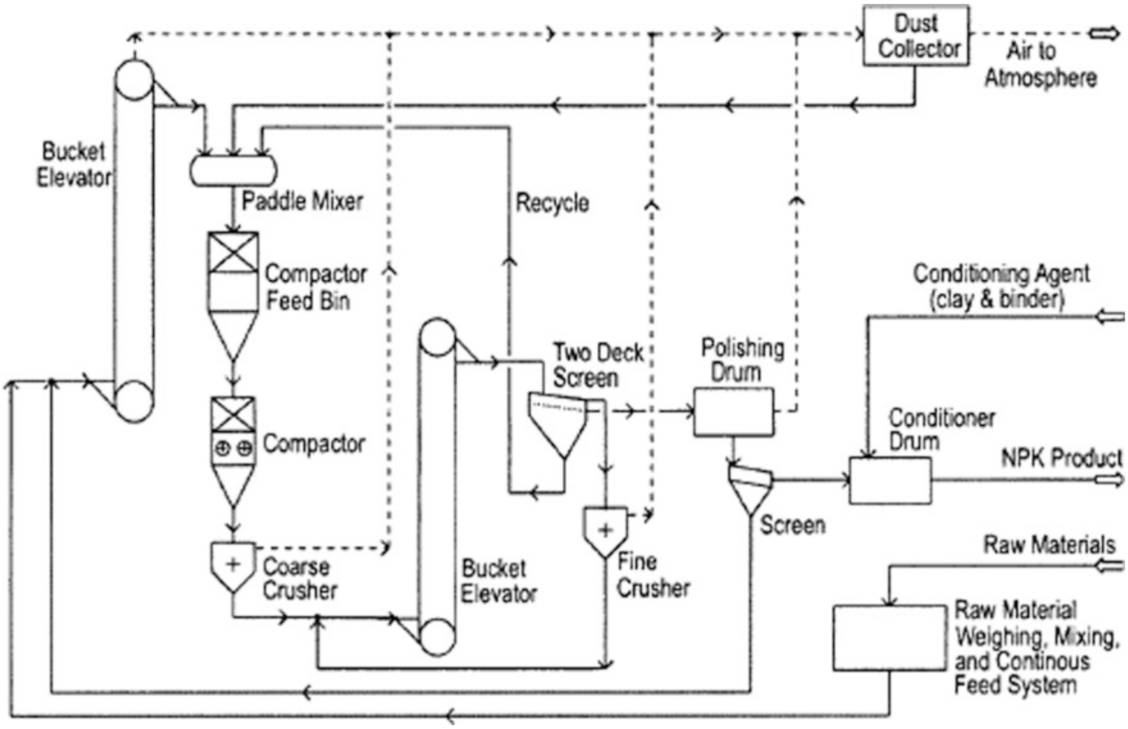

Fig. 24.18 Typical NPK fertilizer compaction granulation plant *(Source: Fertilizer Manual)*

Table 24.3 Typical pressing forces for fertilizer compaction[a]

Feed material	Pressing force[a] (kN/cm)[b]	Water content (%)	Feed particle size (mm)
Ammonium sulfate	100–120	0.5–1.0	<1.0
Potassium chloride			
Feed temperature >120°C	45–50	Nil	<1.0, with max. of 3% <0.06[c]
Feed temperature 20°C	70	Nil	
Potassium sulfate			
Feed temperature >70°C	70	1.0	<0.5
Potassium nitrate	100	0.5–1.0	<1.0
Calcium nitrate	60	Nil	<1.0
Urea	30–40	Nil	1–3
Compound fertilizer containing			
No raw phosphate rock	30–80	<1.0	<1.0
Raw phosphate rock	>80	<1.0	<1.0
Urea	30–40	<1.0	<1.0

[a] Indicated pressing force is for machine having 1.0-m diameter rollers

[b] 1 kN/cm = approximately 0.1 tonne/cm

[c] Size criteria apply to material feed temperature as indicated

that forms the powdered mixture into a dense, hard sheet of material usually about 2–3 cm thick and 60–100 cm wide. The compaction machine consists of two horizontally opposed rollers that turn inward toward each other. The shaft of one roller is fixed while the other is movable. The pressure from a hydraulic system is applied to the movable shaft. The pressure is dependent on the fertilizer materials. The compacted sheet of material is crushed in a controlled manner to form smaller particles. The crusher discharge is screened to obtain the desired product-size fraction. The oversize material is crushed and recycled to the screens and the undersize material is returned to the compaction machine after thorough mixing with fresh feed. This is a dry process and does not involve chemical reaction. Some typical pressing force for fertilizer materials is shown in Table 24.3.

Compacted fertilizers have a more irregular shape as compared with the more smooth and round granules

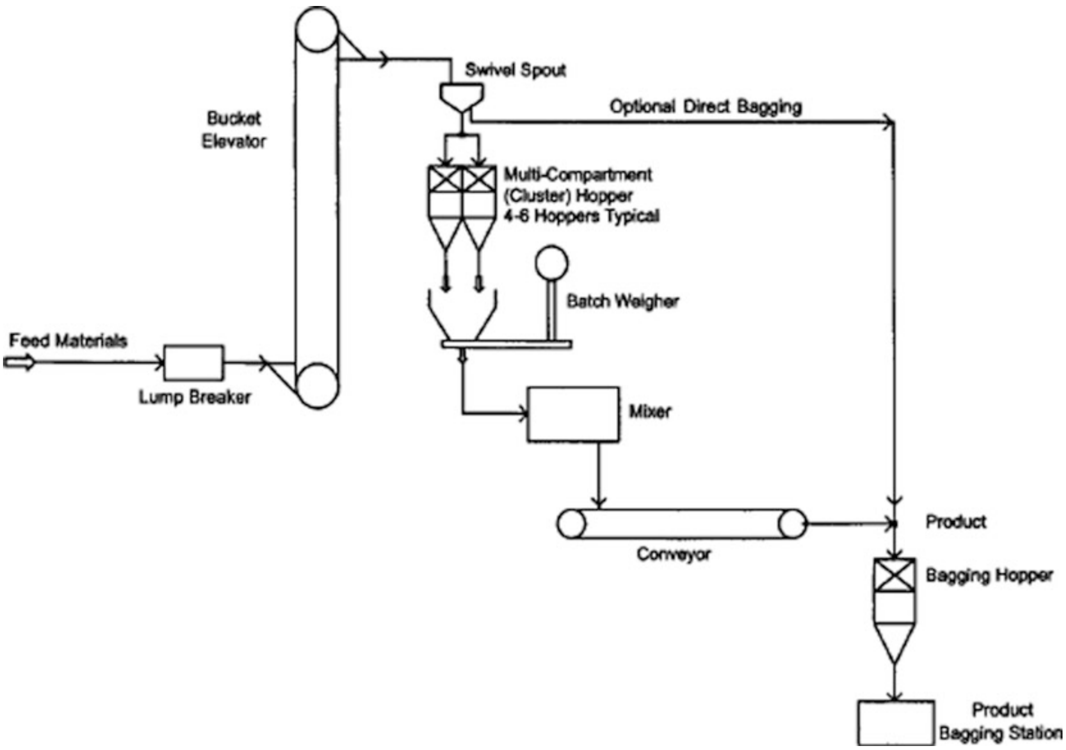

Fig. 24.19 Typical batch-type NPK fertilizer bulk-blending plant *(Source: Fertilizer Manual)*

produced by other granulation processes. This irregular shape may cause some resistance among users who are accustomed to the more traditional spherical fertilizer granules. However, compacted fertilizers are produced and used in Europe.

Bulk Blends

History and Growth. In the "compound" (mixed) fertilizer granulation processes just described, the starting materials are nitrogen, phosphorus, and potassium in the form of (1) nongranular solids, (2) liquids, or (3) gas (ammonia). When nitrogen, phosphorus, and potassium materials are all available from basic producers in granular form, as they now are, granular mixed fertilizers of almost any nutrient proportion (grade) can be made by simple proportioning and dry blending of granular nitrogen, phosphorus, and potassium materials; further granulation or other processing is not required. This is the basis of the presently popular "bulk-blending" system of mixed fertilizer preparation and distribution.

In 2008/2009 about 52 million mt of bulk-blended fertilizers was produced. This corresponded to about 13% of the global fertilizer production.

The simplicity of the bulk-blending procedure is illustrated in Fig. 24.19. The operations consist of (1) inshipment of granular fertilizer materials, (2) temporary storage, (3) proportioning, (4) blending, and (5) movement of the finished blend to the field for spreading.

Key factors in the rapid growth of bulk blending have been: (1) convenience in providing the farmer with a wide choice of plant-food ratios or grades on a "prescription" basis in relatively simple, small mixing plants located in the immediate farm area; (2) economy due to handling in bulk rather than bags; and (3) provision of spreading and other farmers services by the local blender.

Typical blending plants produce and market only 2,000–6,000 tons of blend per year. However, the present trend is for larger capacity plants covering a 30-mile radius of farming area designed to serve relatively large areas. The capital investment in blending plants is comparatively low. Blending plants operate on a quite seasonal basis, and often the operators have supplemental business enterprises.

Intermediates Used in Bulk Blending. The bulk-blending system came into being only after suitable nitrogen, phosphorus, and potassium intermediates became available in granular form. In particular, the introduction of granular DAP of 18–46–0 grade in about 1960, as described in a previous section, was a major catalyst to bulk blending. Characteristics of that product that make it an ideal material for shipping and subsequent blending are: (1) a high plant food content of 64%, (2) a high phosphorus content of 46%,

(3) excellent storage and handling properties, (4) compatibility with essentially all other fertilizer materials, and (5) economy of production near phosphate deposits. Most NPK bulk blends are prepared with DAP as the phosphate source. Granular TSP is used for no-nitrogen (PK) grades, but for NPK blends TSP has the disadvantage of being incompatible (reactive) with urea.

In the preparation of bulk blends, it is of great importance to ensure that all ingredients of the blend are reasonably matched in particle size [33]. The use of unmatched materials results in poor mixing, segregation during handling, and uneven distribution on the field. Nitrogen materials used with the greatest success in bulk blends are (1) granular urea, (2) granular ammonium nitrate, and (3) large-crystal or granulated ammonium sulfate. Prilled ammonium nitrate can also be made of large-enough particle size for good blending, but prilled urea normally is of smaller size than desirable. The chief potash material used in blends is granular-grade potassium chloride, which is sized specially by potash producers for use in blends. Although granular-size potash usually consists of irregular crusher fragments rather than well-rounded granules, studies have shown that this particle shape difference does not promote segregation or otherwise impair blend quality [34]. A somewhat smaller-size, coarse-grade potassium chloride sometimes is used in blends because it is cheaper, but segregation problems are invited. Potassium sulfate and potassium magnesium sulfate are made in granular form for the blending of specialized formulations.

The addition of micronutrients to bulk blends poses special problems because of the small quantities usually added. Although many micronutrients are available in granular form, intergranule spacing on the field can be excessive when the granular micronutrient constitutes only a very small proportion of the blend. Procedures have been devised and used for adding finely powdered micronutrients to blends together with a small amount of liquid binder [35]. The result is that each blend granule is coated with micronutrient, and thus the field distribution is better.

Operating experience and TVA studies have identified several combinations of materials that are incompatible in blends and should be avoided: (1) unammoniated superphosphates react with urea, and the result is wetting and caking and (2) urea in contact with ammonium nitrate forms an extremely soluble hygroscopic mixture that liquefies in the presence of only minute amounts of moisture. Therefore, these two materials can never be used together in the same blend. Essentially all other combinations of available fertilizer materials are compatible in blends.

Equipment and Operating Technique. There are different arrangements of equipment in the blending plants throughout the world. The operations in such plants generally consist of: (1) receipt of the intermediate granular components in bulk by truck or railroad car, (2) storage of the intermediates separately in bins, (3) removal of the granular blend components from storage and weighing in desired proportions, (4) mixing to obtain uniformity, and (5) discharge of the mixed batch directly into a spreader truck or into a holding bin. The most popular type of mixer is the batch-type rotary drum.

Such mixing plants can be highly automated so that the output with a mixer of only 1-ton capacity can be as much as 15–20 tons/h. Mixers of several types are available with capacities ranging between 5 and 8 tons per batch; in some cases batch mixer capacities can be 10 tons per batch [36].

Problems in Bulk Blending. Bulk blending is a simple practice that can provide uniform mixtures in almost any desired proportions. However, unless proper materials are used and certain handling precautions are taken, segregation can occur, and nonuniform blends will result. The factors involved and the precautions that are necessary have been described in several publications [3]. The main requirements are the use of granular materials with a well-matched range of particle size and the handling of the mixture after blending in ways that will minimize segregation. The mixing step is seldom a problem; it is quite easy to obtain a uniform blend by the use of proper materials and a few minutes of mixing. However, maintaining this uniformity during handling on the way to the farm and onto the soil requires precautions. Handling procedures that may cause segregation include coning (as occurs if the blend is allowed to drop from a discharge pipe onto a pile), vibration in hauling vehicles, and ballistic action imparted by some types of spreaders.

The problem of adding small quantities of micronutrient materials to bulk blends was mentioned earlier. This problem is being met by either using micronutrients in granular form or coating the blend particles with finely ground micronutrients and a liquid binder [35].

Fluid Mixtures

Mention was made earlier of the significant quantity of nitrogen applied to farmlands in the form of urea–ammonium nitrate solution and aqua ammonia. Since the late 1950s, there has also been a growing practice of applying mixed fertilizers (NP and NPK) in fluid form. In fact, the growth of the fluids market paralleled bulk-blended products. In 2002/2003 about 25 million mt of fluids was produced and corresponded to 7% of the world production. North America, and Europe are major markets for fluids. Fluids are also used in high-value crops in some countries of the Middle East and Latin America.

Numerous advantages have been cited to explain the growth of fluid mixed fertilizers [3]. Of these, the most significant probably is the ease and the precision with which fluids can be applied to the soil. When placement of the fertilizer is important, as in row fertilization, fluids often have an advantage. Also important is the adaptability of fluids to the homogeneous incorporation of micronutrients, herbicides, and insecticides. Another factor that encouraged the adoption of fluid mixtures was the prior existence of equipment and facilities for handling and applying nitrogen fluids; it was only logical for this practice to be expanded to include the preparation and application of mixtures. There are some claims of agronomic superiority for fluid fertilizers over similarly applied solids, but such claims are debatable and are not widely accepted.

Solution Fertilizers. Fluid fertilizers in use today can be divided into two major categories: (1) solutions, in which the plant food content is entirely in solution, and (2) suspensions, in which the plant food content exceeds its solubility, and the excess is held in suspension, usually by the addition of a suspending agent. The solution-type mixtures were the first to achieve commercial importance. Beginning about 1950, the practice of making solution mixtures was begun with pure electric-furnace orthophosphoric acid (54% P_2O_5) as the source of phosphorus. Ammoniation of this acid yielded an 8–24–0 grade ammonium orthophosphate solution that could be shipped to mixing plants in farm areas and used as a base for blending with other fertilizer materials. Blending usually was with urea–ammonium nitrate solutions (28–32% N) and a pure grade (solution grade) potassium chloride.

With the system that employed these raw materials, numerous advantages of fluid mixtures were established, but a need to improve the economics of the procedure was obvious. Pure electric-furnace acid is much more expensive than wet-process acid, so ways were sought to use the cheaper but impure wet-process acids. Direct ammoniation of wet-process acid causes precipitation of numerous impurities as an intolerable, gelatinous sludge. Also, plant-food solubilities are undesirably limited in the orthophosphate system, so the concentration (grade) of the product made with electric-furnace orthophosphoric acid was limited to 8–24–0. A series of developments by TVA led the way to solving both of these problems.

The problem of limited plant-food solubility was much alleviated by TVA's introduction of superphosphoric acid in 1957 [37]. Superphosphoric acids are acids of high P_2O_5 content (up to 80% P_2O_5) that contain significant proportions of polyphosphates (nonortho, poly merized phosphates). The superphosphoric acid first produced by TVA was a pure electric-furnace product of 76% P_2O_5 content, of which about 50% was in polyphosphate form. With ammoniation of this acid, it was possible to produce an 11–37–0 grade base solution instead of the 8–24–0 grade maximum made from ortho acid. Demonstration use of 11–37–0 base in a number of mixing plants showed that solution mixtures of relatively high concentration could be made. Also, it was found that the polyphosphate content enhanced the solubility of micronutrient additives by a sequestering action.

The unfavorable economics of the electric-furnace acid process, however, discouraged the commercial production of electric-furnace superphosphoric acid; so attention was directed toward concentration of the cheaper wet-process phosphoric acid to give wet-process superphosphoric acid. Satisfactory concentration methods were developed [38], but the effects of acid impurities on the handling properties of the concentrated acids limited the final P_2O_5 concentration and hence the polyphosphate content. The best handling properties were obtained with acids made from calcined rocks and with P_2O_5 concentration limited to 68–70% P_2O_5. In acid of this concentration, from 20 to 35% of the P_2O_5 is in the polyphosphate form, and the acid is referred to as low-conversion superphosphoric acid. Such acid today is the chief source of P_2O_5 for solution-type fertilizers.

The most popular scheme by which solution-type fertilizers are made from low-conversion, wet-process superphosphoric acid is outlined in Fig. 24.20. The first step is ammoniation of the acid to produce ammonium polyphosphate base solution. By carrying out this ammoniation in a pipe reactor, a temperature of over 200°C is developed, which promotes an increase in polyphosphate content to 65–70% of total P_2O_5 in the ammoniated acid [39, 40]. The grade of the resultant base is usually 10–34–0; an 11–37–0 grade can be made, but its storage properties are not as good, especially in cold weather. A sketch of a typical pipe-reactor system for the production of high-polyphosphate base solution from low-conversion, wet-process superphosphoric acid is shown in Fig. 24.21.

More than 100 U.S. plants use this pipe-reactor process to produce an estimated two million metric tons of 10–35–0 or 11–37–0 grade product per year. Other countries such as Belgium and France also use this process to produce ammonium polyphosphate solution. A considerable amount of the solution is used for direct application in the U.S. wheat belt and other areas in which potassium is not deficient. The rest is used in small mix plants to produce mixtures. The ammonium polyphosphate base solution is mixed with nitrogen solutions containing 28–32% N (urea–ammonium nitrate solutions) and sometimes also with potash to produce such clear liquid grades as 21–7–0, 7–21–7, and 8–8–8. As with bulk blending, the solution-mixing operation usually is carried out in small mixing plants located in farm areas (Fig. 24.22).

Suspension Fertilizers. Suspension fertilizers were developed chiefly as a means of breaking the grade barriers imposed on solution fertilizers by solubility limitations. The low solubility of potassium chloride was particularly troublesome, in that high-potash solution grades were not possible.

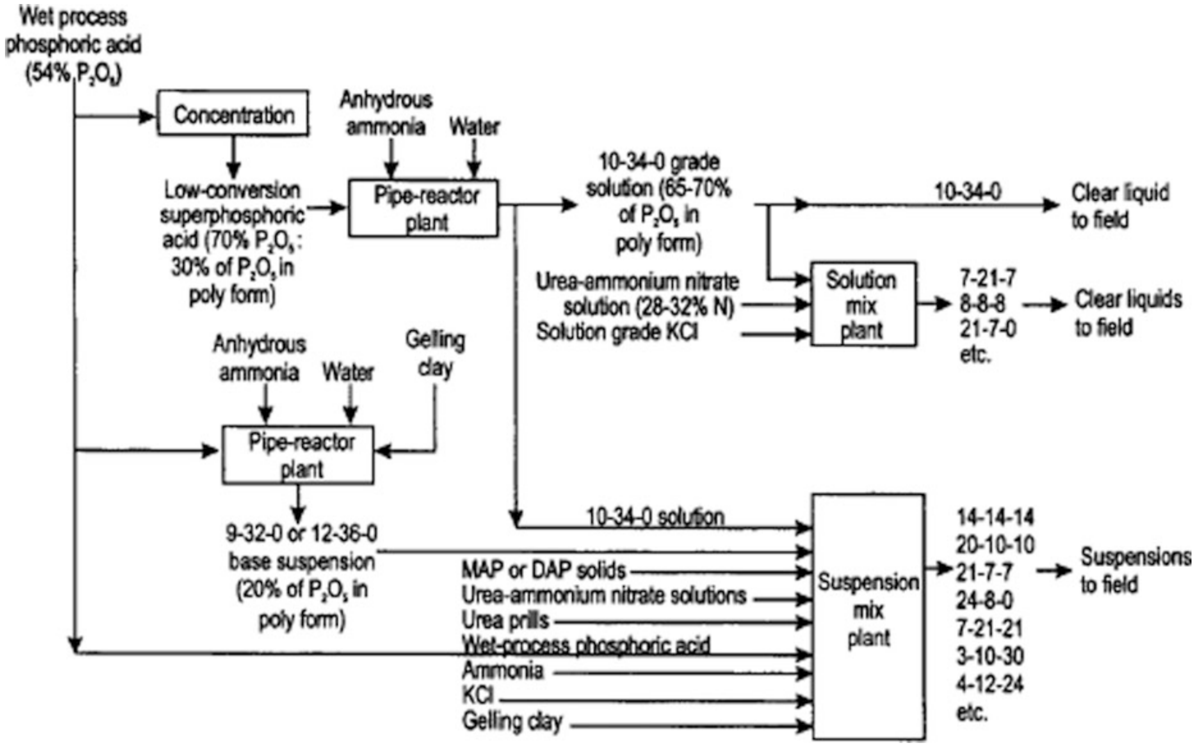

Fig. 24.20 Production methods for solution-type and suspension-type mixed fertilizers

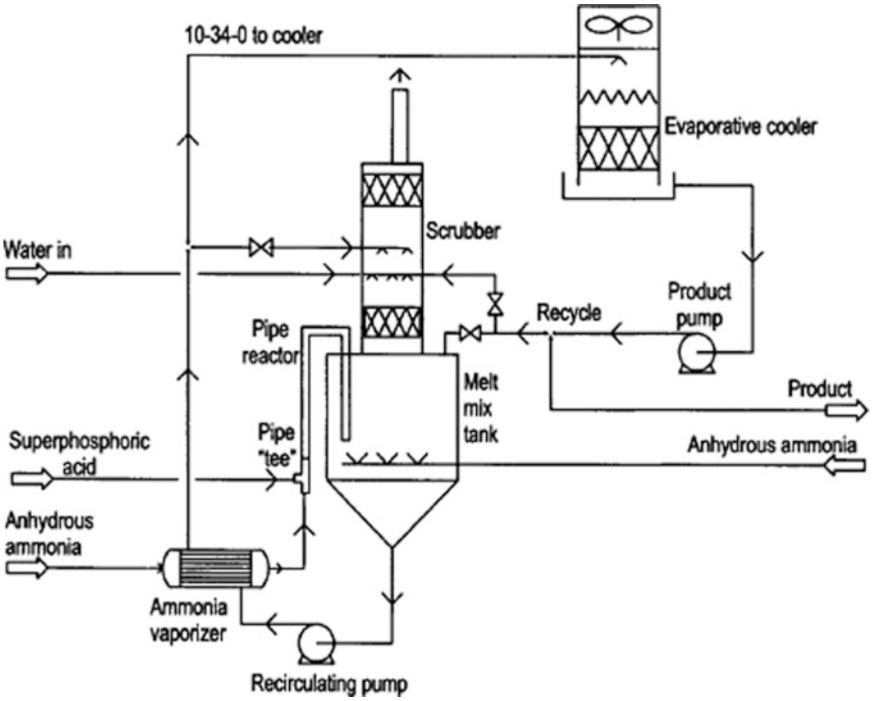

Fig. 24.21 Typical pipe-reactor plant for production of ammonium polyphosphate solution *(Source: Fertilizer Manual)*

The feasibility of preparing and handling suspension-type fertilizers was demonstrated by TVA and others in 1959 [41, 42]. Two essential requirements for the preparation of a successful suspension were shown to be: (1) small particle size of the suspended solids and (2) the addition of a gelling-type clay as a suspending agent along with sufficient

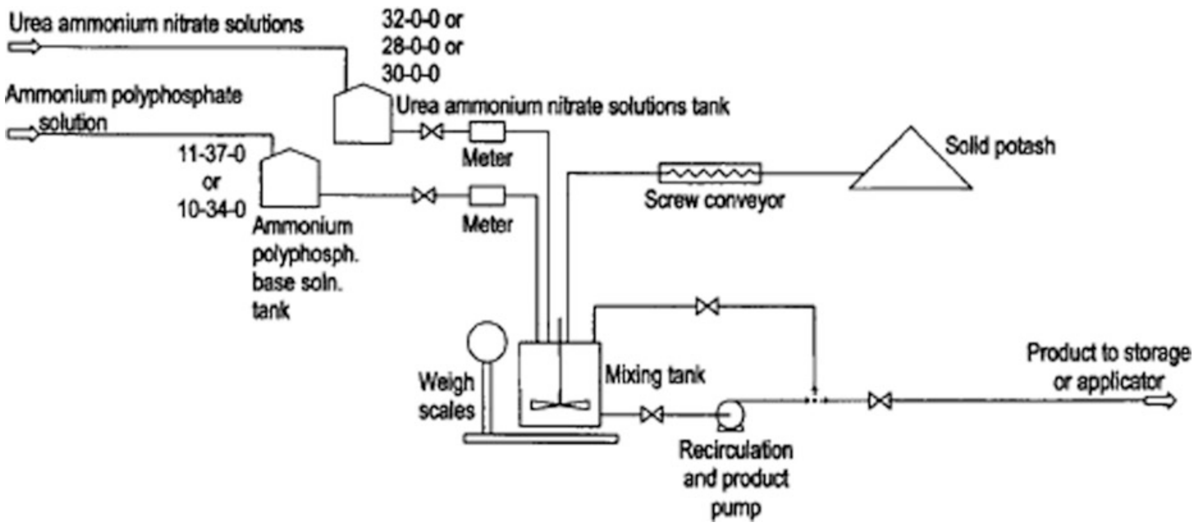

Fig. 24.22 Liquid fertilizer mix plant *(Source: Fertilizer Manual)*

high-shear agitation to properly disperse the clay. The most satisfactory gelling-type clay is attapulgite [43]. Attapulgite is a hydrated magnesium aluminum silicate, which is composed of needle-shaped crystals so small that they can be seen only with the use of high magnification. In the dry state, these crystals bond together in bundles as larger particles. These bundles must be disrupted and the individual crystals freed before they can assume the structural arrangement that is characteristic of a gel. When this disruption of the crystal bundles is carried out in the presence of an electrolyte, such as any of the common fertilizer salts present in fluid fertilizers, the individual crystals immediately assume the regular structural orientation of a weak gel, and thus provide the desired suspending action.

Wetting of the clay by the fluid fertilizer causes some of the required disruption of crystal bundles and freeing of individual crystals but not enough to provide good gelling without high-shear agitation. The addition of 2–3% of attapulgite is sufficient for most fertilizer suspensions. Instead of providing high-shear agitation for the entire batch of suspension, some operators carry out a pre-gelling operation in which high-shear agitation is applied only to the clay plus a limited amount of water or fertilizer solution. The pre-gelled mixture then is added to the major body of fertilizer with only mild mixing. Pre-gelled clay is also marked as liquid clay and is transported in tank cars. The provision of a high-shear mixer is essential not only for gelling of the suspending clay but also for disintegration of any granular products such as DAP or MAP that might be used in the suspension. A high-shear recirculation pump is also an aid to gelling of the clay.

Figure 24.23 shows the layout of a typical suspension mix plant in which all the major suspension ingredients are received as solids. This is presently a popular mode of operation. Raw material costs for such a plant often are less than for bulk blending because nongranular materials can be used. Piping for the optional addition of phosphoric acid and ammonia is shown. Such addition develops heat, which hastens the disintegration of some solids.

The storage and handling properties of suspensions can be enhanced by the inclusion of some polyphosphate in the suspension. Low-temperature storage properties, in particular, are enhanced. One popular method of providing polyphosphate is to supply all or part of the P_2O_5 as 10–34–0 ammonium polyphosphate base solution, such as is used in solution fertilizers. A second method is the use of a pipe reactor to prepare 9–32–0 or 12–36–0 grade ammonium polyphosphate base suspension from relatively inexpensive wet-process orthophosphoric acid (54% P_2O_5), ammonia, and gelling clay [44]. About 20% of the P_2O_5 in the 9–32–0 form or 12–36–0 product is in polyphosphate form. The clay content is 2%. When these base solutions are used for mixing with other suspension ingredients, their clay content often is sufficient to provide all the clay required in the final suspension. Commercial acceptance of 9–32–0 or 12–36–0 base suspension preparation has not yet occurred. At present, apparently it is most economical to furnish polyphosphate as 10–34–0 ammonium polyphosphate solution.

Controlled-Release Fertilizers

The term “controlled-release fertilizer,” as used in the following discussion, refers to fertilizers that release, either by design or naturally, their nutrient content over an extended

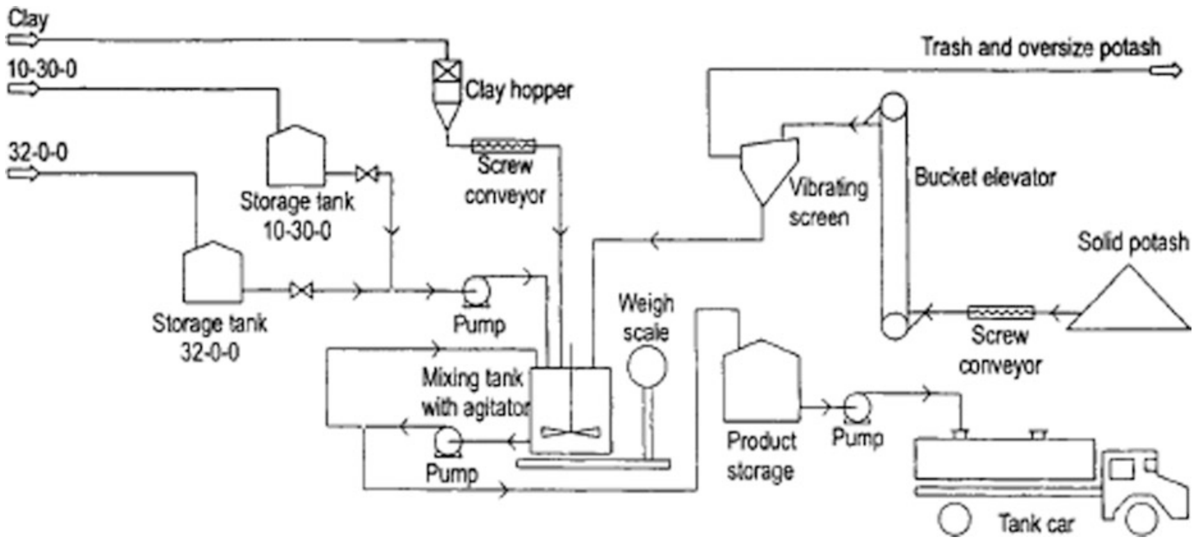

Fig. 24.23 Typical mix plant for production of suspension mixtures *(Source: Fertilizer Manual)*

period of time. Potential advantages claimed for controlled-release fertilizers are increased efficiency of uptake by plants; minimization of losses by leaching, fixation, or decomposition; a reduction in the release of nutrients and by-products to air and water; and avoidance of burning of vegetation or damage to seedlings. In spite of this impressive list of potential advantages, the controlled-release fertilizers have mainly been applied to high-value crops and/or ornamental plants and golf courses. However, there has been progressive increase of controlled-release fertilizers on rice in Japan and more recently corn in the United States and rice in China. The combined total controlled-release fertilizer production in North America (73%), Western Europe and Japan totaled 713,000 tons or 86% of total production in 2009. Agriculture in the "three" regions accounted for only 24% of the consumption. However, in Japan 90% of controlled-release fertilizer is used on agricultural crops. Large and growing markets are emerging in Asia, particularly in China where increase food demand combined with land and labor shortage is expected to raise controlled-release fertilizer consumption to more than one million tons/year.

Controlled-Release Phosphate Fertilizers. Several controlled-release phosphates have been produced commercially. Important among them are ground phosphate rock, basic slag, and fused CMP. These products have been discussed earlier.

Most of the insoluble or slightly soluble phosphate materials are used because they are less expensive than soluble phosphates or because they supply other elements. These products are rarely agronomically superior to soluble phosphates. However, some of them are valued for specialty uses because they may be safely placed in contact with seeds or roots in some situations. Slightly soluble phosphates are found to be useful in tropical agriculture where conditions are quite different from those in temperate zones.

Controlled-Release Nitrogen Fertilizers. Because of economics and environmental considerations, the slow-release nitrogen fertilizers are much more important than phosphate (or potash), particularly under certain soil and climatic conditions. In most cases unutilized phosphate and potash remain available for subsequent crops. In contrast, there is seldom much carryover of fertilizer nitrogen from one crop to the next. Nitrogen applied as fertilizer is lost from the soil through: (1) leaching or surface drainage, (2) volatilization as ammonia, and (3) decomposition. Because of these losses, nitrogen use efficiency by crops seldom exceeds 50 percent and may be as low as 20 percent under flooded rice conditions when grown under conditions of intermittent flooding or poor water control. Thus, improved utilization is particularly important because it would favorably impact the cost of production and simultaneously reduce the release of nitrogen compounds to air and water [45].

Slightly Soluble Materials. One group of controlled-release nitrogen fertilizers comprises chemical compounds that are inherently only slightly soluble in water or soil solution. Urea–aldehyde compounds are the principal representatives of this group that are produced commercially. Isobutylidene diurea (IBDU) is produced in Japan through the reaction of urea with isobutyraldehyde in a 2:1 mole ratio. When pure, it contains 32.18 percent N [46]. Crotonylidene diurea (CDU), also called cyclodiurea, is produced in Japan and Germany through the reaction of urea with crotonaldehyde or acetaldehyde. The pure compound contains about 32 percent nitrogen.

Urea–formaldehyde reaction products, usually called "ureaform," are produced by about six manufacturers in the United States and several other countries. Unlike IBDU and CDU, ureaform is not a definite chemical compound. It contains methylene ureas of different chain lengths; the solubility increases with decrease in chain length. It usually contains about 38 percent nitrogen.

Perhaps the most useful component of ureaform as a slow-release nitrogen material is trimethylene tetraurea; shorter chain lengths are too rapidly decomposed, and longer chains are highly resistant to decomposition. Unfortunately, it is very difficult to produce commercially a pure trimethylene tetraurea; ureaform contains both shorter and longer chains.

A typical ureaform may contain 30 percent of its nitrogen in forms that are soluble in cold water (25 C). The quality of the remaining 70 percent is judged by the percentage that is soluble in hot (boiling) water as determined by prescribed analytical procedures. At least 40 percent of the nitrogen insoluble in cold water should be soluble in hot water for acceptable agronomic response; typical values are 50–70 percent.

Ureaform is produced by reaction of urea with formaldehyde in aqueous solution in the presence of an acid that catalyzes the reaction. The degree of polymerization depends on the mole ratio of urea to formaldehyde and on the pH, time, and temperature of reaction. The reaction is stopped by neutralizing the acid. Production processes have been described by Clark et al. [47] and by Kolterman and Rennie [48].

In Japan, ureaform is also produced as a component of compound fertilizers by the addition of formaldehyde solution to the urea solution fed to the granulator [49]. In one process a methylene urea reactor is used to react urea and formaldehyde solution to produce a slurry that feeds directly to a granulation plant with other materials to make compound fertilizers [50]. Some slow-release nitrogen is formed, and the physical properties of the products are improved.

In the United States, ammoniating solutions containing urea, formaldehyde, and ammonia are used to prepare compound fertilizer containing water-insoluble nitrogen. The composition of one such solution is: urea—35.3 percent, formaldehyde—8.0 percent, CO_2—8.4 percent, NH_3—25.0 percent, and H_2O—23.3 percent. Other solutions with high formaldehyde content (up to 60%) are available for use with additional urea [51].

The addition of sulfuric or phosphoric acid (or superphosphate) neutralizes the ammonia and catalyzes the formation of methylene urea. Products containing about 20–30 percent of their nitrogen in a water-insoluble form are produced. Good control of conditions in the granulator and dryer is needed to produce a satisfactory quality of water-insoluble nitrogen. In some cases, a prereactor is used prior to the granulator [50].

The consumption of ureaform in the United States is approximately 75,000 tons/year, not including that formed in compound fertilizers from solutions. Most of the production goes into compound fertilizer for specialty uses, such as for lawns, flower gardens, and golf courses. The wholesale price of ureaform per unit of nitrogen is about three times that of urea, ammonium nitrate, or ammonium sulfate.

In tests made by TVA and IFDC of many other organic nitrogen-containing compounds as fertilizers, some proved readily available, some slowly available, some inert, and some toxic. Among those that showed promise as slow-release fertilizers were oxamide, glycouril, cyanuric acid, ammeline, and ammelide. For lack of an economical process, none of these materials has been manufactured commercially for fertilizer use.

Magnesium ammonium phosphate ($MgNH_4PO_4$) is a slowly soluble source of nitrogen although it contains more phosphate than nitrogen. The commercial product, called "Mag Amp," contains a variable amount of water of crystallization and some impurities; a typical grade is 8–40–0. A similar product containing potash is marketed under the trade name "En Mag" in the United Kingdom. The grade is 5–24–10. The rate of solution of these slightly soluble materials is controlled by the size and hardness of the granules.

Coated Soluble Materials. A wide range of materials and techniques has been explored with the object of making controlled-release fertilizers by coating soluble fertilizer materials with plastic films, resins, waxes, asphaltic materials, or other barriers. The first commercial production of coated controlled-release fertilizer utilizes a process developed by Archer Daniels Midland Company (ADM). The main component of the coating is a copolymer of dicyclopentadiene with a glycerol ester [52]. Applied in several layers that vary in composition, the coating releases fertilizer solution by osmotic exchange with moisture from the soil. The coated granular fertilizer was manufactured by ADM under the trade name Osmocote starting in 1964. It now is produced and marketed by Sierra Chemical Company under exclusive license from ADM. Three grades of Osmocote are available: 14–14–14, 18–9–9, and 16–4–8. The weight of the coating ranges from 10 to 15 percent of the gross weight. Osmocote products are recommended for turf, floriculture, nursery stock, and high-value row crops.

Sulfur-coated urea (SCU) is a controlled-release material developed by TVA during the 1960s and 1970s [53]. Sulfur was selected as the coating material on the basis of economy and efficiency after many coating materials were tried. Urea was selected as the material to be coated because of its high nitrogen content, low cost, and commercial availability.

Initial studies indicated that sulfur alone was not adequately resistant to moisture penetration. However, it was discovered that the addition of an oil wax sealant over the sulfur coating provided a successful coating. The process has been commercialized and the product is mainly used for turf and golf courses.

In this process granular urea is preheated in the first rotating drum to 77 C with electric radiant heaters to prevent the sulfur from freezing too rapidly on the granules. The molten sulfur is atomized and sprayed onto the rolling bed of granules in the second drum. Wax is applied in the third drum. The coated granules are then cooled in a fluidized bed cooler, and an absorbent powder is applied in a fourth drum to eliminate the tacky condition of the wax and to prevent the granules from floating when applied in water (as in a rice paddy).

The rate of dissolution of coated urea can be varied by varying the thickness of the sulfur coating and, to some extent, by varying the amount of sealant. In addition to the controlled-release characteristics, coated urea has excellent storage and handling characteristics and might even be handled in bulk in humid climates. Also, it may be blended with TSPs or SSPs, which are incompatible with uncoated urea. Also the sulfur coating is a slowly available source of sulfur, which would be an advantage in sulfur-deficient areas.

The sulfur-coating technique may be applied to fertilizers other than urea. Experimental work has included a coating of DAP, potassium chloride, potassium sulfate, and various compound fertilizers, including a pan-granulated urea-potassium chloride product of 32–0–16 grade.

Nitrification Inhibitors. Nitrogen fertilizers in the ammonium form are immobilized by sorption on clay particles and hence are resistant to leaching. However, the ammonium form is converted to the nitrate form under aerobic conditions by microbiological processes known as nitrification. The rate of conversion depends on the temperature; below 10 C it is very slow, but at 20 C and higher it is rapid. The nitrate form is more readily available to most plants although some plants (e.g., rice) can readily use the ammonium form. Thus, some of the purposes of controlled release (resistance to leaching, prevention of denitrification losses, and delayed availability) may be attained by delaying nitrification of ammonium nitrogen.

Numerous organic chemicals have been identified as nitrification inhibitors. The inhibition is due to the toxicity of these chemicals to organisms that convert ammonium nitrogen to nitrite, which is the first step of the nitrification process.

One of the nitrification inhibitors that has received attention in the United States is 2-chloro-6-(trichloromethyl) pyridine which is promoted under the name N-Serve. The minimum concentration of N-Serve in the soil for delaying nitrification at least 6 weeks is said to range from 0.5 to 10 ppm.
