12. Short and Ultrashort Laser Pulses

In this contribution some basic properties of femtosecond laser pulses are summarized. In Sect. 12.1 we start with the linear properties of ultrashort light pulses. Nonlinear optical effects that would alter the frequency spectrum of an ultrashort pulse are not considered. However, due to the large bandwidth, the linear dispersion is responsible for dramatic effects. For example, a 10 fs laser pulse at a center wavelength of 800 nm propagating through 4 mm of BK7 glass will be temporally broadened to 50 fs. In order to describe and manage such dispersion effects a mathematical description of an ultrashort laser pulse is given first before we continue with methods how to change the temporal shape via the frequency domain. The chapter ends with a paragraph on the powerful technique of pulse shaping, which can be used to create complex-shaped ultrashort laser pulses with respect to phase, amplitude and polarization state.

In Sect. 12.2 the generation of femtosecond laser pulses via mode locking is described in simple physical terms. As femtosecond laser pulses can be generated directly from a wide variety of lasers with wavelengths ranging from the ultraviolet to the infrared no attempt is made to cover the different technical approaches.

In Sect. 12.3 we deal with the measurement of ultrashort pulses. Traditionally a short event has been characterized with the aid of an even shorter event. This is not an option for ultrashort light pulses. The characterization of ultrashort pulses with respect to amplitude and phase is therefore based on optical correlation techniques that make use of the short pulse itself. Methods operating in the time–frequency domain are especially useful.

A central building block for generating femtosecond light pulses are lasers. Within only two decades of the invention of the laser the duration of the shortest pulse shrunk by six orders of magnitude from the nanosecond regime to the femtosecond regime. Nowadays femtosecond pulses in the range of 10 fs and below can be generated directly from compact and reliable laser oscillators and the temporal resolution of measurements has outpaced the resolution even of modern sampling oscilloscopes by orders of magnitude. With the help of some simple comparisons the incredibly fast femtosecond time scale can be put into perspective: on a logarithmic time scale one minute is approximately half-way between 10 fs and the age of the universe. Taking the speed of light in vacuum into account, a 10 fs light pulse can be considered as a 3 μm thick slice of light whereas a light pulse of one second spans approximately the distance between earth and moon. It is also useful to realize that the fastest molecular vibrations in nature have an oscillation time of about 10 fs.

It is the unique attributes of these light pulses that open up new frontiers both in basic research and for applications. The *ultrashort pulse duration* for example allows the motion of electrons and molecules to be frozen by making use of so-called pump probe techniques that work similar to strobe light techniques. In chemistry complex reaction dynamics have been

measured directly in the time domain and this work was rewarded with the Nobel price in chemistry for A. H. Zewail in 1999. The *broad spectral width* can be used for example in medical diagnostics or – by taking the longitudinal frequency comb mode structure into account – for high-precision optical frequency metrology. The latter is expected to outperform today's state-of-the-art caesium clocks and was rewarded with the 2005 Nobel price in physics for J. L. Hall and T. W. Hänsch. The extreme concentration of a modest energy content in focused femtosecond pulses delivers *high peak intensities* that are used for example in a reversible light matter interaction regime for the development of nonlinear microscopy techniques. The irreversible light matter regime can be for example applied to nonthermal material processing leading to precise microstructures in a whole variety of solid state materials. Finally the *high pulse repetition rate* is exploited, for example, in telecommunication applications.

These topics have been reviewed recently in [12.1]. The biannual international conference series *Ultrafast Phenomena* and *Ultrafast Optics*, including the corresponding conference proceedings, cover a broad range of applications and latest developments.

Besides the specific literature given in the individual chapters some textbooks devoted to ultrafast laser pulses are recommended for a more in-depth discussion of the topics presented here and beyond (see, for example, [12.2–5] and especially for the measurement of ultrashort pulses see [12.6]).

12.1 Linear Properties of Ultrashort Light Pulses

12.1.1 Descriptive Introduction

It is quite easy to construct the electric field of a *Gedanken* optical pulse at a fixed position in space, corresponding to the physical situation of a fixed detector in space. Assuming the light field to be linearly polarized, we may write the real electric field strength $E(t)$ as a scalar quantity whereas a harmonic wave is multiplied with a temporal amplitude or envelope function $A(t)$

$$E(t) = A(t)\cos(\Phi_0 + \omega_0 t) \tag{12.1}$$

with ω_0 being the carrier circular (or angular) frequency. The light frequency is given by $\nu_0 = \omega_0/2\pi$. In the following, angular frequencies and frequencies are only distinguished from each other via their notation. For illustration we will use optical pulses centered at 800 nm, corresponding to a carrier frequency of $\omega_0 = 2.35\,\mathrm{rad/fs}$ (oscillation period $T = 2.67\,\mathrm{fs}$) with a Gaussian envelope function (the numbers refer to pulses that are generated by the widely spread femtosecond laser systems based on Ti:sapphire as the active medium). For simple envelope functions the pulse duration Δt is usually defined by the FWHM (full width at half-maximum) of the temporal intensity function $I(t)$

$$I(t) = \frac{1}{2}\varepsilon_0 c n A(t)^2\,, \tag{12.2}$$

with ε_0 being the vacuum permittivity, c the speed of light and n the refractive index. The factor $1/2$ arises from averaging the oscillations. If the temporal intensity is given in $\mathrm{W/cm^2}$ the temporal amplitude $A(t)$ (in $\mathrm{V/cm}$ for $n = 1$) is given by

$$A(t) = \sqrt{\frac{2}{\varepsilon_0 c}}\sqrt{I(t)} = 27.4\sqrt{I(t)}\,. \tag{12.3}$$

Figure 12.1a displays $E(t)$ for a Gaussian pulse with $\Delta t = 5\,\mathrm{fs}$ and $\Phi_0 = 0$. At $t = 0$ the electric field strength

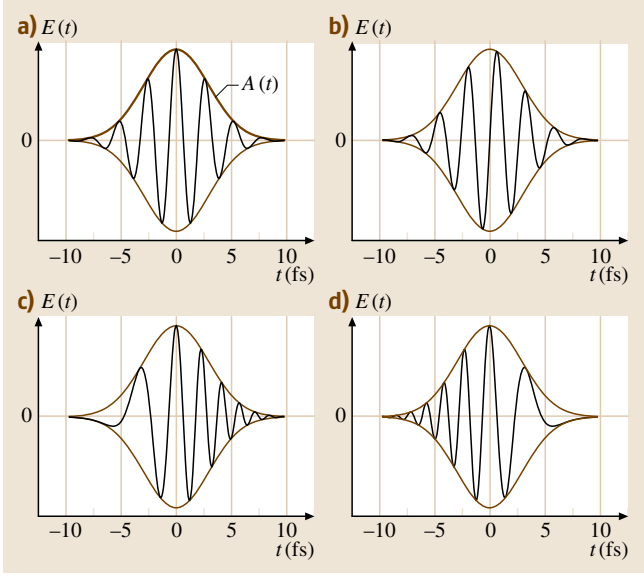

Fig. 12.1a–d Electric field $E(t)$ and temporal amplitude function $A(t)$ for a cosine pulse **(a)**, a sine pulse **(b)**, an up-chirped pulse **(c)** and a down-chirped pulse **(d)**. The pulse duration in all cases is $\Delta t = 5\,\mathrm{fs}$. For **(c)** and **(d)** the parameter a was chosen to be $\pm 0.15/\mathrm{fs}^2$

reaches its maximum value. This situation is called a cosine pulse: for $\Phi_0 = -\pi/2$ we get a sine pulse $E(t) = A(t)\sin(\omega_0 t)$ (Fig. 12.1b) where the maxima of the carrier oscillations do not coincide with the maximum of the envelope $A(t)$ at $t = 0$ and the maximum value of $E(t)$ is therefore smaller than in a cosine pulse. In general Φ_0 is termed the absolute phase or carrier-envelope phase and determines the temporal relation of the pulse envelope with respect to the underlying carrier oscillation. The absolute phase is not important if the pulse envelope $A(t)$ does not significantly vary within one oscillation period T. The longer the temporal duration of the pulses, the more closely this condition is met and the decomposition of the electric field into an envelope function and a harmonic oscillation with carrier frequency ω_0 (12.1) is meaningful. Conventional pulse characterization methods as described in Sect. 12.3 are not able to measure the absolute value of Φ_0. Furthermore the absolute phase does not remain stable in a conventional femtosecond laser system. Progress in controlling and measuring the absolute phase has been made only recently [12.7–10] and experiments depending on the absolute phase are starting to appear [12.11–13]. In the following we will not emphasize the role of Φ_0 any more.

In general, we may add an additional time dependent phase function $\Phi_a(t)$ to the temporal phase term in (12.1)

$$\Phi(t) = \Phi_0 + \omega_0 t + \Phi_a(t) \tag{12.4}$$

and define the momentary or instantaneous light frequency $\omega(t)$ as

$$\omega(t) = \frac{d\Phi(t)}{dt} = \omega_0 + \frac{d\Phi_a(t)}{dt} . \tag{12.5}$$

This additional phase function describes variations of the frequency in time, called a chirp. In Fig. 12.1c,d $\Phi_a(t)$ is set to be at^2. For $a = 0.15/\text{fs}^2$ we see a linear increase of the frequency in time, called a linear up-chirp. For $a = -0.15/\text{fs}^2$ a linear down-chirped pulse is obtained with a linear decrease of the frequency in time. However, a direct manipulation of the temporal phase cannot be achieved by any electronic device. Note that nonlinear optical processes such as, for example, self-phase modulation (SPM) are able to influence the temporal phase and lead to a change in the frequency spectrum of the pulse. In this chapter we will mainly focus on linear optical effects where the spectrum of the pulse is unchanged and changes in the temporal pulse shape are due to manipulations in the frequency domain (Sect. 12.1.3). Before we start, a more mathematical description of an ultrashort light pulse is presented.

12.1.2 Mathematical Description

For the mathematical description we followed the approaches of [12.4, 14–19]. In linear optics the superposition principle holds and the real-valued electric field $E(t)$ of an ultrashort optical pulse at a fixed point in space has the Fourier decomposition into monochromatic waves

$$E(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \tilde{E}(\omega) e^{i\omega t} d\omega . \tag{12.6}$$

The, in general complex-valued, spectrum $\tilde{E}(\omega)$ is obtained by the Fourier inversion theorem

$$\tilde{E}(\omega) = \int_{-\infty}^{\infty} E(t) e^{-i\omega t} dt . \tag{12.7}$$

Since $E(t)$ is real-valued $\tilde{E}(\omega)$ is Hermitian, i. e., obeys the condition

$$\tilde{E}(\omega) = \tilde{E}^*(-\omega) , \tag{12.8}$$

where $*$ denotes complex conjugation. Hence knowledge of the spectrum for positive frequencies is sufficient for a full characterization of a light field without DC component we can define the positive part of the spectrum as

$$\begin{aligned} \tilde{E}^+(\omega) = \tilde{E}(\omega) \quad & \text{for } \omega \geq 0 \quad \text{and} \\ 0 \quad & \text{for } \omega < 0 . \end{aligned} \tag{12.9}$$

The negative part of the spectrum $\tilde{E}^-(\omega)$ is defined as

$$\begin{aligned} \tilde{E}^-(\omega) = \tilde{E}(\omega) \quad & \text{for} \quad \omega < 0 \quad \text{and} \\ 0 \quad & \text{for} \quad \omega \geq 0 . \end{aligned} \tag{12.10}$$

Just as the replacement of real-valued sines and cosines by complex exponentials often simplifies Fourier analysis, so too does the use of complex-valued functions in place of the real electric field $E(t)$. For this purpose we separate the Fourier transform integral of $E(t)$ into two parts. The complex-valued temporal function $E^+(t)$ contains only the positive frequency segment of the spectrum. In communication theory and optics $E^+(t)$ is termed the analytic signal (its complex conjugate is $E^-(t)$ and contains the negative frequency part). By definition $E^+(t)$ and $\tilde{E}^+(\omega)$ as well as $E^-(t)$ and $\tilde{E}^-(\omega)$ are Fourier pairs where only the relations for the

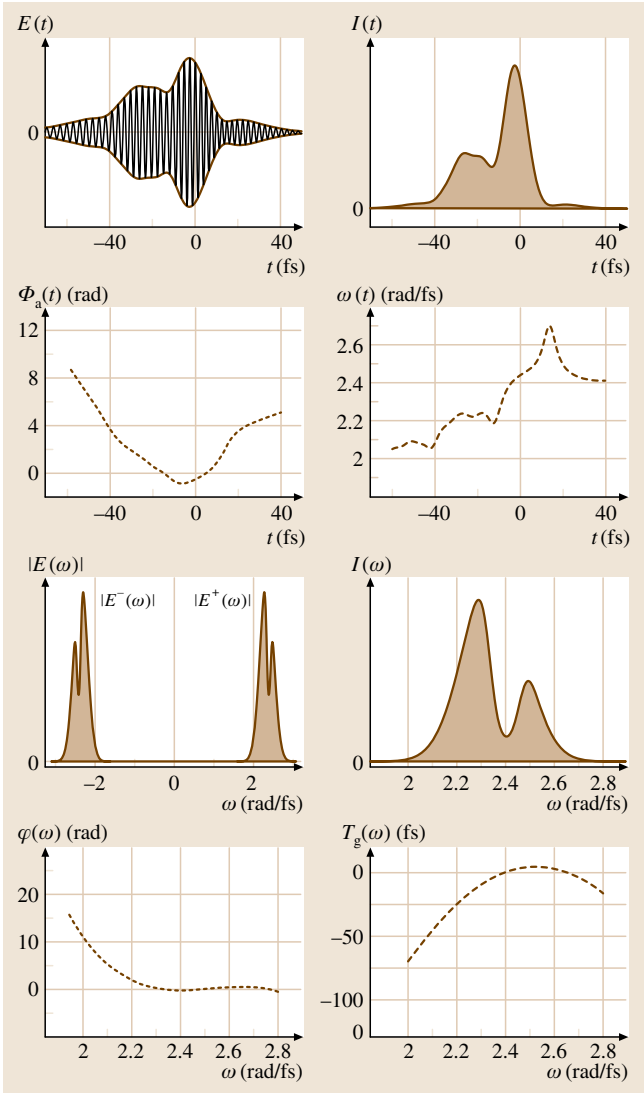

Fig. 12.2 Electric field $E(t)$, temporal intensity $I(t)$, additional temporal phase $\Phi_a(t)$, instantaneous frequency $\omega(t)$, spectrum $|\tilde{E}(\omega)|$, spectral intensity $I(\omega)$, spectral phase $\varphi(\omega)$ and group delay $T_g(\omega)$ of a pulse that looks complicated on first glance (having a relatively simple spectral phase $\varphi(\omega)$). When measured with a spectrometer the spectral intensity as a function of wavelength is usually obtained, and the corresponding transformation on the basis of $I(\lambda)\,\mathrm{d}\lambda = I(\omega)\,\mathrm{d}\omega$ yields $I(\lambda) = -I(\omega)2\pi c/\lambda^2$ where the minus sign indicates the change in the direction of the axis. To avoid phase jumps when the phase exceeds 2π, *phase unwrapping* is employed. That means adding or subtracting 2π to the phase at each discontinuity. When the intensity is close to zero, the phase is meaningless and usually the phase is not plotted in such regions (phase blanking)

positive-frequency part are given as

$$E^+(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \tilde{E}^+(\omega)\,\mathrm{e}^{\mathrm{i}\omega t}\,\mathrm{d}\omega \tag{12.11}$$

$$\tilde{E}^+(\omega) = \int_{-\infty}^{\infty} E^+(t)\,\mathrm{e}^{-\mathrm{i}\omega t}\,\mathrm{d}t\,. \tag{12.12}$$

These quantities relate to the real electric field

$$\begin{aligned} E(t) &= E^+(t) + E^-(t) \\ &= 2\,\mathrm{Re}\{E^+(t)\} \\ &= 2\,\mathrm{Re}\{E^-(t)\} \end{aligned} \tag{12.13}$$

and its complex Fourier transform

$$\tilde{E}(\omega) = \tilde{E}^+(\omega) + \tilde{E}^-(\omega)\,. \tag{12.14}$$

$E^+(t)$ is complex-valued and can therefore be expressed uniquely in terms of its amplitude and phase

$$\begin{aligned} E^+(t) &= |E^+(t)|\,\mathrm{e}^{\mathrm{i}\Phi(t)} \\ &= |E^+(t)|\,\mathrm{e}^{\mathrm{i}\Phi_0}\,\mathrm{e}^{\mathrm{i}\omega_0 t}\,\mathrm{e}^{\mathrm{i}\Phi_a(t)} \\ &= \sqrt{\frac{I(t)}{2\varepsilon_0 cn}}\,\mathrm{e}^{\mathrm{i}\Phi_0}\,\mathrm{e}^{\mathrm{i}\omega_0 t}\,\mathrm{e}^{\mathrm{i}\Phi_a(t)} \\ &= \frac{1}{2}A(t)\,\mathrm{e}^{\mathrm{i}\Phi_0}\,\mathrm{e}^{\mathrm{i}\omega_0 t}\,\mathrm{e}^{\mathrm{i}\Phi_a(t)} \\ &= E_c(t)\,\mathrm{e}^{\mathrm{i}\Phi_0}\,\mathrm{e}^{\mathrm{i}\omega_0 t} \end{aligned} \tag{12.15}$$

where the meaning of $A(t)$, Φ_0, ω_0 and $\Phi_a(t)$ is the same as in Sect. 12.1.1 and $E_c(t)$ is the complex-valued envelope function without the absolute phase and without the rapidly oscillating carrier-frequency phase factor, a quantity often used in ultrafast optics. The envelope function $A(t)$ is given by

$$A(t) = 2|E^+(t)| = 2|E^-(t)| = 2\sqrt{E^+(t)E^-(t)} \tag{12.16}$$

and coincides with the less general expression in (12.1). The complex positive-frequency part $\tilde{E}^+(\omega)$ can be analogously decomposed into amplitude and phase

$$\begin{aligned} \tilde{E}^+(\omega) &= |\tilde{E}^+(\omega)|\,\mathrm{e}^{-\mathrm{i}\phi(\omega)} \\ &= \sqrt{\frac{\pi}{\varepsilon_0 cn}I(\omega)}\,\mathrm{e}^{-\mathrm{i}\phi(\omega)}\,, \end{aligned} \tag{12.17}$$

where $|\tilde{E}^+(\omega)|$ is the spectral amplitude, $\phi(\omega)$ is the spectral phase and $I(\omega)$ is the spectral intensity proportional to the power spectrum density (PSD) – the familiar quantity measured with a spectrometer. From

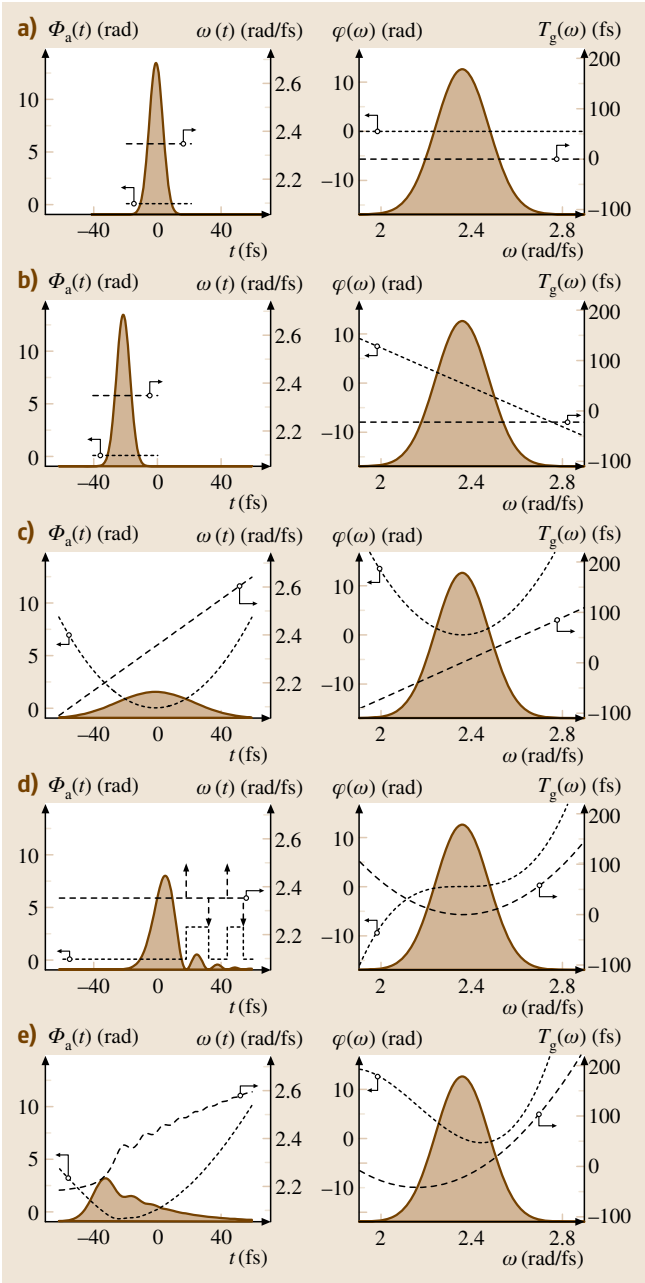

Fig. 12.3a–o Examples for changing the temporal shape of a 800 nm 10 fs pulse via the frequency domain (except **(n)**). *Left*: temporal intensity $I(t)$ (*shaded*), additional temporal phase $\Phi_a(t)$ (*dotted*), instantaneous frequency $\omega(t)$ (*dashed*), *right*: spectral intensity $I(\omega)$ (*shaded*), spectral phase $\phi(\omega)$ (*dotted*) and group delay $T_g(\omega)$ (*dashed*) for a: **(a)** bandwidth-limited Gaussian laser pulse of 10 fs duration; **(b)** bandwidth-limited Gaussian laser pulse of 10 fs duration shifted in time to −20 fs due to a linear phase term in the spectral domain ($\phi' = -20$ fs); **(c)** symmetrical broadened Gaussian laser pulse due to $\phi'' = 200\,\text{fs}^2$; **(d)** third-order spectral phase ($\phi''' = 1000\,\text{fs}^3$) leading to a quadratic group delay. The central frequency of the pulse arrives first, while frequencies on either side arrive later. The corresponding differences in frequencies cause beats in the temporal intensity profile. Pulses with cubic spectral phase distortion have therefore oscillations after (or before) a main pulse depending on the sign of ϕ'''. The higher the side pulses, the less meaningful the FWHM pulse duration; **(e)** combined action of all spectral phase coefficients **(a)**–**(d)**. Phase unwrapping and blanking is employed when appropriate ▶

(12.8) the relation $-\phi(\omega) = \phi(-\omega)$ is obtained. As will be shown in Sect. 12.1.3 it is precisely the manipulation of this spectral phase $\phi(\omega)$ in the experiment which – by virtue of the Fourier transformation (12.11) – creates changes in the real electric field strength $E(t)$ (12.13) without changing $I(\omega)$. If the spectral intensity $I(\omega)$ is manipulated as well, additional degrees of freedom are accessible for generating temporal pulse shapes at the expense of lower energy.

Note that the distinction between positive- and negative-frequency parts is made for mathematical correctness. In practice only real electric fields and positive frequencies are displayed. Moreover, as usually only the shape and not the absolute magnitude of the envelope functions in addition to the phase function are the quantities of interest, all the prefactors are commonly omitted.

The temporal phase $\Phi(t)$ (12.4) contains frequency-versus-time information, leading to the definition of the instantaneous frequency $\omega(t)$ (12.5). In a similar fashion $\phi(\omega)$ contains time-versus-frequency information and we can define the group delay $T_g(\omega)$, which describes the relative temporal delay of a given spectral component (Sect. 12.1.3)

$$T_g(\omega) = \frac{\mathrm{d}\phi}{\mathrm{d}\omega} \,. \tag{12.18}$$

All quantities discussed so far are displayed in Fig. 12.2 for a pulse that initially appears to be complex. Usually the spectral amplitude is distributed around a center frequency (or carrier frequency) ω_0. Therefore – for *well-behaved* pulses – it is often helpful to expand the

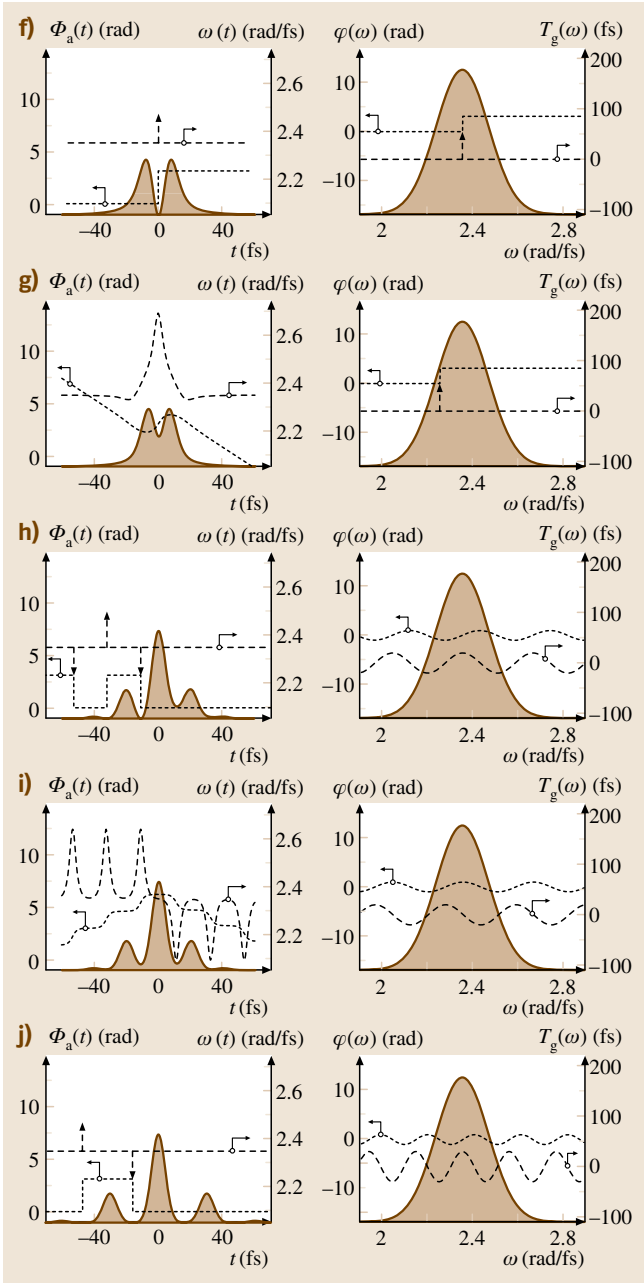

Fig. 12.3 **(f)** π step at the central frequency; **(g)** π step displaced from central frequency; **(h)** sine modulation at central frequency with $\phi(\omega) = 1\sin(20\,\mathrm{fs}(\omega-\omega_0))$; **(i)** cosine modulation at central frequency with $\phi(\omega) = 1\cos(20\,\mathrm{fs}(\omega-\omega_0))$; **(j)** sine modulation at central frequency with $\phi(\omega) = 1\sin(30\,\mathrm{fs}(\omega-\omega_0))$

spectral phase into a Taylor series

$$\phi(\omega) = \sum_{j=0}^{\infty} \frac{\phi^{(j)}(\omega_0)}{j!} \cdot (\omega-\omega_0)^j$$

$$\text{with} \quad \phi^{(j)}(\omega_0) = \left.\frac{\partial^j \phi(\omega)}{\partial \omega^j}\right|_{\omega_0}$$

$$= \phi(\omega_0) + \phi'(\omega_0)(\omega-\omega_0) + \frac{1}{2}\phi''(\omega_0)(\omega-\omega_0)^2 + \frac{1}{6}\phi'''(\omega_0)(\omega-\omega_0)^3 + \ldots \qquad (12.19)$$

The spectral phase coefficient of zeroth order describes in the time domain the absolute phase ($\Phi_0 = -\phi(\omega_0)$). The first-order term leads to a temporal translation of the envelope of the laser pulse in the time domain (the Fourier shift theorem) but not to a translation of the carrier. A positive $\phi'(\omega_0)$ corresponds to a shift towards later times. An experimental distinction between the temporal translation of the envelope via linear spectral phases in comparison to the temporal translation of the whole pulse is, for example, discussed in [12.20, 21]. The coefficients of higher order are responsible for changes in the temporal structure of the electric field. The minus sign in front of the spectral phase in (12.17) is chosen so that a positive $\phi''(\omega_0)$ corresponds to a linearly up-chirped laser pulse. For illustrations see Figs. 12.2 and 12.3a–e.

There is a variety of analytical pulse shapes where this formalism can be applied to get analytical expressions in both domains. For general pulse shapes a numerical implementation is helpful. For illustrations we will focus on a Gaussian laser pulse $E_{\mathrm{in}}^{+}(t)$ (not normalized to pulse energy) with a corresponding spectrum $\tilde{E}_{\mathrm{in}}^{+}(\omega)$. Phase modulation in the frequency domain leads to a spectrum $\tilde{E}_{\mathrm{out}}^{+}(\omega)$ with a corresponding electric field $E_{\mathrm{out}}^{+}(t)$ of

$$E_{\mathrm{in}}^{+}(t) = \frac{E_0}{2} \mathrm{e}^{-2\ln 2 \frac{t^2}{\Delta t^2}} \mathrm{e}^{\mathrm{i}\omega_0 t} \,. \qquad (12.20)$$

Here Δt denotes the FWHM of the corresponding intensity $I(t)$. The absolute phase is set to zero, the carrier frequency is set to ω_0, additional phase terms are set to zero as well. The pulse is termed an unchirped pulse in the time domain. For $\tilde{E}_{\mathrm{in}}^{+}(\omega)$ we obtain the spectrum

$$\tilde{E}_{\mathrm{in}}^{+}(\omega) = \frac{E_0 \Delta t}{2} \sqrt{\frac{\pi}{2\ln 2}} \mathrm{e}^{-\frac{\Delta t^2}{8\ln 2}(\omega-\omega_0)^2} \,. \qquad (12.21)$$

The FWHM of the temporal intensity profile $I(t)$ and the spectral intensity profile $I(\omega)$ are related by $\Delta t \Delta\omega = 4 \ln 2$, where $\Delta\omega$ is the FWHM of the spectral intensity profile $I(\omega)$.

Usually this equation, known as the time–bandwidth product, is given in terms of frequencies ν rather than circular frequencies ω and we obtain

$$\Delta t \Delta \nu = \frac{2 \ln 2}{\pi} = 0.441 \,. \tag{12.22}$$

Several important consequences arise from this approach and are summarized before we proceed:

- The shorter the pulse duration, the larger the spectral width. A Gaussian pulse with $\Delta t = 10$ fs centered at 800 nm has a ratio of $\Delta\nu/\nu \approx 10\%$, corresponding to a wavelength interval $\Delta\lambda$ of about 100 nm. Taking into account the wings of the spectrum, a bandwidth comparable to the visible spectrum is *consumed* to create the 10 fs pulse.
- For a Gaussian pulse the equality in (12.22) is only reached when the instantaneous frequency (12.5) is time-independent, that is the temporal phase variation is linear. Such pulses are termed Fourier-transform-limited pulses or bandwidth-limited pulses.
- Adding nonlinear phase terms leads to the inequality $\Delta t \Delta \nu \geq 0.441$.
- For other pulse shapes a similar time-bandwidth inequality can be derived

$$\Delta t \Delta \nu \geq K \,. \tag{12.23}$$

  Values of K for different pulse shapes are given in Table 12.1 and [12.22].
- Sometimes pulse durations and spectral widths defined by the FWHM values are not suitable measures. This is, for example, the case in pulses with substructure or broad wings causing a considerable part of the energy to lie outside the range given by the FWHM. In these cases one can use averaged values derived from the appropriate second-order moments [12.4, 23]. By this it can be shown [12.6, 24, 25] that, for any spectrum, the shortest pulse in time always occurs for a constant spectral phase $\phi(\omega)$. Taking a shift in the time domain also into account a description of a bandwidth-limited pulse is given by

$$\tilde{E}^+(\omega) = |\tilde{E}^+(\omega)| \, \mathrm{e}^{-\mathrm{i}\phi(\omega_0)} \, \mathrm{e}^{-\mathrm{i}\phi'(\omega_0)(\omega-\omega_0)} \,.$$

160	160.0	160.0	160.2	160.9	163.9	174.4	211.7

One feature of Gaussian laser pulses is that adding the quadratic term $\frac{1}{2}\phi''(\omega_0)(\omega-\omega_0)^2$ to the spectral phase function also leads to a quadratic term in the temporal phase function and therefore to linearly chirped pulses. This situation arises for example when passing an optical pulse through a transparent medium as will be shown in Sect. 12.1.3. The complex fields for such laser pulses are given by [12.26, 27]

$$\tilde{E}^+_{out}(\omega) = \frac{E_0\Delta t}{2} \times\sqrt{\frac{\pi}{2\ln 2}}\, e^{-\frac{\Delta t^2}{8\ln 2}(\omega-\omega_0)^2}\, e^{-i\frac{1}{2}\phi''(\omega_0)(\omega-\omega_0)^2} \tag{12.24}$$

$$E^+_{out}(t) = \frac{E_0}{2\gamma^{\frac{1}{4}}}\, e^{-\frac{t^2}{4\beta\gamma}}\, e^{i\omega_0 t}\, e^{i(at^2-\varepsilon)} \tag{12.25}$$

with

$$\beta = \frac{\Delta t_{in}^2}{8\ln 2}\,, \quad \gamma = 1+\frac{\phi''^2}{4\beta^2}\,, \quad a = \frac{\phi''}{8\beta^2\gamma}\,,$$

and

$$\varepsilon = \frac{1}{2}\arctan\left(\frac{\phi''}{2\beta}\right) = -\Phi_0\,.$$

For the pulse duration Δt_{out} (FWHM) of the linearly chirped pulse (quadratic temporal phase function at^2) we obtain the convenient formula

$$\Delta t_{out} = \sqrt{\Delta t^2 + \left(4\ln 2\frac{\phi''}{\Delta t}\right)^2}\,. \tag{12.26}$$

The statistical definition of the pulse duration derived with the help of the second moment of the intensity distribution uses twice the standard deviation σ to characterize the pulse duration by

$$2\sigma = \frac{\Delta t_{out}}{\sqrt{2\ln 2}}\,, \tag{12.27}$$

which is slightly shorter than the FWHM. These values are exact for Gaussian pulses considering only the ϕ'' part and can be used as a first estimate for temporal pulse broadening whenever ϕ'' effects are the dominant contribution (Sect. 12.1.3). Some values of the symmetric pulse broadening due to ϕ'' are given in Table 12.2 and exemplified in Fig. 12.3c.

Spectral phase coefficients of third order, i. e., a contribution to the phase function $\phi(\omega)$ of the form $\frac{1}{6}\phi'''(\omega_0)\cdot(\omega-\omega_0)^3$ are referred to as third-order dispersion (TOD). TOD applied to the spectrum given by (12.21) yields the phase-modulated spectrum

$$\tilde{E}^+_{out}(\omega) = \frac{E_0\Delta t}{2} \times\sqrt{\frac{\pi}{2\ln 2}}\, e^{-\frac{\Delta t^2}{8\ln 2}(\omega-\omega_0)^2}\, e^{-i\frac{1}{6}\phi'''(\omega_0)\cdot(\omega-\omega_0)^3} \tag{12.28}$$

and leads to asymmetric temporal pulse shapes [12.27] of the form

$$E^+_{out}(t) = \frac{E_0}{2}\sqrt{\frac{\pi}{2\ln 2}}\frac{\Delta t}{\tau_0}\,\mathrm{Ai}\left(\frac{\tau-t}{\Delta\tau}\right) e^{\frac{\ln 2}{2}\cdot\frac{\frac{2}{3}\tau-t}{\tau_{1/2}}}\, e^{i\omega_0 t}$$

$$\text{with } \tau_0 = \sqrt[3]{\frac{|\phi'''|}{2}} \quad \phi^3 = 2(\ln 2)^2\phi'''$$

$$\Delta\tau = \tau_0\,\mathrm{sign}(\phi''')$$

$$\tau = \frac{\Delta t^4}{16\phi^3} \quad \text{and} \quad \tau_{1/2} = \frac{\phi^3}{\Delta t^2} \tag{12.29}$$

where Ai describes the Airy function. Equation (12.29) shows that the temporal pulse shape is given by the product of an exponential decay with a half-life period of $\tau_{1/2}$ and the Airy function shifted by τ and stretched by $\Delta\tau$. Figure 12.3d shows an example of a pulse subjected to TOD. The pulse shape is characterized by a strong initial pulse followed by a decaying pulse sequence. Because TOD leads to a quadratic group delay the central fre-

Table 12.3 Dispersion parameters n, $\mathrm{d}n/\mathrm{d}\lambda$, $\mathrm{d}^2n/\mathrm{d}\lambda^2$, $\mathrm{d}^3n/\mathrm{d}\lambda^3$, T_g, GDD and TOD for common optical materials for $L = 1\,\mathrm{mm}$. quency of the pulse arrives first, while frequencies on either side arrive later. The corresponding differences in frequencies cause beats in the temporal intensity profile explaining the oscillations after (or before) the main pulse. The beating is also responsible for the phase jumps of π which occur at the zeros of the Airy function. Most of the relevant properties of TOD modulation are determined by the parameter $\Delta\tau$, which is proportional to $\sqrt[3]{|\phi'''|}$. The ratio $\Delta\tau/\Delta t$ determines whether the pulse is significantly modulated. If $|\Delta\tau/\Delta t| \geq 1$, a series of sub-pulses and phase jumps are observed. The sign of ϕ''' controls the time direction of the pulse shape: a positive value of ϕ''' leads to a series of post-pulses as shown in Fig. 12.3d whereas negative values of ϕ''' cause a series of prepulses. The time shift of the most intense sub-pulse with respect to the unmodulated pulse and the FWHM of the sub-pulses are on the order of $\Delta\tau$. For these highly asymmetric pulses, the FWHM is not a meaningful quantity to characterize the pulse duration. Instead, the statistical definition of the pulse duration yields a formula similar to (12.26) and (12.27)

$$2\sigma = \sqrt{\frac{\Delta t^2}{2\ln 2} + 8(\ln 2)^2\left(\frac{\phi'''}{\Delta t^2}\right)^2}\,. \tag{12.30}$$

It is a general feature of polynomial phase modulation functions that the statistical pulse duration of a modulated pulse is

$$2\sigma = \sqrt{\tau_1^2 + \tau_2^2}\,, \tag{12.31}$$

where $\tau_1 = \Delta t/\sqrt{2\ln 2}$ is the statistical duration of the unmodulated pulse [cf. (12.21)] and $\tau_2 \propto \phi^{(n)}/\Delta t^{n-1}$

a contribution only dependent on the nth-order spectral phase coefficient. As a consequence, for strongly modulated pulses, when $\tau_2 \gg \tau_1$, the statistical pulse duration increases approximately linearly with $\phi^{(n)}$.

It is not always advantageous to expand the phase function $\phi(\omega)$ into a Taylor series. Periodic phase functions, for example, are generally not well approximated by polynomial functions. For sinusoidal phase functions of the form $\phi(\omega) = A\sin(\omega\Upsilon + \varphi_0)$ analytic solutions for the temporal electric field can be found for any arbitrary unmodulated spectrum $\tilde{E}^+_{\text{in}}(\omega)$. To this end we consider the modulated spectrum (Sect. 12.1.3)

$$\tilde{E}^+_{\text{out}}(\omega) = \tilde{E}^+_{\text{in}}(\omega)\,\mathrm{e}^{-\mathrm{i}A\sin(\omega\Upsilon+\varphi_0)}\,, \tag{12.32}$$

where A describes the amplitude of the sinusoidal modulation, Υ the frequency of the modulation function (in units of time) and φ_0 the absolute phase of the sine function. Making use of the Jacobi–Anger identity

$$\mathrm{e}^{-A\sin(\omega\Upsilon+\varphi_0)} = \sum_{n=-\infty}^{\infty} J_n(A)\,\mathrm{e}^{-\mathrm{i}n(\omega\Upsilon+\varphi_0)}\,, \tag{12.33}$$

where $J_n(A)$ describes the Bessel function of the first kind and order n, we rewrite the phase modulation function

$$\tilde{M}(\omega) = \sum_{n=-\infty}^{\infty} J_n(A)\,\mathrm{e}^{-\mathrm{i}n(\omega\Upsilon+\varphi_0)} \tag{12.34}$$

to obtain its Fourier transform

$$M(t) = \sum_{n=-\infty}^{\infty} J_n(A)\,\mathrm{e}^{-\mathrm{i}n\varphi_0}\delta(n\Upsilon - t)\,, \tag{12.35}$$

where $\delta(t)$ describes the delta function. Since multiplication in the frequency domain corresponds to convolution in the time domain, the modulated temporal electrical field $E^+_{\text{out}}(t)$ is given by the convolution of the unmodulated field $E^+_{\text{in}}(t)$ with the Fourier transform of the modulation function $M(t)$, i. e., $E^+_{\text{out}}(t) = E^+_{\text{in}}(t) * M(t)$. Making use of (12.35) the modulated field reads

$$E^+_{\text{out}}(t) = \sum_{n=-\infty}^{\infty} J_n(A)\,E^+_{\text{in}}(t - n\Upsilon)\,\mathrm{e}^{-\mathrm{i}n\varphi_0}\,. \tag{12.36}$$

Equation (12.36) shows that sinusoidal phase modulation in the frequency domain produces a sequence of sub-pulses with a temporal separation determined by the parameter Υ and well-defined relative temporal phases controlled by the absolute phase φ_0. Provided the individual sub-pulses are temporally separated, i. e., Υ is chosen to exceed the pulse width, the envelope of each sub-pulse is a (scaled) replica of the unmodulated pulse envelope. The amplitudes of the sub-pulses are given by $J_n(A)$ and can therefore be controlled by the modulation parameter A. Examples of sinusoidal phase modulation are shown in Fig. 12.3h–j. The influence of the absolute phase φ_0 is depicted in Fig. 12.3h and i, whereas Fig. 12.3j shows how separated pulses are obtained by changing the modulation frequency Υ. A detailed description of the effect of sinusoidal phase modulation can be found in [12.28].

12.1.3 Changing the Temporal Shape via the Frequency Domain

For the following discussion it is useful to think of an ultrashort pulse as being composed of groups of quasi-monochromatic waves, that is of a set of much longer wave packets of narrow spectrum all added together coherently. In vacuum the phase velocity $v_{\text{p}} = \omega/k$ and the group velocity $v_{\text{g}} = \mathrm{d}\omega/\mathrm{d}k$ are both constant and equal to the speed of light c, where k denotes the wave number. Therefore an ultrashort pulse – no matter how complicated its temporal electric field is – will maintain its shape upon propagation in vacuum. In the following we will always consider a bandwidth-limited pulse entering an optical system such as, for example, air, lenses, mirrors, prisms, gratings and combinations of these optical elements. Usually these optical systems will introduce dispersion, that is a different group velocity for each group of quasi-monochromatic waves, and consequently the initial short pulse will broaden in time. In this context the group delay $T_{\text{g}}(\omega)$ defined in (12.18) is the transit time for such a group of monochromatic waves through the system. As long as the intensities are kept low, no new frequencies are generated. This is the area of linear optics and the corresponding pulse propagation has been termed linear pulse propagation. It is convenient to describe the passage of an ultrashort pulse through a linear optical system by a complex optical transfer function [12.4, 25, 29]

$$\tilde{M}(\omega) = \tilde{R}(\omega)\mathrm{e}^{-\mathrm{i}\phi_{\text{d}}}\,, \tag{12.37}$$

that relates the incident electric field $\tilde{E}^+_{\text{in}}(\omega)$ to the output field

$$\tilde{E}^+_{\text{out}}(\omega) = \tilde{M}(\omega)\tilde{E}^+_{\text{in}}(\omega) = \tilde{R}(\omega)\mathrm{e}^{-\mathrm{i}\phi_{\text{d}}}\tilde{E}^+_{\text{in}}(\omega)\,, \tag{12.38}$$

where $\tilde{R}(\omega)$ is the real-valued spectral amplitude response describing for example the variable diffraction efficiency of a grating, linear gain or loss or direct amplitude manipulation. The phase $\phi_{\text{d}}(\omega)$ is termed the spectral phase transfer function. This is the phase ac-

cumulated by the spectral component of the pulse at frequency ω upon propagation between the input and output planes that define the optical system. It is this spectral phase transfer function that plays a crucial role in the design of ultrafast optical systems. Note that this approach is more involved when additional spatial coordinates have to be taken into account as, for example, in the case of *spatial chirp* (i. e., each frequency is displaced in the transverse spatial coordinates). Neglecting spatial chirp this approach can be taken as a first-order analysis of ultrafast optical systems. Although inside an optical system this condition might not be met, usually at the input and output all frequencies are assumed to be spatially overlapped for this kind of analysis. Note also that the independence of the different spectral components in this picture does not mean that the phase relations are random – they are uniquely defined with respect to each other. That means that the corresponding pulse in the time domain (by making use of (12.11) and (12.13)) is completely coherent [12.30] no matter how complicated the shape of the femtosecond laser pulse appears. In the first-order autocorrelation function a coherence time of the corresponding bandwidth-limited pulse would be observed. Only in the higher-order autocorrelations the uniquely defined phase relations show up (examples of second-order autocorrelations for phase- and amplitude-shaped laser pulses are given in Fig. 12.27). Figure 12.3f–j exemplifies the temporal intensity, spectral intensity and related phase functions for often employed phase functions. Figure 12.3k–m displays the same quantities for amplitude modulation. Figure 12.3n is an example for self-phase modulation and Fig. 12.3o shows a double pulse with pulse to pulse delay of 60 fs.

In the following discussion we will concentrate mainly on pure phase modulation and therefore set $\tilde{R}(\omega)$ constant for all frequencies and omit it initially. To model the system the most accurate approach is to include the whole spectral phase transfer function. Often however only the first orders of a Taylor expansion around the central frequency ω_0 are needed.

$$\begin{aligned}\phi_\mathrm{d}(\omega) = {} & \phi_\mathrm{d}(\omega_0) + \phi_\mathrm{d}'(\omega_0)(\omega-\omega_0) \\ & + \frac{1}{2}\phi_\mathrm{d}''(\omega_0)(\omega-\omega_0)^2 \\ & + \frac{1}{6}\phi_\mathrm{d}'''(\omega_0)(\omega-\omega_0)^3 + \ldots \,. \end{aligned} \tag{12.39}$$

If we describe the incident bandwidth-limited pulse by $\tilde{E}_\mathrm{in}^+(\omega) = |\tilde{E}^+(\omega)|\,\mathrm{e}^{-\mathrm{i}\phi(\omega_0)}\,\mathrm{e}^{-\mathrm{i}\phi'(\omega_0)(\omega-\omega_0)}$ then the overall phase ϕ_op of $\tilde{E}_\mathrm{out}^+(\omega)$ is given by

$$\begin{aligned}\phi_\mathrm{op}(\omega) = {} & \phi(\omega_0) + \phi'(\omega_0)(\omega-\omega_0) \\ & + \phi_\mathrm{d}(\omega_0) + \phi_\mathrm{d}'(\omega_0)(\omega-\omega_0) \\ & + \frac{1}{2}\phi_\mathrm{d}''(\omega_0)(\omega-\omega_0)^2 \\ & + \frac{1}{6}\phi_\mathrm{d}'''(\omega_0)(\omega-\omega_0)^3 + \ldots \end{aligned} \tag{12.40}$$

As discussed in the context of (12.19) the constant and linear terms do not lead to a change of the temporal envelope of the pulse. Therefore we will omit in the following these terms and concentrate mainly on the second-order dispersion ϕ'' (also termed the group velocity dispersion (GVD) or group delay dispersion (GDD)) and the third-order dispersion ϕ''' (TOD) whereas we have omitted the subscript d. Strictly they have units of $\mathrm{fs}^2/\mathrm{rad}$ and $\mathrm{fs}^3/\mathrm{rad}^2$, respectively, but usually the units are simplified to fs^2 and fs^3.

A main topic in the design of ultrafast laser systems is the minimization of these higher dispersion terms with the help of suitably designed optical systems to keep the pulse duration inside a laser cavity or at the place of an experiment as short as possible. In the following we will discuss the elements that are commonly used for the *dispersion management*.

Dispersion Due to Transparent Media

A pulse traveling a distance L through a medium with index of refraction $n(\omega)$ accumulates the spectral phase

$$\phi_\mathrm{m}(\omega) = k(\omega)L = \frac{\omega}{c}n(\omega)L \,, \tag{12.41}$$

which is the spectral transfer function due to propagation in the medium as defined above.

The first derivative

$$\frac{\mathrm{d}\phi_\mathrm{m}}{\mathrm{d}\omega} = \phi_\mathrm{m}' = \frac{\mathrm{d}(kL)}{\mathrm{d}\omega} = L\left(\frac{\mathrm{d}\omega}{\mathrm{d}k}\right)^{-1} = \frac{L}{v_\mathrm{g}} = T_\mathrm{g} \tag{12.42}$$

yields the group delay T_g and describes the delay of the peak of the envelope of the incident pulse. Usually the index of refraction $n(\omega)$ is given as a function of wavelength λ, i. e., $n(\lambda)$. Equation (12.42) then reads

$$T_\mathrm{g} = \frac{\mathrm{d}\phi_\mathrm{m}}{\mathrm{d}\omega} = \frac{L}{c}\left(n + \omega\frac{\mathrm{d}n}{\mathrm{d}\omega}\right) = \frac{L}{c}\left(n - \lambda\frac{\mathrm{d}n}{\mathrm{d}\lambda}\right) . \tag{12.43}$$

As different groups of the quasi-monochromatic waves move with different group velocities the pulse

will be broadened. For second-order dispersion we obtain the group delay dispersion (GDD)

$$\text{GDD} = \phi''_{\text{m}} = \frac{\mathrm{d}^2\phi_{\text{m}}}{\mathrm{d}\omega^2} = \frac{L}{c}\left(2\frac{\mathrm{d}n}{\mathrm{d}\omega} + \omega\frac{\mathrm{d}^2 n}{\mathrm{d}\omega^2}\right) = \frac{\lambda^3 L}{2\pi c^2}\frac{\mathrm{d}^2 n}{\mathrm{d}\lambda^2}\,. \tag{12.44}$$

For ordinary optical glasses in the visible range we encounter normal dispersion, i. e., red parts of the laser pulse will travel faster through the medium than blue parts. So the symmetric temporal broadening of the pulse due to ϕ'' will lead to a linearly up-chirped laser pulse as discussed in the context of (12.19) and Fig. 12.3c. In these cases the curvature of $n(\lambda)$ is positive (upward concavity) emphasizing the terminology that positive GDD leads to up-chirped pulses.

For the third-order dispersion (TOD) we obtain

$$\text{TOD} = \phi'''_{\text{m}} = \frac{\mathrm{d}^3\phi_{\text{m}}}{\mathrm{d}\omega^3} = \frac{L}{c}\left(3\frac{\mathrm{d}^2 n}{\mathrm{d}\omega^2} + \omega\frac{\mathrm{d}^3 n}{\mathrm{d}\omega^3}\right) = \frac{-\lambda^4 L}{4\pi^2 c^3}\left(3\frac{\mathrm{d}^2 n}{\mathrm{d}\lambda^2} + \lambda\frac{\mathrm{d}^3 n}{\mathrm{d}\lambda^3}\right). \tag{12.45}$$

Empirical formulas for $n(\lambda)$ such as Sellmeier's equations are usually tabulated for common optical materials so that all dispersion quantities in (12.43–12.45) can be calculated. Parameters for some optical materials are given in Table 12.3 for $L = 1$ mm.

Note that in fiber optics a slightly different terminology is used [12.25]. There the second-order dispersion is the dominant contribution to pulse broadening. The β parameter of a fiber is related to the second-order dispersion by

$$\beta = \frac{\left.\frac{\mathrm{d}^2\phi_{\text{m}}}{\mathrm{d}\omega^2}\right|_{\omega_0}}{L}\left[\frac{\text{ps}^2}{\text{km}}\right], \tag{12.46}$$

where L denotes the length of the fiber. The dispersion parameter D is a measure for the group delay dispersion per unit bandwidth and is given by

$$D = \frac{\omega_0^2}{2\pi c}\,|\beta|\left[\frac{\text{ps}}{\text{nm km}}\right]. \tag{12.47}$$

Angular Dispersion

Transparent media in the optical domain possess positive group delay dispersion leading to up-chirped femtosecond pulses. To compress these pulses, optical systems are needed that deliver negative group delay dispersion, that is systems where the blue spectral components travel faster than the red spectral components. Convenient devices for that purpose are based on angular dispersion delivered by prisms and gratings. We start our discussion again with the spectral transfer function [12.4]

$$\phi(\omega) = \frac{\omega}{c}P_{\text{op}}(\omega)\,, \tag{12.48}$$

where P_{op} denotes the optical path length. Equation (12.48) is the generalization of (12.41). The group delay dispersion is given by

$$\frac{\mathrm{d}^2\phi}{\mathrm{d}\omega^2} = \frac{1}{c}\left(2\frac{\mathrm{d}P_{\text{op}}}{\mathrm{d}\omega} + \omega\frac{\mathrm{d}^2 P_{\text{op}}}{\mathrm{d}\omega^2}\right) = \frac{\lambda^3}{2\pi c^2}\frac{\mathrm{d}^2 P_{\text{op}}}{\mathrm{d}\lambda^2} \tag{12.49}$$

and is similar to (12.44). In a dispersive system the optical path from an input reference plane to an output reference plane can be written

$$P_{\text{op}} = l\cos\alpha\,, \tag{12.50}$$

where $l = l(\omega_0)$ is the distance from the input plane to the output plane for the center frequency ω_0 and α is the angle of rays with frequency ω with respect to the ray corresponding to ω_0. In general, it can be shown [12.4] that the angular dispersion produces negative group delay dispersion

$$\frac{\mathrm{d}^2\phi}{\mathrm{d}\omega^2} \approx -\frac{l\omega_0}{c}\left(\left.\frac{\mathrm{d}\alpha}{\mathrm{d}\omega}\right|_{\omega_0}\right)^2. \tag{12.51}$$

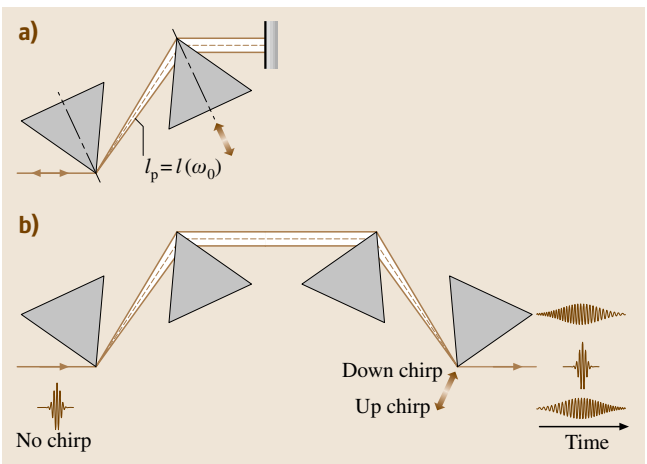

Fig. 12.3a,b Prism sequences for adjustable group delay dispersion. **(a)** Two-prism sequence in double-pass configuration **(b)** four-prism sequence. Note that the spatial distribution of the frequency (spatial chirp) after the second prism can be exploited for phase and/or amplitude manipulations

For pairs of elements (prisms or gratings) the first element provides the angular dispersion and the second element recollimates the spectral components (Fig. 12.3). Using two pairs of elements permits the lateral displacement of the spectral components (spatial chirp) to be canceled out and recovers the original beam profile.

Prism Sequences. Prism pairs [12.31] are well suited to introduce adjustable group delay dispersion (Fig. 12.3). Negative group delay dispersion is obtained via the angular dispersion of the first prism where the second prism is recollimating the beam. Recovering the original beam can be accomplished by either using a second pair of prisms or by using a mirror. Inside a laser cavity one can use either the four-prism arrangement or the two-prism arrangement for linear cavities together with a retroreflecting mirror. Outside a laser cavity the two-prism arrangement is often used, where the retroreflecting mirror is slightly off-axis to translate the recovered beam at the entrance of the system to be picked of by an additional mirror. There is also positive group delay dispersion in the system due to the material dispersion of the actual glass path the laser beam takes through the prism sequence. By translating one of the prisms along its axis of symmetry it is possible to change the amount of glass and therefore the amount of positive group delay dispersion. These devices allow a convenient continuous tuning of group delay dispersion from negative to positive values without beam deviation. The negative group delay dispersion via the angular dispersion can be calculated with the help of (12.48) and (12.50). In the case of minimum deviation and with the apex angle chosen so that the Brewster condition is satisfied (minimum reflection losses), the spectra phase introduced by a four-prism sequence $\phi_p(\omega)$ can be used to approximate the group delay dispersion by [12.4]

$$\frac{d^2\phi_p}{d\omega^2} \approx -\frac{4l_p\lambda^3}{\pi c^2}\left(\frac{dn}{d\lambda}\right)^2 \tag{12.52}$$

and the corresponding third-order dispersion yields approximately

$$\frac{d^3\phi_p}{d\omega^3} \approx \frac{6l_p\lambda^4}{\pi^2 c^3}\frac{dn}{d\lambda}\left(\frac{dn}{d\lambda}+\lambda\frac{d^2n}{d\lambda^2}\right) . \tag{12.53}$$

In order to determine the total GDD and TOD of the four-prism sequence the corresponding contributions of the cumulative mean glass path L (12.44), (12.45) have to be added

$$\frac{d^2\phi_{four-prism}}{d\omega^2} \approx \frac{d^2\phi_m}{d\omega^2}+\frac{d^2\phi_p}{d\omega^2} = \frac{\lambda^3 L}{2\pi c^2}\frac{d^2n}{d\lambda^2}-\frac{4l_p\lambda^3}{\pi c^2}\left(\frac{dn}{d\lambda}\right)^2 , \tag{12.54}$$

$$\frac{d^3\phi_{four-prism}}{d\omega^3} \approx \frac{d^3\phi_m}{d\omega^3}+\frac{d^3\phi_p}{d\omega^3} = \frac{-\lambda^4 L}{4\pi^2 c^3}\left(3\frac{d^2n}{d\lambda^2}+\lambda\frac{d^3n}{d\lambda^3}\right) + \frac{6l_p\lambda^4}{\pi^2 c^3}\frac{dn}{d\lambda}\left(\frac{dn}{d\lambda}+\lambda\frac{d^2n}{d\lambda^2}\right) . \tag{12.55}$$

For a more-detailed discussion and other approaches to the derivation of the total GDD and TOD for a prism sequence see [12.31–35].

In principle one can get any amount of negative group velocity using this method. However a prism distance exceeding 1 m is often impractical. Higher amounts of positive group delay dispersion might be compensated for by the use of highly dispersive SF10 prisms but the higher third-order contribution prevent the generation of ultrashort pulses in the 10 fs regime. Fused quartz is a suitable material for ultrashort pulse generation with minimal higher-order dispersion. For example a four-prism sequence with $l_p = 50$ cm of fused quartz used at 800 nm yields roughly $d^2\phi_p/d\omega^2 \approx -1000\,fs^2$. Estimating a cumulative glass path of $L = 8$ mm when going through the apexes of the prisms yields $d^2\phi_m/d\omega^2 \approx 300\,fs^2$. In this way a maximum group delay dispersion of +700 fs^2 can be compensated.

Note that in such prism sequences the spatial distribution of the frequency components after the second prism can be exploited. Simple apertures can be used to tune the laser or to restrict the bandwidth. Appropriate phase or amplitude masks might be inserted as well.

Grating Arrangements. Diffraction gratings provide group delay dispersion in a similar manner to prisms. Suitable arrangements can introduce positive as well as negative group delay dispersion (see below). When introducing negative group delay dispersion the corresponding device is termed a *compressor*, while a device introducing positive group delay dispersion is termed a *stretcher*. Grating arrangements have the advantage of being much more dispersive but the disadvantage of introducing higher losses than prism arrangements.

As intracavity elements they are used, for example, in high-gain fiber lasers. Outside laser cavities gratings are widely used:

- To compensate for large amounts of dispersion in optical fibers.
- For ultrashort pulse amplification up to the petawatt regime with a technique called chirped pulse amplification (CPA) [12.36]: In order to avoid damage to the optics and to avoid nonlinear distortion of the spatial and temporal profile of the laser beam, ultrashort pulses (10 fs to 1 ps) are typically stretched in time by a factor of 10^3–10^4 prior to injection into the amplifier. After the amplification process the pulses have to be recompressed, compensating also for additional phase accumulated during the amplification process. The topic is reviewed in [12.37].
- For pulse-shaping applications (Sect. 12.1.3).
- In combination with prism compressors to compensate third-order dispersion terms in addition to the group delay dispersion [12.38]. This was the combination employed to establish the long standing world record of 6 fs with dye lasers in 1987 [12.39].

In Fig. 12.4 the reflection of a laser beam from a grating is displayed. The spectrum of an ultrashort laser pulse will be decomposed after reflection into the first order according to the grating equation

$$\sin(\gamma) + \sin(\theta) = \frac{\lambda}{d}\,, \tag{12.56}$$

where γ is the angle of incidence, θ is the angle of the reflected wavelength component and d^{-1} is the grating constant. Blazed diffraction gratings have maximum transmission efficiency when employed in the Littrow configuration, i. e., $\gamma = \theta(\lambda_0) =$ blaze angle. This has

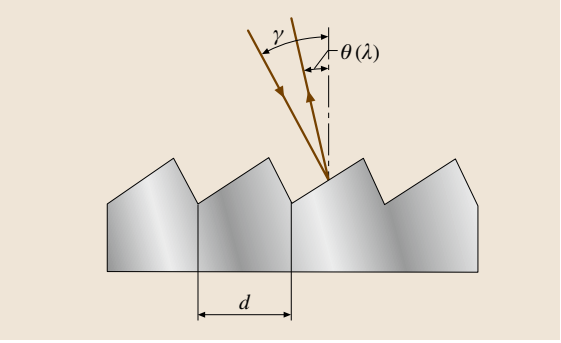

Fig. 12.4 Reflection from a grating: the spectrum of an ultrashort laser pulse will be decomposed after reflection (γ = angle of incidence, $\theta(\lambda)$ = angle of reflection, d^{-1} = grating constant)

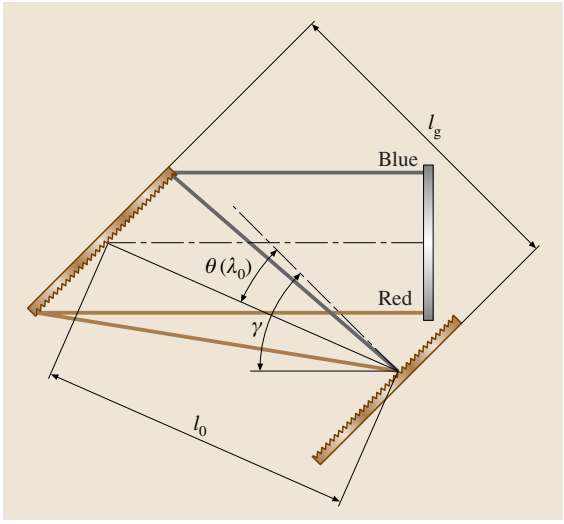

Fig. 12.5 Grating compressor with parallel gratings and a mirror for beam inversion (cf. the corresponding prism setup in Fig. 12.3a). The red spectral components travel a longer optical path than the blue spectral components (l_g denotes the distance between the grating; l_0 denotes the optical path for the center wavelength λ_0 between two gratings; both lengths are used by different authors in deriving the group delay dispersion and the third order dispersion)

the additional advantage that astigmatism is minimized. Blazed gold gratings with an efficiency of 90–95% are commercially available with a damage threshold of $> 250\,\mathrm{mJ/cm^2}$ for a 1 ps pulse. For higher efficiency and higher damage threshold dielectric gratings have been developed, for example, dielectric gratings with 98% efficiency at 1053 nm and a damage threshold $> 500\,\mathrm{mJ/cm^2}$ for fs pulses are available.

A basic grating compressor (Fig. 12.5) consists of two parallel gratings in a double-pass configuration [12.40]. The first grating decomposes the ultrashort laser pulse into its spectral components. The second grating is recollimating the beam. The original beam is recovered by use of a mirror that inverts the beam. As in such a device the red spectral components experience a longer optical path than the blue spectral components, such an arrangement is suitable to compensate for material dispersion.

In Fig. 12.6 different grating configurations are displayed that produce: (a) zero, (b) positive and (c) negative group delay dispersion. Between the gratings an additional telescope is employed.

In Fig. 12.6a, a so-called zero-dispersion compressor is depicted. The system consists of a telescope that

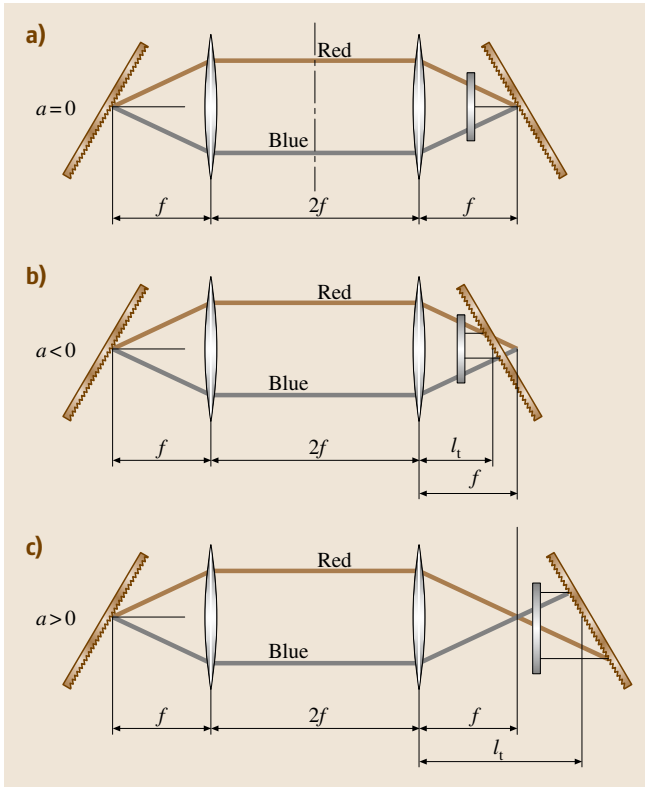

Fig. 12.6a–c Different grating configurations that produce **(a)** zero, **(b)** positive and **(c)** negative group delay dispersion. Arrangement **(a)** corresponds to a zero-dispersion compressor, **(b)** to a stretcher and **(c)** to a compressor. The zero-dispersion compressor is often used in pulse-shaping devices. The *dashed line* in **(a)** indicates the Fourier-transform plane, whereas the stretcher and compressor are key components for chirped pulse amplification

images the laser spot on the first grating onto the second grating. All wavelength components experience the same optical path. In this manner zero net dispersion is obtained. Due to the finite beam size on the grating the components belonging to the same wavelength emerge as a parallel beam and are focused with the lens of focal length f spectrally into the symmetry plane thus providing a Fourier transform plane for pulse shaping, masking or encoding (Sect. 12.1.3, Fig. 12.10).

Translating one of the gratings out of the focal plane closer to the telescope (Fig. 12.6b) results in an arrangement where the red components travel along a shorter optical path. The device introduces positive group delay dispersion (stretcher).

A compressor is realized by translating the grating away from the focal plane (Fig. 12.6c).

The dispersion can be further modified by the use of a magnifying telescope. In order to avoid material dispersion in the lenses and to minimize aberration effects, reflective telescopes and especially Öffner telescopes are usually employed [12.41, 42].

The phase transfer function ϕ_g for these arrangements can be calculated with the help of a matrix formalism [12.43] and considering the case of finite beam size [12.44].

For a reflective setup (neglecting material dispersion) the group delay dispersion and the third-order dispersion of the three telescope arrangements (magnification = 1) in Fig. 12.6 can be described using a characteristic length L

$$\frac{\mathrm{d}^2\phi_g}{\mathrm{d}\omega^2} = -\frac{\lambda^3}{\pi c^2 \mathrm{d}^2}\frac{1}{\cos[\theta(\lambda)]^2}L\,, \tag{12.57}$$

$$\frac{\mathrm{d}^3\phi_g}{\mathrm{d}\omega^3} = \frac{\mathrm{d}^2\phi_g}{\mathrm{d}\omega^2}\frac{3\lambda}{2\pi c}\left(1+\frac{\lambda}{d}\frac{\tan[\theta(\lambda)]}{\cos[\theta(\lambda)]}\right). \tag{12.58}$$

With the help of the grating equation (12.56) $\cos[\theta(\lambda)]$ is given by:

$$\cos[\theta(\lambda)] = \sqrt{1-\left(\frac{\lambda}{d}-\sin\gamma\right)^2}\,. \tag{12.59}$$

In reflective telescope setups usually only one grating is employed using suitable beam-folding arrangements. This reflects the situation when both gratings in Fig. 12.6 are moved out of the focal plane symmetrically. For the telescope arrangements we therefore obtain as the characteristic length $L = 2fa$. According to Fig. 12.6 the parameter a is determined by the distance of the grating to the lens

$$a = \frac{l_t}{f} - 1 \begin{cases} \text{Compressor: } l_t > f,\ a > 0 \\ \text{Zero-dispersion compressor: } l_t = f, \\ \qquad\qquad\qquad\qquad a = 0 \\ \text{Stretcher: } l_t < f,\ a < 0\,. \end{cases} \tag{12.60}$$

For the grating compressor depicted in Fig. 12.5 the characteristic length L is given by

$$L = l_0 = \frac{l_g}{\sqrt{1-\left(\frac{\lambda}{d}-\sin(\gamma)\right)^2}}\,, \tag{12.61}$$

where l_0 is the optical path length of the center wavelength λ_0 between the gratings and l_g is the distance of the gratings.

For the compressor in Fig. 12.5 we obtain a group delay dispersion of $-1\times10^6\,\mathrm{fs}^2$ ($\lambda = 800\,\mathrm{nm}$, $d^{-1} =$

1200 l/mm, $l_0 = 300$ mm; $\gamma = 28,6°$ (Littrow)) being orders of magnitude higher than the example given for the prism sequence.

Dispersion Due to Interference (Gires–Tournois Interferometers and Chirped Mirrors)

The physics behind dispersion due to interference can be illustrated in the following way [12.25]. Periodic structures transmit or reflect waves of certain frequencies. Strong Bragg-type scattering usually occurs for wavelengths comparable to the periodicity of the structure. In this context the periodicity induces a resonance in the transfer function of the system, which then has dispersion associated with it.

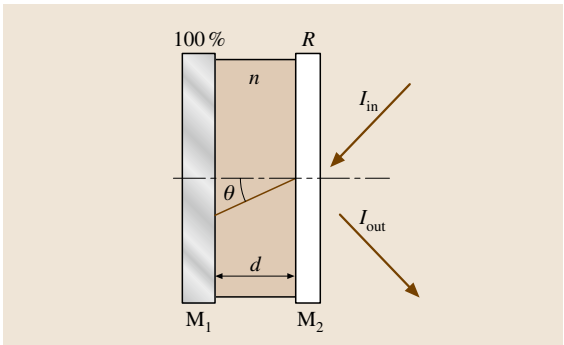

Fig. 12.7 Schematic diagram of a Gires–Tournois interferometer (GTI)

A Gires–Tournois interferometer (GTI) [12.45] is a special case of a Fabry–Pérot interferometer in which one mirror (M1) is a 100% reflector and the top mirror (M2) is a low reflector, typically with a reflectivity of a few percent (Fig. 12.7). The group delay dispersion of such a device is given by (see for example [12.46] or [12.3] and references therein)

$$\frac{\mathrm{d}^2\phi_{\mathrm{GTI}}}{\mathrm{d}\omega^2} = \frac{-2t_0^2(1-R)\sqrt{R}\sin\omega t_0}{(1+R-2\sqrt{R}\cos\omega t_0)^2}\,, \qquad (12.62)$$

where $t_0 = (2nd\cos\theta)/c$ is the round-trip time of the Fabry–Pérot [12.47], n is the refractive index of the material between the two layers, d is the thickness of the interferometer and θ is the internal angle of the beam between the layers. In this formula material dispersion is neglected and R is the intensity reflectivity of the top reflector. The group delay dispersion can be conveniently tuned either by tilting the device or by changing the interferometer spacing. Increasing t_0 increases the dispersion, but at the same time reduces the frequency range over which the group delay dispersion is constant. These devices are typically used in applications employing pulses larger than 100 fs. For picosecond pulses

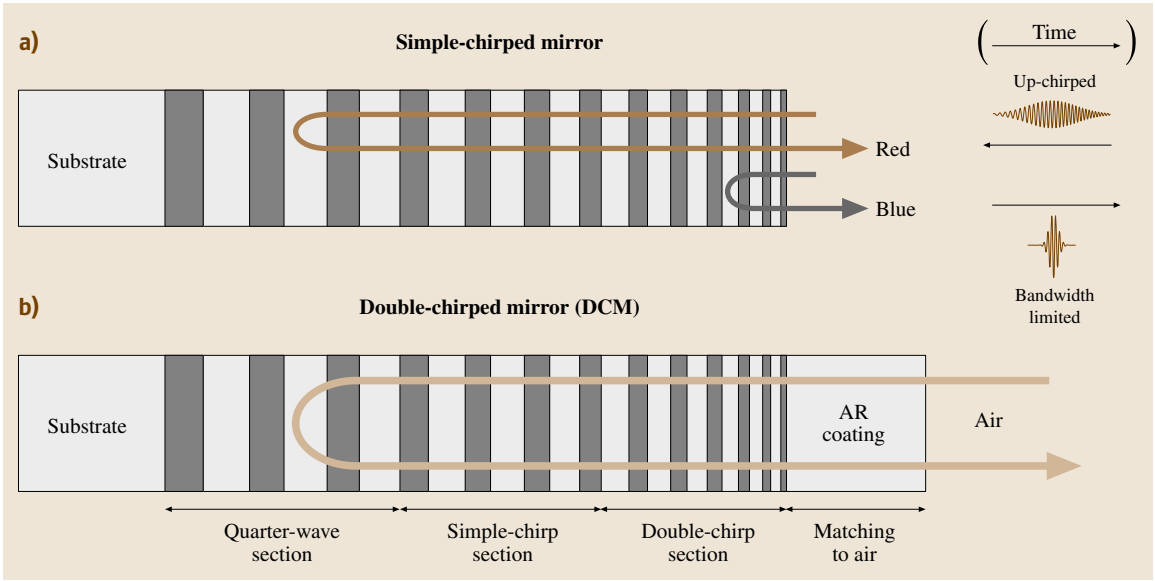

Fig. 12.8a,b Schematic of different types of chirped mirrors: **(a)** simple chirped mirror; the wavelength-dependent penetration depth is depicted. For a proper design, for example, an incoming up-chirped laser pulse can be transformed into a bandwidth-limited pulse after reflection. **(b)** double chirped mirror; impedance matching by an additional antireflection coating on top of the mirror and by a duty-cycle modulation inside the mirror

the mirror spacing is on the order of several mm, for femtosecond lasers the spacing has to be on the order of a few μm. In order to overcome the limitations for femtosecond applications, GTIs were constructed on the basis of dielectric multilayer systems [12.48]. The corresponding spectral transfer functions can be found in [12.4].

Nowadays specially designed dielectric multilayer mirrors offer a powerful alternative for dispersion management. Usually a dielectric mirror consists of alternating transparent pairs of high-index and low-index layers where the optical thickness of all layers is chosen to equal to 1/4 of the Bragg wavelength λ_B. Interference of the reflections at the index discontinuities add up constructively for the Bragg wavelength. If the optical thickness of the layers along the mirror structure is varied, then the Bragg wavelength depends on the penetration depth. Figure 12.8 shows an example where the red wavelength components penetrate deeper into the mirror structure then the blue wavelength components. An up-chirped pulse impinging on the mirror surface can be transformed into a bandwidth-limited pulse after reflection from this mirror. A gradual increase of the Bragg wavelength along the mirror producing a negative group delay dispersion was demonstrated by [12.49] and the corresponding mirror was termed a chirped mirror, allowing for the construction of compact femtosecond oscillators [12.50]. Of course the Bragg wavelength does not have to be varied linearly with the penetration depth. In principle chirp laws $\lambda_B(z)$ can be found for compensation of higher-order dispersion in addition. It was realized, that the desired dispersion characteristics of the chirped mirrors can be spoiled by spurious effects originating from multiple reflections within the coating stack and at the interface to the ambient medium, leading to dispersion oscillations (see the discussion on GTI). An exact coupled-mode analysis [12.51] was used to develop a so-called double-chirp technique in combination with a broadband antireflection coating, in order to avoid the oscillations in the group delay dispersion. Using accurate analytical expressions double chirped mirrors could be designed and fabricated with a smooth and custom-tailored group delay dispersion [12.52] suitable for generating pulses in the two cycle regime directly from a Ti:sapphire laser [12.53]. Double chirping has the following meaning: in conventional chirped mirrors, equal optical lengths of high-index (hi) and low-index (lo) material within one period are employed, i. e., $P_{lo} = P_{hi} = \lambda_B/4$. Double chirping keeps the duty cycle η as an additional degree of freedom under the constraint: $P_{lo} + P_{hi} = (1-\eta)\lambda_B/2 + \eta\lambda_B/2 = \lambda_B/2$. Dispersion oscillations could further be suppressed by a back-side-coated double-mirror design [12.54].

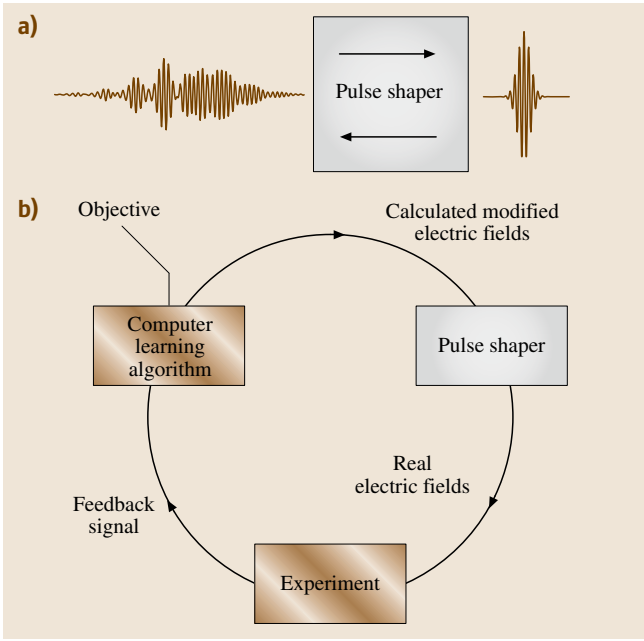

Fig. 12.9 **(a)** Pulse-shaping issues (schematic): creation of bandwidth-limited pulses from complex-structured pulses (*left to right*). Creation of *tailored* pulse shapes (*right to left*). **(b)** Adaptive femtosecond pulse shaping: a femtosecond laser system (not indicated) and a computer-controlled pulse shaper are used to generate specific electric fields that are sent into an experiment. After deriving a suitable feedback signal from the experiment a learning algorithm calculates a modified electric fields based on the information from the experimental feedback signal and the user-defined control objective. The improved laser pulse shapes are tested and evaluated in the same manner. Cycling through this loop many times results in iteratively optimized laser pulse shapes that finally approach the objective

Pulse Shaping

The methods for dispersion management described so far are well suited to compensate higher-order dispersion terms in linear optical setups such as group delay dispersion and third-order dispersion. Much greater flexibility in dispersion management and the possibility of creating complex-shaped laser pulses with respect to phase, amplitude and polarization state is given with the help of (computer-controlled) pulse-shaping techniques (Fig. 12.9a). The issue was recently reviewed by *Weiner* [12.29, 55].

A new class of experiments emerged in which pulse-shaping techniques were combined with some experimental signal embedded in a feedback learning loop [12.56–59]. In this approach a given pulse shape is evaluated in order to produce an improved pulse shape, which enhances the feedback signal (see Fig. 12.9b). These techniques have an impact on an increasing number of scientists in physics, chemistry, biology and engineering. This is due to the fact that primary light-induced processes can be studied and even actively controlled via adaptive femtosecond pulse shaping. For a small selection of work in various areas see [12.60–71].

Because of their short duration, femtosecond laser pulses cannot be directly shaped in the time domain. Therefore, the idea of pulse shaping is to modulate the incident spectral electric field $\tilde{E}^{+}_{\mathrm{in}}(\omega)$ by a linear mask, i. e., the optical transfer function, $\tilde{M}(\omega)$ in the frequency domain. According to (12.38) this results in an outgoing shaped spectral electric field $\tilde{E}^{+}_{\mathrm{out}}(\omega) = \tilde{M}(\omega)\tilde{E}^{+}_{\mathrm{in}}(\omega) = \tilde{R}(\omega)\mathrm{e}^{-\mathrm{i}\phi_{\mathrm{d}}}\tilde{E}^{+}_{\mathrm{in}}(\omega)$. The mask may modulate the spectral amplitude response $\tilde{R}(\omega)$ and the spectral phase transfer function $\phi_{\mathrm{d}}(\omega)$. Furthermore, polarization shaping has been demonstrated [12.72].

One way to realize a pulse shaper is the Fourier-transform pulse shaper. Its operation principle is based on optical Fourier transformations from the time domain into the frequency domain and vice versa. In Fig. 12.10 a standard design of such a pulse shaper is sketched. The incoming ultrashort laser pulse is dispersed by a grating and the spectral components are focused by a lens of focal length f. In the back focal plane of this lens – the Fourier plane – the spectral components of the original pulse are separated from each other, having minimum beam waists. By this means, the spectral components can be modulated individually by placing a linear mask into the Fourier plane. Afterwards, the laser pulse is reconstructed by performing an inverse Fourier transformation back into the time domain. Optically, this is realized by a mirrored setup consisting of an identical lens and grating. The whole setup – without the linear mask – is called a zero-dispersion compressor since it introduces no dispersion if the $4f$ condition is met (see also Fig. 12.6a). As a part of such a zero-dispersion compressor, the lenses separated by the distance $2f$, form a telescope with unitary magnification. Spectral modulations as stated by (12.38) can be set by inserting the linear mask.

Due to the damage threshold of the linear masks used, cylindrical focusing lenses (or mirrors) are normally used instead of spherical optics. The standard

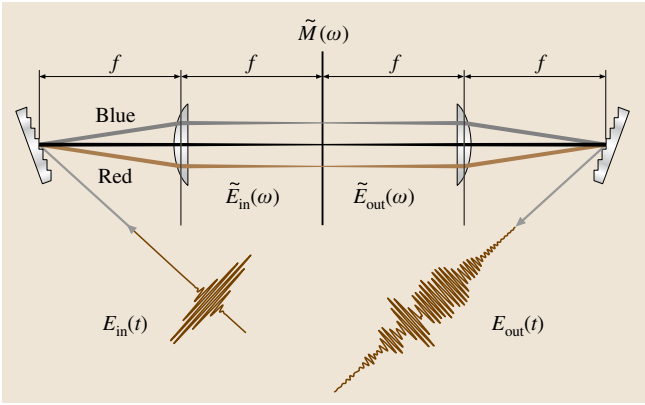

Fig. 12.10 Basic layout for Fourier-transform femtosecond pulse shaping

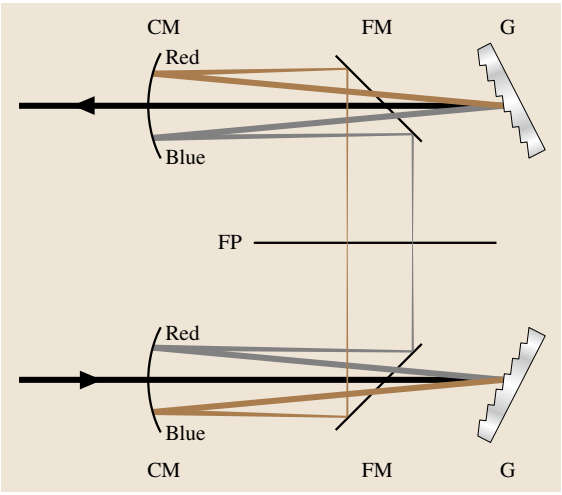

Fig. 12.11 Dispersion-optimized layout for Fourier transform femtosecond pulse shaping. The incoming beam is dispersed by the first grating (G). The spectral components go slightly out of plane and are sagitally focused by a cylindrical mirror (CM) via a plane-folding mirror (FM) in the Fourier plane (FP). Then the original beam is reconstructed by a mirrored setup

design in Fig. 12.10 has the advantage that all optical components are positioned along an optical line (grating in the Littrow configuration). For ultrashort pulses below 100 fs, however, spatial and temporal reconstruction errors become a problem due to the chromatic abberations introduced by the lenses. Therefore, lenses are often replaced by curved mirrors. In general, optical errors are minimized if the tilting angles of the curved mirrors within the telescope are as small as possible.

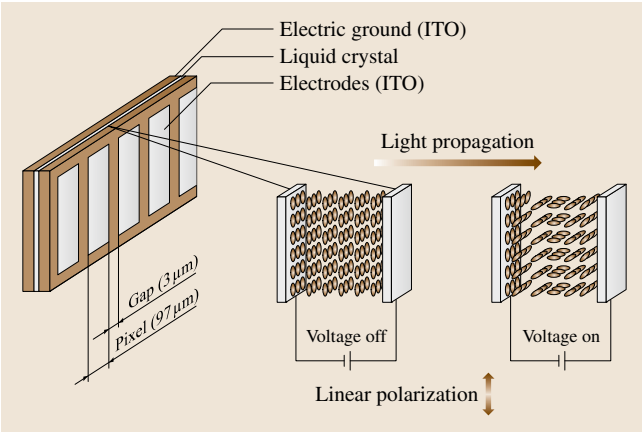

Fig. 12.12 Schematic diagram of an electronically addressed phase-only liquid-crystal spatial light modulator (LC-SLM). By adjusting the voltages of the individual pixels, the liquid-crystal molecules reorient themselves on average partially along the direction of the electric field. This leads to a change in refractive index and therefore to a phase modulation which can be independently controlled for different wavelength components

A folded, compact and dispersion optimized setup is depicted in Fig. 12.11 [12.73]. For ultrashort pulses in the < 10 fs regime prisms have been employed as dispersive elements instead of gratings [12.74].

A very popular linear mask for computer-controlled pulse shaping in such setups is the liquid-crystal spatial light modulator (LC-SLM). A schematic diagram of an electronically addressed phase-only LC-SLM is depicted in Fig. 12.12. In the Fourier plane the individual wavelength components of the laser pulse are spatially dispersed and can be conveniently manipulated by applying voltages at the separate pixels leading to changes of the refractive index. Upon transmission of the laser beam through the LC-SLM a frequency-dependent phase is acquired due to the individual pixel voltage values and consequently the individual wavelength components are retarded with respect to each other. Actual LC-SLMs contain up to 640 pixels [12.75]. In this way, an immensely large number of different spectrally phase modulated pulses can be produced. A phase-only LC-SLM does to a first approximation not change the spectral amplitudes and therefore the integrated pulse energy remains constant for different pulse shapes. By virtue of the Fourier transform properties, spectral phase changes result in phase- and amplitude-modulated laser pulse temporal profiles, as depicted schematically in Fig. 12.13.

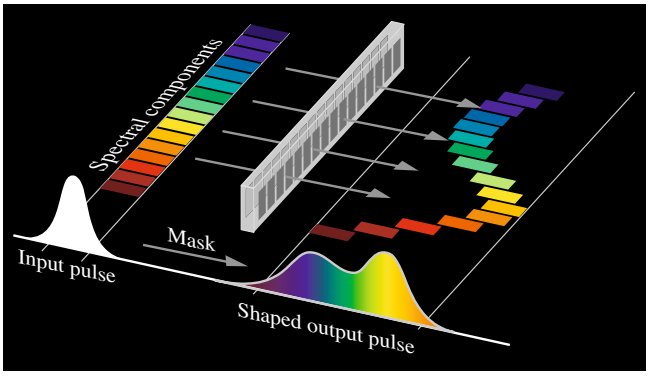

Fig. 12.13 Schematic illustration of shaping the temporal profile of an ultrashort laser pulse by retardation of the spectrally dispersed individual wavelength components in a phase only LC-SLM. The LC-SLM is located in the Fourier plane of the setups displayed in Figs. 12.10 and 12.11

If such an LC-SLM is oriented at 45° with respect to the linear polarization of the incident light field (either with the help of a wave plate or a suitably designed LC-SLM), polarization is induced in addition to retardance. A single LC-SLM together with a polarizer can be used therefore as an amplitude modulator. However, this also leads to phase modulation depending on the amplitude modulation level. For independent phase and amplitude control dual LC-SLMs are currently used. In such a setup a second LC-SLM is fixed back-to-back at −45° with respect to the linear polarization of light in front of the first LC-SLM and the stack is completed with a polarizer. For an early setup for independent phase and amplitude modulations see [12.76] whereas modern configurations are described in [12.55]. Alternatively, simple amplitude modulation functions $\tilde{R}(\omega)$ can be realized by insertion of absorbing material at specific locations in the Fourier plane, thus eliminating the corresponding spectral components within the pulse spectrum [12.77].

For polarization shaping [12.72] the polarizer is removed and spectral phase modulation can be imposed independently onto two orthogonal polarization directions. The interference of the resulting elliptically polarized spectral components leads to complex evolutions of the polarization state in the time domain. As any element between the LC-SLM stack and the experiment can modify the polarization evolution, dual-channel spectral interferometry and experimentally calibrated Jones matrix analysis have been employed for characterization [12.78]. A representation of a complex polarization shaped pulse is displayed in Fig. 12.14. Such pulses open up an immense range of applications,

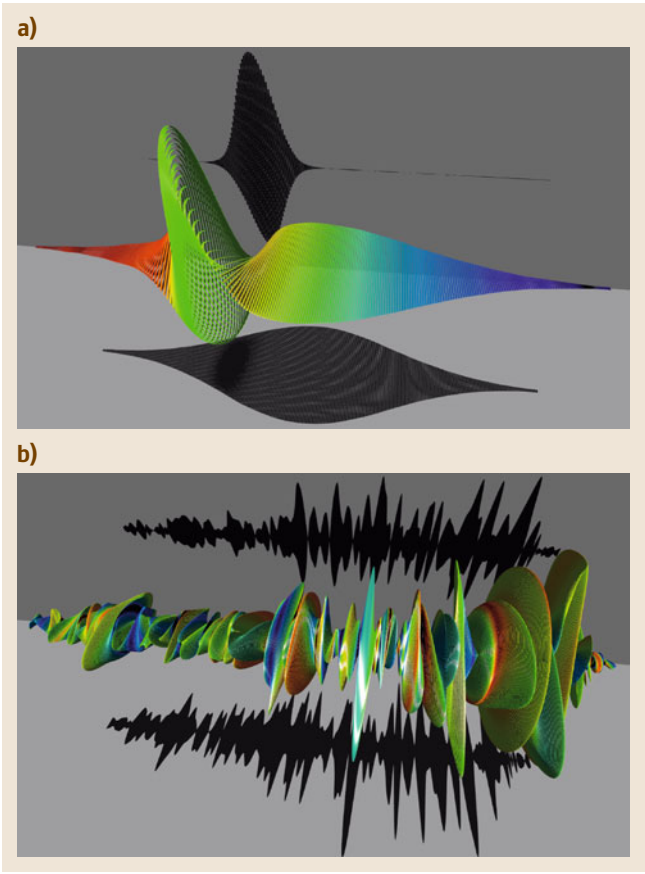

Fig. 12.14a,b Electric field representation for a polarization-modulated laser pulse. Time evolves from *left* to *right*, and electric field amplitudes are indicated by the sizes of the corresponding ellipses. The momentary frequency can be indicated by *colors*, and the *shadows* represent the amplitude envelopes of the orthogonal electric field components. **(a)** A Gaussian-shaped laser spectrum supporting 80 fs laser pulses is taken for an illustrative theoretical example. **(b)** A complex experimentally realized polarization modulated laser pulse is shown. The width of the temporal window is 7.5 ps. (After [12.78])▶

especially in quantum control, because vectorial properties of multiphoton transitions can be addressed [12.79, 80].

Another possibility to realize phase-only pulse shaping is based on deformable mirrors consisting of a small number (∼10) of electrostatically controlled membrane mirrors [12.81]. These devices are placed in the Fourier plane and by a slight out-of-plane tilt upon reflection half of the optics can be saved (Fig. 12.15 for an illustration). The use of a micro-mirror array with 240×200 pixels used in reflection and a waveform update rate larger than 1 kHz has also been demonstrated [12.82].

Acoustooptic modulators (AOMs) can be used for programmable pulse shaping as well. Two different approaches exist.

One approach is depicted in Fig. 12.16 and is reviewed in [12.83, 84]. The AOM crystal is oriented at the Bragg angle to the Fourier plane of a zero-dispersion compressor. In the visible TeO_2 crystals are normally used whereas in the infrared InP crystals are employed. A programmable radio-frequency (RF) signal driving the piezoelectric transducer of the AOM creates an acoustic wave that propagates through the crystal. As light travels at orders of magnitude faster velocity, the acoustic wave can be considered as a fixed modulated grating at the moment the spatially dispersed laser beam hits the crystal. The amplitude and phase of the acoustic wave determine the diffraction efficiency and phase shift at each point in space. The beam is diffracted typically below 1° by the AOM via the photoelastic effect. AOMs can place in the order of thousand independent features onto the spectrum and have a significantly faster update rate than an LC-SLMs. On the other hand the optical throughput of such devices is well below 50% and typical mode-locked laser sources running at 100 MHz repetition rate in general cannot be pulse shaped because the acoustic wave is traveling several tens of microns in 10 ns. This is not a limitation for amplified ultrafast laser systems where the pulse repetition rate is usually slower than the acoustic aperture time, since this allows the acoustic pattern to be synchronized to each amplifier pulse and to be refreshed before the next pulse arrives.

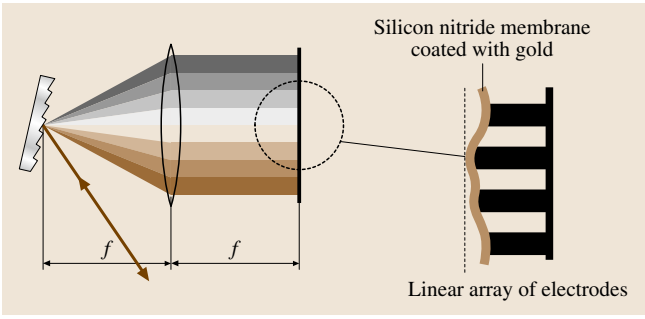

Fig. 12.15 Schematic of a phase-only deformable-mirror pulse shaper

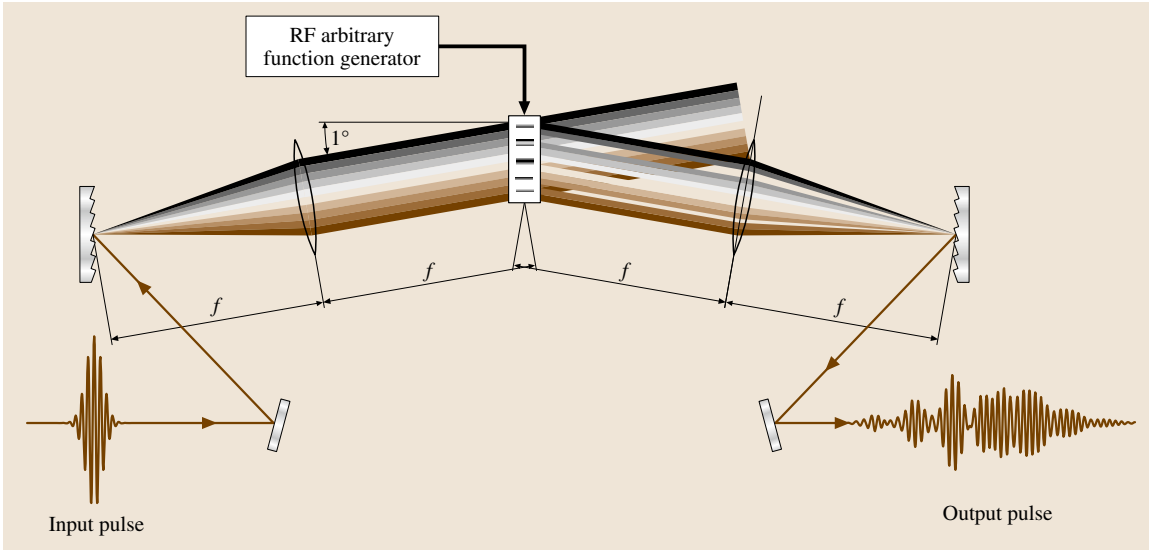

Fig. 12.16 Programmable pulse-shaping device based on the use of an acoustooptic modulator as the spatial light modulator

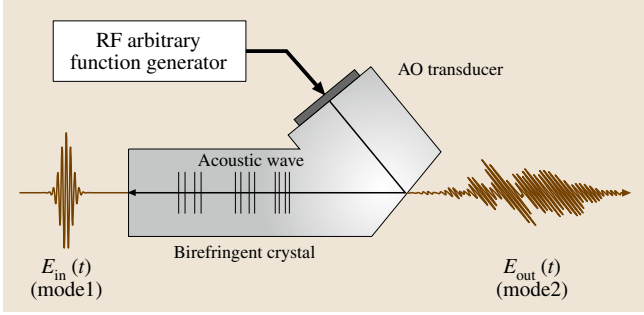

Fig. 12.17 Schematic of an acoustooptic programmable dispersive filter (AOPDF)

The other AOM approach is based on an acoustooptic programmable dispersive filter (AOPDF) and does not need to be placed in the Fourier plane of a $4f$ device [12.85–87]. A schematic of this device is shown in Fig. 12.17. Again, a programmable signal driving the piezoelectric transducer of the AOM creates an acoustic wave that propagates through the crystal and reproduces spatially the temporal shape of the RF signal. Two optical modes can be coupled efficiently by acoustooptic interaction only in the case of phase matching. If there is locally only one spatial frequency in the acoustic grating, then only one optical frequency can be diffracted at that position from the fast ordinary axis (mode 1) to the slow extraordinary axis (mode 2). The incident optical short pulse is initially in mode 1. Different groups of optical frequency components travel a different distance before they encounter phase-matched spatial frequencies in the acoustic grating. At that position part of the energy is diffracted onto mode 2. The pulse leaving the device at mode 2 will be made of all spectral components that have been diffracted at the various positions. If the velocities of the two modes are different, each frequency will see a different time delay. The amplitude of specific frequency components of the output pulse is controlled by the acoustic power at the position where that frequency components are diffracted. With the help of a 2.5 cm long TeO_2 crystal, a group delay range of 3 ps, 6.7 fs temporal resolution and 30% diffraction efficiency has been reported [12.86]. In general pulse shapers based on LC-SLMs or deformable mirrors have low transmission losses, are suitable also for high-repetition-rate mode-locked laser oscillators, do not impose additional chirp and have a low waveform update rate on the order of 10 Hz. Setups based on AOMs have high transmission losses and impose additional chirp, but they have a waveform update rate on the order of 100 kHz. Both AOMs and LC-SLMs can impose on the order of 1000 independent features onto the spectrum and are both suitable for amplitude and phase modulation. Programmable polarization shaping has been demonstrated so far only with LC-SLMs.

The programmable femtosecond pulse-shaping techniques described so far allow control of the temporal profile of an output waveform in phase, amplitude

and polarization. This can be thought of as control over one spatial dimension, the direction of propagation. With that respect this *temporal-only* pulse shaping is one dimensional. Automated two-dimensional phase-only pulse shaping employing an optically addressed reflective two-dimensional SLM with negligible interpixel gaps allows real-space pulse shaping, in which a sample or device is irradiated with different temporally shaped waveforms at different locations [12.88]. The pulse-shaping arrangement is similar to conventional $4f$ spectral filtering arrangements, with the difference that the incoming beam is expanded in one dimension and the two-dimensional SLM is employed in a reflection geometry. Such a unit has been employed for two-dimensional shaping of surface polaritons [12.89].

12.2 Generation of Femtosecond Laser Pulses via Mode Locking

Femtosecond laser pulses can be generated directly from a wide variety of lasers with wavelengths ranging from the ultraviolet to the infrared. This range is greatly extended by the use of nonlinear frequency-conversion techniques. Continuous tuning is achieved, for example, via optical parametric oscillators followed by (cascaded) sum- and difference-frequency mixing. Tuning of amplified femtosecond laser systems is achieved via optical parametric amplifiers. The generation of a white-light continuum is also a standard technique for the generation of new wavelengths. With high-power femtosecond laser systems the x-ray region can be reached by focusing the radiation into a solid-state material or via high-harmonic generation whereas the latter technique also opens the door to the attosecond regime. The THz spectral region can be accessed via femtosecond lasers as well.

With very few exceptions the generation of ultrashort pulses relies on a technique known as mode locking. The topic has been covered in review articles [12.46, 90–93], in several books devoted to ultrashort laser pulses [12.2–5, 94] and in general laser text books [12.47, 95–97]. For a recent compilation of mode locking different laser systems ranging from solid-state lasers through fiber lasers to semiconductor lasers see, for example, [12.98].

Here we will limit the description to the basic concepts of mode locking.

A laser is typically constructed with a pair of mirrors separated by a distance L which enclose a gain medium and other components. In a continuous-wave (CW) laser or in a pulsed laser where the pulse duration is substantially greater then the cavity round-trip time T_{RT}

$$T_{RT} = \frac{2L}{c} \tag{12.63}$$

(c is the velocity of light and for simplicity the refractive index is taken as unity) the radiation energy is spread out fairly uniform between the mirrors. The generation of ultrashort laser pulses is based on the confinement of the energy in the cavity into a small spatial region. This single pulse bounces back and forth between the mirrors at the velocity of light. As indicated in Fig. 12.18 the output beam arises from partial transmission of the intracavity pulse through the output coupler and therefore consists of a train of replicas of the cavity pulse separated by $2L$ in space or by T_{RT} in time. A laser operating in this fashion is said to be mode locked for reasons that will become apparent soon.

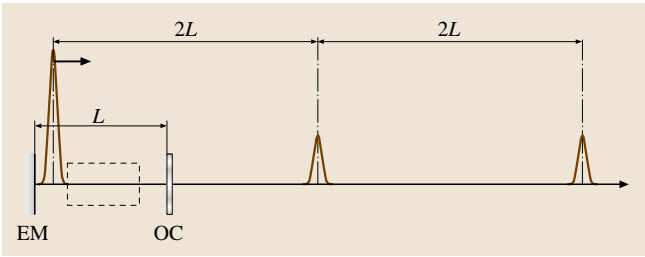

Fig. 12.18 Simple snapshot representation of a mode-locked laser. The pulse is propagating back and forth between the end mirror (EM) and the output coupler (OC). The pulses in the output beam are separated by $2L$ in space (or $2L/c = T_{RT}$ in time). The *dashed box* represents the gain medium and other laser components

In order to understand the physics behind mode locking a more precise discussion is necessary. Generally two conditions govern the frequency spectrum of a laser. On the one hand the overall envelope of the spectrum is determined by the emission profile of the lasing medium and by the characteristics of any wavelength selective element within the cavity. On the other hand for each transverse mode the cavity allows oscillations only at discrete frequencies ν_n the so-called *longitudinal* modes. Usually only one *transverse* mode namely the lowest-order mode having a Gaussian profile is permitted to oscillate in mode-locked laser systems. The corresponding set of longitudinal modes consists of

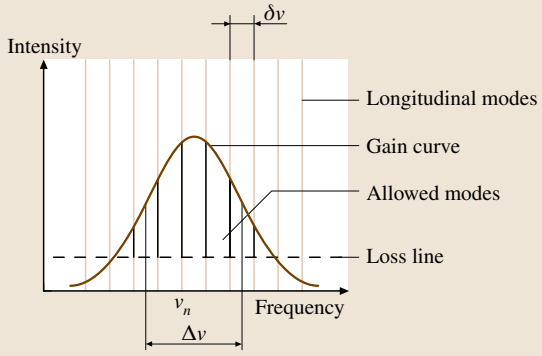

Fig. 12.19 Longitudinal modes in a laser cavity. The spacing $\delta\nu$ of the modes is determined by the cavity length via $\delta\nu = c/2L = 1/T_{RT}$. Only those modes exceeding the loss line will lase. The FWHM of the spectral intensity function $\delta\nu$ is also indicated in addition. In lasers used for pulse generation below 10 fs the number of modes lasing is of the order 10^6

a picket fence of regularly spaced modes – also termed the frequency comb – being separated by a frequency of $\delta\nu$

$$\delta\nu = \nu_{n+1} - \nu_n = \frac{c}{2L} = \frac{1}{T_{RT}} \,. \tag{12.64}$$

Taking both conditions together the emission spectrum of the laser will consist of those modes which have sufficient gain to lie above the threshold for lasing. The corresponding relationships are depicted in Fig. 12.19. The total electric field $E(t)$ resulting from such a multimode oscillation at a fixed point in space, say at one of the mirrors, is given by

$$E(t) = \sum_{n=0}^{N-1} E_n \sin[2\pi(\nu_0 + n\delta\nu)t + \varphi_n(t)] \,, \tag{12.65}$$

where N is the number of oscillating modes, $\varphi_n(t)$ is the phase of the nth mode and ν_0 is the lowest-frequency mode above the lasing threshold.

The average laser power output $P(t)$ is proportional to the square of the total electric field. Unless some method of fixing the relative phases $\varphi_n(t)$ of the modes is used they will generally vary randomly in time. This produces a random variation of the average laser power output $P(t)$ as a result of the random interference between modes.

If the phases are fixed with respect to each other ($\varphi_n(t) \to \varphi_n$), it can be shown that $E(t)$ and accordingly $P(t)$ repeats with the period T_{RT}. In the case that the

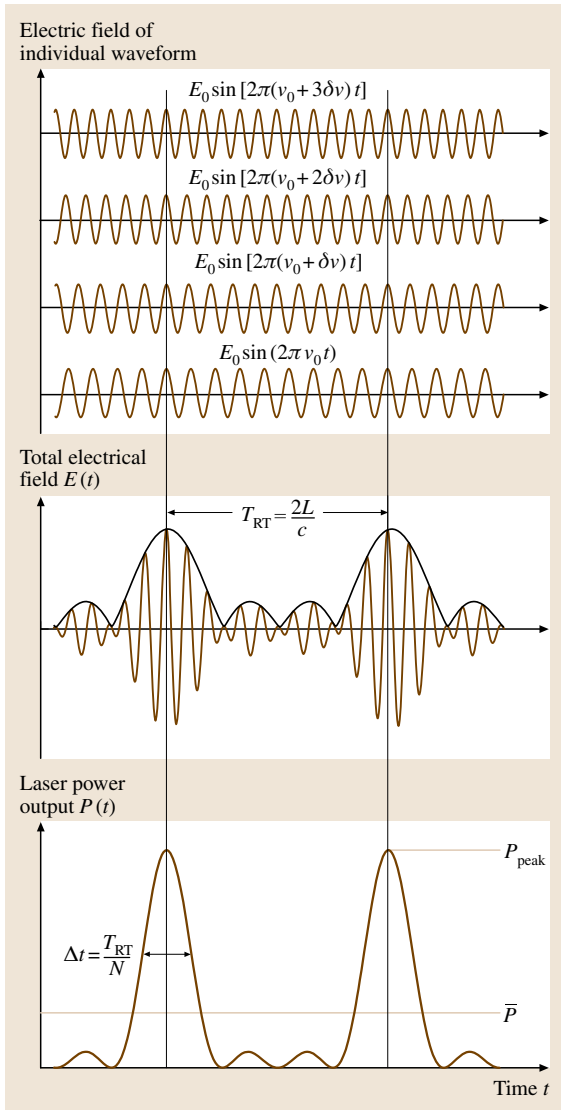

Fig. 12.20 Superposition of four sine waves with equal amplitude E_0, differing in frequency by $\delta\nu$. The electric field of the individual waveforms, the total electric field $E(t)$, its envelope and the output power $P(t)$ as well as the average power $\bar{P}$ are shown

individual φ_n are randomly fixed, each *noise spike* in the random but periodic laser output power has a duration Δt roughly equal to $1/\Delta\nu$ with $\Delta\nu$ being the FWHM of the spectral intensity function (Fig. 12.22e,f). Within this approach the properties of perfectly mode-locked lasers are determined by a linear phase relation $\varphi_n = n\alpha$ amongst the modes, that is, a constant phase re-

lation between two adjacent modes. This is the so-called mode-locking condition. To simplify the analysis of this case identical amplitudes $E_n = E_0$ for all modes are assumed corresponding to a square gain profile and for convenience α is set to zero. The summation of (12.65) then yields

$$E(t) = E_0 \sin\left[2\pi\left(\nu_0 + \frac{N-1}{2}\delta\nu\right)t\right]\frac{\sin(N\pi\delta\nu t)}{\sin(\pi\delta\nu t)} \,. \tag{12.66}$$

The resulting electric field consists of a rapid oscillating part at the light central frequency $\nu_c = \nu_0 + N - 1/2\delta\nu$ with the envelope $\left|\sin(N\pi\delta\nu t)/\sin(\pi\delta\nu t)\right|$ oscillating with $\delta\nu = 1/T_{RT}$. Averaging the fast oscillation ν_c the output power $P(t)$ is given by

$$P(t) = P_0\left(\frac{\sin(N\pi\delta\nu t)}{\sin(\pi\delta\nu t)}\right)^2 \,, \tag{12.67}$$

where P_0 is the average power of one wave.

A discussion of this equation yields important insight into the properties of laser pulses generated via mode locking:

1. The power is emitted in the form of a train of pulses with a period corresponding to the cavity round-trip time $T_{RT} = 1/\delta\nu$.
2. The peak power P_{Peak} increases quadratically with the number N of modes locked together: $P_{Peak} = N^2 P_0$. Mode locking is therefore useful to produce high peak powers and by focusing the laser beam to create high peak intensities; the average power $\bar{P}$ of both a mode-locked and a non-mode-locked laser is given by $\bar{P} = NP_0$.
3. The FWHM pulse duration Δt decreases linearly with the number N of modes locked together or equivalent is approximately the inverse of the gain bandwidth $\Delta\nu$:

$$\Delta t \approx \frac{T_{RT}}{N} = \frac{1}{N\delta\nu} = \frac{1}{\Delta\nu} \,.$$

This is why in the past dye lasers and nowadays solid-state lasers with large gain bandwidths are used to create femtosecond pulses. Ultrafast dye-laser generated pulses as short as 27 fs with around 10 mW of average power [12.99], whereas pulses around 5–6 fs with around 100 mW average power can be produced with Ti:sapphire lasers [12.53, 100]. In general the minimum pulse duration for a given gain profile can be estimated via the bandwidth product introduced in Sect. 12.1.2 and is summarized for various line shapes in Table 12.1.

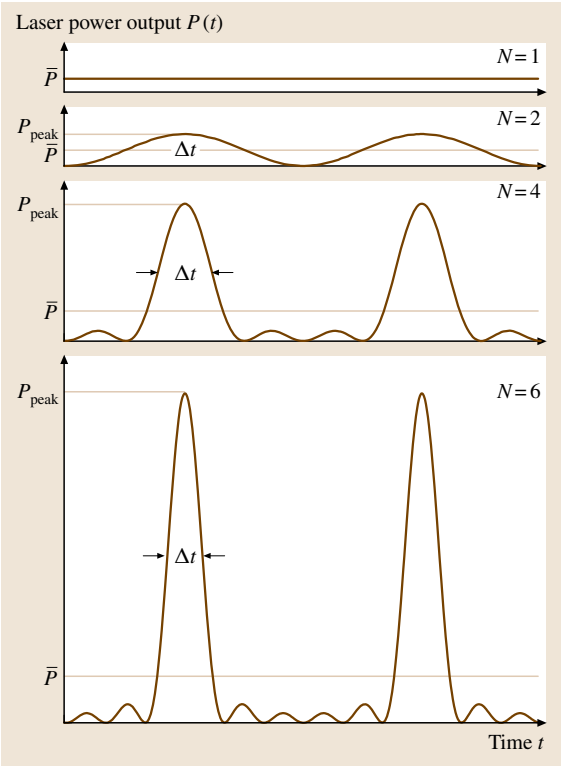

Fig. 12.21 Comparison of the one-, two-, four- and six-mode cases. An increase in the number of modes leads to a decrease in pulse duration. The peak power P_{peak} increases quadratically with the number N of modes locked together, whereas the average power $\bar{P}$ of both a mode-locked and a non-mode-locked laser scales linearly with N

The basic properties of mode locking are visualized with the help of Figs. 12.20–12.22. Figure 12.20 depicts the Fourier synthesis of a pulse obtained by the superposition of four sine waves with same amplitude and $\varphi_n(t) = 0$ according to (12.65), (12.66), and (12.67).

In Fig. 12.21 the dependence of the pulse duration and peak power on the number of locked modes is illustrated for this case. Finally in Fig. 12.22 the shape of the average output power is displayed for $N = 10$ equally spaced modes with different relative amplitudes and phase angles according to (12.65).

In the following we will summarize some more-technical related considerations. Mode locking is essentially achieved by applying a periodic loss (or gain) modulation to the intracavity radiation whose period is matched to the cavity round trip time. The mechanisms can be described either in the frequency or time domain.

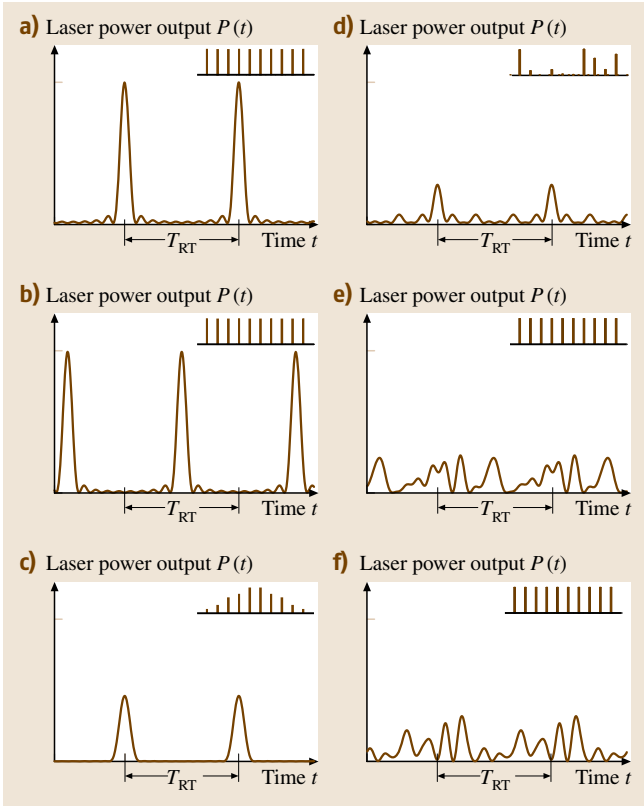

Fig. 12.22a–f Output power for 10 equally spaced modes with different relative amplitudes (as indicated in the *insets*) and phase angles (T_{RT} is the round-trip time): **(a)** linear phase relation $\varphi_n = n\alpha$ amongst the modes (i. e., a constant phase relation between two adjacent modes) with $\alpha = 0$, **(b)** linear phase relation $\varphi_n = n\alpha$ with $\alpha = \pi$, **(c)** Gaussian spectrum with five modes at FWHM and linear phase relation with $\alpha = 0$, **(d)** random spectrum and linear phase relation with $\alpha = 0$, **(e)** constant spectrum and random phase, **(f)** constant spectrum and different random phase

In the frequency domain one can start the consideration from the lowest-loss longitudinal mode. The periodic modulation at the frequency of the round-trip time leads to sidebands whose frequencies coincide with those of the adjacent longitudinal laser modes. In this way energy is shifted from one mode to adjacent modes and as a result all longitudinal modes become finally locked in phase. In the time domain, the periodic modulation can be visualized as an intracavity shutter that is open once per round trip time. Such a stationary time window of minimum loss will provide a higher net gain on each round trip for those photons that are concentrated in that time window.

Approaches for providing the periodic modulation are grouped into active and passive schemes, and hybrid schemes that make use of a combination of the two. Active mode locking is obtained with an active element within the laser cavity, for example an acoustooptic modulator, generating a loss modulation. The modulation has to be precisely synchronized with the cavity round trips. Modulating the gain is also possible and can be achieved by synchronous pumping. In this case the amplifying medium of the laser is pumped with the output of another mode-locked laser whereby the cavity round-trip times for both lasers have to be matched. Passive mode locking is obtained by the laser radiation itself that produces the modulation via the interaction with a nonlinear device in the laser cavity. Typical nonlinear devices are some type of saturable absorbers which exhibit an intensity dependent loss as they interact with the laser radiation. This modulation is thus automatically synchronized to the cavity round-trip frequency. Because pulse timing does not have to be externally controlled there is usually no need for synchronization electronics, making passive schemes conceptually simpler compared to active schemes. Originally organic dyes were used as real saturable absorbers, for example to generate picosecond pulses from solid-state lasers and pulses down to 27 fs from dye lasers [12.99]. The shortest pulses nowadays are generated in solid-state laser media, being passively mode-locked using the optical Kerr effect. This approach was originated by [12.101]. Pulses with less than 6 fs are nowadays generated directly from Ti:sapphire lasers with Kerr-lens mode locking [12.53, 100]. At a center wavelength of 800 nm a pulse duration of 5.4 fs contains only two optical cycles at full-width half-maximum of the pulse intensity.

12.3 Measurement Techniques for Femtosecond Laser Pulses

For energy, power, spectrum and spatial beam measurements of ultrashort laser pulses standard laser diagnostic techniques are employed [12.5, 47]. For a measurement of the pulse duration or more interesting of the time-dependent amplitude and phase of an ultrashort laser pulse, dedicated methods have been

developed and are described in several textbooks and references therein [12.4–6]. Here the basic ideas and underlying concepts are highlighted.

As the time and frequency domain are related by the Fourier transformation (12.6, 12.7, 12.11, 12.12) it should be sufficient to measure amplitude and phase in only one of the domains. Let us first shortly reflect on the frequency domain. All spectrometers no matter whether diffraction-grating or Fourier-transform devices measure a quantity that is proportional to the spectral intensity (Sect. 12.3.3) and therefore the phase information is lost.

On the other hand direct electronic techniques for temporal pulse-width measurements, consisting of fast photodiodes and high-bandwidth (sampling) oscilloscopes, are limited to the several-picosecond regime. Fast photodiodes are therefore not suited to record the temporal profile of an ultrashort laser pulse. Often they are employed to check on the mode-locked operation of an ultrafast oscillator or to derive synchronization signals for amplification setups or synchronized experiments. The only detector that reaches a time resolution below one picosecond is the streak camera. However, a characterization of ultrashort pulses with respect to amplitude and phase requires optical correlation techniques, especially methods that operate in the time–frequency domain. The latter techniques will be described in more detail.

12.3.1 Streak Camera

The basic principle of a streak camera is depicted in Fig. 12.23. The ultrafast optical signal $I(t)$ to be analyzed is focused on a photocathode, where the signal is converted almost instantaneously into a number of electrons. The electrons then pass through a horizontal pair of accelerating electrodes and hit a phosphor screen after passing an electron multiplier (MCP). The screen is then imaged with the help of a highly sensitive camera (not shown). The temporal resolution relies on the concept of transferring a temporal profile into a spatial profile. This is done by passing the electron pulse between a pair of vertical sweep electrodes. A high voltage is applied to the sweep electrodes at a timing synchronized to the incident light. During this high-speed sweep the electrons arriving at different times are deflected at different angles and consequently hit the MCP at different vertical directions. In this manner the vertical position on the phosphor screen serves as a time axis. The brightness of the signal is proportional to the intensity profile of the incident ultrashort optical signal. The horizontal direction of the image corresponds to the horizontal location of

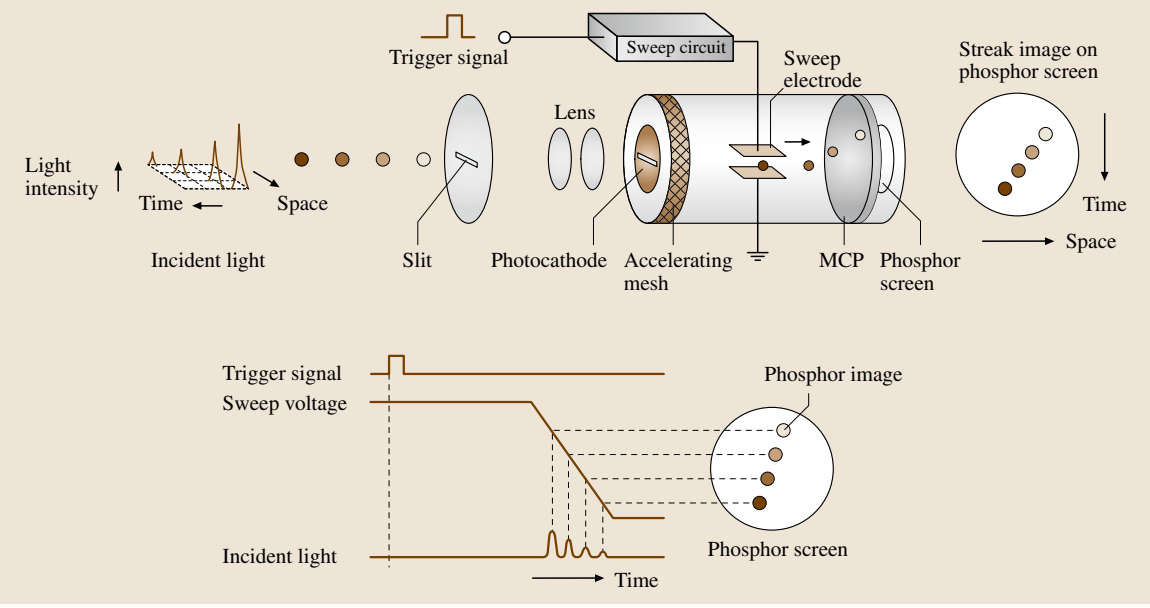

Fig. 12.23 Working principle (*top*) and timing (*bottom*) of a streak camera (after [12.102]). The spatial coordinate might be a wavelength coordinate after having dispersed the ultrashort optical signal with the help of a polychromator

the incident light. For example if the streak camera is used in combination with a polychromator the time variation of the incident light with respect to wavelength can be measured. Time-resolved spectroscopy is therefore one of the application areas of these devices. Commercial devices [12.102, 103] are quoted with a temporal resolution of < 200 fs. Using different photocathode materials a spectral response can be achieved from 115 nm up to 1600 nm. X-ray streak cameras with a temporal resolution of 1.5 ps are quoted as well.

12.3.2 Intensity Autocorrelation and Cross-Correlation

A widely used technique to estimate the pulse duration or to check whether a laser produces pulses rather than statistical intensity fluctuations is to measure the so-called intensity autocorrelation S_{intAC} [12.104]

$$S_{\text{intAC}}(\tau) = \int_{-\infty}^{\infty} I(t)I(t+\tau)\,\mathrm{d}t = \int_{-\infty}^{\infty} I(t)I(t-\tau)\,\mathrm{d}t = S_{\text{intAC}}(-\tau)\,. \quad (12.68)$$

This is the time integral of one pulse intensity multiplied by the intensity of a time-shifted replica of the same pulse as a function of the time shift τ. The intensity autocorrelation has its maximum at $\tau = 0$ and is always symmetrical (12.68). In this fundamental arrangement one pulse serves as a gate to scan the other. It can be realized with any interferometer (Fig. 12.24) that splits the pulse into two pulses and recombines them with an adjustable time delay between them. Note within that context that, for example a 100 fs pulse duration, corresponds to a spatial extent of 30 μm, a dimension readily measurable with standard translation stages. Measuring the spatial overlap of the two pulses requires a nonlinear process to generate a detection signal proportional to the intensity product of the

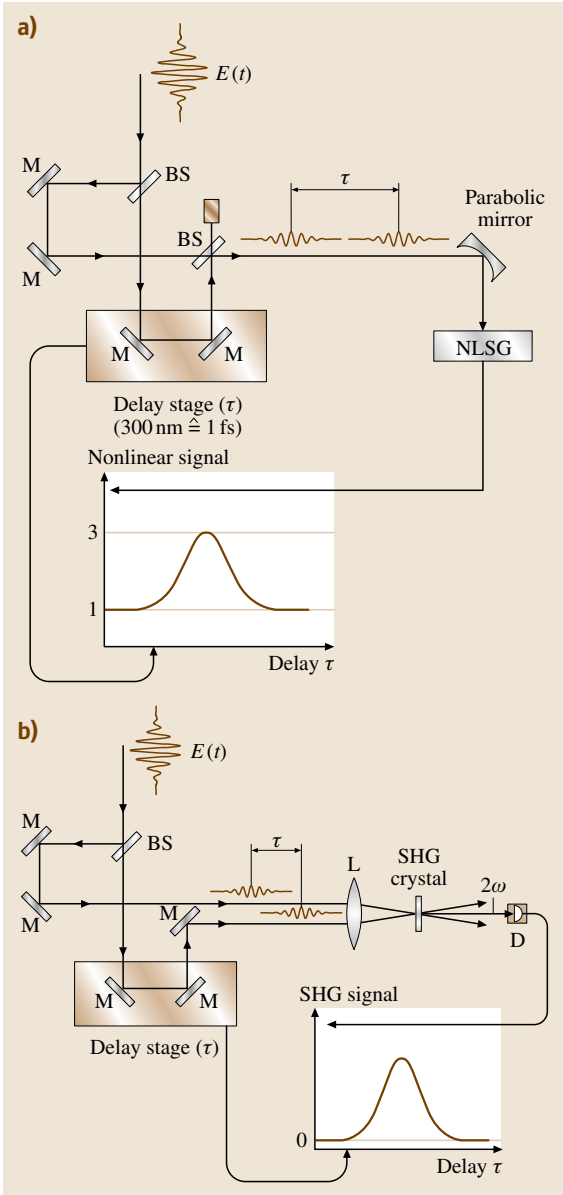

Fig. 12.24a,b Optical layout for autocorrelation setups. **(a)** Collinear autocorrelator (dispersion minimized): the incoming pulse is split into two parts, where one is variably delayed with respect to the other. The pulses are recombined and focused on a nonlinear signal generator (NLSG). Second-harmonic generation in thin crystals and two-photon absorption in semiconductor photodiodes are commonly used for this purpose. Other second-order nonlinear effects can be used as well. The nonlinear signal is measured as a function of delay. If the measurement is performed with interferometric accuracy the interferometric autocorrelation is recorded. If the setup averages the fast oscillations of the light field (12.76) the intensity autocorrelation with background is recorded, having a center-to-offset ratio of 3 : 1 (12.77). **(b)** Noncollinear autocorrelator for recording the background free intensity autocorrelation (M = mirror; BS = beam splitter; SHG = second harmonic generation; D = detector; L = lens) ▶

two pulses. Second-harmonic generation in thin crystals and two-photon absorption in semiconductor photodiodes [12.105, 106] are commonly used (in a *two-photon diode* the photon energy is within the band gap and only simultaneous two-photon absorption can lead to a signal). In the case of frequency-doubling crystals thin crystals have to be used in order to ensure that the ratio of the crystals phase-matching bandwidth to the pulse spectral bandwidth is large. For 100 fs pulses at 800 nm the beta-barium borate (BBO) crystal thickness should not be thicker than $\approx 100\,\mu$m and crystals as thin as 5 μm have been used to measure few-fs pulses [12.6].

The intensity autocorrelation is obtained directly, when the two time-delayed laser pulses are not recombined collinearly but focused at a mutual angle into the thin nonlinear crystal. This leads to the so-called background free intensity autocorrelation. For the collinear setup the intensity autocorrelation is obtained by averaging the fast oscillations of the light field (12.76).

The collinear intensity autocorrelation has a signal-to-background ratio of 3 : 1 (12.77).

The intensity autocorrelation provides only limited information on the pulse shape, because there are infinitely many symmetric and asymmetric pulse shapes that lead to very similar symmetric autocorrelation traces. The procedure to estimate a pulse duration from intensity autocorrelations is to assume a pulse shape and then to calculate the FWHM pulse duration Δt from the known ratio with respect to the FWHM of the intensity autocorrelation $\Delta t_{\mathrm{intAC}}$. In this approach generally Gaussian shapes or hyperbolic secant shapes are assumed. The ratio $\Delta t_{\mathrm{intAC}}/\Delta t$ for various shapes [12.22] is given in Table 12.1.

If a pulse $I_1(t)$ is characterized, for example, in such a way it can be used to gate a second unknown pulse $I_2(t)$ by measuring the intensity cross-correlation S_{intCC} with a suitable nonlinear second-order signal like, for example, sum- or difference-frequency mixing or two-photon photodiodes

$$S_{\mathrm{intCC}}(\tau) = \int_{-\infty}^{\infty} I_1(t) I_2(t+\tau)\,\mathrm{d}t\,. \qquad (12.69)$$

For Gaussian pulse shapes the corresponding FWHM quantities are related by

$$\Delta t_{\mathrm{intCC}}^2 = \Delta t_1^2 + \Delta t_2^2\,. \qquad (12.70)$$

In general the second momenta of the individual pulses have to be considered [12.23].

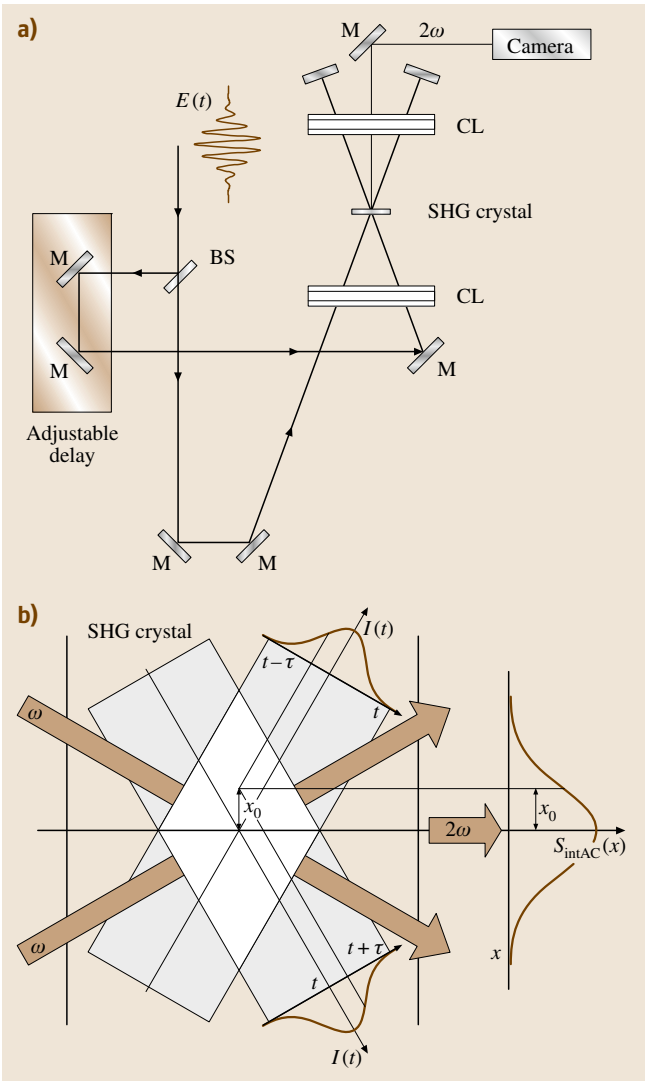

Fig. 12.25 **(a)** Optical layout for a single-shot autocorrelator. The delayed replicas of the incident pulse are focused with the help of a cylindrical lens (CL) onto a second-harmonic generation (SHG) crystal. The spatiotemporal overlap of the two spatially extended pulses is measured via SHG and recorded with a camera (M = mirror; BS = beam splitter). **(b)** Detail of **(a)**. In the region of spatiotemporal overlap, second-harmonic generation is induced via type I phase matching and the autocorrelation in time is transformed into a spatial intensity distribution along the x-axis (after [12.5])

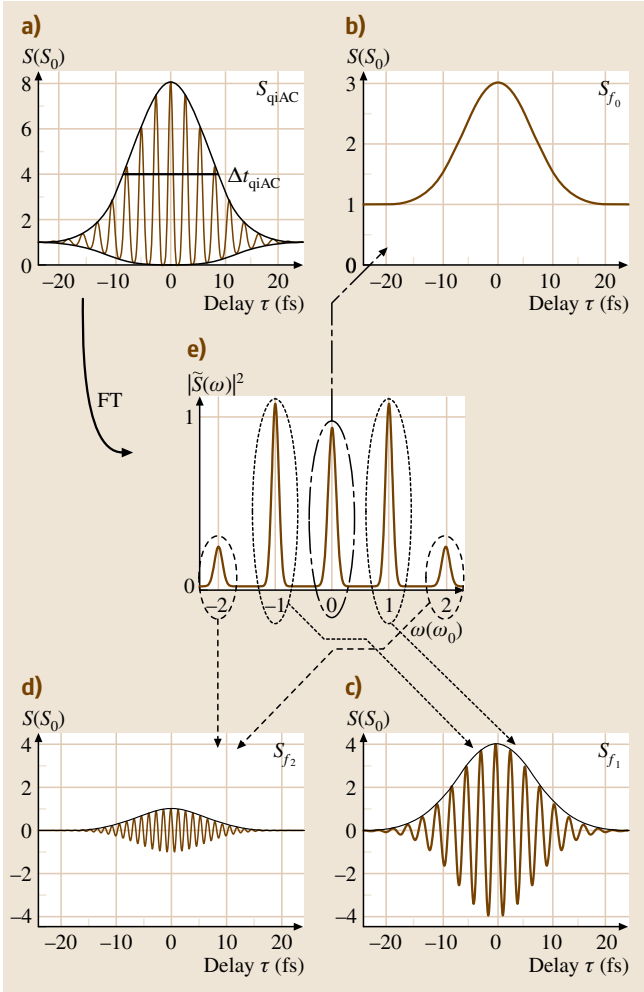
For high-power femtosecond laser systems higher-order cross-correlations $S_{\mathrm{higher\ order\ int\ CC}}$ are a very convenient and powerful tool to determine intensity profiles by making use of nonlinear optical processes of the

order $n+1$ and $m+1$

$$S_{\text{higher order intCC}}(\tau) = \int_{-\infty}^{\infty} I_1^n(t) I_2^m(t+\tau)\,\mathrm{d}t \,. \quad (12.71)$$



In this case the corresponding FWHM quantities assuming Gaussian pulse shapes are given by

$$\Delta t^2_{\text{higher-order intCC}} = \frac{1}{n}\Delta t_1^2 + \frac{1}{m}\Delta t_2^2 \,. \quad (12.72)$$

The intensity autocorrelation does not necessarily have to be recorded by moving one interferometer arm as depicted in Fig. 12.24. In a so-called single-shot autocorrelator [12.107, 108] the two pulses are coupled noncollinearly into a thin frequency-doubling crystal (Fig. 12.25). Only in a small region within the crystal the pulses have spatiotemporal overlap. According to the geometry of the setup in Fig. 12.25b the delay time τ is related to the spatial coordinate x_0. Imaging the frequency-doubled signal yields an intensity autocorrelation as a function of the spatial coordinate

$$S_{\text{intAC}}(x_0) = \int_{-\infty}^{\infty} I(x) I(x+x_0)\,\mathrm{d}x \,. \quad (12.73)$$

These single-shot devices are especially suited for high-intensity femtosecond laser pulses and are therefore convenient tools to adjust low-repetition femtosecond amplifiers. Phase-sensitive setups have also been reported [12.108, 109].

12.3.3 Interferometric Autocorrelations

We will now discuss the case of a collinear autocorrelation in more detail. The simplest interferometric signal is that from a linear detector that records the intensity of the recombined pulses. For identical electric fields E of the two pulses, the signal $S_{\text{linear interferometric AC}}$ as a function of their relative delay τ is

$$\begin{aligned} S_{\text{linear interferometric AC}}(\tau) &= \int_{-\infty}^{\infty} [E(t) + E(t+\tau)]^2 \,\mathrm{d}t \\ &= 2\int_{-\infty}^{\infty} I(t)\,\mathrm{d}t \\ &\quad + 2\int_{-\infty}^{\infty} E(t)E(t+\tau)\,\mathrm{d}t \end{aligned} \quad (12.74)$$

where we have skipped the prefactors defined in Sects. 12.1.1 and 12.1.2. The signal consists of an offset given by the summed intensity of the two pulses and the interference term that is described by an autocorrelation of the electric field. The Wiener–Khintchine theorem states that the Fourier transformation of the

Fig. 12.26a–e Quadratic interferometric autocorrelation **(a)** and the isolated components S_{f_0}, S_{f_1} and S_{f_2} in the time domain **(b)**–**(d)** for a bandwidth-limited Gaussian pulse of 10 fs pulse duration. Note that the offset in **(a)** introduces an additive value at $\omega = 0$ and **(e)** is therefore the Fourier transform of the offset-corrected curve. $\Delta t_{\text{quadratic interferometric AC}}$ is indicated in **(a)** in addition (in the figure qiAC is used as a shorthand notation for quadratic interferometric AC) ◀

autocorrelation of the electric field yields the spectral density [12.110] – a quantity that is proportional to the spectral intensity $I(\omega)$, which is the basis for Fourier spectroscopy. A linear autocorrelation therefore contains no information beyond the amplitude of the spectrum and the total intensity of the pulse.

A solution to this problem is a nonlinear detector that is sensitive to the squared intensity and yields the signal $S_{\text{quadratic interferometric AC}}$

$$S_{\text{quadratic interferometric AC}}(\tau) = \int_{-\infty}^{\infty} \left\{[E(t)+E(t+\tau)]^2\right\}^2 \mathrm{d}t \,. \tag{12.75}$$

Taking the electric field as $E(t) = \mathrm{Re}[A(t)\mathrm{e}^{\mathrm{i}\Phi_\mathrm{a}(t)}\mathrm{e}^{\mathrm{i}\omega_0 t}]$ and defining $S_0 = \int_{-\infty}^{\infty} A^4(t)\,\mathrm{d}t$ in order to normalize one obtains, similar to [12.4, 111],

$$S_{\text{quadratic interferometric AC}}(\tau) = \frac{1}{S_0}\left(S_{f_0} + S_{f_1} + S_{f_2}\right)$$

with

$$S_{f_0} = \int_{-\infty}^{\infty} \left[A^4(t) + 2A^2(t)A^2(t+\tau)\right] \mathrm{d}t \,,$$

$$S_{f_1} = 2\,\mathrm{Re}\left\{\mathrm{e}^{\mathrm{i}\omega_0\tau} \int_{-\infty}^{\infty} A(t)A(t+\tau) \times \left[A^2(t)+A^2(t+\tau)\right] \mathrm{e}^{\mathrm{i}[\Phi_\mathrm{a}(t+\tau)-\Phi_\mathrm{a}(t)]}\,\mathrm{d}t\right\} \,,$$

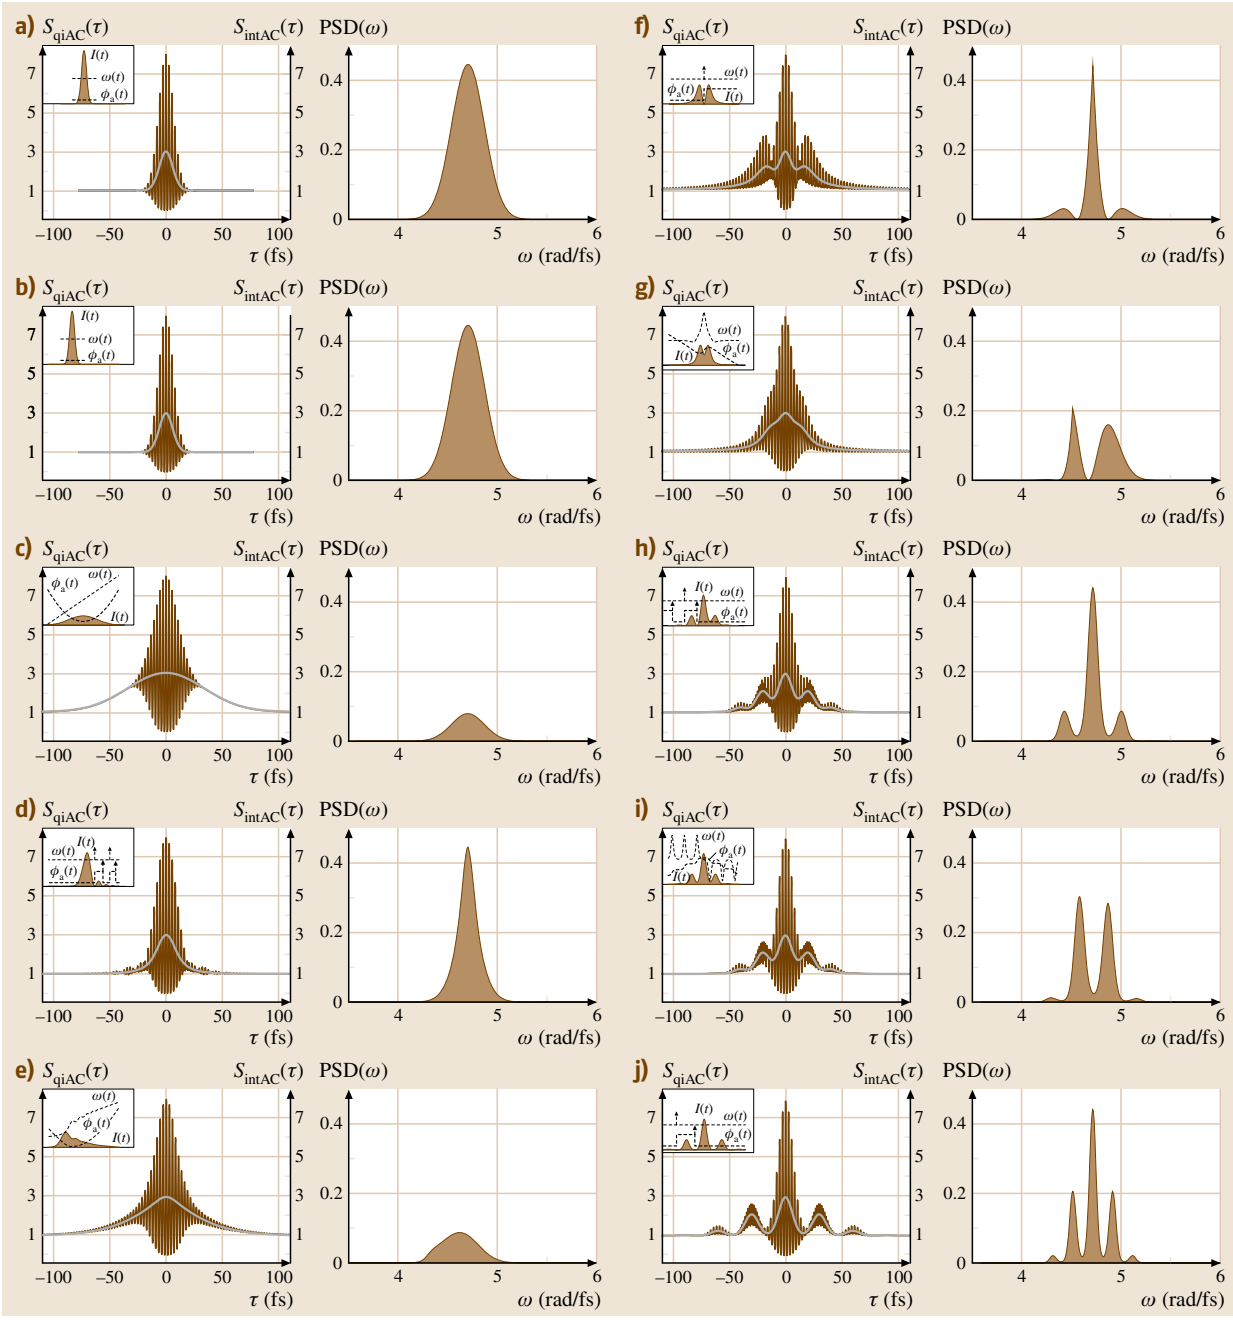
$$S_{f_2} = \mathrm{Re}\left[\mathrm{e}^{\mathrm{i}2\omega_0\tau} \int_{-\infty}^{\infty} A^2(t)A^2(t+\tau) \times \mathrm{e}^{\mathrm{i}2[\Phi_\mathrm{a}(t+\tau)-\Phi_\mathrm{a}(t)]}\,\mathrm{d}t\right] \,, \tag{12.76}$$

where Re denotes the real part. According to (12.48) the signal $S_{\text{quadratic interferometric AC}}$ can be decomposed into three frequency components, S_{f_0}, S_{f_1} and S_{f_2}, at $\omega \approx 0$, $\omega \approx \pm\omega_0$, and $\omega \approx \pm 2\omega_0$, respectively, as illustrated in Fig. 12.26.

S_{f_0} corresponds to an intensity correlation with background. It can be obtained either by Fourier filtering or by averaging the fast oscillations in the experiment directly. With (12.76) it follows that this intensity autocorrelation has a center-to-offset ratio of

$$\frac{S_{f_0}(0)}{S_{f_0}(\infty)} = \frac{\int_{-\infty}^{\infty} 3A^4(t)\,\mathrm{d}t}{\int_{-\infty}^{\infty} A^4(t)\,\mathrm{d}t} = \frac{3}{1} \,. \tag{12.77}$$

S_{f_1} is a sum of two mutual symmetric cross-correlations and depends explicitly on the temporal phase $\Phi_\mathrm{a}(t)$.



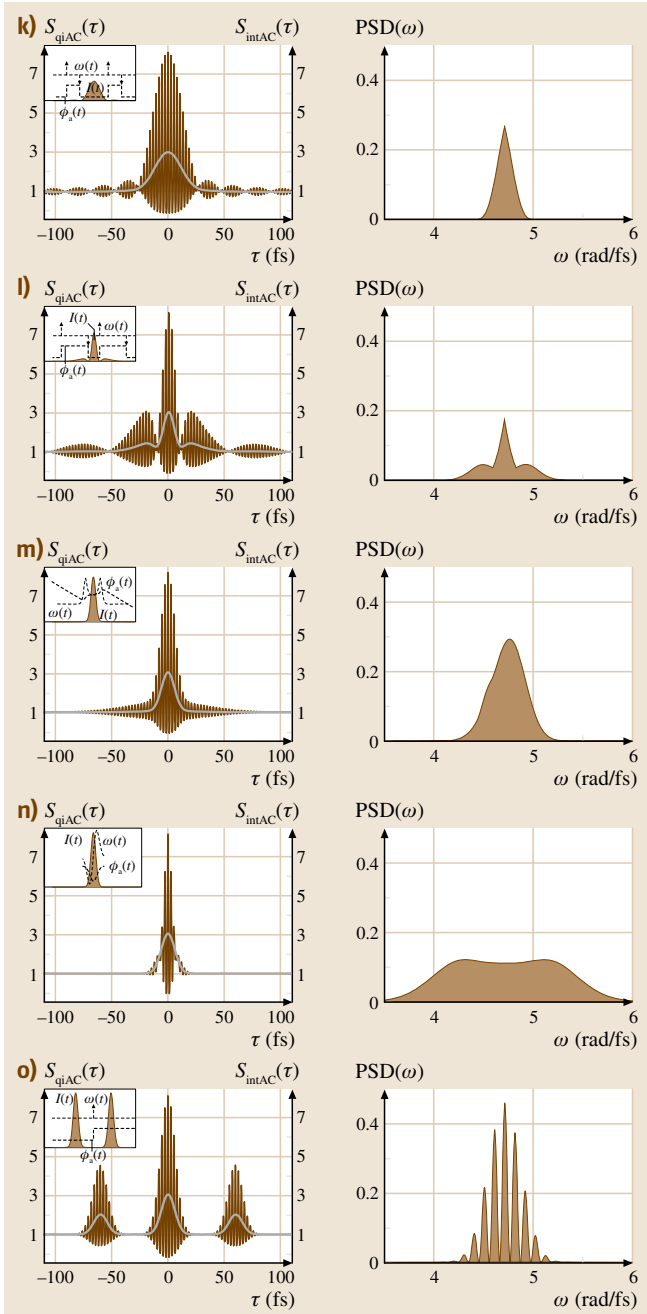
S_{f_2} represents an autocorrelation of the second harmonic field and is therefore related to the spectral intensity of the second-harmonic spectrum. It also depends on the temporal phase $\Phi_\mathrm{a}(t)$. Note that phase-modulated pulses having the same spectral intensity can have very different spectral intensities after frequency doubling (Fig. 12.27). This has been exploited in recent experiments [12.21, 112, 113]. Making use of a pulse shaper (Sect. 12.1.3) that scans calibrated phase functions and at the same time measuring the second-harmonic spectrum is a noninterferometric method to characterize the spectral phase of ultrashort laser pulses [12.114]. All three components add constructively at $\tau = 0$ and yield a center to background ratio of 8 : 1. This can be directly seen from (12.75)

$$\frac{S_{\text{quadratic interferometric AC}}(0)}{S_{\text{quadratic interferometric AC}}(\infty)} = \frac{\int_{-\infty}^{\infty} (E+E)^4\,\mathrm{d}t}{\int_{-\infty}^{\infty} E^4\,\mathrm{d}t + \int_{-\infty}^{\infty} E^4\,\mathrm{d}t} = \frac{16\int_{-\infty}^{\infty} E^4\,\mathrm{d}t}{2\int_{-\infty}^{\infty} E^4\,\mathrm{d}t} = \frac{8}{1} \,. \tag{12.78}$$

The center-to-background ratios are used in experiments to check the proper alignment of the interferometer. In order to derive phase information analytical functions, for example Gaussians, can be fitted to the $S_{\text{quadratic interferometric AC}}$ [12.111]. Taking the knowledge of the spectrum into account iterative algorithms that make no assumptions about the underlying pulse shapes have been reported [12.115, 116]. Both approaches deliver meaningful results only for linear chirps and in the case of nearly no noise. The influence of noise on autocorrelation measurements is discussed in [12.4, 117]. This is an important point as most often measurements are performed over an average of pulse trains. Other sources of systematic error in autocorrelation measurements are discussed in [12.6].

The ratio $\Delta t_{\mathrm{intAC}}/\Delta t$ is only valid for the intensity autocorrelation of a bandwidth-limited pulse. For bandwidth-limited Gaussian pulses the FWHM of a quadratic interferometric autocorrelation signal (taken at 4 in a 8 : 1 plot as displayed in Fig. 12.26a) relates to the pulse duration by

$$\frac{\Delta t_{\text{quadratic interferometric AC}}}{\Delta_t} = 1.6963 \qquad (12.79)$$



for bandwidth-limited Gaussian pulses. Figure 12.27 compiles for different pulses the resulting interferometric autocorrelation traces together with the intensity autocorrelation and the spectrum at the second harmonic of the fundamental.

12.3.4 Time–Frequency Methods

As described above, the interferometric autocorrelation, even together with the independently measured spectrum, does not give sufficient information to characterize arbitrary-shaped ultrashort laser pulses with respect to their temporal amplitude $A(t)$ or temporal intensity $I(t)$ and the temporal phase function $\Phi_a(t)$ or their frequency-domain counterparts (Sect. 12.1.2).

Fig. 12.27a–o *Left*: quadratic interferometric autocorrelation $S_{\text{quadratic interferometric AC}}(\tau)$ (*black*) and intensity autocorrelation $S_{\text{int AC}}(\tau)$ (*grey*) for the pulse shapes of Fig. 12.3 with a central wavelength of 800 nm. The temporal intensity $I(t)$, the additional temporal phase $\Phi_a(t)$ and the instantaneous frequency $\omega(t)$ are shown in the *insets*. *Right*: corresponding power spectrum density PSD(ω) of $S_{\text{qiAC}}(\tau)$ displayed in the region of the second harmonic. Note that for pulses **(a)** to **(j)** the linear spectrum remains unchanged. **(a)** Bandwidth-limited Gaussian laser pulse of 10 fs duration, **(b)** bandwidth-limited Gaussian laser pulse of 10 fs duration shifted in time to −20 fs due to a linear phase term in the spectral domain ($\phi' = -20$ fs), **(c)** symmetrical broadened Gaussian laser pulse due to $\phi'' = 200\,\text{fs}^2$, **(d)** third-order spectral phase ($\phi''' = 1000\,\text{fs}^3$) leading to a quadratic group delay, **(e)** combined action of all spectral phase coefficients **(a)**–**(d)**, **(f)** π step at the central frequency, **(g)** π step displaced from the central frequency, **(h)** sine modulation at the central frequency with $\phi(\omega) = 1\sin[20\,\text{fs}(\omega - \omega_0)]$, **(i)** cosine modulation at the central frequency with $\phi(\omega) = 1\cos[20\,\text{fs}(\omega - \omega_0)]$, **(j)** sine modulation at the central frequency with $\phi(\omega) = 1\sin[30\,\text{fs}(\omega - \omega_0)]$, **(k)** symmetrical clipping of spectrum, **(l)** blocking of the central frequency components, **(m)** off-center absorption, **(n)** self-phase modulation. Note the spectral broadening, **(o)** double pulse, with a pulse-to-pulse delay of 60 fs. Note that the second harmonic field $E^2(t) = A^2(t)\,e^{2i\Phi_a(t)}e^{2i\omega_0 t}$ gives rise to the autocorrelation function S_{f_2} is related to the second harmonic PSD, i. e. squared modulus of the Fourier transform of $E^2(t)$ as displayed in the right column. Hence, the shape of the second harmonic PSD is determined by phase modulation of the linear spectrum and can be used to efficiently control two-photon resonant processes [12.21, 112, 113] ◀ ▶

Techniques have emerged that operate not in the time or frequency domain but in the *joint time–frequency domain*, involving both temporal resolution and frequency resolution simultaneously [12.24, 118] and being able to completely determine the pulse shape [12.6].

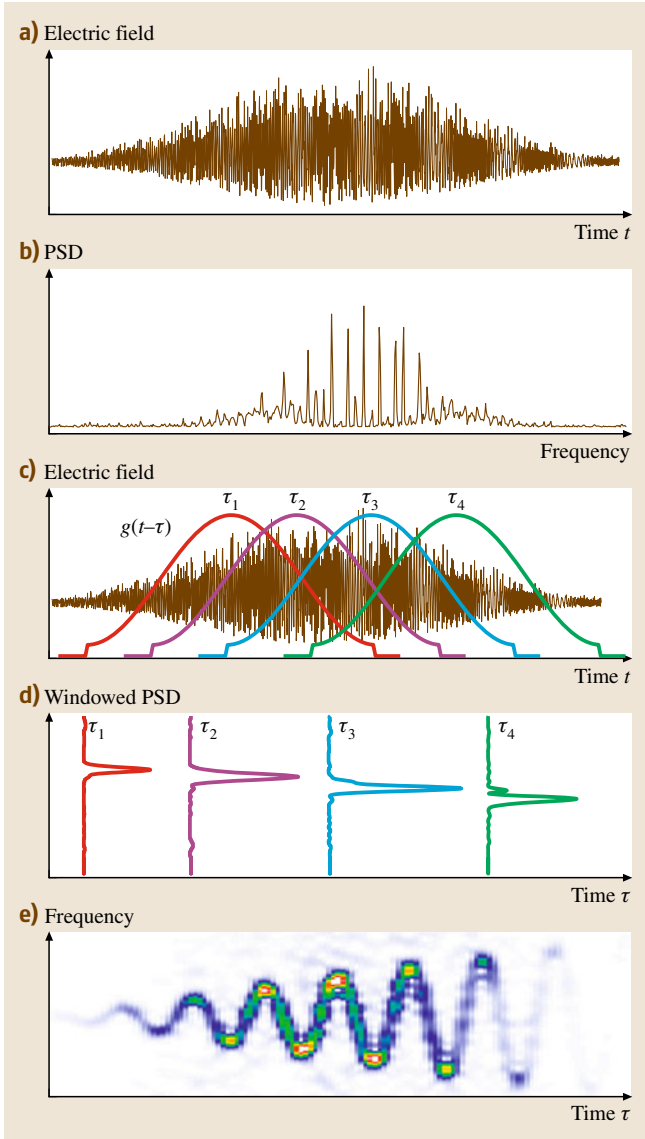


Fig. 12.28a–e Illustration of a short-time Fourier transform of a complicated electric field. **(a)** Electric field as a function of time; **(b)** power spectrum density as a function of frequency; **(c)** gating the electric field; four different time delays are shown; **(d)** power spectrum density for each gate; **(e)** spectrogram, revealing an oscillating instantaneous frequency as a function of time being the origin for the complicated electric field in **(a)**

For illustration purposes we start with an example from music: in order to describe a line of music we use notes. The frequency is indicated by the pitch of the note and the duration of the note indicates how long

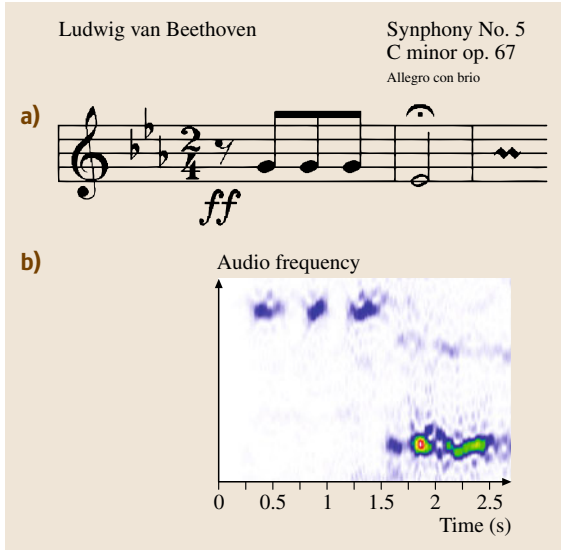

Fig. 12.29a,b Sheet of music **(a)** and corresponding spectrogram **(b)** of Beethoven's fifth symphony

the frequency has to be held. The sheet of music will tell us in what order the notes have to be played and additional information like *piano* and *forte* is given to indicate the intensity to be played. The first few notes of Beethoven's fifth symphony are given as an example in Fig. 12.29a. If an orchestra is playing the music and we wish to graphically record the music, a spectrogram $S_{\text{spectrogram}}(\omega, \tau)$ is a useful quantity. A spectrogram of a function $f(t)$ is defined as the energy density spectrum of a short-time Fourier transform $\text{STFT}(\omega, \tau)$

$$S_{\text{spectrogram}}(\omega, \tau) \equiv |\text{STFT}(\omega, \tau)|^2 = \left| \int_{-\infty}^{\infty} f(t) g(t-\tau) \mathrm{e}^{-\mathrm{i}\omega t} \, \mathrm{d}t \right|^2 , \tag{12.80}$$

where $g(t-\tau)$ denotes the gate (or window) function. The concept behind it is simple and powerful. If we want to analyze what is happening at a particular time, we just use a small portion of the signal centered at that time, calculate its spectrum and do it for each instant of time. A spectrogram corresponding to the beginning of Beethoven's fifth symphony is shown in Fig. 12.29b.

Figure 12.28 shows the concept of STFT on a complicated electric field of a laser. Once an electric field is retrieved in amplitude and phase there are other time – frequency distributions in use for displaying

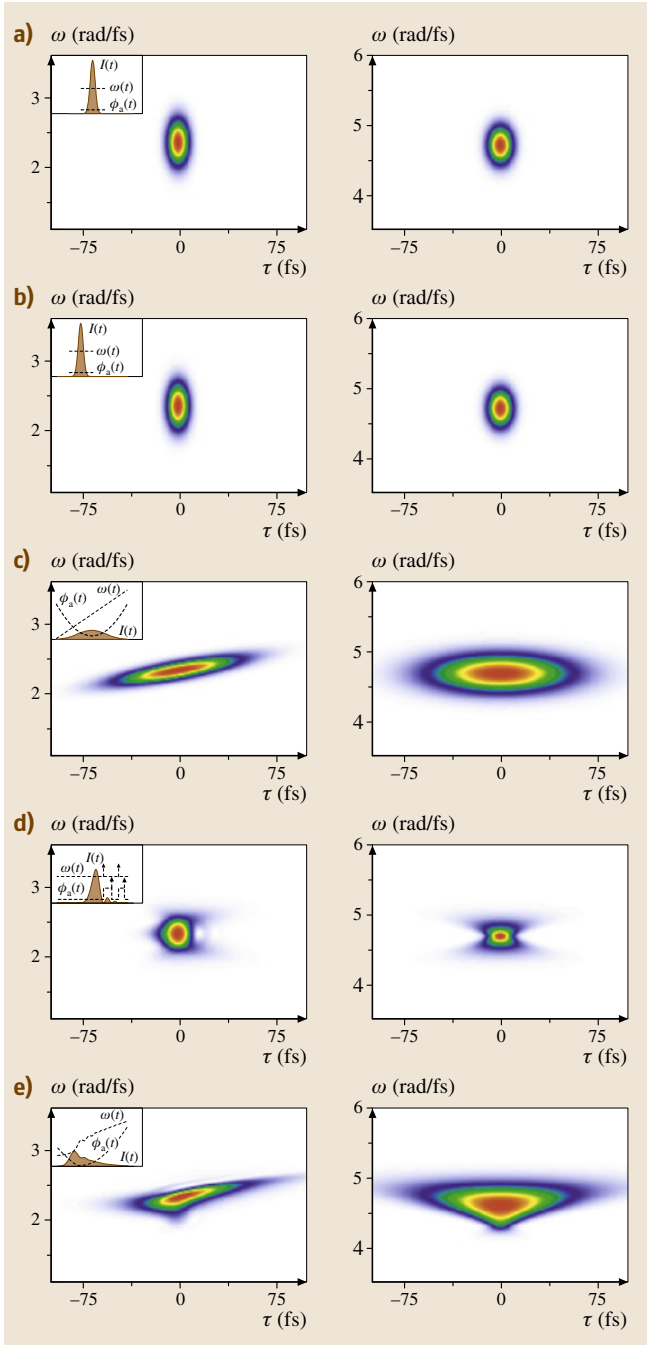

Fig. 12.30a–o Calculated FROG traces at corresponding frequencies for various ultrashort pulse shapes with a central wavelength of 800 nm according to the pulses displayed in Fig. 12.3. *Left*: polarization gate (PG) FROG. *Right*: second-harmonic generation (SHG) FROG. The temporal intensity $I(t)$, the additional temporal phase $\Phi_a(t)$ and the instantaneous frequency $\omega(t)$ are shown in the *insets* as a reminder. **(a)** Bandwidth-limited Gaussian laser pulse of 10 fs duration, **(b)** bandwidth-limited Gaussian laser pulse of 10 fs duration shifted in time to −20 fs due to a linear phase term in the spectral domain ($\phi' = -20$ fs), **(c)** symmetrical broadened up chirped Gaussian laser pulse due to $\phi'' = 200\,\text{fs}^2$, **(d)** third-order spectral phase ($\phi''' = 1000\,\text{fs}^3$) leading to a quadratic group delay, **(e)** combined action of all spectral phase coefficients **(a)**–**(d)**, **(f)** π step at the central frequency, **(g)** π step displaced from the central frequency, **(h)** sine modulation at the central frequency with $\phi(\omega) = 1\sin[20\,\text{fs}(\omega - \omega_0)]$, **(i)** cosine modulation at the central frequency with $\phi(\omega) = 1\cos[20\,\text{fs}(\omega - \omega_0)]$, **(j)** sine modulation at the central frequency with $\phi(\omega) = 1\sin[30\,\text{fs}(\omega - \omega_0)]$, **(k)** symmetrical clipping of spectrum, **(l)** blocking of the central frequency components, **(m)** off-center absorption, **(n)** self-phase modulation, (note the spectral broadening), **(o)** double pulse, with a pulse-to-pulse delay of 60 fs ▶▶

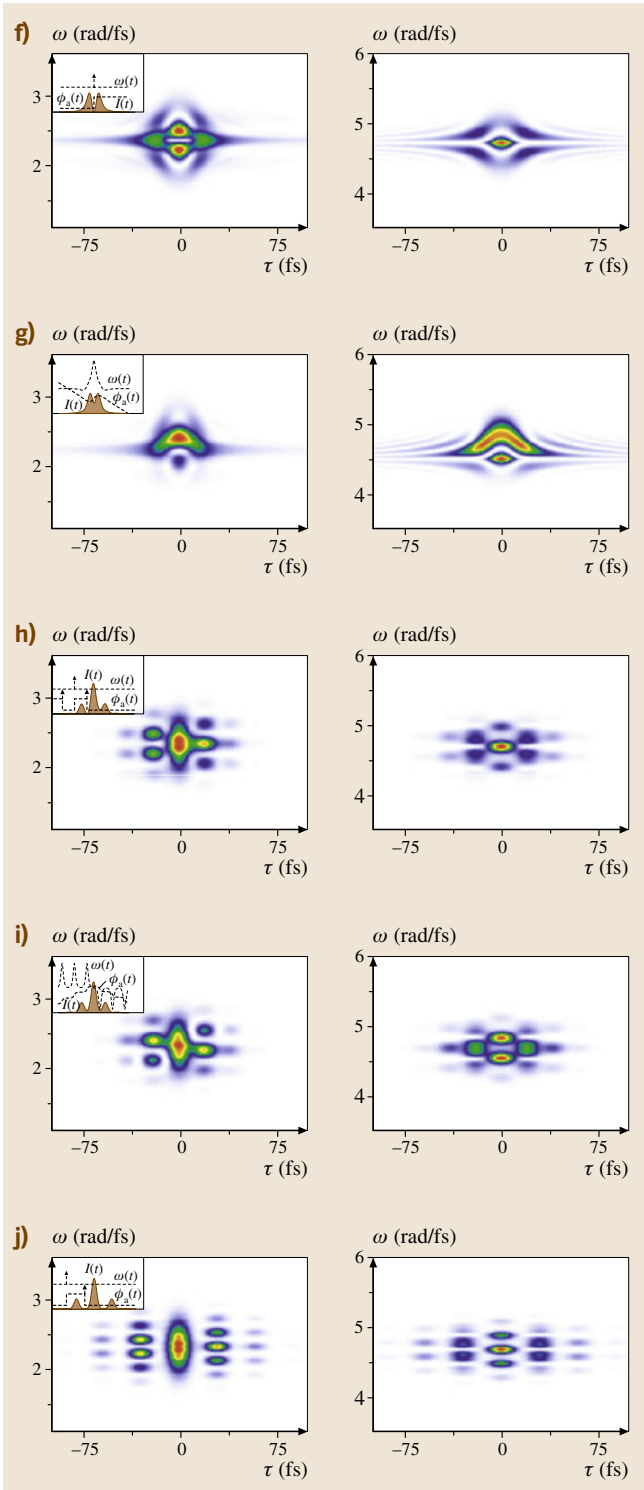
the data like for example the Wigner [12.24, 119–122] and Husimi representations [12.123, 124]. A quantity closely related to the spectrogram is the sonogram $S_{\text{sonogram}}(\omega, \tau)$



$$S_{\text{sonogram}}(\omega, \tau) \equiv \left| \int_{-\infty}^{\infty} \tilde{f}(\omega')\tilde{g}(\omega - \omega')\,\mathrm{e}^{+\mathrm{i}\omega'\tau}\,\mathrm{d}\omega' \right|^2 , \tag{12.81}$$

where $\tilde{g}(\omega - \omega')$ is a frequency gate in analogy to the time gate $g(t - \tau)$ used in the spectrogram. If $\tilde{g}(\omega)$ is the Fourier transform of $g(t)$ then it can be shown that the sonogram is equivalent to the spectrogram [12.6].

In ultrafast optics, the gate to record the spectrogram or the sonogram is usually the pulse itself.

Spectrogram-Based Methods

Recording a spectrogram is accomplished experimentally by gating the pulse with a variable delayed replica of the pulse in an instantaneous nonlinear optical medium followed by spectrally resolving the gated pulse. The basic optical layout of such a device is almost the same as a noncollinear autocorrelation setup depicted in Fig. 12.24b. Only the detector has to be replaced by a spectrometer and camera system in order to spectrally resolve the gated pulse. The corresponding technique has been termed frequency-resolved optical

gating (FROG) and is described in great detail in [12.6, 125] and references therein.

Depending on the instantaneous nonlinear optical effect used to gate the pulse in FROG, several different FROG geometries have been investigated (the setup of Fig. 12.24b would correspond to a second-harmonic-generation (SHG) FROG). These geometries can also be implemented as single-shot devices, similar to the single-shot autocorrelator depicted in Fig. 12.25. The FROG trace $I_{\mathrm{FROG}}(\omega, \tau)$, that is a plot of frequency (wavelength) versus delay, is a spectrogram of the complex amplitude E_{c} (12.15). Neglecting any prefactors, different nonlinear optical effects yield the following expressions according to [12.6, 125].

Polarization-Gate (PG) FROG.

$$I_{\mathrm{FROG}}^{\mathrm{PG}}(\omega, \tau) = \left| \int_{-\infty}^{\infty} E_{\mathrm{c}}(t)\, |E_{\mathrm{c}}(t-\tau)|^2\, \mathrm{e}^{-\mathrm{i}\omega t}\, \mathrm{d}t \right|^2 . \tag{12.82}$$

In a crossed-polarizer arrangement for the probe pulse this technique makes use of induced birefringence in fused silica in the presence of the gate pulse. The third-order optical nonlinearity is the electronic Kerr effect. The FROG traces obtained by this method are very intuitive (Fig. 12.30).

Self-Diffraction (SD) FROG.

$$I_{\mathrm{FROG}}^{\mathrm{SD}}(\omega, \tau) = \left| \int_{-\infty}^{\infty} E_{\mathrm{c}}(t)^2 E_{\mathrm{c}}^*(t-\tau)\, \mathrm{e}^{-\mathrm{i}\omega t}\, \mathrm{d}t \right|^2 . \tag{12.83}$$

In this approach the two beams (with the same polarization) generate a sinusoidal intensity pattern in the nonlinear medium (for example, fused silica) and hence introduce a material grating, which diffracts each beam. One of the diffracted beams is then the signal beam sent to the spectrometer.

Transient-Grating (TG) FROG.

$$I_{\mathrm{FROG}}^{\mathrm{TG}}(\omega, \tau) = \left| \int_{-\infty}^{\infty} E_{\mathrm{c1}}(t) E_{\mathrm{c2}}^*(t) E_{\mathrm{c3}}(t-\tau)\, \mathrm{e}^{-\mathrm{i}\omega t}\, \mathrm{d}t \right|^2 . \tag{12.84}$$

This is a three-beam setup, where two pulses are overlapped in time and space at the optical Kerr medium

(for example fused silica), producing a refractive index grating similar as in SD FROG. In a TG a third pulse is variably delayed and overlapped in the fused silica and is diffracted by the induced grating, producing the signal beam for the spectrometer. The beams in the TG geometry (three input and one output) are kept nearly collinear and form a so-called boxcars arrangement, where the four spots appear in the corners of a rectangle when placing a card into the beams after the nonlinear medium. As TG is a phase-matched process, the sensitivity is higher compared to the SD approach. Depending on which pulse is variably delayed – with the other two coincident in time – the TG FROG trace is mathematically equivalent to the PG FROG (pulse one or three is delayed) or to the SD FROG (pulse two is delayed).

Third-Harmonic-Generation (THG) FROG.

$$I^{\mathrm{THG}}_{\mathrm{FROG}}(\omega,\tau)=\left|\int_{-\infty}^{\infty}E_{\mathrm{c}}(t-\tau)^2E_{\mathrm{c}}(t)\mathrm{e}^{-\mathrm{i}\omega t}\,\mathrm{d}t\right|^2 . \tag{12.85}$$

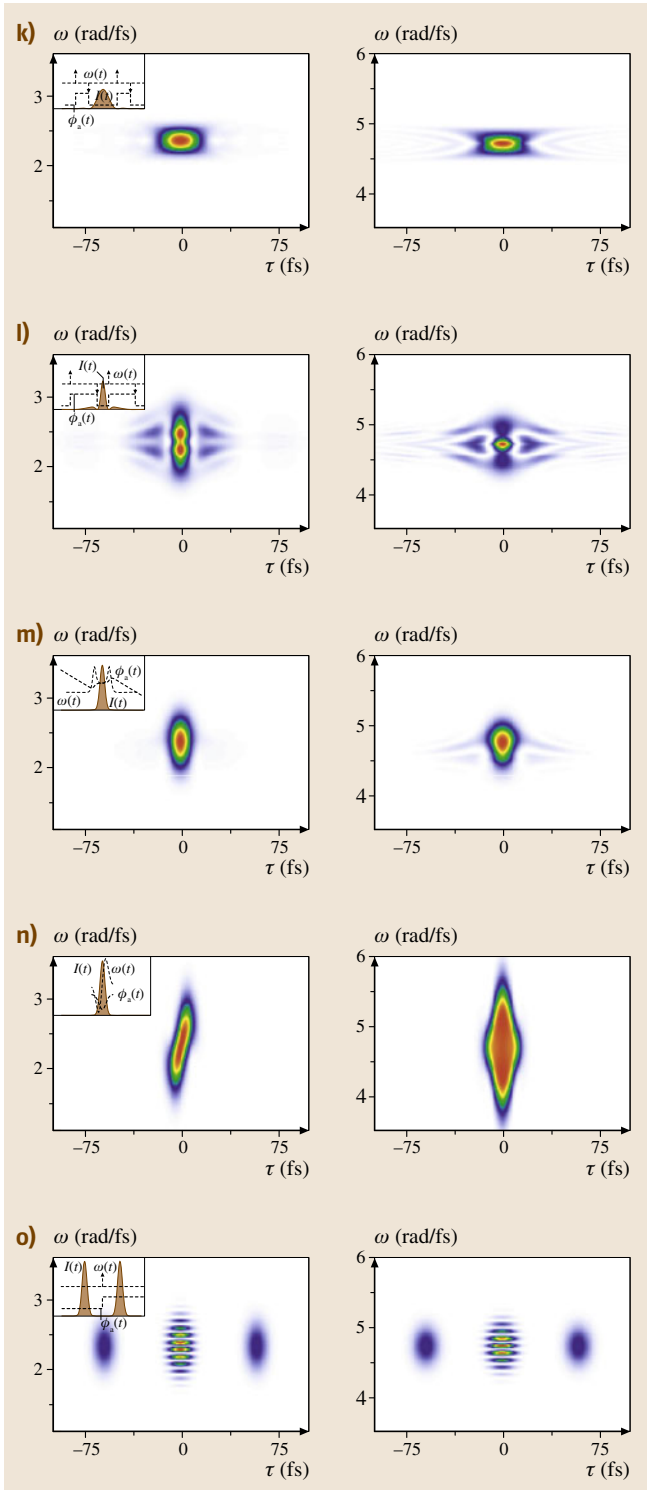
This method makes use of third-harmonic generation as the nonlinear process.

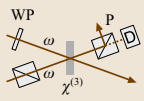
Second-Harmonic-Generation (SHG) FROG.

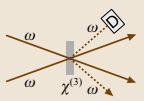
$$I^{\mathrm{SHG}}_{\mathrm{FROG}}(\omega,\tau)=\left|\int_{-\infty}^{\infty}E_{\mathrm{c}}(t)E_{\mathrm{c}}(t-\tau)\mathrm{e}^{-\mathrm{i}\omega t}\,\mathrm{d}t\right|^2 . \tag{12.86}$$

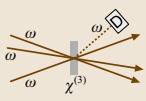
SHG FROG involves spectrally resolving a standard SHG-based noncollinear intensity autocorrelator, which always yields symmetric traces, resulting in a direction of time ambiguity for the SHG FROG. This ambiguity can experimentally be removed, for example, by placing a piece of glass in the beam before the beam splitter to introduce positive chirp or to create satellite pulses via surface reflections. Because of its high sensitivity and as it is based on a standard SHG autocorrelator, this method is widely employed. Examples of SHG FROG traces for various pulse shapes are given in Fig. 12.30.

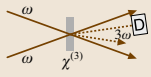
A comparison of the different approaches is given in Table 12.4. Various calculated traces for common ultrashort pulse distortions for the PG and the SHG FROG geometries are given in Fig. 12.30. Calculated FROG traces for the other beam geometries are given











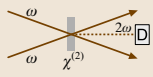


Table 12.4 Comparison of different FROG geometries (PG = polarization gate; SD = self-diffraction; TG = transient grating; THG = third-harmonic generation; SHG = second-harmonic generation). Sensitivities are only approximate and assume 800 nm 100 fs pulses focused to about 100 μm (10 μm for THG) to be measured. In the schematics only the part involving the nonlinear optical effect characterized by its nonlinearity is displayed. Not shown are delay lines and various lenses, as these are common to all setups and are similar to the optical layouts shown in Figs. 12.24b and 12.25. Solid lines indicate input pulses; dashed lines indicate signal pulses. The frequencies shown (ω, 2ω, 3ω) are the carrier frequencies of the pulses taking part and indicate whether the signal pulse has the same carrier frequency as the input pulse or is shifted as in SHG and THG. D denotes a detector being composed of a spectrometer and camera system. (WP = wave plate; P = polarizer) (after [12.6])

Geometry	PG	SD	TG	THG	SHG
Nonlinearity	$\chi^{(3)}$	$\chi^{(3)}$	$\chi^{(3)}$	$\chi^{(3)}$	$\chi^{(2)}$
Sensitivity (single shot) (μJ)	≈ 1	≈ 10	≈ 0.1	≈ 0.03	≈ 0.01

in [12.125]. Measured FROG traces for different geometries are compiled in [12.6].

It is important to note that knowledge of the spectrogram (or sonogram) of the electric field of an ultrashort laser pulse is sufficient to completely determine the electric field in amplitude and phase (besides some ambiguities such as the absolute phase) because a spectrogram is equivalent to the two-dimensional phase-retrieval problem in image science and astronomy [12.126]. In general, phase retrieval is the problem of finding a function knowing only the magnitude (but not the phase) of its Fourier transform. Phase retrieval for a function of one variable is impossible. For example, knowledge of a pulse spectrum does not fully determine the pulse as infinitely many different pulses have the same spectrum (Fig. 12.3a–j). However, phase retrieval for a function of two variables is possible and the FROG trace can be rewritten as the squared magnitude of a two-dimensional Fourier transform [12.125]. Very sophisticated iterative retrieval procedures, which can rapidly retrieve the pulse from the FROG trace with update rates up to several Hz, exist [12.127].

In the following some additional attributes of FROG techniques, which also partially hold for sonogram methods, are summarized:

- As the FROG trace consists of $N \times N$ points, while the intensity and phase on the other hand only have $2N$ points, the FROG trace overdetermines the pulse. This gives rise to an increased robustness of the two-dimensional methods and to an improved immunity towards measurement noise. The noncon-

vergence of the FROG algorithm therefore can be a hint of the presence of systematic errors.

- Other than autocorrelation techniques, FROG offers a built-in consistency check to detect systematic errors. It involves computing the *marginals* of the FROG trace, that is, integrals of the trace with respect to delay or frequency. The marginals can be compared to the independently measured spectrum or autocorrelation. For an SHG FROG the time marginal yields the intensity autocorrelation and the frequency marginal yields the second-harmonic spectrum. The marginals of the SHG FROG traces in Fig. 12.30 are therefore given in the corresponding pictures of Fig. 12.27.
- FROG can also be used in a cross-correlation variant named XFROG [12.129]. In this case a known pulse is used to gate an unknown pulse (usually derived from the known one), where no spectral overlap between the pulses is required. Via sum- or difference-frequency generation or other nonlinear processes, pulses in the ultraviolet (UV) and infrared (IR) spectral range can be characterized. The technique has been refined for measuring pulses in the attojoule (per pulse) regime and is capable of measuring pulses with poor spatial coherence and random phase, such as fluorescence [12.130].
- In the sub-10 fs range SHG FROG has been demonstrated down to 4.5 fs pulse durations with the help of type I phase matching in a 10 μm thick BBO crystal [12.131]. In this regime the noncollinear beam geometry can also introduce beam smearing artefacts. Type II phase matching allows the use of a collinear SHG FROG geometry, which is free of geometrical smearing [12.132, 133]. The FROG traces generated in this arrangement do not contain the optical fringes associated with interferometric autocorrelations and, therefore, can be processed by existing SHG FROG algorithms.
- Making use of a thick SHG crystal as a frequency filter [12.134, 135] allows for the construction of an extremely simple and robust FROG setup that has been demonstrated for 800 nm pulses in the range from 20 fs to 5 ps for different spectral widths of the ultrashort pulses. The device was termed grating-eliminated no-nonsense observation of ultrafast incident laser light E-fields (GRENOUILLE) [12.6]. Spatial temporal distortions such as spatial chirp and pulse front tilt can also be measured via GRENOUILLE [12.136, 137] (spatial chirp: each frequency is displaced in the transverse spatial coordinates, often resulting from misaligned prism pairs and tilted windows; pulse front tilt: the pulse group fronts (intensity contours) are tilted with respect to the perpendicular to the

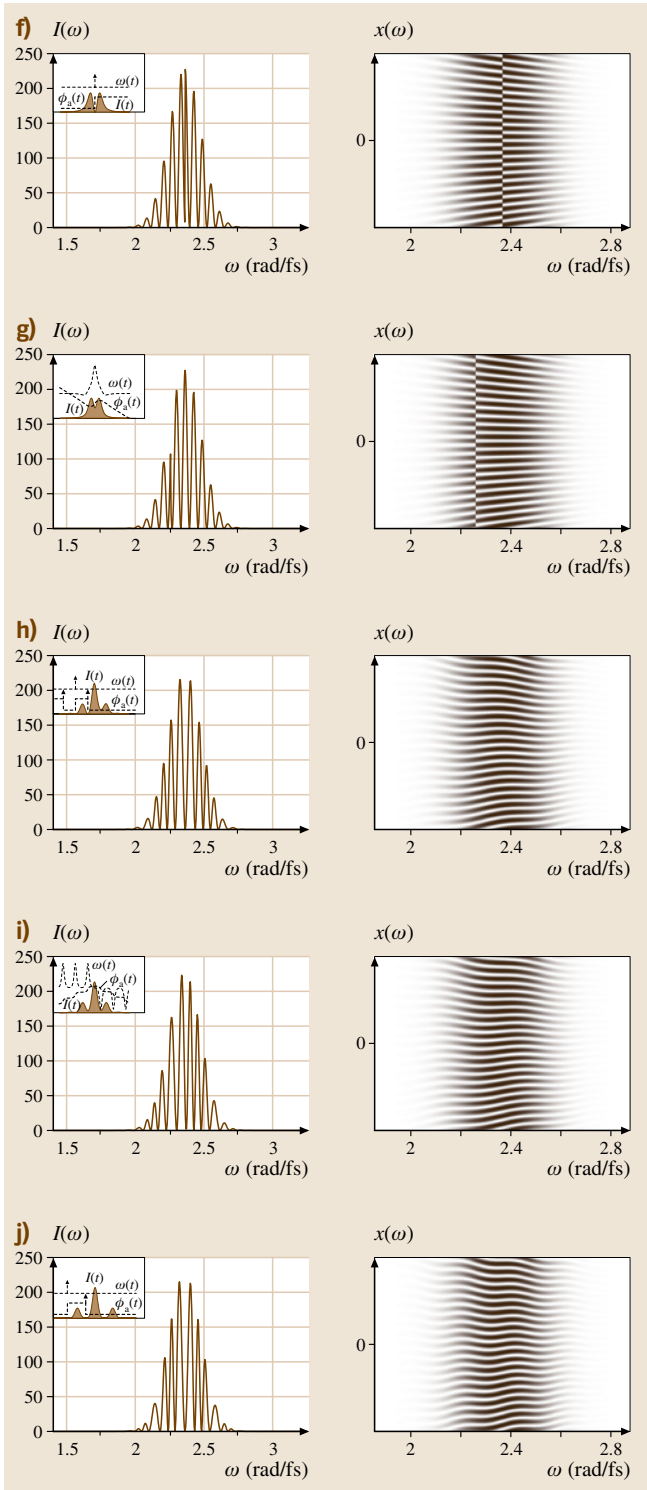
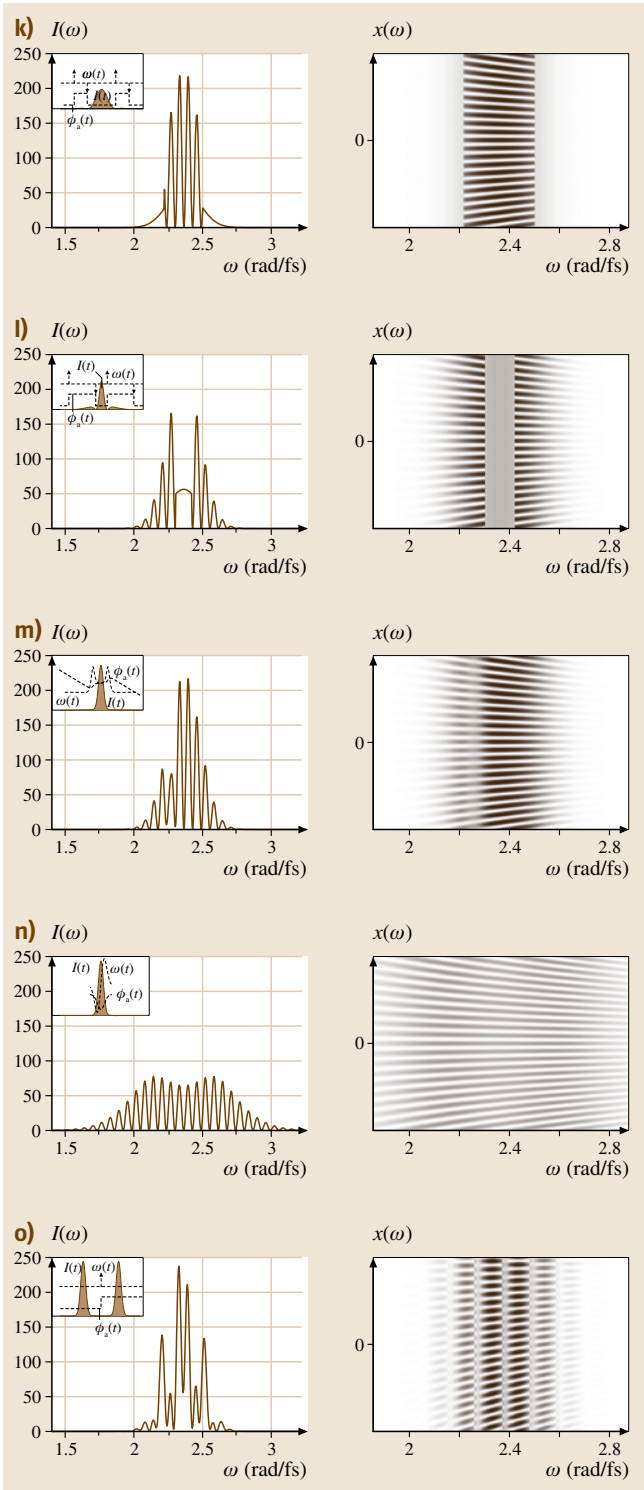
propagation direction, resulting from residual angular dispersion after pulse compressor or stretcher units).

- The wavelength limitation due to nonlinear optical processes can be circumvented by the use of multiphoton ionization as a nonlinearity. Measurements of interferometrically recorded energy-resolved photoelectron spectra generated by above-threshold ionization were demonstrated to yield FROG-type time–frequency distributions that were used to characterize ultrashort laser pulses [12.138]). This approach is potentially applicable to the XUV wavelength region.

Sonogram-Based Methods



Recording the sonogram involves slicing the frequency spectrum and measuring the arrival time of the frequency components. Experimentally this can be achieved, for example, by cross-correlation of a pulse with a frequency-filtered replica of the pulse in an instantaneous nonlinear medium (Fig. 12.31). The corresponding technique is known as frequency-domain phase measurement (FDPM) and is described in [12.139]. The method gives information on the group



delay and an integration can be performed that gives the spectral phase function without any iterative algorithm. An experimental realization has been termed spectrally and temporally resolved upconversion technique (STRUT) [12.140] and also exists in a single-shot version [12.141]. As the sonogram and the spectrogram are mathematically equivalent FROG retrieval algorithms (being in principle somewhat slower) can also be used in this approach [12.141]. From a practical point of view the method is experimentally more involved than a FROG setup and it is less sensitive, because energy is lost at the filter before the nonlinear medium. In the SHG version, the STRUT apparatus and the FROG apparatus are identical when removing the frequency filter and using a spectrometer as the detector in Fig. 12.31.

12.3.5 Spectral Interferometry

The techniques described so far make use of nonlinear optical processes in order to determine the amplitude and phase of ultrashort laser pulses. Although, with the help of SHG FROG, pulses down to the picojoule regime can be measured in a multishot setup, shaped ultrashort laser pulses might spread out their energy over a time scale of picoseconds and thus prevent characterization with the help of nonlinear processes. However, as these pulses are usually created from an oscillator or an amplifier a well-characterized reference pulse is often available. This allows to make use of highly sensitive linear techniques to determine the amplitude and phase of an ultrashort laser pulse. The technique is named spectral interferometry (SI), frequency-domain interferometry or Fourier-transform spectral interferometry [12.6, 142–145]. The basic SI setup is depicted in Fig. 12.32. A well-characterized reference pulse $E_{\mathrm{ref}}(t)$ and a modified signal pulse $E(t)$ derived from an experiment or a pulse shaper are directed collinearly into a spectrometer. The measured SI spectrum $S_{\mathrm{SI}}(\omega)$ is proportional to the square of the Fourier transform of the sum of the two fields:

$$
\begin{aligned}
S_{\mathrm{SI}}(\omega) &\propto |\text{Fourier transform}\,\{E_{\mathrm{ref}}(t)+E(t-\tau)\}|^2 \\
&\propto \left|\tilde{E}_{\mathrm{ref}}(\omega)+\tilde{E}(\omega)\mathrm{e}^{-\mathrm{i}\omega\tau}\right|^2 \\
&\propto \left|\sqrt{I_{\mathrm{ref}}(\omega)}\mathrm{e}^{-\mathrm{i}\phi_{\mathrm{ref}}(\omega)}+\sqrt{I(\omega)}\mathrm{e}^{-\mathrm{i}\phi(\omega)-\mathrm{i}\omega\tau}\right|^2 \\
&= I_{\mathrm{ref}}(\omega)+I(\omega)+\sqrt{I_{\mathrm{ref}}(\omega)}\sqrt{I(\omega)} \\
&\quad\times(\mathrm{e}^{\mathrm{i}\phi_{\mathrm{ref}}(\omega)-\mathrm{i}\phi(\omega)-\mathrm{i}\omega\tau}+\mathrm{c.c.}) \\
&= I_{\mathrm{ref}}(\omega)+I(\omega)+2\sqrt{I_{\mathrm{ref}}(\omega)}\sqrt{I(\omega)} \\
&\quad\times\cos(\phi_{\mathrm{ref}}(\omega)-\phi(\omega)-\omega\tau)\,. \qquad (12.87)
\end{aligned}
$$

The phase difference

$$\Delta\phi(\omega) = \phi_{\mathrm{ref}}(\omega) - \phi(\omega) \tag{12.88}$$

can be extracted from the measured $S_{\mathrm{SI}}(\omega)$. Using the arcos function is not recommended because experimental noise can lead to large phase errors [12.145]. Commonly a Fourier-transform technique is used [12.145, 146] where the phase difference is extracted by the Fourier transform of the measured spectrum, ignoring the negative and zero-frequency components and shifting the positive-frequency components to direct current (DC) in order to remove the delay term $e^{-i\omega\tau}$. An inverse Fourier transform then yields the phase difference $\Delta\phi(\omega)$. With the help of the known reference phase $\phi_{\mathrm{ref}}(\omega)$, $\phi(\omega)$ is finally obtained.

In the following some attributes of SI are summarized:

- SI requires the spectrum of the reference pulse to contain completely the spectrum of the unknown pulse.
- If the reference pulse and the signal pulse are identical, the phase difference is zero. The remaining oscillations on the spectrum due to the delay term are a convenient tool to adjust, for example, interferometric autocorrelator setups.
- Using the FROG technique for characterization of the reference pulse, the combined technique was termed temporal analysis by dispersing a pair of light E-fields (TADPOLE) [12.6, 147].
- SI is a heterodyne technique and amplifies the generally weak signal pulse (12.87). With the help of TADPOLE, pulse trains with an energy per pulse in the zeptojoule (zepto $= 10^{-21}$) regime have been analyzed [12.147].
- Once the reference phase is known, phase retrieval does not require an iterative procedure and is therefore fast. This allows, for example, for the synthesis of arbitrary laser pulse shapes with the help of feedback-controlled femtosecond pulse shaping techniques [12.148]. Together with its high sensitivity, TADPOLE is well suited to the characterization of complex-shaped femtosecond laser pulses. Furthermore, in a dual-channel setup SI has been used to characterize complex polarization-shaped femtosecond laser pulses [12.78]. The setup for the characterization of time-dependent polarization profiles has been called polarization-labeled interference versus wavelength for only a glint (POLLIWOG) [12.149].

- SI can also be implemented in a spatial variation, where the reference pulse and the signal pulse propagate at an angle of 2Θ with respect to each other (Fig. 12.33). The frequency components of the optical fields of the two propagating pulses are mapped in one dimension by a diffraction grating and a cylindrical lens and interfere at the focal plane of the lens. The technique is called spatial–spectral interference (SSI). The corresponding device is a convenient tool for optimizing various setups such as pulse shapers and compressors as the fringe patterns are displayed in real time and the information is encoded in an intuitively interpretable pattern [12.128]. A comparison of calculated SI and SSI traces for various ultrashort pulse distortions is given in Fig. 12.34.
- There also exists a self-referencing variant of SI that does not require separate characterization of the reference pulse. This technique is called spectral phase interferometry for direct electric field reconstruction (SPIDER) [12.17,150] and involves appropriate temporal stretching of a reference pulse followed by sum-frequency generation with two well-displaced copies of the unstretched input pulse. This technique has been successfully demonstrated for the characterization of ultrashort pulses in the few-cycle regime [12.151]. Due to the nonlinear process involved, SPIDER is less sensitive than TADPOLE. A comparison of SHG FROG and SPIDER for sub-ten-femtosecond pulse characterization is given in [12.152]. A spatially resolved version of SPIDER has also been demonstrated [12.153]. A setup that is capable of characterizing a pulse at the interaction point of an experiment, called zero additional phase (ZAP) SPIDER, has been demonstrated for visible and sub-20-femtosecond ultraviolet pulses [12.154].

13. Optical and Spectroscopic Techniques

Spectroscopy is the most important method for gaining detailed information on the structure and dynamics of atoms and molecules. The essential criteria of any spectroscopic technique are the attainable spectral resolution and the sensitivity.

In Sect. 13.1 we will concentrate on stationary methods of spectroscopy where the spectral resolution, the maximum achievable sensitivity and the development of optimum detectors are the main subjects.

In Sect. 13.2 on time-resolved spectroscopy, the realization of short pulse lasers with pulse widths down to femtoseconds are discussed and methods for measuring the time profiles of such short pulses are presented. Furthermore several applications are demonstrated, where a high time resolution is demanded.

Remote sensing of the environment using lidar (light detection and ranging) techniques is reviewed in Sect. 13.3. Air pollutants can be mapped by differential absorption lidar. Three-dimensional mapping of gas distributions are obtained. Lidar measurements on condensed matter targets are also discussed. Water, vegetation and cultural heritage monuments are considered. Emphasis is given to fluorescence lidar techniques, but lidar laser induced break-down spectroscopy is also described. Finally, examples of lidar-like short-range measurements are given.

13.1 Stationary Methods

Basic Principles of Spectroscopic Techniques

All spectroscopic techniques can be classified into those suitable for absorption spectroscopy and others adapted to emission spectroscopy. Emission spectroscopy demands the population of excited states that can emit the radiation. This excitation can be achieved by collisions (examples are gas discharges where electron impact excitation is the main excitation mechanism, or hot gases, such as the atmospheres of stars, where collisions between atoms or ions populate excited states) or by photon absorption (e.g. laser excited fluorescence).

One important criterion of any spectroscopic techniques is its *sensitivity*, which is defined as the minimum detectable number of photons absorbed or emitted on a transition. This is also a measure for the minimum number of atoms or molecules which can be monitored. In particular for analytical investigations the question of how few atoms or molecules can be still detected in the presence of other species and in a rough environment, is of crucial importance for the selection of the optimum technique. The ultimate sensitivity is reached when single atoms or molecules, for instance

as pollutants in a gas, in a liquid or on surfaces can be still measured. One example, where this sensitivity is really needed, is the optical detection of rare isotopes in the presence of other species that are more abundant by many orders of magnitude.

Another essential feature of all spectroscopic techniques is the *spectral resolving power* R. It is defined as

$$R = \left| \frac{\lambda}{\Delta\lambda_{\min}} \right| = \left| \frac{\nu}{\Delta\nu_{\min}} \right| , \tag{13.1}$$

where $\Delta\lambda_{\min}$ or $\Delta\nu_{\min}$ is the minimum spectral interval (measured in wavelengths λ or in frequencies ν) that can be still resolved, i. e. two spectral lines separated by $\Delta\lambda > \Delta\lambda_{\min}$ can be recognized as two separated lines. This minimal interval $\Delta\lambda_{\min}$ depends on the profile of the spectral lines. A criterium postulated by Lord Rayleigh is the following (Fig. 13.1).

Two spectral lines can be regarded as resolved, when the two partly overlapping line-profiles have a dip between the two maxima with intensity $I_{\max}$, which does not exceed $0.8 I_{\max}$.

The spectral resolving power R depends on:

1. The spectroscopic instrument used for the separation of different wavelengths of absorbing or emitting transitions. These can be either spectrometers or interferometers.
2. On the line width of the absorption- or emission lines. For gasesous samples at low pressures this is generally the Doppler-width, at higher pressures the pressure broadened line profiles.

Absorption Techniques

Most spectroscopic applications are based on absorption of radiation. Several techniques have been developed which either use the attenuation of the radiation passing through the absorbing sample, or they monitor different effects caused by the absorption of photons, such as the temperature increase in the sample, the change of electrical conductivity or the light emission induced by the absorption [13.1].

We will start with the classical absorption spectroscopy, in order to see by which factors the sensitivity limits are determined.

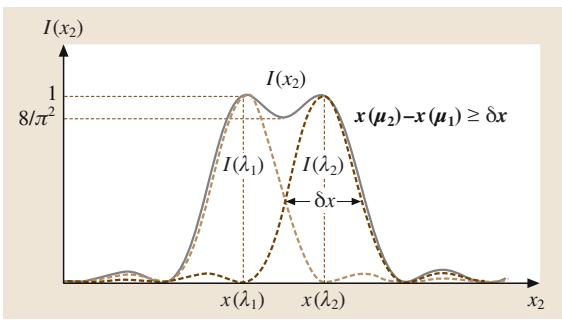

Fig. 13.1 Rayleigh criterium for the resolution of two close spectral line profiles

Classical Absorption Spectroscopy. When a monochromatic electromagnetic wave with frequency ω and intensity I_0 passes through an absorbing sample with absorption path-length L, the transmitted intensity is

$$I_t = I_0 \cdot e^{-\alpha L} . \tag{13.2}$$

The spectral absorption coefficient $\alpha(\omega_{ik})$ of a transition $E_k \rightarrow E_i$ is determined by the absorption cross section σ_{ik} of the individual molecule on the transition $|i\rangle \rightarrow |k\rangle$, the difference $N_k - N_i$ of the populations densities and the ratio g_k/g_i of the statistical weights

$$L(\Omega_{ik}) = \left[N_k - \left(\frac{g_k}{g_i} \right) N_i \right] \sigma_{ik}(\Omega) , \tag{13.3}$$

where the statistical weights $g = (2J+1)$ give the number of possible orientations of the total angular momentum J of the levels involved.

For small absorptions the exponential function in (13.2) can be expanded into

$$I_t \approx I_0(1 - \alpha \cdot L) \tag{13.4}$$

and we obtain from (13.1) for an absorption length L

$$\Delta I = \left[N_k - \left(\frac{g_k}{g_i} \right) N_i \right] \sigma_{ik} L I_0 . \tag{13.5}$$

For nonmonochromatic radiation the total absorption depends on the relation between the spectral width of the absorbing transition and the bandwidth of the incident radiation (Fig. 13.2).

For a spectral bandwidth $\Delta\omega_R$ of the radiation and an absorption halfwidth $\Delta\omega_a$ the relative total absorption is

$$\frac{\Delta I}{I_0} = \frac{L \int \alpha(\omega) I(\omega) \, d\omega}{\int I(\omega) \, d\omega} \approx \bar{\alpha} \frac{\Delta\omega_\alpha}{\Delta\omega_r} , \tag{13.6}$$

where the integration extends over all frequencies, although only the interval $\Delta\omega_a$ within the absorption line profile mainly contributes to the absorption. This demonstrates that for $\Delta\omega_r > \Delta\omega_a$ the relative absorption increases with increasing ratio $\Delta\omega_a/\Delta\omega_R$ of absorption linewidth $\Delta\omega_a$ to radiation bandwidth $\Delta\omega_R$

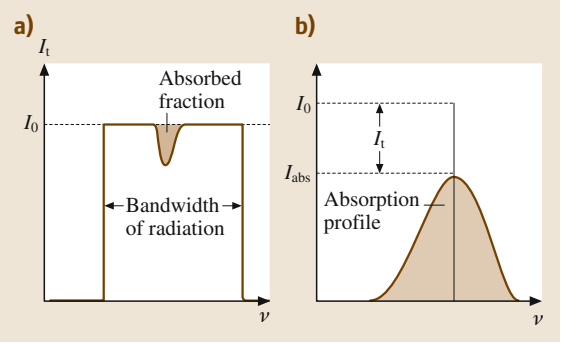

Fig. 13.2a,b Relative absorption by a transition with spectral half-width $\Delta\omega_a$ for different bandwidths $\Delta\omega_r$ of the incident radiation. **(a)** $\Delta\omega_r > \Delta\omega_a$, **(b)** for monochromatic radiation

(Fig. 13.2). The use of narrow-band radiation sources is therefore not only advantageous for the spectral resolution but also for increasing the sensitivity. This is often overlooked. Spectral profiles of absorption lines can be only measured if the bandwidth $\Delta\omega_R$ of the incident radiation is smaller than the absorption line-width $\Delta\omega_a$.

The minimum detectable intensity-change ΔI mainly depends on possible fluctuations of the incident intensity I_0 and on other noise sources such as detector noise. We summarize all noise contributions to a total noise ΔI_{noise}. Small absorptions $\Delta I = I_0 \cdot \alpha \cdot L < \Delta I_{noise}$ need special electronic devices to be still detectable. For the intensity change ΔI the detector gives an output signal $S \propto \Delta I$, while the noise contributes the amount $\delta S \propto \Delta I_{noise}$. A measure for the sensitivity is the achievable signal-to-noise ratio $S/\delta S$. From the condition

$$S \geq \delta S \Rightarrow \Delta I \geq \Delta I_{noise} \qquad (13.7)$$

we obtain with (13.6) the minimum detectable number density of absorbing molecules as

$$\Delta N = \left[N_k - \left(\frac{g_k}{g_i} \right) N_i \right] \geq \frac{1}{\sigma_{ik} L (S\delta S)} \,. \qquad (13.8)$$

This shows that for a high sensitivity the absorption-path length L should be as long as possible, the signal-to-noise ratio $S/\delta S$ as large as possible and transitions with a large absorption cross section σ should be selected. We will see later on, how these requirements can be met experimentally.

Laser-Absorption Spectroscopy. The above mentioned demands for high sensitivity and optimum spectral resolution can be best met when narrow-band lasers are used as radiation sources. Absorption spectroscopy with monochromatic wavelength-tunable lasers resembles in many aspects microwave spectroscopy. The advantage of lasers is their large tuning range and their possible applications in many spectral regions from the far infrared to the extreme ultraviolet.

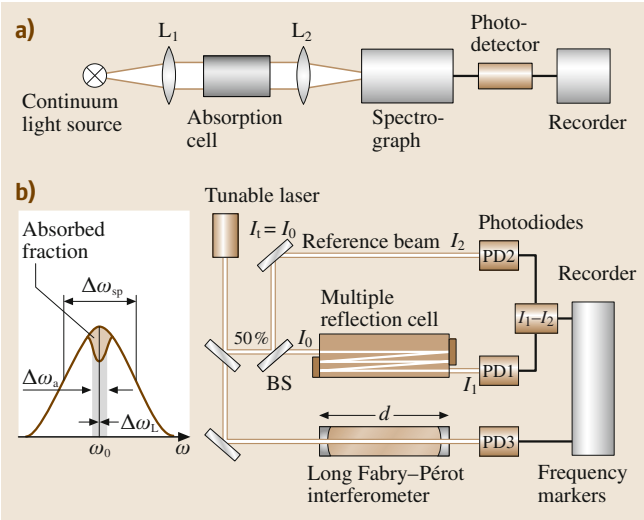

Fig. 13.3a,b Comparison of absorption spectroscopy **(a)** with a broadband incoherent source, **(b)** with a tunable monochromatic laser

A typical experimental setup is shown in Fig. 13.3. The output beam of a tunable laser is split by a 50% beam-splitter BS2 into a reference beam and the signal beam that passes through the absorption cell. Another beam-splitter BS1 directs a small fraction of the laser beam into a long Fabry–Pérot interferometer with mirror separation d which gives equidistant frequency markers separated by $\Delta\nu = c/2d$.

The advantages of this arrangement compared with conventional spectroscopy without lasers can be summarized as follows:

There is no need for a spectrometer for wavelength dispersion because the tunable laser is already monochromatic and the absorption lines appear as dips in the transmitted laser intensity I_t when the laser is scanned through the spectrum.

The spectral resolution is not limited by any instrument, but solely by the width of the absorption lines, which is generally given by their Doppler-width. With Doppler-free techniques (Sect. 13.1.3) even this limitation can be overcome.

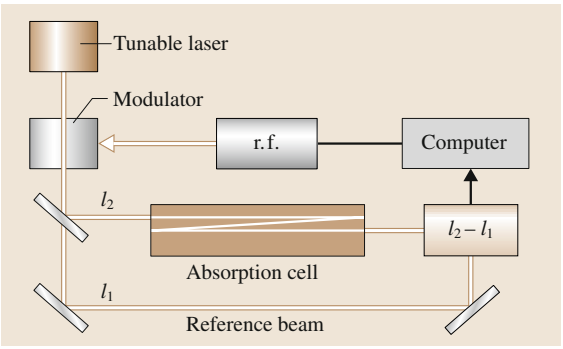

Fig. 13.4 Absorption spectroscopy with a frequency-modulated tunable laser, a reference beam and difference detection

Because of the good collimation of the parallel laser beam a long path length L through the absorption cell can be realized, for instance by multipath arrangements with spherical mirrors (see below). This enhances the sensitivity (since the absorption $\Delta I = I_0 \cdot \alpha \cdot L$ is proportional to the absorption length L) and allows the detection of weak transitions or of tiny densities of absorbing molecules.

The small line width $\Delta\omega_L$ of the laser further increases the sensitivity (13.6).

The latter advantage is often overlooked which is, however, not justified, as the following example illustrates:

Example 13.1: In conventional spectroscopy with a spectral continuum and a wavelength-selecting spectrometer the grating spectrometer may have a resolution of $\delta\nu = 0.5\,\mathrm{cm}^{-1}$, while the Doppler-width of the absorption lines in the visible is typical about $\Delta\nu_a = 0.03\,\mathrm{cm}^{-1}$. This gives for the same absorption $\alpha \cdot L$ an intensity change ΔI that is 16 times smaller than for a monochromatic radiation, resulting in a 16 times smaller sensitivity.

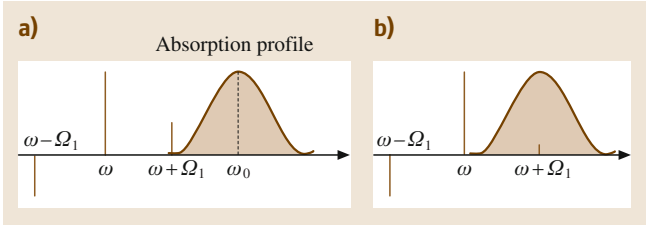

Fig. 13.5 Principle of phase-modulated absorption spectroscopy, where the modulation amplitude is larger than the line width of the absorbing transitions

Modulated Absorption-Spectroscopy. The sensitivity can be further enhanced by modulating the laser frequency ω_L at a modulation frequency f, similar to the situation in microwave spectroscopy [13.2–4]. The incident intensity can then be represented by

$$I(\omega, f) = I_0[1 + \cos(\omega + a \cdot \sin(2\pi \cdot f \cdot t)t)] \,. \quad (13.9)$$

This frequency modulation generates sidebands with the frequencies $\omega = \omega_L \pm n \cdot \Omega$ with $\Omega = 2\pi f$. The modulation amplitude a may be smaller or larger than the line width $\Delta\omega_a$ of the absorption lines. We will at first consider the case where it is larger than the line width of the absorbing transitions. In this case the sidebands lie outside the absorption profile if the frequency ω_L is tuned to the center ω_0 of the absorption line.

The experimental setup of modulation spectroscopy can be realized as follows (Fig. 13.4):

When the laser beam from a tunable laser passes through an electrooptic modulator (this is a crystal which changes its refractive index proportional to the voltage applied to electrodes on opposite sides of the crystal) the optical path length is periodically changed and with it the phase of the optical wave. This phase modulation results in a frequency modulation because the frequency $\omega = \mathrm{d}\phi/\mathrm{d}t$ is the derivative of the phase ϕ. Different from pure frequency modulation here the phases of the two sidebands are opposite (Fig. 13.5). If the transmitted intensity (this is the sum of the intensities of carrier and sidebands) is detected by a phase-sensitive detector (lock-in) tuned to the modulation frequency Ω, the measured signal is zero if there in no absorption, because the lock-in detector measures the two differences $I_c - I_+$ and $I_c - I_-$ of the intensities I_c of the carrier and $I_\pm$ of the two sidebands which have equal amplitudes but opposite signs and therefore cancel each other.

If, however, one of the sidebands coincides with an absorption line this sideband is attenuated and the balance is perturbed. Fluctuations of the incident intensity appear in the carrier as well as in the sidebands and therefore cancel for the difference measurement.

This eliminates most of the noise and therefore increases the sensitivity. When the carrier frequency coincides with the center frequency of the absorption line, the signal is zero. Since the signal has a zero-crossing at the center frequency of the absorbing transition, this frequency can be determined very accurately.

A further enhancement can be achieved, when the absorption path length L is increased. This can be realized by placing the sample inside an optical multipass configuration, which is shown in Fig. 13.6. It consists

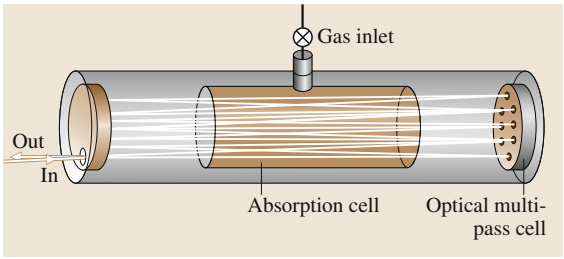

Fig. 13.6 Multipass absorption cell with spherical mirrors

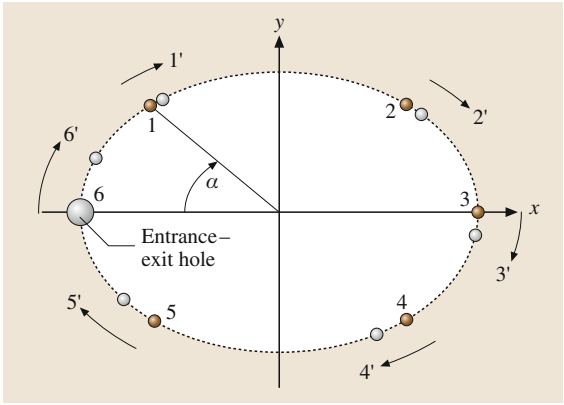

Fig. 13.7 Laser beam spots on the mirror surfaces for successive reflections. *Brown circles* are on mirror M_2, *gray circles* on mirror M_1

of two spherical mirrors with radius of curvature r and a separation $d \approx r$. The incident laser beam enters through a small hole in one of the mirrors, is reflected by the opposite mirror and is focused onto the first mirror. After many round trips the beam leaves through the same hole but under another angle, thus avoiding back-reflection into the source. The laser beam spots on the mirrors form an ellipse (Fig. 13.7) with an angular distance that can be controlled by changing the mirror separation d. Due to the focusing by the spherical mirrors the spot size remains fairly constant even for many passes between the mirrors. This minimizes the overlap of spots from different reflections. Such overlap would result in interferences which change with the wavelength λ. When the laser wavelength is tuned over the spectral region of interest, this would result in perturbing features overlapping the spectral lines. The maximum number of roundtrips is limited by the absorption of the sample and by the reflectivity r of the mirrors.

Example 13.2: With a mirror reflectivity $r = 98\%$ the transmitted intensity has dropped after N round trips without absorption cell to

$$I_t = I_0 \cdot r^{-2N} = 0.01765 \cdot I_0 \quad \text{for } N = 100\,.$$

Assuming an absorption coefficient of $\alpha = 10^{-5}\,\mathrm{m}^{-1}$ and an absorption path length of $2N \cdot L$ the transmitted intensity becomes for $L = 1\,\mathrm{m}$

$$I_t = I_0 \cdot r^{-2N}\, e^{-2N\cdot\alpha\cdot L} = 0.0176\, e^{-0.002}$$
$$\approx 0.01765 \cdot 0.998 \approx 0.01760\,.$$

This illustrates that in fact for weakly absorbing samples not the sample absorption but the mirror reflectivity is the limiting factor for the number of passes.

The enhanced sensitivity is illustrated in Fig. 13.8 where a conventional absorption measurement of a weak overtone absorption line of the H_2O molecule id compared with the signal obtained by the modulation technique. The enhancement of sensitivity amounts to two orders of magnitude.

If the modulation amplitude is smaller than the absorption line width we have the situation depicted in Fig. 13.9. A lock-in detector tuned to the modulation frequency measures the derivative of the absorption pro-

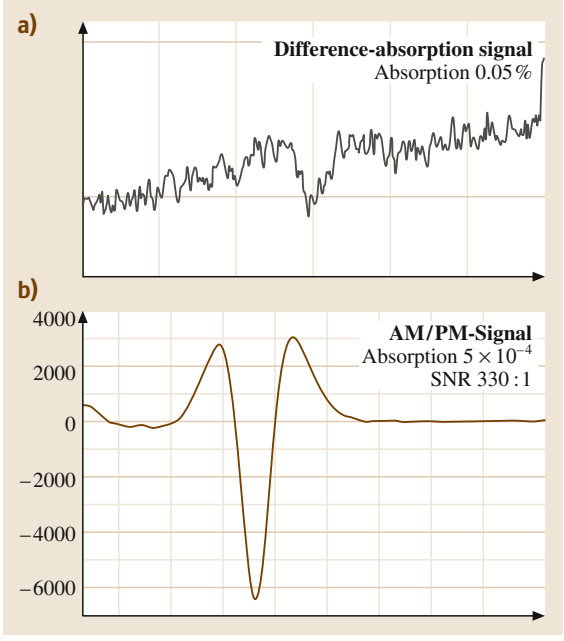

Fig. 13.8a,b Absorption feature of a weak overtone transition in H_2O molecules. **(a)** Measured with conventional unmodulated absorption spectroscopy, **(b)** with a phase-modulated (PM) laser and difference detection

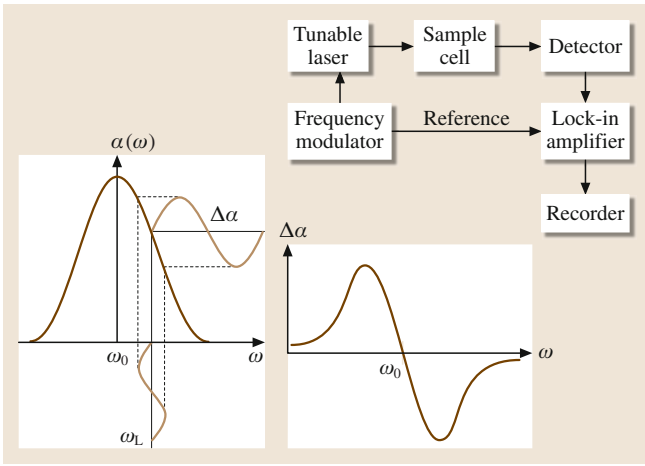

Fig. 13.9 Principle of frequency-modulation spectroscopy with a modulation amplitude smaller than the absorption line width

file. From (13.4) we obtain for $\alpha \cdot L \ll 1$

$$\frac{\mathrm{d}\alpha}{\mathrm{d}\omega} = -\frac{1}{L I_0}\frac{\mathrm{d}I_\mathrm{t}}{\mathrm{d}\omega} \,. \tag{13.10}$$

When inserting the modulated laser frequency

$$\Omega_\mathrm{L} = \omega_0(1 + a \cdot \sin \Omega t) \tag{13.11}$$

this yields the Taylor expansion

$$I_\mathrm{t}(\omega) = I_\mathrm{t}(\omega_0) + \sum_n \frac{\alpha^n}{n!}\sin^n(\Omega t)\left(\frac{\mathrm{d}^n I_\mathrm{t}}{\mathrm{d}\omega^n}\right)_{\omega_0} \,. \tag{13.12}$$

According to trigonometric relations the terms $\sin^n \Omega T$ can be replaced by a linear combination of $\sin(n\Omega t)$ and $\cos(n\Omega t)$. Ordering the different terms with respect to their harmonic frequencies $n\Omega$ one obtains the result

$$\begin{aligned}\frac{\Delta I}{I_0} \approx -aL\Bigg[& C + \left(\frac{\mathrm{d}\alpha}{\mathrm{d}\omega}\right)_{\omega_0}\sin(\Omega t) \\ & - \frac{a}{4}\left(\frac{\mathrm{d}^2\alpha}{\mathrm{d}\omega^2}\right)_{\omega_0}\cos(2\Omega t) \\ & - \frac{\mathrm{d}^2}{24}\left(\frac{\mathrm{d}^3\alpha}{\mathrm{d}\omega^3}\right)_{\omega_0}\sin(3\Omega t) + \cdots \Bigg] \,.\end{aligned} \tag{13.13}$$

This means that the n-th derivative of the absorption profile is obtained if the lock-in detector is tuned to the harmonics $n \cdot \Omega$ of the modulation frequency Ω.

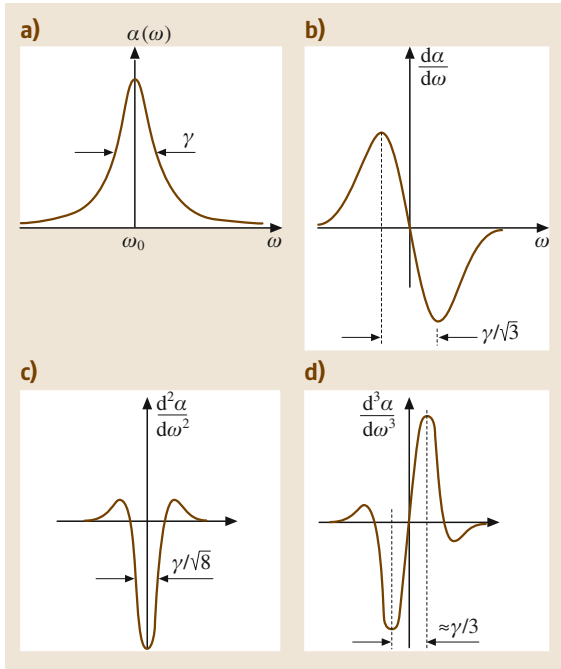

Fig. 13.10 Signal profiles of absorption lines when $\alpha(\omega)$ and its first three derivatives are measured

In Fig. 13.10 the measured profiles for the first three harmonics are illustrated. Since the technical noise generally decreases with increasing frequency, measurements at higher harmonics often yield a higher signal-to-noise ratio [13.3–5].

Optoacoustic and Optothermal Spectroscopy

With the techniques of absorption spectroscopy, discussed so far, the absorption is detected as the difference between transmitted and incident intensity. For small absorptions one has to measure a small difference of two large quantities, which has, of course, a larger noise than if the absorbed radiation power could be directly measured. This can be achieved by several techniques which shall now be discussed. They are based on the energy transfer from the absorbed photons into heat and they monitor different effects caused by the temperature rise of the absorbing sample. We start with the optoacoustic spectroscopy [13.6].

An absorption cell with volume V may contain $N = n \cdot V$ absorbing molecules, which can be excited into the energy level $E_i = E_k + h \cdot \nu$ by absorption of a photon $h \cdot \nu$ (Fig. 13.11). If the excited molecule collides with other atoms or molecules in the cell, it can transfer its excitation energy into translational or internal energy of

the collision partners. If N_1 molecules are excited and transfer their excitation energy to the N molecules in the cell with f degrees of freedom, the energy $E = (f/2)kT$ of each particle is increased and the temperature of the gas rises by

$$\Delta T = \frac{N_1}{N} h \frac{\nu}{fk} . \tag{13.14}$$

For a closed cell the total number N of molecules is constant. A temperature rise therefore increases the gas pressure $p = n \cdot k \cdot T$ by

$$\Delta p = n \cdot k \cdot \Delta T = \frac{N_1}{V} \frac{h\nu}{k} . \tag{13.15}$$

The energy of the absorbed photons is converted into kinetic energy resulting in a pressure rise Δp.

Up to now we have neglected the radiative decay of the excited level. If the emitted fluorescence photons are not absorbed within the cell, their energy is not converted into a pressure increase. With the radiative transition rate R_r and the nonradiative rate R_{nr}, which is caused by collisions, the quantum efficiency is

$$\eta = \frac{R_r}{R_r + R_{nr}} = \frac{1}{1 + \tau_r/\tau_{nr}} \tag{13.16}$$

and the transferred energy decreases to

$$\Delta E = N_1(1-\eta) \cdot h \cdot \nu = N_1 \cdot h \cdot \nu \cdot \frac{\tau_{rad}}{\tau_{rad} + \tau_{nr}} . \tag{13.17}$$

The energy conversion increases with the ratio τ_{rad}/τ_{coll} of radiative lifetime to the collisional deactivation time of the excited level.

If the exciting laser beam is chopped at a frequency f which is smaller than the inverse transfer time $(1/\tau_{coll} + 1/\tau_{rad})$ the pressure in the cell is modulated at the frequency f. A sensitive microphone in the side wall of the cell detects these pressure changes which represent acoustic waves. When the chopping frequency is chosen to coincide with one of the acoustical eigenresonances of the cell, standing acoustic waves are generated with amplitudes that are dependent on the acoustic quality factor Q of the cell and which are much higher than for the nonresonant case.

The technique is quite sensitive, because the acoustic resonator acts as amplifier and stores the energy converted from the excited molecules into standing acoustic waves for a time $T_r \propto Q$. For illustration Fig. 13.12 shows the optoacoustic spectrum of a very weak overtone band in acetylene, with the different rotational lines [13.7]. Since the absorbed optical photon

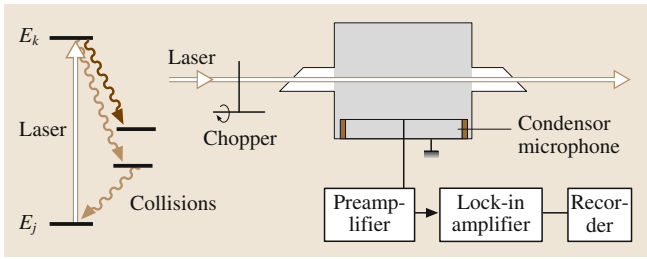

Fig. 13.11 The principle of optoacoustic spectroscopy

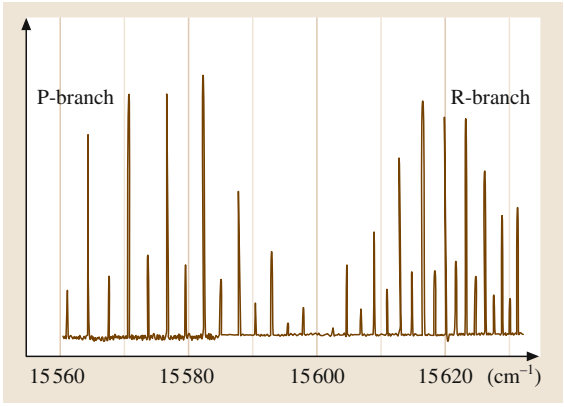

Fig. 13.12 Rotational lines in a vibration overtone transition of acetylene C_2H_2 measured with optoacoustic spectroscopy (after [13.5])

energy is converted into acoustic energy the method is named *optoacoustic spectroscopy*.

The sensitivity can be further enhanced when the acoustic cell is placed inside an optical multiple pass cell (Fig. 13.13). The laser beams inside this cell with spherical mirrors form a hyperboloid and excite acoustic standing waves on those locations in the acoustic cell where the standing acoustic waves have maximum am-

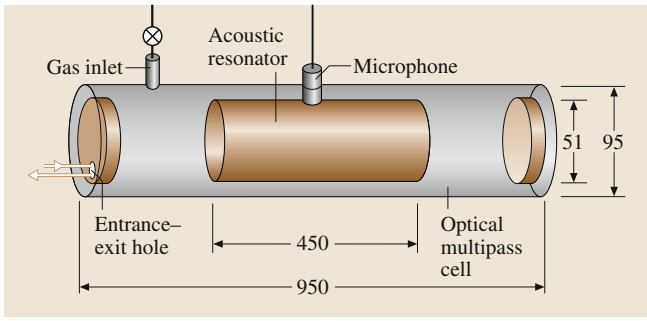

Fig. 13.13 Optoacoustic spectroscopy in an acoustic resonance cell placed inside an optical multipass cell

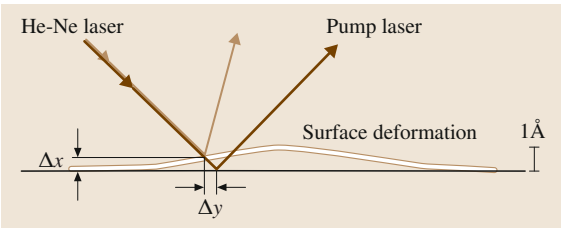

Fig. 13.14 Time-resolved measurements of surface deformations due to local heating induced by a laser pulse (after [13.6])

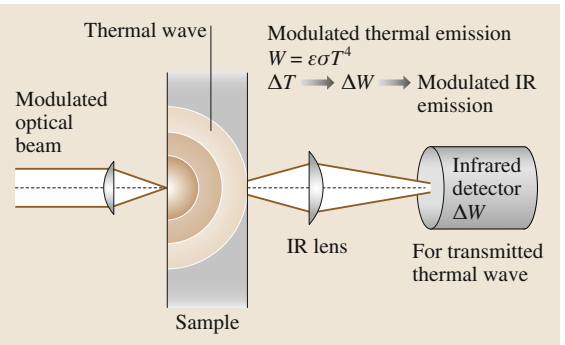

Fig. 13.15 Measurements of thermal waves in a thin metal sheet induced by absorption of a modulated laser beam (after [13.7])

plitude, which optimizes the conversion efficiency for the energy transfer from the excited molecules into the acoustic mode.

The technique can be also applied to the investigation of thin films or of surfaces of solids and liquids. The absorbed incident radiation causes local heating which results in a thermal deformation. This can be detected with a weak probe laser beam, which is incident on the surface under an angle α against the surface normal. For a flat surface the reflection angle is again α. However, if the surface is deformed by local heating, the local surface normal is inclined and therefore the reflection angle is changing (Fig. 13.14) [13.8]. When the surface is heated by a pulsed laser, focused onto the surface, the change of reflection angle of the CW probe laser can be monitored as a function of time. This gives a measure of the time constants of heat transfer from the local spot into the surrounding.

When the heating laser is pulsed or modulated, thermal waves are generated which transfer the heat away from the local heat source at the focus of the laser. At a distance x from the heat source the temperature reaches its maximum at a time delay

$$\Delta t = \left(\rho \cdot \frac{c}{2} k\right) x^2 \qquad (13.18)$$

after the heating pulse, where ρ is the density, c the specific heat and k the thermal conductivity of the sample material. After the thermal diffusion length

$$x = D = \left(\frac{k}{\pi} c \rho f\right)^{1/2} \qquad (13.19)$$

the amplitude of the thermal wave which is generated by a heat source modulated at the frequency f, has decreased to $A_0 \cdot e^{-2\pi} \approx 2 \times 10^{-3} A_0$.

Measurements of such thermal waves allow the determination of the thermal conductivity of the sample. A possible experimental arrangement is shown in Fig. 13.15. The temperature wave, transmitted through the sample can be monitored with an infrared detector. The time constant of this detector limits the time resolution. In case of a sinusoidal modulated heat source the detected signal is also modulated but shows a phase lag which is a measure for the time delay between the generation and the arrival of the thermal wave [13.8–10].

Optogalvanic Spectroscopy

For the spectroscopy of high lying atomic, molecular or ionic levels gas discharges are convenient because here many of these levels are populated by electron impact, in particular metastable levels with long lifetimes. The discharge impedance depends on the number of electrically charged carriers, i. e. electrons and ions, which are created by electron impact-ionization from excited levels of the neutral species. If the population of these excited levels is changed, for instance by absorption of photons, the electron density will change and therefore the impedance of the discharge. If the discharge is fed through a ballast resistor R by a power supply with constant voltage, the impedance change causes a corresponding change of the discharge current and of the voltage drop across the resistor R. This forms the basis for optogalvanic spectroscopy [13.11].

The experimental arrangement is shown in Fig. 13.16. The discharge tube (which might be a hollow cathode discharge or a discharge through a capillary, such as that used for the He-Ne-laser or the argon ion laser) is irradiated by the chopped output beam of a tunable laser (dye-laser or semiconductor laser). This causes a modulation Δi of the discharge current at the chopping frequency f and a corresponding voltage modulation $\Delta U = R \cdot \Delta i$ across the ballast resistor R which is coupled through a capacitance C into a lock-in amplifier and recorded by a computer. If the laser wavelength

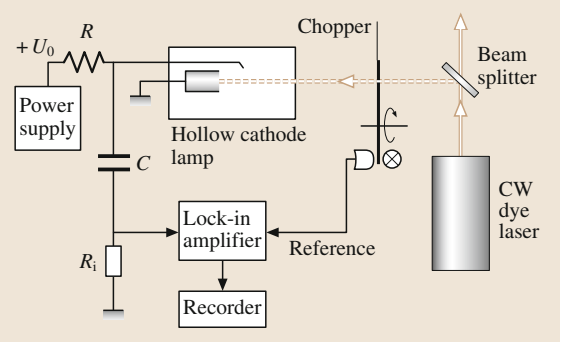

Fig. 13.16 Schematic arrangement for optogalvanic spectroscopy in a hollow cathode discharge

is tuned to a transition $E_i \rightarrow E_k$ the population of the two levels changes due to laser-induced transitions by

$$\Delta n_i = n_{i_0} - n_{i_L} \; ; \; \Delta n_k = n_{k_0} - n_{k_L} \; . \qquad (13.20)$$

The corresponding voltage change is then

$$\Delta V = R\Delta i = a[\Delta n_i \mathrm{IP}(E_i) - \Delta n_k \mathrm{IP}(E_k)] \; , \qquad (13.21)$$

where $\mathrm{IP}(E_i)$ is the ionization probability of level E_i.

The optogalvanic signals might be positive or negative, depending on the different ionization probabilities of the levels E_i and E_k.

Most gas discharge tubes are filled with noble gases. However, if the noble gas is mixed with other volatile components their spectra can be also measured by this technique.

Even molecules can be inserted into the discharge. Since some of the molecules might be fragmentized by electron impact the spectra of the mother molecules and their fragments overlap and the assignment might be difficult [13.12, 13].

In a hollow cathode discharge the ions, impinging onto the inner walls of the hollow cathode release atoms and ions of the wall material by sputtering processes. With higher discharge currents the spectra of these sputtered materials become more and more prominent. This is illustrated in Fig. 13.17 where the optogalvanic spectrum of aluminum, copper and iron is shown which has been measured in a hollow cathode discharge.

Investigations of intensity and time behaviour of optogalvanic signals give information on radiative decay constants of highly excited levels and on collision cross sections for electron impact excitation and ionization. These parameters are important for understanding plasma characteristics.

Ionization Spectroscopy

The most sensitive detection technique is the ionization-spectroscopy. Here a laser is tuned through the spectrum of interest and excites for each absorbing transition a selected upper level. This excited level is ionized by a second laser (Fig. 13.18). If the second laser is sufficiently intense, the ionising transition can be saturated, which means that every excited molecule is ionized before it can emit a fluorescence photon or is deactivated by collisions. The ions can be collected by an electric field, accelerated and imaged onto the cathode of an open ion-multiplier. This is a device that is quite similar to a photo-multiplier. Only the photo-cathode is replaced by a metal cathode, where the ions, impinging

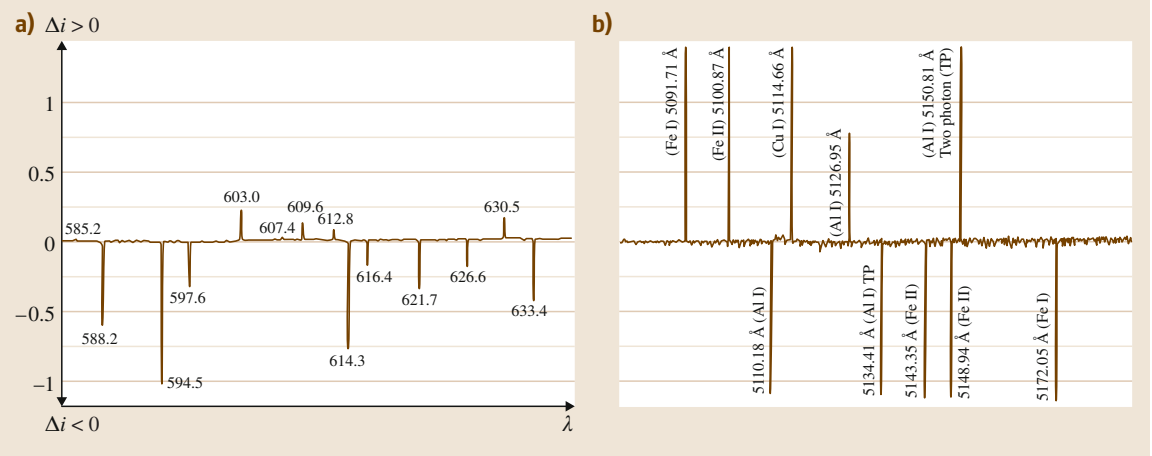

Fig. 13.17a,b Optogalvanic spectrum of a neon discharge in a hollow cathode covered with a mixture of different metals (after [13.10])

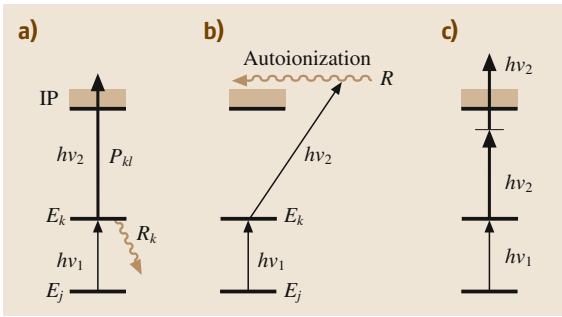

Fig. 13.18a–c Level scheme for multiphoton ionization **(a)** resonant two-photon ionization, **(b)** excitation of auto-ionizing Rydberg states, **(c)** nonresonant two-photon ionization of molecules in a level excited by a third photon

with energies of a few keV produce electrons by ion-bombardment. These electrons are further accelerated and multiplied like in a photo-multiplier.

With an optimum design of the ion collecting system each ion produced through photo-ionization by the second laser, can be imaged onto the ion multiplier and produces a voltage pulse at the multiplier output, that can be counted.

If the first laser with wavelength λ_1 is tuned through the spectral region of interest and the second laser has a fixed wavelength λ_2, the measured ion rate $N_{\text{ion}}(\lambda_1)$ gives essentially the absorption spectrum $\alpha(\lambda_1)$ of transitions from the absorbing levels to the levels excited by laser L_1. The sensitivity of this method is, however by several orders of magnitude higher than in absorption spectroscopy, where the attenuation of the transmitted laser intensity is monitored.

In favourable cases single atoms or molecules can be detected [13.14, 15].

With a photon flux $\dot{N}_{L_2}$ of the ionizing laser the number of ions produced per second is

$$\dot{N}_{\text{ion}} = n_k V \Sigma_{kI} \dot{N}_{L_2} \,, \tag{13.22}$$

where $P_{kI} = \sigma_{kI} \cdot N_{L2}$ is the ionization probability by laser L_1, and n_k is the stationary population density of the excited level $\langle k|$ in the volume V inside the ionizing laser beam, from which ions can be extracted.

The stationary density n_k of molecules in level $|k\rangle$ is determined by the balance between excitation by laser L_1 and depopulation processes. If $R_k + P_{kI}$ is the total relaxation probability of the excited level $|k\rangle$, we obtain

$$\dot{n}_k = 0 = n_i \dot{N}_{L_1} \Sigma_{ik} - n_k (P_{kI} + R_k) \Rightarrow$$
$$n_k = n_i \frac{\dot{N}_{L_1} \Sigma_{ik}}{P_{ki} + R_k} \,. \tag{13.23}$$

With the ion yield efficiency $\eta = P_{kI}/(P_{kI} + R_k)$ this gives for the measured ion rate

$$S = \delta \dot{N}_{\text{ion}} = n_i \dot{N}_{L_1} \dot{N}_{L_2} V \frac{\Sigma_{ik} \Sigma_{kI}}{P_{kI} + Rk} \,, \tag{13.24}$$

where δ is the collection efficiency for the ions onto the detector.

More information on this sensitive technique can be found in [13.14, 15].

Excitation Spectroscopy with Fluorescence Detection

The total fluorescence intensity emitted from an excited level can be measured (without dispersion by a spectrometer) as a function of the wavelength λ of the exciting laser (Fig. 13.19). Each absorbed photon creates a fluorescence photon if other deactivation processes of the excited level (for instance collision-induced radiationles transitions) can be neglected. This *excitation spectroscopy* is a very sensitive version of absorption spectroscopy, as can be seen from the following estimation.

The fluorescence photons, imaged onto the cathode of a photomultiplier, create n_{pe} photo-electrons per s. With the quantum efficiency of the photocathode $\eta_{\text{ph}} = N_{\text{pe}}/N_{\text{fl}}$, the rate of absorbed laser photons N_{a}, the fluorescence quantum yield $\eta_{\text{fl}} = N_{\text{fl}}/N_{\text{a}}$, the geometrical collection efficiency δ of the fluorescence photons onto the photocathode, the measured rate of photo-electrons is given by

$$S = N_{\text{pe}} = N_{\text{a}} \cdot \eta_{\text{fl}} \cdot \eta_{\text{ph}} \cdot \delta \,. \tag{13.25}$$

The absorption rate

$$N_{\text{a}} = n_i \cdot \sigma_{ik} \cdot N_{\text{L}} \cdot A \cdot \Delta x \tag{13.26}$$

depends on the number density n_i of molecules in the absorbing level $\langle i|$ within the excitation volume $V = A \cdot$

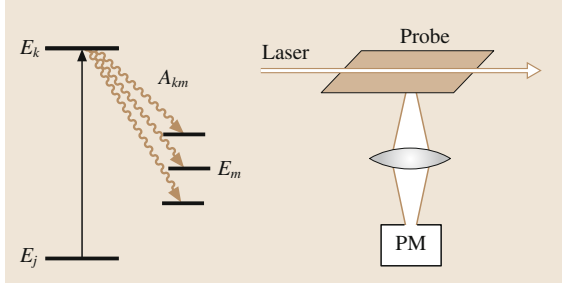

Fig. 13.19 Level scheme and experimental setup for excitation spectroscopy, where the undispersed laser-induced fluorescence is measured as a function of the excitation wavelength (PM = photomultiplier)

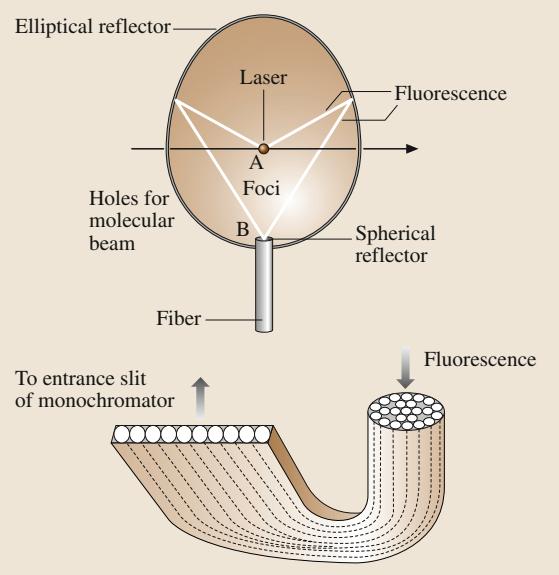

Fig. 13.20 Optical setup with elliptical mirror and fibre bundle for effective collection of fluorescence photons

Δx, the absorption cross section σ_{ik}, the number N_L of laser photons incident per s and cm^2 in a laser beam with cross section A onto the sample with absorption path length Δx.

The collection efficiency δ for fluorescence photons can be enlarged by an elliptical mirror arrangement (Fig. 13.20). When the intersection volume V of laser and molecular beams is placed around one focal point A of the ellipsoid, the fluorescence is imaged into the second focal point B where an optical fiber-bundle transmits it either directly to the photomultiplier or to the entrance slit of the spectrometer.

Example 13.3: With a quantum efficiency $\eta_{ph} = 0.2$ of the multiplier photocathode, a collection efficiency of $\delta = 0.1$ which demands a collection optics for the fluorescence, that covers a solid angle of 0.4π, a fluorescence yield $\eta_k = 1$ for the excited level $\langle k|$ and a laser photon flux of $N_L = 3\times10^{18}$/s, which corresponds to a laser power of 1 W at $\lambda = 500$ nm, an absorption rate $N_a = 10^4$/s (which means a relative absorption of the laser of $\Delta I_L/I_L = 3\times10^{-15}$) gives a photo-electron rate $N_{pe} = 200$/s. If the dark current of the photomultiplier is $N_{pe}(0) = 50$/s, this gives a signal to background ratio of 4, which demonstrates that relative absorptions of less than 10^{-15} can be still detected. This represents a much higher sensitivity as any direct absorption measurement!

Intra-Cavity Absorption

A large enhancement of sensitivity can be achieved when the absorbing sample is placed inside the cavity of the laser [13.16, 17]. This increase of sensitivity has several reasons:

1. When the resonator mirrors have the transmission $T_1 = 0$ and $T_2 > 0$, the radiation intensity inside the cavity is larger by a factor $q = 1/T_2$ than outside and therefore the number of absorbed photons is multiplied by q. This advantage is quite similar to that of a multipass cell. Observing the laser-induced fluorescence emitted from excited atoms or molecules inside the resonator (Fig. 13.21) therefore gives a larger signal proportional to the number of absorbed photons.
2. The output power of the laser depends on the gain of the active medium and the losses inside the laser cavity. Therefore additional losses by absorbing species decrease the output power. This effect is in particular strong if the laser operates closely above the lasing threshold (Fig. 13.22). Under sta-

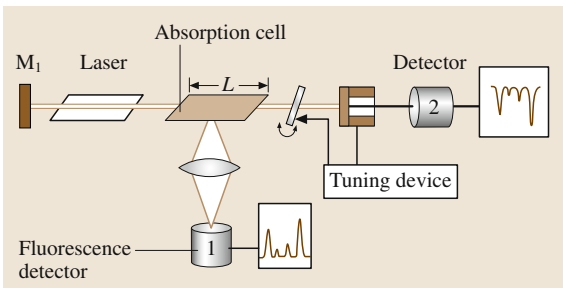

Fig. 13.21 Setup for intracavity absorption, monitored either by the laser-induced fluorescence or by the laser output power

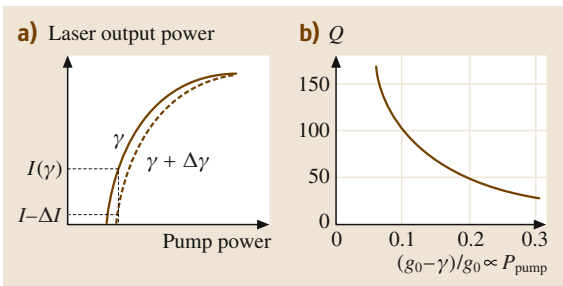

Fig. 13.22 **(a)** Laser output power as a function of pump power with and without an absorbing sample inside the laser cavity. **(b)** Enhancement factor Q as a function of pump power above threshold

tionary conditions the population inversion saturates to such a value, that the saturated gain

$$g_s = \frac{g_0}{1 + I/I_s} = \frac{g_0}{1 + P/P_s} = \gamma \qquad (13.27)$$

just equals the total losses. Here g_0 is the unsaturated gain and I_s is the saturation intensity (Sect. 13.3.1), which decreases the population inversion to one half of its unsaturated value.
This gives for the laser output power

$$P = P_s \frac{g_0 - \gamma}{\gamma} \,. \qquad (13.28)$$

If additional losses are introduced by the absorbing sample the laser power drops to

$$P_a = P - \Delta P = P_s \frac{g_0 - \gamma - \Delta\gamma}{\gamma + \Delta\gamma} \,. \qquad (13.29)$$

The relative change of the output power is then

$$\frac{\Delta P}{P} = \frac{P - P_a}{P} = \frac{g_0 \Delta\gamma}{(g_0 - \gamma)(\gamma + \Delta\gamma)} \approx \frac{g_0}{\gamma} \frac{\Delta\gamma}{g_0 - \gamma} fVN\Delta\gamma \ll \gamma \,. \qquad (13.30)$$

Compared with the single pass absorption $\Delta P = P \cdot \alpha \cdot L$ for an absorption cell with length L outside the laser resonator the sensitivity enhancement is with $\Delta\gamma = \alpha \cdot L$

$$Q = \frac{g_0}{\gamma(g_0 - \gamma)} \,. \qquad (13.31)$$

Just above threshold g_0 is only slightly larger than γ and Q becomes very large.
However, the laser output power becomes more and more unstable the more the threshold is approached. Therefore there is an upper limit for the attainable signal-to-noise ratio.

3. The most sensitive technique of intra-cavity absorption is based on multimode lasers, where the coupling between different modes is essential for the high sensitivity. This can be understood as follows:
Assume, one of the oscillating laser modes coincides with an absorption line of the intra-cavity sample. The power in this mode is then decreased and this mode causes less saturation of the gain medium. The neighbouring laser modes, that are closer to the absorbed mode than the saturation linewidth can take advantage of this decrease in the population inversion and gain intensity. This in turn decreases the gain for the weaker absorbed mode and weakens its power further. This mode-coupling therefore can lead to a complete extinction of the absorbing mode. This means: a tiny absorption can cause a drastic change of the intensity of the absorbed mode.

More detailed calculations show that the relative change of the output power is now

$$\frac{\Delta P}{P} = \frac{g_0 \Delta\gamma}{\gamma(g_0 - \gamma)}(1 + KM) \,, \qquad (13.32)$$

where M is the number of coupled laser modes and K ($0 \le K \le 1$) is a measure for the coupling strength. For $K = 0$ we obtain the same result as for a single mode laser, while for $K = 1$ and a large number M of coupled modes the increase in sensitivity is remarkable.

In real lasers the mode-coupling and the mode frequencies fluctuate in course of time, due to thermal instabilities or fluctuations of the refractive index in the liquid gain medium of dye lasers. This would introduce additional noise and decrease the sensitivity. It is therefore better to pump the laser with a pump laser whose output power follows a step function, that starts at time $t = 0$ and then remains constant. The intra-cavity absorption is measured at times t with $0 \le t \le t_m$ which are shorter than the mean mode lifetime t_m. The experimental setup is shown in Fig. 13.23 [13.18]. The CW broadband dye laser is pumped by an argon laser, whose output can be switched by the acousto-optical modulator AOM1. The laser output through mirror M_0 is gated by AOM2, dispersed by a spectrograph with a CCD array and monitored by a computer.

In the course of time the spectral absorption profiles become deeper and narrower until they reach the spectral resolution of the spectrograph.

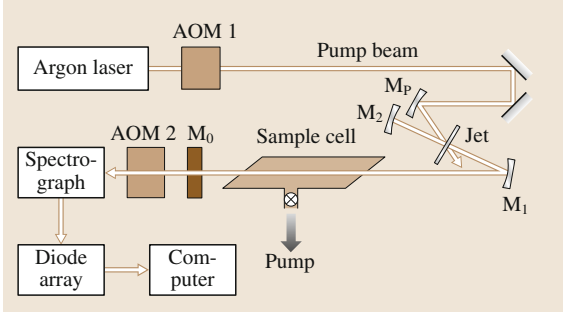

Fig. 13.23 Experimental arrangement for intracavity laser spectroscopy with a step-function pump power and a variable delay for detecting the transmitted dye-laser output

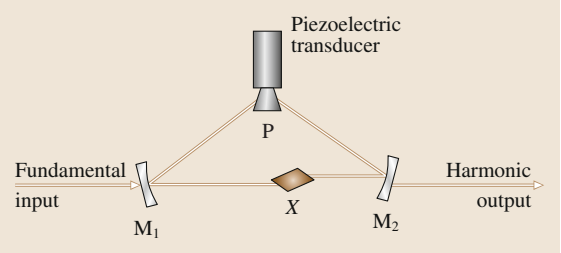

Fig. 13.24 Enhancement cavity for optical frequency doubling

The maximum effective absorption length achieved with this technique is

$$L_{\text{eff}} = c \cdot t_{\max} \,, \tag{13.33}$$

where c is the velocity of light and $t_{\max}$ the maximum observation time.

Example 13.4: With a typical delay time $t_{\max} = 100\,\mu\text{s}$ the effective absorption length becomes $L_{\text{eff}} = 3 \times 10^8 \times 10^{-4}\,\text{m} = 30\,\text{km}$! If an absorption dip in the dispersed output power of 1% can be still detected, this gives a sensitivity limit for the absorption coefficient of $\alpha_{\min} = 3 \times 10^{-9}\,\text{cm}^{-1}\,\text{m}$ [13.19].

Instead of placing the absorbing sample inside the laser resonator also external enhancement resonators can be used. Here a high finesse can be reached with highly reflecting mirrors. This increases the effective path length through the absorbing sample and therefore the sensitivity.

Such enhancement cavities are in particular useful for optical frequency doubling of CW lasers. In order to reduce the number of reflecting surfaces (which always introduce absorption losses) the ring resonator in Fig. 13.24 reduces the number of mirrors to two with the help of a Brewster prism which has negligible reflection losses. Its disadvantage is the astigmatism, which is not eliminated by this geometry. There are more sophisticated designs [13.20] which compensate most of the imaging errors.

13.1.1 Absorption- and Emission-Spectroscopy and Laser-Induced Fluorescence

Up to now we have mainly discussed different techniques of absorption spectroscopy. The spectroscopy of radiation emitted from excited levels of atoms or molecules plays an important role in plasma physics and in particular in astrophysics where the radiation emitted from stars or reflected by planets is the main source of information about extra-terrestrial objects.

Emission spectroscopy requires a sufficient population of excited states and needs dispersive instruments for measuring the spectrum, i. e. the wavelengths, intensities, line profiles and the degree of polarization of the emission lines.

The excited levels can be populated by thermal collisions if the temperature is sufficiently high (e.g. in the atmospheres of stars), or by electron impact in gas discharges. These mechanisms generally populate many levels and the emission spectrum is accordingly complex. The spectral resolution is limited by the dispersing instrument and reaches for grating spectrometers about 0.1–0.01 nm, while with interferometers the Doppler-width of the emission lines can be seen.

The spectrum will become much simpler, if a single upper level can be selectively excited. This is in many cases possible, when a single-mode laser is used for excitation and the fluorescence spectrum emitted by this single level is measured. A typical experimental setup is shown in Fig. 13.25. The fluorescence spectrum, emitted by this excited level, is dispersed by a spectrometer and the fluorescence lines are recorded by a photo-multiplier or a CCD-array. If the fluorescence is, for instance, emitted from a single upper rotational-vibrational level (v', J') of a diatomic molecule the allowed transitions represent a relatively simple vibrational progression with only one or two rotational lines in each vibrational band (Fig. 13.23). The relative intensities of these vibrational bands allow the determination of the Franck–Condon factors. Such a laser-induced fluorescence spectrum is indeed much simpler than the emission spectrum from a gas discharge where many upper levels are populated and the total fluorescence is the superposition of all fluorescence series emitted by the different upper levels.

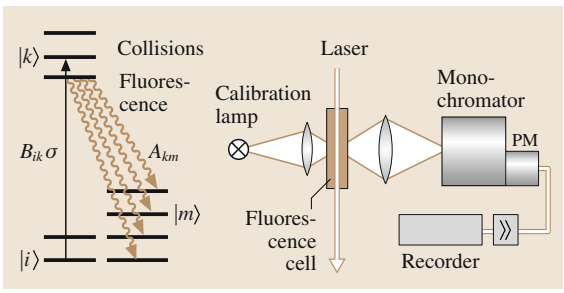

Fig. 13.25 Measurement of dispersed laser-induced fluorescence spectrum with wavelength calibration

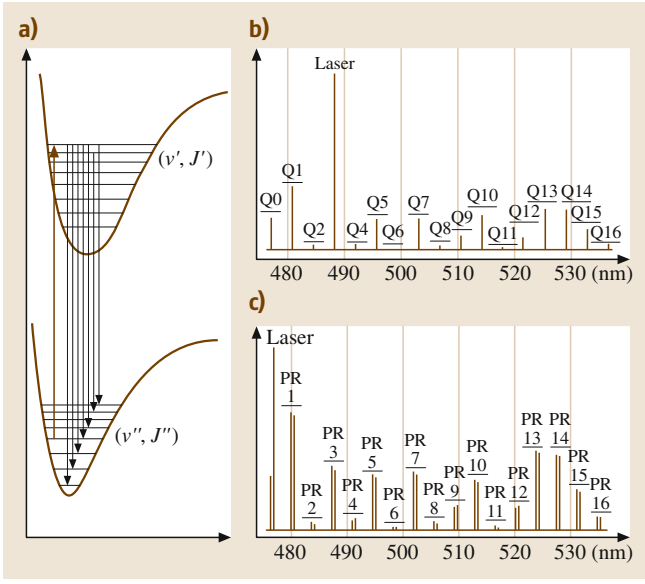

Fig. 13.26a–c Laser-induced fluorescence spectra of the Na_2 molecule for two different selectively excited upper levels: **(b)** $v' = 3$, $J' = 43$, **(c)** $v' = 6$, $J' = 27$ in the $B^1\pi_u$ state

The wavenumbers of the fluorescence lines are equal to the differences between the term values of the upper level and the terminating lower levels. If the upper level is the same for all lines the separations of the fluorescence lines just give the energy differences between the levels in the lower state (Fig. 13.26). The vibrational spacings yield the vibrational constants of the lower electronic state and the rotational spacings the rotational constants and their dependence on the vibrational level. If the Franck–Condon factors for transitions into high vibrational levels of the electronic ground state are sufficiently large (this depends on the excited upper vibrational level), the vibrational levels in the electronic ground state can be measured up to the dissociation energy. This allows a very accurate determination of the potential curve [13.21, 22].

The selective excitation of a single upper level is only possible, if there is no overlap of absorptions lines within their line-width. For excitation in a gas cell the spectral width is generally limited by the Doppler-width. At higher temperatures many levels in the electronic ground state are thermally populated, which results in a higher density of absorption lines, and often the mean distance between different lines is smaller than the Doppler-width. In such cases several upper levels are excited even with a single mode laser. However, even then the resulting fluorescence spectrum is still simpler as the emission spectrum fro a gas discharge.

This problem can be overcome by laser excitation in a cold and collimated molecular beam, where the Doppler-width is greatly reduced and the temperature is decreased due to adiabatic cooling during the expansion of the beam from the reservoir through a nozzle into the vacuum chamber.

The laser-induced fluorescence spectroscopy has proved to be very useful for the investigation of inelastic collisions in excited states. These collisions transfer the initial population from the selectively excited level $|k\rangle$ into neighbouring rotational-vibration levels $|j\rangle$. The fluorescence emitted from these levels is a direct measure for the transfer probability. The ratio $I_{fl}(j)/I_{fl}(k)$ yields the collision cross section for individual transitions, if the densities of the collision partners is known. For such measurements the fluorescence must be dispersed by a spectrometer in order to separate the contributions emitted from the different levels.

13.1.2 Laser Spectroscopy in Molecular Beams

The combination of laser spectroscopy with molecular beam techniques has brought about a wealth of new information [13.23]. First of all there is the possible reduction of the Doppler-width in collimated molecular beams, when a laser beam is crossed perpendicular with the molecular beam. Due to the collimation the velocity components of the molecules parallel to the laser beam are greatly reduced. This line-width reduction allows the resolution of finer details in atomic or molecular spectra.

The second advantage is the drastic reduction of the temperature in a supersonic beam, where adiabatic cooling during the expansion of the molecules from their reservoir at high pressure through a narrow nozzle into the vacuum chamber converts the gas at thermal equilibrium at a temperature T_0 into a directed flow of molecules with a narrow spread of their parallel velocities around the flow velocity u. Through collisions during the expansion this drop of the *translational temperature* is partly transferred to the rotational and vibrational degrees of freedom and the population distribution is compressed into the lowest vibrational-rotational states. Although there might not be a strict thermal equilibrium, the rotational- as well as the vibrational distribution can be approximated by a Maxwell–Boltzmann distribution and a temperature can be attributed. Typical values are $T_{trans} = 0.1 - 1\,K$,

$T_{rot} = 1–10\,K$ and $T_{vib} = 10–100\,K$, depending on the pressure in the reservoir, the nozzle diameter and the specific molecules. This reduction of the population distribution onto the lowest levels results in a drastic simplification of the absorption spectrum and facilitates the assignment considerably [13.24–26].

The third advantage is the possible application of laser spectroscopy in the investigation of collision processes in crossed molecular beams. In particular for experiments on state-to-state inelastic or reactive collisions the laser can prepare the initial state of the collision partners and detect their final states. Therefore maximum information can be obtained about the interaction potential and its dependence on the distance between the collision partners and on their relative orientation.

Reduction of Doppler-Width

In many cases the spectral resolution is limited by the Doppler-width of the absorption lines. This limitation often prevents the recognition of finer details in the spectrum, such as hyperfine splittings, Zeeman-splittings in weak external fields or the rotational structure in molecular spectra. *Doppler-free* techniques that can overcome the limitations set by the Doppler-width are then demanded for getting the full information from atomic or molecular spectra.

An elegant way to reduce the Doppler-width is the reduction of the velocity distribution of atoms or molecules in collimated molecular beams (Fig. 13.27).

Molecules, effusing from a reservoir through a small hole A into a vacuum chamber have to pass through a narrow slit with width b, at a distance d down-streams of the molecular beam in order to reach the interaction region with the laser beam. If we choose the molecular beam axis as the z-axis and the slit along the y-direction, the v_x-component of the molecules passing through the slit is reduced by the geometrical factor

$$v_x \le (b/2d)\cdot v = v_z \cdot \tan\varepsilon\,, \qquad (13.34)$$

where $v = (8kT/\pi m)^{1/2}$ is the mean velocity of particles with mass m, when the temperature of the reservoir is T, v_z is the velocity component parallel to the beam axis and ε with $\tan\varepsilon = b/2d$ is the collimation angle.

If the beam of a tunable single mode laser crosses the molecular beam in x-direction (i. e. perpendicular to the molecular beam axis) behind the slit, only molecules within the narrow interval $v_x \le (b/2d)\cdot v$ contribute to the absorption, which means that the width $\Delta\nu$ of the absorption line is reduced compared to its Doppler-width in a gas at thermal equilibrium.

Example 13.5: With $b = 1\,mm$, $d = 100\,mm \Rightarrow \tan\varepsilon = 5\times10^{-3}$. Instead of a typical Doppler-width of $\Delta\nu_D = 1\,GHz$ in the optical range, the line-width is now reduced by a factor of 200 to $\Delta\nu_D^{red} = 5\,MHz$. This is already in the range of the natural line-width.

The quantitative treatment starts with the density of molecules in the beam with velocities v within the interval dv

$$n(V, r, \Theta)\,dV = \varphi_i \frac{\cos\Theta}{r^2} n v^2 e^{-(v/v_p)^2}\,dv\,, \qquad (13.35)$$

where the normalization factor $C = (4/\sqrt{\pi})/v_p^3$ assures that the total density n of the molecules is

$$n = \int n(v)\,dv \qquad (13.36)$$

and $v_p = (2kT/m)^{1/2}$ is the most probable velocity. The spectral profile of the absorption coefficient is

$$\alpha(\omega, x) = \int n(v_x, x)\,\Sigma(\omega, v_x)\,dv_x\,, \qquad (13.37)$$

with $v_x = (x/r)v \Rightarrow dv_x = (x/r)dv$ and $\cos\Theta = z/r$ (Fig. 13.27b) we derive from (13.35) for the molecular density

$$n(v_x, x)\,dv_x = \varphi n \frac{z}{x^3} v_x^2 \exp\left[-\left(\frac{r v_x}{x v_p}\right)^2\right] dv_x\,. \qquad (13.38)$$

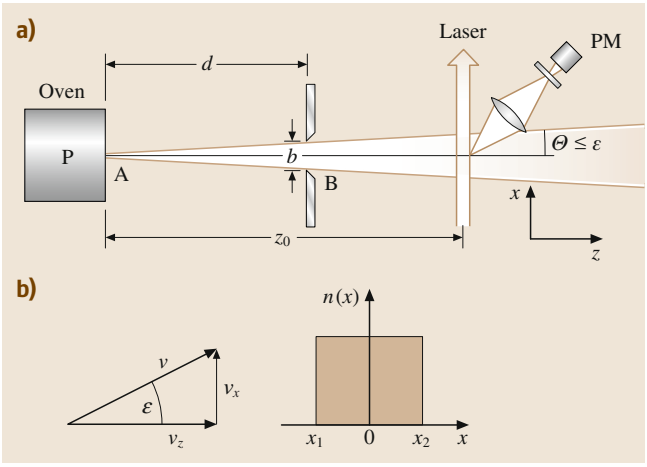

Fig. 13.27 Laser spectroscopy in a collimated molecular beam with reduction of the Doppler width (PM = photomultiplier)

The absorption cross section $\sigma(\omega, v_x)$ is a Lorentzian profile, Doppler-shifted by $k \cdot v_x$

$$\sigma(\omega, v_x) = \Sigma_0 \frac{(\gamma/2)^2}{(\omega - \omega_0 - k v_x)^2 + (\gamma/2)^2} \,. \quad (13.39)$$

Inserting (13.38) and (13.39) into (13.37) gives with $dv_x = d\omega/k$ the spectral profile of the absorption coefficient

$$\alpha(\omega) = \varphi \int_{-\infty}^{+\infty} \frac{e^{-\left(\frac{\omega-\omega_0'}{\omega_0' v_p \sin(\varepsilon/c)}\right)^2}}{(\omega-\omega_0')^2 + (\gamma/2)^2} d\omega_0'$$

$$\text{with} \quad \omega_0' = \omega_0(1 + v_x/c) \quad (13.40)$$

This is the convolution of a Lorentzian and a Gaussian line-profile, which is called a *Voigt-profile*. The Gaussian profile has a width $\Delta\omega_D \cdot \sin\varepsilon$, reduced by a factor $\sin\varepsilon$ against the Doppler-width in a gas at thermal equilibrium.

High resolution absorption spectra can be measured by monitoring the total fluorescence $I_{fl}(\lambda_L)$ as a function of the laser wavelength (excitation spectroscopy), or by resonant two-photon ionization, where the ions are extracted by an electric field from the intersection volume of molecular and laser-beams onto the ion multiplier. A typical experimental arrangement is shown in Fig. 13.28. Here the molecular beam is crossed by several laser beams. In the first crossing point the laser-induced fluorescence is collected to both sides.

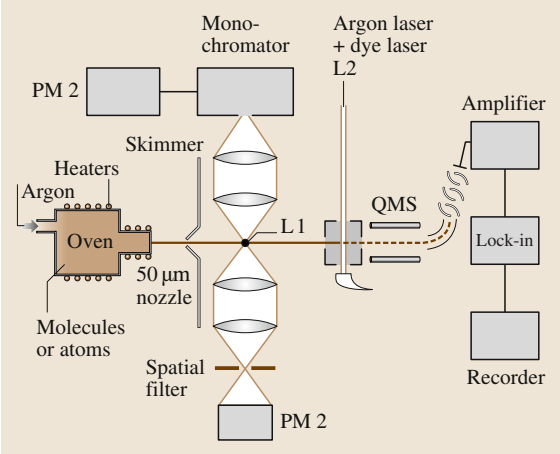

Fig. 13.28 Molecular-beam apparatus with different crossing points with laser beams for measuring the undispersed and the dispersed laser-induced fluorescence, and the ions produced by resonant two-photon ionization with subsequent mass selection by a quadrupole spectrometer (QMS)

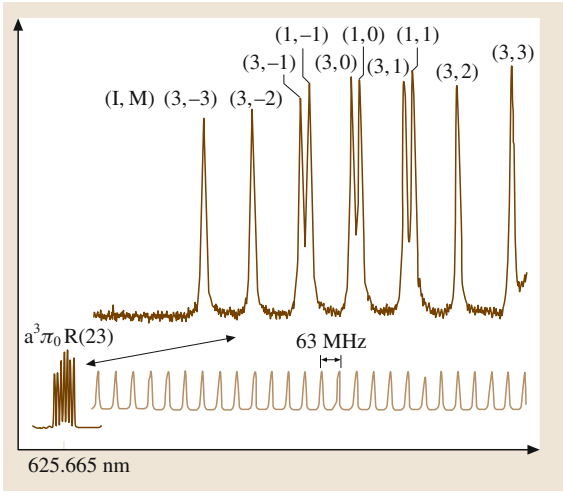

Fig. 13.29 Resolved hyperfine structure (HFS) of a rotational transition in the Na_2 molecule, measured in a collimated molecular beam (after [13.17])

The photo-multiplier PM1 measures the total fluorescence while PM2 behind a monochromator monitors the dispersed fluorescence for a fixed excitation laser wavelength.

The second crossing point between the molecular beam and two superimposed laser beams is located in the ion source of a mass spectrometer. The first laser excites the molecules into an intermediate level $|i\rangle$ and the second CW argon laser brings them from the state $|i\rangle$ into an energy state just above the ionization threshold. This resonant two-photon ionization is very efficient in producing isotope-selective ions, or in case of cluster beams to select specific cluster sizes for ionization. This is very helpful for the assignment of the spectra, if many different masses (e.g. isotopes or different cluster sizes in a cluster beam) are present.

For illustration of the attainable spectral resolution Fig. 13.29 shows the hyperfine-structure of a rotational transition ($j' \leftarrow j'''$) in the electronic transition of Na_2-molecules from the $X\,^1\Sigma_g$ ground state into the mixed $A\,^1\Sigma_u - a\,^3\Pi_u$ where the two states are coupled by spin-orbit coupling [13.27].

Optothermal Spectroscopy in Molecular Beams

The temperature increase caused by the transfer of excitation energy can be also monitored by the change of electrical conductivity with temperature. This is used in the bolometer, which is a detector made of a material with a high temperature coefficient α of the electrical conductivity $\sigma = \sigma_0(1 + \alpha(T))$. Gen-

erally doped semiconductor materials are used. The coefficient α decreases with decreasing temperature. Therefore a bolometer is generally operated at low temperatures, e.g. at $T = 1.5\,\mathrm{K}$, which can be reached by evaporating ^{4}He in a helium cryostat. Even lower temperatures down into the milli-Kelvin range can be obtained by a ^{3}He^{4}He dilution refrigerator.

The temperature increase can be caused by absorption of photons (in this case the bolometer acts as a radiation detector) or by adsorption of excited atoms or molecules at the surface of the bolometer. Here they transfer their excitation energy to the bolometer.

A typical arrangement for molecular spectroscopy in molecular beams is shown in Fig. 13.30 [13.28].

The molecular beam is crossed perpendicular by the beam of a single mode laser, which excites the molecules into long-living higher states (for example excited vibrational levels in the electronic ground state or Rydberg-states with a long radiative lifetime).

The heat transfer rate from N molecules per s with the excitation energy $\Delta E = h \cdot \nu$ is

$$\frac{\mathrm{d}Q}{\mathrm{d}t} = N \cdot \Delta E = N \cdot h\nu \,. \tag{13.41}$$

This results in a temperature increase $\Delta T = T - T_0$ of the bolometer with heat capacity C and heat conduction $G \cdot (T - T_0)$ to the surrounding from the temperature T_0 without molecules impinging on the bolometer to the temperature T that can be determined from the energy conservation

$$P = N \cdot h \cdot \nu = C \cdot \left(\frac{\mathrm{d}T}{\mathrm{d}t}\right) + G \cdot (T - T_0)\,, \tag{13.42}$$

where the incident power equals the thermal energy increase per s of the bolometer and the power conducted to the surrounding. Under stationary conditions $(\mathrm{d}T/\mathrm{d}t = 0)$ the temperature rise is obtained from (13.42) as

$$\Delta T = T - T_0 = N \cdot h \cdot \frac{\nu}{G} \,. \tag{13.43}$$

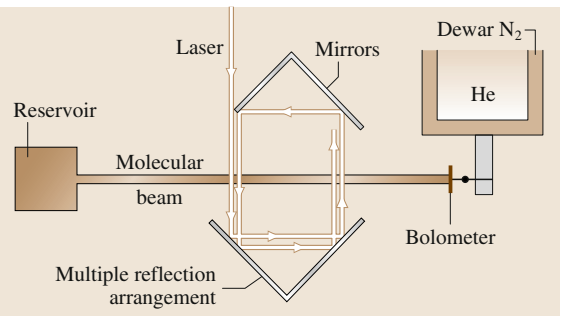

Fig. 13.30 Optothermal spectroscopy in a molecular beam with laser excitation and detection by a cooled bolometer

In order to increase the sensitivity of a bolometer, the heat conductivity to the surrounding should be as small as possible, i. e. the bolometer has to be thermally well isolated.

In order to subtract the background signal caused by the adsorption of molecules in their ground state, the excitation laser is chopped at a frequency f and the optothermal signal is detected through a lock-in amplifier. Now the energy transferred to the bolometer is time-dependent. The time constant of the bolometer should be shorter than the chopping period.

The time constant depends on the heat capacity C and the heat conductivity G. This can be seen as follows: Assume the transferred power is

$$P = P_0(1 + a\cos\Omega t)$$
$$\text{with} \quad a \le 1 \quad \text{and} \quad \Omega = 2\pi f \,. \tag{13.44}$$

Inserting this into (13.42) gives

$$T(\Omega) = T_0 + \Delta T[1 + \cos(\Omega t + \phi)] \,. \tag{13.45}$$

The temperature T is modulated at the same frequency Ω but shows a phase lag ϕ with

$$\tan\phi = \Omega \cdot \frac{C}{G} \tag{13.46}$$

against the modulated incident power, which depends on the heat capacity C, the heat conductivity G and the frequency Ω. The amplitude ΔT of the temperature modulation is

$$\Delta T = \frac{\bar{a} P_0 \Sigma}{\sqrt{\Sigma^2 + \Omega^2 P^2}} \,. \tag{13.47}$$

At the frequency $\Omega_\mathrm{c} = G/C$ the amplitude ΔT decreases by a factor $\sqrt{2}$ against its dc-value.

We see, that the sensitivity is proportional to $1/G$ but the time constant $\tau \sim G/C$. A sufficiently fast and sensitive detector should have a minimum heat capacity. Since C decreases with the temperature, this is again an argument for operating the bolometer at low temperatures [13.29].

In Sect. 13.2 it was shown, that the absorption pathlength should be as large as possible in order to reach a higher sensitivity. Since a single pass through the collimated molecular beam is only about 1 mm, optical arrangements for increasing this absorption length have been designed. In Fig. 13.31 several solutions are illustrated. They consist either of two parallel mirrors,

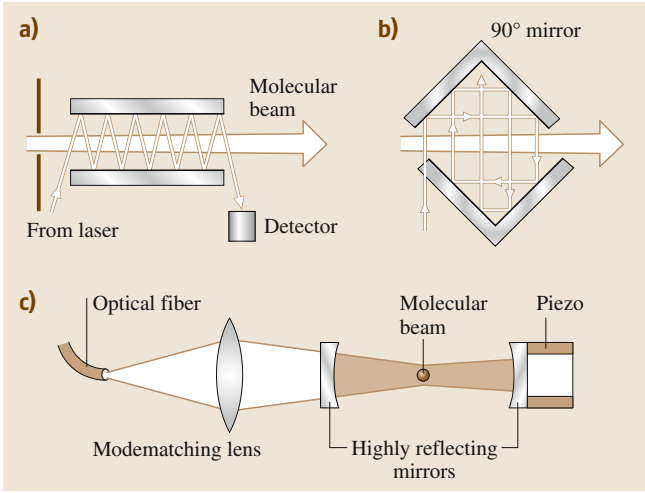

Fig. 13.31a–c Optical arrangements for generating many crossings of the laser beam with the molecular beam. **(a)** two plane-parallel mirrors, **(b)** two cat eyes arrangement, **(c)** crossing point inside a high Q enhancement resonator, where the laser beam is mode-matched to the fundamental mode of the resonator

where the incoming laser beam is reflected back and forth between the mirrors, or of a pair of cat-eyes which are shifted against each other by a small amount δ. In the former arrangement the laser beam passes the molecular beam under an angle $90° - \varepsilon$ and the absorption lines are therefore Doppler-shifted by an amount $\Delta\nu = (v/c) \cdot \sin\varepsilon$, where v is the velocity of the molecules. The largest advantage can be reached, if the crossing point is placed in the beam waist of an external nearly confocal enhancement resonator with highly reflecting mirrors. The incoming laser beam has to be mode-matched to the fundamental mode of the resonator by an appropriate optical design, consisting of two lenses (Fig. 13.29c). With such a design an enhancement of a factor 200 of the optical power in the crossing point can be reached.

13.1.3 Nonlinear Laser Spectroscopy

Several spectroscopic techniques that achieve sub-Doppler resolution are based on the nonlinear interaction of molecules with the laser radiation. When a plane electromagnetic wave passes in x-direction through an absorbing gas we have seen in Sect. 13.1.1, that the attenuation $\mathrm{d}I$ of the intensity is related to the absorption coefficient α by

$$\mathrm{d}I = -\alpha \cdot I \cdot \mathrm{d}x \,. \tag{13.48}$$

The absorption coefficient

$$\alpha = \Delta N \Sigma_{ik}$$

$$\text{with } \Delta N = \left[N_k - \left(\frac{g_k}{g_i} \right) N_i \right]$$

is determined by the population difference ΔN and the absorption cross section σ. This gives for (13.48) the relation

$$\mathrm{d}I = -\left[N_k - \left(\frac{g_k}{g_i} \right) N_i \right] \Sigma_{ik} I \, \mathrm{d}x \,. \tag{13.49}$$

For sufficiently small intensities I the population densities N_i and N_k are not much affected, because relaxation processes can refill the population N_k of the absorbing level (Fig. 13.32a). In this case the absorption coefficient α is independent of the intensity I and integration of (13.48) yields *Beer's* law of linear absorption

$$I = I\,\mathrm{e}^{-\delta N \Sigma x} \,. \tag{13.50}$$

For larger intensities the absorption rate can exceed the relaxation rates refilling the absorbing level $\langle k|$ (Fig. 13.32b). This means that the population N_k decreases with increasing intensity I and therefore also the absorption coefficient decreases. Instead of (13.51) we have to write

$$\mathrm{d}I = -\Delta N(I) \cdot I \cdot \sigma \cdot \mathrm{d}x \,. \tag{13.51}$$

The change $\mathrm{d}I$ of the intensity and therefore also the absorbed power depends in a nonlinear way on the incident intensity. We can write the intensity dependent population of the absorbing level $|k\rangle|$ as a power series

$$N_k = N_{k_0}(1 - aI - bI^2 - \cdots) \tag{13.52a}$$

and a corresponding relation for the upper level $|i\rangle|$

$$N_i = N_{i_0}(1 + aI - bI^2 \cdots) \,. \tag{13.52b}$$

For the population difference we obtain

$$\Delta N = \Delta N_0(1 - 2aI - 2bI^2 - \cdots) . \qquad (13.53)$$

Inserting this into (13.51) gives

$$dI = \Delta N_0 \Sigma dx(I - 2aI^2 - 2bI^3 - \cdots) . \qquad (13.54)$$

The first term describes the linear absorption, the second term is quadratically dependent on I and diminishes the absorption because $d(\Delta N)/dI < 0$.

The nonlinear absorption can be demonstrated by measuring the intensity of the laser-induced fluorescence $I_{fl}(I_L)$ as a function of the laser intensity (Fig. 13.32c). One can see, that at first I_{fl} increases linearly with I_L, but for higher laser intensities the increase is less than linear, because the population difference and therefore the absorption coefficient decreases which causes a smaller relative absorption of the laser intensity dI_L/I_L. For large laser intensities the fluorescence intensity approaches a constant value (saturation) which is limited by the rate of the relaxation processes refilling the absorbing level $|k\rangle$.

This saturation of the absorption can be used for Doppler-free spectroscopy [13.30, 31], as will be outlined in the next section.

Saturation Spectroscopy

We consider a sample of atoms or molecules in the gas phase with a Doppler-broadened absorption profile around the center frequency ω_0. When a monochromatic laser beam with frequency ω passes in x-direction through the sample, only those molecules can absorb the laser photons that are Doppler-shifted into resonance with the laser frequency. Since the Doppler shift is $\Delta\omega = k \cdot v_x$ these molecules must have velocity components v_x, that satisfy the relation

$$\omega = \omega_0(1 + kv_x) \pm \gamma , \qquad (13.55)$$

where γ is the homogeneous line-width of the transition. Because of saturation the population N_k in the absorbing level of these molecules decreases and N_i increases accordingly. In the velocity distribution $N_k(v_x)$ of all molecules a narrow dip is burnt with a spectral width γ, while a corresponding peak appears in the distribution $N_i(v_x)$ of molecules in the upper level (Fig. 13.33a).

If the laser beam is reflected by a mirror back into the sample, its k-vector is reversed and molecules with opposite velocity components interact with the reflected beam (Fig. 13.33b). Now two holes, symmetric to $v_x = 0$ are burnt into the velocity distribution of the inversion $\Delta N(v_x)$, i. e. two different velocity classes $\pm(v_x \pm \gamma)$ interact with the two laser beams.

When the laser frequency ω_L is tuned over the Doppler-broadened absorption profile the two holes move towards each other when ω_L approaches the center frequency ω_0 of the molecular transition. For $\omega_L = \omega_0$ only one velocity class in the interval dv_x around $v_x = 0$ interact with both laser beams. The molecules experience the double intensity and there-

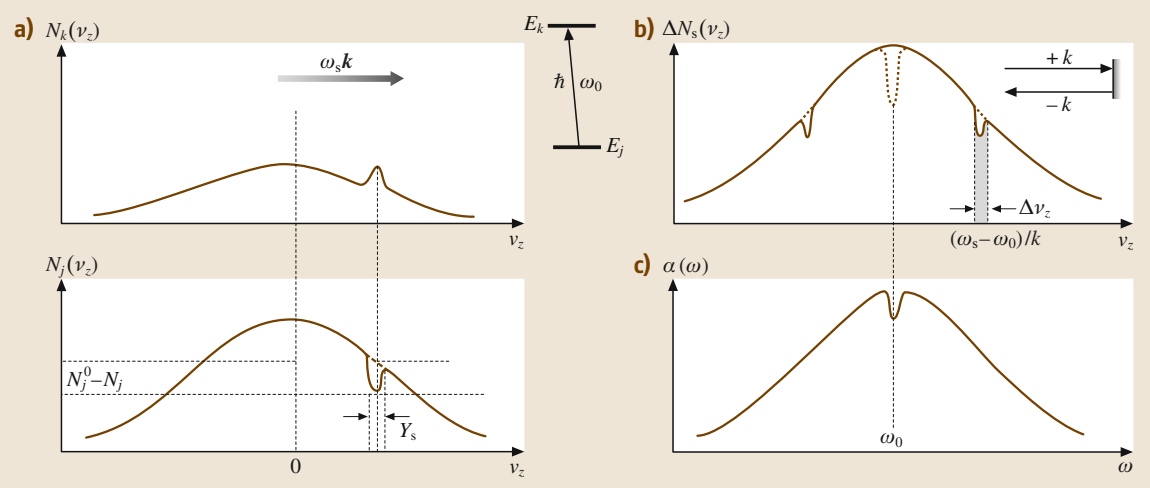

Fig. 13.33a–c Principle of saturation spectroscopy of Doppler-broadened transitions: **(a)** saturation hole and saturation peak in the velocity distribution of lower and upper level population, **(b)** situation for a standing wave, **(c)** Lamb dip in the Doppler-broadened absorption profile

fore the population inversion ΔN will more decrease for $\omega_L = \omega_0$ than for $\omega_L \neq \omega_0$. The absorption coefficient $\alpha(\omega)$ with a Doppler-broadened profile therefore has a dip around the center frequency ω_0 (Fig. 13.33c). This dip, caused by saturation of the population is called *Lamb-dip* after *Willis Lamb*, who explained this saturation effect quantitatively.

The width of the Lamb-dip equals the natural line-width of the molecular transition, broadened by saturation. It is about two orders of magnitude smaller than the Doppler-width.

This narrow Lamb-dip is used for Doppler-free spectroscopy (called saturation -or Lamb-dip-spectroscopy). Assume two transitions from a common level $\langle c|$ into two slightly split levels $\langle a|$ and $\langle b|$. If the splitting is smaller than the Doppler-width the two Doppler-broadened spectral lines cannot be resolved. However, the two Lamb-dips of these transitions are well separated (Fig. 13.34).

A possible experimental arrangement is shown in Fig. 13.35. The beam of a wavelength-tunable laser is split by beam-splitter BS into a strong pump beam and a weak probe beam, which pass into opposite directions through the sample cell. The detector measures the transmitted probe beam intensity as a function of the laser frequency ω_L. Each time the laser frequency coincides with the center frequency of a molecular transition, a Lamb-peak appears in the transmitted intensity, because the absorption exhibits a dip at this frequency.

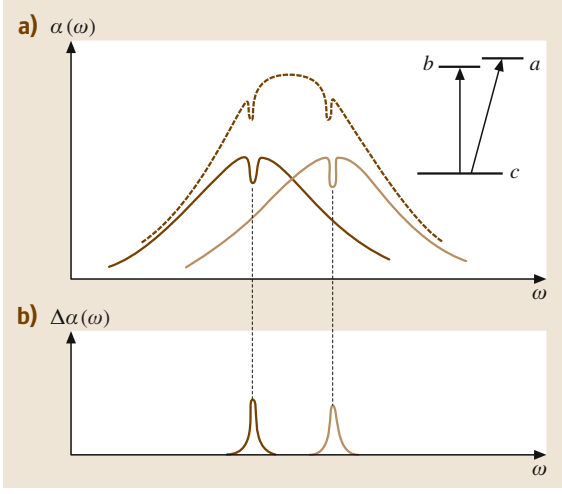

Fig. 13.34 Resolution of the two Lamb dips of two close overlapping Doppler-broadened transitions with a common lower level

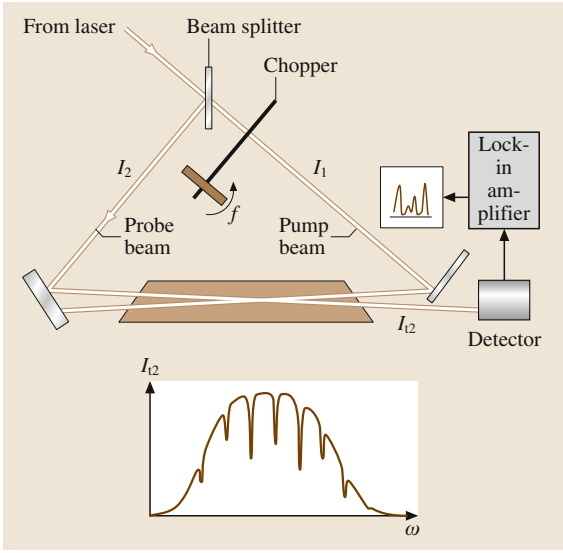

Fig. 13.35 Experimental arrangement for saturation spectroscopy with detection of the transmitted probe beam, resulting in Lamb dips on a Doppler-broadened background

The Doppler-broadened background can be eliminated when the pump beam is periodically chopped. Now a lock-in detector measures the difference of the transmitted probe intensity with the pump beam on and off. The result is a Doppler-free spectrum (Fig. 13.36) with a better signal-to-noise ratio.

Even with low power lasers saturation spectroscopy can be performed, when the sample is placed inside the laser resonator, where the intensity is much higher than outside the resonator (Fig. 13.37). The standing wave inside the resonator can be composed of a back-and forth travelling wave. Therefore the conditions for producing a Lamb-dip are automatically fulfilled. Either the laser-induced fluorescence from the sample molecules can be monitored which exhibits the Lamb-dips, or the laser intensity transmitted through one of the resonator mirrors is measured, which shows corresponding narrow peaks in the laser output power at the center-frequencies of the absorption lines of the sample molecules. If the resonator length is modulated while the laser wavelength is scanned, the first derivative of the Lamb-dips or peaks is measured with a lock-in, tuned to the modulation frequency f. Since the modulation of the absorption is not harmonic (even if the laser frequency is modulated sinusoidally), the modulated laser output also contains higher harmonics

(Sect. 13.1.1). When the lock-in is tuned to $3f$ the third derivative spectrum is obtained. Here the Doppler broadened background is essentially suppressed. In Fig. 13.37b such a third-derivative spectrum is shown for the rotational transition $B^3\Pi_u(v'=58, J'=99) \leftarrow X^1\Sigma_g^+(v''=1, J''=98)$ in the I_2-molecule with its 21 hyperfine components.

For more details see [13.32–34].

Polarization Spectroscopy

While in saturation spectroscopy the selective decrease of absorption by the pump-laser was monitored by the counter-propagating probe laser, in polarization spectroscopy it is the birefringence induced by the pump laser that is monitored by the probe laser [13.22]. The principle is shown in Fig. 13.39. The sample is placed between two crossed polarizers P_1 and P_2 which attenuate the linearly polarized probe laser by a factor 10^5–10^7, depending on the quality of the polarizers. A larger portion of the laser beam is split off by the beam-splitter BS and acts as a pump beam which passes in the opposite direction through the sample cell. If the pump laser beam is circularly polarized (e.g. σ^+-polarization), it induces transitions with $\Delta M = +1$, where $M \cdot h$ is the projection of the angular momentum J of the sample molecules onto the direction of the pump beam. Due to saturation some of the M-sublevels are partly depopulated (for our example in Fig. 13.39a these are the levels with $M = -2, -1, 0$). This leads to a partial orientation of the molecules because their angular momentum J has is no longer an isotropic orientational distribution but points more against the direction of the pump beam.

The linearly polarized probe beam can be composed of a σ^+ and a σ^- component. The two components experience a different absorption and a different index of refraction when passing through the sample of orientated molecules. Adding the two components again after they have passed the sample results in an elliptical polarization of the probe beam with the major axis rotated by a small angle α against the initial polarization direction, because of the different phase shifts of the σ^+ and the σ^- component. Now a small component of the electric vector parallel to the transmission axis of the second polarizer exists, which is transmitted to the detector. We will discuss this now more quantitatively.

The linearly polarized probe wave

$$E = E_0 \cdot e^{i(\omega t - kz)} \quad \text{with } E_0 = \{E_0, 0, 0\} \qquad (13.56)$$

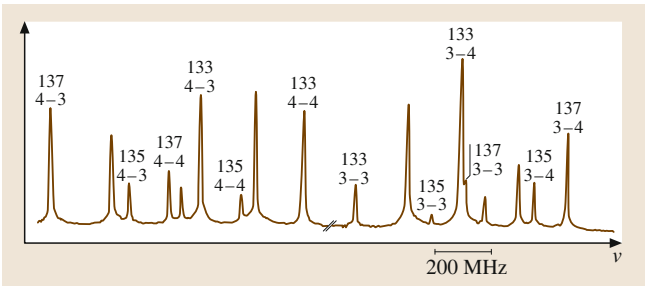

Fig. 13.36 Saturation spectrum of the hyperfine-components of the $6^2S_{1/2} \rightarrow 7^2P$ transition at $\lambda = 459.3$ nm in a mixture of the isotopes ^{133}Cs, ^{135}Cs and ^{137}Cs (after [13.21])

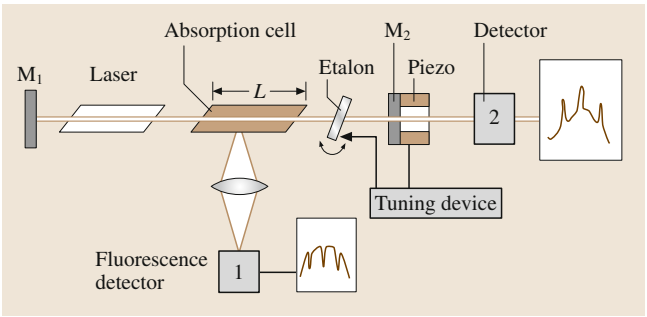

Fig. 13.37 Saturation spectroscopy with the sample inside the laser resonator

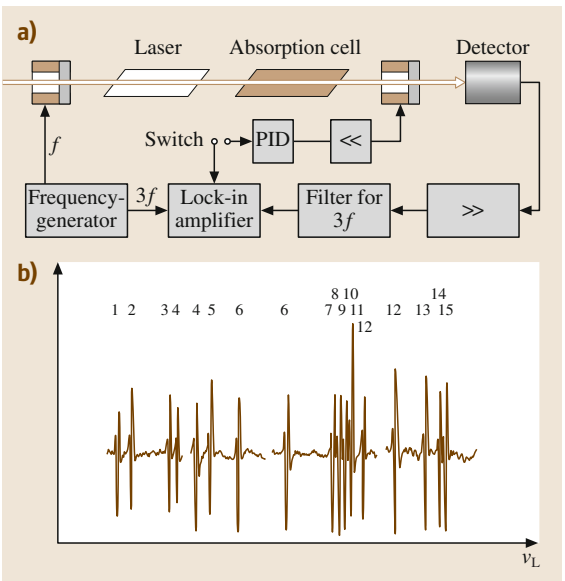

Fig. 13.38a,b Third-derivative technique for saturation spectroscopy inside the laser cavity. **(a)** Experimental arrangement; **(b)** third-derivative saturation spectrum of the hyperfine components of a rotational transition in I_2

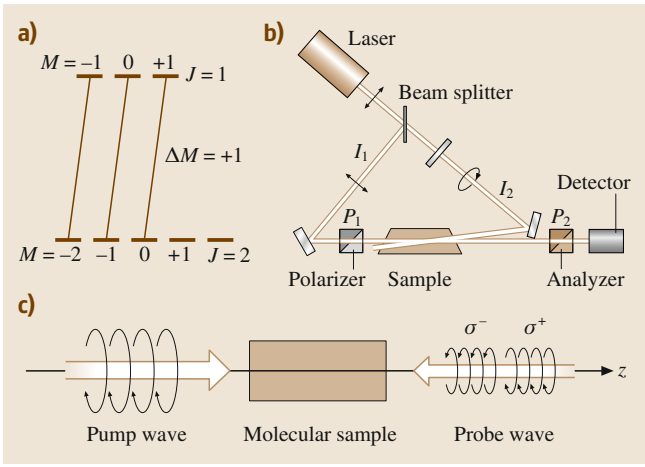

Fig. 13.39 Level scheme and experimental setup for Doppler-free polarization spectroscopy

can be composed of a σ^+ and a σ^- component

$$E^+ = E_0^+ \, e^{i(\omega t - k^+ z)} \,, \quad E_0^+ = \tfrac{1}{2} E_0 (\hat{x} + i\hat{y}) \,,$$
$$E^- = 0 E_0^+ \, e^{i(\omega t - k^- z)} \,, \quad E_0^- = \tfrac{1}{2} E_0 (\hat{x} - i\hat{y}) \,, \tag{13.57}$$

where $\hat{x}$ and $\hat{y}$ are unit vectors.

The two components experience the different absorption coefficients α^+ and α^- and also different refractive indices n^+ and n^-. After a path-length L through the sample region that has been orientated by the pump laser the two components are

$$E^+ = E_0^+ \, e^{i(\omega t - k^+ L + i\alpha^+ L/2)} \,,$$
$$E^- = E_0^+ \, e^{i(\omega t - k^- L + i\alpha^- L/2)} \,. \tag{13.58}$$

Because of the difference $\Delta n = n^+ - n^-$ a phase difference

$$\Delta\Phi = (k^+ - k^-)L = (\omega L/c)(n^+ - n^-) \tag{13.59}$$

has developed between the two components and because the difference $\Delta\alpha = \alpha^+ - \alpha^-$ also a difference

$$\Delta E_0 = (E_0/2)[e^{-\alpha^+ L/2} - e^{-\alpha^- L/2}] \tag{13.60}$$

of the two amplitudes.

The windows of the absorption cell are slightly bent because of the external atmospheric pressure and they show therefore a birefringence which is different for the two circularly polarized components and cause an additional phase shift.

Behind the exit window the electric field vector of the probe beam is obtained by adding the σ^+ and σ^-

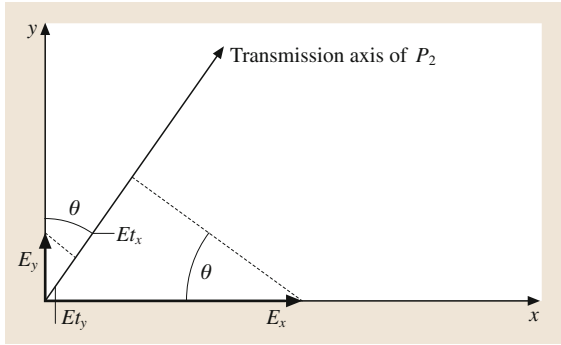

Fig. 13.40 Transmitted polarization components through the analyzer

components. This gives a slightly elliptical polarized wave with a major axis that is tilted by the small angle θ against the x-axis. This increases the transmittance through the crossed analyser. The transmitted amplitude becomes (Fig. 13.40)

$$E_t = E_x \sin\theta + E_y \cos\theta \,. \tag{13.61}$$

The detector signal is proportional to the transmitted intensity. Besides the signal there is also a frequency-independent background, due to the residual transmission ξ of the crossed polarizers.

Similar to the case in saturation spectroscopy the line profile of the signals are Doppler-free and are determined by the homogeneous line width γ (natural line-width plus collision broadening plus saturation broadening), because only molecules with velocity components $v_x = 0 \pm \gamma \cdot k$ can interact with both counter-propagating laser beams.

The final result for the transmitted intensity, measured when the laser frequency is tuned over an absorption line of the sample molecules, is

$$I_t = I_0 \, e^{-\alpha L} \left(\Sigma^2 + \Theta'^2 + \frac{1}{4}\Delta\alpha_\omega^2 + \Theta' \Delta\alpha_0 L \frac{x}{1+x^2} \right)$$
$$+ \left[\frac{1}{4}\Delta\alpha_0 \Delta\alpha_\omega L + \left(\frac{\Delta\alpha_0 L}{4} \right)^2 \right] \frac{1}{1+x^2}$$
$$\text{with} \quad x = \frac{\omega_0 - \omega}{\gamma_s/2} \,. \tag{13.62}$$

The advantages of polarization spectroscopy, compared to saturation spectroscopy are as follows:

1. The technique is essentially background-free. Besides the small residual terms $I_0 \cdot \xi$ with $\xi = 10^{-5} - 10^{-7}$ the detector receives only a signal when the pump beam is not blocked. In saturation spectroscopy the pump beam changes the absorption of

the probe beam by a small amount and the small difference of two large signals is detected. The sensitivity of polarization spectroscopy is therefore much higher.

2. Uncrossing of the polarizers ($\theta > 0$) increases the dispersion term in (13.62). Such a dispersion signal is ideally suited to stabilize a laser frequency onto the zero crossing of the signal, which occurs at the center of the Doppler-free absorption line. Choosing $\theta = 0$ yields Lorentzian line profiles, where the magnitude of the signals can be optimized by changing the birefringence of the windows (e.g. by sqeezing them gently).
3. It turns out that the signal magnitude and profile depends on the specific molecular transition. For a circularly polarized pump beam the signals of Q-lines ($\Delta J = 0$) are suppressed, while for a linearly polarized pump beam the magnitude of the signals for P- and R lines ($\Delta J = \pm 1$) decreases rapidly with increasing rotational quantum number J. The assignment of a complex molecular spectrum is therefore facilitated.

Doppler-Free Two-Photon Spectroscopy

For sufficiently strong laser intensities it can happen that an atom or molecule absorbs simultaneously two photons $\hbar \cdot \omega_1$ and $\hbar \cdot \omega_2$ from two lasers, or two photons $\hbar \cdot \omega_1$ from the same laser. Depending on the relative orientations of the two photon-spins transitions with $\Delta L = 0$ or $\Delta L = \pm 2$ are induced. Two-photon transitions are weaker by several orders of magnitude than allowed one-photon transitions. Therefore lasers with sufficient high intensities are demanded for their observation. The probability of two-photon absorption is much enhanced if a molecular level E_m is close to the energy $E_k + \hbar \cdot \omega_1$ or $E_k + \hbar \cdot \omega_2$.

For a two-photon transition from the initial lower level $\langle k|$ to the final level $\langle f|$ in a molecule at rest the energy conservation demands

$$E_f - E_k = \hbar \cdot (\omega_1 + \omega_2) \,. \qquad (13.63)$$

When the molecule moves with the velocity v the frequency ω of the light-wave is shifted in the molecular frame to $\omega' = \omega - k \cdot v$. The resonance condition (13.63) now becomes

$$E_f - E_k = \hbar \cdot (\omega_1 + \omega_2) - hv \cdot (k_1 + k_2)' \,. \qquad (13.64)$$

If the two photons come from two in opposite directions travelling beams from the same laser, we have the situation that $\omega_1 = \omega_2$ and $k_1 = -k_2$. This has the consequence that the last term in (13.64), which contains

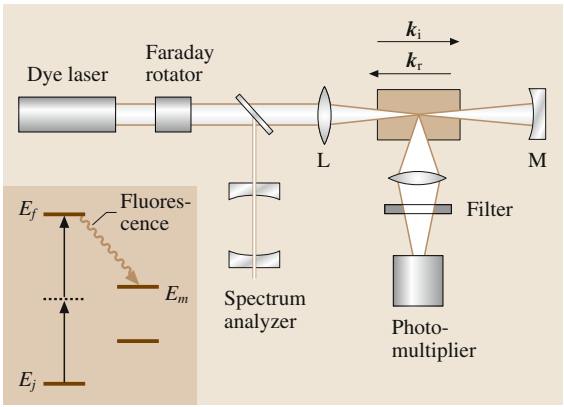

Fig. 13.41 Doppler-free two-photon spectroscopy

the velocity of the molecule, is zero. The two-photon absorption becomes in this case independent of the molecular velocity, which means that all molecules within the velocity distribution contribute to the two-photon absorption, which is now Doppler-free. The experimental arrangement is shown in Fig. 13.41. The sample is placed inside the resonator of a single-mode laser. The two-photon transition is monitored by the laser-induced fluorescence, emitted from the upper level E_f into intermediate levels E_m that are connected to $\langle f|$ by allowed one-photon transitions. A Faraday-rotator acts as optical diode and prevents the reflected beam from passing back into the laser, because this could cause instabilities of the laser.

When the laser frequency ω is tuned over the two-photon resonance the signal consists of a narrow peak (produced by two photons with opposite k-vector) and a Doppler-broadened background, produced by two photons from the same beam with parallel k-vectors (Fig. 13.42). The Doppler-width is twice as large as

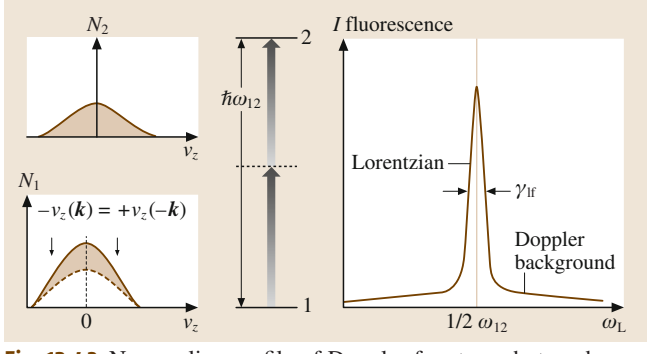

Fig. 13.42 Narrow line profile of Doppler-free two-photon absorption with Doppler-broadened background

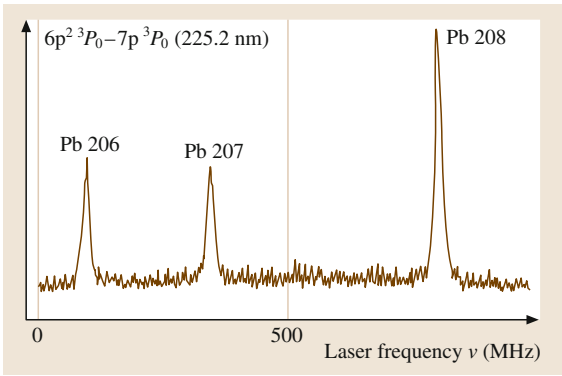

Fig. 13.43 Doppler-free two-photon spectrum of the $6p_3^2 P_0 \rightarrow 7p^3 P_0$ transition in the different isotopes of lead (after [13.23])

that of a one-photon transition with frequency ω. The probability that the two photons come from opposite beams is twice as large as that for two photons from the same beam. This implies that twice as many molecules contribute to the narrow peak than to the broad background. The narrow peak is therefore $2 \cdot \Delta\omega_D / \Delta\omega_n$ times as high than the background. Since the Doppler-width $\Delta\omega_D$ is about two orders of magnitude larger than the natural line-width $\Delta\omega_n$ the background can be neglected.

In Fig. 13.43 the Doppler-free spectrum of lead atoms on the transition $7p^3P_0 \leftarrow 6p^2\ ^3P_0$ at $\lambda = 450.4$ nm illustrates the high spectral resolution allowing the measurement of the isotope shifts [13.35].

A very interesting application of two-photon spectroscopy is the precise measurement of the 1S→2S transition in anti-hydrogen. The goal of this research is the proof or disproof of the CPT theorem, which says that the simultaneous reversal of charge, parity, and time obeys symmetry conservation rules; i. e., that antimatter should have the same atomic structure as matter, besides the opposite charge of the particles. In the case of hydrogen, this means that the frequency of the 1S→2S transition should be the same for hydrogen atoms as for anti-hydrogen atoms.

The experiments are based on the successful Doppler-free spectroscopy of hydrogen [13.36], which will be transferred to the investigation of the anti-atom. The challenging problem, however, is the production of cold anti-hydrogen atoms. They are formed by slowing down fast antiprotons stored in a storage ring at the Centre Européen de Recherches Nucléaires (CERN) by a specially designed decelerator. They are then trapped in a Penning trap, where they collide with positrons to form anti-hydrogen atoms. Since only a few anti-atoms are produced, their spectroscopy demands very sensitive techniques. It is expected that the first results will be obtained in 2011 [13.37].

The magnetic moment of antiprotons could be obtained from measurements of the hyperfine structure of antiprotonic He^+ ions [13.38].

13.1.4 Polarimetry and Ellipsometry

Similar to the principle in polarization spectroscopy a technique, called *polarimetry*, uses the change of the polarization of a light-wave which has passed through an anisotropic sample. However, different from polarization spectroscopy the anisotropy is not induced by a polarized pump wave but is inherent to the sample, which consists of so-called *active molecules*. For example, all chiral molecules, such as butanol (Fig. 13.44) or blood-sugar, turn the polarization vector of a linearly polarized wave by an angle

$$\alpha = (n^+ - n^-)\pi \cdot \frac{d}{\lambda} \qquad (13.65)$$

where n^+ and n^- are the refractive indices for σ^+ and σ^- light and d the path-length through the sample (Fig. 13.45).

In solids an optical anisotropy can be induced by internal or external stress. In such cases optical polarimetry can give a two-dimensional picture of the stress distribution. This is used by glass blowers to check whether the glass after tempering is stress-free. For mechanical engineering models of Plexiglas can be used to test the stress distribution in frame constructions of buildings and bridges [13.39, 40].

The technique of *spectral ellipsometry* uses the polarization characteristics of an optical wave and their

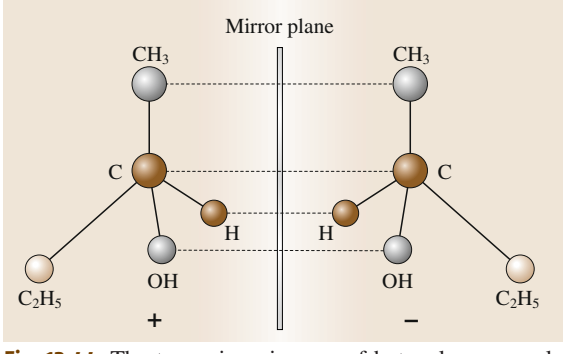

Fig. 13.44 The two mirror images of butanol as example of chiral molecules

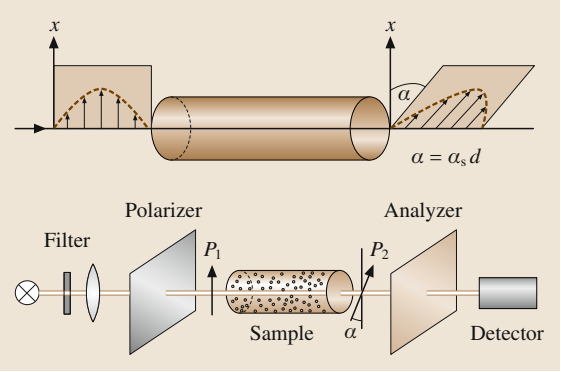

Fig. 13.45 Principle and experimental setup for polarimetry

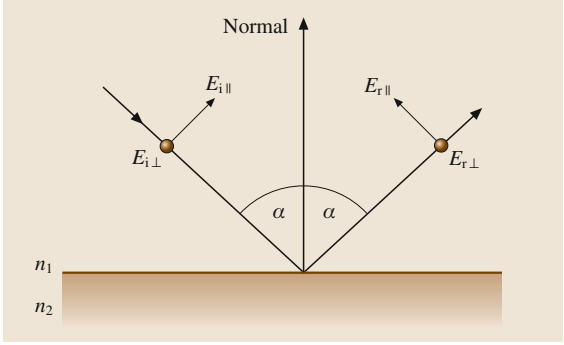

Fig. 13.47 Illustration of the Fresnel formulas for the components of the electric field vectors of the incident and reflected wave

changes when the wave is reflected by a surface or transmitted through a sample for sensitive detection of material parameters, such as absorption and birefringence. It is generally applied to solids and liquids, where there are no sharp absorption lines. Therefore the main emphasis is put upon the sensitivity rather than on the spectral resolution. Besides tunable lasers as radiation sources also broad band incoherent light sources are used in combination with a monochromator for wavelength selection.

The basic principle is illustrated in Fig. 13.46: The incident light passes through a polarizer P and is reflected at the surface of the sample. The polarization characteristics of the reflected light are analyzed by the analyzer A and the photomultiplier behind the spectrometer monitors the intensity of a selected spectral interval transmitted through the spectrometer.

Depending on the absorption coefficient $\alpha(\omega)$ the light with intensity I_0 penetrates into the sample. After a penetration depth $d = 1/\alpha$ its intensity has decreased to I_0/e and the reflected light with intensity $I_\mathrm{r} = r \cdot I_0$ gives information on the complex reflection coefficient r which also depends on the absorption coefficient α. For linearly polarized incident light the reflected light is generally elliptically polarized which gives the name to the method [13.41, 42].

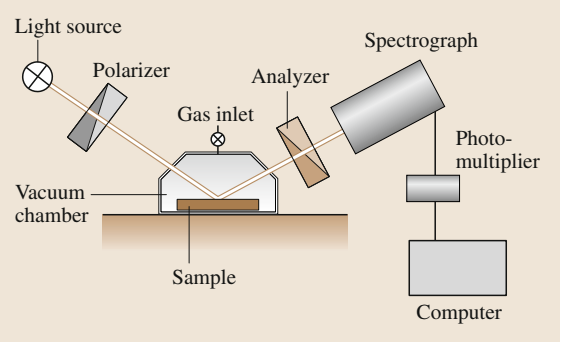

Fig. 13.46 Schematic experimental arrangement for ellipsometry

For nonabsorbing samples the refractive index n is real and the intensity and the polarization characteristics of the reflected light is governed by the Fresnel formulas. We can compose the electric vector of the incident linearly polarized light of a component $E_\parallel$ parallel and a component $E_\perp$ perpendicular to the plane of incidence (Fig. 13.47). The amplitude reflection coefficient for the two components [13.43]

$$\mathrm{P}_{||} = \frac{E_{\mathrm{r}||}}{E_{\mathrm{i}||}} = \frac{n_2 \cos\alpha - n_1 \cos\beta}{n_2 \cos\alpha + n_2 \cos\beta} , \tag{13.66a}$$

$$\mathrm{P}_{\perp} = \frac{E_{\mathrm{r}\perp}}{E_{\mathrm{i}\perp}} = \frac{n_1 \cos\alpha - n_2 \cos\beta}{n_1 \cos\alpha + n_2 \cos\beta} , \tag{13.66b}$$

is then determined by the refractive indices n_1 and n_2 of the two media and the angle α against the surface normal. Using the Snellius refraction law $\sin\alpha/\sin\beta = n_2/n_1$ we can replace the refractive indices by the refraction angle β and obtain

$$\mathrm{P}_{||} = \frac{\tan(\alpha-\beta)}{\tan(\alpha+\beta)} ,$$

$$\mathrm{P}_{\perp} = \frac{\sin(\alpha-\beta)}{\sin(\alpha+\beta)} . \tag{13.67}$$

The reflected intensity is then

$$I_{\mathrm{r}||} = I_{\mathrm{i}||} \frac{\tan^2(\alpha-\rho)}{\tan^2(\alpha+\rho)} ,$$

$$I_{\mathrm{r}\perp} = \frac{\sin^2(\alpha-\rho)}{\sin^2(\alpha+\rho)} .$$

Since the reflection coefficients for the two components are different, the plane of polarization of the reflected wave is tilted against that of the incident wave. If γ_i is the angle of the electric vector E of the incident wave against the plane of incidence, the angel γ_r of the reflected wave becomes according to the Fresnel formulas

$$\tan\gamma_r = \frac{E_{r\perp}}{E_{r||}} = -\frac{\cos(\alpha-\beta)}{\cos(\alpha+\beta)}\tan\gamma_i\,. \qquad (13.68)$$

For absorbing materials the index of refraction

$$n = n' - i\kappa \qquad (13.69)$$

becomes complex where both the real part n' and the imaginary part κ depend on the wavelength. This introduces a phase shift, which is generally different for the two polarization components. The reflected light is the elliptically polarized.

13.1.5 Optical Pumping and Double-Resonance

We have discussed in Sect. 13.3 that emission spectra become much simpler when a single level is selectively populated. Such a selective population or depletion of a level by absorption of photons is called optical pumping, when a noticeable population change ΔN against the thermal population is achieved. The technique of optical pumping is, however, more general than just changing the population of a level. It can also create an alignment of atoms or molecules in the *labelled* level, as we have seen for the example of polarization spectroscopy. This changes the polarization characteristics of a wave transmitted through the sample.

Optical pumping forms the basis for various double-resonance techniques. Assume the pump laser is tuned to a selected transition $|i\rangle \rightarrow |k\rangle$ (Fig. 13.48) and depletes the lower level $|i\rangle$. If a second radiation field (a radio-frequency, microwave, infrared or visible radiation) with tunable frequency is simultaneously applied to the sample, the depleted level will be partly refilled, when the frequency of this second radiation field coincides with a transition $|i\rangle \rightarrow |m\rangle$ from the depleted level $|i\rangle$ to other levels $|m\rangle$. This can be monitored either by the increased absorption of a probe laser or by the increase of the fluorescence induced by the pump laser.

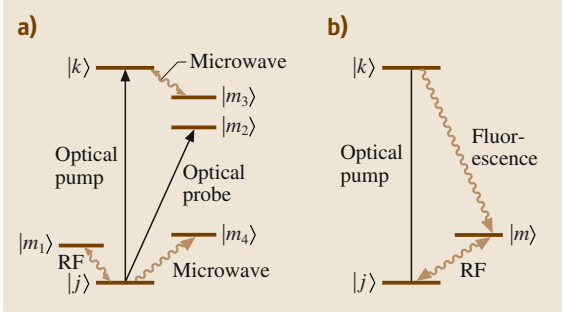

Fig. 13.48 Schematic level scheme for optical pumping and optical–microwave double resonance with fluorescence detection

If, for example, the pump laser depletes a hyperfine component of an atomic state, the depleted level can be refilled by RF-transitions $|ij\rangle \rightarrow |in\rangle$ from another hfs-component, which is not depleted by the pump (Fig. 13.48). When the laser-induced fluorescence is observed as a function of the radiofrequency, a peak is measured at the resonance frequency ω_{inj}, which gives the separation of the two hfs levels. In this case the RF-optical double resonance acts like an amplifier of the RF-transitions, because:

1. the optical pump increases the population difference ΔN between the two hfs-levels and therefore the absorption of the RF.
2. The absorption of one RF-photon is monitored by emission of a visible photon, which has an energy about 10^6 times larger than the RF photon and can be detected with a much larger efficiency.

The accuracy of the measuring the level separation by the radio-frequency is much higher than by determining it through the difference of the frequencies of two optical transitions from the two hfs levels into a level in the upper excited state. The RF-transition can occur in the lower as well as in the upper state of the optical transition. In the latter case one observes a dip in the fluorescence intensity from level $|k\rangle$ when the RF is tuned through resonance.

Optical-microwave double resonance can be applied to transitions between two rotational levels of molecules, where the optical pump depletes one of the levels in the ground state or populates one of the two levels in an excited state (Fig. 13.49). Besides increasing the absorption of the microwave the double-resonance in excited states transfers the accuracy of microwave spectroscopy to measurements of excited states that are thermally not populated and are therefore not accessible to conventional microwave spectroscopy.

An interesting application of this double resonance spectroscopy is the modification of the Rabi technique of RF transitions in molecular beams [13.44, 45]. The inhomogeneous magnetic fields A and B are replaced by two beams of the pump laser (Fig. 13.50).

Radiofrequency- or microwave transitions in a region between the two crossing points induce population changes which are detected by the corresponding changes in the laser-induced fluorescence in the second crossing point B. Since the fluorescence detection is very sensitive (Sect. 13.1.1), this method is very useful for measuring small level splittings of free molecules or Zeeman or Stark-splittings in a homogeneous magnetic or electric field in the region C with high accuracy.

Similar to the simplification of the fluorescence spectrum by selective excitation of a single upper level, double resonance methods are valuable tools for assigning complex absorption spectra. Assume the probe laser is tuned through the absorption spectrum and the absorption is monitored via the laser-induced fluorescence. When the pump laser, tuned to a specific optical transition is chopped, the population of the upper and the lower level of the pump transition are modulated with opposite phases. Measuring the LIF induced by the probe laser with a lock-in amplifier while the probe laser frequency is tuned, yield only those transitions out of the whole spectrum, that start or terminate on the modulated levels. Since one level of these probe transitions is already known, the assignment of the other level can be readily performed when applying the selection rules for the probe transitions [13.46, 47].

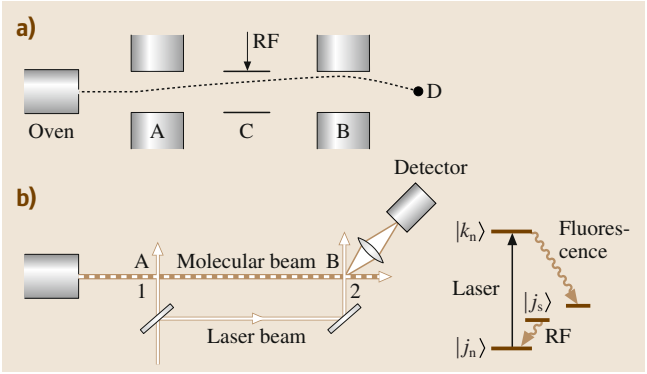

Fig. 13.50 Optical double resonance in a molecular beam as a substitute for the conventional Rabi technique

13.1.6 Spectroscopy with Optical Frequency Combs

Recently, a new technique has been developed that allows the direct comparison of widely separated reference frequencies and measures the absolute frequencies of spectral lines with unprecedented accuracy. It is based on the realization of optical frequency combs and has been successfully applied to high-resolution spectroscopy with very high sensitivity. Its basic principle can be understood as follows: The frequency spectrum of a continuous mode-locked laser emitting a regular train of short pulses consists of a comb of equally spaced frequency components which coincide with the longitudinal modes of the laser cavity. According to the Fourier theorem, the spectral width of this comb spectrum is inversely proportional to the temporal width ΔT of the laser pulses. With femtosecond pulses from a Ti:sapphire Kerr lens mode-locked laser, the comb spectrum extends over more than 30 THz.

The spectral width can be further increased by focusing the laser pulses into a specially structured optical fiber, where self-phase modulation occurs, which broadens the spectrum considerable, spanning more than one octave, corresponding to a spectral width of about 300 THz [13.48, 49].

Detailed measurements have shown that the modes of the comb are precisely equidistant, even in the far wings of the comb [13.50]. This strictly regular frequency spacing is essential for precise optical frequency measurements. The frequency comb can be calibrated by a self-referencing technique (Fig. 13.51). Here, the frequency $\omega_{\text{He-Ne}}$ of a He-Ne laser at $\lambda = 3\text{–}39\,\mu\text{m}$ is twice doubled in nonlinear optical crystals. The frequency $4\omega_{\text{He-Ne}}$ is then stabilized onto one component of the comb. With frequency sum generation and optical frequency dividers the frequency $7\omega_{\text{He-Ne}}$ is generated. One half of this frequency is stabilized onto another component of the frequency comb. By adjusting the laser cavity length L it is possible for the mode spacing to be tuned in such a way that both fre-

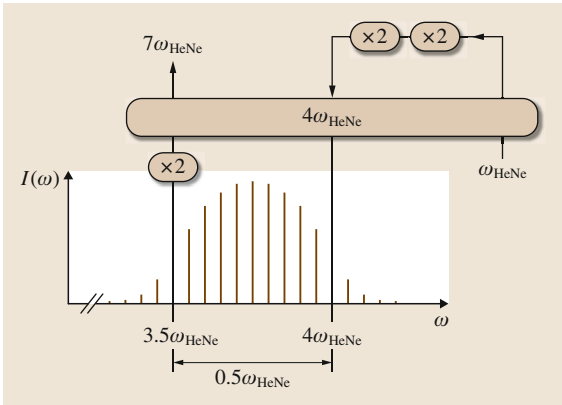

Fig. 13.51 Self-calibration of the optical frequency comb (after [13.50])

quencies $3.5\omega_{He\text{-}Ne}$ and $4\omega_{He\text{-}Ne}$ coincide exactly with components of the comb and that also the microwave frequency of the Cs standard equals an integer multiple of the repetition rate of the femtosecond pulses, i. e., of the frequency spacing between the comb components. Counting the number of components between $4\omega_{He\text{-}Ne}$ and $3.5\omega_{He\text{-}Ne}$ links the frequency $0.5\omega_{He\text{-}Ne}$ to the Cs standard. This gives the absolute frequency $\omega_{He\text{-}Ne}$. The optical frequency ω_s of a spectral line can be expressed as

$$\omega_s = n \cdot \omega_r + m \cdot \Delta\omega_c + \Delta\omega_{offs} \,, \qquad (13.70)$$

where n is a large integer (e.g., $n = 10^5$), m is the number of comb components between the component onto which $n\omega_r$ is locked and the component next to the spectral line frequency, $\Delta\omega_c = 2\pi/T$ is the frequency spacing between adjacent comb components (which equals the mode spacing of the laser resonator), and $1/T$ is the repetition rate of the femtosecond pulses, where $T = c/L$ is the roundtrip time of the pulses through the laser with roundtrip length L. The offset frequency $\Delta\nu_{offs}$ takes into account that the frequency ω_s may not exactly match a component of the frequency comb. Since the offset frequency lies in the radiofrequency range, it can be readily measured by a heterodyne technique, where the spectral line frequency and the frequency of the nearest comb component are superimposed and the difference frequency is measured with a spectrum analyzer [13.50].

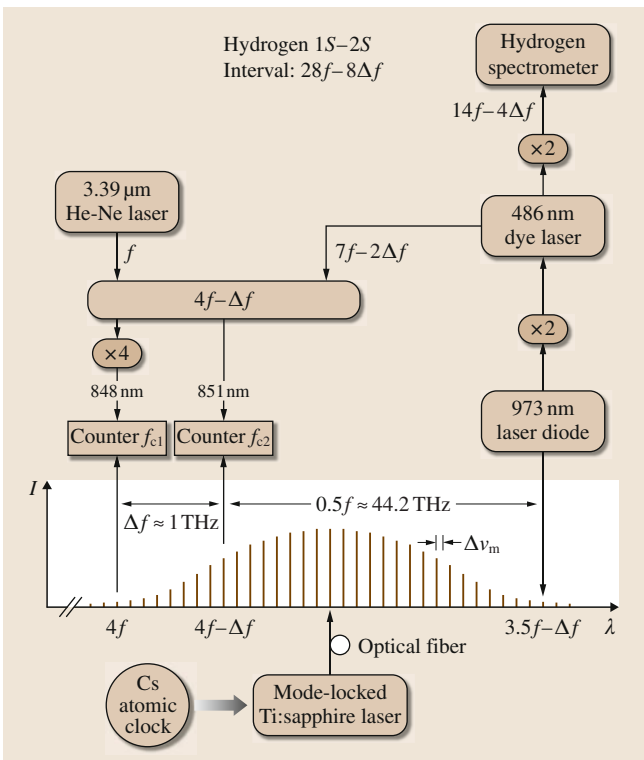

Fig. 13.52 Setup for measuring the absolute frequency of the hydrogen $1S \rightarrow 2S$ transition with the optical frequency comb (after [13.51])

The advantage of this technique is illustrated in Fig. 13.52 by the measurement of the absolute frequency of the 1S→2S transition in the hydrogen atom [13.51]. The doubled frequency of a diode laser at $\lambda = 973$ nm controls the frequency of a continuous-wave (CW) dye laser oscillating at $\lambda = 486$ nm. The output of this dye laser is frequency-doubled and is stabilized onto the two-photon transition 1S→2S of hydrogen atoms in an atomic beam. The frequency of the diode laser nearly matches a comb component at $3.5\omega_{He\text{-}Ne}$, while $4\omega_{He\text{-}Ne}$ coincides exactly with a comb component. The difference Δf can be measured, and therefore the 1S→2S hydrogen transition is linked to the frequency of the He-Ne Laser, which in turn is linked to the Cs frequency standard.

The optical frequency comb can be used for highly sensitive absorption spectroscopy.

As discussed above, the sensitivity is dramatically improved when the absorbing sample is placed in a high-finesse optical cavity, because the effective path length is increased. When the equidistant lines from a laser frequency comb are simultaneously injected into the cavity over a large spectral range, multiple trace gases may be identified within a few milliseconds [13.52, 53]. However, efficient analysis of the light transmitted through the cavity remains challeng-

ing. Here, a novel approach, called cavity-enhanced, frequency-comb, Fourier-transform spectroscopy, fully overcomes this difficulty and enables measurement of ultrasensitive, broad-bandwidth, high-resolution spectra within a few tens of microseconds without any need for detector arrays, potentially from the terahertz to ultraviolet regions.

For illustration of the sensitivity, the authors recorded within a period of just 18 μs, the spectra of the ammonia 1.0 μm overtone bands comprising 1500 spectral elements and spanning 20 nm, with a resolution of 4.5 GHz and a noise equivalent absorption at 1 s averaging of $1 \times 10^{-10}\,\mathrm{cm}^{-1}\mathrm{Hz}^{-1/2}$. This allows time-resolved spectroscopy of rapidly evolving single events.

High-resolution spectroscopy in the extreme ultraviolet region becomes conceivable with high harmonic frequency combs. Here, a series of harmonics up to 19th order was generated in a xenon gas inside a resonator, which opens the possibility of measuring the absolute frequency of the 1S→2S transition in helium ions He^+ at 60 nm [13.54].

The sensitivity of two-photon spectroscopy can be enhanced by using an optical frequency comb. This has been demonstrated by measuring the 6S→8S transition in the cesium atom [13.55].

The importance of high-precision optical frequency measurements is partly based on the chance to determine possible temporal changes of the fundamental physical constants, such as the fine structure constant or the ratio of the electron to proton mass [13.56]. Since such possible changes are very slow, the accuracy of the measurements must be extremely high in order to find them within a reasonable time span. Frequency comb measurements are now close to this demanded accuracy, and they may contribute to finding deviations from physical models accepted up to now. These measurements are therefore not only of practical use but also of fundamental nature.

13.2 Time-Resolved Methods

13.2.1 Basic Principles

The *high-resolution techniques*, outlined in Sect. 13.1 allow the very precise determination of energy levels in atoms and molecules from which the structure of atoms and molecules can be inferred. Their high sensitivity makes them useful for analytical applications where already a tiny number of molecules can be detected. These CW-techniques may be called static methods.

On the other hand the investigation of dynamical processes demands *time-resolved* methods, where the time resolution covers the large span from many seconds to attoseconds (10^{-18} s) [13.57–62]. Examples are the decay of excited atomic or molecular states populated by short pulses of light in the ultraviolet, optical or infrared spectral region. The excitations of valence electrons generally decay within 10^{-3}–10^{-9} s, while high energy atomic states populated by inner-shell excitation with subsequent x-ray emission might decay in times as short as 10^{-15} s. Metastable states of atoms or molecules may live for milliseconds to even many seconds, while the dissociation of molecules excited into states with repulsive potentials can occur within less than 10^{-12} s [13.63, 64]. Relaxation of excited electrons in metals or semiconductors occurs within a time scale of 10^{-13}–10^{-15} s and excited states of atomic nuclei can even decay in times shorter than 10^{-18} s.

Another class of time-dependent processes are collision-induced transitions in atoms or molecules, where two partners A and B collide and the internal structure of A or B may be changed during the collision and energy may be exchanged between the collision partners. Examples are energy transfer between the internal energies of A and B or deactivation of excited states in one of the collision partners. Such processes generally take place within the nano-to femto-second time scale, depending on the density and the relative velocity of the collision partners [13.65].

The time resolution achieved in spectroscopy is determined by the light source and the detector. In the prelaser period flash lamps with pulse durations between 10^{-3} to 10^{-6} s have been used and the available detectors were also limited in their time resolution to about 10^{-6} s. The invention of pulsed lasers has changed the situation dramatically. It is now possible to produce sub-femto-second pulses down to about 10^{-16} s using high harmonic generation by femtosecond lasers which allow a time resolution down to 10^{-17} s. Also the limit in time resolution of detectors could be overcome by new detection techniques, such as pump- and probe experiments.

In this article different techniques of time-resolved spectroscopy, detection schemes and a selection of possible applications are presented and their advan-tages and limitations are discussed.

13.2.2 Wavelength-Tunable Short Pulses

The generation and detection of short laser pulses with fixed centre frequencies has been already discussed in detail in Chap. 12 of this handbook. For many applications in time-resolved spectroscopy wavelength-tunable pulses are demanded. They can be produced in different ways:

1. A laser with a broad spectral gain profile is used as light source and the wavelength is tuned across the gain profile by wavelength-selecting elements (such as prisms, gratings or interferometers) inside the laser cavity.
2. Optical parametric amplification in nonlinear optical crystals are used where a pump photon is split in a nonlinear crystal into two photons, called signal and idler, and both the signal and the idler can be tuned over a wide range in the visible or infrared region, either by seeding the system with a wavelength-tunable laser, and/or by just using an optical parametric oscillator and changing the phase-matching conditions of the crystal [13.66,67].
3. Optical frequency mixing in nonlinear crystals (sum- or difference-frequency) can transfer the tuning range of visible lasers into the ultraviolet or infrared region [13.67].

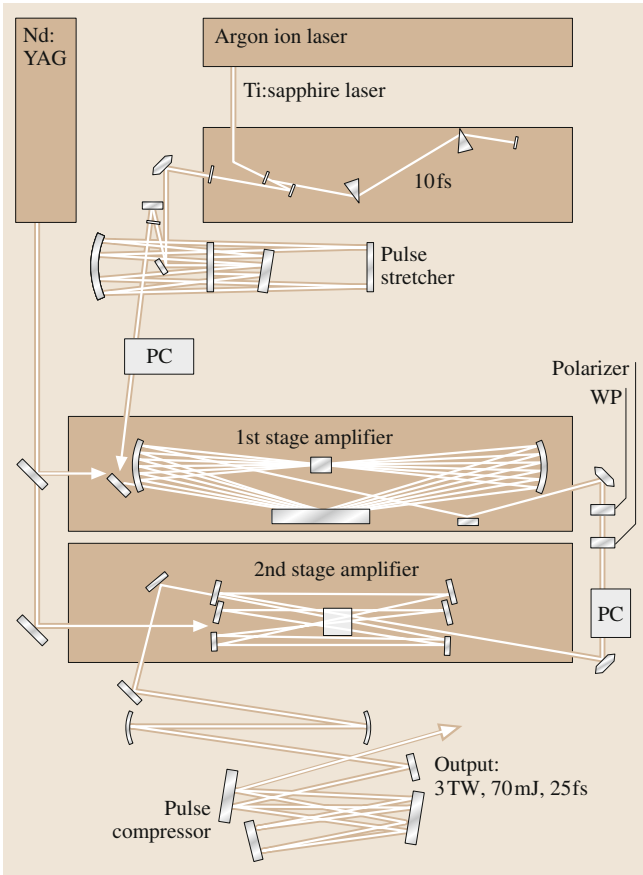

Fig. 13.53 Regenerative amplifier system for ultrafast chirped pulses (after [13.53])

For the generation of ultra short pulses generally Ti:sapphire lasers are used. They can deliver high peak powers but have only moderate pulse energies. Their wavelength can be tuned over the gain profile of the laser. There are two ways of amplifying their pulse energies: Conventional amplification in a gain medium with inverted population, which is pumped by a powerful pump laser, or parametric amplification. While the first method has only moderate gain in one amplifying stage and therefore needs several successive stages, the second method exhibits much larger gain already in a single stage.

In particular for the production of coherent radiation in the vacuum ultraviolet (VUV), where either high harmonics of the fundamental laser wavelength are produced or several successive steps of frequency doubling or tripling in nonlinear crystals and in gases are necessary [13.68], high peak powers and pulse energies of the laser output in the visible are needed. We therefore start with experimental techniques for the amplification of wavelength-tunable short pulses.

Generation of Tunable Femto-Second Pulses with High Peak Powers

The output pulses from a femto-second oscillator can be amplified in a regenerative amplifier. A schematic diagram of the setup for a high power femto-second laser system is depicted in Fig. 13.53 [13.69]. The laser oscillator consists of a Ti:Sapphire crystal in a resonator formed by two spherical and a flat mirror. Two prisms serve as dispersion compensators. The crystal is pumped by a mode-locked argon laser. The femto-second output pulses generally show a frequency-chirp (the optical frequency varies from the leading to the trailing edge of the pulse). These chirped pulses are expanded in time by a grating pair, where the two gratings are not parallel as for pulse compression, but arranged in such a way, that the time profile of the chirped optical pulse becomes broader (pulse stretcher). This pulse stretching is necessary before the pulses are amplified in order to avoid excessively high peak pow-

ers in the amplifier, which would destroy the optics. The amplifier, generally a Ti:sapphire crystal pumped by a pulsed solid state laser, is placed inside a multiple reflection device which allows the laser pulse to travel many times through the amplifying medium. The energy of the pump pulse must be sufficiently high in order to restore the inversion of the gain medium between two successive traversals of the amplified pulses (regenerative amplifier). The energy amplification of this multipass device might be as high as 10^6. The repetition rate of the amplified output pulses is limited by that of the pump laser for the regenerative amplifier and is generally not higher than 10 kHz while the mode-locked oscillator before amplification has a repetition frequency of about 100 MHz, which means that only every 10 000th pulse of the mode-locked train is amplified. These amplified pulses are selected by a Pockels-cell (PC) and are then further amplified in a second amplifier stage before they are compressed by a parallel grating pair, resulting in ultrashort pulses with peak powers up to 10 TW [13.70, 71].

Example 13.6: The oscillator may deliver output pulses with 50 fs pulse width and 30 nJ energy. This gives a peak power of 600 kW. With an energy amplification of 10^6 for the stretched pulse the peak power of the amplified and recompressed pulse is then 600 GW. If a compression down to 10 fs can be reached the peak power is even 3 TW.

Optical pulse compression can be also realized by the nonlinear dispersion in optical transparent materials. By compressing the output pulses of a multistage Ti:Sapphire laser amplifier system in a Neon-gas-filled hollow fibre, optical pulses with duration of 5 fs and pulse energy of 1 mJ (peak power 0.2 TW) could be generated [13.73].

Optical Parametric Systems

Optical parametric devices, delivering femto-second pulses with widely tunable wavelengths from the ultraviolet into the near infrared spectral region represent very useful tools for spectroscopy [13.66, 72, 74–76]. Their basic principle can be described as follows (Fig. 13.54).

A pump photon with energy $\hbar\omega_p$ and wavevector $\boldsymbol{k}_p$ is split by parametric interaction in a nonlinear optical crystal (e.g. β-barium-borate BBO) into a signal photon $\hbar\omega_1$ and an idler photon $\hbar\omega_2$, such that energy conservation

$$\omega_p = \omega_1 + \omega_2 \qquad (13.71a)$$

and momentum conservation

$$\boldsymbol{k}_p = \boldsymbol{k}_1 + \boldsymbol{k}_2 \qquad (13.71b)$$

for the frequencies ω_i and the wave vectors $\boldsymbol{k}_i$ are fulfilled. The phase velocities of pump, signal and idler wave are matched by proper orientation of the birefringent crystal. Since the extraordinary index of refraction depends on the angle between the beam propagation and the optical axis of the nonlinear crystal, tilting of the crystal allows continuous wavelength tuning of signal and idler wave. If besides the pump wave, a weak signal wave (seed beam) is sent into the nonlinear crystal the signal wave will be enhanced much more than the idler wave. For the generation of high power ultrashort pulses a noncollinear optical parametric amplifier (NOPA) has proved to be efficient [13.72]. Its basic principle is shown in Fig. 13.55. It consists of three main functional blocks:

1. The continuum generation by focussing a small fraction of the NIR pump beam into a sapphire disc
2. The parametric amplification of the seed light in a BBO crystal pumped by the frequency doubled pump light
3. The compression of the broad band output pulses.

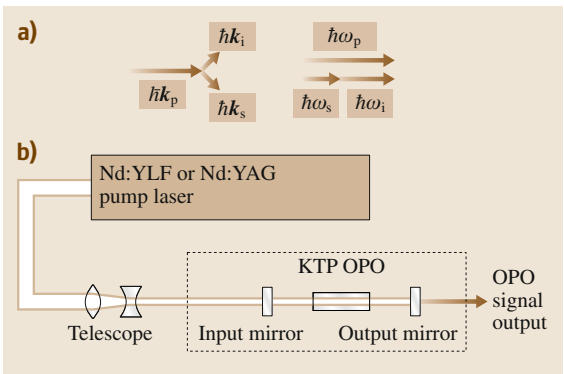

Fig. 13.54 Principle of optical parametric processes

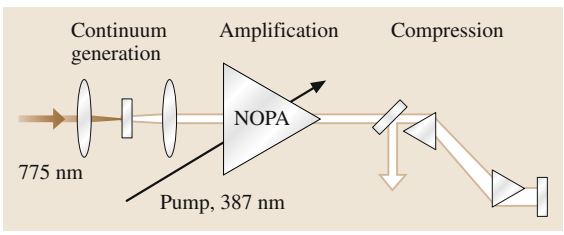

Fig. 13.55 Schematic illustration of a noncollinear parametric amplifier NOPA (after [13.72])

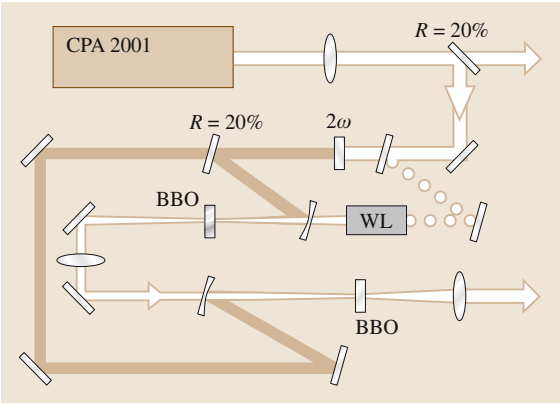

Fig. 13.56 Schematic setup for a widely tunable optical parametric amplifier (after [13.60])

The difference of this system, compared to amplification by an inverted gain medium is the following: While for conventional amplification the inversion can be stored for a time depending on the relaxation rates of the active medium, in parametric amplification there is only gain during the time of the pump pulse. It is therefore necessary that seed- and pump-pulse overlap in time. This can be achieved by using the same laser source for seed and pump. If for instance, the pump beam is provided by the frequency-doubled output of a Ti:Sapphire femtosecond laser and the seed beam comes from the spectral continuum (generated by focussing the output beam of the Ti:Sapphire-laser at $\lambda = 800\,\text{nm}$ into a sapphire plate) both beams are generated by the same laser and the time overlap is guaranteed (Fig. 13.56). The phase-matching condition ((13.71a) and (13.71b)) selects from the continuum of difference frequencies $\omega = \omega_p - \omega_s$ the desired wavelength for amplification (Fig. 13.55b). If the output of the OPA is mixed with the pump beam in a second BBO crystal sum- or difference frequencies can be generated and this widely tunable intense coherent source proves very useful for spectroscopy in a broad spectral range [13.76].

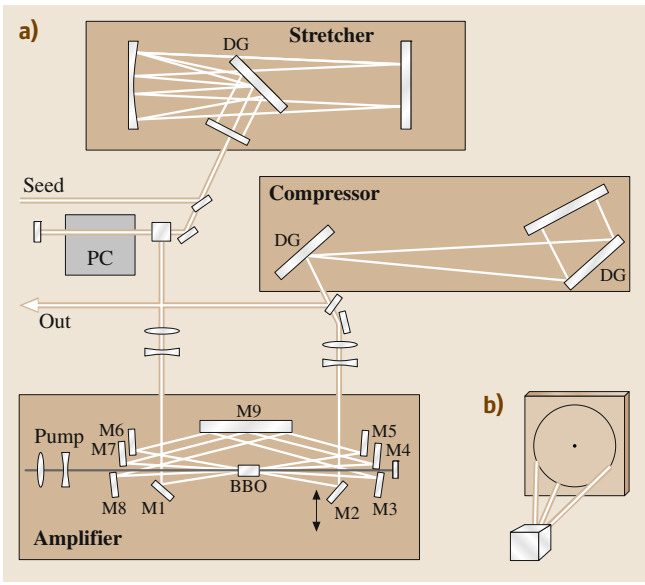

Fig. 13.57 **(a)** Schematic diagram for multipass noncollinear optical parametric chirped pulse amplifier (DG = diffraction grating, PC = Pockels cell) **(b)** beam alignment in the amplifier. The pump beam (not shown) aims at the *center of the circle* (after [13.61])

In Fig. 13.57 a possible experimental setup for multipass noncollinear parametric chirped pulse amplification is shown [13.77]. The seed source is a Kerr-lens mode-locked Ti:Sapphire laser, which delivers a 78 Mhz train of pulses with 30 nm spectral width. After passing a pulse stretcher the prolonged pulses enter the multipass parametric amplifier with a BBO crystal which is pumped by the frequency-doubled output of a Nd:YAG laser with a pulse width of 8 ns. Pump beam and seed beam cross each other in the BBO crystal under an angle of 2.4°. The amplified pulses are compressed by a grating pair. With such an arrangement terawatt femtosecond pulses can be realized [13.78].

Ultraviolet pulses with duration of 7 fs are efficiently generated by frequency doubling the output of a noncollinear optical parametric amplifier [13.79]. The ultraviolet pulses are tunable between 275 to 335 nm. The acceptance bandwidth of the doubling crystal is increased by a factor of 80 through high order achromatic phase-matching. The chirp of the visible pulses and the dispersion introduced along the beam path are compensated partially before and partially after the doubling crystal [13.80].

Using femtosecond terawatt pulses at $\lambda = 395\,\text{nm}$ as pump and short seed pulses together with chirped pulse amplification yields output pulses of 10 fs in the millijoule energy range as well as increased fidelity of stretching and compression [13.81].

Generation of Attosecond Pulses

When an intense visible laser pulse is focused into a noble gas, high harmonics of the fundamental wavelength are generated. This can be understood as follows: Due to the strong electric field of the light, rapid multiphoton ionization of the gas atoms takes place within a fraction of the optical cycle of the light. The electric field of the

focused light pulse can far exceed the Coulomb field of the atomic core, and field strengths of up to 10^{10} V/m have been realized. The free photoelectrons are accelerated back and forth through the atomic core by the alternating electric field, which changes its direction so fast that the electrons cannot leave the atom. During this acceleration period they emit radiation from the visible down to the x-ray region. Although the period of the electron movement is that of the fundamental light wave, high harmonics are generated due to the nonlinear interaction with the atomic force field and the electric field of the light wave (Fig. 13.58). Coherent x-ray radiation up to photon energies of 700 eV has been observed when a 10 fs pulse of several mJ energy (peak power 10^9 W) is focused into a sample, where an intensity of 10^{19} W/m^2 was reached for focus diameter of 10 μm. The photon yield was nearly constant over several hundred eV [13.82, 83]. This system represents an intense source of soft x-ray radiation which can compete well with synchrotron radiation regarding spectral intensity, but is much cheaper than an electron accelerator and storage ring.

Since the intensity of the n-th harmonics is proportional to the n-th power of the fundamental intensity, the higher harmonics are preferentially produced during the peak of the femtosecond pulse, and their time profile is therefore much narrower than that of the fundamental pulse. Due to this process, x-ray pulses are available with wavelengths $\lambda_X = \lambda_F/n$ in the far UV.

Example 13.7: With $\lambda_F = 500$ nm and $n = 100$ the wavelength of the high harmonics is $\lambda_X = 5$ nm, which is in the soft x-ray region and can be used for x-ray diagnostics of ultrafast processes.

The high harmonics are preferentially generated at times where the electric field of the fundamental wave has maxima. Therefore, the attosecond pulses are emitted every half-cycle of the optical femtosecond pulse. This means that the process of high-order harmonic generation of femtosecond pulses leads to the production of a train of attosecond extreme ultraviolet (XUV) pulses with a repetition rate which is twice the oscillation period of the fundamental wave. *Corkum* and coworkers have shown that, using three laser frequencies from an optical parametric amplifier, one can achieve a single attosecond pulse from a laser pulse [13.84, 85].

Instead of using isolated atoms in an atomic beam as the nonlinear medium, also solid surfaces can produce high harmonics. The relativistic interaction of an ultra-intense, few-cycle laser pulse with a solid surface

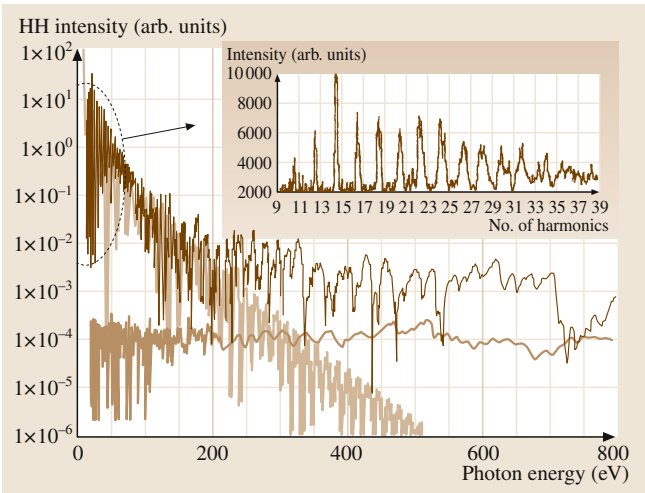

Fig. 13.58 Generation of high harmonics of focused intense femtosecond pulses (after [13.83])

produces a dense plasma and results in high-harmonic radiation with unprecedented characteristics [13.86]. In contrast with atomic high-harmonic generation (HHG), isolated pulse generation appears to be feasible for a broad range of frequencies, up to relative bandwidths of 50% of the entire harmonic spectrum, implying the feasibility of isolated XUV/soft-x-ray pulses of a few attoseconds in duration. Furthermore, the efficiency of few-cycle-driven surface HHG is predicted to surpass that of atomic HHG by several orders of magnitude. The possibility of generating single attosecond pulses gives the prospect of attosecond pump/attosecond probe spectroscopy [13.87].

Measuring Spectral and Time Profiles of Ultrashort Optical Pulses

Often ultrashort laser pulses show a time-dependent frequency profile, where the optical frequency of the pulse changes during the pulse width ΔT (chirp). Furthermore, its time- and frequency profile may change on its way from the point of generation to the point where the measurement takes place, because of the dispersion of air and of any optical elements through which the pulse is passing. There are several detection techniques, which can measure the time- and frequency profile of the pulses [13.88–90].

One of them is the FROG-method (frequency-resolved optical gating) which has been already discussed in Sect. 12.3 of this handbook. Recently a new technique for direct electric field reconstruction has been developed [13.89], which is capable to mea-

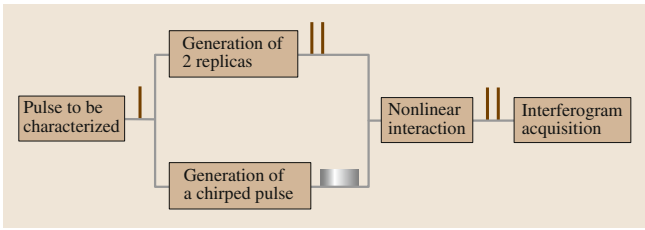

Fig. 13.59 Experimental setup for the SPIDER detection technique (after [13.66])

sure not only the temporal shape but also the phase of ultra-short pulses directly at the interaction point of a spectroscopic measurement. It is called SPIDER (spectral phase interferometry for direct electric field reconstruction). It is a modification of spectral shearing interferometry which relies on the measurement of interferences between two replicas of the wave front one wants to characterize, displayed by a small amount X along the spatial x-axis (Fig. 13.59). For an electric field

$$E(x) = \sqrt{I(x)}\,\mathrm{e}^{\mathrm{i}\varphi(x)} \tag{13.72a}$$

which interferes with a spatially shifted replica of itself

$$E(x+X) = \sqrt{I(x+X)}\,\mathrm{e}^{\mathrm{i}\varphi(x+X)}\,. \tag{13.72b}$$

The interference pattern is recorded by a square law detector as

$$S(x) = I(x) + I(x+X) + 2\sqrt{I(x)}\sqrt{I(x+X)}\cos\left[\varphi(x) - \varphi(x+X)\right]\,. \tag{13.72c}$$

The measurement of the intensity at a point x is directly related to the phase difference

$$\Delta\varphi(x) = \varphi(x) - \varphi(x+X) \tag{13.72d}$$

between the phase of the initial wavefront at point x and at point $x+X$. This phase difference can be extracted for the interference pattern by Fourier-transform techniques [13.90].

Now a third pulse which is obtained from the initial pulse by a beam-splitter, is sent through a dispersive medium where the pulse gets a frequency chirp and becomes much broader. It is superimposed in a nonlinear crystal with the two replicas of the short unknown pulses. During the short pulse the chirped pulse can be regarded as monochromatic, but during the delay time $\tau = X/c$ between the two replica pulses the frequency of the chirped pulse has changed from ω_c to $\omega_\mathrm{c} + \Omega$. Therefore the sum-frequency is accordingly changed.

The total signal measured by the square-law detector after sum-frequency generation is given by

$$S(\omega_\mathrm{s}) = I(\omega+\omega_\mathrm{c}) + I(\omega+\omega_\mathrm{c}+\Omega) + 2\sqrt{I(\omega+\omega_\mathrm{c})}\sqrt{I(\omega+\omega_\mathrm{c}+\Omega)} \times\cos(\phi(\omega+\omega_\mathrm{c}) - \phi(\omega+\omega_\mathrm{c}+\Omega))\,. \tag{13.72e}$$

This signal contains all information on the phase and spectral profile of the unknown pulse, which can be obtained by a Fourier-transform from the measured signal as a function of the delay time τ which is related to the phase difference $\Delta\phi = \Omega/\tau$.

The advantages of the SPIDER-technique can be summarized as follows:

1. The experimental setup is simple and does not involve any moving parts.
2. The interferogramm is measured with a 1-dimensional spectrometer.
3. The acquisition of the experimental trace is done in a single shot.
4. The reconstruction of the pulse shape from the experimental data is quick and shows low sensitivity to the noise background.

One disadvantage is that this technique does not characterize the pulses at the position of the experiment, because they split the beam before the actual characterization, thus introducing additional phase through the material dispersion. Therefore a modification of the SPIDER-technique has been developed [13.88–90], which is called ZAP-SPIDER (zero additional phase SPIDER).

Its basic principle is based on the interference between a pair of temporally delayed pulses that are spectrally shifted against each other (Fig. 13.60): The unknown pulse to be characterized is sent into a nonlinear crystal where it overlaps with two strongly chirped auxiliary pulses coming from different directions, which are replicas of the same parent pulse. The nonlinear interaction between the three pulses results in two approximately monochromatic pulses at the sum- and difference frequencies which overlap in the BBO crystal with the pulses to be characterized. For visible pulses the crystal is adjusted for sum frequency mixing and for UV pulses for difference frequency mixing. Changing the time delay between the unknown pulse and the auxiliary pulses results in mixing the unknown pulse with different frequencies (because of the strong chirp) of the auxiliary pulses. One thus obtains two spectrally sheared replicas with centre frequencies at ω_0

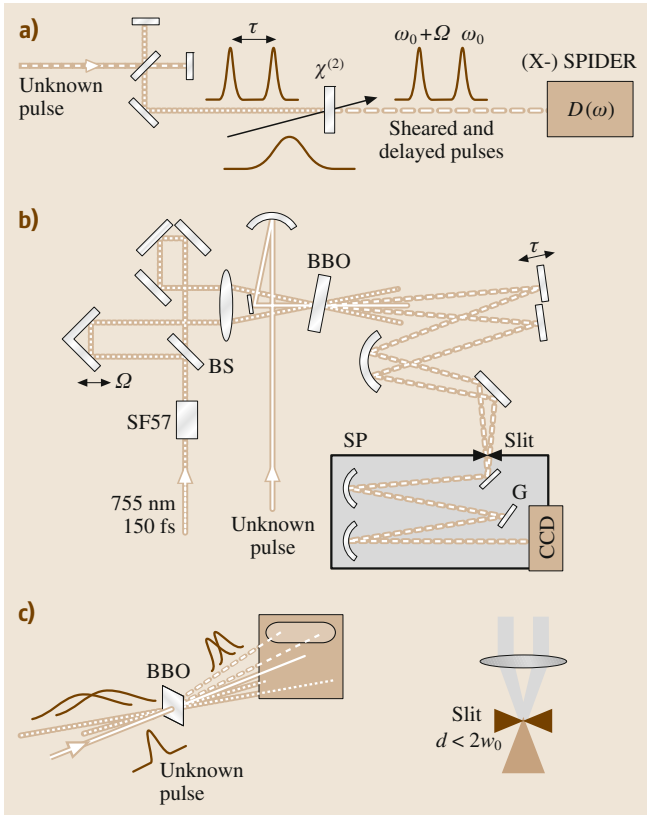

Fig. 13.60 **(a)** Setup for the ZAP-SPIDER method. **(b)** Experimental setup. SF57 = dispersive glass, BS = beam splitter, Ω = delay for adjusting the spectral shear, τ = delay to adjust mean fringe spacing. **(c)** Interference of two spatially separated beams focused into a thin slit (after [13.68]) ▶

and $\omega_0 + \Omega$, which propagate into two different directions, because of the phase-matching condition in the nonlinear crystal. The two pulses are recombined with a small delay τ in a spectrograph. The resulting interferogramm encodes the phase difference between pairs of sheared frequencies. The complete spectral phase of the unknown pulse is then obtained from a Fourier transform and a special filtering technique [13.89].

A good comparison between different techniques for measuring ultrashort optical pulses can be found in [13.90].

Measurements of Attosecond Pulse Time Profiles

The time profile of attosecond pulses can be measured using optical-field-driven attosecond streaking, which is similar to the FROG technique discussed above [13.91]. Atoms in a beam are ionized by an attosecond vacuum ultraviolet (VUV) laser pulse. The photoelectrons are released in a direction parallel to the direction of the laser field with the time profile shown by the red curve in Fig. 13.61. They suffer a change of their initial velocities that is proportional to the vector potential of the laser field at the instant of release (shown as the black curve). Within a half-cycle of the laser field, this vector potential is monotonic and allows one to derive the

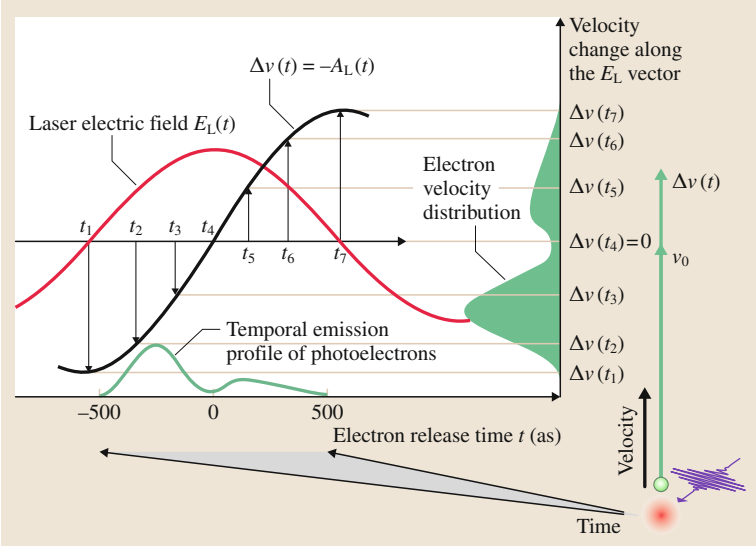

Fig. 13.61 Concept of optical-field-driven attosecond streaking (after [13.91])

intensity profile of the attosecond XUV pulse from the final energy distribution of the photoelectrons.

13.2.3 Time-Resolved Spectroscopy

In this section some techniques are described which allow to study dynamical problems with a time resolution ranging from microseconds to attoseconds. We will at first discuss a sensitive method of absorption spectroscopy transferred to measurements in the time domain. Then an old problem will be presented, namely the determination of lifetimes of excited states of atoms and molecules. These lifetime-measurements yield very accurate values of transition probabilities and give for example, together with measurements of line intensities, information about the abundance of different elements in the atmospheres of stars.

Cavity-Ring-Down Spectroscopy

During the last years a new very sensitive technique of absorption spectroscopy has been developed which is named *cavity-ringdown spectroscopy* (CRDS). It measures the absorption of a sample placed inside an optical cavity by monitoring the time decay of the radiation power stored in the cavity [13.92].

Instead of measuring the small difference between incident and transmitted radiation power in conventional absorption spectroscopy, this technique measures, after how many roundtrip times in the cavity the power has dropped to $1/\mathrm{e}$ of its initial value. Its basic principle can be understood as follows.

When a laser pulse with input power P_0 is sent into an optical cavity with two highly reflecting mirrors the pulse will be reflected back and forth between the two mirrors (Fig. 13.62a). For each roundtrip a small fraction will be transmitted through the end mirror M_2 to the detector. With a mirror reflectivity $R_1 = R_2 = R$, transmission $T = 1 - R - A$ where A includes all losses of the cavity (absorption, diffraction, scattering except those losses introduced by the absorbing sample) the transmitted power of the first output pulse is

$$P_1 = T^2 \mathrm{e}^{-\alpha L} P_0 \,, \tag{13.73a}$$

where α is the absorption coefficient of the absorbing sample with absorption length L inside the optical cavity with mirror separation d. If the sample fills the whole cavity we obtain $L = d$. For each additional roundtrip the pulse power decreases by the factor $R^2 \exp(-2\alpha L)$: After n roundtrips the output power of the $(n+1)$-th pulse has decreased to

$$P_{n+1} = (R \cdot \mathrm{e}^{-\alpha L})^{2n} P_1 \tag{13.73b}$$

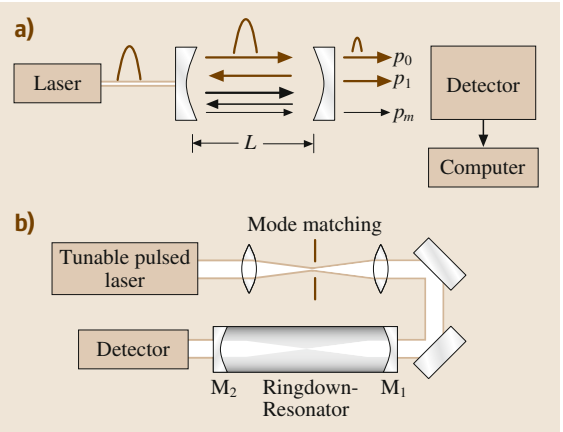

Fig. 13.62 (a) Setup for cavity-ring-down spectroscopy. (b) Coupling of incident laser beam into the ring-down cavity with mode-matching optics

with $R = 1 - (T + A)$ and $A + T \ll 1 \rightarrow \ln(1 - A - T) \approx -(A + T) = R - 1$ this can be written as

$$P_{n+1} = P_1 \mathrm{e}^{-2n(1-R+\alpha L)} \,. \tag{13.73c}$$

The time interval between two successive pulses equals the roundtrip time $T = 2d/c$. The envelope of the discrete pulse sequence is the continuously decaying function of the output power from the resonator with the absorbing sample

$$P(t) = P_1 \mathrm{e}^{-t/\tau_1} \tag{13.73d}$$

with the time constant (Fig. 13.62b)

$$\tau_1 = \frac{d/c}{1 - R + \alpha L} \,. \tag{13.74a}$$

The empty cavity ($\alpha = 0$) has the longer decay time

$$\tau_2 = \frac{d/c}{1 - R} \,. \tag{13.74b}$$

The difference of the reciprocal decay times

$$\frac{1}{\tau_1} - \frac{1}{\tau_2} = \left(\frac{c}{d}\right) \cdot \alpha L \tag{13.75}$$

directly yields the absorption αL.

Example 13.8: $R = 0.999, d = L = 1\,\mathrm{m}, \alpha = 10^{-6}\,\mathrm{cm}^{-1} = 10^{-4}\,\mathrm{m}^{-1} \rightarrow \tau_1 = 3.03\,\mu\mathrm{s}$, $\tau_2 = 3.33\,\mu\mathrm{s}$. The difference is small. However, with $R = 0.9999$ we obtain $\tau_1 = 16.5\,\mu\mathrm{s}$ and $\tau_2 = 33\,\mu\mathrm{s}$. This shows how important a high reflectivity of the cavity mirrors is.

A more detailed treatment of CRDS has to take into account the mode structure of the cavity, because the

high Q-value of the cavity can be obtained only for those frequencies, which match the optical modes of the cavity. For all those wavelength λ_i contained in a laser pulse, for which $\nu_i = c/\lambda_i \neq m \cdot c/2d$, the cavity-$Q$ and with it the sensitivity will be small. Therefore small absorption lines at those wavelengths may just escape detection. There are several solutions to this problem:

1. The laser pulse is sent into the high-Q cavity without mode matching optics. It then excites not only longitudinal modes but also many transverse modes. In a nonconfocal cavity the frequencies of these transverse modes are closely spaced and fill the frequency distance $\Delta\nu = c/2d$ between the longitudinal modes. Their frequency separation is smaller than the Doppler-width of the absorption lines, insuring that all absorption lines are detected. The advantage of this method is the simple experimental setup without mode-matching optics. Its disadvantage is the smaller sensitivity because the average over all transversal and longitudinal modes yields a smaller Q-value, than for a single longitudinal mode.
2. The phase-fronts of the incoming pulses are imaged by a suitable optical system into the cavity in such a way, that they coincide exactly with those of the fundamental modes of the cavity (Fig. 13.8b). This gives the highest possible Q-value. However, now the cavity length has to be stabilized onto the laser frequency and has to be synchronously tuned when the laser frequency is tuned through the absorption spectrum, insuring that the cavity mode is always in resonance with the laser frequency. With this mode-matching setup the spectral resolution is limited either by the Doppler-width of the absorption lines or by the pulse length ΔT which gives a Fourier-limited resolution $\Delta\nu = 1/(2\pi\Delta T)$.

The highest Q-value and therefore the highest sensitivity is achieved with CW lasers where the output beam of the laser is sent through a modulator that forms pulses of wanted length ΔT and a spectral bandwidth which is adapted to the width of the cavity modes. Since this width $\Delta\nu$ is smaller than the Doppler-width, once can measure the line profiles and can investigate the influence of pressure broadening. In Fig. 13.63 a possible setup for cavity ringdown spectroscopy with an external cavity CW diode laser is shown [13.93].

The output beam is pulsed by an acousto-optical modulator and the length of the ringdown cavity is slowly changed by a saw tooth voltage to the piezo, onto which one of the mirrors is mounted.

The achievable sensitivity is limited by the accuracy of measuring the decay times τ_1 and τ_2. This accuracy

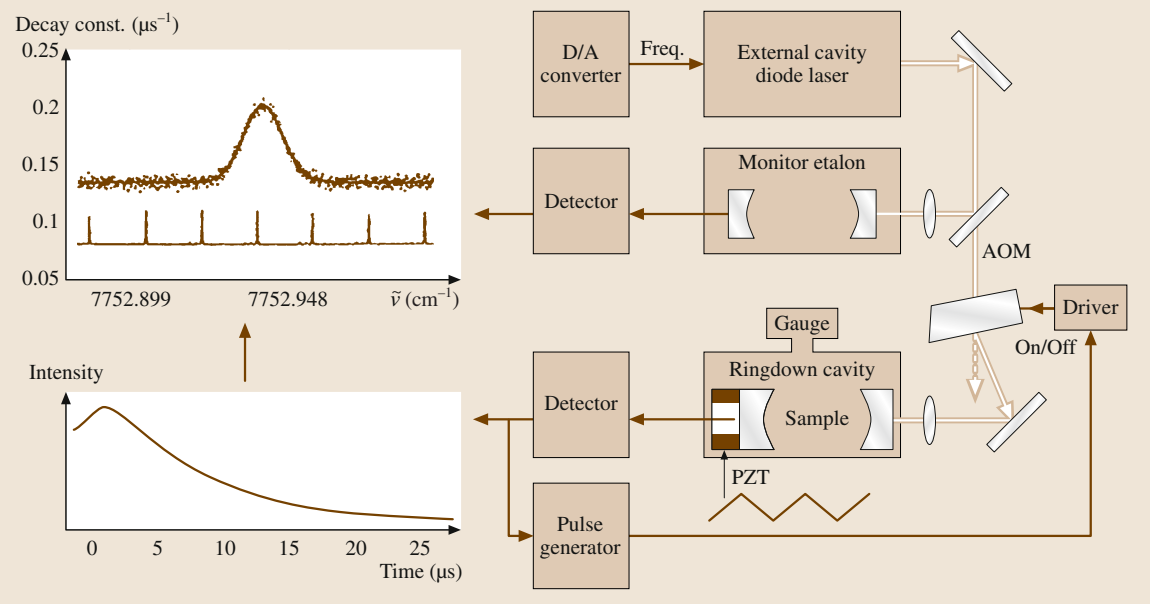

Fig. 13.63 Experimental arrangement for cavity-ring-down spectroscopy with a CW external cavity diode laser (after [13.73])

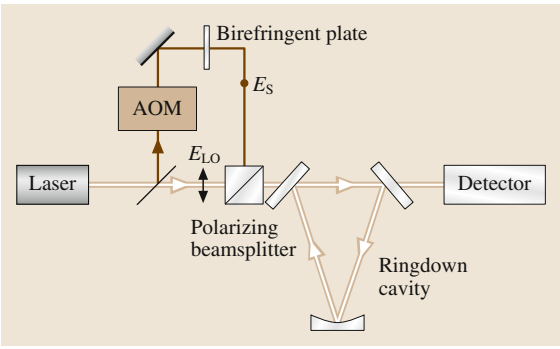

Fig. 13.64 Heterodyne detection of ring-down signals (after [13.74])

in turn is limited by the noise of the decay curve. The main sources of noise are intensity fluctuations of the laser and fluctuations and drifts of the cavity length.

A particularly sensitive technique which can eliminate at least part of this noise is based on heterodyne measurements (Fig. 13.64).

The output beam of a CW laser is split into two partial beams. One of them is directly sent through a mode-matching optics into the cavity, which is stabilized onto the laser frequency. The output signal of the cavity serves as local oscillator.

The optical frequency of the second beam is shifted by an acousto-optic modulator by exactly the mode-separation $\Delta\nu = c/2d$ thus matching the neighbouring mode. The amplitude of this *signal beam* is modulated at a frequency of 40 kHz. Both partial beams are again superimposed before they enter the cavity and are in resonance with two adjacent longitudinal cavity modes. The transmitted power

$$P_t \approx |E_s(t) + E_{LO} \cdot e^{i(2\pi t\delta\nu + \Phi)}|^2$$
$$= |E_s(t)|^2 + |E_{LO}|^2 + 2E_s E_{LO} \cos(2\pi\delta\nu t + \Phi) \quad (13.76)$$

is measured by the detector. While the second beam consists of pulses with 25 µs pulse width and results in an exponential decay of the transmitted signal, the power of the fist beam is constant and can be therefore used to stabilize the cavity.

The interference term in (13.76) is the product of the large amplitude of the local oscillator (note that the transmitted amplitude of the CW beam $A_t = (1-A)^2 \cdot e^{-\alpha L}$ is for $A \ll 1$ and $\alpha L \ll 1$ nearly that of the incident amplitude) and the much smaller amplitude E_s of the modulated signal beam. Measuring the decay of this interference term at the frequency $\Delta\nu = c/2d$ yields a much larger signal as obtained with the conventional cavity ring-down technique, which now decay with the time constant 2τ, but has a much better signal-to-noise ratio.

The combination of pulsed CRDS with Fourier spectroscopy combines the sensitivity of CRDS with the multiplex advantage of Fourier spectroscopy [13.94]. As in the case of *normal* CRD spectroscopy, the measurement is independent of light intensity fluctuations, provided the spectral intensity distribution of the light source is known and is constant during the measurement.

Another modification of CRDS is phase-shift CRFS. Here, the absorption spectrum is extracted from a measurement of the wavelength-dependent phase shift (PS) that an intensity-modulated CW light beam experiences upon passing through a high-Q optical cavity. The incident light is modulated according to

$$I = I_0(1 + a \cdot \sin \Sigma t) ,$$

and the fluorescence emitted by the excited molecules for optical frequencies of the incident light which coincide with absorption lines shows the modulation

$$I_{Fl} = I_{Fl_0}[1 + b \cdot \sin(\Sigma t + \phi)]$$

at the same frequency Σ but with a phase shift ϕ which is related to the lifetime τ of the excited molecules by

$$\tan\phi = \Sigma \cdot \tau .$$

As the PS-CRD measurement method is independent of random light source intensity fluctuations, it can be performed in a cavity without any stabilization of the cavity length, as is explicitly demonstrated in [13.95].

More information on CRDS can be obtained from the reviews [13.92, 96, 97].

Lifetime Measurements

The population N_i of an excited state $|i\rangle$ of a free atom decays exponentially from the value $N_i(0)$ at time $t = 0$, to the value

$$N_i(t) = N_i(0) \cdot e^{-t/\tau} \quad (13.77)$$

at time $t > 0$. The quantity τ is the mean spontaneous lifetime of state $|i\rangle$. It is related to the total transition probability A_i by $A_i = 1/\tau_i$. Typical values of lifetimes of excited valence electrons lie in the nanosecond range.

If the excited atom A collides with other atoms or molecules B, its population can additionally decrease by inelastic collisions. The rate of such deactivating collisions

$$R_i = N_B \cdot \sigma_{inel} \cdot \langle v_r \rangle \quad (13.78a)$$

depends on the number density N_B of the collision partners B, on the collision cross section σ and the relative velocity v_r. The total transition probability for deactivating the excited state $|i\rangle$ is then increased to

$$A_i^{\text{eff}} = A_i^{\text{spont}} + R_i \qquad (13.78b)$$

and the effective lifetime of the excited state is reduced according to

$$\frac{1}{\tau_i^{\text{eff}}} = \frac{1}{\tau_i^{\text{spont}}} + R_i \,. \qquad (13.79)$$

The experimental technique for measuring lifetimes depends on the order of magnitude for τ. For lifetimes in the micro- to nanosecond range, the atoms can be excited by a short laser pulse (e.g. a nanosecond pulse) and the decay of the laser-induced fluorescence is monitored with a fast oscilloscope. Digital transient recorders can measure decay curves with a time resolution in the picosecond range.

For small intensities another method is more suitable. It is based on time correlation spectroscopy of single fluorescence photons [13.98]. Its principle is depicted in Fig. 13.65. The sample atoms or molecules are irradiated by a regular time sequence of short pulses delivered from a mode-locked cavity dumped CW-laser. The cavity dumping frequency is chosen such that the time interval between two successive pulses is at least three times the expected lifetime of the excited molecules. A fraction of each laser pulse is sent to a fast photodiode, which delivers the trigger signal to define the starting time $t = 0$ of a time-to-amplitude converter TAC. This TAC delivers a ramp voltage $U = a \cdot t$.

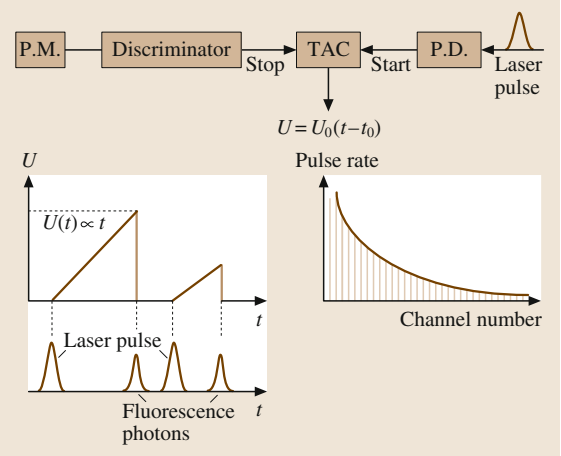

Fig. 13.65 Single-photon delayed coincidence technique

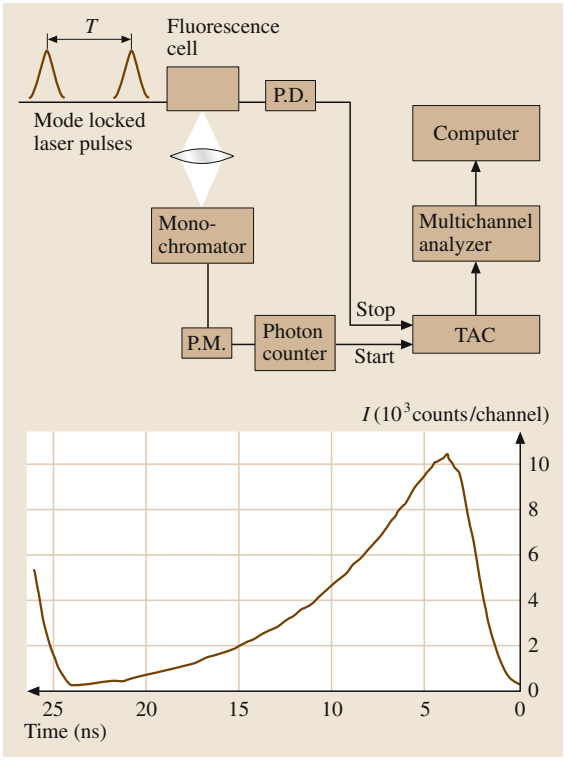

Fig. 13.66 Experimental arrangement for lifetime measurements and decay curve of the excited $B^1\Pi_u$ state of the Na_2 molecule. The time scale runs from *right to left*

The first fluorescence photon detected at time t_1 after the excitation pulse stops the ramp. The output voltage $U = a \cdot t_1$ is stored in a multichannel analyser or in a computer. Measuring many events yields the probability distribution of decay times which gives the exponential decay of (13.77). The detected fluorescence rate should be smaller than the repetition rate $f = 1/T$ of the laser pulses in order to insure, that at most one fluorescence photon is detected during the time T between two excitation pulses. With a ramp time of 50 ns and 1000 channels the time resolution is 50 ps. In order to reduce the dead time of the TAC, the time sequence is often inverted: The TAC is started by the fluorescence photon, emitted at time t_1 after the excitation pulse and is stopped by the next excitation pulse. Since the repetition rate of the pulses from a mode-locked laser is very stable, the true delay time t_1 can be directly inferred from the measured time difference $T - t_1$. In Fig. 13.66 the whole setup for this method is depicted and a decay curve of an excited level of the Na_2 molecule with the inverted time scale is shown for illustration [13.99].

Pump- and Probe-Techniques

If a time resolution in the pico- to femto-second range is demanded, the direct detection by electronic devices is not fast enough. Here a new technique has been developed, which uses a fast pump pulse that excites or depletes a specific level in atoms or molecules, and a delayed fast probe pulse, that probes the effect of the pump pulse at a controlled time delay (Fig. 13.67). Generally both pulses come from the same laser. The output pulse of the laser is split by a beam splitter into two parts, which travel through different path lengths before they are recombined by a second beam splitter. The pump pulse depletes the lower level of the pump transition in a molecule and populates the upper level. The probe pulse can either probe the depletion of the lower level, or it can further excite the excited molecules. The intensity of the fluorescence from the excited levels can serve as monitor (Fig. 13.68a). The intensity of the probe-laser-induced fluorescence from level $|2\rangle$ is measured as a function of the delay time between pump and probe. If the sum of the photon energies is above the ionization limit, the probe laser can even ionize the excited molecules. The measured ion rate $N_{\text{ion}}(t)$ as the function of the delay time t of the probe pulse then gives the time-dependent population of the upper level $|1\rangle$.

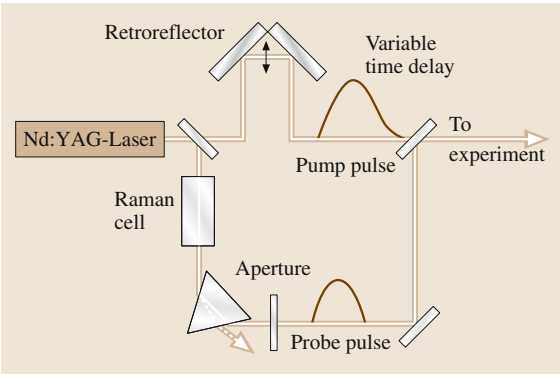

Fig. 13.67 Pump-and-probe technique

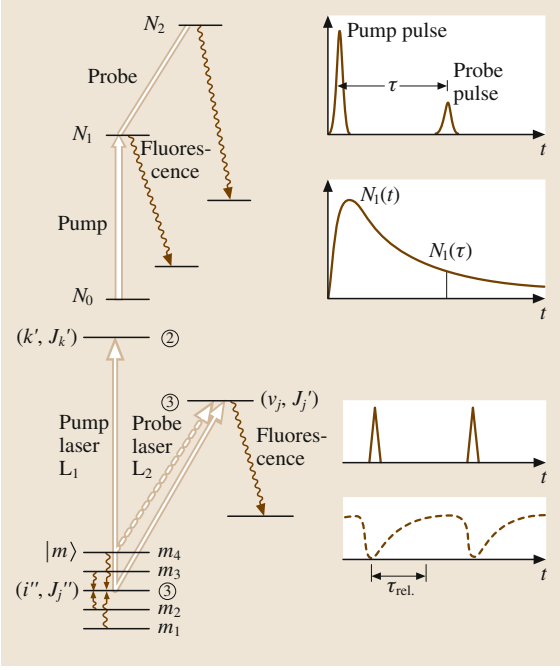

Fig. 13.68 Possible level schemes for the pump-and-probe technique

The depleted lower level can be refilled by fluorescence from the upper level or by inelastic collisions. The weak probe pulse monitors this refilling process by measuring the fluorescence intensity induced by the probe pulse as a function of the delay time (Fig. 13.68b) because the fluorescence intensity is proportional to the population of the lower level. With this technique a time resolution of a few femto-seconds can be achieved. Note, that the time resolution of the detector can be much worse.

Often it is desirable that pump and probe laser have different wavelengths. When two different lasers are used for the pump and the probe pulses even a good time synchronization between the two pulses shows a jitter, that might be as large as a few nanoseconds. Therefore a time resolution in the femto second range cannot be achieved. There are, however, ways to get around this problem. If a tunable laser is pumped by a short laser pulse, a fraction of the pump pulse energy can be used as the pump for the experiment and the tunable laser pulse as the probe. Another method uses the Raman shift of a fixed frequency laser. Selecting different molecules in the Raman-shifter the wavelength of the probe pulse can be shifted against that of the pump pulse into resonance with another transition of the sample molecule. With this technique the time dependent population of other vibrational or rotational levels than those connected with the pump transition can be monitored.

An even more general technique uses a white light source as pump and a NOPA as probe (Fig. 13.69). If the output of the NOPA is superimposed in the sample with the spectral continuum from the white light source, generated by the same Ti:Sapphire laser that also pumps the NOPA, the whole spectrum of the sample within the bandwidth of the white light source and the dynamics of

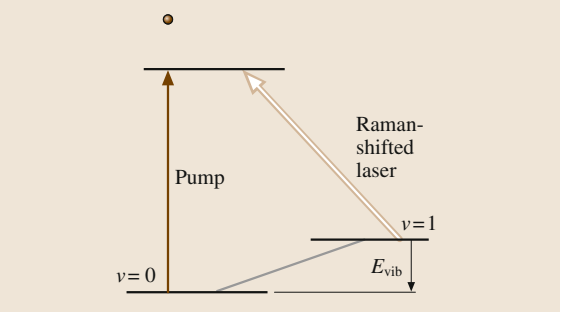

Fig. 13.69 Schematic level scheme for pump-and-probe experiments with a Raman-shifted probe beam

the sample molecules can be measured with the pump- and probe technique, where the delay between pump and probe can be mechanically adjusted by a proper optical delay line.

Examples

Examples for applications of this pump-and-probe-technique are measurements of fast relaxation processes of excited vibrational levels of molecules in liquids, induced by collisions [13.100], which play an important role for chemical reactions. The enhancement of the reaction rate by vibrational excitation of the reactants can select specific reactions. For the investigation of such processes infrared pico- to femto-second laser pulses are used as pump and probe. With frequency-doubled visible laser photons excited electronic states of molecules can be populated which may either dissociate, or transfer their excitation energy in collisions to their collision partner. The pump-and-probe-technique can measure the energy transfer times.

If polyatomic molecules are photo-ionized by two or more photons in a short laser pulse, the excited molecular ions can be into excited states which either radiate

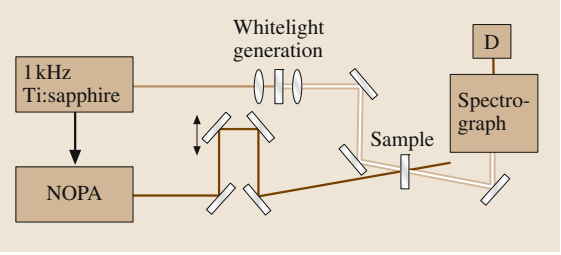

Fig. 13.70 Pump-and-probe technique with a white-light continuum and a noncollinear optical amplifier, allowing measurements of the dynamical processes over a broad spectral range

or dissociate into different neutral or ionized fragments (Fig. 13.70). The ionized fragments can be detected by a time-of-flight mass spectrometer. The detection of the neutral fragments, which are much more abundant at low excitation energies of the molecular parent ion, can be measured by ionizing them with a second laser pulse (probe pulse). It is interesting to follow the reaction paths in the excited parent molecules that lead to the measured fragmentation which often involves energy conversion from electronic to vibration energy of the excited species.. This can be achieved by varying the time delay between the pump- and the probe pulse and observing the fragment mass spectrum as a function of the delay time [13.101].

13.2.4 Coherent Time-Resolved Spectroscopy

While in the foregoing sections mainly the intensity profiles of the short pulses were utilized for spectroscopic measurements for many experiments the information about the phase of the optical oscillation is important. If definite correlations between the phases of optical pulses can be established, the phases of molecular wave functions in excited states can be controlled if these levels are excited by such phase-controlled pulses. In these cases new interference effects are observed which can give more detailed information on these states and their time evolution. We will illustrate this by several examples.

Quantum Beat Spectroscopy

Quantum beat spectroscopy is based on the coherent simultaneous excitation of two or more molecular levels from a common lower level by a short optical pulse (Fig. 13.71).

The wave function of these levels at the time $t = 0$ of the exciting pulse is then the coherent superposition

$$\Psi(t=0) = \Sigma c_k \psi_k(0) \qquad (13.80)$$

of the wave functions of the different excited states. If the levels $|k\rangle$ decays with the decay constant $\gamma_k = 1/\tau_k$ into a lower level $|m\rangle$, the wave function $\Psi(t)$ becomes

$$\Psi(t) = \Sigma c_k \psi_k(0) \mathrm{e}^{-\mathrm{i}(\omega+\gamma/2)t} \qquad (13.81)$$

with $\omega_{km} = (E_k - E_m)/\hbar$. If this decay is due to population decay the fluorescence power emitted by the excited levels is proportional to the square of the transition matrix element and we obtain the signal

$$S(t) \approx I_{\mathrm{Fl}}(t) = C|\langle\psi_m|\boldsymbol{\varepsilon}\cdot\boldsymbol{\mu}|\Psi(t)\rangle|^2\,, \qquad (13.82)$$

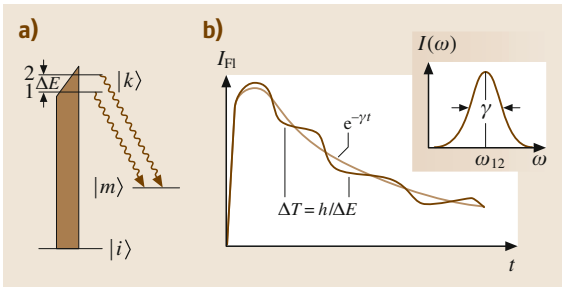

Fig. 13.71a,b Quantum-beat spectroscopy **(a)** level scheme, **(b)** quantum beats observed in the fluorescence of two coherently excited levels and the Fourier transform of the beat signal

where C is a constant factor, depending on the experimental conditions, $\boldsymbol{\varepsilon}$ is the polarization unit vector of the emitted light, $\mu = e \cdot \boldsymbol{r}$ is the electric dipole operator.

If we insert (13.81) into (13.82), we obtain for the example of two excited levels $|1\rangle$ and $|2\rangle$ with equal decay constants $\gamma_1 = \gamma_2 = \gamma$ the result

$$I(t) = C\,\mathrm{e}^{-\gamma t}(A + B \cdot \cos \omega_{12} t) \qquad (13.83)$$

with $A = c_1^2 |\langle \psi_m | \varepsilon \cdot \mu | \psi_1 \rangle|^2 + c_2^2 |\langle \psi_m | \varepsilon \cdot \mu | \psi_2 \rangle|^2$ and $B = 2c_1 c_2 |\langle \psi_m | \varepsilon \cdot \mu | \psi_1 \rangle| \cdot |\langle \psi_m | \varepsilon \cdot \mu | \psi_2 \rangle|$.

The intensity $I(t)$ shows an exponential decay superimposed by a modulation with the frequency $\omega_{12} = (E_1 - E_2)/\hbar$. Which directly yields the level separation $\Delta E = (E_1 - E_2)$.

If the levels are separated by an external electric or magnetic field, the measured splittings yield the electric or magnetic dipole moments in these states. Since the dipole moments depend on the coupling of angular momenta, the specific coupling scheme for the investigated states can be inferred. Often the total angular momentum of a molecular level results from coupling of this level with other levels in different electronic states, e.g. spin orbit couplings between singlet and triplet states. In such cases quantum beat spectroscopy can give valuable information about these couplings, because it measures the lifetimes and the energy separation simultaneously. Figure 13.72 illustrates the Zeeman quantum-beats of excited levels in the propynal molecule [13.102] where the Fourier transform of the measured complex beat signal yields the energy levels involved.

Molecular Wave-Packet Dynamics

Another example for time resolved coherent spectroscopy is the investigation of wave packet dynamics of electronically excited molecules. The femto-second pump laser with optical frequency $\nu = E/h$, a time duration Δt and Fourier-limited energy width $\Delta E = \hbar/\Delta t$ excites coherently a group of vibrational levels within the energy range $E \pm \Delta E$. The superposition of their wave functions represents a wave packet which moves with the average vibrational frequency between the inner and outer turning points of the potential. For the example of the Na_2 molecule shown in Fig. 13.73, the wave packet is excited by two-photon absorption from the electronic ground state into the $2^1\Pi_g$ state. The further excitation of the excited molecule by the probe laser depends on the delay between pump and probe pulse. If the molecule is excited at that time, when the wave packet is at the inner turning point, molecular Na_2^+ ions are formed, while excitation at the outer turning point leads to dissociation into $Na + Na^+$ and produces atomic Na^+ ions [13.103]. This is an example how a specific product channel can be selected just

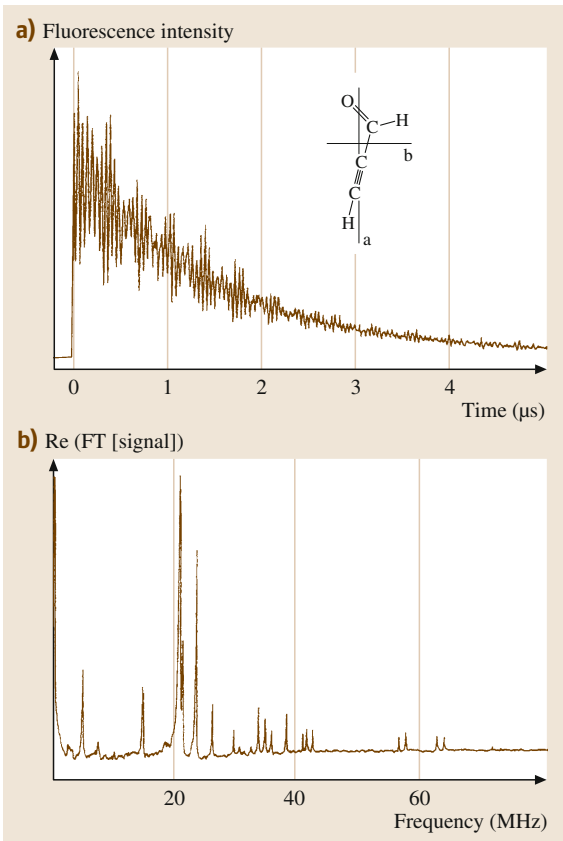

Fig. 13.72a,b Zeeman quantum beat fluorescence signal of excited propynal molecules where at least seven levels were coherently excited (after [13.79])

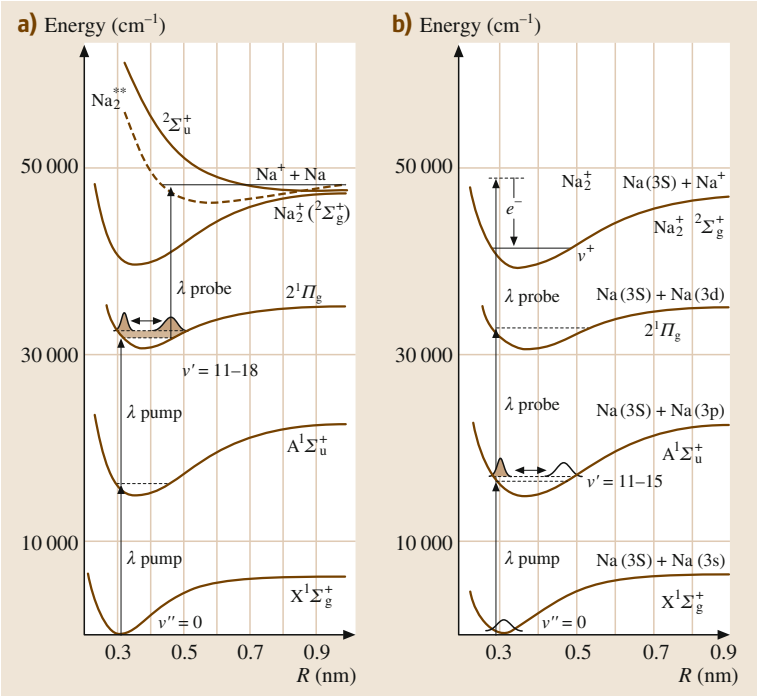

Fig. 13.73 Wave-packet dynamics and coherent control for the dissociation and selective ionization of the Na_2 molecule (after [13.80])

by choosing the proper time delay between pump- and probe-pulse.

Photon Echoes

The time resolved coherent excitation of molecules can be also used to obtain information not only about the population decay but also on the phase decay. This is realized with the technique of photon echoes which can be understood as follows.

Assume N molecules have been simultaneously excited by a short laser pulse from a lower level $|1\rangle$ into the upper level $|2\rangle$. The total fluorescence power emitted on the transition $|2\rangle \rightarrow |1\rangle$ is given by

$$P_{\mathrm{Fl}} = \Sigma \hbar\omega \cdot A_{21} \,, \qquad (13.84)$$

where D_{21} is the dipole matrix element for the transition $|2\rangle \rightarrow |1\rangle$ and g_1 and g_2 are the statistical weight factors of levels $|1\rangle$ and $|2\rangle$. The sum extends over all N molecules.

With coherent excitation at time $t = 0$ a definite phase relation is established between the wave functions of the N molecules in level $|2\rangle$. We therefore obtain

$$|\Sigma D_{12}|^2 = |N \cdot D_{12}|^2 = N^2 |D_{12}|^2 \,, \qquad (13.85)$$

whereas for incoherent excitation the phases of the N molecules are random and the result would be $N \cdot |D_{12}|^2$. This shows that the total fluorescence power at a time t just after the excitation pulse, where the molecules are still in phase, is N times larger than that for incoherent excitation.

In order to produce photon echoes the molecules are excited at time $t_1 = 0$ by a $\pi/2$-pulse (Fig. 13.74). This is a pulse with a controlled energy that changes the phase of the wavefunctions of both levels by $\pi/2$ and creates equal populations in levels $|1\rangle$ and $|2\rangle$. Such a system represents an oscillating dipole with oscillation frequency $\omega_{12} = E/\hbar$.

Because of the finite line width $\Delta\omega$ of the absorbing transition $|1\rangle \rightarrow |2\rangle$ (for example the Doppler width) the frequencies ω_{12} of the N molecules are not all equal but are distributed within the interval $\Delta\omega$. This causes the phases of the N oscillating dipoles to develop in time at different rates after the end of the $\pi/2$-pulse. At a time $t_2 < T_1$ which is still smaller than the population decay time T_1 but larger than the phase relaxation time T_2 the phases of the N dipoles are randomly distributed.

The molecules are now irradiated at time $t = t_2$ by a second pulse with twice the energy of the first excitation pulse. This pulse inverts the phase of the induced polarization and is therefore called a π-pulse. It causes a reversal of the phase development for each dipole. After the time $t_3 = 2t_2$ all molecules are again in phase and

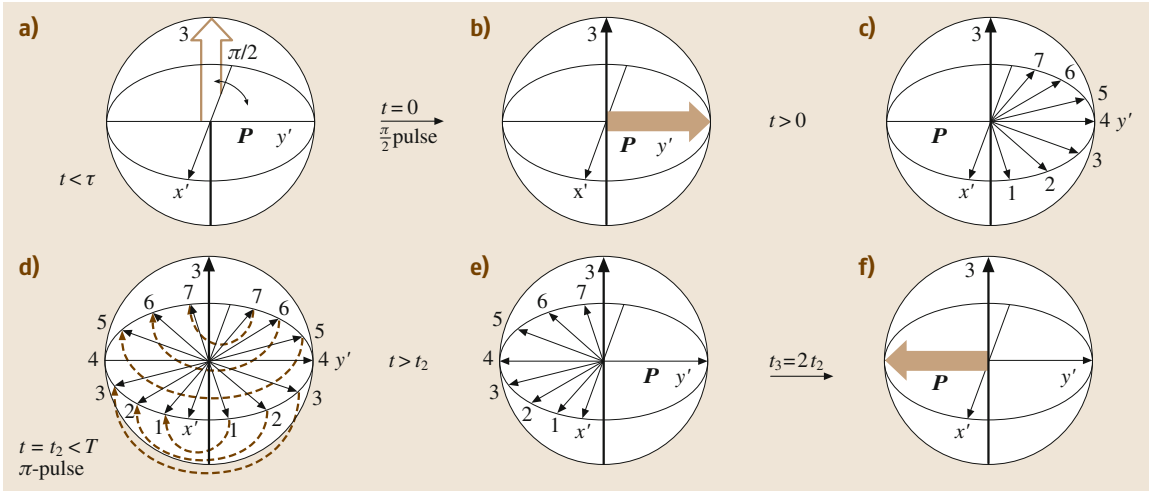

Fig. 13.74 Pulse sequence for the generation of photon echoes and the time evolution of the pseudo-polarization vector, where the photon echo is emitted at $t = 2\tau$

they emit a signal which is proportional to N_2^2, where

$$N_2(2t_2) = N_2(0) \cdot \mathrm{e}^{-2t_2/T_1} \qquad (13.86)$$

is the population of molecules in the excited state $|2\rangle$, that have survived the time $2t_2$ after excitation by the first pulse. This signal is called *photon echo*. It is much stronger than the incoherent fluorescence which is emitted at all times $t > 0$ but is only proportional to $N_2(t)$.

The amplitude of the photon echo decreases with increasing time delay due to the population relaxation with the *longitudinal relaxation time* T_1.

A second, generally faster relaxation process is the phase relaxation with the *tranverse relaxation time* T_2. It can have several causes:

1. Phase-perturbing collisions change the phase of the oscillating dipoles and therefore prevent them to be all in phase at $t = 2t_2$. Since such collisions give rise to a homogeneous line broadening, this contribution to the echo decay is the homogeneous part.
2. The different velocities of the molecules within their Doppler-width also cause different phase shifts (inhomogeneous part).

This second contribution, however, does not prevent the dipoles to restore their phase at the echo time $t = 2t_2$ and therefore does not diminish the amplitude of the photon echo. The Fourier-transform of the decay times of the photon echo gives therefore Doppler-free line widths.

The time evolution of the system can be best described by the *pseudo-polarization vector*, which is defined as

$$P = \{P_x, P_y, P_z\} ,$$

where P_x and P_y describe the components of the atomic polarization by the optical wave traveling into the z-direction and $P_z = D_{12} \cdot \Delta N$ is the product of the transition dipole moment D_{12} and the population difference $\Delta N = N_1 - N_2$ between the two levels. The time development of P describes the time-dependent polarization of the molecular system. This is schematically depicted in Fig. 13.75 where relaxation processes have been neglected.

More detailed information about photon echoes and their applications can be found in [13.104, 105].

13.2.5 Applications of Short Laser Pulses

In this section some selected applications of short laser pulses in the time scale between 10^{-9} to 10^{-17} s will be presented, in order to give a feeling for the large variety of possible applications of light pulses in different time domains.

Applications in Chemistry and Molecular Dynamics

The dream of chemists is the control of chemical reactions by excitation with properly formed laser pulses. This dream has meanwhile become true at least for some favourable cases by a method called coherent control. Its implementation demands very short laser pulses because of the following reason: In order to enhance

a specific reaction one has to excite specific molecular levels, which decay into the wanted reaction channel. The density of states in electronically excited molecules increases strongly with excitation energy and with the number of atoms in a molecule and also the interaction between different states increases. Even if a single selected level has been excited by photon absorption the excitation energy is spread among many interacting states within a short time, thus washing out the wanted selectivity. Therefore the wanted reaction has to start, before this energy redistribution takes place. The method of coherent control can overcome these difficulties because it uses femtosecond pulses and prepares a favourable excited state which leads to the optimization of the wanted reaction. Its basic principle is as follows.

The reaction path of an excited polyatomic molecule often depends on the spatial distribution of the molecular wave function in this state, which can be controlled by the shape and frequency distribution of the excitation pulse. When the molecules under investigation are excited by femtosecond pulses with special time profiles the rate of the wanted reaction is monitored and serves as input signal for an optimization procedure where the time profile of the pulse is modified until the optimum reaction rate has been achieved. This optimization can be reached even if the detailed nature of the excited state wavefunction is not known. Since the spatial and time distribution of the molecular wave packet is created by the coherent excitation of ultrashort laser pulses with controlled time-frequency and phase-profiles, the technique is called *coherent control*. The pulse shaping (Fig. 13.75) can be performed as follows.

The incoming beam is diffracted by an optical grating in the focal plane of a lens. Since the diffraction angle depends on the wavelength, the different spectral components in the pulse are spatially separated and pass through a mask, consisting of many liquid crystal pixels. The refractive index of these pixels can be controlled by a proper applied voltage, thus introducing a controlled phase shift of the light passing through the different pixels. These phase shifts can be independently changed for the different spectral components. After passing through a second lens which refocuses the parallel light onto a second grating recombining the spatially separated spectral components. Their superposition gives a pulse shape, which depends on the amplitudes and the phases of these spectral components and can be therefore changed by the voltages applied to the pixels which are in turn controlled by the optimization signal. A learning algorithm changes the different

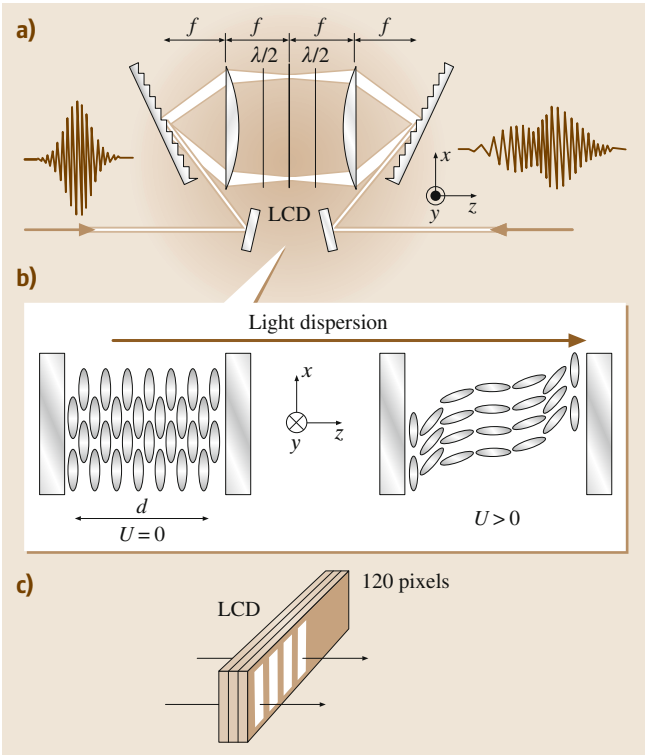

Fig. 13.75 Pulse shaping for coherent control by controlling the refractive index of transparent pixels in a liquid-crystal mask

voltages in small steps until an overall optimum of the reaction rate has been reached [13.106–108].

This technique has been successfully applied to a number of molecules [13.109], including even large biological molecules such as the carotenoid molecules, which play the important role in photosynthetic light harvesting [13.110].

In many cases already excitation of higher vibration levels in the electronic ground state can enhance a chemical reaction considerably, in particular if local bonds can be excited. For instance the excitation of a local vibration involving the double bond in ethylene $CH_2{=}CH_2$ will lead to a fragmentation in two CH_2 radicals, while excitation of a single bond will split off a hydrogen atom. Here pulse shaping in the infrared spectral region is demanded in order to excite the wanted vibrational mode. Unfortunately there are no liquid masks available for the mid-infrared. It is, however, possible to transfer the pulse shape of a visible pulse by difference frequency mixing in a nonlinear crystal to the pulse with the difference frequency in the infrared [13.111].

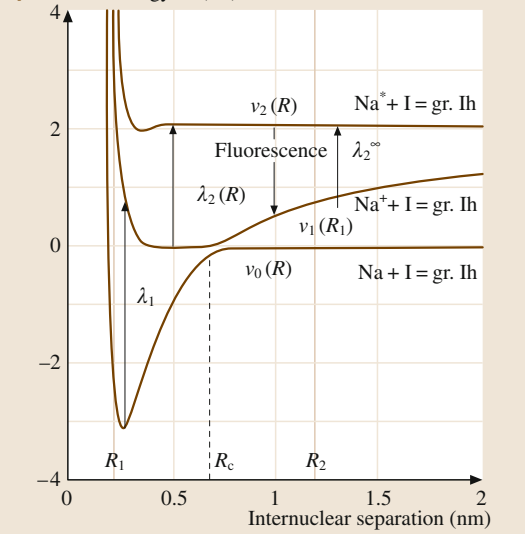

Fig. 13.76a,b Time-resolved spectroscopy of the dissociation of NaI (after [13.90]). **(a)** Potential diagram with the pump transition at λ_1 and the probe transition at $\lambda_2(R)$. **(b)** Atomic Na fluorescence $I_{Fl}(\Delta t)$ as a function of the delay time Δt with λ_2 tuned to the atomic Na transition (*curve a*) and to $\lambda_2(R)$ with $R < R_c$ (*curve b*)

The application of femtosecond spectroscopy to fast molecular processes allows one for the first time to observe in real time the breaking and formation of chemical bonds. We will illustrate this by some examples. The first one is the photodissociation of NaI [13.62, 112]. The adiabatic potential diagram of NaI (Fig. 13.76a) shows an avoided crossing between the repulsive potential of the two interacting neutral atom Na + I and attractive Coulomb potential of the ions $Na^+ + I^-$, which is maily responsible for the strong binding of NaI at small internuclear distances R. If the molecule NaI is excited by a short laser pulse with wavelength λ_1 the excited molecule with reduced mass μ starts to move towards larger distances R with a velocity $v(R) = [(2/\mu)(E - E_{pot}(R))]^{1/2}$. When it reaches the avoided crossing at $R = R_c$ it may either stay on the potential curve $V_1(R)$ and oscillate back and forth between R_1 and R_2, or it may tunnel to the potential curve $V_0(R)$, where it separates into Na + I.

This can be measured with a probe pulse with a wavelength λ_2 tuned into resonance with the transition from $V_1(R)$ into the excited state potential $V_2(R)$ that dissociates into Na∗ + I. Since the dissociation time (a few picoseconds) is very short compared with the lifetime of the excited Na∗(3p) atom, the dissociation NaI∗ molecule emits nearly exclusively on the atomic resonance fluorescence at $\lambda = 589$ nm. Monitoring the intensity of the atomic fluorescence as a function of the delay time, yields the time behaviour of the dissociation process: If the probe laser wavelength λ_2 is tuned to to a transition at $R < R_c$ one obtains the lower curve in Fig. 13.76b, showing the oscillation of the system between R_1 and R_2, while for $R > R_c$ the upper curve is obtained, giving the number of molecules in the potential $V_0(R > R_c)$.

The second example is the isomerization of Stilbene, i. e. the photo-induced structural change of excited Stilbene form *trans*- to *cis*-Stilbene (Fig. 13.77). Since the structural change also causes a corresponding change of the rotational constants, a pump-and-probe experiment of the rotating molecule can measure the rotational period and with it the rotational constants [13.113].

Often the molecular structure in excited electronic states is not known and in may cases it even might change with time, due to isomerization processes. Here a very elegant technique has been developed which is based on time-resolved Laue diagrams of excited molecules. The molecules are excited by a femtosecond

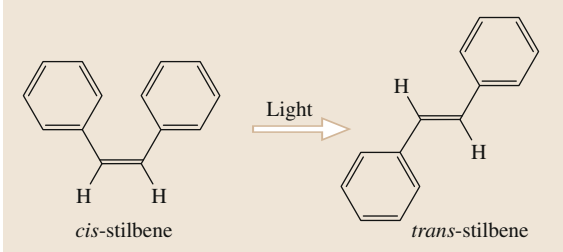

Fig. 13.77 Isomerization of stilbene

pulse. Part of the same laser pulse is focused onto a target where a very hot plasma is produced which emits short x-ray pulses in the femto- to attosecond range. They are used to take a Laue diagram of the excited molecule. Varying the time delay between the excitation- and the x-ray pulses can follow up the structural change of the excited molecule [13.63, 64, 113–115].

Ultrafast Processes in Biology

Many primary processes of biological reactions proceed on a femtosecond time scale. Examples are the visual process in the retina cells of the eye after photon excitation, or the photosynthesis of green plants. The investigation of the different steps in this complex processes demands a combination of spectroscopic techniques with high time resolution and spectral selectivity [13.116–118].

The first steps in the visual process after the excitation of retinal molecules in the protein rhodopsin in the retina of the eye are isomerization processes where the structure of the molecules in the excited states is changing in such a way, that the energy is decreasing. This can be studied by time-resolved Raman-spectroscopy, which gives the information on vibrational frequencies [13.119].

In the photosynthesis of green plants the light harvesting molecules are carotenoids, which absorb in the blue-green spectral range and transfer their excitation energy to chlorophyll molecules. These transfer processes are in competition with radiationles deactivation. Both kinds of processes proceed on a femtosecond time scale. The final outcome of such transfer processes is the proton transfer in chlorophyll which has been found to be the most important process in the photosynthesis of green plants. It consists of many steps which can be followed up by femtosecond spectroscopy. With coherent control, those intermediate processes that decrease the efficiency of proton transfer can be suppressed thus increasing the yield [13.120].

Applications in Medicine

Although for many medical applications ultrashort lasers do not play an essential role, there are some examples where femtosecond pulses are superior to longer laser pulses [13.121] because of the following reasons: Femtosecond lasers allow the application of high peak powers but low energy to human tissues. Because of the low energy damaging high temperatures are avoided but the resultant nonlinear effects cause absorption in regions of the body which are transparent for linear absorption. Sending the laser pulses through a microscope with large numerical aperture, small focal spots can be realized and micro-surgery is possible. This is, for instance, used for intra-ocular and intra-stromal refractive surgery. The high peak power may result in microplasma formation with subsequent stress waves into the surrounding tissue and chemical reactions. If the limits of unwanted destruction are precisely known, this can be used for wanted surgery effects. Therefore femtosecond lasers enable the creation of spatially extremely confined chemical, thermal and mechanical effects in biological media.

Another area where the high time resolution is essential is optical tomography: Here the output beam of the laser is split into a reference beam and a part which is sent into selected parts of the body (Fig. 13.78), for instance into the brain.

The interference between the reference beam and the radiation backscattered from a thin region of the sample is measured as a function of the delay time between reference and backscattered signal pulse. Any change in composition of the tissue gives changes in the interference pattern. The spatial localization becomes better with increasing spectral width of the

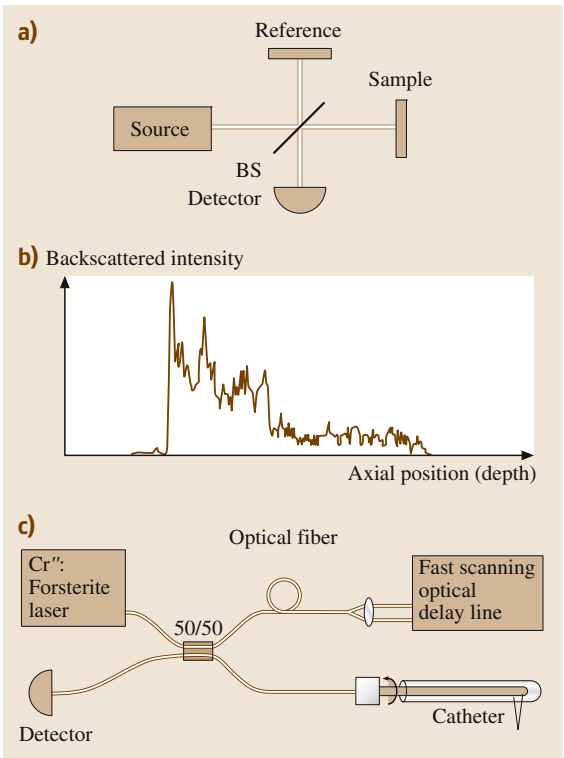

Fig. 13.78a–c Optical coherence tomography

radiation source. Therefore often light emitting diodes or broad band pulsed lasers are used. Examples where this technique has been successfully applied, are detection of tumors in the brain or in the female breast or of plaques in arteries, which might cause heart attack [13.122].

A modern device of an interferometer for optical tomography using optical fibres and fibre beam splitter is shown in Fig. 13.78b.

Applications in Geodesy and Environmental Research

The short laser pulses are well suited for accurate distance measurements. When a pulse is emitted at time $t = 0$ and is reflected by a target at time $t = t_1$ the backscattered light, collect by a telescope, is received at $t = t_2 = 2t_1$. The distance between receiver and target is then $d = t_1/c$, where c is the speed of light. With intense picosecond laser pulses the distance between the retro reflector, placed by astronauts on the moon, and the receiver could be measured within a few centimeters [13.123]. In order to decrease the divergence of the beam caused by diffraction, the laser beam has to be enlarged by a telescope.

For many applications in distance measurements this method has become the standard technique. For shorter distances pulsed diode lasers have sufficient intensity to give a good signal-to-noise ratio and accuracies with uncertainties within the mm–cm range.

For environmental studies of our atmosphere different techniques have been developed (Sect. 13.3). The LIDAR (light detection and ranging) is based on the Mie-backscattering by aerosols in the atmosphere. Pollutant molecules in the atmosphere lead to specific absorption of the beam, if the laser wavelength is tuned to an absorption line of these molecules, thus decreasing the intensity of the backscattered pulse. For LIDAR measurements the backscattered intensity is alternately measured on an absorption wavelength λ_1 and a wavelength λ_2 where the molecules do not absorb. The ratio of the two backscattered intensities measured at time t

$$I_b(\lambda_1, t) = A \cdot \exp(-2\alpha_1 L) \quad \text{and}$$
$$I_b(\lambda_2, t) = A \cdot \exp(-2\alpha_2 L) \qquad (13.87)$$

gives the absorption $L \cdot (\alpha_2 - \alpha_1)$. Here $L = t/c$ is the distance to the backscattering target and $\alpha = N \cdot \sigma$ is the absorption coefficient, which depends on the density N of the absorbing molecules and the absorption cross section σ. The scattering cross section does not differ much for the two close wavelengths λ_1 and λ_2.

If this intensity ratio signal is measured at two different times t_1 and t_2, the ratio of the two signals just gives that absorption which takes place within the spatial range $\Delta L = L_1 - L_2$ (differential LIDAR) [13.124].

With femtosecond terawatt lasers a long plasma channel can be produced along the laser beam [13.125]. Due to self-focusing caused by the nonlinear part of the refractive index the laser beam shows in atmospheric!air a series of plasma regions along the beam (like sausages on a string), which emit brilliant white light. These bright plasma spots can be used as spatially well defined and spectrally broad light source in the atmosphere. If the telescope is directed towards one of these plasma regions the received radiation has passed through the atmospheric layer between the telescope and the light source. The resultant absorption lines of this layer can be spectrally resolved and give for a single laser shot the whole spectrum of absorbing molecules in this layer [13.126]. The advantage of this method is the simultaneous detection of the whole spectrum of all absorbing constituents. Its disadvantage is that it only measures the total absorption integrated over the path length from the radiation source to the detector without giving information about the local variation of the density of absorbing molecules. This disadvantage can be partly compensated by viewing different parts of the plasma channel, which extends over several hundred meters.

Applications of Femtosecond Lasers in Material Science and Processing

The ultimate switching time in semiconductor chips is limited by the relaxation time and diffusion time of excited electrons. With decreasing size of electronic devices the electronic properties of metals are changing with the size of the nanostructures. Here femtosecond spectroscopy can get information about the different processes. One example is the investigation of the electron–lattice interaction in single silver nanoparticles [13.126].

Also in material processing short pulse lasers play an increasing role. Although there are many applications of CW-lasers and laser pulses with pulse widths in the milli- to nano-second range for welding or cutting of materials or for drilling holes into specific hard materials, such as diamonds, ceramics, where mechanical drills are hard to use, femtosecond pulses have specific characteristics which make them in many cases superior to longer laser pulses. For example for drilling holes with diameters below 100 μm but a larger depth, femtosecond pulses give cleaner and better defined holes.

This is due to the fact, that the material is just evaporated without forming liquid drops which detoriate the crater edge [13.127–129].

Applications of Attosecond Pulses

Although the first realization of attosecond pulses is only a few years old, there are already numerous applications. The high harmonic generation discussed before produces ultra-short x-ray pulses, which can be used for x-ray diagnostics of ultra-fast processes. One example is the production of Laue-diagrams of excited vibrating molecules. Since for ordinary Laue-diagrams the molecular vibrations wash out the exact geometry of the molecule, pulses with a pulse duration short compared to the vibrational period, can give sharp Laue-diagrams of the molecular structure at a specific moment of the vibration. Therefore direct information can be gained about the change of the molecular geometry when the molecule is excited. For bio-molecules such a change might be essential for the biological function of the molecule. The experimental technique uses the femtosecond pulse at the fundamental frequency or at its second harmonics for excitation of the molecule and the x-ray attosecond pulse, generated as high harmonics by the same femtosecond pulse for obtaining the Laue diagram [13.130].

Another interesting application is the diagnostics of laser produced high temperature plasmas and inertial confined fusion. The fast ignition process can occur within attoseconds and the detailed diagnostics of these processes and their time sequence may result in a better understanding and optimization of laser-induced fusion processes [13.131].

The high peak powers attainable with femto- and atto-second pulses can generate electron bunches with high energies reaching beyond 1 MeV. There are serious estimations that even GeV electron pulses can be produced by wake-field acceleration in laser produced plasmas. This new kind of particle accelerators has found wide interest, since it might be also used for proton acceleration. Although the practical realization might be still far ahead, many laser laboratories and theoretical groups are working on this subject with increasing success [13.132].

A very interesting field is the study of electron dynamics during photoionization of atoms or molecules. The ejected electron might be forced by the strong laser field to return to the ion core before it can escape (Fig. 13.79a). The resulting interference between the wave functions of the outgoing and the returning electron give information on the structure of the electronic wavefunction of that orbital from which the electron was released [13.133]. As illustrated in Fig. 13.79b this techniques may be regarded as molecular interferometry in analogy to optical interferometry. Depending on the phase of the optical field, angular asymmetries of the ejected photoelectrons are observed, which can be utilized to measure the absolute phase of optical fields [13.134].

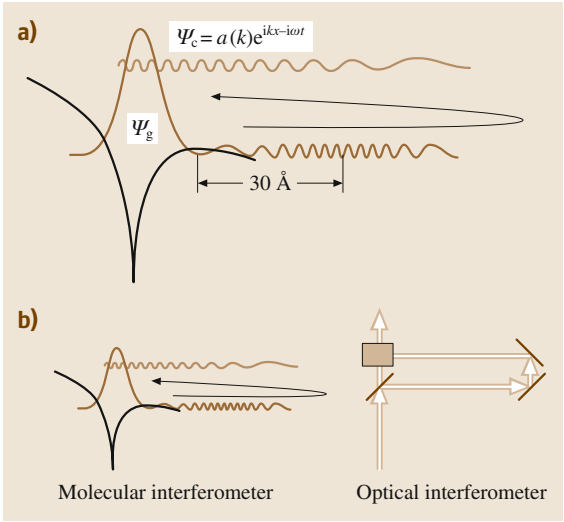

Fig. 13.79 **(a)** One-dimensional cut through an atomic potential in the strong field of a high-power femtosecond laser, showing the paths of the wave packets of the photodetached and returning electron, **(b)** comparison between molecular and optical interferometers (after [13.98])

A very interesting application is the development of an attosecond photoelectron emission microscope for observation of electrons emitted from a nanostructured surface. Such a device combines photoelectron energy spectroscopy (with resolution ≈ 60 meV) with the nanometer (≈ 10–20 nm) resolution of electron microscopy. Attosecond temporal resolution comes from exciting the photoelectrons with an attosecond XUV probe following the excitation under study. This will provide direct and noninvasive access to spatiotemporal dynamics of nanoplasmonic fields [13.135].

There are a wealth of further applications, such as the time resolution of inner shell ionization, time resolution of electron tunneling, or measurements of the electron energy distribution and its time development in semiconductors after excitation with attosecond pulses. More information can be found in [13.135–138].

13.3 Lidar

13.3.1 Lidar Basics

Lidar stands for light detection and ranging and is the optical counter-part for radar (radio detection and ranging). As the name suggests we here deal with range-resolved mapping techniques, where a micro-wave transmitter is replaced with a pulsed laser system. Photons back-scattered from solid targets or from aerosol particles or molecules of the atmosphere are recorded using an optical telescope and an appropriate detection system. Range information is obtained through the time delay of the back-scattered photons. Solid or liquid targets give rise to a sharp echo in the back-scattered radiation at a time delay

$$T = \frac{2R}{c} , \tag{13.88}$$

where R is the distance and c is the velocity of light. This means, that a time delay of 1 µs corresponds to a distance of 150 m. We thus see that for laser pulses of a typical length of 10 ns, resulting in an echo width of 1.5 m (light travels 30 cm in a ns), a quite good range resolution can be obtained. This is the basis for normal pulsed laser range-finders. For laser light with a sharp emitted wavelength the elastically scattered echo is detected at the same wavelength. However, also weak inelastically scattered Raman components, specific to the molecules irradiated can be detected off-set from the laser frequency by the molecular vibrational frequency. More prominently, also laser-induced fluorescence (LIF) from the target molecules is observed on the long-wavelength side, in particular if the laser emits at ultra-violet (UV) wavelengths. The LIF signal is frequently spectrally broad, but still certain information on the target molecules can be obtained. In contrast, if a sufficiently powerful laser beam is focused onto a target, the pulses might induce an optical break-down and LIBS (laser-induced break-down spectroscopy) signals from the free atoms and ions in the hot plasma can be recorded providing elemental information.

It may be more unexpected, that a signal from the free atmosphere itself is obtained when the laser pulse traverses it. This is due to elastic Mie- and Rayleigh scattering from particles and molecules, respectively. Raman and fluorescence signals can also occur. Fluorescence from atoms or molecules in the atmosphere is normally quenched due to collisional deexcitation, but is prominent if the pressure is low, such as in the earth's mesosphere. With reference to Fig. 13.80 [13.139], showing a lidar measurement scenario, the intensity of the backscattered radiation, $P(\lambda, R)$, as a function of range R, is given by

$$P(\lambda, R) = CWn_b(R)\sigma_b \frac{\Delta R}{R^2} \times \exp\left(-2\int_0^R [\sigma(\lambda)N(r) + K_{ext}(r)]\, dr\right) , \tag{13.89}$$

where C is a system constant, W is the transmitted pulse energy, and $n_b(R)$ is the number density of scattering objects with backscattering coefficient σ_b. Generally, the signal is for realistic atmospheres dominated by the elastic Mie scattering from particles. A main, and expected observation from (13.89) is that the signal falls off with a $1/R^2$ dependence, basically reflecting the normal illumination law. Further, an exponential light attenuation due to absorbing molecules or atoms of a concentration $N(r)$ and with wavelength-dependent absorption cross section $\sigma(\lambda)$ occurs, integrated over the range R, which is traversed twice. There is also attenuation K_{ext} due to scattering particles with negligible wavelength dependence for small frequency excursions. In the differential absorption lidar (DIAL) approach, which is used for the monitoring of minor species such as air pollutants, a tuneable laser is intermittently fired at a wavelength λ_{on} for which a gas of interest absorbs, and at a reference, nonabsorbed wavelength λ_{off}, which is located so close that the scattering properties are the same. All on-resonance lidar transients are averaged in one computer memory, and all off-resonance (reference) transients are averaged in a second one. By then dividing the two signals, as indicated in (13.90), and in Fig. 13.80, it is possible to eliminate basically all unknown system and atmospheric parameters, leaving a ratio signal which only depends on the differential absorption coefficient for the gas (ideally the off-resonance cross section is zero, but this is not always the case)

$$\frac{P(\lambda_{on}, R)}{P(\lambda_{off}, R)} = \exp\left[-2(\sigma_{on} - \sigma_{off})\int_0^R N(r)\, dr\right] . \tag{13.90}$$

We note, that the $1/R^2$ dependence is now eliminated, and in particular that the ratio is independent of the range-dependent number of scattering particles.

Thus the method works without a knowledge of this otherwise very crucial parameter. The range-resolved concentration of gas molecules can be obtained from the slope of the ratio curve as evaluated in (13.91) and indicated in Fig. 13.80. Clearly the range of useful measurements is limited by the signal-to-noise ratio, and for very long ranges basically zero is divided by zero. Measurement in different directions allows a three-dimensional picture of the gas distribution to be determined

$$N(R, R+\Delta R) = \frac{1}{2\Delta R(\sigma_{on} - \sigma_{off})} \times \ln \frac{P(\lambda_{off}, R+\Delta R)P(\lambda_{on}, R)}{P(\lambda_{on}, R+\Delta R)P(\lambda_{off}, R)} . \quad (13.91)$$

LIDAR work was pioneered by *Fiocco* and *Smullin* [13.140]. *Shotland* performed first DIAL work on water vapour [13.141], and early DIAL experiments on an air pollutant (NO_2) were demonstrated by *Rothe* et al. [13.142, 143] and *Grant* et al. [13.144]. Our own LIDAR work started in 1975.

Lidar techniques are extensively discussed in a number of monographs [13.145–147], and [13.148, 149] represent recent additions. Lidar achievements are reported in biennial International Laser Radar Conferences (ILRC), arranged by the International Coordination-Group for Laser Atmospheric Studies (ICLAS). The most recent one was arranged in St. Petersburg, Russia, in 2010 [13.150]. The literature mentioned provides comprehensive coverage of the field. In the present account, the field will be mainly illustrated by examples from the laboratory of the present author, and further information on this work can be found, e.g. in the reviews [13.151–153].

The next session discusses the basic instrumentation used in lidar measurements. Then atmospheric applications including meteorology, pollution monitoring and

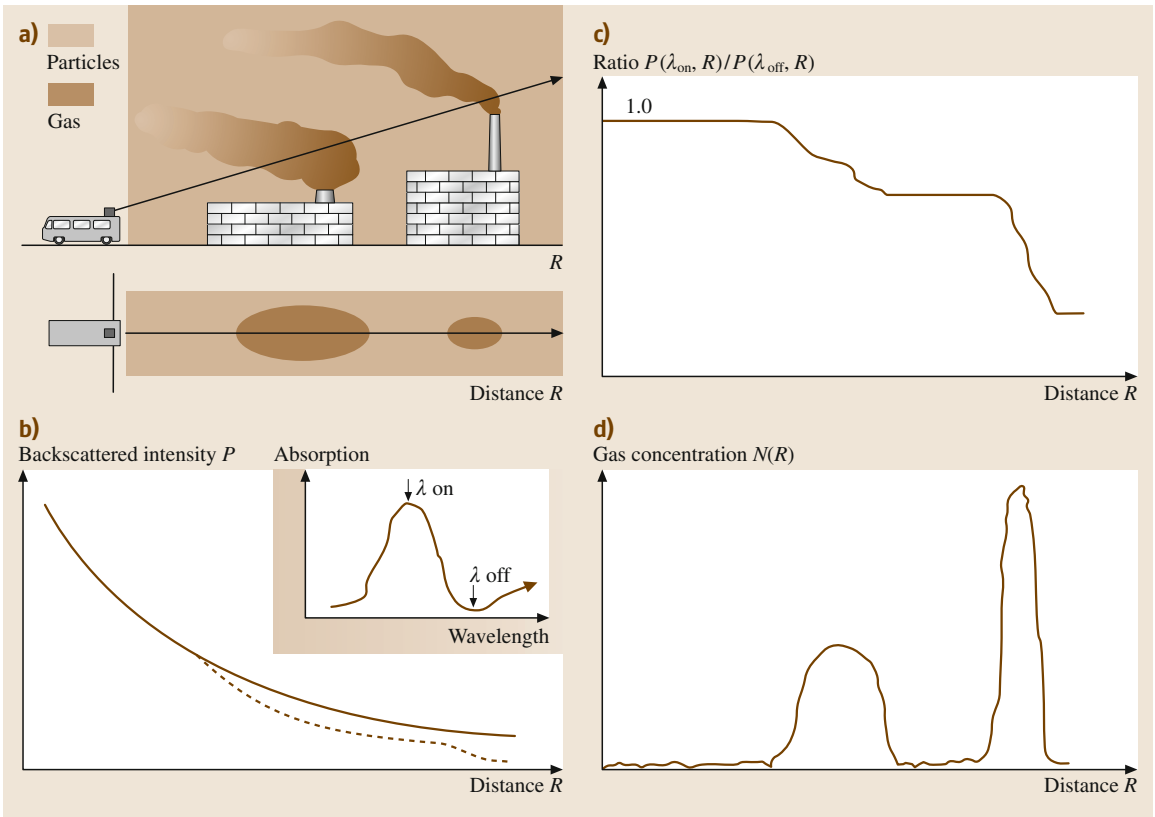

Fig. 13.80a–d The principles of LIDAR **(a)** scenario of LIDAR measurement at an industrial plant, with the atmosphere also seen from above **(b)** LIDAR curves for on- and off-resonant wavelengths **(c)** divided DIAL curve, on/off **(d)** evaluated gas concentrations for the chosen direction (after [13.139])

space experiments will be presented. Section 13.3.4 deals with lidar experiments on fixed targets, including altimeter, LIF and LIBS lidar applications. Unconventional lidar-like applications in other fields of science, such as medicine and materials sciences, will then be exemplified. Finally, some conclusions are being drawn.

13.3.2 Instrumentation

A lidar system consists of a transmitting laser, a receiving telescope, a detector, signal handling electronics and a computer for capturing the signals and evaluating the data. The system can be placed fixed or be installed in a truck, an airborne platform or a satellite. Means for scanning the laser beam for interrogating a certain area are also frequently provided. The laser transmitter should be pulsed to provide adequate range resolution. For studying particles in the atmosphere, i. e. aerosols, a fixed frequency laser, such as a Q-switched Nd:YAG laser operating at 1064 nm can be used. Flashlamp pumping is now increasingly being replaced by pumping by powerful diode lasers which provide higher efficiency, lower heat dissipation and longer lifetime. It is common to also use harmonics of the emission at 532, 355 and 266 nm, generated with high efficiency in nonlinear optical crystals. By using a number of such frequencies information on the size of the scattering particles can be obtained due to the wavelength dependence of the Mie scattering. Clearly, particles both backscatter through σ_b and attenuate through K_{ext}. For evaluation of the particle concentrations and properties a relation between these two quantities must be established, which is a key aspect in inversion algorithms being developed for this purpose. For using the DIAL method a narrow-band tuneable laser must be used, and here dye lasers or titanium-doped sapphire lasers can be employed with the second or third harmonic of the Nd:YAG laser normally used as the pump. Such pump radiation can also be frequency converted over wide wavelength ranges using an optical parametric oscillator (OPO). By nonlinear harmonic generation, or mixing with fixed frequency radiation, tuneable radiation in a wide range from the deep UV to the mid-IR spectral region can be obtained. Excimer lasers, crudely tuneable by stimulated Raman scattering in hydrogen or deuterium gas, are sometimes used in the UV region, mostly for ozone monitoring.

The laser radiation is normally sent with a controlled divergence into the atmosphere by using a beam expander. A folding and beam-directing mirror is frequently used, also for directing backscattered radiation into the receiving telescope, which is normally of a Newtonian or Cassegrainian typ and with a typical diameter of 10–100 cm.

The laser beam typically has a divergence of 1 mrad and the telescope field-of-view is selected to match this value using an appropriate aperture. Backscattered light is detected by a photomultiplier tube or an avalanche photodiode placed behind a narrow-band filter matching the detection wavelength and blocking out sunlight. Gain-switching is frequently employed to handle the large signal dynamic range otherwise obtained. The signal is digitized with a transient recorder and signal averaging is performed till an adequate signal-to-noise ratio is obtained also at the longest ranges of interest. In order to ascertain the validity of (13.91) in DIAL measurements (i. e. that the particle scattering did not change between on- and off-resonance measurements) the laser wavelength has to be switched back and forth between adjacent shots.

In the IR region, where photomultiplier tubes having high efficiency and amplification are not available, it can be advantages to use *heterodyne* or *coherent* detection of the lidar signal. Then the lidar signal is mixed at the detector with a frequency off-set laser frequency and the beat-note is detected at an intermediate frequency. This technique is best achieved if the system is equipped with a CW seeding laser which is pulse-amplified in the lidar transmitter. The seeding laser then also is a suitable local oscillator for the heterodyne detection. Clearly, Doppler shifts due to moving atmospheric particles occur, and this is a basis for lidar detection of wind speed.

When LIF or LIBS signals from solid targets are to be detected, the detector is replaced with an optical multichannel analyzer, i. e., a spectrometer followed by a gated and image-intensified CCD. The spectrometer can be fibre-coupled to the focal plane of the telescope, and by properly gating the system, the full LIF- or LIBS signal can be captured for each laser shot, with suppression of the ambient light, which can be made negiligible during the short gate when the desired signal is present.

An example of a mobile laser radar system is shown in Fig. 13.81 [13.154]. The system, currently used by the Lund University group, has a Nd:YAG-pumped OPO as a transmitter, which covers the spectral range 220–3500 nm by nonlinear optics wavelength extensions. A vertically looking 40 cm diameter Newtonian telescope is used in conjunction with a roof-top computer-controlled scanning mirror which selects the measurement direction for the aligned transmission and detection lobes. A gated spectrometer is also shown for solid target applications. Equipped with a motor gen-

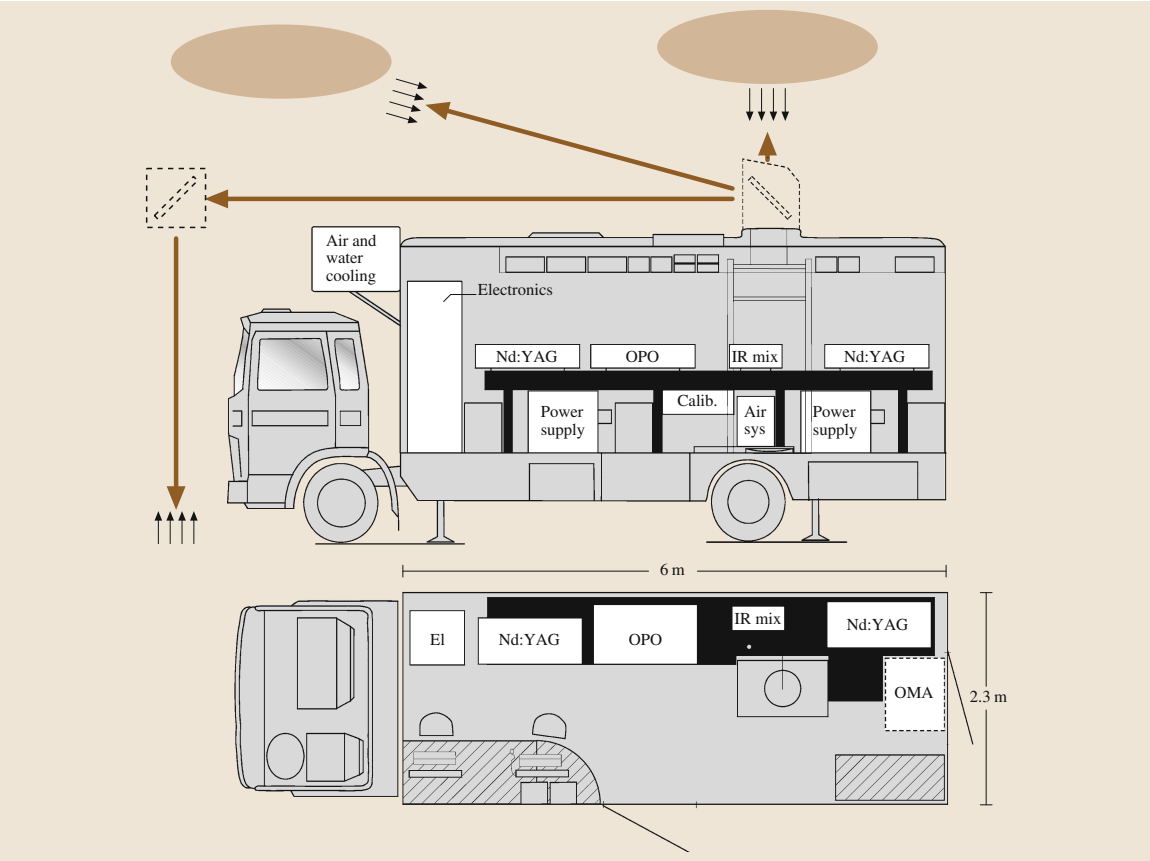

Fig. 13.81 Lund University mobile LIDAR system configured for vertical traverses or free scanning atmospheric measurements, and for water sounding downwards (after [13.154])

erator, towed by the truck and providing electricity, a fully autonomous lidar system is obtained for land- and ship-borne applications. The examples of lidar experiments shown in the figures of the present paper all were obtained using this system. Clearly, an airborne or satellite-installed lidar system must fulfill stringent requirements with regards to weight, efficiency and reliability. We will discuss this further below.

13.3.3 Atmospheric Lidar Applications

Mesosphere

There are numerous applications of lidar techniques for atmospheric sounding. A specialized one is to investigate the low-density layers of atoms, such as sodium, potassium and iron in the mesosphere at heights of about 100 km, where meteorites impinging on the earth's upper atmosphere are vaporized. The pressure is so low that collisional de-excitation of the laser-excited species (at about 589, 765 and 372 nm, respectively) is negligible and bright atomic fluorescence can be observed. The layers exhibit gravitational wave patterns and by probing the line-shapes with a narrow-band excitation laser temperature as well as velocities can be derived from line-widths and shifts. A recent utilization of the bright emission is for *laser guide star* applications [13.155], where the localized emission is used for active control of astronomical telescopes to compensate for atmospheric turbulence by *adaptive optics*.

Meteorology

Accurate weather forecasting requires powerful prediction models and equally important, accurate input data. Traditionally, synoptic observations from a global network of observational sites have been used. With the availability of meteorological satellites in geostationary

orbits global coverage of many important parameters has been achieved. However, for increasing the prediction accuracy global wind fields and vertical water vapour profiles are much needed. Such information can be obtained with lidar techniques. Actually, we have already discussed above how Doppler heterodyne techniques can be used to measure wind speed range-resolved. The Doppler shift in the line profile of the scattering molecules and particles can also be observed in direct intensity measurements where a narrow-band transmitter is used to induce the scattering and the so called double-edge technique [13.156, 157] is used for observing wind-induced frequency shifts. By using a Fabry–Perót interferometer or optically thick atomic or molecular gas cells in the path of the detected light it can partially be blocked out. When the profile then is moved in frequency due to the wind, more or less of the light is *scraped off* by the sharp edge filter, and the data can be converted into velocity. After extensive fixed-system and airborne tests the technique is now ready for satellite global coverage within ESA's AEOLUS project, where a frequency-tripled Nd:YAG laser at 355 nm is used.

Water vapour can be measured by DIAL but also more simply using Raman scattering of this high-concentration molecule. By blocking the elastically scattered laser radiation at, e.g., 355 nm and by only monitoring the intensity of the Raman–Stokes shifted water–vapour line at 408 nm through a narrow-band interference filter vertical profiles for many kilometers are readily obtained.

We have already discussed above that while aerosols and cloud particles yield a strong elastic Mie scattering signal the interpretation is complex due to the interplay of backscattering and extinction. Accurate measurements of the aerosol influence on the earth's radiation budget are very important in assessing global change and warming. The uncertainty in the aerosol load is presently the single most important uncertainty in modelling the climate forcing [13.158]. By using strong Raman scattering from the uniformly mixed major species nitrogen, in the case for 355 nm excitation centred at 387 nm, it is possible to measure the particle extinction independently, since the Raman signal can only be reduced by the particles. In contrast, the elastic signal due to particles is increased by an increasing load of particles but reduced by attenuation. By studying the detected depolarization of primary linearly polarized laser light it is possible to determine the shape of the scattering particles. Spherical particles (like water droplets) keep the initial polarization, while elongated particles, like ice needles and snow crystals, exhibit depolarization. A complication is that multiple scattering in spherical particles is also depolarizing. After many years of extensive studies in fixed and airborne lidar installations, a dedicated satellite system CALIPSO was launched in 2006, now providing global coverage of particle scattering and depolarization using 1064 and 532 nm radiation from a Nd:YAG laser, designed to operate for few years at 20 Hz.

Backscattered signal due to particles and molecules can further be separated by using a Fabry–Pérot interferometer or a gas filter to block the spectrally sharp Mie signal (the particles only move due to wind), while the wings of the Doppler-broadened Rayleigh scattering passes (molecules move at thermal velocities, typically few hundred meters per second). This technique then obviously also leads to a possibility to measure atmospheric temperature range-resolved. A further method to measure temperature by lidar is to use the rotational Raman signal from nitrogen, which maps out the Boltzmann thermal population distribution on the different rotational levels of the ground-state molecule.

Global warming is a great concern, and believed to be primarily induced by carbon dioxide emissions due to increasing burning of fossil fuels. Thus, a detailed mapping of sources and sinks of this gas is important, and many projects aiming at DIAL monitoring of CO_2 around 2 μm using Tm,Ho:YLF lasers are now under way.

Minor Species and Pollution

Minor species and pollutant gases in the troposphere can be mapped using the DIAL technique. Raman lidar does not have the required sensitivity and fluorescence does not work, because of the quenching at atmospheric pressures. As a first illustration we will discuss a very special pollutant, mercury, actually the only one present in the atmosphere as a free atom, rather than as a molecular compound. Disregarding isotopic shifts and hyperfine structure, mercury atoms have a single transition rather then a multitude of vibrational-rotational transitions over which the molecules are distributed. Thus we automatically gain a sensitivity increase of about a factor of 1000 for mercury, which is needed, since the background levels of this gas is on the ppt ($1 : 10^{12}$) level. Mercury, atmospherically present in atomic form to about 90%, is emitted from chlor-alkali plants producing sodium hydroxide (the cathode in the cells for electrolysis of brine is liquid mercury, into which the sodium ions move forming amalgam, which on washing yields the natron lye). Further, coal-fired power plants and incineration plants including crema-

tories emit mercury. It is also an interesting geophysical tracer gas related to ore deposits, geothermal reservoirs and volcanic activities. DIAL measurements are performed using the 254 nm mercury transition, which can be induced using a frequency-doubled dye laser or OPO. An illustration of atomic mercury DIAL at a chlor-alkali plant is shown in Fig. 13.82 [13.159, 160]. Individual lidar returns for the on and off-resonance wavelengths yield the divided, DIAL, curve exhibiting a slope indicating the presence of mercury. From a number of such measurements, taken fan-like and perpendicularly through the plume downwind from the plant, a plume cross-section showing spatially resolved concentration can be generated as illustrated in the figure. The area-integrated concentration times the perpendicular wind speed yields the flux, which is the environmentally important parameter. This reasoning can convincingly be supported by a consideration of units

$$\frac{[\mathrm{g}]}{[\mathrm{m}^3]}[\mathrm{m}][\mathrm{m}]\frac{[\mathrm{m}]}{[\mathrm{s}]} = \frac{[\mathrm{g}]}{[\mathrm{s}]} \qquad (13.92)$$

yielding the proper flux unit g/s. Typical fluxes for plants of this kind can be tens of g/h. Atomic mercury monitoring is considered as a special case study in [13.151] and is also discussed in [13.152] regarding geophysical emissions. We performed lidar measurements of mercury at the three largest mercury mines in the world: Almaden (Spain), Abbadia S. Salvatore (Italy) and Idrija (Slovenia).

Another pollutant of even more concern is sulphur dioxide SO_2 which heavily contributes to the acidification of lakes and to atmospheric!loading with sulphate particles. Sulphur dioxide is emitted from volanoes, but the main sources are anthropogenic and due to the combustion of sulphur-containing fuels. We illustrate SO_2

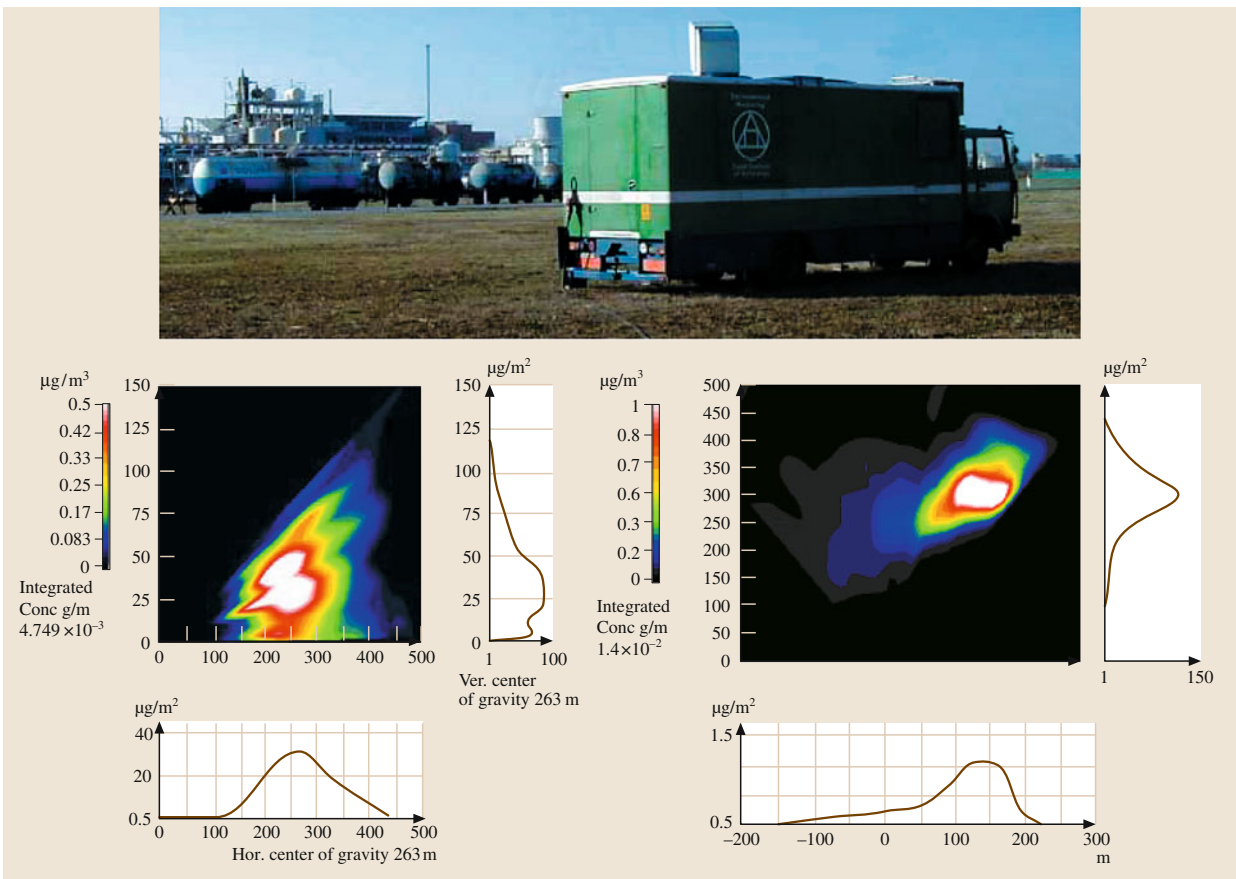

Fig. 13.82 DIAL measurements of atomic mercury. *Top*, mobile LIDAR system seen at the Rosignano Solvay chlor-alkali plant, *bottom left*, vertical scan, and *bottom right*, horizontal scan (from [13.159, 160])

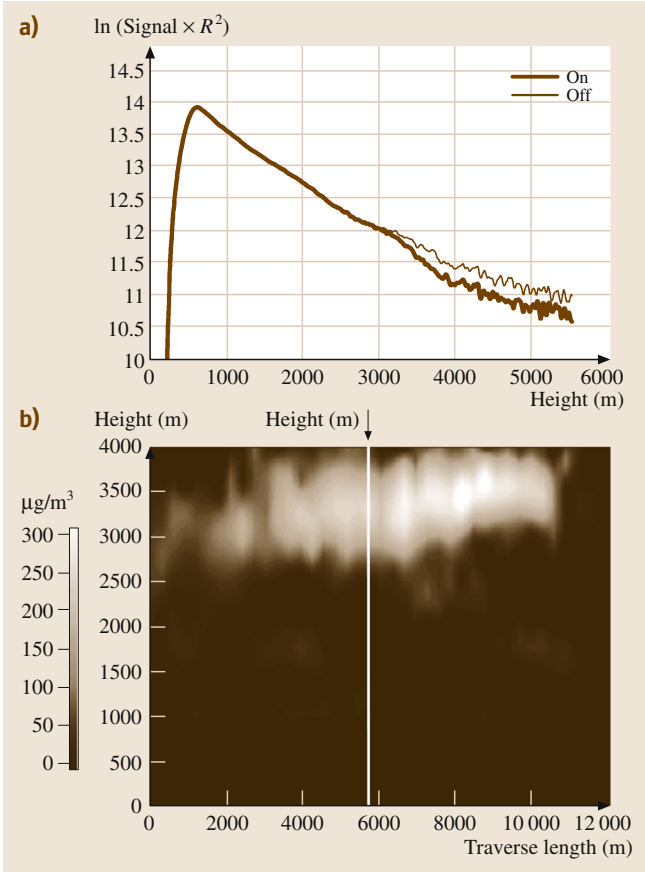

Fig. 13.83a,b DIAL monitoring of SO_2 from Mt. Etna. The measurements were performed in a 12 km scan with the system firing vertically from the aft deck of the research vessel *Urania*, making a traverse under the volcanic plume off the city of Catania. On- and off-resonance LIDAR curves are shown in the *upper part* of the figure for one particular location (after [13.161])

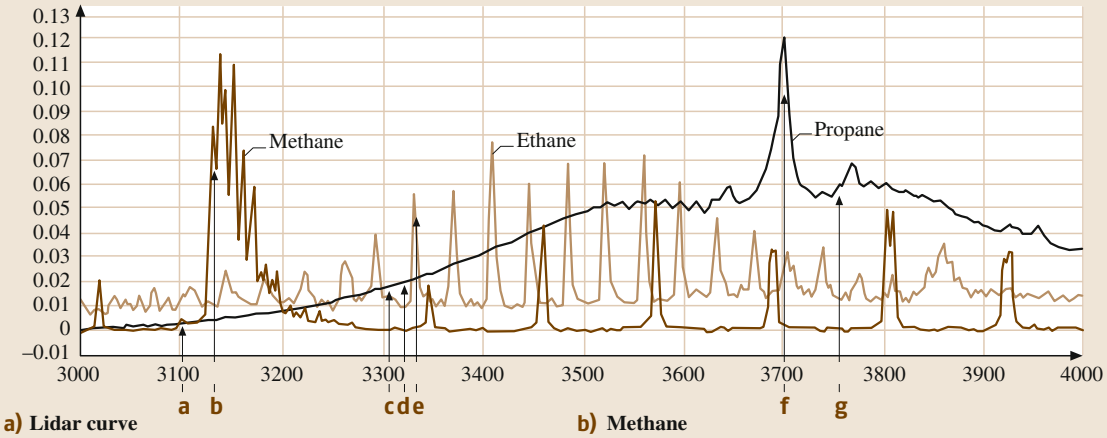
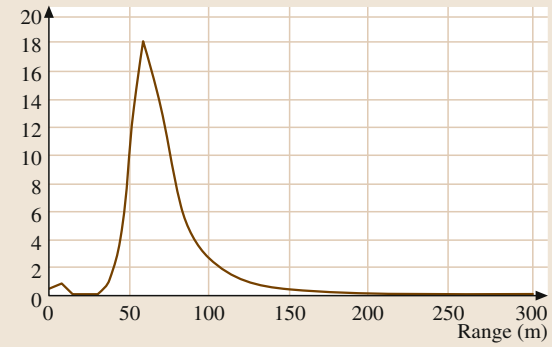


monitoring with the case of volcanic emission. Figure 13.83 shows data from shipborne measurements of the Italian volcano Mt. Etna, where the Swedish mobile lidar system is placed on the aft deck of the Italian research vessel *Urania*, making a 12 km long underpass of the volcanic plume, which is encountered at about 3 km height [13.161]. Individual *on* and *off* lidar returns are also shown at a particular location to illustrate how the plume cross section is built up. It can be noted that the curves are identical up till the height of the plume, where they run apart. Both curves also show an extended backscattering due to volcanic aerosols above the smooth background. It is interesting to note that the aerosol plume is slightly below the SO_2 plume due to gravitational separation. The recording yielded a flux of about 50 t/h as the background emission for this active volcano. Lidar measurements of geophysical gases are discussed in [13.152].

As a third example of lidar measurements we will discuss the monitoring of hydrocarbons, which poses special challenges. The primary C–H stretch vibrational transition in hydrocarbons is around 3.4 μm with small variations between different species. The individual rotational structures also lead to heavy spectral overlap between different hydrocarbons. Thus, in the presence of several hydrocarbons it is not possible to use the basic DIAL concept with an *on* and an *off* wavelength, but rather several, carefully selected wavelengths allowing the different overlapping species to be measured together. We have developed a swiftly tuneable OPO for lidar applications, where switching to up to 60 wavelengths can be accurately performed between adjacent laser shots, and where lidar transients can be averaged for each selected wavelength [13.154, 162]. We illustrate the monitoring of a controlled release of a mixture of methane, ethane and propane with selected DIAL curves showing differential absorption for each gas at the location of gas release 60 m away from the lidar system. The wavelength pairs chosen are shown in the spectral inset; in particular the absence of a DIAL signal when two off-resonance curves are divided is also illustrated. In the case of methane monitoring we note that the DIAL curve has a continuous slope, apart of the step at the release. This is due to the ambient presence of methane in the atmosphere at a level of a few ppm. It is difficult to achieve large ranges in the IR region due to the reduced Mie and Rayleigh scattering for longer wavelengths. However, effective remote sensing of hydrocarbons can be achieved using gas correlation imaging as developed in our group [13.163] and now employed in gas processing plants.



Nitrogen oxides are also important pollution gases. At all high-temperature combustion NO is emitted, and it is rather quickly reacting to NO_2. DIAL measurements for these gases can be made around 226 and 450 nm, respectively. Actually, NO_2 is the only pollutant in the atmosphere which has a colour (brownish) because it absorbs in the visible region.

Because of its paramount importance for shielding the earth from hard UV radiation ozone has been stud-

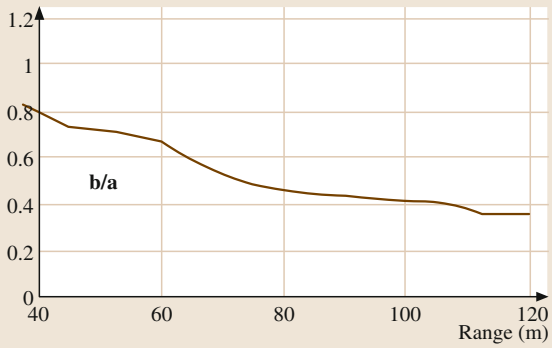


Fig. 13.84a–e Illustration of simultaneous measurements of methane, ethane and propane as evaluated from measurements on a calibrated gas mixture release. Seven different probing wavelengths are indicated and differential absorption in the gases is observed (after [13.154]) ▶

ied much by lidar techniques. The stratospheric ozone layer at 20–30 km height is being depleted due to catalytic reactions with fluorinated hydrocarbons (freons), which rise to the high altitudes since they are inert and do not undergo atmospheric chemistry in the troposphere. Much lidar work has been performed both with fixed and airborne installations. Actually, due to atmospheric chemistry involving hydrocarbons, ozone concentrations at ground levels are frequently elevated, causing damage to health and vegetation.

13.3.4 Lidar Monitoring of Condensed Targets

Laser Altimeters and Bathymeters

As already discussed in the introduction, laser ranging by observing the elastically backscattered echo from a solid target is a straight-forward application of lasers. With pulsed lasers a time-of-flight measurement is performed, while the phase shifts on reflected modulated CW beams also can be used. Then modulation must occur at many different frequencies, where the information on the low-frequency components gives a crude distance estimation, while the higher frequencies better and better determine the distance. Since many distances modulo the modulation wavelength are compatible with a particular high-frequency phase shift, the successively slower modulations ascertain that the right multiple is chosen. Scanning airborne system can map out surface topography with great precision. Laser ranging towards the retro-reflectors placed by the Apollo astronauts provides distance measurements to the moon to an accuracy of about 1 cm. The GLAS (geoscience laser altimeter system) is part of the ICESat satellite launched in 2003 and was mainly intended for accurate height measurements, primarily for studying the polar ice cover development. However, cloud and aerosol data are also obtained. A lidar ranging instrument was important in the successful landing of the Japanese space vehicle HAYABUSA on an asteroid, Itokawa in 2006. Orbiting laser rangefinders will also be used in missions to Mercury and Mars.

The range-resolution of terrestrial laser altimeters is so good that the echo from tree canopies can be resolved from the ground echo. In this way forestry applications have become possible, and biomass assessments can be made in not easily accessible areas, such as jungles. Related, and preceding this application in time, laser bathymetry of shallow waters has been successfully applied with airborne lidar systems. In order to suppress the strong surface echo and allow the picking up of the weak bottom return, a linearly polarized laser can be used. If detection is made at a polarization perpendicular to the primary one, the polarized surface return is strongly attenuated while the depolarized return from the bottom can be favoured. Depths below 40 m are rarely accessible, and normally much shallower waters are measured, of main interest for maritime charting. The preferred laser wavelength in bathymetry applications is 532 nm from a frequency doubled Nd:YAG laser, since water has its maximum transmission in the blue-green spectral region.

Fluorescence and Raman Lidar Studies of Water, Vegetation and Buildings

As discussed in the introduction, the lidar echo from a fixed target consists not only of the strong elastic back-scattering, but also of laser-induced fluorescence (LIF) and Raman components. These features, occurring red-shifted with regard to the laser pump frequency, can be isolated with a spectrometer, where additional suppression of the elastic return is provided with a coloured-glass long-pass filter.

An example of an arrangement for lidar studies of condensed targets is given in Fig. 13.85 [13.164]. Frequency-tripled Nd:YAG radiation at 355 nm effectively induces fluorescence, leaving a sufficiently large Stokes-shifted wavelength range to be captured with available efficient detection systems. Two detection arrangements are shown; one where the fluorescence light is captured with an obtical fibre in the image plane of the telescope and brought to the entrance slit of the spectrometer with a gated and image-intensified CCD detector. Frequently, a multifibre arrangement is used, where a cylindrical detection area is transformed into a slit-shape to match the input of the spectrometer. In a second, imaging arrangement, the laser beam is widened to illuminate a larger area on the target and a special beam-splitting optical arrangement [13.165] is used to simultaneously capture the same image, filtered through 4 individual bandpass filters leaving the images detected simultaneously in the four quadrants of the CCD detector. Such an arrangement can be used for small targets and at background illumination conditions allowing an expanded laser beam with correspondingly weak signal generation from any individual target point. More of general purpose is to have a few cm diameter beam with intense radiation (outperforming the sun background in that spot) and then to sweep this point over the target in a whisk-broom mode. The field is reviewed, e.g. in [13.153].

As an example of individual spectra recorded in such a mode we show in Fig. 13.86 vegetation

spectra, captured at distances ranging from 64 to 210 m [13.166]. The dual-peaked chlorophyll signals are clearly seen as well as a blue light distribution related to leaf wax layer and other leaf structures. The relative intensity of the two red peaks gives information on the chlorophyll concentration, since the first peak is self-absorbed with increasing levels of the pigment. There has been a considerable effort in vegetation monitoring using LIF aiming at the detection of water-related and other environmental stress factors. LIF data may supplement reflectance data now monitored extensively using satellite sensors for land coverage assessment (e.g. LANDSAT, SPOT and ENVISAT sensors).

Cultural heritage studies with spectroscopic methods is an emerging area of laser application. In the same way as specific LIF signatures are obtained from vegetation targets, the surface of stone monuments, such as cathedrals and castles, may also reveal aspects in fluorescence not visible to the naked eye or in reflectance spectroscopy. Following first point-monitoring applications by *Raimondi* et al. [13.167] we have extended the techniques to multispectral imaging with measurement campaigns performed, e.g. at the Lund Cathedral (Sweden) [13.164] and the Parma Cathedral and Baptistery [13.168]. An example from recent measurements at the Övedskloster castle in Southern Sweden is shown in Fig. 13.87. Here the beam was scanned sequentially line by line from a distance of about 40 m [13.169,170]. Examples of individual spectra recorded are shown in the figure featuring different amounts of chlorophyll from mostly invisible algal growth. It can be seen that the edges of the tiles are preferred algal locations as is the upper parts of the ornamental urns. The chlorophyll amount is encoded on the greyscale of the pixels having at least a minimum amount of chlorophyll.

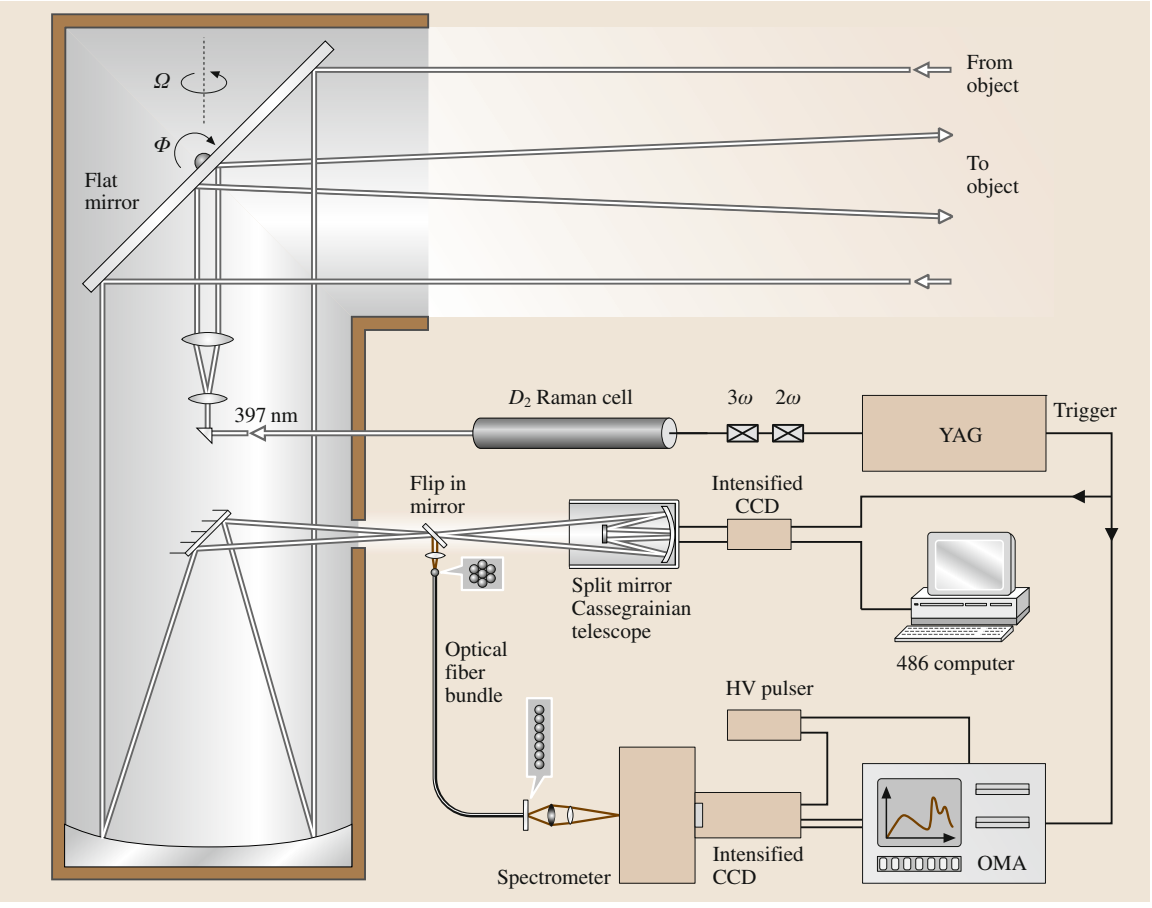

Fig. 13.85 Fluorescence LIDAR system lay-out for point monitoring and multispectral imaging (after [13.164])

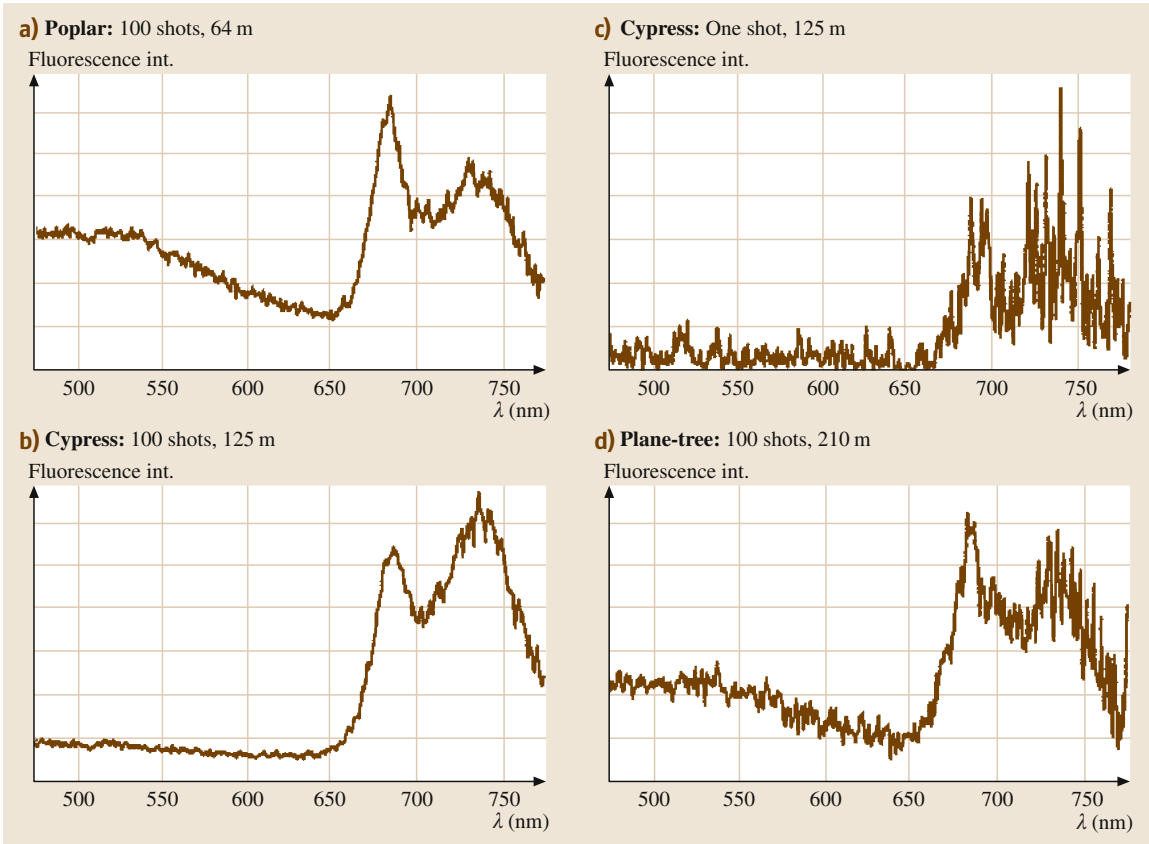

Fig. 13.86a–d Remote fluorescence LIDAR spectra, recorded at different stand-off ranges (after [13.166])

A further example is given in Fig. 13.88 with data from a recent measurement campaign [13.171–173] at the Flavian amphitheatre Coliseum, inaugurated in Rome in 80 AD. The monument is constructed out of travertine quarried nearby in Tivoli. Spectra show differences in stone surface even if they appear similar. Chlorophyll invasion is very evident at certain places, and corrosion protection on iron bars applied during historical preservation efforts also has very characteristic appearance, as shown in the figure, which also includes a photograph from the measuring site.

Very recently, developments of fluorescence lidar techniques for studies in animal ecology have been carried out; e.g., damselflies, flying close to the surface of a river, were studied by folding the laser beam from a 150 m-distant mobile lidar system using a river-side mirror [13.174]. Echoes were observed every time an insect passed the lidar beam. By prior dusting of captured insects with dyes, high species and gender specificity could be achieved, using multiple range-resolved fluorescence band recordings. With such a lidar system employed in vertical sounding, feasibility studies regarding the identification of night-migrating birds have also been performed. The plumage autofluorescence provides a signature which allows certain bird species to be distinguished [13.175].

The first application of fluorescence lidar techniques were in the field of water monitoring, as reviewed, e.g. in [13.176, 177]. Land-based, ship- as well as air-borne campaigns have been pursued. An important aspect of water fluorescence monitoring is the assessment or the general level of dissolved organic matter (DOM) in water. DOM gives rise to broad, bluish fluorescence spectrum. By normalising the DOM signal to the Raman signal due to the water O–H stretch vibrational mode at a Stokes shift of about 3400 cm^{-1} a convenient intrinsic reference is obtained, which makes the measurement independent of a knowledge of the effective sampling volume. For 355 nm excitation the O–H stretch Raman signal of liquid water occurs at 404 nm. By analyzing the shape of the wa-

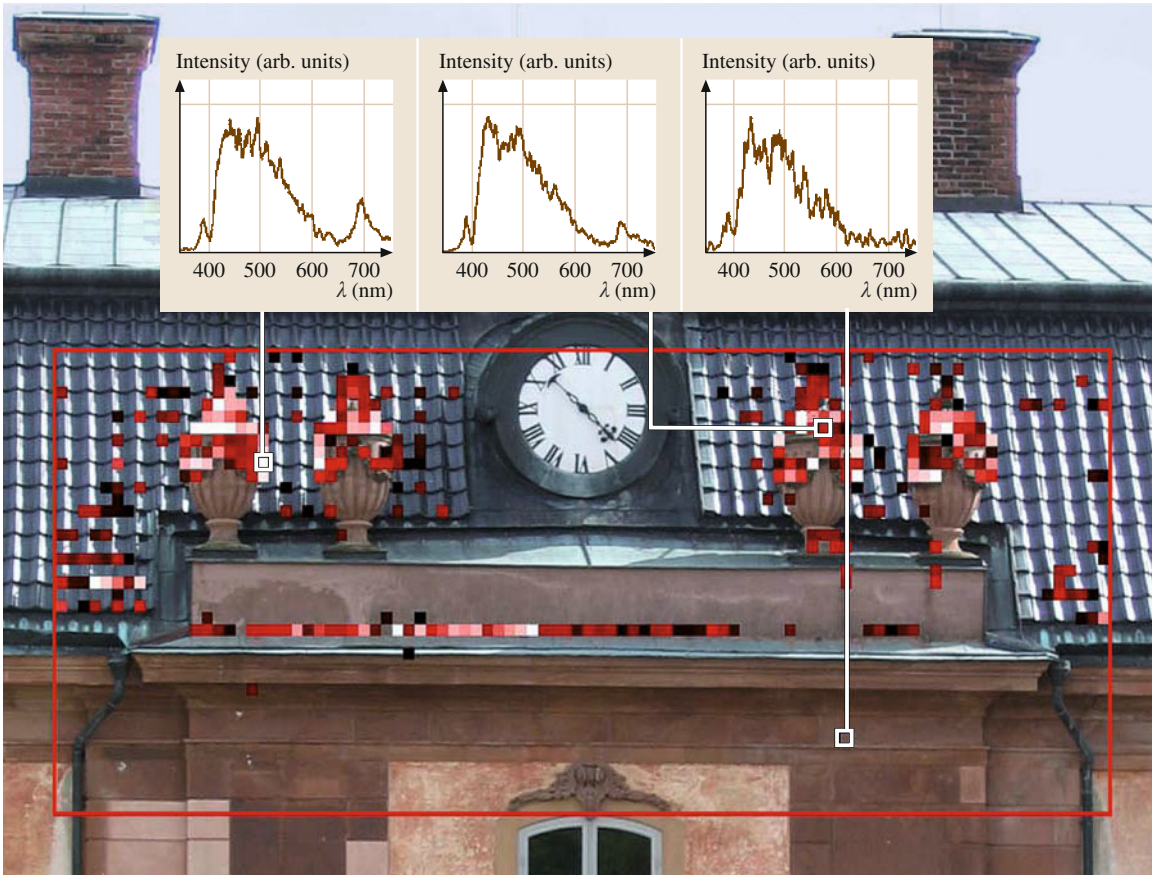

Fig. 13.87 Fluorescence LIDAR imaging of a section of the Övedskloster castle, Sweden. Three spectra illustrate the measurements, and an image with a colorscale indicates the amount of algae invasion (after [13.169, 170])

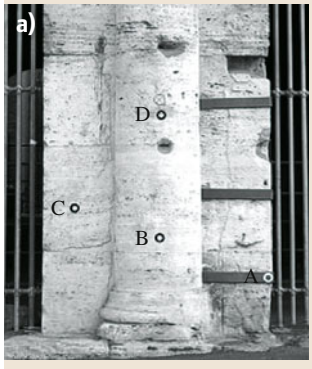
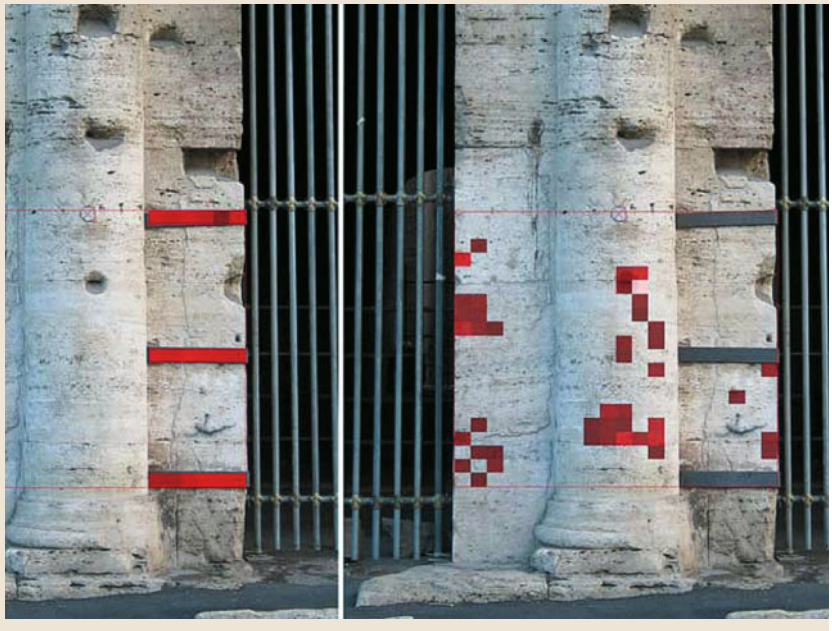


ter Raman peak with a high spectral resolution system it is possible to remotely also measure the water temperature depth-resolved with a bathymetric system.



Other prominent spectral features in lidar spectroscopic studies of water are due to chlorophyll, which is present in all pelagic algae, and accessory pigments, e.g. phycocyanine and phycoerytrine, which are present in red algae. The characteristic fluorescence of these pigments peak at 690, 660 and 590 nm, respectively.

The strongest signals received in aquatic monitoring are from oil spills covering the surface [13.178]. At the same time as a strong oil fluorescence is replacing the DOM signal in the blue-green region, the water Raman signal disappears, since even a layer few micrometers thick becomes optically thick for the exciting UV radiation. Thus oil spills have a very clear spectral signature. Laboratory studies of different types of crude oils and lighter fractions show that oils of specific origins can be identified. Extensive airborne work for oil spill detection and characterization, complementing data from SLAR (side-looking airborne radar) and SAR (synthetic aperture radar) has been pursued.

A main limitation of fluorescence lidar is its limited range which makes satellite implementation difficult. However, passive techniques using sunlight-induced fluorescence have been considered for marine oil slick detection and is now being developed for vegetation monitoring [13.179]. A normal reflectance spectrum of a ground surface carries the dark and narrow Fraunhofer signature lines from the sun with the same contrast as in the direct sunlight. However, fluorescence transfers part of the radiation from short to longer wavelengths due to the Stokes shift, and tends to reduce the Fraunhofer line contrast, a phenomenon directly signalling that fluorescence is present.

Laser-Induced Break-Down Spectroscopy (LIBS) Lidar

We will finish this section of lidar measurements on condensed targets by a discussion of remote laser-induced break-down spectroscopy (LIBS). The LIBS technique makes use of focused laser beams from pulsed lasers, where a laser spark is produced at the target surface due to the strong heating by the pulse [13.180]. The technique is a valuable analytical analysis method for elemental measurements of the same kind as in flame emission spectroscopy where vapourization occurs due to the thermal heating. By expanding the lidar beam and focusing it is possible to reach a sufficiently small spot-size to induce plasma break-down at a considerable distance if the pulse energy is large enough [13.181]. The technique is being developed also for space exploration, e.g. rock characterization from Mars landers [13.182]. We have recently performed first imaging lidar LIBS measurements at a distance of 60 m and with pulse energies at 355 nm of the order of 200 mJ [13.183]. The same detection system as for LIF is employed, and by gating a few hundred nanoseconds late it is possible to observe the cooling plasma, in which narrow atomic emission lines are obtained rather than broadened structures observed in the prompt plasma, where strong fields due to electrons etc. are present. This effect is seen in Fig. 13.89, where a LIBS spectrum from a sheet of lead is observed at 60 m distance at different delays [13.170].

Small amounts of material are ablated in the LIBS plasma. This can be utilized for cleaning of soiled surfaces in the cultural heritage sector. Such remote cleaning is illustrated in Fig. 13.90. Here samples of mortar, alabaster and marble were studied in a distance of 60 m. On white marble samples the cleaning process is self-terminating, since no absorption is obtained once the dirty surface is removed from the white original material. The ablation and cleaning process could in principle also be controlled spectroscopically by simultaneously monitoring the plasma spectrum.

13.3.5 Unconventional Lidar Applications

Lidar techniques are normally and conventionally associated with long-range atmospheric measurements. However, a key aspect in these measurements is that they are performed time-resolved and nonintrusively. Using topographic (condensed) targets, the range-resolution aspect is also sometimes suppressed. In the measurement of combustion processes optical techniques are used at distances of typically 1 m, but motivated by the remote and nonintrusive nature of optical spectroscopy, avoiding the prohibiting heat and pressures characteristic of such systems. Elastic scattering, Raman, fluorescence and CARS (coherent anti-stokes Raman scattering) techniques are being employed [13.184]. Range-resolved measurements in large-scale burners are now being developed making the parallels with lidar very close [13.185].

Optical mammography for the detection of breast cancer [13.186] can truly be characterized as short-range lidar. Biological tissue is a strongly scattering medium, in which also molecular compounds can be detected using differential absorption. It can be convenient to use white laser light generated by self-phase modulation of femto-second laser pulses in such measurements, and molecules, such as tumour seeding agents can be detected [13.187]. Such techniques can be extended to the monitoring of pharmaceutical tablets, which are strongly scattering [13.188, 189]. Using white light laser bursts the concentration of the active molecular components in the drug can be evaluated from their imprint in the detected scattered light. These examples constitute multiple-scattering cases much similar to the onces pertaining to cloud physics.

The lidar analogy becomes almost complete in the GASMAS (gas in scattering media absorption spectroscopy) technique [13.190, 191], where free gas enclosures (pores) in highly scattering materials such as wood, foods and construction materials are being studied. Normally, CW diode laser spectroscopy is being applied for path-integrated measurements of the free gas signature (e.g. molecular oxygen and water vapour). Gas concentration determination becomes possible if an independent *lidar* measurement of the time history of the photons inside the sample is being made [13.192]. The GASMAS technique also gives interesting insight in everyday processes such as the drying of materials, e.g. wood [13.193]. The technique has recently been extended to the monitoring of oxygen gas inside the human si-

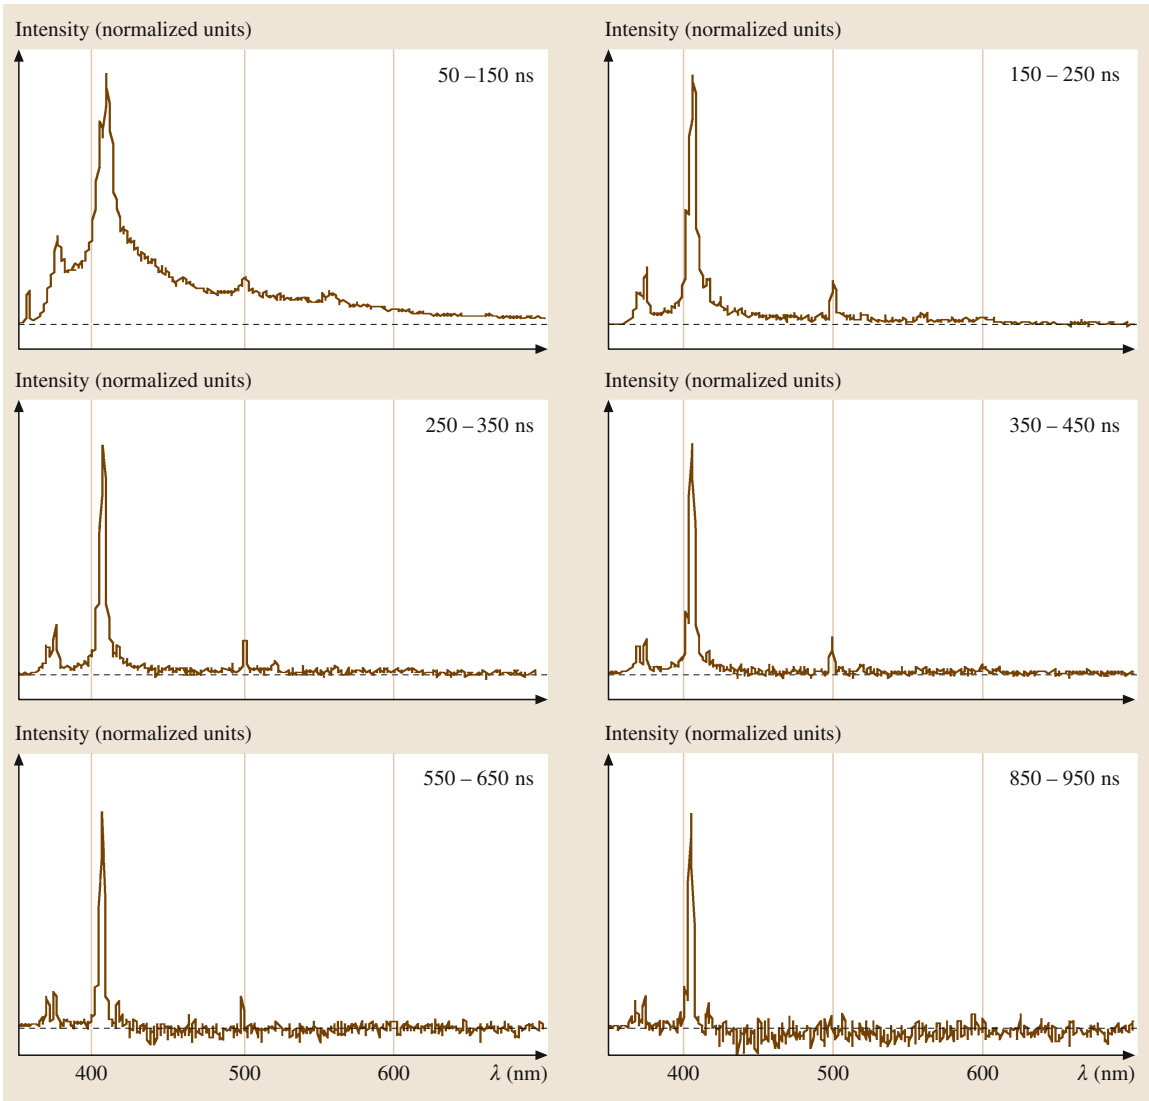

Fig. 13.89 Laser-induced breakdown spectra (LIBS) recorded with a LIDAR system at 60 m stand-off distance for a lead plate for different time delays. The lines become narrower and more well defined as the plasma cools (after [13.170])

nus cavities [13.194–196], where the laser light is being launched through the scattering forehead, passes the sinus, scatters in the brain with a fraction returning back through the sinus, passes the forehead and enters the *lidar* detector. The gas is being detected through its sharp differential absorption superimposed on the backscattering spectrum from the bulk molecules having a very slow wavelength dependence (like in atmospheric lidar). Some illustrations of *unconventional* lidar work are given in Fig. 13.91.

The many parallels between environmental and medical laser spectroscopy are being pointed out, e.g. in [13.197,198], and further aspects of multidisciplinary spectroscopy bridging many disciplines are discussed in [13.199].

13.3.6 Discussion and Outlook

As we have seen, lidar techniques provide a wide spectrum of applications regarding the monitoring of the

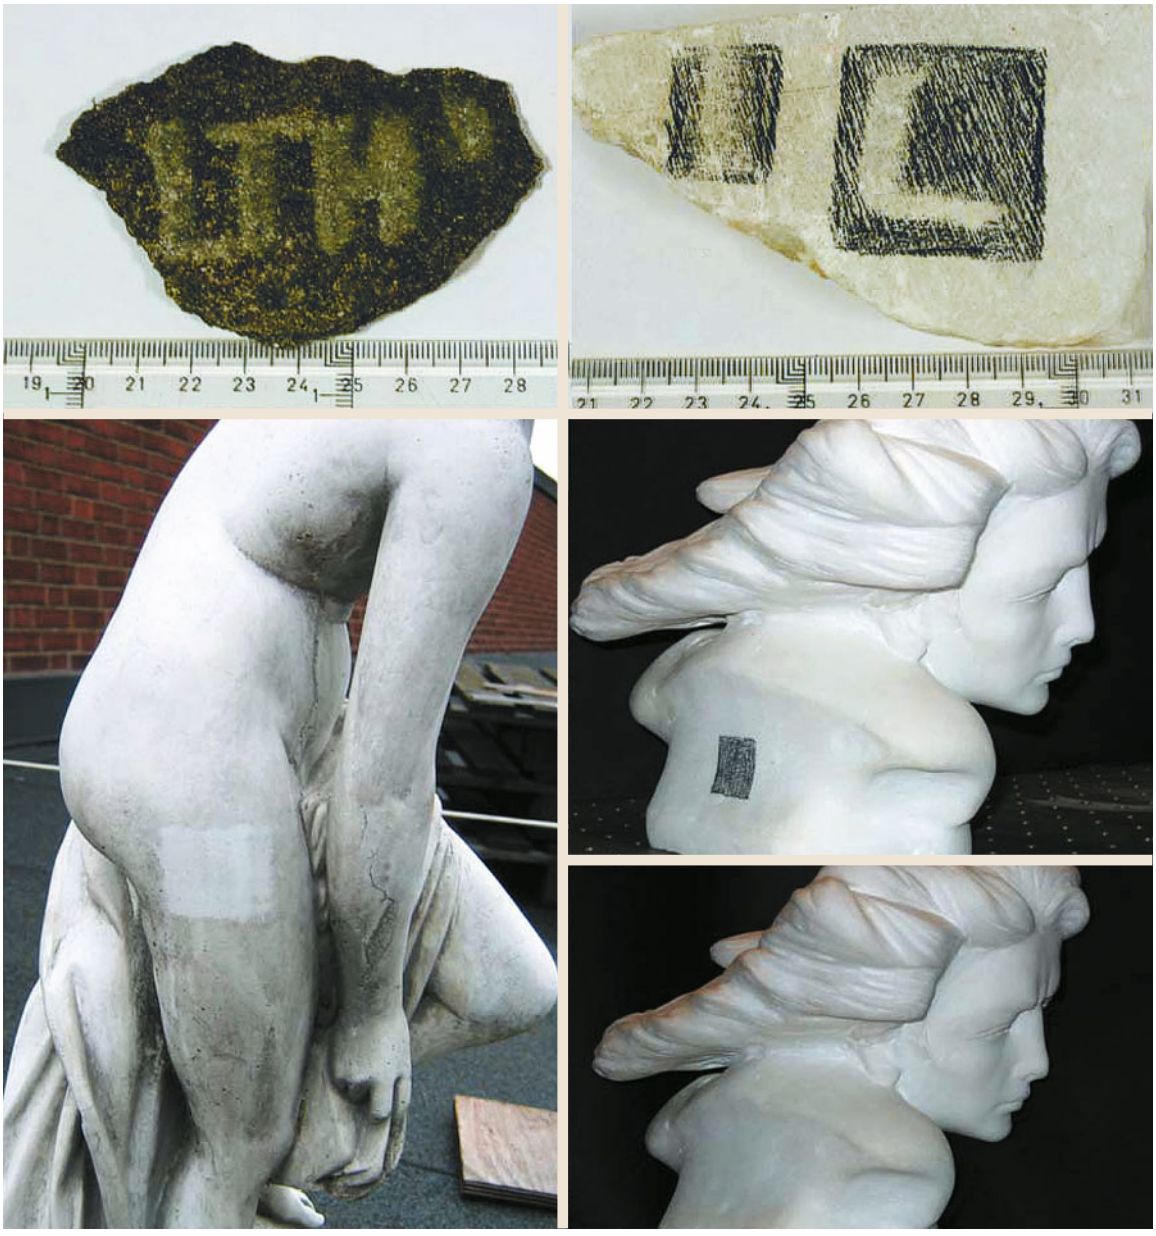

Fig. 13.90 Illustration of remote plasma ablation on different samples placed at 60 m distance from the LIDAR system. *Top*: ablation patterns for concrete and Italian alabaster; *Bottom left*: illustration of the cleaning of an Italian garden statue; *right*: a soiled Carrara marble statue before (*upper figure*) and after (*lower figure*) remote laser cleaning (after [13.183])

environment. The rapid development of efficient diode-pumped solid state lasers, sensitive detectors, and fast electronics and data handling all have contributed to make the applications of lidar more attractive. With ever more strict considerations regarding the monitoring of the status of the environment, the utilization of lidars in surveillance and monitoring systems and networks will be a driving force in the development of the field. Satellite-borne equipment is now planned for many missions taking advantage of the emerging robustness and

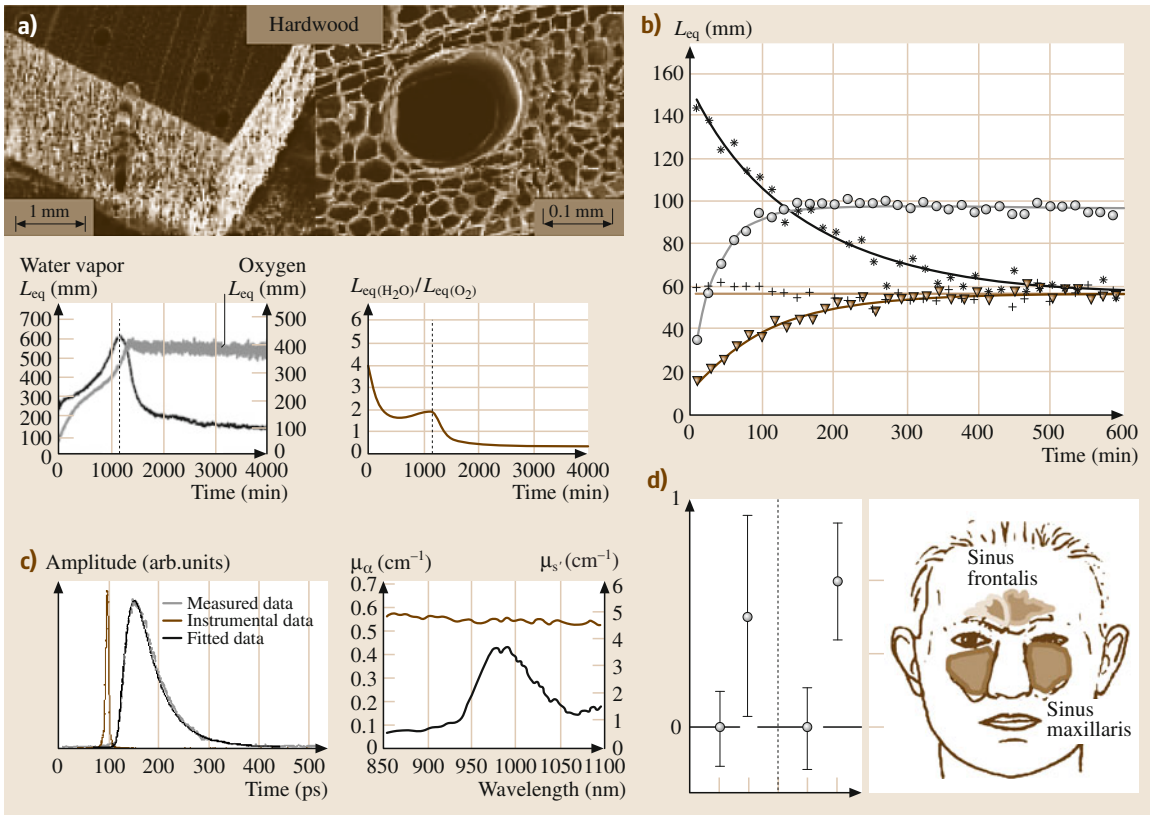

Fig. 13.91a–d Illustration of different kinds of unconventional short-range *LIDAR* measurements. **(a)** Monitoring of the drying of wood. Microscope images of wood structure with pores are shown above the temporal development of molecular water and molecular oxygen signals, and their ratio value during a two-day drying process (after [13.193]). **(b)** Molecular oxygen signals from apple exposed to pure oxygen or nitrogen gas before being taken into ambient air where normal interior gas conditions are restored with a certain time constant (after [13.191]). **(c)** Time-resolved measurements of light scattered in a white pharmaceutical tablet, and (*right*) observation of the liquid-water absorption spectrum (after [13.188]). **(d)** Observation of free oxygen gas in the frontal sinus cavities when light is launched into the forehead and backscattered light is detected. Nonzero signals are seen on both sinuses, while zero signal results off the sinuses (after [13.194])

reliability of the techniques. A major impact on global atmospheric monitoring and meteorology can be expected.

Recent trends in the lidar field include the use of intense laser beams of terawatt peak power and femtosecond duration. Reasonably small, table-top systems became available after the introduction of the chirped-pulse-amplification (CPA) technique [13.200]. Filamentation and channelling due to self-focusing occurs in the atmospheric propagation keeping the beam together with intense generation of white light through nonlinear effects, most prominently self-phase modulation [13.201]. Free atmosphere measurements, including studies of airborne bio-aerosols, as well as remote LIBS measurements have been demonstrated [13.202, 203]. Clearly, eye-safety considerations are here challenging with laser light present at all wavelengths. Lidar systems operating outside the human cornea transmission region 400–1400 nm are most convenient for more general application due the strongly relaxed safety aspects.

Lidar techniques and methods have also stimulated extension into more unconventional fields, such as biology and medicine. Many lidar concepts can be scaled down to the cm level, where new medical diagnostics techniques are now emerging.

14. Optical Fibers

With the development of extremely low-loss optical fibers and their application to communication systems, a revolution has taken place during the last 40 years. In 2001, using glass fibers as the transmission medium and lightwaves as carrier waves, information was transmitted at a rate more than 1 Tbit/s (which is roughly equivalent to transmission of about 15 million simultaneous telephone conversations) through one hair thin optical fiber. Experimental demonstration of transmission at the rate of 14 Tbit/s over a 160 km long single fiber was demonstrated in 2006, which is equivalent to sending 140 digital high definition movies in 1 s. Very recently record transmission of more than 100 Tbit/s over 165 km single mode fiber has been reported. These can be considered as extremely important technological achievements. In this chapter we will discuss the propagation characteristics of optical fibers with special applications to optical communication systems and also present some of the noncommunication applications such as sensing.

14.1 Some Historical Remarks

The appearance of the telephone in the late 19th century revolutionized communication among people. The history of the invention of the telephone is quite complex and disputed. In 1831 Michael Faraday reported a series of experiments showing that electrical current is generated with relative motion between a metallic conducting loop and a magnet or with a changing magnetic field through the loop. In 1854 the first practical suggestion of an electric telephone was made by M. Charles Bourseul, a French telegraphist, but it seems that nothing came of the suggestion. Then in 1861 the German school teacher Johann Philip Reis built an apparatus that converted sound to electricity and back to sound. The instrument built by Reis transmitted musical sounds and even words; but his apparatus lacked perfection. In 2002, the US House of Representatives passed a resolu-

tion recognizing the achievements of Antonio Meucci, an Italian immigrant as the inventor of telephone; indeed Meucci demonstrated his *teletrofono* in New York in 1860. Alexander Graham Bell took out his patent in 1876, 16 years later.

The idea of using light waves for communication can be traced back as far as 1880 when Alexander Graham Bell invented the photophone shortly after he invented the telephone in 1876. In this remarkable experiment, speech was transmitted by modulating a light beam, which traveled through air to the receiver. The transmitter consisted of a flexible reflecting diaphragm which could be activated by sound and which was illuminated by sunlight. The reflected beam was received by a parabolic reflector placed at a distance. The parabolic reflector concentrated the light on a photoconducting selenium cell, which formed a part of a circuit with a battery and a receiving earphone. Sound waves present in the vicinity of the diaphragm vibrated the diaphragm, which led to a consequent variation of the light reflected by the diaphragm. The variation of the light falling on the selenium cell changes the electrical conductivity of the cell, which in turn changes the current in the electrical circuit. This changing current reproduces the sound on the earphone. This was the first experiment on optical communication. To quote from [14.1]:

> *In 1880 he (Graham Bell) produced his photophone which to the end of his life, he insisted was … the greatest invention I have ever made, greater than the telephone … Unlike the telephone it had no commercial value.*

After this beautiful experiment by Alexander Graham Bell, not much work was carried out in the field of optical communications. This is because of the fact that there was no suitable light source available that could reliably be used as the information carrier. The advent of lasers in 1960 immediately triggered a great deal of investigations aimed at examining the possibility of building optical analogs of conventional communication systems. The very first such modern optical communication experiments involved laser beam transmission through the atmosphere. However, it was soon realized that laser beams could not be sent in open atmosphere through reasonably long distances to carry signals unlike, for example, microwave or radio systems operating at longer wavelengths. This is due to the fact that a light beam (of wavelength about 1 μm) is severely attenuated and distorted owing to scattering and absorption by the atmosphere. Thus for reliable long distance lightwave communication under terrestrial environments it would be necessary to provide a transmission medium that can protect the signal carrying light beam from the vagaries of the terrestrial atmosphere. In 1966, *Kao* and *Hockham* [14.2] made an extremely important suggestion; they said that optical fibers based on silica glass could provide the necessary transmission medium if metallic and other impurities could be removed from silica. In 1966, when the paper by Kao and Hockham was published, the most transparent glass available had extremely high losses (of more than about 1000 dB/km implying a power loss by a factor of 100 in traversing through only 20 m of the fiber); the high loss was primarily due to trace amount of impurities present in the glass. Obviously this loss is too high even for short distances such as a few hundred meters. Their 1966 paper triggered the beginning of serious research in removing traces of impurities present in the glass, which resulted in realization of low-loss optical fibers. In 1970, Kapron, Keck, and Maurer (at Corning Glass in USA) were successful in producing silica fibers with a loss of about 17 dB/km at the helium neon laser wavelength of 633 nm. Since then, the technology has advanced with tremendous rapidity. By 1985 glass fibers were routinely produced with extremely low losses: less than 0.25 dB/km, which corresponds to a transmission of more than 94% of the incident power after traversing 1 km of the optical fiber. Because of such low losses, the distance between two consecutive repeaters (used for amplifying and reshaping the attenuated signals) could be as large as 250 km. Dr. Charles Kao received half of the 2009 Nobel Prize in Physics for *groundbreaking achievements concerning the transmission of light in fibers for optical communication*. Professor Joseph Nordgren, Chair, Nobel Committee said: *Charles Kao's discovery made in 1966 led to a breakthrough in Fiber Optics … … revolutionized the way in which information can be transmitted globally*.

14.2 The Optical Fiber

At the heart of an optical communication system is the optical fiber that acts as the transmission channel carrying the light beam loaded with information. The light beam is guided through the optical fiber due to the phe-

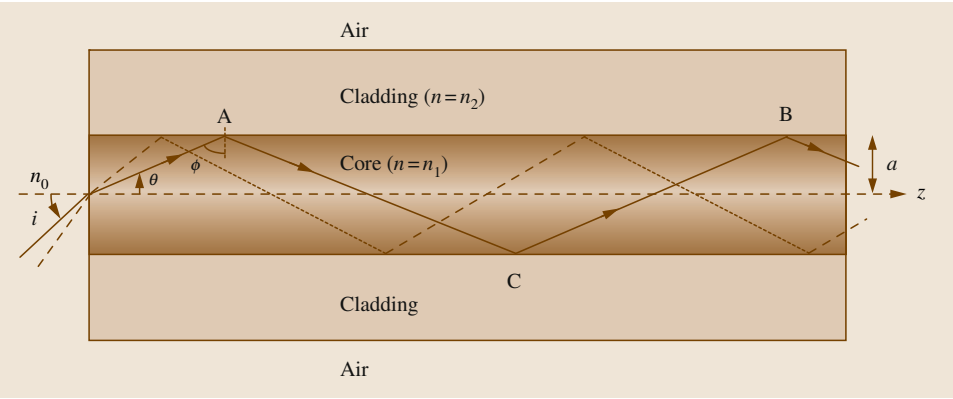

Fig. 14.1 Ray propagation through a step index optical fiber

nomenon of total internal reflection (often abbreviated as TIR). Figure 14.1 shows an optical fiber consisting of a (cylindrical) central dielectric core (of refractive index n_1) cladded by a material of slightly lower refractive index n_2 ($< n_1$). One usually defines a parameter Δ ($= (n_1 - n_2)/n_2$), which represents the fractional difference in the refractive index between core and cladding. The necessity of a cladded fiber (Fig. 14.1) rather than a bare fiber, i. e., without a cladding, was felt because of the fact that for transmission of light from one place to another, the fiber must be supported, and supporting structures may considerably distort the fiber, thereby affecting the guidance of the light wave. This can be avoided by choosing a sufficiently thick cladding.

When a light pulse propagates through an optical fiber it suffers from attenuation due to various mechanisms and also the pulse broadens in time leading to what is termed as pulse dispersion. Apart from this, due to the high intensity of light present in the fiber, nonlinear optical effects come into play. Attenuation, pulse dispersion and nonlinear effects represent three of the most important characteristics that determine the information transmission capacity of optical fibers. Obviously, the lower the attenuation (and similarly, the lower the dispersion and smaller the nonlinear effects) the greater the required repeater spacing, and, therefore the higher the information carrying capacity and the lower the cost of the communication system.

14.3 Attenuation in Optical Fibers

Losses in optical fiber are specified in terms of the unit dB/km. This is defined as

$$\alpha(\mathrm{dB/km}) = \frac{10}{L\ (\mathrm{km})} \log\left(\frac{P_{\mathrm{in}}}{P_{\mathrm{out}}}\right) . \qquad (14.1)$$

Here P_{in} and P_{out} are the input and output powers corresponding to an optical fiber of length L (km). Figure 14.2 shows a typical dependence of fiber attenuation coefficient α as a function of wavelength of a typical silica optical fiber [14.3]. It may be seen that the loss is about 0.25 dB/km at a wavelength of around 1550 nm. Various methods, such as the modified chemical vapor deposition (MCVD) process or the outside vapor deposition (OVD) process allows one to fabricate such fibers with very low losses. The losses are caused due to various mechanisms such as Rayleigh scattering, absorption due to metallic impurities and water in the fiber, and intrinsic absorption by the silica molecule itself. The Rayleigh scattering loss varies as $1/\lambda_0^4$, i. e., shorter wavelengths scatter more than longer wavelengths. Here λ_0 represents the free space wavelength. This is the reason why the loss coefficient decreases up to about 1550 nm. The two absorption peaks around 1240 and 1380 nm are primarily due to traces of OH^- ions and traces of metallic ions. For example, even 1 ppm (part per million) of iron can cause a loss of about 0.68 dB/km at 1100 nm. Similarly a concentration of 1 ppm of OH^- ion can cause a loss of 4 dB/km at 1380 nm. This shows the level of purity that is required to achieve low-loss optical fibers. If these impurities are completely removed, the two absorption peaks will disappear (Fig. 14.3), and we will have very low loss in the entire range of wavelength from 1250–1650 nm [14.4]. In a typical commercially available fiber the loss is about 0.29, 0.19, and 0.21 dB/km at $\lambda_0 = 1310$, 1550, and 1625 nm, respectively. Such fibers

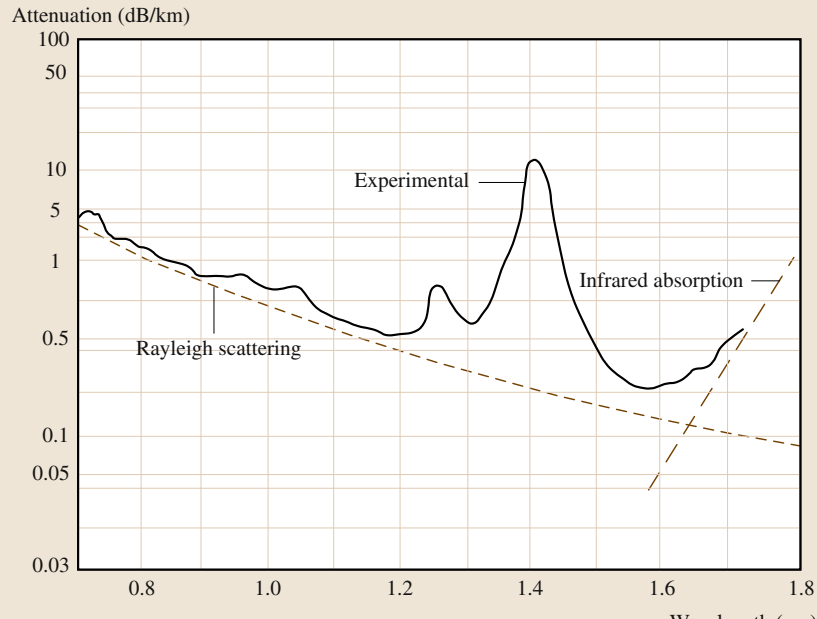

Fig. 14.2 Attenuation spectrum of a typical silica optical fiber (after [14.3])

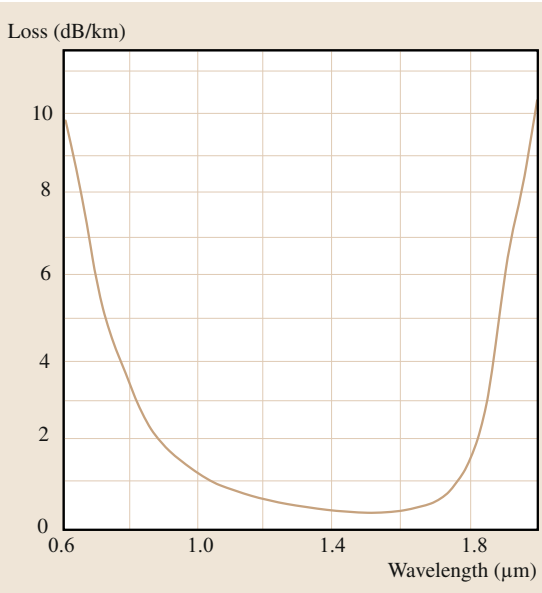

Fig. 14.3 Loss spectrum of ultimately low water content optical fiber. Note that the low loss window extends from 1250–1650 nm (≈ 50 THz) and such fibers are now available commercially (after [14.4]) ◀

open up a bandwidth of more than 50 THz for communication. For $\lambda_0 > 1600$ nm the increase in the loss coefficient is due to the absorption of infrared light by silica molecules. This is an intrinsic property of silica and no amount of purification can remove this infrared absorption tail.

As can be seen, there are two windows at which loss attains its minimum value in silica fibers. The first window is around 1300 nm (with a typical loss coefficient of less than 1 dB/km) where fortunately (as we will see later) the material dispersion is negligible. However, the loss attains its absolute minimum value of about 0.2 dB/km around 1550 nm. The latter window has become extremely important in view of the availability of erbium doped fiber amplifiers.

14.4 Modes of a Step-Index Fiber

The modal analysis of an optical fiber allows us to understand its propagation characteristics, which play an extremely important role in the design of a fiber optic communication system. The step-index fiber (Fig. 14.1)

is characterized by the following refractive index distribution

$$\begin{aligned} n(r) &= n_1 \quad 0 < r < a \quad \text{core}\,, \\ &= n_2 \quad r > a \quad \text{cladding}\,, \end{aligned} \tag{14.2}$$

where r represents the cylindrical radial coordinate. In actual fibers $\Delta \ll 1$ and this allows use of so-called scalar wave approximation (also known as weakly guiding approximation). In this approximation, the modal fields are assumed to be nearly transverse and can have an arbitrary state of polarization. Thus, the two independent sets of modes can be assumed to be x-polarized and y-polarized, and in the scalar approximation they have the same propagation constants. These linearly polarized (LP) modes are usually referred to as LP modes. In this approximation, the transverse component of the electric field (E_x or E_y) satisfies the scalar wave equation

$$\nabla^2 \Psi = \frac{n^2}{c^2}\frac{\partial^2 \Psi}{\partial t^2}\,, \tag{14.3}$$

where c ($\approx 3\times 10^8$ m/s) is the speed of light in free space. In most practical fibers n^2 depends only on the cylindrical coordinate r and, therefore, it is convenient to use the cylindrical system of coordinates and write the solution of (14.3) in the form

$$\Psi(r, \phi, z, t) = \psi(r, \phi)\mathrm{e}^{\mathrm{i}(\omega t - \beta z)}\,, \tag{14.4}$$

where ω is the angular frequency and β is known as the propagation constant. Equation (14.4) defines a propagating mode of the fiber. Since ψ depends only on r and ϕ, the modes represent transverse field configurations that do not change as they propagate through the optical fiber except for a phase change. From (14.4) we can define the phase velocity and group velocity of the mode as

$$v_\mathrm{p} = \frac{\omega}{\beta} = \frac{c}{n_\mathrm{eff}(\omega)} \quad \text{and} \quad v_\mathrm{g} = \left(\frac{\mathrm{d}\beta}{\mathrm{d}\omega}\right)^{-1}\,, \tag{14.5}$$

where

$$n_\mathrm{eff} = \frac{\beta}{k_0} \tag{14.6}$$

is referred to as the effective index of the mode and $k_0 = \omega/c$ represents the free space propagation constant.

Substituting for Ψ in (14.3) we obtain

$$\frac{\partial^2 \psi}{\partial r^2} + \frac{1}{r}\frac{\partial \psi}{\partial r} + \frac{1}{r^2}\frac{\partial^2 \psi}{\partial \phi^2} + \left[k_0^2 n^2(r) - \beta^2\right]\psi = 0\,. \tag{14.7}$$

Equation (14.7) can be solved by using the method of separation of variables and because the medium has cylindrical symmetry, the ϕ dependence will be of the form $\cos l\phi$ or $\sin l\phi$, and for the function to be single valued (i. e., $\Phi(\phi + 2\pi) = \Phi(\phi)$) we must have $l = 0, 1, 2, \ldots$ Thus the complete transverse modal field is given by

$$\Psi(r, \phi, z, t) = R(r)\mathrm{e}^{\mathrm{i}(\omega t - \beta z)}\begin{bmatrix}\cos l\phi \\ \sin l\phi\end{bmatrix}\,, \tag{14.8}$$

where $R(r)$ satisfies the radial part of the equation

$$r^2\frac{\mathrm{d}^2 R}{\mathrm{d}r^2} + r\frac{\mathrm{d}R}{\mathrm{d}r} + \left\{\left[k_0^2 n^2(r) - \beta^2\right]r^2 - l^2\right\}R = 0\,. \tag{14.9}$$

Before we write the solutions of (14.9), we will make some general comments about the solutions of (14.9) for an arbitrary cylindrically symmetric profile having a refractive index that decreases monotonically from a value n_1 on the axis to a constant value n_2 beyond the core–cladding interface $r = a$ (Fig. 14.4). The solutions of (14.9) can be divided into two distinct classes:

1. Guided modes

$$n_2^2 < \frac{\beta^2}{k_0^2} < n_1^2\,. \tag{14.10}$$

For β^2 lying in the above range, the fields $R(r)$ are oscillatory in the core and decay in the cladding and β^2 assumes only discrete values; these are known as the *guided modes* of the fiber. For a given value of l, there will be several guided modes, which are

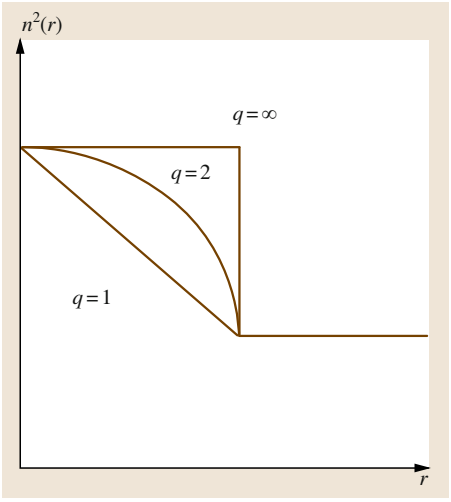

Fig. 14.4 Refractive index variation of a graded index optical fiber with power law profile

designated LP_{lm} modes ($m = 1, 2, 3, \ldots$); LP stands for linearly polarized. Further, since the modes are solutions of the scalar wave equation, they can be assumed to satisfy the orthonormality condition

$$\int_0^\infty \int_0^{2\pi} \psi^*_{lm}(r,\phi)\psi_{l'm'}(r,\phi) r\,\mathrm{d}r\,\mathrm{d}\phi = \delta_{ll'}\delta_{mm'} \,. \tag{14.11}$$

2. Radiation mode

$$0 < \frac{\beta^2}{k_0^2} < n_2^2 \,. \tag{14.12}$$

For such β values, the fields are oscillatory even in the cladding and β can assume a continuum of values. These are known as the *radiation modes*.

Now, for a step-index profile, the well behaved guided mode solution of (14.9) can be written in terms of Bessel functions J_l and K_l

$$\psi(r,\phi) = \begin{cases} \dfrac{A}{J_l(U)} J_l\left(\dfrac{Ur}{a}\right) \begin{pmatrix} \cos l\phi \\ \sin l\phi \end{pmatrix} ; & r < a \\ \dfrac{A}{K_l(W)} K_l\left(\dfrac{Wr}{a}\right) \begin{pmatrix} \cos l\phi \\ \sin l\phi \end{pmatrix} ; & r > a \end{cases} , \tag{14.13}$$

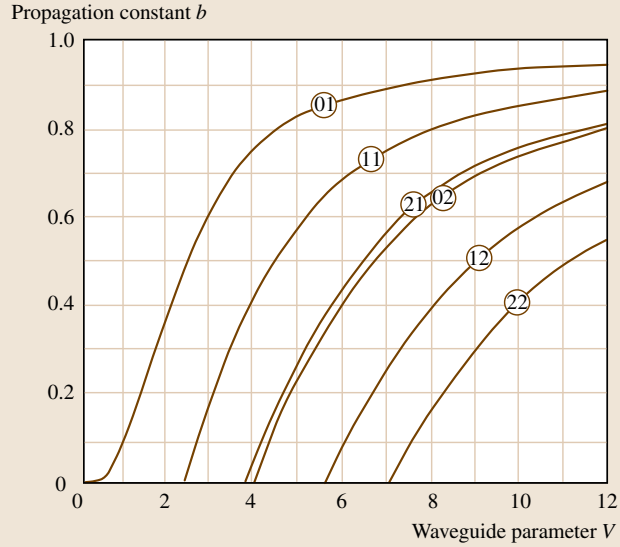

Fig. 14.5 Variation of normalized propagation constant b with V for a step index fiber (after [14.5])

where A is a constant and we have assumed continuity of ψ at the core–cladding interface and

$$U \equiv a\sqrt{k_0^2 n_1^2 - \beta^2} \quad \text{and} \quad W \equiv a\sqrt{\beta^2 - k_0^2 n_2^2} \,. \tag{14.14}$$

The normalized waveguide parameter V is defined by

$$V = \sqrt{U^2 + W^2} = k_0 a\sqrt{n_1^2 - n_2^2} \,. \tag{14.15}$$

The waveguide parameter V (which also depends on the operating wavelength λ_0) is an extremely important quantity characterizing an optical fiber. For guided modes $n_2^2 k_0^2 < \beta^2 < n_1^2 k_0^2$ and, therefore, both U and W are real. It is convenient to define the normalized propagation constant

$$b = \frac{\frac{\beta^2}{k_0^2} - n_2^2}{n_1^2 - n_2^2} = \frac{W^2}{V^2} \,. \tag{14.16}$$

Thus $W = V\sqrt{b}$ and $U = V\sqrt{1-b}$. Using (14.10), we see that guided modes are characterized by $0 < b < 1$. Continuity of $\partial\psi/\partial r$ at $r = a$ and use of identities involving Bessel functions give us the following transcendental equations, which determine the allowed discrete values of the normalized propagation constant b of the guided LP_{lm} modes [14.6]

$$V(1-b)^{\frac{1}{2}} \frac{J_{l-1}\left[V(1-b)^{\frac{1}{2}}\right]}{J_l\left[V(1-b)^{\frac{1}{2}}\right]} = -Vb^{\frac{1}{2}} \frac{K_{l-1}\left(Vb^{\frac{1}{2}}\right)}{K_l\left(Vb^{\frac{1}{2}}\right)} ; \quad l \geq 1 \tag{14.17}$$

and

$$V(1-b)^{\frac{1}{2}} \frac{J_1\left[V(1-b)^{\frac{1}{2}}\right]}{J_0\left[V(1-b)^{\frac{1}{2}}\right]} = Vb^{\frac{1}{2}} \frac{K_1\left(Vb^{\frac{1}{2}}\right)}{K_0\left(Vb^{\frac{1}{2}}\right)} ; \quad l = 0 \tag{14.18}$$

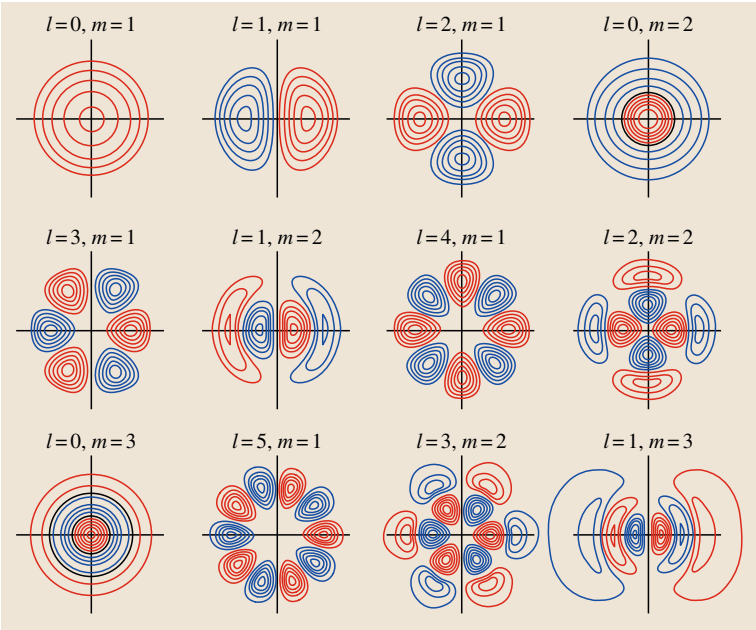

Fig. 14.6 Field patterns of some low order LP_{lm} guided modes (after [14.7])

The solution of the above transcendental equations will give us universal curves describing the dependence of b (and therefore of U and W) on V. For a given value of l, there will be a finite number of solutions and the mth solution ($m = 1, 2, 3, \ldots$) is referred to as the LP_{lm} mode. The variation of b with V form a set of universal curves, which are plotted in Fig. 14.5 [14.5]. As can be seen at a particular V value the fiber can support only a finite number of modes. Figure 14.6 shows the typical field patterns of some of the low order LP_{lm} modes of a step-index fiber.

Guided and radiation modes form a complete set of solutions in the sense that any arbitrary field distribution in the optical fiber can be expressed as a linear combination of the discrete guided modes $\psi_j(x, y)$ and the continuum radiation modes $\psi(x, y, \beta)$

$$\Psi(x, y, z) = \sum a_j \psi_j(x, y) \mathrm{e}^{-\mathrm{i}\beta_j z} + \int a(\beta)\psi(x, y, \beta)\mathrm{e}^{-\mathrm{i}\beta z}\,\mathrm{d}\beta \qquad (14.19)$$

with $|a_j|^2$ being proportional to the power carried by the jth guided mode and $|a(\beta)|^2\,\mathrm{d}\beta$ being proportional to the power carried by radiation modes with propagation constants lying between β and $\beta + \mathrm{d}\beta$. The constants a_j and $a(\beta)$ can be determined from the incident field distribution at $z = 0$.

We may mention that if one solves the vector wave equation, the modes are classified as HE_{lm}, EH_{lm}, TE_{0m}, and TM_{0m} modes, the correspondence is $LP_{0m} = HE_{lm}$; $LP_{1m} = HE_{2m}$, TM_{0m}, and $LP_{lm} = HE_{l+1,m}$, $EH_{l-1,m}$ ($l \geq 2$) [14.8].

14.5 Single-Mode Fibers

As is obvious from Fig. 14.5, for a step-index fiber with $0 < V < 2.4048$ we will have only one guided mode – namely, the LP_{01} mode also referred to as the fundamental mode. Such a fiber is referred to as a single-mode fiber and is of tremendous importance in optical fiber communication systems. As an example, we consider a step-index fiber with $n_2 = 1.447$, $\Delta = 0.003$ and $a = 4.2\,\mu\mathrm{m}$ giving $V = 2.958/\lambda_0$, where λ_0 is measured in $\mu\mathrm{m}$. Thus for $\lambda_0 > 1.23\,\mu\mathrm{m}$, the fiber will be single-mode. The wavelength for which $V = 2.4045$ is known as the *cut-off wavelength* and is denoted by λ_c. In this example, $\lambda_\mathrm{c} = 1.23\,\mu\mathrm{m}$.

For a single-mode step-index fiber, a convenient empirical formula for $b(V)$ is given by

$$b(V) = \left(A - \frac{B}{V}\right)^2 \; ; \quad 1.5 \lesssim V \lesssim 2.5 \, , \tag{14.20}$$

where $A \approx 1.1428$ and $B \approx 0.996$.

14.5.1 Spot Size of the Fundamental Mode

The transverse field distribution associated with the fundamental mode (LP_{01} mode) of a single-mode fiber is an extremely important quantity and it determines various important parameters like splice loss at joints between fibers, launching efficiencies from sources, bending loss, etc. For a step-index fiber one has analytical expression for the fundamental field distribution in terms of Bessel functions. For most single-mode fibers with a general transverse refractive index profile, the fundamental mode field distributions can be well approximated by a Gaussian function, which may be written in the form

$$\psi(x, y) = A\, e^{-\frac{x^2+y^2}{w^2}} = A\, e^{-\frac{r^2}{w^2}} \, , \tag{14.21}$$

where w is referred to as the spot size of the mode field pattern and $2w$ is called the mode field diameter (MFD). MFD is a very important characteristic of a single-mode optical fiber. For a step-index fiber one has the following empirical expression for w [14.9]

$$\frac{w}{a} \approx 0.65 + \frac{1.619}{V^{3/2}} + \frac{2.879}{V^6} \; ; \quad 0.8 \le V \le 2.5 \, , \tag{14.22}$$

where a is the core radius. As an example, for the step-index fiber considered earlier and operating at 1300 nm we have $V \approx 2.28$ giving $w \approx 4.8\,\mu$m. Note that the spot size is larger than the core radius of the fiber; this is due to the penetration of the modal field into the cladding of the fiber. The same fiber will have a V value of 1.908 at $\lambda_0 = 1550$ nm giving a value of the spot size $\approx 5.5\,\mu$m. Thus, in general, the spot size increases with wavelength. The standard single-mode fiber designated as G.652 fiber for operation at 1310 nm has an MFD of $9.2 \pm 0.4\,\mu$m and an MFD of $10.4 \pm 0.8\,\mu$m at 1550 nm.

For $V \ge 10$, the number of modes (for a step-index fiber) is approximately $\frac{1}{2}V^2$ and the fiber is said to be a multimoded fiber. Different modes (in a multimoded fiber) travel with different group velocities, leading to what is known as intermodal dispersion; in the language of ray optics, this is known as ray dispersion arising due to the fact that different rays take different amounts of time in propagating through the fiber. Indeed in a highly multimoded fiber, we can use ray optics to calculate pulse dispersion.

14.6 Ray Analysis of a Multimode Optical Fiber

A broad class of graded-index fibers can be described by the following refractive index distribution

$$\begin{aligned} n^2(r) &= n_1^2 \left[1 - 2\Delta \left(\frac{r}{a}\right)^q\right] \, , \quad 0 < r < a \, , \\ &= n_2^2 = n_1^2 (1 - 2\Delta) \, , \quad r > a \, , \end{aligned} \tag{14.23}$$

where r corresponds to a cylindrical radial coordinate, n_1 represents the value of the refractive index on the axis (i. e., at $r = 0$), and n_2 represents the refractive index of the cladding; $q = 1$, $q = 2$ and $q = \infty$ correspond to the linear, parabolic, and step-index profiles, respectively (Fig. 14.4). Equation (14.23) describes what is usually referred to as a power law profile, which gives an accurate description of the refractive index variation in most fibers. The total number of modes in a highly multimoded graded-index optical fiber characterized by (14.23) is approximately given by

$$N \approx \frac{q}{2(2+q)} V^2 \, . \tag{14.24}$$

Thus, a parabolic index ($q = 2$) fiber with $V = 10$ will support approximately 25 modes. Similarly, a step index ($q = \infty$) fiber with $V = 10$ will support approximately 50 modes. When the fiber supports such a large number of modes, then using of ray (or geometric optics) gives very accurate results. In this section we will use ray optics to obtain the propagation characteristics of a multimode graded-index fiber.

In homogeneous media the refractive index n is constant and light rays travel along straight lines. However in graded index media, in which n depends on the spatial coordinates, light rays propagate along curved paths. For the sake of simplicity, we assume that the refractive index varies only along the x-direction; such a medium can be thought of as a limiting case of a medium consisting of a continuous set of thin slices of media of different refractive indices (Fig. 14.7a). At each interface, the light ray satisfies Snell's law and one

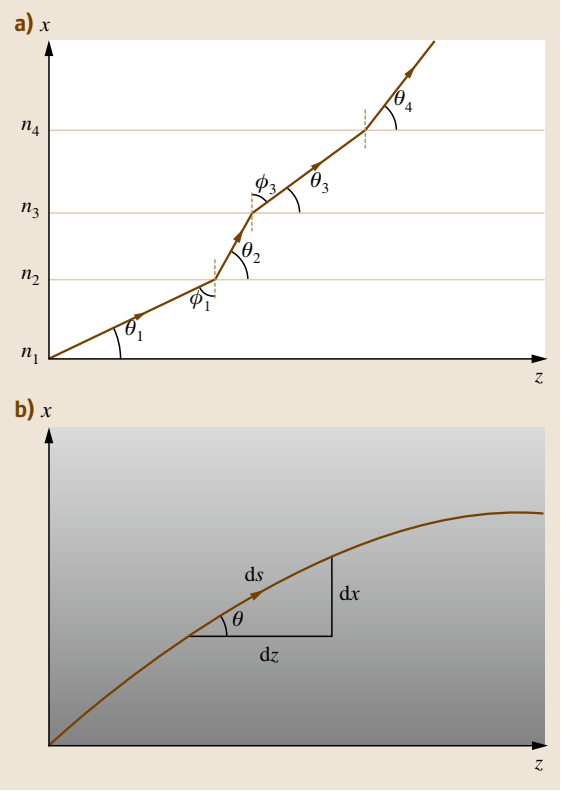

Fig. 14.7 **(a)** In a layered structure, the ray bends in such a way that the product $n_i \cos\theta_i$ remains constant. **(b)** In a medium with continuously varying refractive index, the ray path bends in such a way that the product $n(x)\cos\theta(x)$ remains constant

obtains (Fig. 14.7a)

$$n_1 \sin\phi_1 = n_2 \sin\phi_2 = n_3 \sin\phi_3 = \ldots$$

Thus, we may state that the product

$$n(x)\cos\theta(x) = n(x)\sin\phi(x) \qquad (14.25)$$

is an invariant of the ray path; we will denote this invariant by $\tilde{\beta}$. In (14.25), $\theta(x)$ is the angle that the ray makes with the z-axis. The value of the invariant $\tilde{\beta}$ may be determined from the fact that if the ray initially makes an angle θ_1 (with the z-axis) at a point where the refractive index is n_1, then the value of $\tilde{\beta}$ is $n_1 \cos\theta_1$. Thus, in the limiting case of a continuous variation of the refractive index, the piecewise straight lines shown in Fig. 14.7a form a continuous curve, which is determined from the equation

$$n(x)\cos\theta(x) = n_1 \cos\theta_1 = \tilde{\beta}\,, \qquad (14.26)$$

implying that as the refractive index changes, the ray path bends in such a way that the product $n(x)\cos\theta(x)$ remains constant. Equation (14.26) can be used to derive the ray equation; if $\mathrm{d}s$ represents the infinitesimal arc length along the curve (Fig. 14.7b), then

$$(\mathrm{d}s)^2 = (\mathrm{d}x)^2 + (\mathrm{d}z)^2$$

or

$$\left(\frac{\mathrm{d}s}{\mathrm{d}z}\right)^2 = \left(\frac{\mathrm{d}x}{\mathrm{d}z}\right)^2 + 1\,. \qquad (14.27)$$

Now, if we refer to Fig. 14.7b, we find that

$$\frac{\mathrm{d}z}{\mathrm{d}s} = \cos\theta = \frac{\tilde{\beta}}{n(x)}\,. \qquad (14.28)$$

Thus, (14.27) becomes

$$\left(\frac{\mathrm{d}x}{\mathrm{d}z}\right)^2 = \frac{n^2(x)}{\tilde{\beta}^2} - 1\,. \qquad (14.29)$$

For a given $n(x)$ variation, (14.29) can be integrated to give the ray path $x(z)$; however, it is often more convenient to cast (14.29) in a slightly different form by differentiating it with respect to z to obtain

$$\frac{\mathrm{d}^2x}{\mathrm{d}z^2} = \frac{1}{2\tilde{\beta}^2}\frac{\mathrm{d}n^2}{\mathrm{d}x}\,, \qquad (14.30)$$

which represents the rigorously correct ray equation when the refractive index depends only on the x-coordinate. Thus, in a homogeneous medium for which $n(x)$ is a constant, the ray paths are straight lines. In a parabolic index medium characterized by refractive index distribution

$$\begin{aligned} n^2(r) &= n_1^2\left[1 - 2\Delta\left(\frac{x}{a}\right)^2\right]\,; \quad |x| < a\,, \\ &= n_2^2 = n_1^2(1-2\Delta)\,; \quad |x| > a\,. \end{aligned} \qquad (14.31)$$

In the core of the waveguide, the ray paths (as obtained by solving (14.30)) will be given by

$$x = \pm x_0 \sin[\Gamma(z - z_0)]\,. \qquad (14.32)$$

We can always choose the origin such that $z_0 = 0$ so that the general ray path would be given by

$$x = \pm x_0 \sin\Gamma z\,, \qquad (14.33)$$

where

$$x_0 = \frac{1}{\gamma}\sqrt{n_1^2 - \tilde{\beta}^2}\,; \quad \gamma = \frac{n_1\sqrt{2\Delta}}{a} \qquad (14.34a)$$

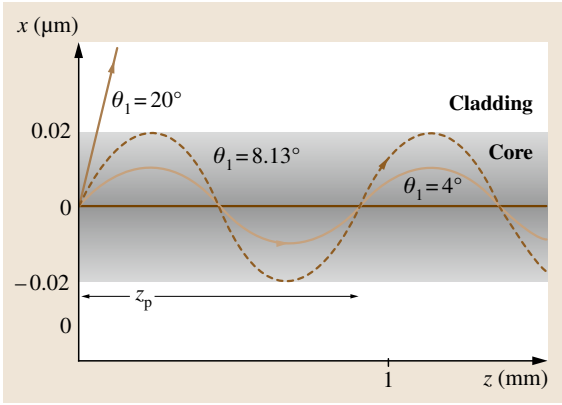

Fig. 14.8 Typical ray paths in a parabolic index medium for parameters given by (14.35) for $\theta_1 = 4$, 8.13 and 20°

and

$$\Gamma = \frac{\gamma}{\tilde{\beta}} = \frac{n_1\sqrt{2\Delta}}{a\tilde{\beta}} \,. \tag{14.34b}$$

Figure 14.8 shows typical ray paths corresponding to

$$n_1 = 1.5\,, \quad \Delta = 0.01 \quad \text{and} \quad a = 20\,\mu\text{m} \tag{14.35}$$

for different values of $\tilde{\beta}$. Obviously for the rays to be guided in the fiber we must have

$$n_2 < \tilde{\beta} < n_1 \quad \text{(guided rays)}\,. \tag{14.36}$$

Now, the path of rays in a medium having a general refractive index variation given by $n(x, y, z)$ is described by the ray equation [14.10]

$$\frac{\mathrm{d}}{\mathrm{d}s}\left(n\frac{\mathrm{d}\mathbf{r}}{\mathrm{d}s}\right) = \nabla n\,, \tag{14.37}$$

where $\mathrm{d}s$ is the arc length along the ray and is given by

$$\mathrm{d}s = \sqrt{1 + \left(\frac{\mathrm{d}x}{\mathrm{d}z}\right)^2 + \left(\frac{\mathrm{d}y}{\mathrm{d}z}\right)^2}\,. \tag{14.38}$$

For a given refractive index distribution, the solution of the ray equation will give us the path of rays in that medium. In an optical fiber, the refractive index depends only on the r-coordinate, and hence the z-component of (14.37) gives us

$$\frac{\mathrm{d}}{\mathrm{d}s}\left(n\frac{\mathrm{d}z}{\mathrm{d}s}\right) = \frac{\partial n}{\partial z} = 0\,.$$

Thus,

$$n\frac{\mathrm{d}z}{\mathrm{d}s} = n(r)\cos\theta = \text{a constant} = \tilde{\beta}\,, \tag{14.39}$$

where θ is the angle of the ray with the z-axis. Equation (14.39) is often referred to as the *generalized Snell's law*. For a parabolic index fiber ($q = 2$), meridional rays (in the $x-z$ plane) would be given by (14.32).

Using (14.39), the x- and y-components of (14.37) give us

$$\begin{aligned}\frac{\mathrm{d}^2x}{\mathrm{d}z^2} &= \frac{1}{2\tilde{\beta}^2}\frac{\partial n^2}{\partial x}\,,\\ \frac{\mathrm{d}^2y}{\mathrm{d}z^2} &= \frac{1}{2\tilde{\beta}^2}\frac{\partial n^2}{\partial y}\,,\end{aligned} \tag{14.40}$$

which are rigorously correct equations for n^2 independent of z. For a given $n^2(x, y)$, (14.40) can be solved to obtain the ray paths through the fiber.

For a parabolic index fiber given by (14.23) with $q = 2$, (14.40) can be solved exactly and we obtain the ray paths as

$$\begin{aligned}x(z) &= A\sin\Gamma z + B\cos\Gamma z\,,\\ y(z) &= C\sin\Gamma z + D\cos\Gamma z\,,\end{aligned} \tag{14.41}$$

where Γ is defined in (14.34b) and A, B, C, and D are constants to be determined from the initial launch conditions of the ray.

14.7 Pulse Dispersion in Optical Fibers

In digital communication systems, information to be sent is first coded in the form of pulses and then these pulses of light are transmitted from the transmitter to the receiver where the information is decoded. The larger the number of pulses that can be sent per unit time and still be resolvable at the receiver end, the larger the transmission capacity of the system. A pulse of light sent into a fiber broadens in time as it propagates through the fiber; this phenomenon is known as pulse dispersion and occurs primarily because of the following four mechanisms:

1. In multimode fibers, dispersion is caused by different rays taking different times to propagate through a given length of the fiber. In the language of wave optics, this is known as *intermodal dispersion* be-

cause it arises due to different modes traveling with different group velocities.
2. Any given light source emits over a range of wavelengths and, because of the dependence of the refractive index on wavelength, different wavelengths take different amounts of time to propagate along the same path. This is known as material dispersion and, obviously, it is present in both single-mode and multimode fibers.
3. In single-mode fibers since there is only one mode there is no intermodal dispersion. However, apart from material dispersion, we have what is known as waveguide dispersion. Physically, this arises due to the fact that the spot size (of the fundamental mode) depends explicitly on the wavelength.
4. A single-mode fiber can support two orthogonally polarized LP_{01} modes. In a perfectly circular core fiber laid along a perfectly straight path, the two polarizations propagate with the same velocity. However, due to small random deviations from circularity of the core or due to random bends and twists present in the fiber, the orthogonal polarizations travel with slightly different velocities and are coupled randomly along the length of the fiber. This phenomenon leads to polarization mode dispersion (PMD), which becomes important for high-speed communication systems operating at 40 Gb/s and higher.

Obviously, waveguide dispersion and polarization mode dispersion are present in multimode fibers also, however, the effects are very small and can be neglected.

14.7.1 Ray Dispersion for a Power Law Profile

In this subsection, we will assume multimode fibers and use geometric optics to calculate ray dispersion. For the power law profile (14.23), it is possible to calculate the pulse broadening due to the fact that different rays take different amounts of time in traversing a certain length of the fiber; in the language of wave optics, this implies that different modes travel with different group velocities (and hence ray dispersion is also referred to as intermodal dispersion). The time taken to propagate through a length z of a multimode fiber described by a q-profile (14.23) depends only on the parameter $\tilde{\beta}$ and is given by [14.6, 11]

$$\tau(\tilde{\beta}) = \left(A\tilde{\beta} + \frac{B}{\tilde{\beta}}\right) z \,, \tag{14.42}$$

where

$$A = \frac{2}{c(2+q)}; \; B = \frac{q n_1^2}{c(2+q)} \,. \tag{14.43}$$

For rays to be guided in the fiber $n_2 < \tilde{\beta} < n_1$. For example, for a step-index fiber ($q = \infty$)

$$\tau(\tilde{\beta}) = \frac{n_1^2}{c\tilde{\beta}} z \,.$$

Thus,

$$\tau_{\max} = \tau(\tilde{\beta} = n_2) = \frac{n_1^2}{c n_2} z$$

and

$$\tau_{\min} = \tau(\tilde{\beta} = n_1) = \frac{z}{c/n_1} \,.$$

Thus, the ray dispersion in a step-index fiber is given by

$$\begin{aligned} \Delta\tau = \tau_{\max} - \tau_{\min} &= \frac{n_1}{c}\frac{(n_1 - n_2)}{n_2} z \\ &\approx \frac{n_1 \Delta}{c} z \,. \end{aligned} \tag{14.44}$$

Thus, for $n_1 = 1.46$, $\Delta = 0.01$, the ray dispersion would be 50 ns/km.

Similarly, for a parabolic index fiber ($q = 2$) and

$$\tau(\tilde{\beta}) = \frac{1}{2c}\left(\tilde{\beta} + \frac{n_1^2}{\tilde{\beta}}\right) z \,. \tag{14.45}$$

Thus

$$\tau_{\max} = \tau(\tilde{\beta} = n_2) = \frac{1}{2c}\left(n_2 + \frac{n_1^2}{n_2}\right) z$$

and

$$\tau_{\min} = \tau(\tilde{\beta} = n_1) = \frac{z}{c/n_1}$$

and the ray dispersion in a parabolic-index fiber is given by

$$\Delta\tau = \tau_{\max} - \tau_{\min} = \frac{n_2 \Delta^2}{2c} z \,. \tag{14.46}$$

For $n_1 = 1.46$, $\Delta = 0.01$, the ray dispersion would be about 0.24 ns/km. Thus, we find that for a parabolic index fiber the intermodal (or ray) dispersion is reduced by a factor of about 200 in comparison to the step-index fiber. It is for this reason that parabolic index fibers were used in early fiber-optic communication systems and are still used in many multimode fiber communication stems. Physically, although the ray (corresponding

to $\theta_1 = 8.13°$ in Fig. 14.8) traverses a larger path in comparison to the straight line path along the z-axis, it does so in a medium of *lower average refractive index*; thus the greater path length is compensated for by a greater *average speed* and hence *all* rays take almost same time to propagate through a certain distance of the waveguide.

The optimum profile leading to minimum pulse dispersion corresponds to $q \approx 2 - 2\Delta$ and the pulse dispersion is given by

$$\Delta\tau \approx \frac{n_1 \Delta^2}{8c} z \,. \tag{14.47}$$

14.7.2 Material Dispersion

Consider a plane wave propagating along the $+z$-direction in a homogenous medium, then

$$E(z,t) = A\,\mathrm{e}^{\mathrm{i}(\omega t - kz)} \,. \tag{14.48}$$

If the wave is propagating in a medium characterized by the refractive index variation $n(\omega)$, then

$$k(\omega) = \frac{\omega}{c} n(\omega) \,. \tag{14.49}$$

The phase velocity of the wave is given by

$$v_\mathrm{p} = \frac{\omega}{k} \,. \tag{14.50}$$

A temporal pulse travels with the group velocity given by

$$v_\mathrm{g} = \frac{1}{\mathrm{d}k/\mathrm{d}\omega} \,. \tag{14.51}$$

Thus,

$$\frac{1}{v_\mathrm{g}} = \frac{\mathrm{d}k}{\mathrm{d}\omega} = \frac{1}{c}\left[n(\omega) + \omega\frac{\mathrm{d}n}{\mathrm{d}\omega}\right] \,. \tag{14.52}$$

In free space, $n(\omega) = 1$ at all frequencies; hence

$$v_\mathrm{g} = v_\mathrm{p} = c \,. \tag{14.53}$$

Since

$$\omega = \frac{2\pi c}{\lambda_0} \tag{14.54}$$

we get

$$\frac{1}{v_\mathrm{g}} = \frac{1}{c}\left[n(\lambda_0) - \lambda_0\frac{\mathrm{d}n}{\mathrm{d}\lambda_0}\right] \tag{14.55}$$

and the time taken by a pulse to traverse a length L of the dispersive medium is given by

$$\tau = \frac{L}{v_\mathrm{g}} = \frac{L}{c}\left[n(\lambda_0) - \lambda_0\frac{\mathrm{d}n}{\mathrm{d}\lambda_0}\right] \,. \tag{14.56}$$

For a source having a spectral width of $\Delta\lambda_0$, the temporal broadening of a pulse will, therefore, be given by

$$\Delta\tau_\mathrm{m} = \frac{\mathrm{d}\tau}{\mathrm{d}\lambda_0}\Delta\lambda_0 = -\frac{L\Delta\lambda_0}{\lambda_0 c}\left(\lambda_0^2\frac{\mathrm{d}^2 n}{\mathrm{d}\lambda_0^2}\right) \,. \tag{14.57}$$

The quantity $\Delta\tau_\mathrm{m}$ is usually referred to as material dispersion because it is due to the material properties of the medium – hence the subscript m. Indeed, after propagating through a length L of the dispersive medium, a pulse of temporal width τ_0 will become broadened to τ_f where

$$\tau_\mathrm{f}^2 = \tau_0^2 + (\Delta\tau_\mathrm{m})^2 \,. \tag{14.58}$$

The material dispersion coefficient (which is measured in ps/(km nm), km, length of the fiber; nm, spectral width of the source) is given by

$$D_\mathrm{m} = \frac{\Delta\tau_\mathrm{m}}{L\Delta\lambda_0} = -\frac{10^4}{3\lambda_0}\left(\lambda_0^2\frac{\mathrm{d}^2 n}{\mathrm{d}\lambda_0^2}\right) \text{ ps/(km nm)}$$

(material dispersion coefficient) , (14.59)

where we have used $c \approx 3\times10^8$ m/s $= 3\times10^{-7}$ km/ps and λ_0 in (14.59) is measured in μm and the quantity inside the parentheses is dimensionless. The quantity D_m is usually referred to as the material dispersion coefficient (because it is due to the material properties of the medium) and hence the subscript m on D; it is tabulated (for pure silica) in Table 14.1.

At a particular wavelength, the value of D_m is a characteristic of the material and is (almost) the same for *all* silica fibers. When D_m is negative, it implies that the longer wavelengths travel faster; this is referred to as normal group velocity dispersion (GVD). Similarly, a positive value of D_m implies that shorter wavelengths travel faster; this is referred to as anomalous GVD.

The spectral width $\Delta\lambda_0$ of an LED operating around $\lambda_0 = 825$ nm is about 20 nm; at this wavelength for pure silica $D_\mathrm{m} \approx 84.2$ ps/(km nm). Thus, a pulse will broaden by 1.7 ns/km of fiber. It is interesting to note that for operation around $\lambda_0 \approx 1300$ nm (where $D_\mathrm{m} \approx 2.4$ ps/(km nm)), the resulting material dispersion is only 50 ps/km of the fiber. The very small value of $\Delta\tau_\mathrm{m}$ is due to the fact that the group velocity is approximately constant around $\lambda_0 = 1300$ nm. Indeed, the wavelength $\lambda_0 = 1270$ nm is usually referred to as the zero material dispersion wavelength, and it is because of such low material dispersion that the optical communication systems shifted their operation to around $\lambda_0 = 1300$ nm.

Optical communication systems in operation today use LDs (laser diodes) with $\lambda_0 \approx 1550$ nm having a spectral width of about 2 nm. At this wavelength the material dispersion coefficient is 21.5 ps/(km nm) and the material dispersion $\Delta\tau_m$ would be about 43 ps/km.

14.7.3 Dispersion and Bit Rates in Multimode Fibers

In multimode fibers the total dispersion consists of intermodal dispersion ($\Delta\tau_i$) and material dispersion ($\Delta\tau_m$) and is given by

$$\Delta\tau = \sqrt{(\Delta\tau_i)^2 + (\Delta\tau_m)^2}\,. \qquad (14.60)$$

In one type of extensively used coding referred to as NRZ (nonreturn to zero) the maximum permissible bit rate is approximately given by

$$B_{max} \approx \frac{0.7}{\Delta\tau}\,. \qquad (14.61)$$

Operation around 1310 nm minimizes $\Delta\tau_m$ and hence almost all multimode fiber systems operate at this wavelength region with optimum refractive index profiles having small values of $\Delta\tau_i$.

As an example, we consider a parabolic index multimode fiber with $n_1 \approx 1.46$, $\Delta \approx 0.01$ operating at 850 nm with an LED of spectral width 20 nm. For such a fiber, the ray dispersion (as calculated in Sect. 14.7.1) is about 0.24 ns/km. If the source is an LED with $\Delta\lambda_0 = 20$ nm, then using Table 14.1, the material dispersion $\Delta\tau_m$ is 1.7 ns/km. Thus, the total dispersion will be

$$\Delta\tau = \sqrt{(\Delta\tau_i)^2 + (\Delta\tau_m)^2} = \sqrt{0.24^2 + 1.7^2} = 1.72\,\text{ns/km}\,.$$

Using (14.61), this gives a maximum bit rate of about 400 (Mbit km)/s, giving a maximum permissible bit rate of 20 Mbit/s for a 20 km link. If we now shift the wavelength of operation to 1300 nm and use the same parabolic index fiber, we can see that the ray dispersion remains the same as 0.24 ns/km, while the material dispersion (for an LED of $\Delta\lambda_0 = 20$ nm) becomes 0.05 ns/km. The material dispersion is now negligible in comparison to ray dispersion. Thus, the total dispersion and maximum bit rate are, respectively, given by

$$\Delta\tau = \sqrt{0.24^2 + 0.05^2} \approx 0.25\,\text{ns/km} \Rightarrow B_{max} \approx 2.8\,(\text{Gbit km/s})\,.$$

In the examples discussed, the maximum bit rate has been estimated by considering the fiber only. In an

actual link, the temporal response of the source and detector must also be taken into account.

We end this section by mentioning that around 1977, we had the first-generation optical communication systems which used graded-index multimode fibers, and the source used was the LED operating at 850 nm wavelength; the loss was ≈ 3 dB/km, the repeater spacing was ≈ 10 km, and the bit rate was ≈ 45 Mbit/s. Around 1981, we had the second-generation optical communication systems which again used graded-index multimode fibers but now operating at 1300 nm wavelength (so that the material dispersion was very small); the bit rate was almost the same (≈ 45 Mbit/s), but since the loss was ≈ 1 dB/km and the dispersion was also less, the repeater spacing increased to ≈ 30 km.

14.7.4 Dispersion in Single-Mode Fibers

In the case of a single-mode optical fiber, the effective index n_{eff} ($\equiv \beta/k_0$) of the mode depends on the core and cladding refractive indices as well as the waveguide parameters (refractive index profile and radii of various regions). In fact, the total dispersion is given by (14.57)

$$\Delta\tau_{\text{total}} = -\frac{L\Delta\lambda_0}{\lambda_0 c}\left(\lambda_0^2\frac{\mathrm{d}^2 n_{\text{eff}}}{\mathrm{d}\lambda_0^2}\right) . \qquad (14.62)$$

Now, n_{eff} would vary with wavelength even if the core and cladding media were assumed to be dispersionless (i. e., the refractive indices of core and cladding are assumed to be independent of wavelength). This dependence of effective index on wavelength is due to the wave-guidance mechanism and leads to what is referred to as *waveguide dispersion*. Waveguide dispersion can be understood from the fact that the effective index of the mode depends on the fraction of power in the core and the cladding at a particular wavelength. As the wavelength changes, this fraction also changes. Thus, even if the refractive indices of the core and the cladding are assumed to be independent of wavelength, the effective index will change with the wavelength. It is this explicit dependence of $n_{\text{eff}}(\lambda_0)$ on λ_0 that leads to waveguide dispersion.

The normalized propagation constant b depends only on V, and assuming since $\Delta \ll 1$, we have

$$b = \frac{n_{\text{eff}}^2 - n_2^2}{n_1^2 - n_2^2} \approx \frac{n_{\text{eff}} - n_2}{n_1 - n_2}$$

and hence

$$\frac{\beta}{k_0}(= n_{\text{eff}}) \approx n_2 + b(n_1 - n_2) .$$

Differentiating the above equation with respect to wavelength and neglecting the wavelength dependence of $(n_1 - n_2)$ we obtain

$$D_{\text{T}} = D_{\text{m}} + D_{\text{w}} ,$$

where

$$D_{\text{w}} = -\frac{n_2\Delta}{c\lambda_0}\left(V\frac{\mathrm{d}^2(bV)}{\mathrm{d}V^2}\right) . \qquad (14.63)$$

A simple empirical expression for waveguide dispersion for step-index fibers is

$$D_{\text{w}} = -\frac{n_2\Delta}{3\lambda_0}\times 10^7[0.080 + 0.549(2.834 - V)^2]$$
$$\text{ps/(km nm)} \quad (1.3 \le V \le 2.2) , \qquad (14.64)$$

where λ_0 is measured in nanometers.

Thus, the total dispersion in the case of a single-mode optical fiber can be attributed to two types of dispersion, namely material dispersion and waveguide dispersion. Indeed, it can be shown that the total dispersion coefficient D_{T} is given to a good accuracy by the sum of material (D_{m}) and waveguide (D_{w}) dispersion coefficients [14.13].

In the single-mode regime, the quantity within the parentheses in (14.63) is usually positive; hence, the waveguide dispersion is negative. Since the sign of material dispersion depends on the operating wavelength region, it is possible that the two effects, namely, material and waveguide dispersions cancel each other at a certain wavelength (Fig. 14.9). Such a wavelength, which is a very important parameter of single-mode

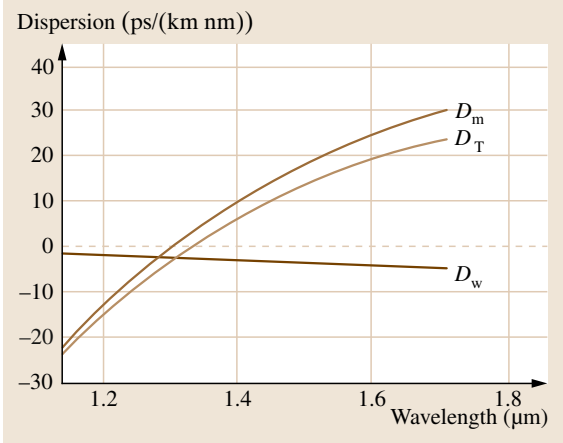

Fig. 14.9 Variation of material (D_{m}), waveguide (D_{w}), and total dispersion (D_{T}) with wavelength for a standard single-mode fiber

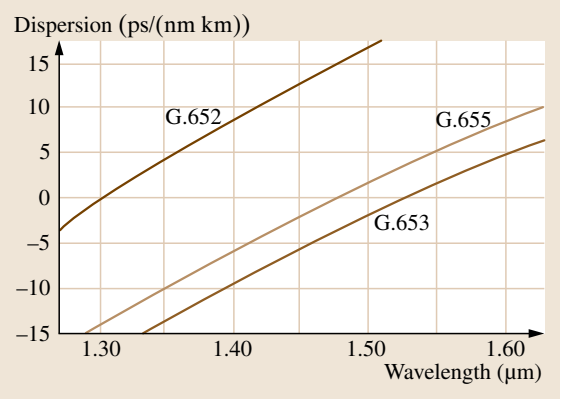

Fig. 14.10 Variation of total dispersion for three types of standard single-mode fibers

Table 14.2 Values of dispersion and dispersion slope for some standard fibers at 1550 nm (after [14.14])

Fiber type	D (ps/(km nm))	S (ps/(km nm^2))
Standard SMF (G.652)	17	0.058
LEAF (Corning)	4.2	0.085
Truewave-reduced slope (OFS)	4.5	0.045
TeraLight (Alcatel)	8.0	0.057

fibers, is referred to as zero-dispersion wavelength (λ_{ZD}). For typical step-index fibers, zero dispersion wavelength falls in the 1310 nm wavelength window. Since the lowest loss in an optical fiber occurs at a wavelength of 1550 nm, and optical amplifiers are available in the 1550 nm window, fiber designs can be modified to shift the zero dispersion wavelength to the 1550 nm wavelength window. Such fibers are referred to as dispersion shifted fibers (with zero dispersion around 1550 nm) or nonzero dispersion shifted fibers (with finite but small dispersion around 1550 nm). With proper fiber refractive index profile design it is also possible to have a flat dispersion spectrum leading to dispersion flattened designs. Figure 14.9 gives the spectral variations of a standard SMF (with zero dispersion close to 1310 nm), while Fig. 14.10 shows the total dispersion in three standard types of fibers, namely G.652, G.653, and G.655 fibers, also referred to as conventional single-mode fibers, dispersion shifted fibers (DSF), and nonzero dispersion shifted fibers (NZ-DSF). G.655 fibers have a small but finite dispersion around the 1550 nm wavelength. The small dispersion is required to avoid four-wave mixing.

It appears that when an optical fiber is operated at the zero dispersion wavelength, the pulses will not suffer any dispersion at all. In fact, zero dispersion only signifies that the second-order dispersive effects are absent. In this case, the next higher order dispersion, namely third-order dispersion characterized by $d^3\beta/d\omega^3$, will become the dominating term in determining the dispersion. Thus in the absence of second-order dispersion, we can write for dispersion suffered by a pulse

$$\Delta\tau = \frac{L(\Delta\lambda_0)^2}{2}\frac{dD}{d\lambda_0}\,, \tag{14.65}$$

where $S = dD/d\lambda_0$ represents the dispersion slope at zero dispersion wavelength and is measured in units of ps/(km nm^2). Third-order dispersion becomes important when operating close to the zero-dispersion wavelength. In the presence of only third-order dispersion, the pulse does not remain symmetric. Table 14.2 lists values of D and S for some standard fibers at 1550 nm.

14.7.5 Dispersion and Maximum Bit Rate in Single-Mode Fibers

In a digital communication system employing light pulses, pulse broadening would result in an overlap of adjacent pulses, resulting in inter symbol interference leading to errors in detection. Apart from this, since the energy in the pulse is reduced within the time slot, the corresponding signal to noise ratio (SNR) will decrease. One can offset this by increasing the power in the pulses. This additional power requirement is termed *dispersion power penalty*. Increased dispersion would imply increased power penalty.

In order to keep the interference between adjacent bits below a specified level, the root mean square width of the dispersed pulse needs to be kept below a certain fraction ε of the bit period. For a 2 dB power penalty, $\varepsilon \approx 0.491$ [14.15]. Using this condition we can estimate the maximum bit rate B for a given link length L and dispersion coefficient D operating at 1550 nm as

$$B^2DL < 1.9\times10^5\ \text{Gb}^2\,\text{ps/nm}\,, \tag{14.66}$$

where B is measured in Gb/s, D in ps/(km nm) and L in km. Thus, for a bit rate of 2.5 Gb/s the maximum allowed dispersion (DL) is approximately 30 400 ps/nm, while for a bit rate of 10 Gb/s the maximum allowed dispersion is 1900 ps/nm.

14.7.6 Dispersion Compensating Fibers

There already exist millions of kilometers of conventional single-mode fibers in underground ducts operating at 1310 nm and these fibers have very low dispersion at the operating wavelength. One could significantly increase the transmission capacity of these systems by operating these fibers at 1550 nm (where the loss is extremely small), and we can have the added advantage of using EDFA (erbium-doped fiber amplifiers) for optical amplification in this wavelength range. However, if we operate conventional single-mode fibers at 1550 nm, we will have a significant residual dispersion of about 17 ps/(km nm). Such a large dispersion would result in significant decrease in the information carrying capacity of the communication system. On the other hand, replacing the existing conventional single-mode fibers by lower dispersion fibers would involve huge costs. As such, in recent years there has been a considerable amount of work in upgrading the installed 1310 nm optimized optical fiber links for operation at 1550 nm. This is achieved by developing fibers with very large negative dispersion coefficients, a few hundred meters to a kilometer of which can be used to compensate for dispersion accumulated over tens of kilometers of the fiber in the link.

By changing the refractive index profile, we can alter the waveguide dispersion and hence the total dispersion. Indeed, it is possible to have specially designed fibers whose dispersion coefficient (D) is large and negative at 1550 nm. These types of fibers are known as dispersion compensating fibers (DCFs). A short length of DCF can be used in conjunction with the 1310 nm optimized fiber link so as to have small total dispersion value at the end of the link. There are a number of different fiber designs with optimized refractive index profiles that have an extremely large negative dispersion coefficient and a small length of which can compensate for the accumulated dispersion of a link. Some of the important ones include depressed clad designs, W-type fiber designs, dual core coaxial designs, etc. [14.16–19].

If $D_T(\lambda_n)$ and L_T represent the dispersion coefficient and length of the transmission fiber and $D_C(\lambda_n)$ and L_C represent the corresponding quantities of the DCF, then for achieving zero net dispersion at a chosen wavelength λ_n we must have

$$D_T(\lambda_n)L_T + D_C(\lambda_n)L_C = 0\,. \tag{14.67}$$

Hence, for given values of $D_T(\lambda_n)$, L_T, and $D_C(\lambda_n)$, the length of the DCF required is given by (14.67) showing that $D_C(\lambda_n)$ and $D_T(\lambda_n)$ should have opposite signs. Also, the larger the value of $D_C(\lambda_n)$, the smaller the length of the required DCF. Since the wavelength dependence of dispersion of the link fiber and the dispersion compensating fiber are in general different, in general, the DCF would compensate for dispersion only at the design wavelength. However, in a wavelength division multiplexed system it is necessary to compensate for the accumulated dispersion of all the wavelength channels simultaneously. For this to happen we must have

$$\frac{1}{D_T(\lambda_n)}\left.\frac{\mathrm{d}D_T(\lambda)}{\mathrm{d}\lambda}\right|_{\lambda=\lambda_n} = \frac{1}{D_c(\lambda_n)}\left.\frac{\mathrm{d}D_c(\lambda)}{\mathrm{d}\lambda}\right|_{\lambda=\lambda_n}, \tag{14.68}$$

which implies that the relative dispersion slope (RDS), which is the ratio of the dispersion slope (S) and dispersion coefficient (D) of the two fibers evaluated at the wavelength λ_n, must be equal. Typically RDS of the G.652 fiber is about 0.0034 nm^{-1}, while that of the large effective area fiber (LEAF) from Corning is about 0.0202 nm^{-1}. DCFs with similar RDS values are commercially available.

14.7.7 Polarization Mode Dispersion (PMD)

A perfectly circular single-mode fiber actually supports two orthogonally polarized modes with equal propagation constant. When such a fiber is laid along a perfect straight path, the two orthogonally polarized fundamental modes of the fiber have identical group velocities, and any pulse launched into the fiber undergoes dispersion only due to material dispersion and waveguide dispersion effects. However, in actual fibers, there is always a very small ellipticity of the fiber cores, or there are nonsymmetric strains in the fiber, or the fibers have bends and twists when laid in the link; this causes a difference of velocities between the two orthogonal polarized modes. This difference leads to the phenomenon of polarization mode dispersion. The effect of PMD is as if the fiber supported two modes with two different velocities; thus a pulse launched with some arbitrary polarization state would split into two pulses due to the two different velocities. Locally PMD is due to differential velocities of the two polarizations while globally it is combined with random polarization coupling along the fiber length. Since the fiber property as well as the external perturbation is random along the length of the fiber, this effect is a random phenomenon. Due to the random nature, the PMD effect increases as

the square root of length rather than as length. PMD is usually measured in terms of the quantity of differential group delay (DGD) between the two polarizations. In order that PMD does not cause increased bit error rates, the DGD should be less than 10% of the bit period. Thus, for a 2.5 Gb/s system which consists of pulses of duration 400 ps, the maximum allowed PMD is 40 ps and for a 40 Gb/s system the maximum allowed PMD is only 2.5 ps. If the PMD of the fiber is 0.5 ps/km$^{0.5}$, then for a 40 Gb/s link the maximum length due to PMD effects will be 25 km. Thus PMD effects become extremely important for systems operating at high bit rates of typically 40 Gb/s and higher. Commercially available single-mode fibers typically have PMD of less than 0.2 ps/km$^{0.5}$. In an actual system, contribution to PMD also comes from other components used in the link, such as optical amplifiers, dispersion compensating elements, etc.

14.8 Fiber Gratings

When a germanium-doped silica core fiber is exposed to ultraviolet radiation (with a wavelength around 0.24 μm), the refractive index of the germanium-doped region increases; this is due to the phenomenon known as *photosensitivity* which was discovered by Kenneth Hill in 1974. The refractive index increase can be as large as 0.001 in the core of the fiber. If the fiber is exposed to a pair of interfering UV beams, then in regions of constructive interference, the refractive index increases while it does not change in regions of destructive interference. This results in a periodic variation of the refractive index along the length within the core of the fiber and is referred to as a fiber Bragg grating (FBG). The period of the grating can be controlled by appropriately choosing the angle between the interfering beams.

Optical fiber gratings that consist of a periodic modulation of the refractive index along the core of an optical fiber have very interesting spectral properties and are finding many applications in fiber optic communications and sensing. There are two main types of fiber gratings, namely FBGs and long period gratings (LPG). FBGs couple light from a forward propagating guided mode to a backward propagating guided mode in the fiber, while LPGs couple light from a guided mode to another guided mode or a cladding mode propagating along the same direction. The former corresponds to contra directional coupling while the latter to co-directional coupling. FBGs have periods of the order of half a micrometer for operation around the 1550 nm window, while LPGs have periods of a few hundred micrometers.

14.8.1 Fiber Bragg Gratings

If we consider a sinusoidal refractive index modulation with a period Λ within the *core of a single-mode optical fiber*, when a guided mode propagates through such a grating then the forward propagating mode can get strongly coupled to a backward propagating mode with the same effective index when the following Bragg condition is satisfied

$$\lambda_B = 2\Lambda n_{\text{eff}} , \tag{14.69}$$

where n_{eff} is the effective index of the propagating mode and λ_B is the Bragg wavelength. Such a periodic index modulation within the fiber is referred to as an FBG. Thus, when broadband light or a set of wavelengths are incident on an FBG, then only the wavelength corresponding to λ_B will be reflected; the other wavelengths are just transmitted to the output (Fig. 14.11).

Coupled-Mode Theory

One of the standard methods of analysis of FBG is using the coupled mode theory [14.6]. In this, the total field at any value of z is written as a superposition of the two interacting modes and the coupling process results in a z-dependent amplitude of the two coupled modes. If we represent the amplitudes of the forward and backward propagating modes (assumed to be modes of the same order) as $A(z)$ and $B(z)$, then we can derive the following coupled mode equations describing their variation with z [14.6] as

$$\frac{dA}{dz} = \kappa B e^{i\Gamma z} ,$$
$$\frac{dB}{dz} = \kappa A e^{-i\Gamma z} . \tag{14.70}$$

Here, $\Gamma = 2\beta - K$, where β represents the propagation constant of the modes, and $K = 2\pi/\Lambda$ represents the spatial frequency of the grating, which is described by the following refractive index variation

$$n_g^2(x, y, z) = n^2(x, y) + \Delta n^2(x, y) \sin(Kz) . \tag{14.71}$$

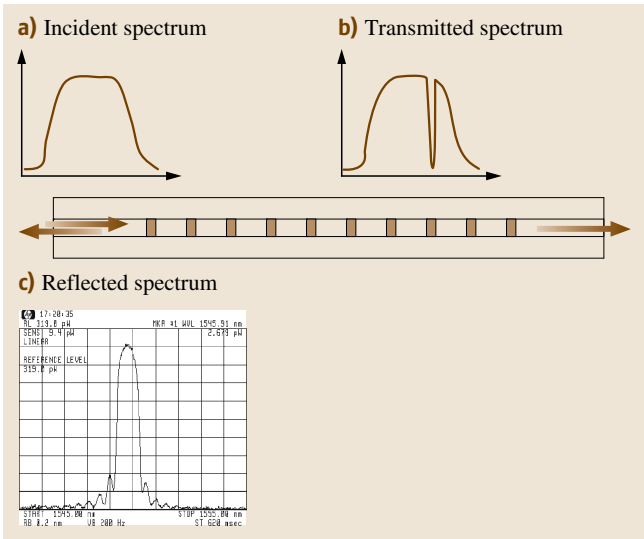

Fig. 14.11a–c The transmitted (a) and reflected (b) spectrum from an FBG. The reflected spectrum (c) is an actual measured spectrum

In (14.70), κ represents the coupling coefficient defined by

$$\kappa = \frac{\omega\varepsilon_0}{8} \iint \psi^* \Delta n^2(x, y)\psi \, \mathrm{d}x \, \mathrm{d}y \,, \tag{14.72}$$

where $\psi(x, y)$ represents the normalized transverse modal field distribution. If the perturbation in the refractive index is constant and finite only within the core of the fiber, we obtain the following simple expression for the coupling coefficient

$$\kappa \approx \frac{\pi \Delta n I}{\lambda_\mathrm{B}} \,, \tag{14.73}$$

where, under the Gaussian approximation with modal width w_0 the overlap integral I is given by [14.6]

$$\kappa \approx \frac{\pi \Delta n}{\lambda_\mathrm{B}} \left(1 - \mathrm{e}^{-(2a^2/w_0^2)}\right) \,, \tag{14.74}$$

where a is the core radius. If we assume that at the input of the grating $z = 0$, only the forward propagating mode is incident. Then the boundary conditions are $A(z = 0) = 1$ and $B(z = L) = 0$, where L is the length of the grating, and we obtain the following expression for the reflectivity of the grating

$$R = \frac{\kappa^2 \sinh^2(\Omega L)}{\Omega^2 \cosh^2(\Omega L) + \frac{\Gamma^2}{4} \sinh^2(\Omega L)} \,, \tag{14.75}$$

where

$$\Omega^2 = \kappa^2 - \frac{\Gamma^2}{4} \,. \tag{14.76}$$

For a given set of parameters, the reflection coefficient can be shown to be maximum when $\Gamma = 0$, i. e., $2\beta = K$, which implies (14.69), i. e., the Bragg condition. In such a case the reflection coefficient given by (14.75) becomes

$$R = \tanh^2 \kappa L \,. \tag{14.77}$$

Hence, as κL increases, the grating reflectivity increases and approaches unity (Fig. 14.12).

If $\Gamma \neq 0$ then we have the nonphase matched case and the reflectivity is smaller than that given by (14.77). Thus peak reflectivity appears when the Bragg condition is satisfied.

Figure 14.13 shows the vector diagram for the case of reflection from FBG for the cases when the Bragg condition is satisfied and not satisfied. The wave vectors of the incident wave and the reflected waves are denoted by $+\beta$ and $-\beta$, respectively, and that of the grating by the spatial frequency vector K. As can be seen from the figure, for phase matched interaction, the three vectors add to give zero.

Figure 14.14 shows a comparison of measured and simulated spectrum (using (14.76)). The peak reflection occurs around a wavelength of 1550.9 nm. As can be seen, the reflectivity peaks at the Bragg wavelength and on either side the reflectivity drops and becomes oscillatory. One can define the spectral bandwidth of the

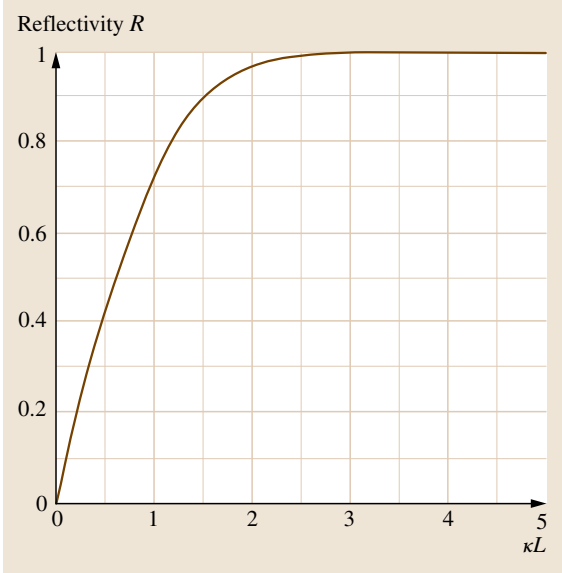

Fig. 14.12 Variation of reflectivity of a fiber Bragg grating as a function of κL

grating in terms of the grating parameters as ([14.6])

$$\Delta\lambda \approx \frac{\lambda_B^2}{n_{\text{eff}} L}\left(1+\frac{\kappa^2 L^2}{\pi^2}\right)^{1/2} . \qquad (14.78)$$

From (14.77) and (14.78) it also follows that one can design gratings having the same peak reflectivity but different bandwidths by appropriate choice of the peak index modulation and grating length. A given peak reflectivity implies a given value of κL (i. e., $\Delta n L$). The bandwidth can be increased or reduced by decreasing or increasing the grating length while keeping the product $\Delta n L$ constant. It is also possible to deduce the characteristics of the grating (length, period of the grating, and the index modulation) by measuring the reflectivity spectrum (peak reflection wavelength, peak reflectivity and the bandwidth).

Some Applications of FBGs

Fiber Bragg gratings find many applications. These include applications in add/drop multiplexers, fiber grating sensors, to provide external feedback for laser diode wavelength locking, dispersion compensation, etc. Here we discuss the application of chirped FBG to dispersion compensation and to sensors.

Dispersion Compensation

As mentioned in Sect. 14.8, when pulses of light propagate through an optical fiber link they suffer from dispersion due to the dependence of group velocity of the mode on the wavelength. This dispersion needs to be compensated in the link and this can be achieved either through the use of the dispersion compensating fibers discussed earlier or with the help of *chirped FBGs*. In chirped FBGs the period of the grating varies with the position along the fiber length and this leads to a variation of Bragg wavelength along the grating (Fig. 14.15). When light propagates through such a grating, different wavelength components present in the incident wave will be reflected at different positions along the grating; this will lead to different wavelength components having different time delays to return to the input end. By using an appropriately chirped FBG one can indeed compensate for the differential delay of different wavelengths accumulated while propagating through an optical fiber link.

Let us consider propagation of a pulse of light through an optical fiber operating at a wavelength longer than the zero dispersion wavelength of the fiber. This would correspond to, say, operating a G.652 fiber (having a zero dispersion at 1310 nm) at a wavelength of 1550 nm. Thus if we consider three wavelength com-

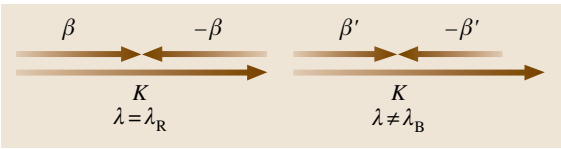

Fig. 14.13 Vector diagrams representing contra directional coupling when the Bragg condition is satisfied and when it is not satisfied

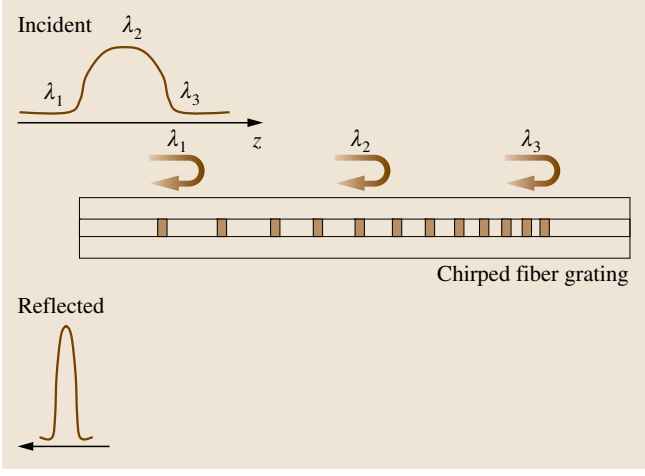

Fig. 14.15 Dispersion compensation using a chirped FBG

ponents such that $\lambda_1 > \lambda_2 > \lambda_3$ contained within the pulse, then, we can see that due to dispersion in the fiber, wavelength λ_1 would suffer larger delay than wavelength λ_2, which in turn will suffer a delay longer than λ_3 while propagating through the fiber. In order to compensate for this dispersion, we need to delay the wavelength component λ_3 more than the component λ_2, which in turn should suffer a delay more than at λ_1. In order to achieve this, the chirped grating is designed so that wavelength λ_1 reflects from the near end of the grating, λ_2 reflects from a portion farther away while λ_3 reflects from the far end so as to compensate for the differential delay between all the wavelength components and thus leading to dispersion compensation.

Let us consider a linearly chirped FBG with a linearly varying spatial frequency as given by

$$K(z) = K_0 + \frac{Fz}{L_g^2} \,. \tag{14.79}$$

Here K_0 is the grating spatial frequency at $z = 0$, the input position of the grating, L_g is the length of the grating, and F is the chirp parameter. If Λ_f and Λ_b represent the spatial periods of the FBG at $z = 0$ (front) and $z = L_g$ (back), then the wavelengths which undergo reflections at $z = 0$ and $z = L_g$ are approximately given by

$$\lambda_f = 2n_{eff}\Lambda_f \,; \quad \lambda_b = 2n_{eff}\Lambda_b \,, \tag{14.80}$$

where we have neglected the wavelength dependence of n_{eff}. Thus from (14.79), we can write

$$\frac{1}{\Lambda_b} - \frac{1}{\Lambda_f} = \frac{F}{2\pi L_g} \approx \frac{2\, n_{eff}\Delta\lambda}{\lambda_a^2} \,,$$

where $\Delta\lambda = \lambda_b - \lambda_f$ represents the bandwidth of the chirped grating, and $\lambda_a = (\lambda_f + \lambda_b)/2$ represents the average wavelength. The bandwidth over which the chirped FBG will operate is given by

$$\Delta\lambda = \frac{F\lambda_a^2}{4\pi n_{eff} L_g} \,. \tag{14.81}$$

The time delay between the wavelengths λ_f and λ_b which are reflected from the front and far end of the grating is

$$\Delta\tau = \frac{2L_g}{c/n_{eff}} = \frac{2n_{eff}L_g}{c} \,. \tag{14.82}$$

This $\Delta\tau$ is over a wavelength range of $\Delta\lambda$ and hence the dispersion introduced by the grating is given by

$$\frac{d\tau}{d\lambda} = \frac{8\pi n_{eff}^2}{c\lambda_a^2}\frac{L_g^2}{F} \,. \tag{14.83}$$

Note that for the case shown in Fig. 14.15 longer wavelengths suffer less delay in returning from the grating and hence this corresponds to normal dispersion; such a normal dispersion can compensate for the anomalous dispersion of the fiber if the fiber is operated at wavelengths greater than the zero dispersion wavelength. If we consider a link fiber with dispersion coefficient D and length L_f, the accumulated dispersion in the link would be DL_f. In order to compensate for this accumulated dispersion we require that

$$DL_f = -\frac{8\pi n_{eff}^2}{c\lambda_a^2}\frac{L_g^2}{F} \,. \tag{14.84}$$

The spectral bandwidth over which dispersion compensation will take place is given by (14.81).

As an example let us consider a chirped grating of length 11 cm with the chirp parameter $F = 640$, operating at an average wavelength of 1550 nm. If the effective index of the fiber mode is 1.45, then using (14.81) and (14.83) we obtain for the dispersion of the grating as 1380 ps/nm operating over a bandwidth of 0.61 nm. This grating can compensate for dispersion accumulated over a fiber with a dispersion coefficient of 17 ps/(km nm) and of length 81 km over a bandwidth of 0.61 nm, which approximately corresponds to 76 GHz of frequency bandwidth. It is interesting to note that the difference in period between the front and back end of the 11 cm long grating is only about 0.25 nm, while the average period of the grating is about 0.534 μm.

In order to achieve dispersion compensation over larger bandwidths multiple chirped gratings over the same section of the fiber have been suggested. Chirped dispersion compensating gratings are commercially available for compensation of accumulated dispersion of up to 80 km of G.652 fiber for up to 32 wavelength channels. Unlike dispersion compensating fibers, chirped FBGs provide with the possibility of tweaking the required dispersion compensation especially for 40 Gb ps systems where the margin of dispersion available is rather small. Also by using nonlinearly chirped FBGs it has been shown that delay variation from −200 ps to −1200 ps is achievable [14.20].

Sensing

FBG Based Sensors. FBGs have a great potential for applications as sensors for sensing mechanical strain, temperature, acceleration, etc. Since the Bragg wavelength depends on both the refractive index of the fiber as well as on the period of the grating, any external parameter that changes any of these would result in a change in the reflected wavelength. Thus by measur-

ing the *changes in the reflected wavelength*, the external perturbations affecting the grating could be sensed. This is the basic principle of their application in sensing.

For the change in the Bragg wavelength, because of a change ΔT in the temperature and $\Delta\varepsilon$ in strain, we can write

$$\Delta\lambda_B = 2\Lambda\left(\frac{\partial n_{\text{eff}}}{\partial T}\Delta T + \frac{\partial n_{\text{eff}}}{\partial \varepsilon}\Delta\varepsilon\right) + 2n_{\text{eff}}\left(\frac{\partial \Lambda}{\partial T}\Delta T + \frac{\partial \Lambda}{\partial \varepsilon}\Delta\varepsilon\right) . \quad (14.85)$$

FBGs show typical strain sensitivities of about 1.3 pm/με at 1550 nm. The temperature sensitivity of FBGs is about 6 pm/°C. The changes in the peak wavelength are indeed very small and hence special techniques need to be developed for sensing such small changes. Also techniques to deconvolve the changes in temperature and strain by measuring the changes in the Bragg wavelength need to be implemented for precise sensing.

One of the important attributes of FBG sensors is that they can be multiplexed into a single fiber. FBGs with different Bragg wavelengths are fabricated at different points along the length of a single-mode fiber. Light from a broad band source is coupled into the fiber and light at different wavelengths are reflected from the individual gratings and are analyzed by the detection circuit. The wavelengths of the FBGs are so chosen that they do not overlap with each other and fall within the band of the source. By measuring the changes in the Bragg wavelength of individual FBGs, the strains or temperature changes at each of the location of the FBG can be independently measured. Among the various issues in connection with FBG sensors, is the problem of separating the changes brought about by temperature and strain. Fiber optic sensing technology is rapidly advancing and FBGs are now being tested for structural monitoring. In the future it may be possible to multiplex perhaps 100 sensors on a single fiber, which gives enormous capability to structural monitoring.

14.8.2 Long Period Gratings

Long period gratings (LPG) are periodic perturbations along the length of the fiber with periods of greater than 100 μm which induce coupling between two co-propagating guided core modes or between a guided core mode and a cladding mode propagating in the same direction. Coupling due to periodic perturbation being wavelength selective, these gratings act as wavelength dependent loss components (Fig. 14.16). This makes them attractive candidates for applications in wavelength filters with specific application in gain flattening of erbium doped fiber amplifiers (EDFA), band rejection filters, WDM isolation filters or as polarization filtering components, sensors, etc. [14.21–23].

Coupled Mode Theory

An LPG corresponds to a periodic perturbation of the core refractive index as given by (14.71). Using coupled mode theory one can obtain the following expression for the fractional power remaining in the core and cladding when only the core mode is excited at $z = 0$

$$P_{\text{co}} = 1 - \frac{\kappa^2}{\gamma^2}\sin^2\gamma z ,$$
$$P_{\text{cl}} = 1 - P_{\text{co}} . \quad (14.86)$$

Here $\Gamma = \beta_1 - \beta_2 - K$, where β_1 and β_2 are the propagation constants of the two interacting modes, and K represents the spatial frequency of the grating. The coupling coefficient is now defined by

$$\kappa = \frac{\omega\varepsilon_0}{8}\iint \psi_1 \Delta n^2 \psi_2 \,\mathrm{d}x\,\mathrm{d}y , \quad (14.87)$$

where $\psi_1(x, y)$ and $\psi_2(x, y)$ represent the normalized field distributions of the interacting modes and β_1 and β_2 represent their propagation constants. In (14.86)

$$\gamma = \sqrt{\kappa^2 + \frac{\Gamma^2}{4}} . \quad (14.88)$$

It can be seen from (14.86) that unlike the case of FBG the exchange of energy between the core mode and the cladding mode is periodic with distance, and complete transfer of energy from the guided mode to the cladding

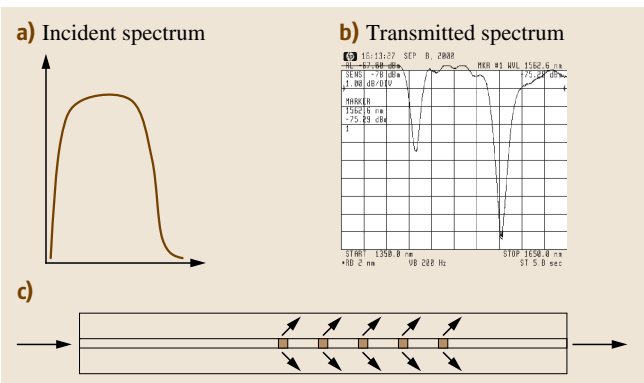

Fig. 14.16 A long period grating coupling light from the core mode to other co-propagating core or cladding modes leading to transmission dips

mode is possible if $\Gamma = 0$, if the following condition is satisfied

$$\beta_{co} = \beta_{cl} + K \,. \tag{14.89}$$

If n_{eff}^{co} and n_{eff}^{cl} represent the effective indices of the interacting core and cladding modes, respectively, then from (14.89) we obtain for the required period of the LPG

$$\Lambda = \frac{\lambda_0}{n_{eff}^{co} - n_{eff}^{cl}} \,. \tag{14.90}$$

The typical difference between the effective indices of the core and the cladding mode would be approximately equal to the index difference between the core and the cladding, which for typical telecommunication fibers is approximately 0.003. Thus, for an LPG to operate at a wavelength of 1550 nm the required grating period is approximately 520 μm, which is much larger than that of an FBG.

If (14.90) is not satisfied then the exchange of energy is less efficient. Figure 14.17 shows the vector diagram corresponding to phase matched interaction between a core mode with propagation constant β_{co} and a cladding mode with propagation constant β_{cl} propagating along the same direction.

Figure 14.18 shows the comparison of the measured and simulated transmission spectra of an LPG fabricated using the fiber fusion splice machine [14.24]. One can see multiple dips in the transmission spectrum corresponding to the coupling of the LP_{01} guided mode to individual cladding modes. Note that if the perturbation is azimuthally symmetric, then coupling from the LP_{01} core mode will take place only to LP_{0m} cladding modes.

LPGs have found many applications. The spectral variation of gain of an EDFA is not flat and this causes problems in their applications in DWDM optical fiber communication systems. Since LPGs can induce spectrally dependent loss, they find applications as gain flattening filters for erbium doped fiber amplifiers (EDFA) [14.23]. By designing LPGs with the desired loss at the desired wavelength (≈ 1532 nm for EDFA), they can flatten the gain of an EDFA. LPGs also find wide applications as sensors and they exhibit greater sensitivity to temperature and strain. By combining LPGs with FBGs it is possible to design sensors to discriminate between strain and temperature.

14.9 Fiber Optic Couplers

In-line optical fiber components form important devices in various applications such as in communication, sensing, signal processing, etc. Such components are being used for various functions such as multiplexing and demultiplexing, wavelength filtering, optical add-drop multiplexing, splitting power among various fiber outputs, combining different wavelengths, etc. The fiber Bragg grating and long period grating discussed in Sect. 14.8 are among the most important components. In this section we shall discuss another very important component, namely a fiber coupler that has applications in power division, wavelength multiplexing and demultiplexing, etc.

In fiber optic communication systems, it is often necessary to tap a small amount of power from the signal. It may also be necessary to split the signal into two (or more) parts so that the same signal can reach two (or more) destinations. All this can be achieved by means of a coupler, which is essentially a fiber optic beam splitter and is one of the most important in line fiber

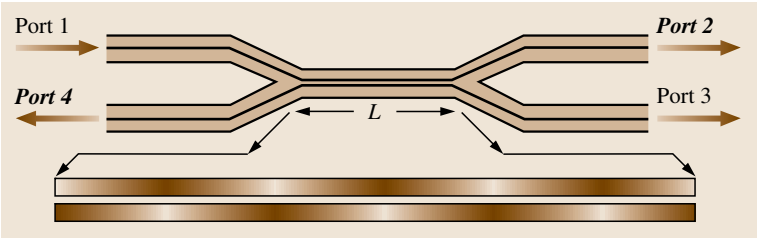

Fig. 14.19 A directional coupler consists of two closely lying fibers leading to coupling of light from one fiber to the other via the evanescent fields of the fibers. If the fibers have the same propagation constant then the power exchange is complete

components The schematic of a typical fiber optic directional coupler is shown in Fig. 14.19. The device works on the basic fact that even though light is confined to propagate along the core of the fiber, a small fraction of the light extends beyond the core – cladding interface which of course propagates along with the light within the core at the same speed. Thus, when two fiber cores are brought sufficiently close (separation of the order of a micrometer or so) to each other laterally, periodic exchange of power takes place from one fiber to the other (Fig. 14.19). The fractional power emanating from the two output ports depends on the length L of the interaction region.

If at the input of the coupler power is launched in one of the fiber inputs then the powers propagating in each of the fibers at any value of z (the propagation distance from the input end) is given by [14.6]

$$P_1(z) = P_1(0)\left(1 - \frac{\kappa^2}{\gamma^2}\sin^2\gamma z\right) \tag{14.91}$$

and

$$P_2(z) = P_1(0)\frac{\kappa^2}{\gamma^2}\sin^2\gamma z\,, \tag{14.92}$$

where

$$\gamma^2 = \kappa^2 + \frac{(\Delta\beta)^2}{4}\,, \tag{14.93}$$

$$\Delta\beta = \beta_1 - \beta_2\,, \tag{14.94}$$

with β_1 and β_2 representing the propagation constants of the modes of the two individual fibers, κ representing the coupling constant representing a measure of the strength of interaction between the two fibers, which depends on the fiber parameters, the spacing between the fiber cores, and the wavelength of operation.

By using the fields of the LP_{01} modes of a step-index fiber, it is possible to obtain the following approximate expression for κ for a coupler consisting of two identical fibers [14.25]

$$\kappa = \frac{\lambda_0}{2\pi n_1}\frac{U^2}{a^2V^2}\frac{K_0(Wd/a)}{K_1^2(W)}\,, \tag{14.95}$$

where λ_0 is the free space wavelength, n_1 and n_2 are the core and cladding refractive indices, respectively, a is the core radius, d is the separation between the fiber axes, $K_n(x)$ is the modified Bessel function of order n, and U, W and V are defined in (14.14), (14.15).

If the propagation constants of the two fibers are not equal $\Delta\beta = \beta_1 - \beta_2 \neq 0$, then from (14.91) we can see that the power exchange between the two fibers is incomplete. The maximum power transferred from one fiber to the other depends on the value of $\Delta\beta/\kappa$; the larger the value of this quantity, the smaller the power transferred.

If the propagation constants of the modes of the two fibers are identical then $\Delta\beta = 0$ and the power exchange between the two fibers is complete. The length required for complete power transfer is called the coupling length and is given by

$$L_c = \frac{\pi}{2\kappa}\,. \tag{14.96}$$

Stronger interaction implies larger value of κ and a shorter coupling length. Since κ depends on the wavelength of operation, the coupling length also depends on the wavelength of operation.

Depending on the coupler length it is possible to have an arbitrary fraction of power exiting from the coupled port (Port 3). Thus by choosing an appropriate length of the coupler it is possible to achieve equal power outputs from the two ports. Such a coupler is referred to as a 3 dB coupler. Many 3 dB couplers can be connected one after the other to split the power further into multiple ports.

Fiber optic couplers are usually specified by some important characteristics. These include the following:

- The coupling ratio, which is the ratio of the power in the coupled port to the total output power

$$R\,(\mathrm{dB}) = 10\log\left(\frac{P_3}{P_2 + P_3}\right)\,. \tag{14.97}$$

Thus for an input power of 1 mW if the total output power is 0.9 mW and the coupled port carries

a power of 0.1 mW, then the coupling ratio is about 9.5 dB.

- Excess loss, which is the difference in power between the total output power and the input power and is usually expressed in dB

$$L_{\text{ex}}\ (\text{dB}) = 10 \log \left(\frac{P_1}{P_2 + P_3} \right) . \qquad (14.98)$$

Thus, if the excess loss is 1 dB, then this implies that for an input power of 1 mW, the total output power (sum of powers from both the output ports) is about 0.79 mW; the remaining 0.21 mW is lost due to scattering, absorption, etc.

- Insertion loss which is the ratio of input power to the coupled power

$$I\ (\text{dB}) = 10 \log \left(\frac{P_1}{P_3} \right) . \qquad (14.99)$$

- Directivity specifies the power returning in the second input port and is measured in dB

$$D\ (\text{dB}) = 10 \log \left(\frac{P_4}{P_1} \right) . \qquad (14.100)$$

If for an input power of 1 mW a power of 0.01 μW emerges from the second input port, then the ratio of the two powers is 0.00001 and the directivity is −50 dB.

Tap couplers are couplers in which the fractional power appearing in the coupled port is a very small fraction of the light input into the coupler. Thus tap couplers tapping 1 or 5% of the light beam are used in many applications such as in EDFAs.

Directional couplers have many interesting applications in power splitting, wavelength division multiplexing/demultiplexing, polarization splitting, fiber optic sensing, etc.

Power Dividers

One of the most important applications of a fiber directional coupler is as a power divider. In many applications, such as in local area networks or in fiber optic sensing, it is necessary to split or combine optical beams. Such a fiber optic directional coupler forms an ideal component since it is compact and possesses low loss. One of the important issues in such couplers is the wavelength dependence of the coupler. Wavelength flattened couplers are characterized by coupling ratios which remain almost constant for a given band of wavelengths such as the C-band (1530–1565 nm). If power is to be divided into many ports then 3 dB couplers can be concatenated to split from one input port into multiple ports.

Wavelength Division Multiplexers/Demultiplexers

Since the extent of field penetrating into the cladding depends on wavelength, the coupling process is wavelength dependent. Thus it is possible to design couplers such that when power at two different wavelengths are incident in the same port of a coupler, one of the wavelengths exits from one port while the other wavelength exits from the other port (Fig. 14.20). Such a coupler is used to multiplex (combine) or demultiplex (separate) two wavelengths. These are referred to as wavelength division multiplexing (WDM) couplers and find applications in EDFAs to combine the pump and signal power or to separate two wavelengths which are sufficiently separated such as 1310 and 1550 nm, etc. If we use the same coupler in the reverse direction then the two wavelengths incident on the coupler and appear at the same port as shown in Fig. 14.20b, forming a wavelength division multiplexer.

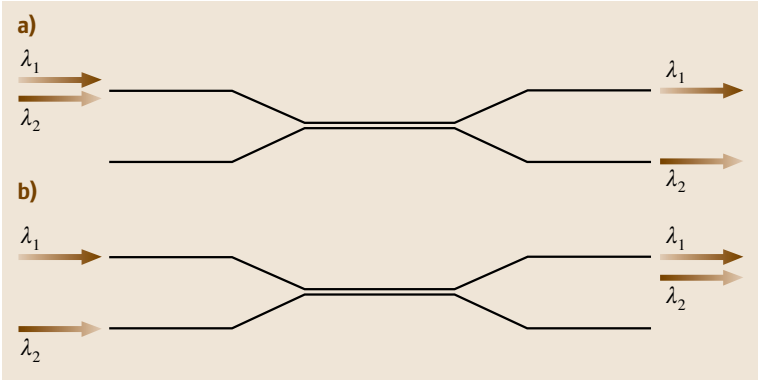

Fig. 14.20 (**a**) Wavelength division demultiplexer and (**b**) wavelength division multiplexer based on fiber optic couplers

14.10 Erbium Doped Fiber Amplifier (EDFA)

In traditional long distance optical fiber communication systems, compensation of loss and dispersion is usually accomplished by using electronic regenerators in which the optical signals are first converted into electrical signals, then processed in the electrical domain, and then reconverted into optical signals. Whenever the system limitation is due to insufficient optical power rather than dispersion, then what is needed is just amplification of the signal, and optical amplifiers can indeed perform this job. Optical amplifiers are devices that amplify the incoming optical signals in the optical domain itself without any conversion to the electrical domain and have truly revolutionized long distance fiber optic communications. Compared to electronic regenerators, optical amplifiers do not need any high speed electronic circuitry, are transparent to bit rate and format, and most importantly can amplify multiple optical signals at different wavelengths simultaneously. Thus their development has ushered in the tremendous growth of communication capacity using wavelength division multiplexing (WDM) in which multiple wavelengths carrying independent signals are propagated through the same single-mode fiber, thus multiplying the capacity of the link. Of course compared to electronic regenerators, they have some drawbacks too; they do not compensate for dispersion accumulated in the link and they also add noise to the optical signal. As we will see later, this noise leads to a maximum number of amplifiers that can be cascaded so that the received signal to noise ratio is within the limits.

Optical amplifiers can be used at many points in a communication link. A booster amplifier is used to boost the power of the transmitter before launching into the fiber link. The increased transmitter power can be used to go farther in the link. The preamplifier placed just before the receiver is used to increase the receiver sensitivity. In line amplifiers are used at intermediate points in the link to overcome fiber transmission and other losses. Optical amplifiers can also be used for overcoming splitter losses, for example, for distribution of CATV.

The three main types of optical amplifiers are the EDFA, the Raman fiber amplifier (RFA), and the semiconductor optical amplifier (SOA). Today most optical fiber communication systems use EDFAs due to their advantages in terms of bandwidth, high power output, and noise characteristics. Detailed discussions on EDFAs can be found in many texts [14.26–28].

Optical amplification by EDFA is based on the process of stimulated emission, which is the basic principle behind laser operation. Figure 14.21 shows the three lowest lying energy levels of an erbium ion in a silica matrix. A pump laser at 980 nm excites the erbium ions from the ground state to the level marked E_3. The level E_3 is a short-lived level and the ions jump down to the level marked E_2 after a time lasting less than a microsecond. The lifetime of level E_2 is much larger and is about 12 ms. Hence ions brought to level E_2 stay there for a long time. Thus by pumping hard enough, the population of ions in the level E_2 can be made larger than the population of level E_1 and thus achieve population inversion between levels E_1 and E_2. In such a situation, if a light beam at a frequency $\nu_0 = (E_2 - E_1)/h$ falls on the collection of erbium ions, it will get amplified. For erbium ions, the frequency ν_0 falls in the 1550 nm band and thus it is an ideal amplifier for signals in the 1550 nm window, which is the lowest loss window of silica based optical fibers. In the case of erbium ions in the silica matrix, the energy levels are not sharp but are broadened due to interaction with other ions in the silica matrix. Hence the system is capable of amplifying optical signals over a band of wavelengths.

Let N_1 and N_2 represent the number of erbium ions per unit volume in the ground level and the excited level, respectively, and let $I_p(z)$ and $I_s(z)$ represent the variation of intensity of the pump at frequency ν_p (assumed to be at 980 nm) and the signal at frequency ν_s assumed to be in the region of 1550 nm. As the beams propagate

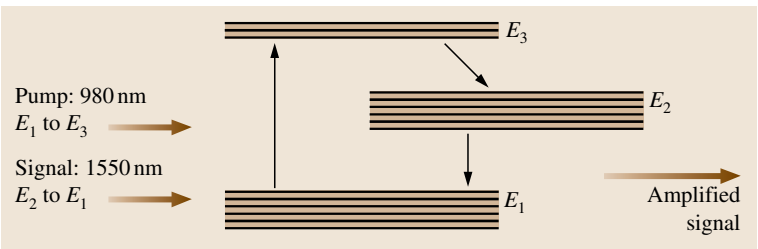

Fig. 14.21 Three lowest lying energy levels of erbium in a silica matrix

through the fiber, the pump would induce absorption from E_1 to E_3, while the signal would induce absorption and stimulated emissions between levels E_2 and E_1. Under the assumption that the lifetime of level E_3 is very small, $N_3 \approx 0$ and we can write for the rate of change of population of level E_2 [14.6]

$$\frac{dN_2}{dt}\left(=-\frac{dN_1}{dt}\right)=-\frac{N_2}{t_{sp}}+\frac{\sigma_{pa}I_p}{h\nu_p}N_1 - (\sigma_{se}N_2-\sigma_{sa}N_1)\frac{I_s}{h\nu_s}\,. \tag{14.101}$$

Here σ_{pa} (σ_{sa}) and σ_{pe} (σ_{se}) are the absorption and emission cross sections at the pump (signal) wavelengths, respectively; t_{sp} is the spontaneous life time of the level E_2. Subscripts p and s correspond to pump and signal, respectively. The absorption and emission cross sections depend on the frequency, the specific ion, as well as on the pair of levels for a given ion. Figure 14.22 gives the typical absorption and emission cross section of erbium ions in a silica glass fiber [14.29].

In (14.101) the first term on the right-hand side corresponds to spontaneous emission, the second term to pump absorption, while the third term corresponds to signal transitions. The pump and signal intensity variation with z are caused due to absorption and stimulated emission and can be described by

$$\frac{dI_p}{dz}=-\sigma_{pa}N_1I_p\,;$$
$$\frac{dI_s}{dz}=-(\sigma_{sa}N_1-\sigma_{se}N_2)I_s\,. \tag{14.102}$$

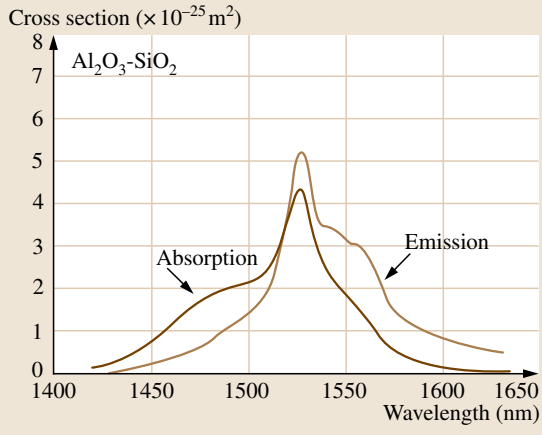

Fig. 14.22 Absorption and emission cross section of erbium ions in a silica matrix (after [14.29])

In the case of optical fibers, since the pump and signal beams propagate in the form of modes, we should describe amplification in terms of powers rather than in terms of intensities.

If we assume that both the pump and the signal fields exist in the fundamental transverse mode of the fiber, then we can write

$$I_p(r,z)=P_p(z)f_p(r)\,,$$
$$I_s(r,z)=P_s(z)f_s(r)\,, \tag{14.103}$$

where $P_p(z)$ and $P_s(z)$ represent the z-dependent powers at the pump and signal wavelength, respectively, and the quantities $f_p(r)$ and $f_s(r)$ represent the transverse dependence of the modal intensity patterns at the pump and signal waves, respectively. These are normalized so that

$$2\pi\int_0^\infty f_p(r)r\,dr=1\,,$$
$$2\pi\int_0^\infty f_s(r)r\,dr=1\,. \tag{14.104}$$

Using the expressions for the intensity in terms of the powers, (14.102) gives us

$$\frac{dP_p}{dz}=-2\pi\sigma_{pa}P_p(z)\int_0^\infty f_p(r)N_1(r,z)r\,dr\,,$$
$$\frac{dP_s}{dz}=2\pi P_s(z)\int_0^\infty f_s(r)(\sigma_{se}N_2-\sigma_{sa}N_1)r\,dr\,. \tag{14.105}$$

Equation (14.101) can be solved under steady state to obtain the dependence of N_1 and N_2 on r and z, and (14.105) can be solved to obtain the power variation at the signal and pump wavelength along the length of the fiber. These then give us the gain of the amplifier and its dependence on various parameters such as length of the doped fiber, the pump power, input signal power, etc. In writing the above equation amplified spontaneous emission (ASE) has been neglected; for high gain amplifiers the effect of ASE on the gain characteristics need to be included in the analysis.

A typical EDFA consists of a short piece (≈ 20 m in length) of erbium doped fiber (EDF), which is pumped by a 980 nm pump laser through a WDM coupler. The WDM coupler multiplexes light of wavelength 980 and 1550 nm from two different input arms to a single output arm. The 980 nm pump light is absorbed

by the erbium ions to create population inversion between levels E_2 and E_1. Thus, incoming signals in the 1550 nm wavelength region are amplified as they propagate through the population inverted doped fiber.

Figure 14.23 shows typical measured gain spectra of an EDFA for various input signal powers. As can be seen in the figure, EDFA can provide amplifications of greater than 20 dB over the entire band of 40 nm from 1525 to about 1565 nm. This wavelength band is referred to as the C band (conventional band) and is the most common wavelength band of operation. We also note that the gain decreases and the spectrum flattens as the input signal power increases showing signal saturation. With proper amplifier optimization, EDFAs can also amplify signals in the wavelength range of 1570–1610 nm; this band of wavelengths is referred to as the L-band (long wavelength band). With novel doped fiber profiles it is possible to achieve amplification in the short wavelength band of 1480–1520 nm by using EDFAs [14.30, 31]. In these designs, the emission in the C-band needs to be continuously filtered out so that the wavelengths in the S-band can use the population inversion for amplification. The C-band and L-band amplifiers together can be used to simultaneously amplify 160 wavelength channels. Such systems are indeed commercially available now.

It can be seen from Fig. 14.23 that although EDFAs can provide gains over an entire band of 40 nm, for low input signal powers the gain is not flat, i. e., the gain depends on the signal wavelength. Thus if multiple wavelength signals with same power are input into the amplifier, then their output powers will be different. In a communication system employing a chain of amplifiers, a differential signal gain among the various signal wavelengths (channels) from each amplifier will result in a significant difference in signal power levels and hence in the signal to noise ratio (SNR) among the various channels. In fact, signals for which the gain in the amplifier is greater than the loss suffered in the link, will keep on increasing in power level while those channels for which the amplifier gain is less than the loss suffered will keep on reducing in power. The former channels will finally saturate the amplifiers and will also lead to increased nonlinear effects in the link, while the latter will have reduced SNR leading to increased errors in detection. Thus such a differential amplifier gain is not desirable in a communication system and it is very important to have gain flattened amplifiers. Wavelength filters with appropriate filter characteristics compensating for the gain variation can be designed to flatten the gain of the amplifier. Such filters are usually placed

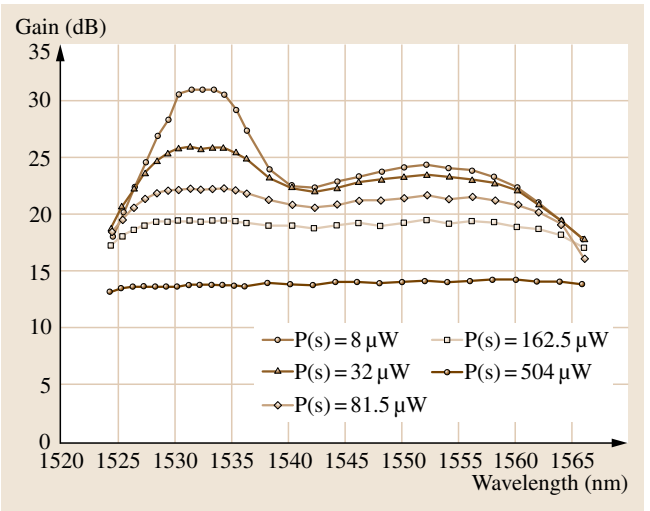

Fig. 14.23 Measured gain spectra of an EDFA at different input signal power levels

within the amplifier between two gain units to optimize in terms of gain efficiency and noise characteristics. Filters based on fiber Bragg gratings, long period gratings, or thin film filters are used. A typical gain flatness of better than 0.5 dB can be achieved and commercially available EDFAs are all gain flattened. Other techniques involving modification of the refractive index profile to flatten the gain have also been demonstrated.

14.10.1 Noise in EDFA

In an EDFA population inversion between two energy levels of erbium ion leads to optical amplification by the process of stimulated emission. Erbium ions occupying the upper energy level can also make spontaneous transitions to the ground level and emit radiation. This radiation appears over the entire fluorescent band of emission of erbium ions and travels both in the forward as well as in the backward direction along the fiber. Part of the spontaneous emission generated at any point along the fiber is coupled into the propagating mode of the fiber and can also become amplified just like the signal as it propagates through the population inverted fiber. The resulting radiation is called amplified spontaneous emission (ASE). This ASE is the basic mechanism leading to noise in the optical amplifier [14.27]. ASE appearing in wavelength region not coincident with the signal can be filtered using an optical filter. On the other hand, the ASE that appears in the signal wavelength region cannot be separated

and constitutes the minimum added noise from the amplifier.

If P_{in} represents the signal input power (at frequency ν) into the amplifier and G represents the gain of the amplifier, then the output signal power is given by GP_{in}. Along with this amplified signal, there is also ASE power, which can be shown to be given by [14.27]

$$P_{ASE} = 2n_{sp}(G-1)h\nu B_o\,, \tag{14.106}$$

where B_o is the optical bandwidth over which the ASE power is being measured (which must be at least equal to the optical bandwidth of the signal) and $n_{sp} = N_2/(N_2 - N_1)$. Here N_2 and N_1 represent the population densities in the upper and lower amplifier energy levels of erbium in the fiber. The minimum value for n_{sp} corresponds to a completely inverted amplifier for which $N_1 = 0$ and thus $n_{sp} = 1$. For a gain of 20 dB, typical ASE powers within a band of 0.1 nm are about 0.6 μW (= −32 dBm), which corresponds to an ASE noise spectral density of −22 dBm/nm. We can define the optical signal to noise ratio (OSNR) as the ratio of the output optical signal power to the ASE power

$$\text{OSNR} = \frac{P_{out}}{P_{ASE}} = \frac{GP_{in}}{2n_{sp}(G-1)h\nu B_o}\,, \tag{14.107}$$

where P_{in} is the average power input into the amplifier (which is about half of the peak power in the bit stream, assuming equal probability of ones and zeroes).

Each amplifier in a chain adds noise and thus in a fiber optic communication system consisting of multiple spans of optical fiber links with amplifiers, OSNR will keep falling and at some point in the link when the OSNR falls below a certain value, the signal would need to be regenerated. Hence there is a maximum number of amplifiers that can be placed in a link beyond which the signal needs to be regenerated. For a link consisting of multiple spans of transmission fiber and EDFAs compensating the loss of each span, the OSNR is given by

$$\begin{aligned}\text{OSNR (dB)} \approx\; & P_{out}\,\text{(dBm)} - 10\log(n) + 58 - F\,\text{(dB)} \\ & - 10\log(N+1) - L_{sp}\,\text{(dB)}\,,\end{aligned} \tag{14.108}$$

where P_{out} is the total output power from the amplifier in dBm, n represents the number of wavelength channels in the link, F represents the noise figure (14.109) of each EDFA (assumed to be the same), N represents the number of amplifiers, and L_{sp} the loss of each span. As a typical example we consider a link consisting of EDFAs with the following specifications: $P_{out} = 17$ dBm, $n = 32$, $F = 5$ dB, and $L_{sp} = 20$ dB. If we require an OSNR of 22 dB at the end of the link, then using (14.108) the maximum number of amplifiers that can be used in the link comes out to be about 18. If more than this number of amplifiers are employed then the OSNR will fall below the required value of 22 dB. Thus for proceeding further along the length, the signal needs to be regenerated. It is also interesting to note from (14.108) that for achieving the same OSNR at the output of the link, the number of amplifiers in the chain can be increased by reducing the noise figure of each amplifier, by increasing the output power of the amplifiers, or by decreasing the span loss. Indeed by choosing smaller span loss, the number of amplifiers can be increased significantly so that the distance for regeneration can be made very large. Thus reducing each span loss by 3 dB would result in a doubling of the maximum allowed number of amplifiers (all other parameters being the same). Of course in this case, we would have to employ a larger number of amplifiers.

The above discussion was based on the optical signal to noise ratio of the amplifier. When the amplified output is received by a detector, then the detector converts the optical signal into an electric current and the noise characteristics of the generated electrical signal are of importance. Apart from the optical signal, the amplified spontaneous emission within the bandwidth of the signal also falls on the photodetector. However, the ASE noise is completely random and contains no information. The photodetector would convert the total optical power received into electrical current and in the current there would be beating between the signal and noise fields and between noise fields at different frequencies. These lead, respectively, to signal-spontaneous beat noise and spontaneous-spontaneous beat noise. Under normal circumstances, the signal-spontaneous noise term and the signal shot noise terms are the important noise terms and assuming the input to the amplifier to be shot noise limited we can calculate the output SNR from the noise terms. The amplifier noise figure defined as the ratio of input electrical SNR to output electrical SNR is given by

$$F = \frac{1 + 2n_{sp}(G-1)}{G}\,. \tag{14.109}$$

Thus, the noise figure depends on the inversion through n_{sp} and on the amplifier gain through G. For large gains $G \gg 1$, the noise figure is approximately given by $2n_{sp}$. Since the smallest value of n_{sp} is unity, the smallest noise figure is given by 2 or in decibel units as 3 dB.

The noise figure is a very important characteristic of an amplifier and determines the overall performance of any amplified link. Noise figures of typical commercially available EDFAs are about 5 dB.

14.11 Raman Fiber Amplifier (RFA)

Another very important fiber based amplifier is the Raman fiber amplifier (RFA), which is based on the phenomenon of stimulated Raman scattering. The attractive feature of RFAs is that they can be made to work in any wavelength band by simply choosing appropriate pump wavelengths; they also have a large bandwidth and have lower noise figures compared to EDFA. Apart from this, the link fiber can itself be used as the amplifier and thus the signal is amplified as it covers the distance along the communication link itself; such amplifiers are referred to as distributed amplifiers.

When we send a strong light beam at a wavelength of 1450 nm through a long (≈ 10 km) optical fiber, the light beam undergoes Raman scattering from the molecules of the glass fiber and this gives rise to scattered light at higher wavelengths. Figure 14.24 shows a typical spontaneous Raman spectrum from an optical fiber pumped by radiation at 1450 nm. As can be seen, the scattered radiation occupies a large band and the peak of the scattered radiation lies at about 100 nm away from the pump wavelength. Indeed Raman scattering in silica leads to a Raman shift of 13–14 THz which corresponds to about 100 nm at a wavelength of 1550 nm.

If in addition to the strong pump light we also launch a weak light beam (referred to as the signal beam) with its wavelength lying within the band of spontaneous Raman scattering, then this leads to what is referred to as stimulated Raman scattering. In this case, the pump and signal wavelengths are coherently coupled by the Raman scattering process and the scattered radiation is coherent with the incident signal radiation, much like stimulated emission that occurs in the case of a laser. It is this process that is used to build Raman fiber amplifiers (Fig. 14.25). Since the spontaneous Raman scattering spectrum is broad, the corresponding gain spectrum of the Raman amplifier is also very broad. The other interesting feature is that no matter what the wavelength of the pump light is, the fiber can act like an amplifier in the wavelength range corresponding to the spontaneous Raman scattering spectrum.

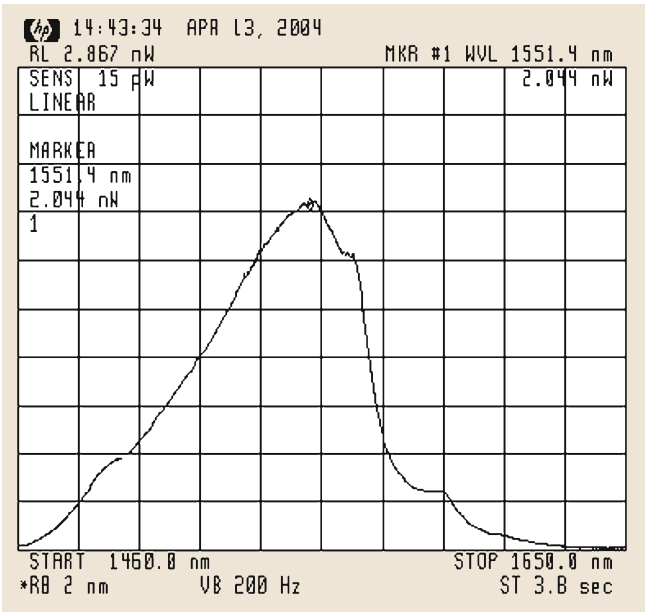

Fig. 14.24 Spectrum of spontaneous Raman scattering from 25 km of a standard single-mode fiber pumped by a pump at 1450 nm

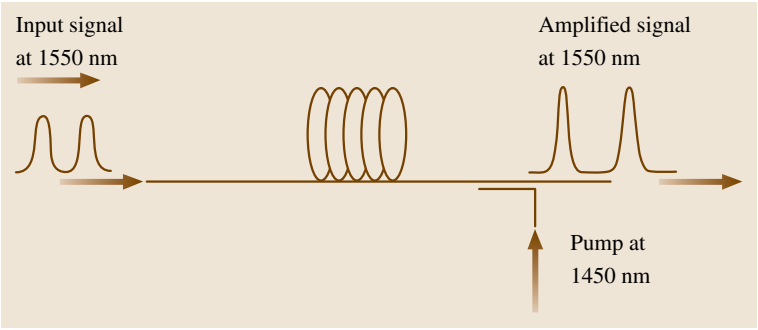

Fig. 14.25 Raman amplification by counter propagating pump

The propagation equations describing the variation of signal power (P_s) and pump power (P_p) along the length of the fiber for a counter pumped Raman amplifier are given by [14.32]

$$\frac{dP_s}{dz} = \gamma_R P_p P_s - \alpha_s P_s ,$$
$$\frac{dP_p}{dz} = \frac{\nu_p}{\nu_s}\gamma_R P_p P_s + \alpha_p P_p , \qquad (14.110)$$

where ν_p and ν_s are the pump and signal frequencies, γ_R is the Raman gain efficiency defined by

$$\gamma_R = \frac{\iint g_R(\nu, r)\psi_p^2\psi_s^2 r\,dr}{2\pi \iint \psi_p^2 r\,dr \iint \psi_s^2 r\,dr} \approx \frac{g_R(\nu)}{A_{eff}} , \qquad (14.111)$$

where ψ_p and ψ_s are the transverse variation of pump and signal modal fields, and g_R represents the material Raman gain coefficient and A_{eff} is the effective area defined by

$$A_{eff} = \frac{2\pi \iint \psi_p^2 r\,dr \iint \psi_s^2 r\,dr}{\iint \psi_p^2\psi_s^2 r\,dr} . \qquad (14.112)$$

Since the modal field profiles depend on the fiber refractive index profile, the value of γ_R can be very different for various fibers. For example for standard SMFs, γ_R is about $0.5–1\,W^{-1}\,km^{-1}$, for dispersion compensating fibers it is about $2.5–3\,W^{-1}\,km^{-1}$ and for highly nonlinear fibers it is about $6.5\,W^{-1}\,km^{-1}$. Photonic crystal fibers and holey fibers can have extremely small mode effective areas and hence can provide extremely large Raman gains. The larger the value of γ_R, the larger the stimulated Raman scattering and the larger the corresponding gains that are achievable. Figure 14.26 shows a typical length variation of pump and signal power of a counter pumped Raman amplifier.

Like any amplifier, in the case of Raman amplifiers also the amplified signal is accompanied by noise generated due to amplification of spontaneous Raman scattering that takes place within the fiber. Since amplification takes place over a long length of the fiber, additional noise due to the phenomenon of double Rayleigh scattering (DRS) is also generated. Signals propagating in the forward direction suffer Rayleigh scattering and generate power in the backward direction. The backward propagating signals can undergo further Rayleigh scattering (DRS) and generate power in the forward direction. These signals also use the same pump power to get amplified and constitute DRS noise. This noise becomes important for reasonably large pump powers and long interaction lengths when the gain becomes large. Apart from the amplified spontaneous Raman scattered light in the backward direction can get Rayleigh scattered to the forward direction which would also add to noise.

One can obtain approximate expressions for the Raman gain and spontaneously emitted noise power, which are given by

$$G\,(\mathrm{dB}) = 10\log\left(\frac{P_s(L)}{P_s(0)\,e^{-\alpha_s L}}\right) \approx 4.34\frac{\gamma_R}{\alpha_p}P_p(L) , \qquad (14.113)$$

where the last approximation is valid for $\alpha_p L \gg 1$ and

$$P_{sp}(L) = 2h\nu\Delta\nu \times\left[\frac{4.34}{G}\exp\left(\frac{G}{4.34}\right) - \left(1+\frac{4.34}{G}\right)\right] . \qquad (14.114)$$

Here G defines the on-off gain which is the ratio of output power with the Raman pump on to that of the output power when the Raman pump is switched off.

In Raman amplifiers the pump beam can propagate in the same direction as the signal or in the reverse direction. The former case is referred to as co-propagating (forward pumping) and the latter one as contra-propagating (backward pumping). The Raman scattering phenomenon is an extremely fast process with time scales in the femtosecond (10^{-15} s) regime. This can lead to transfer of power fluctuations from the pump to the signal. One way to avoid this is to have backward pumping (Fig. 14.25) wherein the gain fluctuations induced by the pump fluctuations become averaged out and thus the noise in the signal due to pump fluctuations is much lower.

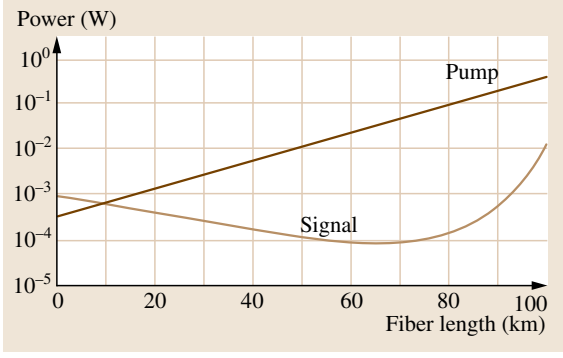

Fig. 14.26 Signal and pump power variation along the length of a fiber Raman amplifier

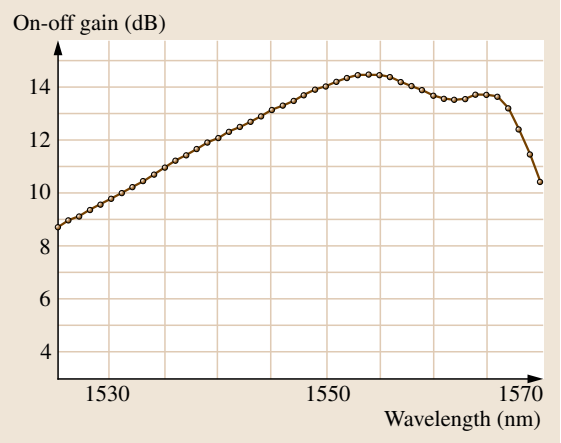

Fig. 14.27 Typical on-off gain spectrum of a fiber Raman amplifier

Figure 14.27 shows a measured on–off gain spectrum of a backward pumped Raman fiber amplifier corresponding to an input pump power of 750 mW at a wavelength of 1453 nm and an input signal power of 0.14 mW over a 25 km long span of single-mode fiber. On–off gains greater than 12 dB are easily achievable.

Since the gain spectrum depends on the pump wavelength, it is indeed possible to achieve large flat gain using multiple pumps. Thus using 12 pumps with wavelengths lying between 1410 and 1510 nm, a total flat gain bandwidth of 100 from 1520–1620 nm (covering the C-band and the L-band) has been demonstrated. Since Raman fiber amplifiers can operate at any signal wavelength region, they allow us to expand the operation region of fiber optic communication systems to other bands wherein EDFAs do not operate. Apart from this, Raman amplifiers can also be used to extend the operation of optical fiber communication systems in C-band. The repeaterless length can be increased by use of Raman amplifier at the terminal. Similarly when the bit rate of a communication channel is increased, then for the system to operate without signal degradation (within a certain bit error rate), the receiver would need more power. In this case, the additional Raman gain that is realized by propagating an appropriate pump with the signal can be used to increase the transmission bit rate for the same distance between the transmitter and receiver.

Since the gain coefficient depends on the effective area of the fiber, the Raman gain spectrum could be modified by proper fiber designs with appropriate spectral dependence of effective area. Thus, recently novel fiber designs were proposed that can give flat Raman gain with just a single pump [14.33, 34]. For nice reviews of fiber Raman amplifiers, readers are referred to [14.32, 35, 36].

14.12 Nonlinear Effects in Optical Fibers

Consider a light beam having a power of 100 mW propagating through an optical fiber having an effective mode area of 50 μm^2. The corresponding optical intensity is 2×10^9 W/m^2. At such high intensities, the nonlinear effects in optical fibers start to influence the propagation of the light beam and can significantly influence the capacity of a WDM optical fiber communication system [14.37]. The most important nonlinear effects that affect optical fiber communication systems include self phase modulation (SPM), cross phase modulation (XPM), and four-wave mixing (FWM). Stimulated Raman scattering (SRS) and stimulated Brillouin scattering (SBS) are also important nonlinear phenomena, and earlier we saw how SRS can be used for optical amplification. In this section, we will discuss mainly SPM, XPM, and FWM, which affect pulse propagation through optical fibers.

14.12.1 Self Phase Modulation (SPM)

The lowest order nonlinearity present in an optical fiber is the third order nonlinearity. Thus in an optical fiber, the polarization generated consists of a linear and a nonlinear term

$$P = \varepsilon_0 \chi E + \varepsilon_0 \chi^{(3)} E^3 \,, \tag{14.115}$$

where χ and $\chi^{(3)}$ represent the linear and third-order susceptibility of the medium (silica), and E represents the electric field of the propagating light wave/pulse.

If we consider light at frequency ω propagating along the z-direction with propagating constant k, then its electric field is given by

$$E = E_0 \cos(\omega t - kz) \,, \tag{14.116}$$

then

$$P = \varepsilon_0 \chi E_0 \cos(\omega t - kz) + \varepsilon_0 \chi^{(3)} E_0^3 \cos^3(\omega t - kz) \,. \tag{14.117}$$

Expanding $\cos^3\theta$ in terms of $\cos\theta$ and $\cos 3\theta$, we obtain the following expression for the polarization at frequency ω,

$$P = \varepsilon_0 \left(\chi + \tfrac{3}{4}\chi^{(3)} E_0^2\right) E_0 \cos(\omega t - kz) \,. \tag{14.118}$$

For a plane wave, the intensity is given by

$$I = \tfrac{1}{2} c \varepsilon_0 n_0 E_0^2 \,, \tag{14.119}$$

where n_0 is the refractive index of the medium at low intensity. Thus,

$$P = \varepsilon_0 \left(\chi + \frac{3}{2}\frac{\chi^{(3)}}{c\varepsilon_0 n_0} I\right) E \,. \tag{14.120}$$

The polarization P and electric field are related through the equation

$$P = \varepsilon_0 (n^2 - 1) E \,, \tag{14.121}$$

where n is the refractive index of the medium. Comparing (14.120) and (14.121), we obtain

$$n^2 = n_0^2 + \frac{3}{2}\frac{\chi^{(3)}}{c\varepsilon_0 n_0} I \,, \tag{14.122}$$

where

$$n_0^2 = 1 + \chi \,. \tag{14.123}$$

Since the last term in (14.10) is usually very small, we obtain

$$n \approx n_0 + n_2 I \,, \tag{14.124}$$

where

$$n_2 = \frac{3}{4}\frac{\chi^{(3)}}{c\varepsilon_0 n_0^2} \tag{14.125}$$

is the nonlinear coefficient. Thus, (14.124) shows that the refractive index of the medium becomes intensity dependent and the coefficient n_2 represents the strength of the intensity dependence. It is this intensity dependent refractive index that gives rise to SPM.

In the case of an optical fiber, the light beam propagates as a mode having a specific transverse electric field distribution and thus the intensity is not constant across the cross section. In such a case, it is convenient to express the nonlinear effect in terms of the power carried by the mode (rather than in terms of intensity). If the linear propagation constant of the mode is represented by β, then in the presence of nonlinearity the effective propagation constant is given by

$$\beta_{\mathrm{NL}} = \beta + \gamma P \,, \tag{14.126}$$

where

$$\gamma = \frac{k_0 n_2}{\tilde{A}_{\mathrm{eff}}} \,; \quad \tilde{A}_{\mathrm{eff}} = 2\pi \frac{\left(\int \psi^2(r) r \,\mathrm{d}r\right)^2}{\int \psi^4(r) r \,\mathrm{d}r} \tag{14.127}$$

represent the nonlinear coefficient and the nonlinear mode effective area, respectively, and β is the propagation constant of the mode at low powers. If we assume the mode to be described by a Gaussian function, then $\tilde{A}_{\mathrm{eff}} = \pi w_0^2$, where w_0 is the Gaussian mode spot size. Note that the nonlinear coefficient γ of the fiber depends on the effective area of the mode; the larger the effective mode area, the smaller the nonlinear effects. Table 14.3 gives the mode effective area of some common fiber types.

If α represents the attenuation coefficient of the optical fiber, then the power propagating through the fiber decreases exponentially as $P(z) = P_0 \mathrm{e}^{-\alpha z}$, where P_0 is the input power and α is the attenuation coefficient. In such a case, the phase shift suffered by an optical beam in propagating through a length L of the optical fiber is given by

$$\Phi = \int_0^L \beta_{\mathrm{NL}} \,\mathrm{d}z = \beta L + \gamma P_0 L_{\mathrm{eff}} \,, \tag{14.128}$$

where

$$L_{\mathrm{eff}} = \frac{1 - \mathrm{e}^{-\alpha L}}{\alpha} \tag{14.129}$$

Fiber type	Effective area ($\mu\mathrm{m}^2$)
Single-mode fiber (SMF) G652	≈ 85
Dispersion shifted fiber (DSF)	≈ 46
Nonzero DSF (NZDSF)	≈ 52 ($D > 0$), 56 ($D < 0$), 73
Dispersion compensating fiber (DCF)	≈ 23 ($D < 0$)
Photonic crystal fiber/holey fiber	≈ 3

Table 14.3 Mode effective area of typical commercially available fibers

is called the effective length of the fiber. If $\alpha L \gg 1$ then $L_{\text{eff}} \sim 1/\alpha$ and if $\alpha L \ll 1$ then $L_{\text{eff}} \sim L$. For single-mode fibers operating at 1550 nm, $\alpha \approx 0.25$ dB/km and thus $L_{\text{eff}} \sim L$ for $L \ll 20$ km and $L_{\text{eff}} \approx 20$ km for $L \gg 20$ km.

Since the propagation constant β_{NL} of the mode depends on the power carried by the mode, the phase Φ of the emergent wave depends on its power and hence this is referred to as SPM.

For a light pulse P_0 in (14.128) becomes time dependent and this leads to an additional time dependent phase apart from $\omega_0 t$. Thus the output pulse is chirped and the instantaneous frequency of the output pulse is given by

$$\omega(t) = \frac{\mathrm{d}}{\mathrm{d}t}(\omega_0 t - \gamma P_0 L_{\text{eff}}) = \omega_0 - \gamma L_{\text{eff}} \frac{\mathrm{d}P_0}{\mathrm{d}t} . \tag{14.130}$$

The leading edge of the pulse corresponds to the positive values of $\mathrm{d}P_0/\mathrm{d}t$ and the trailing edge to negative values of $\mathrm{d}P_0/\mathrm{d}t$. Thus in the presence of SPM, the leading edge is downshifted in frequency while the trailing edge is upshifted in frequency. The frequency at the center of the pulse remains unchanged from ω_0. Figure 14.28 shows an input unchirped and an output chirped pulse generated due to SPM. The output chirped pulse with the same temporal width has a larger frequency spectrum. These new frequencies were generated by the nonlinear process.

The chirping due to nonlinearity without any corresponding increase in pulse width leads to spectral broadening of the pulse. This spectral broadening coupled with the dispersion in the fiber leads to modified dispersive propagation of the pulse in the presence of nonlinearity. In the normal dispersion region the chirping due to dispersion is to downshift the leading edge and upshift the trailing edge of the pulse. This is of the same sign as that due to SPM. Thus, in the normal dispersion regime (wavelength less than the zero dispersion wavelength) the chirping due to dispersion and nonlinearity add. Thus at high powers, where the nonlinear effects are not negligible, the pulse will suffer additional dispersion as compared to the dispersion of the same pulse at low powers. On the other hand, in the anomalous dispersion region (wavelength greater than the zero dispersion wavelength), the chirping due to dispersion is opposite to that due to nonlinearity, and thus in this wavelength region, nonlinearity and dispersion induced chirpings can partially or even totally cancel each other. When total cancelation takes place, the pulse neither broadens in time nor in its spectrum, and such a pulse is called a *soliton*. Such solitons can hence be used for dispersion less propagation of pulses to realize very high bit rate systems.

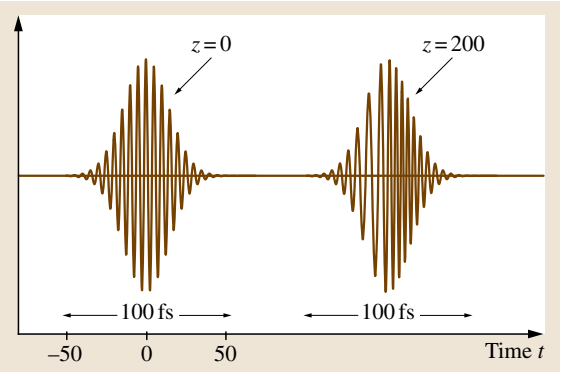

Fig. 14.28 An unchirped pulse at the input after propagating through an optical fiber is chirped due to SPM

Assuming only second-order dispersion and $\chi^{(3)}$ nonlinearity, the amplitude $A(z, t)$ of the electric field of an incident pulse can be shown to satisfy [14.38]

$$\frac{\partial A}{\partial z} = \mathrm{i}\frac{\beta_2}{2}\frac{\partial^2 A}{\partial T^2} - \mathrm{i}\gamma|A|^2 A , \tag{14.131}$$

where $\beta_2 = \mathrm{d}^2\beta/\mathrm{d}\omega^2$ and $T = t - z/v_{\text{g}}$. Equation (14.131) is referred to as the nonlinear Schrödinger equation and describes the propagation of a pulse in a medium possessing second-order dispersion and $\chi^{(3)}$ nonlinearity. The solution of the above equation give us solitons, which are described mathematically by

$$A(z, t) = \sqrt{P_0}\,\mathrm{sech}\left(\sqrt{\frac{P_0\gamma}{|\beta_2|}}\,T\right) \mathrm{e}^{-\mathrm{i}\gamma P_0 z/2} . \tag{14.132}$$

Equation (14.132) shows that the peak power required to form a soliton is related to the pulse width and dispersion coefficient D. As an example, for a soliton pulse at 1550 nm with full width at half maximum of $\tau_{\text{f}} = 10$ ps propagating in a fiber with $\gamma = 2.4\,\text{W}^{-1}\,\text{km}^{-1}$ and $D = 2$ ps/(km nm) and the required peak power will be $P_0 = 33$ mW.

A heuristic derivation of the power required to form a soliton by cancelation of chirping due to dispersion and nonlinearity can be found in [14.6].

Even if the cancelation between dispersive and nonlinear chirping is not perfect, the nonlinear effects in an optical fiber lead to reduced pulse broadening in the anomalous dispersion region. Thus the net dispersion suffered by the pulse decreases as the power increases.

This fact needs to be kept in mind while designing dispersion compensation schemes.

14.12.2 Cross Phase Modulation

Consider the simultaneous launching of two or more different light beams of different wavelengths into an optical fiber. In such a case, each individual light wave will lead to a change in refractive index of the fiber due to the intensity dependent refractive index. This change in refractive index of the fiber then affects the phase of the other light beam(s); this results in what is referred to as cross phase modulation (XPM).

To study XPM, we assume simultaneous propagation of two waves at two different frequencies through the medium. If ω_1 and ω_2 represent the two frequencies, then one obtains for the variation of the amplitude A_1 of the frequency ω_1 as

$$\frac{\mathrm{d}A_1}{\mathrm{d}z} = -\mathrm{i}\gamma\left(\tilde{P}_1 + 2\tilde{P}_2\right)A_1\,, \tag{14.133}$$

where $\tilde{P}_1$ and $\tilde{P}_2$ represent the powers at frequencies ω_1 and ω_2, respectively. The first term in (14.133) represents SPM while the second term corresponds to XPM. If the powers are assumed to attenuate at the same rate, i. e.,

$$\tilde{P}_1 = P_1\,\mathrm{e}^{-\alpha z}\,, \quad \tilde{P}_2 = P_2\,\mathrm{e}^{-\alpha z}\,, \tag{14.134}$$

then the solution of (14.133) is

$$A_1(L) = A_1(0)\mathrm{e}^{-\mathrm{i}\gamma(P_1+2P_2)L_{\mathrm{eff}}}\,, \tag{14.135}$$

where, as before, L_{eff} represents the effective length of the medium. When we are studying the effect of power at ω_2 on the light beam at frequency ω_1, we will refer to the wave at frequency ω_2 as pump and the wave at frequency ω_1 as probe or signal. From (14.135) it is apparent that the phase of signal at frequency ω_1 is modified by the power at another frequency. This is referred to as XPM. Note also that XPM is twice as effective as SPM.

Similar to the case of SPM, the instantaneous frequency of a signal at frequency ω_0 in the presence of XPM is given by

$$\omega(t) = \omega_0 - 2\gamma L_{\mathrm{eff}}\frac{\mathrm{d}P_2}{\mathrm{d}t}\,, \tag{14.136}$$

where P_2 is the power carried by the other wavelength. The part of the signal that is influenced by the leading edge of the pump will be downshifted in frequency (since in the leading edge $\mathrm{d}P_2/\mathrm{d}t > 0$) and the part overlapping with the trailing edge will be upshifted in frequency (since $\mathrm{d}P_2/\mathrm{d}t < 0$). This leads to a frequency chirping of the signal pulse just like in the case of SPM. Conventional detectors detect the intensity variation of the signal and hence are not affected by phase variations caused by XPM. However, these phase variations are converted to intensity variations due to dispersive effects in the fiber and these intensity variations can cause further bit errors in a fiber optic communication system.

If the two light waves are pulses, then XPM leads to chirping of the pulses. In the presence of finite dispersion (i. e., operation away from the zero dispersion wavelength), the two pulses will move with different velocities and thus the pulses will walk off from each other. In case the pulses enter the fiber together, then due to walk off each pulse will see only the trailing or the leading edge of the other pulse which will lead to chirping. On the other hand, if the *collision* is complete, i. e., if the pulses start separately and walk through each other and again separate as they propagate through the fiber, then there would be no XPM induced chirping since the pulses would have interacted with both the leading and the trailing edge of the other pulse. In an actual system, this cancelation will not be perfect since the pulses suffer attenuation and this leads to reduced nonlinear interaction as the pulses walk through each other.

14.12.3 Four-Wave Mixing (FWM)

Consider the incidence of three waves at three frequencies ω_2, ω_3, and ω_4 into an optical fiber. In the presence of the three waves, the third-order nonlinearity in the fiber leads to the generation of a nonlinear polarization at a frequency ω_1 given by

$$\omega_1 = \omega_3 + \omega_4 - \omega_2\,. \tag{14.137}$$

This nonlinear polarization can, under some circumstances, lead to the generation of electromagnetic waves at the new frequency ω_1. This phenomenon is referred to as four-wave mixing (FWM). In a dense wavelength division multiplexed (DWDM) system, FWM leads to cross talk among different wavelength channels of the system.

The nonlinear polarization at frequency ω_1 due to the presence of other waves is given by

$$P_{\mathrm{NL}}^{\omega_1} = \tfrac{1}{2}\left(p_{\mathrm{nl}}\,\mathrm{e}^{\mathrm{i}(\omega_1 t - \beta_1 z)} + \mathrm{c.c.}\right)\,, \tag{14.138}$$

where

$$p_{\mathrm{nl}} = \frac{3\varepsilon_0}{2}\chi^{(3)}A_2^* A_3 A_4 \psi_2 \psi_3 \psi_4\,\mathrm{e}^{-\mathrm{i}\Delta\beta z}\,, \tag{14.139}$$

where $\Delta\beta = \beta_3 + \beta_4 - \beta_2 - \beta_1$, and A_i and ψ_i represent the amplitudes and modal field profiles corresponding to modes at frequency ω_i. From the expression for the nonlinear polarization it can be seen that, in general, the velocity of the nonlinear polarization is not equal to the velocity of the electromagnetic wave that it is generating. For efficient generation of the electromagnetic wave at the frequency ω_1, there must be phase matching, i. e., the velocity of the nonlinear polarization (which acts as the source of the radiation at frequency ω_1) and the electromagnetic wave (at frequency ω_1) must be equal. For this to happen we must have $\Delta\beta = 0$. Assuming the frequencies to be closely and equally spaced (i. e., $\omega_1 = \omega_2 - \Delta\omega$, $\omega_3 = \omega_2 - 2\Delta\omega$, $\omega_4 = \omega_2 + \Delta\omega$) and making a Taylor series expansion of all βs about a frequency ω_2, we obtain

$$\Delta\beta = -\frac{4\pi D\lambda^2}{c}(\Delta\nu)^2 \,, \tag{14.140}$$

where $\Delta\omega = 2\pi\Delta\nu$ represents the frequency spacing between adjacent channels. Thus, when the channels lie around the zero dispersion wavelength of the fiber, $D = 0$ and we have phase matching and thus an efficient FWM. If one wishes to reduce FWM, then one must operate away from the zero dispersion wavelength. This has led to the development of nonzero dispersion shifted fibers (NZ-DSF), wherein a finite but small dispersion (≈ 2–$8\,\mathrm{ps/(km\,nm)}$) is introduced to reduce FWM effects in an actual fiber optic communication system (Fig. 14.10). On the other hand, if a strong FWM is desired for an application such as all-optical signal processing or wavelength conversion, then the interacting wavelengths must lie close to the zero dispersion wavelength.

Assuming that all frequencies have the same attenuation coefficient α and neglecting depletion due to conversion, the power generated at the frequency ω_1 due to mixing of the other three frequencies can be shown to be

$$P_1 = 4\gamma^2 P_2 P_3 P_4 L_{\mathrm{eff}}^2 \eta \mathrm{e}^{-\alpha L} \,, \tag{14.141}$$

where

$$\eta = \frac{\alpha^2}{\alpha^2 + \Delta\beta^2}\left(1 + \frac{4\mathrm{e}^{-\alpha L}\sin^2\frac{\Delta\beta L}{2}}{(1-\mathrm{e}^{-\alpha L})^2}\right) . \tag{14.142}$$

As evident from (14.142), maximum conversion occurs when $\eta = 1$, i. e., $\Delta\beta = 0$. If we assume all wavelengths to carry the same power P_{in}, then under phase matching, the ratio of the power generated due to FWM to that exiting from the fiber is given by

$$R = \frac{P_{\mathrm{g}}}{P_{\mathrm{out}}} = \frac{P_1(L)}{P_{\mathrm{in}}\mathrm{e}^{-\alpha L}} = 4\gamma^2 P_{\mathrm{in}}^2 L_{\mathrm{eff}}^2 \,. \tag{14.143}$$

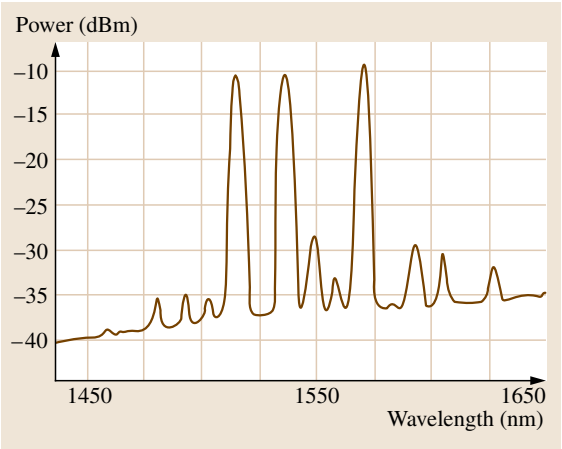

Fig. 14.29 New frequency components generated due to four-wave mixing in an optical fiber operating close to the zero dispersion wavelength. The input consists of the three large amplitude frequencies (after [14.39])

Thus, if in each channel we have an input power of 1 mW, then for $\gamma = 1.73\times10^{-3}\,\mathrm{m^{-1}\,W^{-1}}$, $L_{\mathrm{eff}} = 20\,\mathrm{km}$, the FWM generated output will be about 0.5% of the power exiting in the channel. This gives us the level of crosstalk among the channels created due to FWM.

Figure 14.29 shows the output spectrum measured at the output of a 25 km long dispersion shifted fiber ($D = -0.2\,\mathrm{ps/(km\,nm)}$ at the central channel) when three 3 mW wavelengths are launched simultaneously. Notice the generation nine new frequencies with different amplitudes (with a maximum peak ratio of 1% to the input signals) due to FWM. Newly generated waves will interfere with power present in those channels and lead to cross talk. By choosing a nonzero value of dispersion, the four-wave mixing efficiency can be significantly reduced. The larger the dispersion coefficient, the smaller can be the channel spacing for the same cross talk.

Since dispersion leads to increased bit error rates in fiber optic communication systems, it is important to have low dispersion. On the other hand, lower dispersion leads to cross talk due to FWM. This problem can be resolved by noting that FWM depends on the local dispersion value in the fiber while the pulse spreading at the end of a link depends on the overall dispersion in the fiber link. If one chooses a link made up of positive and negative dispersion coefficients, then by an appropriate choice of the lengths of the positive and negative dispersion fibers, it would be possible to achieve a zero total link dispersion while at the same time maintaining

a large local dispersion. This is referred to as dispersion management in fiber optic systems.

Although FWM leads to cross talk among different wavelength channels in an optical fiber communication system, it can be used for various optical processing functions such as wavelength conversion, high speed time division multiplexing, pulse compression, optical amplification, etc. [14.41, 42]. For such applications, there is a concerted worldwide effort to develop highly nonlinear fibers with much smaller mode areas and higher nonlinear coefficients. Some of the very novel fibers that have been developed recently include holey fibers, photonic bandgap fibers, or photonic crystal fibers, which are very interesting since they posses extremely small mode effective areas ($\approx 2.5\,\mu m^2$ at 1550 nm) and can be designed to have zero dispersion even in the visible region of the spectrum [14.43, 44]. This is expected to revolutionize nonlinear fiber optics by providing new geometries to achieve highly efficient nonlinear optical processing at lower powers.

14.12.4 Supercontinuum Generation

Supercontinuum (SC) generation is the phenomenon in which a nearly continuous spectrally broadened output (bandwidth > 1000 nm) is produced through nonlinear effects on high peak power picosecond and femtosecond pulses. Such broadened spectra find applications in spectroscopy, optical coherence tomography, WDM source for optical communication by slicing the spectrum, etc. Supercontinuum generation in an optical fiber is a very convenient technique since the intensity levels can be maintained high over long interaction lengths by choosing small mode areas and the dispersion profile of the fiber can be appropriately designed by varying the transverse refractive index profile of the fiber. The spectral broadening that takes place in the fiber is attributed to a combination of various third-order effects such as SPM, XPM, FWM, and Raman scattering. Since dispersion plays a significant role in the temporal evolution of the pulse, different dispersion profiles have been used in the literature to achieve broadband SC. Some studies have used dispersion decreasing fibers, dispersion flattened fibers, while others have used a constant anomalous dispersion fiber followed by a normal dispersion fiber.

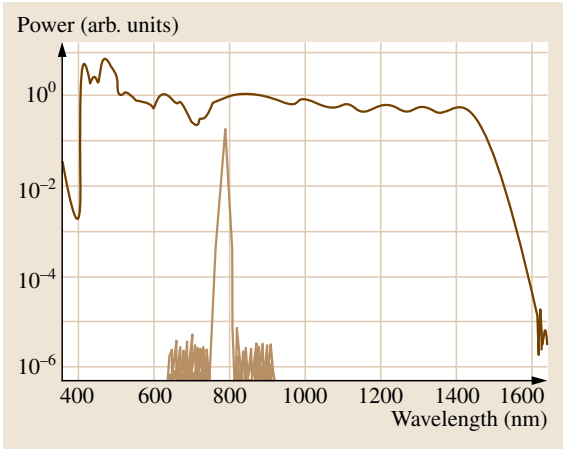

Fig. 14.30 Spectral broadening by supercontinuum generation (after [14.40])

Figure 14.30 shows the input and output broadened spectra obtained by passing a light pulse through a photonic crystal fiber [14.40].

14.13 Microstructured Fibers

A standard optical fiber guides light using the phenomenon of total internal reflection. Recently there has been intense activity in realization of optical fibers guiding light using Bragg reflections or photonic bandgap effects. Photonic crystals are periodic structures fabricated in an optical material with periodicities comparable to the optical wavelength. These can be one-dimensional (like fiber Bragg gratings), two-dimensional, or three-dimensional. Structures with appropriate symmetry and periodicities can exhibit photonic bandgaps, which are regions of optical wavelengths where light cannot propagate through the structure, much like the bandgaps for electrons in crystals. Thus such structures allow control of light propagation and find applications in semiconductor lasers, light modulators, integrated optical devices, nonlinear devices, etc. Microstructured fibers have a periodic arrangement of holes in a silica background material running all along the length of the fiber and can lead to guidance of light using the bandgap effects. Figure 14.31 shows two types of such fibers, one having solid silica core and the other having an air hole at the center. Since confinement can be accomplished using the bandgap effect it is possible to realize optical fibers with air cores; such holey fibers are finding many applications. It is also possible to realize fibers

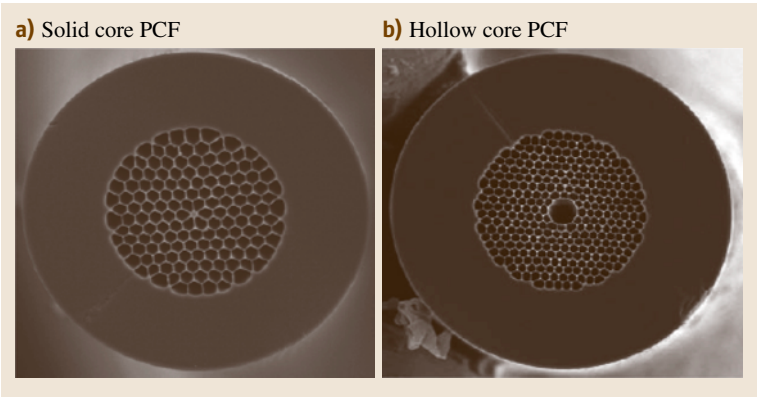

Fig. 14.31 Solid core and hollow core photonic crystal fibers (courtesy of Blaze Photonics, UK)

with solid cores with mode effective areas in the region of 3 μm^2. Since nonlinear effects depend on the intensity of light such fibers can give rise to very interesting nonlinear effects even at moderate power levels. Microstructured fibers exhibit the very interesting property of being single-mode over a very large range of wavelengths. This can be understood from the fact that due to the presence of holes in the cladding, as the wavelength changes the fraction of light power in the holes changes and this leads to an effective cladding refractive index, which becomes highly wavelength dependent and increases with increasing wavelength leading to an effective V-number, which results in single-mode operation. Such fibers are also referred to as endlessly single-mode fibers. The dispersion of microstructured fibers can also be controlled by appropriate design and it is possible to achieve zero dispersion in the visible range using silica, which is otherwise not possible using conventional fiber designs. Supercontinuum generation, which requires control of dispersion and nonlinearity, is one such application and devices based on such fibers are now commercially available. With technological inputs, propagation loss in these fibers have been reduced significantly and photonic crystal fibers with a loss value of 0.3 dB/km were realized recently [14.45].

15. Integrated Optics

This chapter reports concepts and realizations of integrated optical circuits, i. e., the concept of optical waves which are traveling through planar circuits and confined in one or two directions. Integrated optical components such as array waveguide gratings (AWGs) turned out to be a key enabler for modern broadband optical communications based on wavelength division multiplexing (WDM). The requirements on integrated optical circuits range from passive functions such as beam splitters and optical filters over slow and fast optical switches to active transmitters and receivers. The material systems include glasses, polymers, $LiNbO_3$, silicon, and III–V semiconductors.

Weakly guiding integrated optical circuits, the traditional approach exhibiting waveguiding properties close to those of standard single-mode fibers (SSMF), offer ease of fabrication through single-mode field diameters of several wavelengths and large radii of curvature. Such components are based on a low refractive index contrast between the waveguide and its environment.

Modern approaches aim at increasingly compact circuits to meet the system-driven requirements, mainly cost and footprint. They are based on waveguides with high refractive index contrast or photonic crystal waveguides and submicron waveguide cross-sections, e. g., on silicon, which exhibit single-mode field diameters much smaller than the wavelength and thus extremely small radii of curvature.

References 1248

The term "integrated optics" was introduced by *Miller* [15.1] in 1969. At that time, it served as a synonym for the concept of planar optical circuits that enable monolithic integration on one chip of optical transmitting and receiving devices, together with the passive devices required for distribution, connection, and filtering.

15.1 Introduction

During the pioneering period of integrated optics, activities worldwide focused on demonstrating active and passive components compatible with the technologies used in integrated optics. The distributed feedback (DFB) laser was the first milestone in this development. Numerous passive components, such as directional couplers, Y-splitters, waveguide crossings, Bragg gratings, transmission gratings, acoustooptical filters, optical switches, and modulators, were also demonstrated for the first time during this phase. In addition to the InGaAsP/InP and GaAlAs/GaAs III–V semiconductor material systems, which enable monolithic integration of laser diodes, photodiodes, and passive components, chips were also fabricated in a range of dielectric material systems, especially in lithium niobate ($LiNbO_3$), in glass-based material systems (special glasses for ion exchange, glass on silicon SiO_2/Si), in silicon-on-insulator (SOI), and in polymers – acrylates, polyimides, and polycarbonates – which do not allow monolithic integration.

During the following period (from the mid 1980s onward) it became increasingly possible to fabricate circuits in integrated optics, i. e., chips with a large number of identical components and monolithically integrated chips with optical transmitters, receivers, and passive optics. Table 15.1 presents a few typical examples and the material systems used to fabricate them.

At the same time, complex single components such as focusing reflection gratings, optical phased arrays, and polarization-independent acoustooptical filters were realized for the first time. When integrated optics appeared in the marketplace in the mid 1990s, testing and measuring methods became standardized [15.29, 30].

Driven by their ease of fabrication, development was focused on weakly guiding waveguides for a long time. During recent years, we can observe a trend towards strong waveguiding, which allows realization of more compact circuits and enables new types of building blocks such as on-chip resonators.

Ever since the pioneering era of integrated optics it was anticipated that the obvious advantages of monolithic integrability of active and passive optical devices and the associated electronics within optoelectronic integrated circuits (OEIC) based on III–V technologies would squeeze out *hybrid integration* based on the SiO_2/Si, glass, polymer, and $LiNbO_3$ material systems [15.31]. For a number of reasons, things have turned out differently. For one thing, the complexity of III–V technologies, which is driven in particular by the integration of essentially diverse components, leads to high upfront development costs and thus to high effective unit costs in the still very limited markets for integrated optical circuits. For another, so far, III–V components have failed to match several of the essential performance criteria of hybrid technologies in terms of fiber–chip coupling, waveguide losses, and polarization dependence. Moreover, optical phased arrays show that the realizability of complex single components is an

Table 15.1 Examplary integrated optical circuits and material systems used to fabricate them

Optical circuit	Material system
1 : *N* splitter [15.2]	Glass (1 : 32), SiO_2/Si (1 : 32)
Optical backplane [15.3, 4]	Polymers
Optical phased array (arrayed waveguide grating (AWG)) [15.5–7]	SiO_2/Si, InGaAsP/InP, Polymers, SOI
Optical switching matrix (optical cross connect (OCC or OXC)) [15.8–16]	InGaAsP/InP (4×4, 1×8), SiO_2/Si (8×8, 16×16), $LiNbO_3$ (8×8)
Tunable wavelength-division multiplexing (WDM) filter [15.17]	SiO_2/Si (cascaded Mach–Zehnder coupler), $LiNbO_3$ (acoustooptical filter)
Laser modulator component [15.18]	InGaAsP/InP
Laser booster component [15.19]	InGaAsP/InP
Bidirectional transmitter/receiver [15.20, 21]	InGaAsP/InP
WDM multichannel receiver [15.6, 22–24]	InGaAsP/InP, Ge-on-Si on SOI
WDM multichannel transmitter [15.19, 25]	InGaAsP/InP, InP on SOI
Heterodyne receiver [15.26]	InGaAsP/InP
Optical memory [15.27, 28]	InGaAsP/InP, InP on SOI

additional – and these days decisive – strength of integrated optics. In this area, however, III–V technologies offer no advantages at all against the competing technology of hybrid integration, e.g., *planar lightwave circuits (PLCs)* [15.32].

15.1.1 Waveguide Structures

Figure 15.1 shows several typical integrated optics strip waveguides. Lateral waveguide structures are usually defined lithographically (mostly using contact or projection lithography). In the case of multimode structures in polymers, molding techniques are applied also.

Step-index waveguides (Fig. 15.1a–d) – rib waveguides, strip-loaded waveguides, buried-strip, and buried-rib waveguides – are mostly made in InGaAsP/InP, GaAlAs/GaAs, silicon or SiO_2/Si using wet or dry etching techniques. Waveguides of these types have also been realized in polymers using lithography and/or molding techniques. The fabrication process chosen determines the range of parameters of feasible layer thicknesses and material compositions (refractive indices). The fabrication method and the required aspect ratio (waveguide height/width) determine the precise form of the waveguide, its surface properties, and the typical fabrication tolerances, i. e., the fluctuations in refractive index and waveguide dimensions from chip to chip and wafer to wafer, respectively. The next two waveguide classes (Fig. 15.1e,f) – buried or unburied waveguides with graded index profile – are typical for diffusion and ion-exchange processes, i. e., for waveguide structures in $LiNbO_3$ or suitable glasses. The refractive index profile and its tolerances are defined essentially by the diffusion or ion-exchange process. The last two waveguide classes – photonic crystal (Fig. 15.1g) and plasmonic (Fig. 15.1h) waveguides – aim at compact circuits and near fields.

The typical dimensions of a strip waveguide constitute an additional classification criterion. On the one hand, they convey a sense of the difficulties associated with the fabrication of integrated-optics chips. On the other hand, they determine the necessary spot magnification in fiber–chip coupling and thus the design of the coupling optics, hence in turn the alignment tolerances for fiber–chip coupling and ultimately the setup costs. The maximum thickness d_c of a single-mode, symmetrical slab waveguide is given by [15.33]

$$d_c = \frac{\lambda}{2n_{cl}\sqrt{2\Delta}}\,, \tag{15.1}$$

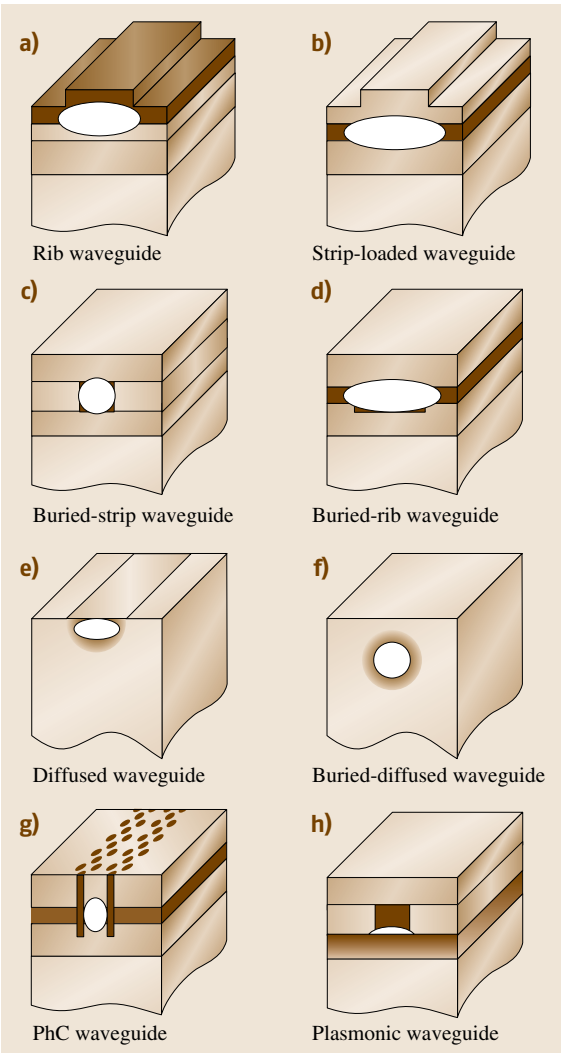

Fig. 15.1a–h Common single-mode, integrated optical waveguide profiles: step-index **(a–d)** and graded-index **(e,f)**, photonic crystals (PhC PhC) **(g)**, plasmonic **(h)**. The field distribution of the guided wave is indicated as *white area*

where n_{cl} is the cladding's refractive index, n_{co} is that of the core, and $\Delta = \left(n_{co}^2 - n_{cl}^2\right) / \left(2n_{co}^2\right)$ is the waveguide's relative refractive index contrast. The relative refractive index contrast takes on values of $\Delta \approx 10^{-3}$ for fiber-matched single-mode waveguides (field radius $\approx 5\,\mu m$). In contrast, for more strongly guiding waveguides, such as those in the InGaAsP/InP material system, it reaches values of $\Delta > 10^{-2}$. Modern waveguide concepts rely on strongly guiding waveguides

with $\Delta > 10^{-1}$. The relative refractive index contrast Δ (Sect. 15.3.1) determines not only the waveguide's dimensions and the near-field spot size at the chip's end face, but also the waveguide's minimum radius of curvature and finally the dimensions of a circuit.

15.1.2 Controlling Integrated Optical Devices

Depending on the material system used, optical components can be controlled by various linear and nonlinear effects (Sect. 15.5).

The most common scalar effect, the thermooptical effect [15.34, 35], describes the dependence of the refractive index n on the device temperature T. The associated coefficient differs from zero in the majority of materials. The thermooptical effect serves on the one hand for fine-tuning of components such as lasers and optical filters for WDM applications, and on the other hand, it is also applied in optical switches, attenuators, and tunable optical filters. Far enough away from any atomic resonances, the refractive index and the temperature are related linearly to a good approximation. Therefore, the thermooptical effect is mostly described by a single quantity, the normalized thermooptical coefficient $\left[(1/n)\,(\mathrm{d}n/\mathrm{d}T)\right]$. Table 15.2 presents the standardized thermooptical coefficient and the thermal expansion coefficient for a number of materials commonly used in integrated optics. We can see that, in most cases, thermal expansion contributes only slightly to the thermooptical coefficient. Moreover, it is evident that the changes due to atomic resonances and to thermal expansion mostly work in opposite directions. Polymers, of which poly(methyl methacrylate) (PMMA) can serve as a typical example, often exhibit a very high negative thermooptical coefficient, i. e., the effective refractive index decreases when the waveguide is heated. The typical response times of the thermooptical effect are in the range of milliseconds, and are driven by heat transport.

Table 15.2 Normalized thermooptical coefficient $[(1/n)\times(\mathrm{d}n/\mathrm{d}T))]$ and thermal expansion coefficient (α_L) for different materials

Material		$1/n\,\mathrm{d}n/\mathrm{d}T$ (10^{-6}/K)	α_L (10^{-6}/K)
InP		58.0	4.9
GaAs		66.7	5.7
Silicon (crystal)		53.4	3.0
Silicon (poly)		50–60	2.5–4.0
$LiNbO_3$	o	24.1	16.7
	e	2.4	2.0
Silicate glasses		4–7	0.3–0.6
PMMA		−93	80

Several other physical phenomena modify not only the magnitude of the refractive index or of the dielectric function, but also the form and orientation of the index ellipsoid. Nonlinear optical (NLO) effects of first order (also known as $\chi^{(2)}$ effects), such as the Pockels effect, do not occur in isotropic materials and in crystals that exhibit an inversion center (e.g., diamond structure). Second-order NLO effects ($\chi^{(3)}$ effects), e.g., the Kerr effect or the elastooptical effect, do occur in general, i. e., they even cause anisotropy in otherwise isotropic materials. More detailed discussion of isotropic and anisotropic effects in material systems typical in integrated optics, in particular the numerous phenomena that occur in III–V semiconductors, can be found in Sect. 8.6.

15.2 Waveguide Theory

device design and the corresponding mathematical methods of integrated optics are related in many respects to those of fiber optics, and due to the mathematical equivalence of the scalar Helmholtz equation and Schrödinger's equation, to those of quantum mechanics. However, as a result of the great variety of structures, numerical recipes e.g., those based on finite elements (FE) and finite differences (FD), are often preferred in integrated optics [15.36, 37]. In the 1990s, the computational methods of integrated optics reached a level of maturity that permitted ad hoc layout of almost any waveguide structure, especially passive ones [15.38]. Benchmark tests [15.39, 40] have shown, however, that the analysis of integrated optical geometries with large refractive index contrast, many guided modes, and/or large beam divergence, can only be carried out with sufficient precision by the most advanced methods. After the turn of the millennium, true high-index waveguides, photonic crystals, and plasmonic waveguides entered the arena of integrated optics. They required the treatment of reflections in integrated optical circuits and the analysis of periodic waveguide structures.

15.2.1 Eigenmode Analysis

An eigenmode is a wave that maintains its shape when propagating along a longitudinally invariant waveguide structure. Photonic crystal waveguides which are not longitudinally invariant guide the optical wave by refocusing, and have to be treated in another way (Sect. 15.2.2). The electromagnetic field of an eigenmode l is described by the equations

$$\mathbf{E}^{(l)}(\mathbf{r}_t, z) = \mathbf{e}^{(l)}(\mathbf{r}_t)\,e^{ik_0 n_l z}\,,$$
$$\mathbf{H}^{(l)}(\mathbf{r}_t, z) = \mathbf{h}^{(l)}(\mathbf{r}_t)\,e^{ik_0 n_l z}\,, \qquad (15.2)$$

where $n_l = \beta/k$ is the effective refractive index of the eigenmode l, z is its direction of propagation, and $\boldsymbol{r}$ is a position vector in the plane transverse to it. Figure 15.2 shows the dielectric profile $n^2(x)$ of a virtual, asymmetric waveguide and the various modes that can be guided by a waveguide structure.

The guided modes form a discrete spectrum in the range $n_{max}^2 > n_l^2 \geq n_s^2$ between the largest refractive index n_{max} of the waveguide structure and the largest refractive index n_s^2 at infinity (usually that of the waveguide substrate). During the course of geometric-optical analysis, these can be understood as beams of rays that are guided by total reflection within the waveguide. The partial beams (Brillouin waves) resulting from total reflection, however, interfere constructively only for a few reflection angles, at which the guided modes then exist. While symmetric waveguide structures always exhibit at least one guided mode, asymmetric refractive index profiles possess guided modes only above a minimum size. The optical field in Fig. 15.2a shows the typical field profile of the fundamental mode, i. e., of the guided mode with the maximum effective refractive index. The optical field of the l-th highest mode has $l+1$ minima and maxima, but just like the field of the fundamental mode it vanishes at infinity. Different refractive indices for the substrate n_s and external space n_o result in an asymmetric optical field.

The radiation modes form a continuous spectrum, with the eigenmodes in the range $n_s^2 > n^2 \geq n_o^2$ (Fig. 15.2b) being only partly oscillatory at infinity, whereas in the range $n_o^2 > n^2 \geq 0$ (Fig. 15.2c) they have a purely oscillatory character at infinity. Together with the evanescent modes ($n^2 < 0$), which are of practical significance only in the treatment of waveguide discontinuities, the guided modes and the propagable radiated modes form a complete system of functions, i. e., every field distribution can be described as a linear combination of these modes. The leaky waves (*leaky modes*)

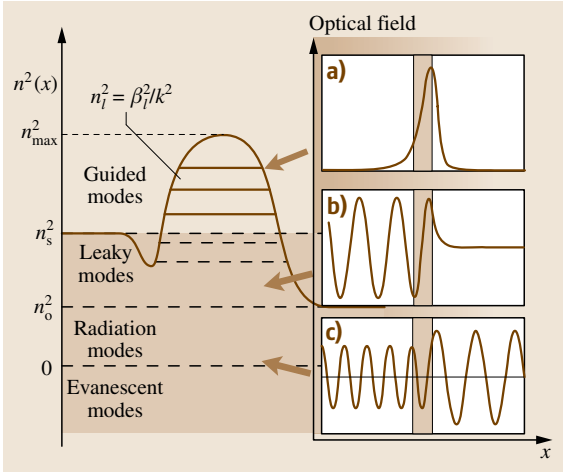

Fig. 15.2a–c Dielectric profile $n^2(x)$ of a slab waveguide, the various modes that can be guided by this waveguide structure, and field profiles for the fundamental mode **(a)** and for two different types of radiation modes **(b, c)**. The continuous ranges of the spectrum are *shaded*

do not constitute true eigenmodes of the waveguide structure, but rather resonances in the radiation spectrum. They can be regarded as guided modes below cutoff.

The notation for guided eigenmodes depends on the waveguide structure. Thus, the eigenmodes of slab waveguides, transverse modes each with three nonvanishing vector components, are referred to as transverse electric (TE_l) modes and transverse magnetic (TM_l) modes. The terms H_l modes and E_l modes are also used in the literature, with reference to the nonvanishing longitudinal field components for the TE_l and TM_l modes. The fundamental mode ($l = 0$) of the slab waveguide has no nodes (zeros), while the l-th highest mode has l nodes.

The eigenmodes of integrated optical strip waveguides with hybrid character are referred to as HE_{lm} and EH_{lm} modes, correspondingly. In the limit of weak lateral guidance, they merge into the H_l modes (TE_l modes) or E_l modes (TM_l modes) of the slab waveguide [15.41]. The index pairs or order lm of the eigenmodes are interpreted according to the axes of the coordinate system chosen for the eigenmode analysis. Cartesian coordinates (x, y) are often used for integrated optical waveguides in view of the layer structure required by the technology, whereas cylindrical coordinates (r, φ) are generally used for fibers.

Fundamental Equations

The vector **H**-field formulation of the integrated optical eigenvalue problem with the Helmholtz operator [15.5]

$$\mathcal{H}_H = \frac{1}{k_0^2}\Delta_t + n^2 + \frac{2}{k_0^2 n}(\nabla_t n)\times\nabla_t\times , \tag{15.3}$$

in particular the frequently used representation in Cartesian coordinates [15.33]

$$\begin{aligned}
&\frac{\partial^2 h_x^{(l)}}{\partial x^2} + \frac{\partial^2 h_x^{(l)}}{\partial y^2} + \frac{2}{n}\frac{\mathrm{d}n}{\mathrm{d}y}\left(\frac{\partial h_y^{(l)}}{\partial x} - \frac{\partial h_x^{(l)}}{\partial y}\right) \\
&\qquad + (k_0 n)^2 h_x^{(l)} = (k_0 n_l)^2 h_x^{(l)} , \\
&\frac{\partial^2 h_y^{(l)}}{\partial x^2} + \frac{\partial^2 h_y^{(l)}}{\partial y^2} - \frac{2}{n}\frac{\mathrm{d}n}{\mathrm{d}x}\left(\frac{\partial h_y^{(l)}}{\partial x^2} - \frac{\partial h_x^{(l)}}{\partial y^2}\right) \\
&\qquad + (k_0 n)^2 h_y^{(l)} = (k_0 n_l)^2 h_y^{(l)} ,
\end{aligned} \tag{15.4}$$

is usually the starting point of numerical eigenmode analyses of z-invariant waveguides used in integrated optics today. It is preferred over competing formulations, since the transverse components of the magnetic field at dielectric boundary surfaces exhibit neither discontinuities nor logarithmic singularities. The longitudinal field component h_z results directly from the requirement that magnetic fields do not have sources ($\nabla - \mathbf{H} = 0$). For the analysis of fibers, in contrast, the field equations for the two longitudinal field components (E_z, H_z) are mostly used.

The eigenmodes of weakly guiding waveguides ($|\Delta n| \ll |\bar{n}|$) exhibit a weakly pronounced hybrid character. The vector coupling in (15.3), described by the operator $(\nabla_t n)\times\nabla_t\times$, can then be treated as a perturbation. In the limit of vanishing vector coupling, the eigenmodes of the waveguide are replaced by the eigenmodes of the scalar Helmholtz operators [15.41–43]

$$\mathcal{H}_s = \frac{1}{k_0^2}\nabla_t^2 + n^2 . \tag{15.5}$$

When using Cartesian coordinates, the associated eigenvalue equations decouple completely, which results in

$$\frac{\partial^2 \psi_l}{\partial x^2} + \frac{\partial^2 \psi_l}{\partial y^2} + (k_0 n)^2 \psi_l = (k_0 n_l)^2 \psi_l , \tag{15.6}$$

where ψ_l is an arbitrary transverse vector component of the electric or magnetic field. The hybrid modes can be approximated with first-order Rayleigh–Schrödinger perturbation theory.

Slab Waveguide

The slab waveguide forms the most elementary waveguide. Its examination helps to assess the behavior of the more complex rib, strip, and diffused waveguides. Whereas strip waveguides generally exhibit hybrid eigenmodes, slab waveguides support only two types of transverse modes, each with three nonvanishing vector components. The description of slab waveguides uses a Cartesian coordinate system whose x-axis is normal to the waveguide's layers and whose z-axis indicates the optical wave's direction of propagation. The transverse electric (TE) modes have one electric (E_y) and two magnetic field components (H_x, H_z), whereas the transverse magnetic (TM) modes have one magnetic (H_y) and two electric field components (E_x, E_z). The two sets of eigenmodes $E_y^{(l)}$ and $H_y^{(l)}$ belong to the Helmholtz operators

$$\mathcal{H}_{\mathrm{TE}} = \frac{1}{k_0^2}\frac{\mathrm{d}^2}{\mathrm{d}x^2} + n^2 , \tag{15.7}$$

$$\mathcal{H}_{\mathrm{TM}} = \frac{1}{k_0^2}\frac{\mathrm{d}^2}{\mathrm{d}x^2} - \frac{2}{k_0^2 n}\frac{\mathrm{d}n}{\mathrm{d}x}\frac{\mathrm{d}y}{\mathrm{d}x} + n^2 . \tag{15.8}$$

With $\omega = k_0 c$, the additional, nonvanishing field components of the TE_l mode result in

$$\begin{aligned}
H_x^{(l)} &= \frac{\mathrm{i}\beta_l}{\omega\mu_0} E_y^{(l)} , \\
H_z^{(l)} &= \frac{-\mathrm{i}}{\omega\mu_0}\frac{\partial E_y^{(l)}}{\partial x} ,
\end{aligned} \tag{15.9}$$

while for the TM_l mode we have

$$\begin{aligned}
E_x^{(l)} &= \frac{-\mathrm{i}\beta_l}{n^2\omega\epsilon_0} H_y^{(l)} , \\
E_z^{(l)} &= \frac{\mathrm{i}}{n^2\omega\epsilon_0}\frac{\partial H_y^{(l)}}{\partial x} .
\end{aligned} \tag{15.10}$$

A quasi-analytical algorithm based on the characteristic matrix [15.44]

$$\mathcal{M} = \begin{pmatrix} \cos\delta & -\sin\delta/Y \\ Y\sin\delta & \cos\delta \end{pmatrix} \tag{15.11}$$

is highly effective for numerical computation of the eigenmodes of arbitrarily constructed slab waveguides with step-index profiles.

This method enables direct computation of the supermodes of interacting coupler structures (Sect. 15.3.3). It can also be used for analysis of graded index profiles, where the continuously varying refractive index profile is approximated by an arbitrarily fine step-index profile.

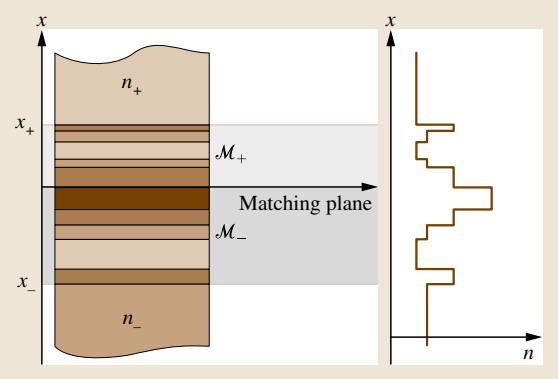

Fig. 15.3 Slab waveguide composed from two slab packets which are described by the characteristic matrices $\mathcal{M}_+$ and $\mathcal{M}_-$

The characteristic matrix $\mathcal{M}$ describes a layer of thickness d and refractive index n by means of its equivalent phase thickness $\delta = kd\sqrt{n^2 - n_l^2}$ and its characteristic admittance $Y = \sqrt{n^2 - n_l^2}$. A slab waveguide of arbitrary layout (Fig. 15.3) is described by two slab stacks with characteristic matrices $\mathcal{M}_+$ and $\mathcal{M}_-$ multiplied together. The continuous extension of the fields within the slab packets is guaranteed by the use of the characteristic matrices. The continuous extension of the fields at the matching plane between the two slab packets leads to the characteristic equation

$$\frac{m_{11}^{(+)} - \mathrm{i}Y_+ m_{12}^{(+)}}{m_{21}^{(+)} - \mathrm{i}Y_+ m_{22}^{(+)}} = -\frac{m_{22}^{(-)} - \mathrm{i}Y_- m_{12}^{(-)}}{m_{21}^{(-)} - \mathrm{i}Y_- m_{11}^{(-)}} , \qquad (15.12)$$

at whose zero points the effective refractive indices of the TE modes are found. For an electric field E_y within a layer of thickness d and refractive index n in the region $(x_0 \le x < x_0 + d)$, we have

$$E_y^{(l)}(x) = E_{y,0} \cos\left[\frac{\delta}{d}(x - x_0)\right] + \frac{H_{z,0}}{Y} \sin\left[\frac{\delta}{d}(x - x_0)\right] . \qquad (15.13)$$

For $\delta > 0$, i. e., $n^2 > n_l^2$, the solutions are oscillatory; for $\delta < 0$ they are hyperbolic.

Calculation of the TM modes is performed in an analogous way. Starting from the modified characteristic matrix

$$\tilde{\mathcal{M}} = \begin{pmatrix} \cos\delta & -\sin\delta/Z \\ Z\sin\delta & \cos\delta \end{pmatrix} , \qquad (15.14)$$

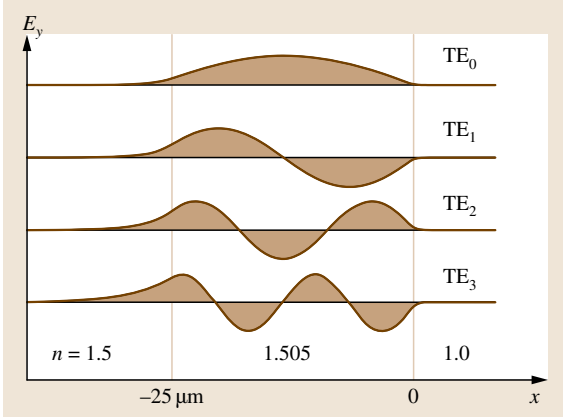

Fig. 15.4 Guided TE modes at $\lambda = 1.5\,\mu\mathrm{m}$ (TE_0, TE_1, TE_2, TE_3) of a asymmetric slab waveguide ($d = 25\,\mu\mathrm{m}$, $n_{\mathrm{co}} = 1.505$) enclosed by a substrate of refractive index $n_{\mathrm{s}} = 1.5$ on the *left* and by air ($n_{\mathrm{o}} = 1$) on the *right*

which describes a layer in terms of its equivalent phase thickness and its characteristic impedance $Z = \sqrt{n^2 - n_l^2}/n^2$, results in the characteristic equation for the TM modes,

$$\frac{\tilde{m}_{11}^{(+)} - \mathrm{i}Z_+ \tilde{m}_{12}^{(+)}}{\tilde{m}_{21}^{(+)} - \mathrm{i}Z_+ \tilde{m}_{22}^{(+)}} = -\frac{\tilde{m}_{22}^{(-)} - \mathrm{i}Z_- \tilde{m}_{12}^{(-)}}{\tilde{m}_{21}^{(-)} - \mathrm{i}Z_- \tilde{m}_{11}^{(-)}} . \qquad (15.15)$$

The TE_l (or TM_l) mode of a slab waveguide always has l nodes (zeros) and $l+1$ minimum/maximum values. Figure 15.4 shows the guided TE modes of an asymmetric slab waveguide ($d = 25\,\mu\mathrm{m}$, $n_{\mathrm{co}} = 1.505$) that is enclosed by a substrate and by air. As a result of the different refractive indices for the substrate $n_{\mathrm{s}} = 1.5$ and superstrate $n_{\mathrm{o}} = 1$, the optical field is noticeably displaced towards the substrate.

A symmetric slab waveguide based on a single layer, i. e., a waveguide layer of thickness d and refractive index n_{co} that is embedded in a cladding of refractive index n_{cl}, has exactly l guided modes when the parameter $V = k_0 d\sqrt{n_{\mathrm{co}}^2 - n_{\mathrm{cl}}^2}$ satisfies the condition $l - 1 \le V/\pi < l$. The symmetric single-layer slab supports at least one guided mode. The effective refractive index of eigenmode l is located in an interval described by the condition $l \ge \delta_l/\pi < l+1$, where $\delta_l = k_0 d\sqrt{n_{\mathrm{co}}^2 - n_l^2}$ denotes the phase thickness of the waveguide layer. Sufficiently far away from the cutoff, we find for the TE_l modes,

$$n_l^2 = n_{\mathrm{co}}^2 - \left[\frac{(l+1)\pi}{kd}\right]^2 \left(1 - \frac{4}{V} + \ldots\right) . \qquad (15.16)$$

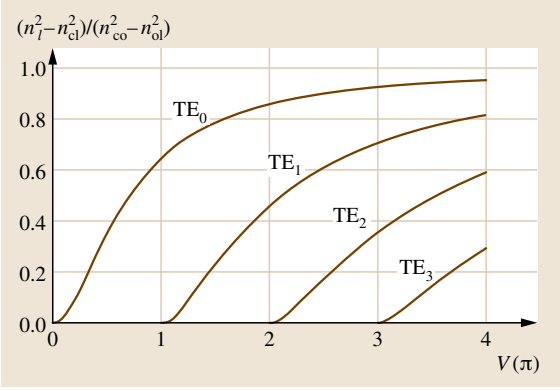

Fig. 15.5 Effective refractive index (normalized to the refractive index contrast) as a function of the V parameter for the TE modes of a symmetric slab waveguide with a step-index profile

Figure 15.5 shows for illustration the effective refractive index (normalized to the refractive index contrast) as a function of the V parameter for the TE modes of a symmetric slab waveguide with a step-index profile.

15.2.2 Photonic Crystal Waveguiding

Photonic crystal waveguides that are not longitudinally invariant guide the optical wave by refocusing, and have to be treated in another way than conventional waveguides (Sect. 15.2.1). In fact, a planar photonic crystal waveguide guides its eigenmodes by two completely different mechanisms. In the vertical direction, the mode is supported by a conventional slab waveguide. In the lateral direction, the mode is confined between two two-dimensional (2-D) photonic crystal mirrors. For both polarizations, these mirrors act only in the full, i. e., polarization-independent, bandgaps of the photonic crystals. Usually, the waveguide channel is formed by an integer number of missing rows in a single 2-D photonic crystal. Such a waveguide is denoted as W_n if n rows of the photonic crystal are missing. Photonic crystal waveguides are described using the same coordinate system used for slab waveguides.

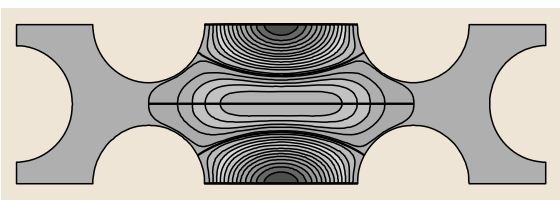

Fig. 15.6 Fundamental TM mode and the corresponding phase fronts over one period of a photonic crystal

Although the true 2-D photonic crystal waveguide forms an unrealistic device, it serves as a good vehicle to study the most important aspects of photonic crystal waveguiding:

- True 2-D photonic crystal channel waveguides support true, i. e., lossless, eigenmodes.
- Figure 15.6 displays the waveguiding mechanism for a W_1 waveguide embedded between photonic crystal mirrors. It shows the z-component of the magnetic field H_z; several contours of constant phase are marked by thick lines. It becomes obvious that the mode is guided by periodic refocusing. The period is given by the period of the channel waveguide. Since photonic crystal waveguide modes do not exhibit straight phase fronts, decomposition of the optical field into an amplitude and a phase factor is not feasible (Sect. 15.2.2).
- The true 2-D photonic crystal and any channel waveguides built into it support only transverse modes. The TE modes exhibit one electric (E_x) and two magnetic components (H_y, H_z) field components. The TM modes exhibit one magnetic (H_x) and two electric components (E_y, E_z) field components. The TE and TM modes are solutions of the following equations:

$$\frac{1}{n^2}\nabla_t^2 E_x = k_0^2 E_x \,, \tag{15.17}$$

$$\nabla_t \cdot \frac{1}{n^2}\nabla_t H_x = k_0^2 H_x \,. \tag{15.18}$$

- The TE and TM bandgaps are not aligned. The following rules of thumb may help to select an appropriate photonic crystal structure for a device.
  - The fundamental bandgap is usually the largest bandgap.
  - For a given lattice, the size of the fundamental bandgap increases with increasing refractive index contrast. For lattices of low symmetry and/or for low refractive index contrasts, the TE and/or TM bandgaps may fade away.
  - For a given lattice and layout of the Brillouin zone, the size of the fundamental TM bandgap is larger for a photonic crystal with holes while the TE bandgap is larger for a photonic crystal with rods (inverse structure).
  - For a given hole/rod size and refractive index contrast, the centers of TE and TM bandgaps of hexagonal lattices are best aligned. The

misalignment of bandgaps increases with decreasing symmetry of the lattice.
– Even for moderate refractive index contrasts, the centers of TE and TM bandgaps cannot be aligned such that a full bandgap is obtained [15.45].

Any other photonic crystal waveguide supports hybrid modes described by the full vectorial Helmholtz equation

$$\nabla \times \left(\frac{1}{n^2} \nabla \times \mathbf{H} \right) = k_0 \, \mathbf{H} \, . \tag{15.19}$$

Realistic planar photonic crystals (Fig. 15.1g) based on slab waveguides are nonperiodic in the vertical direction. As a consequence, they do not support true eigenmodes, i. e., realistic photonic crystal waveguides are always slightly lossy. Their modes are *nearly* transverse. The magnitude of the nontransverse field components – E_x for TE-like modes and H_x for TM-like modes – increases with increasing refractive index contrast between the slab waveguide and the background material.

For a discussion of the out-of-plane radiation, let us consider a slab-based photonic crystal with reciprocal lattice vectors $\mathbf{Q}_1$ and $\mathbf{Q}_2$ stimulated at a frequency ω by an input mode with (in-plane) wave vector $\mathbf{q}_p^{(\mathrm{in})}$. The device may – just as a conventional Bragg grating – radiate optical power into the exterior domain, sub- or superstrate with refractive index n_B^2. The radiation process with an outgoing plane wave ($\mathbf{q}^{(\mathrm{out})}$) is governed by the conservation of the in-plane components of the wave vectors, i. e., $\mathbf{q}_p^{(\mathrm{in})} + \mathbf{q}_p^{(\mathrm{out})} = m\mathbf{Q}_\mathrm{l}$, and, in addition, by the conservation of the optical power, i. e., $|\mathbf{q}^{(\mathrm{out})}|^2 = k_0^2 \epsilon_\mathrm{B}$. In the terminology of photonic crystals, the regions in the band structure where both conditions cannot be concurrently satisfied are called *above light-line*, whereas the other regions are labeled *below light-line*.

Figure 15.7 shows schematically a section of a photonic band structure for a channel waveguide supporting two modes (dark lines). The two lowest bands of the bulk photonic crystal are shown as light lines, and the region *above light-line* is displayed as a shaded area. If a mode – of either the slab or the channel waveguide – crosses the light line in the band structure, its power is radiated out-of-plane, i. e., out of the plane defined by the slab waveguide. If a mode of the channel waveguide crosses a band of the bulk photonic crystal, its power is radiated in-plane, i. e., into the slab waveguide. The modes of the channel waveguide look like

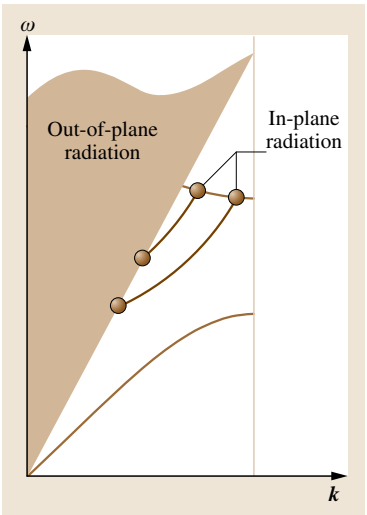

Fig. 15.7 Schematic photonic crystal band structure demonstrating in-plane and out-of-plane radiation

defect states in solid-state physics. Therefore, channel waveguides between photonic crystals are designated as *defect waveguides* in the photonic crystal community.

The efficiency of the radiation process in the regions above the light-line is driven by the layout of the elementary cell and by the density of photonic states close to the point of operation. Therefore, quantitative numerical analysis of the radiation efficiency, which allows derivation of realistic propagation losses for a perfectly fabricated device, requires full three-dimensional computation. For typical high-index-contrast structures, numerical results indicate that these losses are ≈ 0.1 dB/row [15.46].

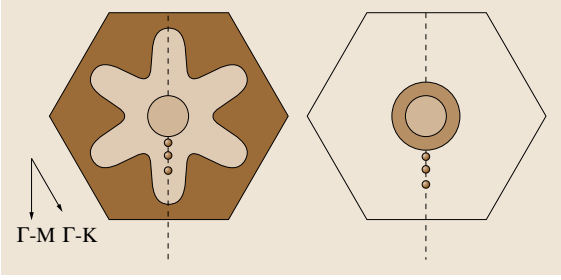

Fig. 15.8 Comparison of waveguiding mechanisms of a hexagonal photonic crystal waveguide operated in the photonic bandgap with a conventional strip waveguide. The regions where the optical power is radiated out-of-plane are weakly *shaded*, and the regions where the optical power is radiated in-plane are *shaded*. The elementary cell of the photonic crystal is indicated for the conventional waveguide to ease comparison between the two cases

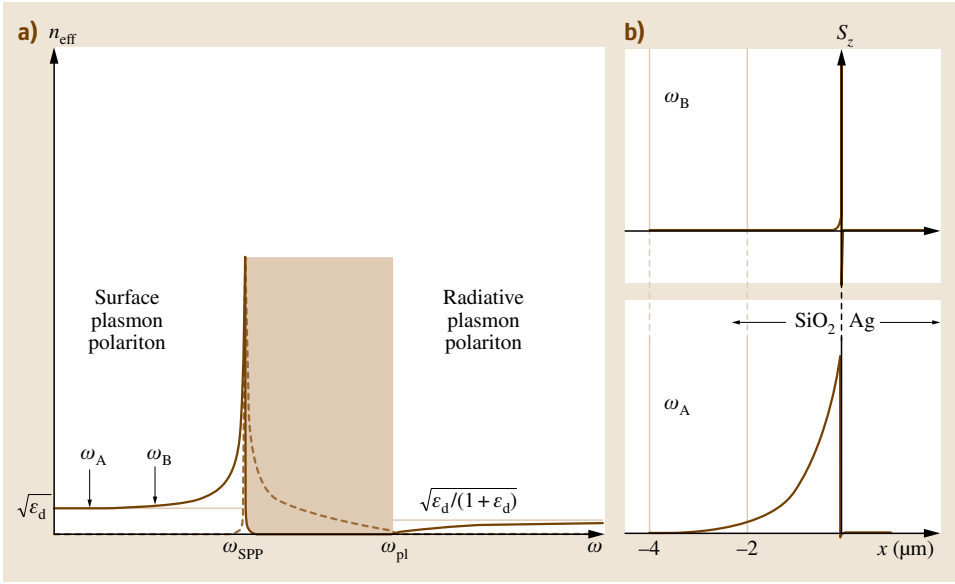

Fig. 15.9a,b Ag/SiO_2 interface ($\varepsilon_{\mathrm{d}} = 2.25$): SPP dispersion **(a)** and z-component of Poynting vector for two vacuum wavelengths **(b)**. Real part n'_{SPP} and imaginary part n''_{SPP} are shown as *solid* and *dashed lines*, respectively. The wavelengths of the respective eigenmodes are $\lambda_0 = 1.5\,\mu\mathrm{m}$ (ω_{A}) and $\lambda_0 = 0.5\,\mu\mathrm{m}$ (ω_{B})

Figure 15.8 shows a comparison of waveguiding mechanisms of a photonic crystal waveguide operated in the photonic bandgap with a conventional strip waveguide. Obviously, for a conventional waveguide, the cut-off refractive index where the waveguide starts to radiate is always below the effective refractive indices of the guided modes. For photonic crystal waveguides the cut-off where the waveguide starts to radiate into the photonic crystal is often above the effective refractive indices of the guided modes, as shown in Fig. 15.8. If the photonic crystal exhibits an omnidirectional bandgap, it will not radiate.

The design of the slab waveguide which is responsible for the vertical guidance of the mode propagating through the photonic crystal differentiates between the strongly guiding silicon-on-insulator (SOI) material system ($\Delta n \approx 2$) and the weakly guiding III–V material systems ($\Delta n < 0.5$). As a consequence, the photonic crystals in the SOI material system can be (and are) operated below light cone, whereas weakly guiding photonic crystal devices made using III–V compounds must be operated above light cone.

15.2.3 Plasmonic Waveguides

At the interface of two half-spaces, one filled with a dielectric medium and the other with a metallic conductor, the coupling between the electromagnetic field and electronic plasma oscillations results in a single, TM-polarized eigenmode traveling along the interface. Such a mode is designated as surface plasmon polariton (SPP) [15.47]. Its dispersion is dominated by the dispersion of the metal. The frequency-dependent relative dielectric permittivity which is related to the complex refractive index – $\sqrt{\epsilon_{\mathrm{m}}} = n_{\mathrm{m}} + \mathrm{i}\kappa_{\mathrm{m}}$ – can be approximated for many metals by a complex Drude formula

$$\epsilon_{\mathrm{m}} = 1 - \frac{\omega_{\mathrm{pl}}^2}{\omega(\omega + \mathrm{i}\gamma)} \,, \tag{15.20}$$

where ω_{pl} is the plasma frequency, i. e., the resonance frequency of the volume plasmon, and γ is the corresponding loss term (*collision frequency*). The values of ω_{pl} and γ result from fits of experimental data, and slightly different Drude parameters are reported in the literature. From Table 15.3, it becomes evident that metals exhibit significant losses at optical frequencies. The lowest losses make the noble metals silver (Ag) and gold (Au) preferred materials for any plasmonic waveguide.

The eigenmode of the SPP can be derived by using the boundary conditions of the magnetic field at the metal–dielectric interface. Its propagation constant

$$\tilde{n}_{\mathrm{SPP}} = \sqrt{\frac{\epsilon_{\mathrm{d}}\epsilon_{\mathrm{m}}}{\epsilon_{\mathrm{d}} + \epsilon_{\mathrm{m}}}} = n'_{\mathrm{SPP}} + \mathrm{i}n''_{\mathrm{SPP}} \,, \tag{15.21}$$

is always complex-valued due to the loss in the metallic region. In (15.21), ϵ_{d} and $\epsilon_{\mathrm{m}} = \epsilon'_{\mathrm{m}} + \mathrm{i}\epsilon''_{\mathrm{m}}$ are the relative dielectric permittivity of the dielectric and the metal, respectively.

The solution of (15.21) for a silver–glass interface is shown in Fig. 15.9. It exhibits two resonances at ω_{SPP}

Table 15.3 Parameter for the complex Drude formula (15.20) for several metals [15.49]

Metal	$\hbar\omega_{pl}$ (eV)	λ_{pl} (nm)	γ/ω_{pl} (%)
Ag	9.02	137	0.24
Au	8.89	139	0.80
Al	12.04	103	1.07
Cu	8.76	141	1.09

and ω_{pl} and a bandgap in between these resonances. For Drude metals, $\omega_{SPP} = \omega_{pl}/\sqrt{\epsilon_d + 1}$. In the frequency range below the surface plasmon resonance frequency ω_{SPP}, the surface plasmon polariton is a guided, i. e., nonradiative, mode. The plots of the Poynting vector in Fig. 15.9 also show that the power in the metal travels backward, a peculiarity of SPPs. In the frequency range above the volume plasmon frequency ω_{pl}, the metal becomes transparent, and the surface plasmon polariton (SPP) becomes a radiation mode. The frequency region in between ω_{SPP} and ω_{pl} is called the plasmonic bandgap. In that region for an ideal, i. e., lossless, metal the solutions of (15.21) are purely imaginary, i. e., the SPP becomes an evanescent mode which does not propagate any more. For a discussion of quasibound modes in real metals see [15.48].

In the context of integrated optics, only the frequency range below ω_{SPP} is of practical interest. At small frequencies, i. e., long wavelengths (frequency ω_A in Fig. 15.9), most of the power of the surface plasmon polariton is confined in the dielectric half-space. Its effective refractive index is close to that of the dielectric material, and the losses are moderate. When the frequencies approach the SPP resonance (frequency ω_B in Fig. 15.9), an increasing fraction of the power of the surface plasmon polariton is confined in the metallic half-space. The effective refractive index as well as the waveguide loss increase rapidly. The decrease of the effective wavelength $\lambda_{SPP} = \lambda/n'_{SPP}$ increases the spatial resolution achievable in sensing applications. Furthermore, the group velocity, i. e., the speed of signal transport, decreases significantly (slow light).

In summary, a SPP at the interface between two half-spaces can be made well confined, but only at the expense of increasing propagation loss.

To overcome these problems, surface plasmon polaritons of a thin metallic film embedded between two dielectric half-spaces were considered. If the thickness of the metallic film becomes smaller than their penetration depth, the SPPs of the two interfaces become coupled (*tunneling*). This configuration supports exactly two SPPs, an asymmetrical and a symmetrical

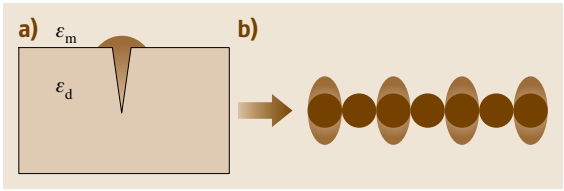

Fig. 15.10a,b Cross section V-groove SPP waveguide **(a)** (power flow into the plane of the paper) and plasmonic waveguide formed by a 1-D array of nanoparticles **(b)**

mode. The latter, called a long-range surface plasmon polariton (LR-SPP), exhibits low losses as long as the mode is dominantly confined in the dielectric half-spaces, and the speed of signal transport is close to that in the dielectric material [15.50].

A metallic strip waveguide supports four families of modes which can be classified by the symmetrical and asymmetrical superposition of the elementary SPPs of each opposite interfaces. Similar to the LR-SPP of the thin metallic film, the LR-SPP of the metallic strip can be assigned to the twofold symmetrical superposition of elementary SPPs. For small waveguide cross sections that do not support higher-order modes, losses of 1 dB/mm can be achieved for a $4\,\mu m \times 20\,nm$ Au waveguide embedded in SiO_2, theoretically [15.51].

Surface plasmon polaritons can not only be guided by conventional strip or slab waveguides but also by chains of metallic nanoparticles [15.52, 53] or V-groove waveguides [15.54] (Fig. 15.10).

Planar plasmonic waveguides can be analyzed using matrix methods [15.55]. Any 2-D cross section or volume containing metals requires fully vectorial methods due to the hybrid character of the modes. The pronounced field enhancement at the metallic edges and the logarithmic singularities at the corners are extremely demanding for eigenmode solvers [15.56].

Complex photonic integration requires a small device footprint as well as low losses. To compare different waveguiding approaches, several figures of merit (FOM) have been defined [15.57–59]. For 2-D confinement the quantity

$$\text{FOM} = \sqrt{\frac{\pi}{A_{\text{eff}}}} L_p \,, \tag{15.22}$$

where A_{eff} is the effective mode area and $L_p = 1/(k_0 n'')$ is the characteristic length for the mode's loss, represents a reasonable figure to quantify the demand on compact circuits exhibiting moderate propagation losses, e.g. for signal transport. A comparison of this FOM for plasmonic and popular conventional waveg-

uides in the Si/SiO_2 or the silicon-on-insulator (SOI) material systems can hardly display any advantage of a plasmonic solution. Nevertheless, propagating and localized SPPs offer unique possibilities in sensors and/or for tailoring of optical properties for artificial media. In such a context, it is useful that the losses of SPPs can be compensated by optical gain [15.60].

15.2.4 Coupled Mode Theory (CMT)

Coupled mode theory (CMT) [15.61–63] describes the propagation of the optical field in a waveguide structure consisting of two or more, mostly single-mode strip waveguides. It targets weakly coupled waveguide structures in which the input optical power is exchanged solely between the guided modes of the individual strip waveguides; i. e., no (or little) radiation emission takes place. The theory of coupled modes forms the basis for the treatment of directional coupling structures (Sect. 15.3.3) and structural elements based on them, e.g., Mach–Zehnder couplers (Sect. 15.4.4). The optical field $\Psi(\mathbf{r}_t, z) = \sum_{l=1}^{N} a_l(z)\psi_l(\mathbf{r}_t)$ of a structure composed of N single-mode strip waveguides can, therefore, be represented by a superposition of the fundamental modes $\psi_l(\mathbf{r}_t)$ of the individual strip waveguides. The expansion coefficients $a_l(z)$ satisfy a system of linear ordinary differential equations

$$-\mathrm{i}\frac{\mathrm{d}a_l}{\mathrm{d}z} = \sum_{m=1}^{N} \kappa_{lm} a_m \,, \tag{15.23}$$

referred to as the *coupled mode* equations. The coupling coefficients κ_{lm} can be understood, on the one hand, as purely phenomenological parameters derived as fitted from experimental or beam-propagation method (BPM) results. It is also possible, however, to compute the coupling coefficients in the form of overlap integrals, i. e., *from first principles*.

The diagonal elements $\kappa_{ll} \approx k_0 n_l$ are given by the effective propagation constants of the individual strip waveguides, which are slightly corrected (*self-coupling* [15.61,62]). For the nondiagonal elements, we obtain in the case of weak coupling

$$\kappa_{lm} \propto \exp\left(-k_0\sqrt{n_l^2 - n_\mathrm{B}^2}\, d_{lm}\right) \,, \tag{15.24}$$

where d_{lm} denotes the spacing between the two coupled waveguides l and m, and n_B is the background refractive index. From (15.24) we can see that the coupling coefficient decreases exponentially with increasing spacing. For this reason, in general only the coupling between directly adjoining strip waveguides contributes to the behavior of a complicated waveguide structure.

If the waveguide structure consists of lossless waveguides, the optical power is conserved,

$$\frac{\mathrm{d}}{\mathrm{d}z}\sum_{l=1}^{N} |a_l|^2 = 0 \,. \tag{15.25}$$

For the coupling coefficients we then have $\kappa_{lm} = \kappa_{lm}^*$; i. e., the matrix of coupling coefficients is Hermitian ($\mathcal{K} = \mathcal{K}^\dagger$).

15.2.5 Theory of Local Normal Modes

The theory of local normal modes deals with mode conversion in a tapered, i. e., slowly changing, waveguide structure. In this theory, the optical field is developed along the propagation direction z according to the local eigenmodes $\psi_l(\mathbf{r}_t, z)$ of the waveguide structure

$$\Psi(\mathbf{r}_t, z) = \sum\!\!\!\!\!\!\int_l a_l(z) \exp\left[\mathrm{i}k_0 \int_0^z \mathrm{d}\zeta n_l(\zeta)\right] \psi_l(\mathbf{r}_t, z) \,. \tag{15.26}$$

In this equation and below, the combined sum and integral symbol indicates that we have to sum over all guided modes and integrate over all radiation modes. The oscillatory contribution of type $\exp(\mathrm{i}\Phi)$ describes the propagation of the perfectly tapered modes; the spatial expansion of the coefficients $a_l(z)$ is determined solely by mode conversion. The mode conversion from and to the radiation field is usually of crucial importance in horn structures (tapering), therefore the expansion (15.26) must take both guided and radiation modes into consideration.

The expansion coefficients are obtained from a system of nonautonomous ordinary differential equations

$$\frac{\mathrm{d}a_l}{\mathrm{d}z} = \sum\!\!\!\!\!\!\int_{m\neq l} \kappa_{lm}(z) a_m \,, \tag{15.27}$$

the local normal mode equations. The coupling coefficients

$$\kappa_{lm} = \frac{1}{n_m^2 - n_l^2} \int \mathrm{d}^2 r_t \psi_l(\mathbf{r}_t, z)^* \frac{\partial n(\mathbf{r}_t, z)^2}{\partial z} \psi_m(\mathbf{r}_t, z) \tag{15.28}$$

have resonance denominators $1/\left(n_m^2 - n_l^2\right)$; i. e., the coupling strength decreases with increasing difference between the effective refractive indices n_m and n_l. The essential contributions to mode conversion are

made, therefore, by closely adjacent modes. The main contributions of the overlap integrals are related to modifications of the waveguide structure, typically at its edges. The local normal mode equations (15.27) are usually solved by successive iteration.

15.2.6 Beam Propagation

The term "beam propagation method" (BPM) covers a selection of algorithms that simulate the propagation of an arbitrary coherent light beam in a semispace ($z > 0$) that has an arbitrary refractive index distribution [15.36, 37, 64–72].

All the currently widely used algorithms proceed stepwise; i. e., they transport the optical field in one step from sectional plane z to sectional plane $z + \Delta z$. The step size Δz is always so small that the change in the refractive index profile over one propagation step can be neglected. The Helmholtz equations that govern the propagation of the optical field are written in the form

$$\frac{\partial^2 \Psi(\mathbf{r}_\mathrm{t}, z)}{\partial z^2} = -k_0^2 \mathcal{H} \Psi(\mathbf{r}_\mathrm{t}, z)\,, \qquad (15.29)$$

where $\mathcal{H}$ denotes the Helmholtz operator used in each particular case (15.3, 15.5, 15.7, 15.8).

The equations for the propagation of the slowly varying amplitudes $\psi_\pm(\mathbf{r}_\mathrm{t}, z) = \Psi_\pm(\mathbf{r}, z) \exp\left(\pm \mathrm{i} k_0 \bar{n} z\right)$ in the forward (+) and backward direction (−) (forward/backward Helmholtz equations),

$$\frac{\partial \psi_\pm(\mathbf{r}_\mathrm{t}, z)}{\partial z} = \pm \mathrm{i} k_0 (\sqrt{\mathcal{H}} - \bar{n}) \psi_\pm(\mathbf{r}_\mathrm{t}, z)\,, \qquad (15.30)$$

are obtained by extracting the roots of the corresponding Helmholtz equations. The background refractive index

$$\bar{n}(z)^2 = \int \mathrm{d}^2 r_t \psi_\pm(\mathbf{r}_\mathrm{t}, z)^* \mathcal{H} \psi_\pm(\mathbf{r}_\mathrm{t}, z) \qquad (15.31)$$

must be adjusted during the simulation [15.73] in such a way that the oscillations of the optical field are eliminated as far as possible. Careful treatment of the boundary conditions at the lateral boundaries of the computational window [15.74–77] is essential to avoid artificial reflections and/or losses at the boundaries. Equations (15.30) define two initial-value problems that have the formal solutions

$$\psi_\pm(\mathbf{r}_\mathrm{t}, z \pm \Delta z) = \exp\left[\pm \mathrm{i} k_0 \left(\sqrt{\mathcal{H}} - \bar{n}\right) \Delta z \psi_\pm(\mathbf{r}_\mathrm{t}, z)\right]. \qquad (15.32)$$

The algorithms discussed briefly below take different approaches for the computation of the propagator $\exp\left[\pm \mathrm{i} k_0 \left(\sqrt{\mathcal{H}} - \bar{n}\right) \Delta z\right]$.

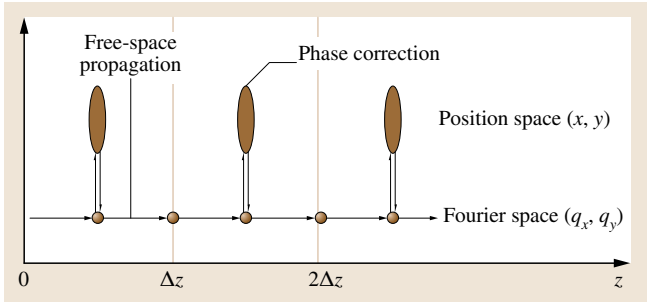

Fig. 15.11 Classical beam propagation method (BPM) for several propagation steps

Classical BPM with Fourier Transforms

In the classical beam propagation method [15.64], the propagator for the scalar Helmholtz equation

$$\exp\left[\mathrm{i} k_0 (\sqrt{\mathcal{H}} - \bar{n}) \Delta z\right] = \exp\left(\mathrm{i} \frac{\mathcal{Q} \Delta z}{2}\right) \exp(\mathrm{i} \Delta \Phi_\mathrm{L}) \exp\left(\mathrm{i} \frac{\mathcal{Q} \Delta z}{2}\right) \qquad (15.33)$$

is split into a diffractive part with operator $\mathcal{Q} = \nabla_t^2 / [k_0 \bar{n} + \sqrt{\nabla_t^2 + (k_0 \bar{n})^2}]$, which describes the beam's propagation in a homogeneous half-space with background refractive index $\bar{n}$, and a phase correction $\Delta \Phi_\mathrm{L} = k_0 [n(\mathbf{r}_\mathrm{t})^2 - \bar{n}^2] \Delta z / (2\bar{n})$, which accounts for the effect of inhomogeneities. Figure 15.11 illustrates the procedure using the classical BPM for a few propagation steps. The phase correction is symbolized here as a lens, since the operator's effect in the paraxial limit can be understood as that of a thin lens. Since the operator $\mathcal{Q}$ is diagonal in Fourier space, it is necessary to alternate constantly during the computation between position and Fourier space by means of numerical Fourier transformation, as indicated in Fig. 15.11.

The classical beam propagation method is rarely used nowadays, since the underlying split-step algorithm requires very small step sizes and therefore involves high numerical cost.

Eigenmode-Based Method

Whereas in the classical beam propagation method the optical field is expanded by plane waves, the eigenmode-based algorithms [15.66] rely on an expansion of the optical field in eigenmodes $\psi_l(\mathbf{r}_\mathrm{t}, z)$ of the local refractive index profile. In the scalar case, the expansion coefficients become

$$a_l(z) = \int \mathrm{d}^2 r_t \psi_l(\mathbf{r}_\mathrm{t}, z)^* \Psi(\mathbf{r}_\mathrm{t}, z)\,. \qquad (15.34)$$

Since the form of the eigenmodes is conserved during propagation, the optical field after one step is given by

$$\Psi(\mathbf{r}_t, z+\Delta z) = \sum_l a_l(z)\exp(\mathrm{i}k_0 n_l \Delta z)\psi_l(\mathbf{r}_t, z)\,. \tag{15.35}$$

The core of such a BPM method is an eigenmode solver which determines *sufficiently* many eigenmodes such that a good representation of the initial field is obtained. The radiation field is usually approximated by the box modes of the computational window enclosed by metallic walls.

Provided that all guided and nonguided eigenmodes are taken into account, eigenmode-based algorithms deliver the exact solution of the propagation equation (15.30); i. e., they are also suitable for simulation of nonparaxial beam propagation. Since the decomposition of the optical field into eigenmodes is numerically costly, eigenmode-based algorithms are used preferentially for propagation problems with few relevant eigenmodes.

Ray Tracing

Ray tracing methods, based on a solution of the eikonal equation, are often preferred for describing the propagation of optical fields in multimode waveguide structures. This is due to the fact that the computational cost of the BPM method described above increases for the same discretization due to the enlargement of the computational domain. Furthermore, in many cases the computational cells need to be made finer, since otherwise diffraction phenomena, e.g., along caustics, lead to instabilities in the numerical algorithm. Moreover, the beam propagation method, as a strictly monochromatic approach, is less suitable for describing the propagation of incoherent or partly coherent (i. e., spectrally broadband) beams.

Unlike in straight lens design, ray tracing in multimode structures requires nonsequential ray tracing methods [15.78] supporting nonparaxial and reflected rays. The calculation of insertion losses and crosstalk attenuations requires tools that measure numerically the optical power incident on a control surface. Ray tracing programs that meet these requirements are available commercially. The error sources when tracing rays in multimode waveguides are mostly not the approximations underlying the eikonal equation, but inadequate knowledge of the details of the initial ray bundle at the start of the simulation.

15.2.7 Scattering Codes

BPMs simulate the propagation of an arbitrary coherent light beam in a half-space ($z > 0$). Thus, beam propagation methods are per se unidirectional; i. e., they are not able to handle reflections. Extensions of the BPM based on the Airy summation of the reflected partial waves [15.79] and on the basis of bidirectional transfer matrices [15.80] were implemented to overcome this problem. However, these extensions are restricted to the treatment of reflecting interfaces which are perpendicular to the propagation direction. As a consequence, the BPM cannot adequately describe integrated optical circuits exhibiting large refractive steps and/or photonic crystals.

Light scattering comprises by definition any effect of homogeneous and inhomogeneous obstacles on an incident field. In the context of this definition, beam propagation (Sect. 15.2.6) is designated as forward scattering. Parallel to the development of photonic crystal waveguides, scattering codes have been developed and/or enabled to treat complex inhomogeneous obstacles and not only elementary geometries such as homogeneous spheres (Mie scattering) and reflection gratings [15.81]. For application in integrated optics, a circuit or an essential part of it is treated as a complex obstacle illuminated with very special fields such as eigenmodes of waveguides.

Scattering codes are differentiated into two classes: time-domain algorithms solving the time-dependent Maxwell equations, and frequency-domain solvers solving the vectorial Helmholtz equation, i. e., the frequency-domain Maxwell equations. It should be noted that the underlying algorithms have to deal with the rapidly varying optical field and not with the amplitudes like the BPM; i. e., the computational effort of scattering codes is orders of magnitudes higher than that of the BPM (Sect. 15.2.6).

Due to the numerical effort, the numerical efficiency of a scattering code to obtain the accuracy required for the considered application is crucial. It is driven by the numerical efficiency of the algorithm itself, but to the same extent by the size and discretization of the computational domain. Scattering codes are differentiated by:

- Nonuniform and adaptive meshes.
  Modern finite-difference solvers allow for nonuniform grids and subgrids; advanced finite-element solvers support meshes adapted by an error estimator. For critical applications such as the layout of WDM filters or analysis of fabrication tolerances,

both techniques reduce the computational effort by orders of magnitude.

- Handling of dielectric and metallic interfaces.
  Some codes such as edge element solvers allow direct treatment of dielectric interfaces and reduction of the mesh at interfaces.
- Quality of transparent boundary conditions and perfectly matched layers (PMLs), respectively.
  Due to the artificial reflections at an imperfectly implemented transparent boundary, the computational window must be enlarged; i. e., the numerical effort will increase. In addition, the imperfection of the PMLs limits the best possible accuracy obtainable for a scattering code.

In general, time-domain solvers suffer from a number of restrictions. First, the time window of the simulation must be chosen large enough that all transient phenomena can fade away at the end of the simulation. This feature drives up the computational time for any kind of resonator exhibiting multiple reflections. In addition, an increase of spatial resolution must always be accompanied by a decrease of the time step (magic steps); i. e., the accuracy can be increased only at high numerical cost.

Finite-difference time-domain (FDTD) solvers represent the most frequently used scattering codes today. They can be implemented as easily as any finite-difference algorithm. Highly sophisticated packages equipped with nonuniform meshes and good PMLs are commercially available. Finite-element time-domain (FETD) solvers with similar features are also available.

Frequency-domain solvers [15.82] avoid any time-step problems and may overcome other restrictions too. However, spectral characteristics require repeated computations. A frequency-domain finite-element solver was able to simulate an apparent negative refractive index in photonic crystals [15.83] and was the first code to correctly simulate the experimental results for left-handed materials [15.84].

Rigorous coupled wave analysis [15.85], which is widely applied to investigate the scattering on simple shapes such as the elementary cell of a grating, does not play a serious role in integrated optics since its complex geometries would require an exorbitant number of plane waves to be taken into account.

15.2.8 Impact of Computational Approaches

In integrated optics, the long cycle times and the high cost of chip fabrication lead to great interest in quantitative predictions of chip properties. These rely in particular on precise knowledge regarding the eigenmodes and on (frequently more qualitative) simulation of beam propagation. Due to the great structural variety, the necessary solvers, eigenmode solvers, and BPM simulators are based on partly or fully numerical methods. In integrated optics, as in related disciplines, the following evaluation criteria play a prominent role from the user's point of view.

- *Accuracy*
  For eigenmode analysis the accuracy of the computation, if feasible together with an error estimate, is the basic demand on a numerical method, since essential parameters of integrated optical components (such as the coupling lengths of directional couplers) are sensitive to the effective refractive indices or their differences. A relative error of $|\delta n_{\mathrm{eff}}/n_{\mathrm{eff}}| < 10^{-6}$ in the effective refractive indices is mandatory in many applications. Unlike eigenmode analysis, the beam propagation method is often used for more qualitative investigations. The absolute requirements in terms of accuracy are then significantly relaxed, but the variance between the results of different numerical approaches must still be small so that numerical studies of related structures do not result in erroneous conclusions.
- *Universal applicability, stability*
  Users mostly turn to costly numerical approaches to obtain assured predictions. Consequently, approximations and additional assumptions, e.g., the rounding of refractive index profiles or the replacement of multi-quantum-well (MQW) layered structures by a layer of averaged refractive index, should be avoided as far as possible. Moreover, the solver should be capable of processing refractive index profiles which can be arbitrarily chosen over a wide range. This requirement implies that the algorithms remain stable over a wide range of parameters. Although the computational framework used in integrated optics has reached a high level of maturity, benchmark tests [15.39, 40] with critical structures – large refractive index contrasts, many guided modes, or large beam divergence – still regularly reveal significant stability problems.
- *Numerical efficiency*
  In an era of rapidly increasing computational power, the efficiency of numerical methods – runtime behavior and memory requirements – is no longer the highest priority. However, where use of a particular method exceeds the limits of the existing computer

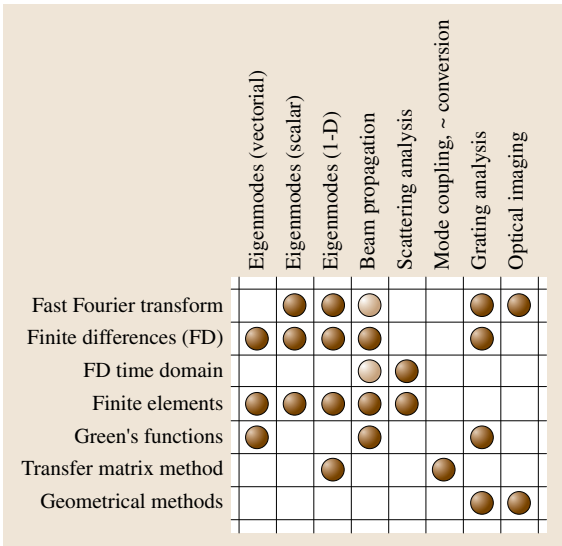

Fig. 15.12 Use of numerical methods in integrated optics

hardware, its chances of being integrated into a design flow decrease considerably.

- *Simplicity*
  Numerical methods should always be simple and reliable. In particular, the choice of the computational window and its adequate discretization often prove in practice to be a serious obstacle to use. Adaptive methods offer the user great benefits in this regard, always assuming good software engineering.

Figure 15.12 provides an overview of several common numerical methods and their use in integrated optics [15.36, 38]. In addition to purely numerical approaches, classical methods based on the Fourier transform and geometrical methods for ray tracing and for calculating optical path lengths (Huygens principle) are used. If one applies the above criteria consistently, modern, mostly adaptive methods (e.g., adaptive finite-element methods (FEM)) stand out clearly.

The difficulties involved in the implementation of electromagnetic FEM solvers and the even now still poor availability of the relevant software in the marketplace, mean that standard finite-difference (FD) methods continue to enjoy great popularity. These algorithms run mostly on a rigid lattice; i. e., the distance between two neighboring lattice points $\Delta x = x_{m+1} - x_m$ remains constant across the whole computational window. The derivatives in the differential equations are replaced by the central differences

$$f_m = f(x_m)\,,$$
$$f'_m = \frac{f_{m+1} - f_{m-1}}{2\Delta x}\,,$$
$$f''_m = \frac{f_{m+1} - 2f_m + f_{m-1}}{\Delta x^2}\,.$$

Systems of linear differential equations are reduced, therefore, to systems of linear algebraic equations. Since the finite differences link only adjacent points, the corresponding systems of equations consist of band matrices for whose handling – e.g., inversion, eigenvalue analysis – efficient algorithms are available. Conservation laws can get lost in the numerical representation through the discretization of the derivatives. Implicit formulations, e.g., the Crank–Nicholson scheme, avoid this defect and the artificial gain or loss caused by it, albeit at the expense of increased numerical cost.

15.3 Building Blocks of Integrated Optics

This section discusses several basic components in integrated optics. Some of these components – curved waveguides, horn structures (tapers), symmetric directional couplers, and Bragg gratings – have been and still are fabricated as fiber components. Others, and in particular more complex basic components such as multimode couplers and optical phased arrays, have so far been realized exclusively in integrated optical form.

15.3.1 Curved Waveguides

The curved waveguide is not a standalone building block. As a connecting element within integrated optical components and circuits, however, it does play a central role, since the radii of curvature according to the technology platform's design rules affect the space requirements of integrated optical circuits greatly. When designing curved waveguides, the foremost issues are minimizing the space requirements of integrated optical circuits on the one hand and avoiding unnecessary losses on the other. For applications in interferometry, another aspect is the adjustment of the correct phase shift. The eigenmodes of a weakly guiding waveguide forming part of a circle (Fig. 15.13) with refractive index profile $n(\rho, y)$ and radius of curvature R are obtained as solutions of the implicit eigenvalue

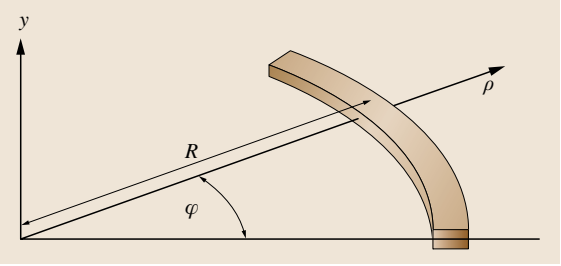

Fig. 15.13 Curved waveguide

problem

$$\frac{\mathrm{d}^2\phi_l}{\mathrm{d}\rho^2}+\frac{1}{\rho}\frac{\mathrm{d}\phi_l}{\mathrm{d}\rho}+\frac{\mathrm{d}^2\phi_l}{\mathrm{d}y^2}+\left[k_0 n(\rho,y)\right]^2\phi_l - \left(k_0 n_l\frac{R}{\rho}\right)^2\phi_l = 0\,. \tag{15.36}$$

Through transformation of the optical field $\phi_l = \sqrt{R/\rho}\psi_\mathrm{L}$, by using local Cartesian coordinates $\rho = R+x$, and by Taylor expansion at the waveguides center, we obtain the simplified eigenvalue problem

$$\frac{\mathrm{d}^2\psi_l}{\mathrm{d}x^2}+\frac{\mathrm{d}^2\psi_l}{\mathrm{d}y^2}+\left[k_0 n_\mathrm{eq}(x,y)\right]^2\psi_l = (k_0 n_l)^2\psi_l \tag{15.37}$$

of a straight waveguide. In the literature, several formulas are suggested for the equivalent refractive index profile $n_\mathrm{eq}(x,y)$. Comparative numerical studies [15.86] indicate that

$$n_\mathrm{eq}(x,y)^2 = n(x,y)^2\left(1+2\frac{x}{R}\right) \tag{15.38}$$

offers the best approximation for curvature losses. Figure 15.14 shows as an example the equivalent refractive index profile of a curved step-index waveguide. Obviously, the curvature losses are caused by tunneling of the optical field through a barrier that becomes smaller with decreasing radius of curvature. The caustic radius

$$x_\mathrm{c} = \frac{n_l^2-n_\mathrm{cl}^2}{2n_\mathrm{cl}^2}R\,, \tag{15.39}$$

which reads as $x_\mathrm{c}\approx R(n_l-n_\mathrm{cl})/n_\mathrm{cl}$ in the case of weak guiding, describes the distance between the waveguide's center and the end of this barrier. For the case of large radii of curvature, the insertion loss $\mathrm{IL}_\mathrm{rad}\propto\exp(-\chi R)$ caused by radiation, which follows from asymptotic expansion, increases exponentially with decreasing radius of curvature. The constant χ depends on the type of waveguide used and on its parameters. For precise computation of the radiation losses, it is required to resort

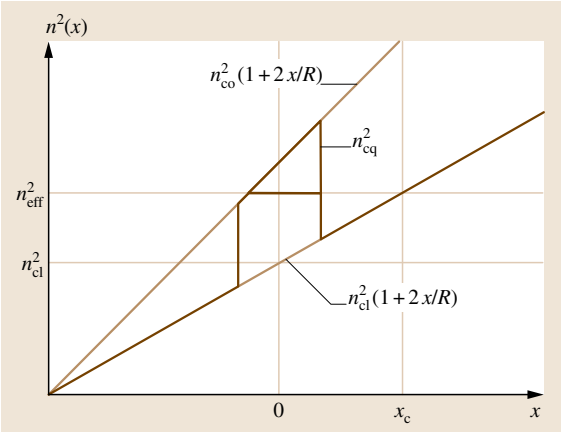

Fig. 15.14 Equivalent refractive index profile of a curved step-index waveguide

to numerical propagation of the fields using the beam propagation method [15.87] or to the numerical solution of (15.36) [15.86].

In addition to radiation losses, the waveguide's curvature results in displacement of the optical field towards the exterior of the waveguide. The Rayleigh–Ritz variational method can be applied to estimate this displacement. The shifted Gaussian function $\psi_\mathrm{test} = (1+\alpha x/R)\exp\left(-x^2/x_0^2-y^2/y_0^2\right)$ approximating the fundamental mode of a parabolic slab waveguide with effective refractive index n_eff represents a usual choice for the trial function. The minimum/maximum condition $\partial\tilde{n}_\mathrm{eff}^2/\partial\alpha = 0$ yields $\alpha = (k_0 n_\mathrm{eff}x_0)^2/2$, which for the displacement Δx of the optical field then results in

$$\Delta x = \frac{(k_0 n_\mathrm{eff})^2 x_0^4}{4R}\,. \tag{15.40}$$

The loss caused by the displacements at the transition between the two circular arcs of an S-curve is

$$\mathrm{IL}_\mathrm{if} = 10\log(e)\left(\frac{\Delta x_1^2}{x_1^2}+\frac{\Delta x_2^2}{x_2^2}\right)\,, \tag{15.41}$$

where Δx_1 and x_1 are the displacement of the fields and the field radius of curvature, and Δx_2 and x_2 are the corresponding parameters of the second curvature. The transition loss can be greatly suppressed by fitting a suitably dimensioned offset at the transition between the two circular arcs or completely suppressed by having a continuous curvature along the S-curve.

In many applications, a rough layout of the waveguide curvatures is adequate. As a rule of thumb, the caustic radius must be significantly larger than the sum

of the field radius x_0 and the displacement Δx caused by the curvature, i. e., $x_c > x_0 + \Delta x$.

Ring resonators are closed circular waveguide loops which are apt for frequency filtering purposes in high-index-contrast configurations. If the bend waveguide is considered as a one-dimensional (1-D) r-dependent refractive index profile, a quasi-analytical approach to the eigenmode analysis can be chosen and the lossy bend modes may be normalized [15.88]. By this, an efficient calculation of the interaction of the ring resonator with input and output waveguide by a CMT ansatz is feasible.

15.3.2 Horn Structures (Tapers)

Horn structures (tapers) [15.89–93] include all types of waveguide structures that change along the optical mode's direction of propagation so slowly (adiabatically) that the distribution of optical power over the local eigenmodes remains conserved during propagation. They are used especially in high-index material systems in order to facilitate fiber–chip coupling by enlarging the near-field cross section on the chip side.

Given an otherwise fixed refractive index profile, the field radius of the fundamental mode of a waveguide can be increased both by increasing and by decreasing the waveguide's cross section. However, by means of the theory of local normal modes (Sect. 15.2.5), it can be shown that increasing the waveguide's cross section is preferable, since it leads to a gradual improvement in waveguiding and thus to a reduction in mode conversion to the radiation field. Decreasing the waveguide's cross section, in contrast, leads to a gradual degradation of waveguiding and thus to an increasing tendency to radiation. Regarding ease of fabrication, often both methods are combined. In the InGaAsP/InP material system (Fig. 15.15), for example, normally the lateral field width (parallel to the chip's surface) is increased by widening the waveguide. The vertical field width, on the other hand, is often increased by reducing the layer thickness, since in this way epitaxial growth of thick layers can be avoided.

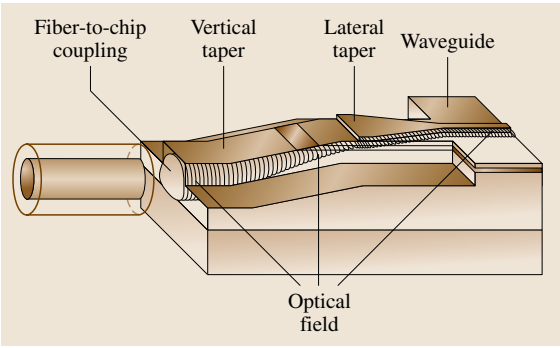

Fig. 15.15 Horn structures (taper) in the InGaAsP/InP materials system

Although the theory of local normal modes (Sect. 15.2.5) forms a suitable basis for the design of waveguide tapers, nowadays most of them are designed using the beam propagation method (Sect. 15.2.4).

15.3.3 Directional Couplers

The directional coupler represents another basic component in integrated optics. On the one hand, it is a free-standing building block, and on the other, an integral part of assembled components such as Mach–Zehnder couplers, optical switches, and modulators.

The coupled mode equations for an ideal directional coupler consisting of two parallel, lossless, single-mode waveguides with effective refractive indices $n_0^{(1)}$ and $n_0^{(2)}$ are

$$-\mathrm{i}\frac{\mathrm{d}}{\mathrm{d}z}\begin{pmatrix} a_1 \\ a_2 \end{pmatrix} = \begin{pmatrix} k_0 n_0^{(1)} & \kappa \\ \kappa & k_0 n_0^{(2)} \end{pmatrix}\begin{pmatrix} a_1 \\ a_2 \end{pmatrix} . \qquad (15.42)$$

The coupling coefficient κ – a real number – describes the cross-coupling of the optical power between the two waveguides. The eigenmodes of the entire directional coupler, known as supermodes, are given by $n_{0/1} = \bar{n} \pm \delta_{\mathrm{eff}}/k_0$, where $\bar{n} = \left(n_0^{(1)} + n_0^{(2)}\right)/2$ denotes the mean refractive index of the two single waveguides, $\delta = k_0\left(n_0^{(1)} - n_0^{(2)}\right)/2$ the half-detuning of their eigenmodes, and

$$\delta_{\mathrm{eff}} = \sqrt{\delta^2 + \kappa^2} \qquad (15.43)$$

the half effective detuning of the supermodes in the directional coupler. The coupling coefficients κ can be obtained either by computing the overlap integrals or from the effective refractive indices n_0 and n_1 of the supermodes calculated with an eigenmode solver by means of $\delta_{\mathrm{eff}} = k_0(n_0 - n_1)/2$. In most cases, the self-coupling [15.61, 62] may be ignored.

The transfer matrix of an ideal directional coupler describing the evolution of the amplitudes of the two single waveguides is given by

$$\mathcal{U}_{\mathrm{CM}}(z) = \begin{pmatrix} A^{\ominus} & A^{\otimes} \\ -A^{\otimes *} & A^{\ominus *} \end{pmatrix} \qquad (15.44)$$

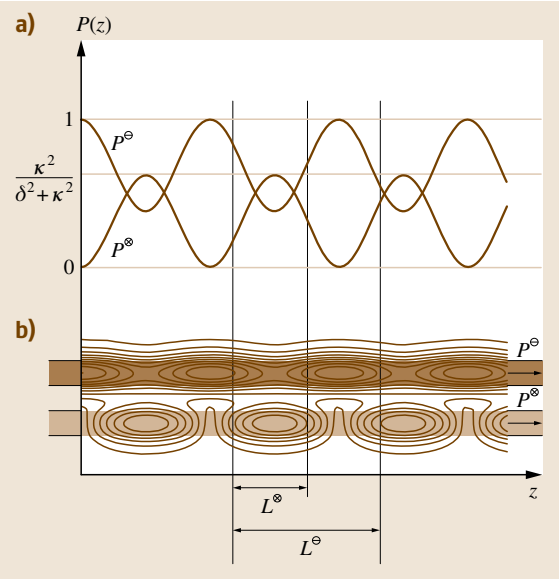

Fig. 15.16a,b Power evolution in both waveguides **(a)** and BPM simulation of the field propagation **(b)** for a directional coupler (without leads)

with the coefficients

$$A^{\ominus} = \cos(\delta_{\text{eff}} z) + \mathrm{i}\delta \sin(\delta_{\text{eff}} z)/\delta_{\text{eff}} ,$$
$$A^{\otimes} = \mathrm{i}\kappa \sin(\delta_{\text{eff}} z)/\delta_{\text{eff}} . \qquad (15.45)$$

A realistic directional coupler consists not only of two parallel waveguides, but also of the necessary leads. The transfer matrix of the realistic directional coupler is, therefore, calculated as the product of the transfer matrices of a chain of ideal directional couplers, modeling the leads by stepwise adaption.

Figure 15.16a shows for an idealized directional coupler (without leads), excited via one of the two waveguides, the evolution of the optical power in the nonexcited

$$P^{\otimes} = \left|A^{\otimes}\right|^2 = \left|\frac{\kappa}{\delta_{\text{eff}}}\right|^2 \sin^2(\delta_{\text{eff}} L) \qquad (15.46)$$

and in the excited waveguide, $P^{\ominus} = 1 - P^{\otimes}$, respectively. A BPM simulation of the directional coupler is placed underneath for illustration (Fig. 15.16b). We can see that the directional coupler returns to the initial state ($P^{\otimes} = 0$) after twice the coupling length $L^{\ominus} = \pi/\delta_{\text{eff}}$, and maximum cross-coupling ($P^{\otimes}_{\text{max}} = |\kappa/\delta_{\text{eff}}|^2$) is reached after the coupling length $L^{\otimes} = L^{\ominus}/2$. For ideal directional couplers the optical power always remains conserved during propagation.

Symmetrical Directional Couplers (SDC)

SDCs consist of two identical strip waveguides ($\delta = 0$, $\delta_{\text{eff}} = |\kappa|$). They always permit complete crossover of the optical power ($P^{\otimes}_{\text{max}} = 1$). Realistic symmetrical couplers, i. e., couplers with leads, are described by the transfer matrix

$$\mathcal{U}_{\asymp} = \begin{pmatrix} \cos\varphi & \mathrm{i}\sin\varphi \\ \mathrm{i}\sin\varphi & \cos\varphi \end{pmatrix} . \qquad (15.47)$$

The coupling phase φ of a coupler of length L is given by the integral

$$\varphi = -\int_{-L/2}^{L/2} \mathrm{d}z |\kappa(z)| \qquad (15.48)$$

over the local coupling coefficient $\kappa(z)$ along the coupler. The real, symmetrical directional coupler couples the optical power ($P^{\otimes} = \sin^2\varphi$) completely there and back. Symmetrical directional couplers are normally used as broadband components. In the past, great efforts were made to develop spectrally flat, fiber-based, and integrated optics directional couplers for use as branching devices, taps or beam splitters. The effects of material and waveguide dispersion on the coupling coefficients have to be taken into account during device layout.

Asymmetrical Directional Couplers (ADC)

ADCs [15.94] are formed from two strip waveguides with different layout ($\delta \neq 0$). If an asymmetrical coupler consists of one high-refractive-index waveguide with small cross section and one low-refractive-index waveguide with large cross section, the effective refractive indices of the relevant eigenmodes can have the same value at one particular wavenumber $k_0^{(c)}$ (Fig. 15.17). This is the only wavenumber where the asymmetrical directional coupler can cross-couple the input optical power completely. In spectral regions close to the crossover point, the filter curve (Fig. 15.18) of the asymmetrical directional coupler,

$$P^{\otimes}(k_0) = F(\Delta k_0) \sin^2(\delta_{\text{eff}} L) , \qquad (15.49)$$

exhibits resonant behavior. The maxima of the filter curve lie along a Lorentz curve

$$F(\Delta k_0) = \frac{(\chi_c/2)^2}{(\chi_c/2)^2 + (\Delta k_0)^2} , \qquad (15.50)$$

whose half-width is given by $\chi_c = 2|\kappa/(\partial\delta/\partial k_0)|$. The challenges involved in realizing two waveguides with

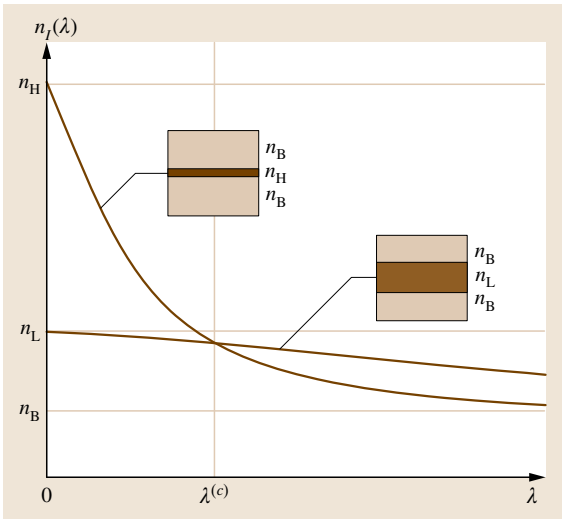

Fig. 15.17 Dispersion curves of both waveguides forming an asymmetric directional coupler

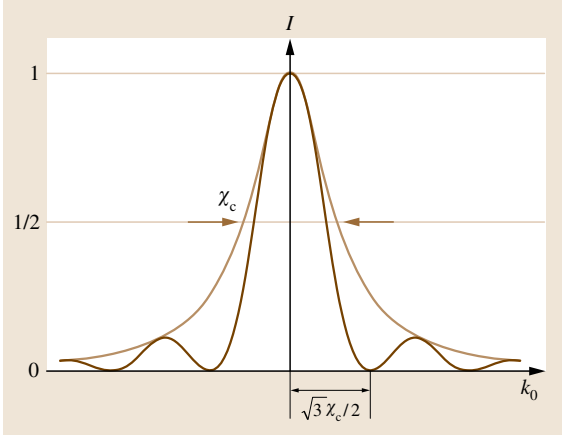

Fig. 15.18 Filter curve and envelope of the maxima for an asymmetric directional coupler

completely different properties mean that few structural elements of this type have been built. The superposition of the coupler with periodic structures ($\Delta\kappa$-Koppler), however, can increase the scope for the design significantly (Sect. 15.4.4).

15.3.4 Multimode Interference Couplers

The classical directional coupler with two ports on the input and two ports on the output side (Sect. 15.3.3) relies on the interference of the fundamental mode and the first excited mode of a coupled waveguide structure. The multimode interference coupler (MMI), in contrast, utilizes the imaging properties [15.95, 96] of a laterally multimode and strongly guiding waveguide, whose eigenmodes can be represented to a good approximation as the direct product $\phi_{0l}(x, y) = \chi_0(x)\psi_l(y)$ of a transversal fundamental mode $\chi_0(x)$ and a lateral mode $\psi_l(y)$. The propagation of the lateral modes $\psi_l(y)$ is analyzed below. Figure 15.19 shows two typical lateral structures of the multimode interference coupler. The wide-strip waveguide as the core of the multimode interference coupler has refractive index n_{co}. Its eigenmodes are approximated for further theoretical analysis by the eigenmodes

$$\psi_l(y) = \sin\left[\pi(l+1)\frac{y}{W}\right] \tag{15.51}$$

of a metallic box of width W. The effective refractive indices of the waveguide are then given by

$$\begin{aligned} n_l &= \sqrt{n_{co}^2 - \left[\frac{\pi(l+1)}{k_0 W}\right]^2}\,, \\ &\approx n_{co} - l(l+2)\frac{\pi}{3k_0 L_{01}^{\otimes}}\,, \end{aligned} \tag{15.52}$$

where

$$L_{01}^{\otimes} = \frac{2k_0 n_{co} W^2}{3\pi} \tag{15.53}$$

denotes the coupling length between the fundamental mode and the next highest mode. Simulations of beam propagation in the multimode interference coupler using the beam propagation method [15.97] have shown that, for (realistic) dielectric waveguides, the box width $W \approx \lambda/\left(2\sqrt{n_{co}^2 - \tilde{n}_0^2}\right)$ is given to a good approximation by the region between the extrapolated zeros of the fundamental mode of the dielectric waveguide with effective refractive index $\tilde{n}_0$ (Fig. 15.20). For operation in integrated optics circuits, usually only the input and output of eigenmodes of symmetrical strip waveguides are of significance, i. e., injection of symmetrical and antisymmetrical functions $\Psi_{in}(y) = \pm\Psi_{in}(y - 2y_{WG})$ with center of symmetry at the center y_{WG} of the coupled waveguide. Moreover, in practical operation, only those elements where one normal and one laterally reversed image of the eigenmode are superposed are used. The images of the left-hand boundary of the wide-strip waveguide are shifted by $y_l - y_m = 2(l-m)W/N$ relative to each other. This makes it also possible to divide the input power nonuniformly [15.98, 99]. Finally, the superimposed images are separated completely at the output of real multimode couplers, such

that neighboring images can be coupled into neighboring strip waveguides with little crosstalk. Under these conditions, the wide variety of possible configurations is reduced to two basically different configurations, one for an even (Fig. 15.19a) and one for an odd (Fig. 15.19b) number of part images. The input and output ports are marked by circles in Fig. 15.19. For the optical field near the output port with $y_{out} = l_{out} W/N$, we obtain

$$\Psi_{out}\left(y_{out} + \Delta y, \frac{3L_{01}^{\otimes}}{N}\right) = A\Psi_{in}(y_{in} + \Delta y)\cos\left(\frac{\Delta\varphi}{2}\right) e^{i(\varphi_0+\bar{\varphi})}, \quad (15.54)$$

where $y_{in} = l_{in} W/N$ is the position of the input port, $\bar{\varphi}$ is the mean phase of the two superimposed images, and

$$\Delta\varphi = l_{in} l_{out} \frac{\pi}{N} + \Delta\varphi_s \quad (15.55)$$

is their phase difference. The normalization constant has the value $A = \sqrt{2/N}$ when the output port lies at the edge of the wide-strip waveguide; otherwise it has the value $A = 2/\sqrt{N}$. The additional phase shift

$$\Delta\varphi_s = \begin{cases} \pi & \text{for symmetrical fields} \\ 0 & \text{for antisymmetrical fields} \end{cases} \quad (15.56)$$

is caused by the different behavior of symmetrical and antisymmetrical fields under lateral reversal. A detailed analysis of (15.55) permits further conclusions:

- For $N = 4M - 2$ and with excitation through the central input port ($l_{in} = N/2$), the optical power is distributed uniformly across the output ports.
- For $N = 3M$ and with excitation through the input port at the end of the first ($l_{in} = N/3$) or second third ($l_{in} = 2N/3$) of the wide-strip waveguide, the optical power is distributed uniformly across the output ports. The output ports at the positions $N = 6M - 6$, however, always remain without power.
- The symmetrical and antisymmetrical fields are distributed equally only for $N = 4M - 2$ and with excitation by the input ports $l_{in} = N/(4M - 2)$. In other words, when coupling laterally multimode strip waveguides, the even and odd modes are treated unequally in most configurations.
- If symmetrical fields are injected, no images occur at the edge of the wide-strip waveguide ($l_{out} = 0$ or $l_{out} = N$). In contrast, if antisymmetrical fields are injected, half-images can be observed at the edge, often at high relative power.

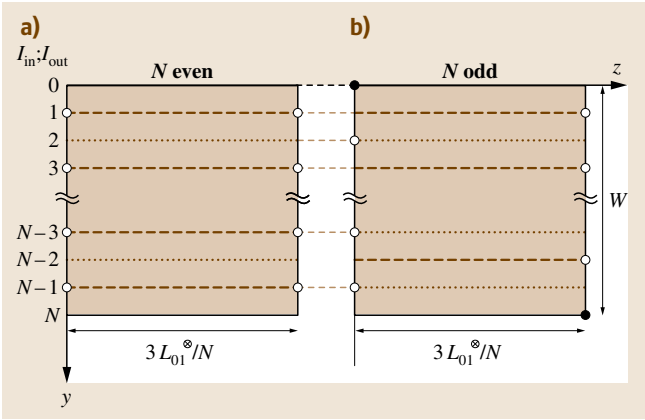

Fig. 15.19 Two typical lateral structures for multimode couplers [multimode interference coupler (MMI)] of length $3L_{01}^{\otimes}/N$. The input and output ports are marked by *circles*

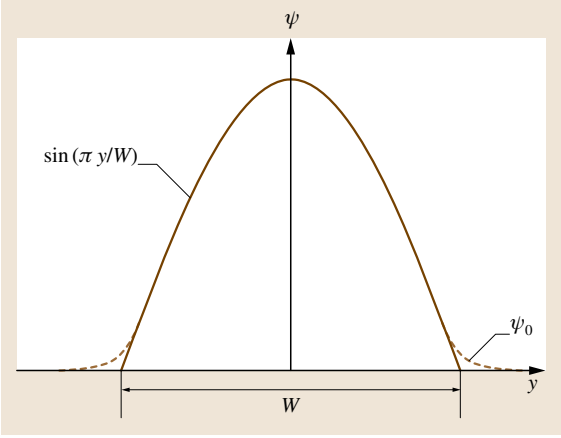

Fig. 15.20 Effective box width W for multimode couplers for a dielectric waveguide

Table 15.4 presents the attainable power ratios for multimode couplers with one and two output ports [15.99], which just like the input ports lie on the grid discussed above [$y_M = (M-1)y/W$]. The optical power at the output ports is scaled by the injected power. When coupling symmetrical fields (symmetrical case) the sum of the output power corresponds to the input power; the coupling of antisymmetrical fields gives rise to losses through half-images at the edge of the wide-strip waveguide. Based on the designs considered in Table 15.4, the distributions can be varied continuously by means of linear tapering (butterfly MMI coupler) [15.100]. Similarly, the components can be significantly shortened by tapering [15.101]. As

Table 15.4 Power ratios for multimode couplers with one and two output ports

N	Output	Input	P_{out}/P_{in} (%)	
			Symmetrical case	Antisymmetrical case
2	1	1	100.0	100.0
3	1	2	100.0	33.3
	2	1	100.0	33.3
4	1 : 3	1	14.6 : 85.4	85.4 : 14.6
		3	85.4 : 14.6	14.6 : 85.4
	2	2	100.0	0.0
5	2 : 4	1	72.4 : 27.6	7.6 : 52.4

	1 : 3	2	72.4 : 27.6	7.6 : 52.4
		4	27.6 : 72.4	52.4 : 7.6

a result of its good imaging properties, the multimode coupler tends to have significant feedback effects on the input [15.102].

The ease of fabrication of strongly guiding waveguides is of decisive importance for the realization of MMI couplers. For this reason, nowadays most components are fabricated in III–V semiconductors (essentially in the InGaAsP/InP material system). In such applications, these components are mostly used as beam splitters; however, they have also been used to flatten the filter curves in optical phased arrays [15.6].

15.3.5 Diffraction Gratings and Phased Arrays

Optical filters whose selectivity relies on interference between numerous partial beams obtained from one input beam in a slab waveguide are referred to in integrated optics quite generally as planar spectrographs. Special implementations include transmission gratings, reflection gratings, and optical phased arrays (also arrayed waveguide gratings (AWG) or PHASAR). In wavelength-division multiplexing (WDM) systems, in particular for applications involving many WDM channels, planar spectrographs are used as WDM multiplexers and demultiplexers at the segment ends and in optical add/drop multiplexers (OADMs) and optical cross-connects.

Due to the advantages of planar technology, focusing spectrographs can be easily fabricated in integrated optics. Aberration analysis plays an important role in their design, since aberrations affect both the spectral resolution and crosstalk suppression significantly.

Theory of Focusing Spectrographs

The theoretical treatment of planar spectrographs [15.5, 103] is based on optical ray tracing by means of the light path function

$$F(y) = F_I(y) + \overline{PD} - \overline{OD} + m\lambda G(y)\,. \qquad (15.57)$$

This technique is a generalization of the Huygens principle to the analysis of focusing spectrographs. The light path function describes here the effective optical path length difference between two rays that reach an observation point $D = (y_D, z_D)$ originating from input port I (I_T for transmission gratings and phased arrays, and I_R for transmission gratings) via different paths. The ray of interest crosses the grating line $z_G(y)$ at the point $P = [y, z_G(y)]$, and the reference ray at the center $O = (0, 0)$ of the grating line (Fig. 15.21).

For this discussion, the coordinate system is chosen in such a way that the grating line touches the y-axis at its center. The first term $F_I(y)$ in (15.57) describes the optical path length difference in the input region. This expression differs between various types of spectrographs. The next two terms $\overline{PD} - \overline{OD}$ describe the optical path length difference on the output side. The last term, $m\lambda G(y)$, describes the additional optical path length difference that needs to be added for the analysis of a spectrograph operated in the m-th diffraction order (Huygens principle). If the light path function $F(y) \equiv 0$ vanishes along the entire grating line, a focusing spectrograph images the optical field at the input port perfectly, i. e., without any aberrations. This condi-

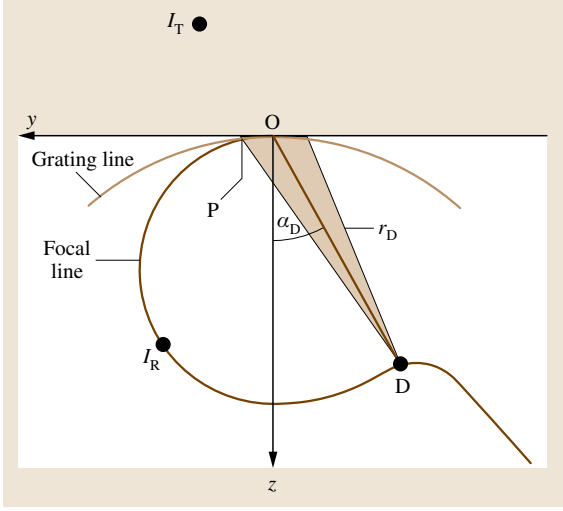

Fig. 15.21 Coordinate system for the analysis of focusing spectrographs

tion can be satisfied at a few image points only, namely at the spectrograph's stigmatic points. The aberrations are small in their vicinity.

For aberration analysis of planar spectrographs, the light path function $F(y)$ is expanded into a – usually rapidly converging – Taylor series. If only the two leading coefficients of the Taylor expansion vanish, the imaging of the optical field of the input port is distorted. In the first step, the diffraction angle is determined via $F'(0) = 0$ from the grating equation (Fermat's principle)

$$\sin\alpha_D = -F_I'(0) - m\lambda G'(0)\,. \tag{15.58}$$

The image of the input port $[F''(0) = 0]$ is located at a distance

$$r_D = \frac{\cos^2\alpha_D}{-m\lambda G''(0) - F_I''(0) + z_G''(0)\cos\alpha_D} \tag{15.59}$$

from the center of the grating line. The focal line on which the images of the input port are located is given by

$$\boldsymbol{r}_f = r_D \begin{pmatrix} -\sin\alpha_D \\ \cos\alpha_D \end{pmatrix}\,. \tag{15.60}$$

It is noteworthy that focusing spectrographs do not always form a real image; for example, the images of straight chirp-free gratings always lie at infinity.

The other expansion coefficients $[F^{(\nu)}(0),\ \nu > 2]$ vanish only for special configurations. They classify the spectrograph's aberrations. The leading term $F'''(0)$ describes the coma, and the following term $F^{(IV)}(0)$ the spherical aberrations. To achieve the desired spectral resolution within the smallest space, one always attempts to minimize aberrations. Like any imaging system, spectrographs produce a sharp image of the input port if the optical path difference between the central ray and the $1/e^2$-ray of the injected beam satisfies $F(y_{1/e}) < \lambda/10$. Aberrations play an important role in the design of spectrographs, since aberrations influence the attainable crosstalk suppression significantly and ultimately determine their use as part of a system.

The ratio of the spot magnifications m_D and m_E for two arbitrarily chosen observation points D and E is

$$\frac{m_D}{m_E} = \frac{r_D\cos\alpha_E}{r_E\cos\alpha_D}\,. \tag{15.61}$$

The lines of constant spot magnification form a family of circles that each touch the grating line at the center. The spot magnification determines the effectiveness associated with coupling to the waveguides in the output region and, just like the aberrations, the spectrograph's crosstalk suppression.

A chirp-free spectrograph $[G^{(\nu)}(0) = 0,\ \nu > 1]$ whose grating line lies on a semicircle $z_G(y) = R - \sqrt{R^2 - y^2}$ of radius R, is termed a generalized Rowland mounting if the input port is placed such that the phase portrait is also linear along the grating line $[F_I^{(\nu)}(0) = 0,\ \nu > 1]$. The focal line of a generalized Rowland mounting is formed by a circle of radius $r = R/2$, which touches the grating line at the center O. The crucial significance of the Rowland mounting is highlighted by the aberrations theorem: *It is impossible to build a planar spectrograph that exhibits neither coma nor spherical aberrations. Only generalized Rowland mountings exhibit no coma.* Rowland mountings exhibit in addition wavelength-independent spot magnification. Focusing planar spectrographs are often designed as Rowland configurations due to these properties.

The line shape of the diffracted peak at an arbitrary output port is given to a good approximation by the Fourier transform of the envelope of the optical field along the grating line. Conversely, the Fourier transform of a single aperture at the grating line forms the envelope of all diffracted beams at the focal line (Fig. 15.22). The

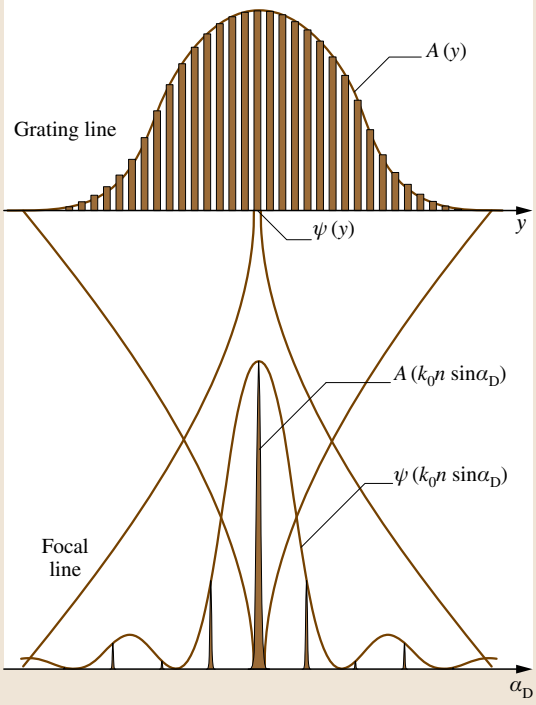

Fig. 15.22 Diffraction efficiency of spectrographs

grating's efficiency is optimized by aligning all apertures towards one point on the focal line (blaze point).

Planar spectrographs whose waveguide structures are dispersion free form strictly periodical filters since, for the light path function, $F(y, m, \nu) \equiv F(y, m \pm l, \nu \pm l\Delta\nu_{\mathrm{FSR}})$ applies with $\nu \propto 1/\lambda$. The free spectral range (FSR) $\Delta\nu_{\mathrm{FSR}} = \nu/m$ denotes the spectral distance to the adjacent diffraction order. The spectral resolution of a spectrograph is determined by the number N of the illuminated apertures and by the diffraction order m envisaged for its operation. Applying the Rayleigh criterion (RC), we obtain

$$\Delta\lambda_{\mathrm{RC}} = \frac{\lambda}{|m|N} \,. \tag{15.62}$$

The spectral resolution that a spectrograph achieves as part of a transmission system depends essentially on the required crosstalk attenuation. The manufacturing of spectrographs can always be simplified at the expense of a decreased free spectral range, since its grating period increases linearly with the diffraction order while the free spectral range decreases at the same time. Planar spectrographs used in optical transmission systems are often operated at the largest possible diffraction order; components with diffraction orders $|m| > 100$ have been fabricated. The number of channels N_{ch} which can be resolved is given by the ratio of free spectral range and spectral resolution.

Reflection and Transmission Gratings

For gratings, the optical path length difference in the input region is given by the optical path length difference $F_{\mathrm{I}}(y) = \overline{\mathrm{IP}} - \overline{\mathrm{IO}}$ between the focal radius and the central ray from input port I to the grating, (15.57). For the derivatives needed in (15.58) and (15.59), this results in $F'_{\mathrm{I}}(0) = \sin\alpha_{\mathrm{I}} x$ and $F''_{\mathrm{I}}(0) = \cos^2\alpha_{\mathrm{I}} - z''_{\mathrm{G}}(0)\cos\alpha_{\mathrm{I}}$. The spot magnification of a focusing grating is therefore $m_\circ = (r_{\mathrm{D}}\cos\alpha_{\mathrm{I}})/(r_{\mathrm{I}}\cos\alpha_{\mathrm{D}})$, where α_{D} denotes the diffraction angle and r_{D} the distance of the image point from the center of the grating line. α_{I} and r_{I} are the corresponding parameters for the input side.

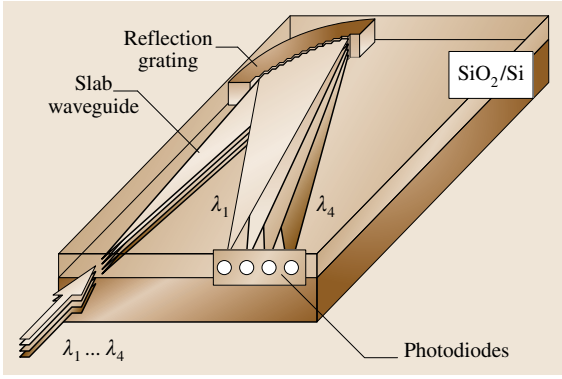

Fig. 15.23 Flat-field spectrograph in the SiO_2/Si materials system

Transmission gratings can be realized as amplitude and/or phase gratings. Pure amplitude gratings modulate the amplitude distribution through a series of mostly equidistant slits. They are only rarely used these days for commercial applications, due to the associated loss of typically 3 dB. Pure phase gratings modify the phase portrait without modifying the amplitude distribution. They are far more attractive technically, but more difficult to fabricate. Integrated optical transmission gratings were realized by various groups as early as the 1970s and 1980s [15.104, 105].

Due to their folded beam path, focusing reflection gratings always provide a more compact layout.

Since reflection gratings are metallized, usually, the boundary conditions differ for the vector components of the electric and the magnetic field; i. e., reflection gratings are sensitive to the polarization of the incident beam. Thus, Wood anomalies or the excitation of surface plasmons can result in sharp drops in efficiency [15.81]. Planar spectrographs with reflection gratings have been fabricated successfully in various material systems, including SiO_2/Si, InGaAsP/InP, and polymers. The grating itself was either etched in a slab waveguide or mounted on the chip's end face. Due to the lithography-based fabrication process, curved and chirped gratings can also be produced with no additional complexity. Figure 15.23 shows as an example a flat-field spectrograph in the SiO_2/Si material system [15.106, 107]. The input port and the focal line in these components are located at the end face of the chip. Rowland mountings have been realized by a number of groups in the InGaAsP/InP and SiO_2/Si material systems [15.108, 109], partly with integrated photodiodes and/or optical preamplifiers. Integrated optical gratings have been realized for up to 128 wavelength channels for channel spacings of 0.5–4 nm.

Optical Phased Arrays

The optical phased array [also arrayed waveguide grating (AWG) or PHASAR] is a phase transmission grating that fits very well with the waveguide-based technologies of integrated optics. In contrast to conventional phase transmission gratings, it allows for large phase shifts and thus for operation at very high diffraction orders.

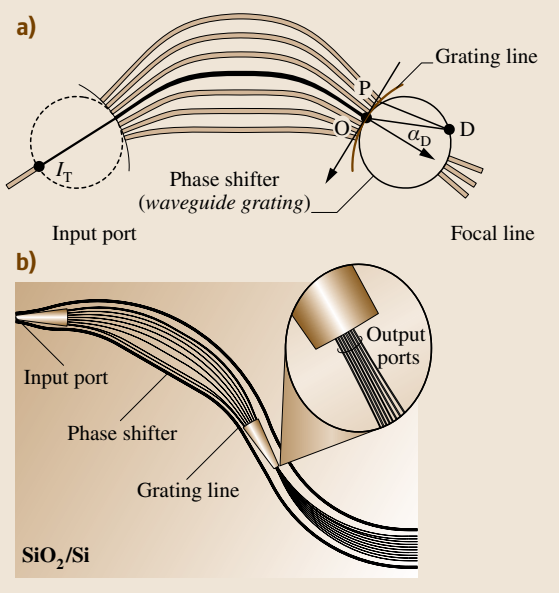

Fig. 15.24a,b Optical phased array [also arrayed waveguide grating (AWG) or PHASAR]. Schematic representation **(a)** and realization in the SiO_2/Si materials system

Figure 15.24 shows a schematic diagram of an optical phased array, and for illustration the realization of a component in the SiO_2/Si material system. The input port I_T is located at the input of the left-hand slab waveguide. Starting from this point, the injected beam widens under the effect of diffraction in the input-side slab waveguide. At the phase shifter's input, the far field is decomposed into N partial beams that are injected into the phase shifter's strip waveguide array. In the phase shifter, the phasings of the partial beams are adjusted relative to each other. The phase shifter's output forms the grating line, the waveguide ends replacing the grooves or slits of a conventional grating (Fig. 15.24b). The grating period of the phased array is determined by the separation between the waveguide centers at the phase shifter's output. To minimize the reciprocal effects between the partial beams in the phase shifter, optical phased arrays are mostly operated at the highest feasible diffraction order. Blazing of optical phased arrays is done by aligning the waveguides at the phase shifter's output to a point on the focal line.

For phased arrays, the optical path difference in the input region in (15.57) is given by $F_I(y) = \overline{IP_I} - \overline{IO_I} + (n_p/n_s)\left(\widetilde{P_IP} - \widetilde{O_IO}\right)$, where O is the center of the grating line and P is the point at which the focal radius passes the grating line. The two other points, O_I and P_I, are the corresponding points at the phase shifter's input. The quantities $\widetilde{P_IP}$ and $\widetilde{O_IO}$ denote the arc lengths of the strip waveguides coming out of P and O. The phase differences caused by the different effective refractive indices n_p and n_s of the strip and slab waveguides, respectively, are taken into account by means of the ratio n_p/n_s. If the inputs of the phase shifter are located on a circle whose center lies at the input port, the difference between the two terms $(\overline{IP_I} - \overline{IO_I})$ makes no contribution.

Many optical phased arrays have been constructed as Rowland mountings [15.6], i. e., with $G(y) = y/\Lambda$, where L denotes the phased array's grating constant (projected onto the y-axis). The grating line then forms a semicircle with radius R. The input-side slab waveguide and the phase shifter are designed such that the phase (projected onto the y-axis) also increases linearly. For the optical path length difference in the input region we then obtain $F_I(y) = (-m\lambda_C/\Lambda - \sin\alpha_C)\, y = n_p \Delta L/(n_s \Lambda)$, where λ_C is the design wavelength (in the material), α_C is the diffraction angle at this wavelength, and ΔL is the optical path length difference between two adjacent strip waveguides of the phase shifter. Phased arrays realized in Rowland configuration likewise exhibit no coma. Furthermore, they have a stigmatic point at the vertex of the Rowland circle ($\alpha_D = 0$). Figure 15.24b shows the most common layout used nowadays [15.110]. In addition, a second layout [15.111, 112] is used, in which however the phase shifter's output waveguides are not directed towards a blaze point. Figure 15.25 shows a set of filter curves for an optical phased array in the glass on sili-

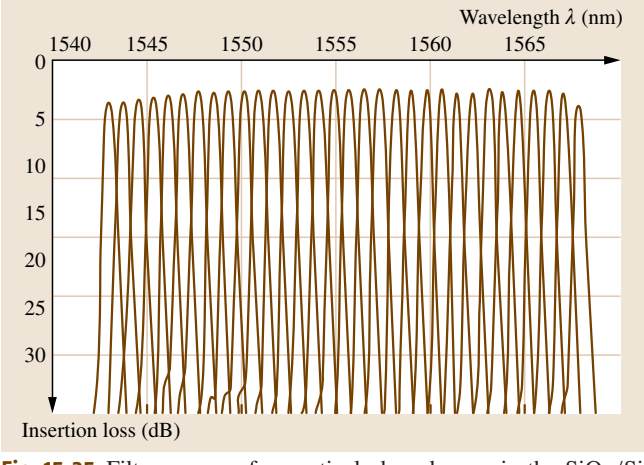

Fig. 15.25 Filter curves of an optical phased array in the SiO_2/Si materials system

con ((SiO_2/Si)) material system. The filter curves are parabolic to a good approximation. For many applications, however, flattened filter curves are specified, since the broadening of the pass band means that the requirements in terms of stabilizing the transmitting components can be lowered. To this end, a range of methods – the use of multimode waveguides and Y-splitters on the output side [15.113], the use of multimode couplers on the input side [15.114], and modifications of the phase shifter [15.115] – have been demonstrated successfully. Only multimode waveguides on the phased array's output side may result in flattened filter curves without additional losses, theoretically. All other methods lead to extra losses of typically 2–3 dB.

Optical phased arrays are used as wavelength multiplexers and demultiplexers in WDM-based transmission networks. Components in the glass-on-silicon material system (SiO_2/Si) are available commercially. In the InGaAsP/InP material system, optical phased arrays have been integrated successfully with photodiodes, optical amplifiers, optical modulators, and optical switches [15.18]. Optical phased arrays have been demonstrated in other material systems also: ion exchange in glass, $LiNbO_3$, and polymers. So far, optical phased arrays have been realized with up to 512 wavelength channels and (with few exceptions [15.116]) for channel spacings of 10–400 GHz.

15.3.6 Contradirectional Couplers

Contradirectional coupling is the optical waveguide analog of Bragg reflection in crystals. However, whereas the back-coupling in the crystal is caused by the crystallographic lattice itself, in the waveguide it needs to be initiated by suitable periodic or nearly periodic structures. The following discussion will only briefly describe the Bragg grating, the simplest contradirectional coupler. A treatment of the contradirectional directional coupler, a directional coupler with integrated Bragg grating, can be found in [15.117].

The partial waves reflected by a grating of period Λ under normal incidence interfere constructively for all those wavelengths λ_B for which the Bragg condition

$$l\frac{\lambda_B}{n} = \Lambda \qquad (15.63)$$

is satisfied, where the order l is a integer number. Near every resonance, i. e., for small deviations of the wavenumber $\delta = k_0 n - \pi l/\Lambda$, the grating's effect can be analyzed using the theory of coupled modes [15.118, 119]. The transfer matrix of the Bragg grating which describes the expansion of the amplitudes for the forward and reflected waves is given by

$$\mathcal{U}_{BG} = \begin{pmatrix} A^{\ominus} & A^{\otimes} \\ A^{\otimes *} & A^{\ominus *} \end{pmatrix} \qquad (15.64)$$

with coefficients

$$A^{\ominus} = \cos(\delta_{\text{eff}} z) - \frac{\mathrm{i}\delta \sin(\delta_{\text{eff}} z)}{\delta_{\text{eff}}} ,$$

$$A^{\otimes} = \frac{\mathrm{i}\chi \sin(\delta_{\text{eff}} z)\, \mathrm{e}^{\mathrm{i}Qz}}{\delta_{\text{eff}}} ,$$

where χ is the coupling coefficient of the grating and $\delta_{\text{eff}} = \pm\sqrt{\delta^2 - |\chi|^2}$ is the effective detuning of the coupled modes. The amplitudes of the forward and reflected waves $a^{(+)}$ and $a^{(-)}$ of lossless gratings satisfy the conservation law

$$\frac{\mathrm{d}}{\mathrm{d}z}\left(|a^{(+)}|^2 - |a^{(-)}|^2\right) = 0 . \qquad (15.65)$$

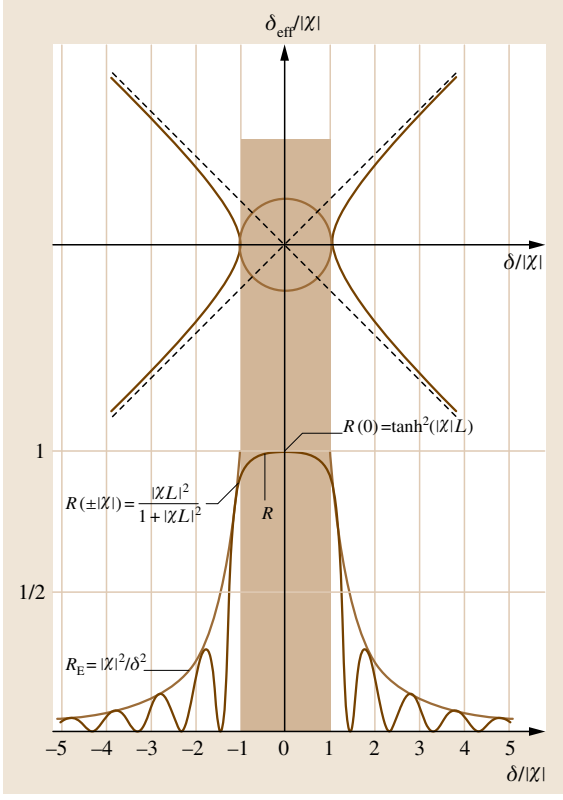

Fig. 15.26 Dispersion curve and filter characteristic of a Bragg grating with $|\chi|L = 3$

The Bragg grating's reflectance is given by $R = |A^{\otimes}/A^{\ominus}|^2$; for a grating of length L we obtain

$$R = \frac{|\chi|^2 \sin^2(\delta_{\text{eff}} L)}{\delta_{\text{eff}}^2 \cos^2(\delta_{\text{eff}} L) + \delta^2 \sin^2(\delta_{\text{eff}} L)} , \tag{15.66}$$

and the transmittance is $T = 1 - R$.

Figure 15.26 shows the dispersion relation and the filter characteristic of a Bragg grating. The stop band, in which the effective detuning δ_{eff} of the grating becomes imaginary, is shaded. We can see that the optical wave in the stop band of a grating of finite length is not reflected completely. For the reflectivity at the center of the stop band we have $R(0) = \tanh^2(|\chi|L)$, at the edge of the stop band $R(|\chi|) = |\chi L|^2/(1 + |\chi L|^2)$. From these relationships it becomes evident that the strength of a Bragg grating is determined by the parameter χL. Whereas Bragg gratings exhibit a very narrow stop band for $|\chi|L < 1$, the reflectivity of a component with $|\chi|L > 10$ is high ($> 99\%$) across the whole stop band. The number of zeros and their positions likewise depend on the Bragg grating's length. In contrast, the envelope of the filter curve $R_{\text{E}} = |\chi|^2/\delta^2$ with $\delta^2 > |\chi|^2$ which covers all maxima is independent of the Bragg grating's length. The envelope, which in a strictly periodic Bragg grating falls off only slowly, can be made significantly steeper at the edges of the grating by decreasing the coupling coefficient (κ-tapering) [15.120].

When operating Bragg gratings, a number of parasitic effects occur, such as Goos–Hänchen shift [15.121], Brewster angle, polarization conversion [15.122, 123], and radiation into the substrate or the external space [15.124].

Bragg gratings have been fabricated in nearly all material systems [15.104, 123, 125], mostly by holographic exposure and direct electron-beam lithography. Distributed feedback (DFB) and distributed Bragg reflector (DBR) lasers (Sect. 11.3) were the main application of (etched) Bragg gratings for a long time. In recent years, however, refractive index gratings are made increasingly in the SiO_2/Si material system by ultraviolet (UV) projection of phase masks [15.126, 127]. As with fiber Bragg gratings (Sect. 14.8), dispersion compensation is gaining in importance in addition to their use as band stop filters.

15.4 Integrated Optical Circuits

The transfer matrices $\mathcal{U}$ of a component or an integrated optical circuit are just the propagators of the optical field

$$\tilde{\mathcal{U}} = \mathrm{e}^{\mathrm{i}\bar{\varphi}}\mathcal{U} \tag{15.67}$$

except for an additional mean phase shift $\bar{\varphi}$. The magnitude of the latter depends on the details of the design, in particular also on the length of the leads. Usually, the mean phase shift does not affect the function of a component; in the following, it is chosen such that the transfer matrices of lossless components are unitary ($\mathcal{U}^{-1} = \mathcal{U}^{\dagger}$) and unimodular ($\det\mathcal{U} = 1$). The transfer matrices are also referred to in the literature as transmission matrices. In addition to the $\mathcal{U}$ notation chosen here, $\mathcal{T}$ is common also [15.128].

The transfer matrices are suitable (Sects. 15.3.3 and 15.3.6) for describing codirectionally and contradirectionally coupled optical fields. In an optical circuit in which codirectional waves are coupled, the optical power remains conserved if the amplitudes satisfy the equation

$$\frac{\mathrm{d}}{\mathrm{d}z} \sum_{m=1}^{N} |a_m|^2 = 0 . \tag{15.68}$$

The corresponding unitary unimodular transfer matrices form the group SU(N). If contradirectional cross-coupling occurs in an optical circuit, the returning waves must be taken into consideration also. The optical power remains conserved in such a circuit if the amplitudes satisfy the conservation law

$$\frac{\mathrm{d}}{\mathrm{d}z} \sum_{m=1}^{N} \left(\left|a_m^{(+)}\right|^2 - \left|a_m^{(-)}\right|^2 \right) = 0 . \tag{15.69}$$

In this case, the unitary unimodular transfer matrices form the group SU(N, N). For the most important special cases, the codirectional four-port and the contradirectional two-port, the transfer matrices have the form

$$\mathcal{U}_{\pm} = \begin{pmatrix} A^{\ominus} & A^{\otimes} \\ \mp A^{\otimes *} & A^{\ominus *} \end{pmatrix} . \tag{15.70}$$

For the lossless codirectional four-port (upper sign) under excitation via an input port, the relative optical power emerging at the diagonally opposite port is given by $P^{\otimes} = |A^{\otimes}|^2$, and at the directly opposite port

by $P^{\ominus} = |A^{\ominus}|^2$. For the lossless contradirectional two-port (lower sign) under excitation from one side, the reflectance is given by $R = |A^{\otimes}/A^{\ominus}|^2$ and the transmittance by $T = 1 - R$.

Since the transfer matrices of lossless, compound components (Sect. 15.4.3) are unitary and unimodular, the response of a component to waves traveling in the return direction is described by the adjoint matrix $\mathcal{U}^{\dagger}$. Further advantages become available by using a multitude of special mathematical methods; for example, the group SU(2) can be mapped bijectively to the group SO(3) of rotations in 3-space; therefore, the effect of a lossless four-port can be interpreted as motion on a spherical surface S^2 [15.129].

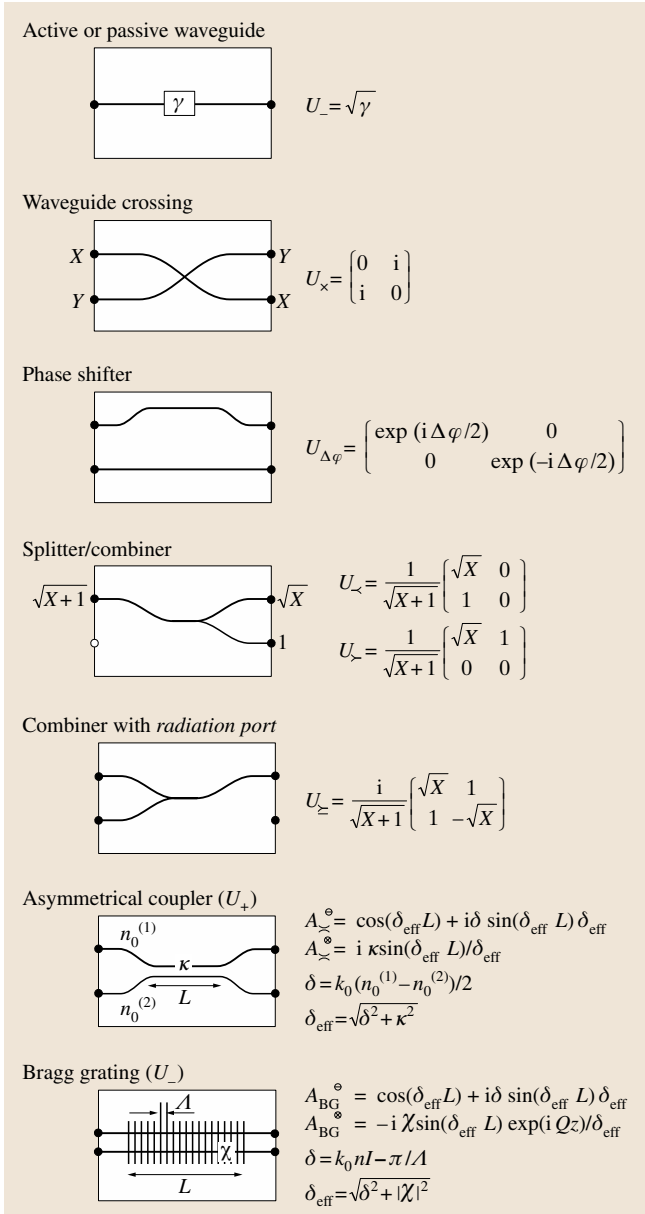

Fig. 15.27 Transfer matrices of some elementary components

15.4.1 Further Basic Components

Figure 15.27 shows the transfer matrices $\mathcal{U}$ for a number of elementary components [15.5]. Most of those shown are asymmetric against transposing the input ports, i. e., under the transformation $\alpha_1^{(\mathrm{in})} \Leftrightarrow \alpha_2^{(\mathrm{in})}$, $\alpha_1^{(\mathrm{out})} \Leftrightarrow \alpha_2^{(\mathrm{out})}$. The transfer matrix for a component with transposed input ports can, however, be obtained directly from the initial matrix through the following transformation:

$$\mathcal{U}_{\updownarrow} = \begin{pmatrix} U_{22} & U_{21} \\ U_{12} & U_{11} \end{pmatrix} . \tag{15.71}$$

Active and passive single-mode waveguides and taper are described by the transfer matrix

$$\mathcal{U}_{-} = \sqrt{\gamma} , \tag{15.72}$$

where γ denotes the ratio of output to input power. For a lossless waveguide, $\gamma = 1$. The mean phase shift (15.67) of a straight single-mode waveguide of length L is $\bar{\varphi} = -k_0 n L$, where n is the effective refractive index of the fundamental mode.

Phase shifters consist, in the simplest case, of two fully decoupled single-mode waveguides. By using two waveguides with length difference of $\Delta L = L_1 - L_2$ and difference of $\Delta n = n_1 - n_2$ between their effective refractive indices, two waves are generated at the output with an additional phase difference of

$$\Delta\varphi = -k_0 \bar{n} \Delta L - k_0 \Delta n \bar{L} , \tag{15.73}$$

where $\bar{L} = (L_1 + L_2)/2$ is the mean length and $\bar{n} = (n_1 + n_2)/2$ is the mean effective refractive index of the two waveguides. The associated transfer matrix is

$$\mathcal{U}_{\Delta\varphi} = \begin{pmatrix} \exp\left(\frac{\mathrm{i}\Delta\varphi}{2}\right) & 0 \\ 0 & \exp\left(\frac{-\mathrm{i}\Delta\varphi}{2}\right) \end{pmatrix} . \tag{15.74}$$

Waveguide crossings serve solely for the purpose of swapping around two input ports. The transfer matrix of the ideal waveguide crossing is, therefore, given by

$$\mathcal{U}_{\times} = \begin{pmatrix} 0 & \mathrm{i} \\ \mathrm{i} & 0 \end{pmatrix} . \tag{15.75}$$

Since the waveguides forming the crossing are coupled in the crossing region, even if only weakly, often real waveguide crossings are modeled as directional couplers.

Y-splitters can be operated as beam splitters or beam combiners. The Y-splitter does constitute a three-port, but is treated as a four-port. The transfer matrix of a Y-splitter operated as a $1 : X$ beam splitter with a power-free additional port is

$$\mathcal{U}_{\prec} = \frac{1}{\sqrt{X+1}} \begin{pmatrix} \sqrt{X} & 0 \\ 1 & 0 \end{pmatrix} , \tag{15.76}$$

where the input port is given by the first element of the amplitude vector (Fig. 15.27). The optical waves are in phase at the output ports, since the optical wave coupled into the Y-splitter's input arm is tapered in the fundamental mode of the branched waveguide structure.

The transfer matrix of a Y-splitter operated as a $1 : X$ beam combiner is

$$\mathcal{U}_{\succ} = \frac{1}{\sqrt{X+1}} \begin{pmatrix} \sqrt{X} & 1 \\ 0 & 0 \end{pmatrix} , \tag{15.77}$$

where the output port is given again by the first element of the amplitude vector. The behavior of a beam combiner depends on the phase shift between the optical waves fed into the two arms of the combiner. If the two waves are in phase and their levels matched, the fundamental mode of the branched waveguide structure is excited, which is then tapered without loss into the fundamental mode of the single waveguide region of the Y-splitter. If, on the other hand, the next highest mode of the branched waveguide structure is produced through superposition of the two in-coupled waves, the in-coupled power is radiated off completely. If the optical power is coupled only in one of the two arms of the Y-splitter, then both the fundamental mode and the next highest mode of the branched waveguide structure undergo excitation. Some of the optical power, 50% for a $1 : 1$ splitter, is lost through radiation in this case.

Y-splitters also normally suffer from losses through radiation; the transfer matrix cannot, therefore, be unitary. By introducing a virtual *radiation port* [15.5], however, it is possible to describe the effect of a Y-splitter by a unitary transfer matrix

$$\mathcal{U}_{\succeq} = \frac{\mathrm{i}}{\sqrt{X+1}} \begin{pmatrix} \sqrt{X} & 1 \\ 1 & -\sqrt{X} \end{pmatrix} , \tag{15.78}$$

where the power radiated off in the Y-splitter's input arm is collected in the virtual radiation port. This port must not, of course, be connected to other parts of the circuit.

15.4.2 Compound Components and Networks

The transfer matrices of the basic components (Sect. 15.4.1) form the building blocks for the design and analysis of compound components and integrated optical circuits, i. e., networks with more complex topology.

The transfer matrices of compound components are obtained directly by multiplying the transfer matrices of their separate elements. The mean phase shift of the complete component, just like that of its individual parts, is of no significance in the analysis of compound components, i. e., the transfer matrices derived in Sect. 15.4.1 are equivalent to the component's full propagators [15.5]. Below we discuss Mach–Zehnder couplers, directional couplers with periodic structures, and compound Bragg gratings as examples of compound components.

For an analysis of networks with more complex topology, the network is divided into individual stages. In every stage there could be, at the same time, ports coupled with one another and also uncoupled ports. Figure 15.28 shows for illustration one stage of a notional network made up of elementary two- and four-ports. The associated transfer matrix has the form of a block matrix, where the 2×2 blocks in the diagonal each describe two coupled input ports, whilst individual elements in the diagonal represent uncoupled input ports. Due to the coherent coupling, the mean phase shifts $\bar{\varphi}$ of the individual components are essential for the network's behavior. The determinant of one stage

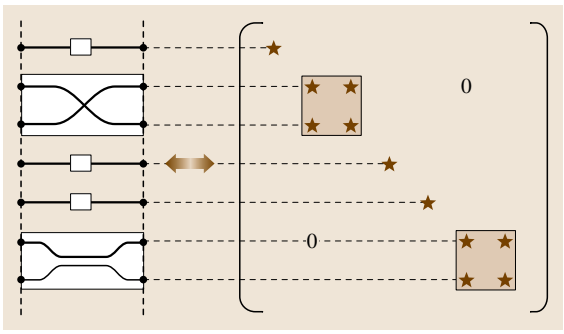

Fig. 15.28 Transfer matrix for one stage of an optical network with N input and output ports each

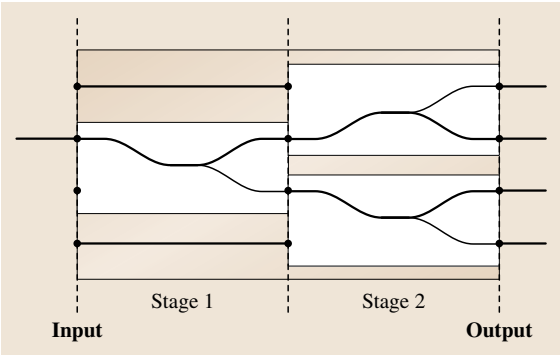

Fig. 15.29 1 : 4 splitter consisting of cascaded Y-splitters

of a network consisting of P elementary components or subnetworks is given by

$$\det\mathcal{U} = \prod_{m=1}^{P} \exp(\mathrm{i}N_m\bar{\varphi}_m)\det\mathcal{U}_m \ , \qquad (15.79)$$

where N_m is the number of input ports of the component m of a $2N_m$-port; i. e., $\sum_{m=1}^{P} N_m = N$ applies. The transfer matrix that describes one stage of a network can in turn be made unimodular and unitary by introducing a mean phase shift, which leads to $\sum_{m=1}^{P} N_m\bar{\varphi}_m = 0$. Finally, the transfer matrix of the complete network is obtained by multiplying together the transfer matrices of the separate stages, in analogy with compound components.

As an illustrative example, we derive below the transfer matrix of a 1 : 4 splitting device (Fig. 15.29), consisting of three symmetric Y-splitters ($X = 1$). When using Y-splitters with a virtual *radiation port*, we obtain with (15.78) for the transfer matrix of the 1 : 4 splitter

$$\mathcal{U} = \frac{1}{2}\begin{pmatrix} -\mathrm{i} & \mathrm{i} & 0 & 0 \\ \mathrm{i} & \mathrm{i} & 0 & 0 \\ 0 & 0 & \mathrm{i} & \mathrm{i} \\ 0 & 0 & \mathrm{i} & \mathrm{i} \end{pmatrix}\begin{pmatrix} \sqrt{2} & 0 & 0 & 0 \\ 0 & \mathrm{i} & \mathrm{i} & 0 \\ 0 & \mathrm{i} & -\mathrm{i} & 0 \\ 0 & 0 & 0 & \sqrt{2} \end{pmatrix}$$
$$= \frac{1}{2}\begin{pmatrix} -\mathrm{i}\sqrt{2} & -1 & -1 & 0 \\ \mathrm{i}\sqrt{2} & -1 & -1 & 0 \\ 0 & -1 & 1 & \mathrm{i}\sqrt{2} \\ 0 & -1 & 1 & -\mathrm{i}\sqrt{2} \end{pmatrix} . \qquad (15.80)$$

When coupling via port 2, the optical power is distributed uniformly across the four output ports, and all outgoing partial waves are in phase. Since the transfer matrix is unitary, the adjoint matrix describes the associated beam combiner. From that we see that, when exciting the beam combiner via one of the four input ports, 75% of the optical power reaches the virtual radiation ports, i. e., is radiated, e.g., into the slab waveguide.

15.4.3 Mach–Zehnder Devices

Mach–Zehnder devices are compound components in which a phase shifter is embedded between Y-splitters or directional couplers. Below we discuss three variants [15.130]. The transfer matrices of the basic components, $\mathcal{U}_{\Delta\varphi}$, $\mathcal{U}_{\succ}$, $\mathcal{U}_{\prec}$, $\mathcal{U}_{\succeq}$, and $\mathcal{U}_{\asymp}$, can be found in Sect. 15.4.1.

Mach–Zehnder Interferometers

Figure 15.30a depicts a two-port device in which the phase shifter converts phase changes $\Delta\varphi$ into intensity changes. The transfer factor of the Mach–Zehnder interferometer is

$$\mathcal{U} = \begin{pmatrix} 0 & 1 \end{pmatrix}\mathcal{U}_{\succ}\mathcal{U}_{\Delta\varphi}\mathcal{U}_{\prec}\begin{pmatrix} 1 \\ 0 \end{pmatrix}$$
$$= \cos\left(\Delta\varphi/2\right) \ . \qquad (15.81)$$

The vectors at the beginning and end of the matrix product in (15.81) filter out the two active ports of the Mach–Zehnder interferometer. The relative optical power at the output port is then $P_{\mathrm{out}} = \cos^2\left(\Delta\varphi/2\right)$. The optical waves are in phase at the start of the phase shifter, since the optical wave coupled into the Y-splitter's input arm is tapered in the fundamental mode of the branched waveguide structure. If the two partial waves are shifted by $\Delta\varphi = 2m\pi$ relative to each

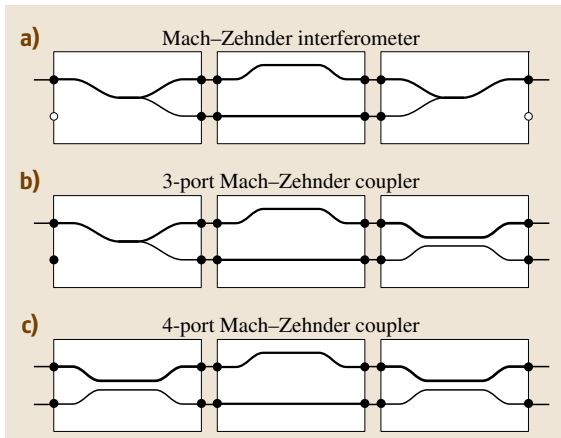

Fig. 15.30a–c Mach–Zehnder interferometer **(a)**, three-port **(b)**, and four-port **(c)** Mach–Zehnder couplers

other in the phase shifter, at the end of the phase shifter the fundamental mode of the branched waveguide structure is transferred again loss-free into the fundamental mode at the Mach–Zehnder interferometer's output, i. e., the two-port is open. If, on the other hand, the two partial waves are shifted by $\Delta\varphi = (2m-1)\pi$ relative to each other in the phase shifter, the next highest mode of the branched waveguide structure is radiated off completely when passing the second Y-splitter, i. e., the two-port is closed.

Mach–Zehnder interferometers in $LiNbO_3$ are used nowadays as fast modulators in high-bit-rate transmission systems.

Mach–Zehnder Couplers

Mach–Zehnder couplers exhibit three or four ports (Fig. 15.30b,c). Unlike the Mach–Zehnder interferometer, these components are used preferentially as optical switches or lossless optical filters. Thus, Mach–Zehnder couplers are used in glass- or polymer-based material systems, for example as the basic structure for thermooptical switches.

The three-port Mach–Zehnder coupler (Fig. 15.30b) consists of a phase shifter connected on the input side to a Y-splitter and on the output side to a symmetric directional coupler. Its transfer matrix is $\mathcal{U} = \mathcal{U}_{\succeq}\mathcal{U}_{\Delta\varphi}\mathcal{U}_{\succeq}$ with the coefficients $A^{\ominus} = \left[-\sin(\phi+\Delta\varphi/2)+\mathrm{i}\cos(\phi-\Delta\varphi/2)\right]/\sqrt{2}$ and $A^{\otimes} = \left[\sin(\phi-\Delta\varphi/2)-\mathrm{i}\cos(\phi+\Delta\varphi/2)\right]/\sqrt{2}$.

The optical power at the output port aligned with the input port is given by

$$P^{\ominus} = \frac{1+\sin(2\phi)\sin(\Delta\varphi)}{2} \,. \tag{15.82}$$

Only if the symmetric directional coupler works as a perfect beam splitter ($\phi = (2m+1)\pi/4$) the three-port Mach–Zehnder coupler achieves perfect extinction at each of its two output ports by tuning of the phase shifter [15.5].

The four-port Mach–Zehnder coupler (Fig. 15.30c), in which the phase shifter is enclosed between two symmetric directional couplers with the same phase thickness ϕ, is described by the transfer matrix $\mathcal{U} = \mathcal{U}_{\succeq}\mathcal{U}_{\Delta\varphi}\mathcal{U}_{\succeq}$ with coefficients $A^{\ominus} = \cos(2\phi)\cos(\Delta\varphi/2)+\mathrm{i}\sin(\Delta\varphi/2)$ and $A^{\otimes} = \mathrm{i}\sin(2\phi)\cos(\Delta\varphi/2)$. Under excitation via an input port, the relative optical power at the diagonally opposite port is

$$P^{\otimes} = \sin^2(2\phi)\cos^2(\Delta\varphi/2). \tag{15.83}$$

The four-port Mach–Zehnder coupler too permits perfect extinction for both output ports by tuning of the phase shifter only when the symmetric directional coupler works as a perfect beam splitter. However, at the diagonally opposite port, perfect extinction occurs even when this condition is not met.

15.4.4 Mach–Zehnder Devices with Periodic and Semiperiodic Overlay

If a unimodular transfer matrix of (15.70) type describes the effect of one period of a lossless waveguide structure, a transfer matrix of the same type with coefficients $A_N^{\ominus} = \cos(N\theta)+\mathrm{i}\Im(A^{\ominus})\sin(N\theta)/\sin\theta$ and $A_N^{\otimes} = A^{\otimes}\sin(N\theta)/\sin\theta$ describes the behavior of a cascaded waveguide structure with N periods, where $\cos\theta = (\mathrm{Tr}\,\mathcal{U})/2 = \Re(A^{\ominus})$ applies for the angle [15.5].

For the codirectional four-port under excitation via an input port, we obtain for the relative optical power at the directly or diagonally opposite port

$$P_N^{\ominus} = \cos^2(N\theta)+\Im(A^{\ominus})^2\frac{\sin^2(N\theta)}{\sin^2\theta} \,,$$
$$P_N^{\otimes} = \left|A^{\otimes}\right|^2\frac{\sin^2(N\theta)}{\sin^2\theta} \,. \tag{15.84}$$

Due to the effect of the periodic structures, the diagonally opposite port remains completely power-free not only for $A^{\otimes} = 0$ but in addition for

$$\Re(A^{\ominus}) = \cos\left(\frac{m\pi}{N}\right) \,. \tag{15.85}$$

The directly opposite port remains completely power-free only if the two conditions

$$\Im(A^{\ominus}) = 0 \,,$$
$$\Re(A^{\ominus}) = \cos\left[\frac{(2m-1)\pi}{2N}\right] \tag{15.86}$$

are satisfied concurrently. If $\Im(A^{\ominus}) \equiv 0$ applies in the entire parameter space, the second condition in (15.86) is met for a large number of parameter combinations; otherwise the directly opposite port remains power-free at best for a few parameter combinations.

For numerous applications and especially for use in optical filters, the coupling coefficient (κ tapering) and/or the period (chirping) of periodic structures is varied. This is because the envelope of the cross-coupled optical power of a coupler is determined to a good approximation by the Fourier transform of the tapered coupling coefficient [15.120]

$$P_E = \left|\mathcal{F}[\kappa]_{\Delta k_0}\right|^2 \,. \tag{15.87}$$

It is, therefore, possible to reduce the sidebands of the filter characteristics significantly by changing the coupling coefficient adiabatically. By varying the period of

Bragg gratings (chirping), both the width of the stop band and the grating's dispersion can be increased. The relationships for the strictly periodic case (15.84, 15.85, 15.86) are then used for rough layout of semiperiodic components. The final design is obtained by multiplying together the transfer matrices of the tapered structure sectionwise.

$\Delta\beta$ Couplers

$\Delta\beta$ couplers [15.131] are symmetric directional couplers that become locally asymmetric on applying a control voltage. One period of a $\Delta\beta$ coupler consists of two equally long sections with opposite detuning. The transfer matrix for one period of the coupler is then $\mathcal{U} = \mathcal{U}_{\gtrless}(\delta)\mathcal{U}_{\lessgtr}(-\delta)$, and for its coefficients we get $A^{\ominus} = \left|A_{\delta}^{\ominus}\right|^2 - \left|A_{\delta}^{\otimes}\right|^2 = 1 - 2\left|A_{\delta}^{\otimes}\right|^2$ and $A^{\otimes} = 2A_{\delta}^{\ominus *}A_{\delta}^{\otimes}$. Under excitation via one input port, the relative optical powers at the two output ports are given by $I^{\ominus} = \cos^2(N\theta)$ and $I^{\otimes} = \sin^2(N\theta)$, respectively. Just one output port of the $\Delta\beta$ coupler remains completely power-free if the condition

$$\sin^2\theta_c \sin^2\left(\frac{\delta\Lambda}{2}\right) = \sin^2\left(\frac{m\pi}{4N}\right) \qquad (15.88)$$

with $\tan\theta_0 = \kappa/\delta$ is satisfied. Specifically, if m is even, then the output port diagonally opposite the input port is power-free, whereas if m is odd, then it is the one directly opposite. Figure 15.31 shows the state diagram of the $\Delta\beta$ coupler, i. e., the combinations of the coupling coefficient κ and the detuning δ for which one of the output ports at a time remains power-free.

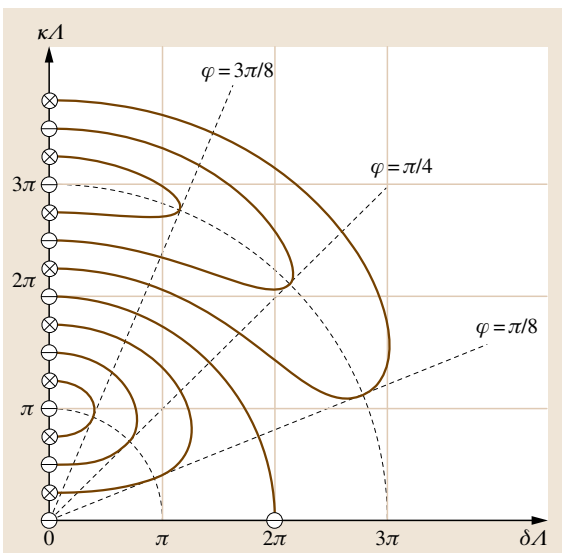

Fig. 15.31 Switching diagram of the $\Delta\beta$ coupler

$\Delta\kappa$ Couplers

$\Delta\kappa$ couplers [15.132, 133] are asymmetric directional couplers with periodically varying coupling coefficients. In the limiting case of weak variation ($\Delta\kappa \to 0$), the $\Delta\kappa$ coupler behaves like an asymmetric directional coupler whose transfer matrix has the coefficients $A_{\delta}^{\ominus} = \cos(\delta_{\text{eff}}\Lambda) + \mathrm{i}\delta\sin(\delta_{\text{eff}}\Lambda)/\delta_{\text{eff}}$ and $A_{\delta}^{\otimes} = \mathrm{i}\kappa\sin(\delta_{\text{eff}}\Lambda)/\delta_{\text{eff}}$. The optical power coupled in via an input port is cross-coupled completely to the diagonally opposite output port if the period satisfies the condition

$$\Lambda = \frac{m\pi}{\delta_{\text{eff}}} . \qquad (15.89)$$

The filter curve in the vicinity of this resonance resembles that of an asymmetric directional coupler (Sect. 15.3.3), i. e., the maxima of the curve are located along a Lorentz line. Complete cross-coupling of the optical power is possible only if the coupling length is an integer multiple of the period length $L^{\otimes} = N\Lambda$.

Acoustooptic Devices

Acoustooptic devices are based on dynamic gratings that are generated by means of a traveling surface acoustic wave (SAW), mostly a Rayleigh wave. The acoustic wave generates local strains in the material, which via the elastooptic effect cause changes in the index ellipsoid, essentially strain-induced birefringence. In lithium niobate ($LiNbO_3$), the preferred material system for acoustooptic components, an additional indirect electrooptic interaction takes place due to the piezoelectric effect.

The analysis of TE–TM coupling in a straight waveguide using the theory of coupled modes again leads to (15.49), where δ is the half-detuning between the TE and TM modes. The resonance condition (15.89) remains unchanged. The filter characteristic in the vicinity of this resonance equals, in turn, that of an asymmetric directional coupler; i. e., the maxima of the filter curve are located along a Lorentz line whose width is determined by the strength of the strain double refraction.

The strength of the acoustooptic coupling along the coupler can be adapted locally by conducting the acoustic wave in an acoustic directional coupler (SAW coupler). At the expense of a second acoustic wave, it is possible to decrease the sidebands in the filter characteristic to $< -30\,\text{dB}$ [15.134]. By injecting several acoustic waves, signals with different wavelengths can

be decoupled simultaneously. The interference of the different acoustic waves, however, leads to an amplitude modulation of the transmitted signals and thus – especially for small channel spacings – to a significant degradation in signal transmission [15.135].

Figure 15.32 shows an acoustooptic add/drop multiplexer. It consists of two polarization beam splitters before and after the acoustooptic interaction zone. The acoustic wave is conducted through acoustic directional couplers; the piezoelectric surface exciters are mostly configured as interdigitated structures. Surface wave absorbers are built in to attenuate the outgoing acoustic waves.

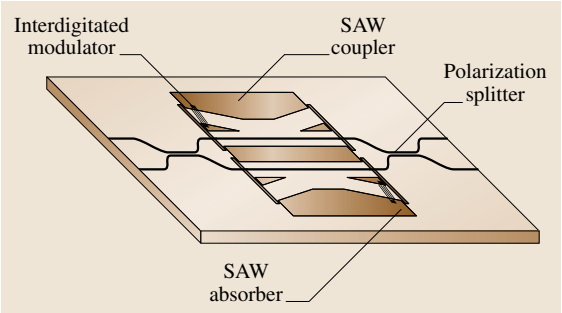

Fig. 15.32 Polarization-independent acoustooptic filter (after [15.17])

15.5 Integrated Optical Technology Platforms

Integrated optical chips are fabricated at present in a number of material systems. Table 15.5 provides an overview of the currently most important representatives, their areas of application, and reference values for several important platform parameters. Due to their good performance characteristics, especially their low

losses at the fiber–chip coupling (FC coupling) and the low propagation losses of waveguides, glass-based technologies aim for operation in high-end systems of optical communication technology, which in the wavelength range 1.3/1.5 μm run in single-mode fiber systems. Switching and tuning of components are possible only by means of the thermooptic (TO) effect; typical switching times lie in the millisecond range. Polymers, in contrast, aim at the low-cost market of short- and medium-distance links, operating preferentially in the 0.6–0.8 μm wavelength range and using multimode glass and plastic fibers. A further important argument for the use of polymers in such applications is the realizability of large-area circuits. At 1.5 μm, the propagation losses of the polymers used for waveguide fabrication exceed 1 dB/cm; however, through fluorination or deuteration of the polymer they can be reduced to < 0.5 dB/cm at the cost of reduced polymer adhesion. Lithium niobate ($LiNbO_3$) features large acoustooptic and electrooptic coefficients. It is used nowadays solely for special components in high-end systems – Mach–Zehnder modulators for 10–40 Gbit/s systems and acoustooptic filters – that cannot be fabricated in other material systems or not to a comparable quality. Unlike competing technologies, III–V semiconductors permit fabrication of semiconductor lasers and photodiodes and consequently monolithic integration of active and passive components on a single chip. A wide selection of effects is available in III–V semiconductors for controlling the refractive index. The quaternary InGaAsP material system is used in the 1.3/1.5 μm wavelength range, i. e., predominantly in optical communication technology. The ternary GaAlAs material system is used in the 0.6−0.8 μm wavelength range, i. e., with emphasis on optical short-distance and interconnection technology. The high upfront development costs, especially for chips with integrated transmitters and receivers, have so far prevented wide use of the III–V material systems in larger integrated optical circuits. In addition to the approaches presented here, other material systems [15.136], such as silicon (silicon-on-insulator, SOI) and silicon–germanium [15.137], which may offer some very specific advantages, are being investigated.

Table 15.5 shows several important platform parameters – wafer size, the number of process steps required to fabricate a wafer, and the smallest possible radius of curvature, which influence the size of a circuit decisively – to illustrate the fabrication effort involved. Like the typical losses, obviously these measures are snapshots that will change in the course of further process developments. Accurate knowledge of the material's properties, in particular the material's dispersion $n(\lambda)$, is indispensable for the design of many components. The dispersion relationships are mostly formulated as purely empirical ones, e.g., Taylor expansions for commercial glasses, or as semi-empirical ones, i. e., theoretically justified equations, e.g., the Sellmeier equation (Chap. 5), with a series of adjustment parameters.

15.5.1 Glass-Based Material Systems

Glass-based waveguides are fabricated nowadays essentially by means of two different technologies: diffusion of the waveguide in a glass substrate through ion exchange [15.2, 138, 139] on the one hand, and deposition of glass layers and their structuring through dry etching technology [15.140–144] on the other. The waveguide structures are traditionally fiber-matched, i. e., the size of the near field of the integrated optical strip waveguide is adapted to that of a standard single-mode fiber. More recently, as part of the trend towards increasing complexity and in order to reduce the radii of curvature within optical circuits, waveguides are increasingly fabricated with higher refractive index contrast, so that their fundamental modes then exhibit a reduced field radius. In addition, Bragg gratings have already been realized in integrated optical waveguides through exposure to UV [15.126, 127].

Special glasses are used as substrates for ion exchange. Ions from a salt melt are exchanged for ions from the substrate glass at 170–500 °C through apertures in a metal mask. The exchange process can be carried out either purely thermally, or field-assisted with static electric fields of 20−250 V/mm normal to the wafer surface. In the case of the substrate glass BGG31 which is used for commercial components, for example, the waveguides are formed by silver diffusion (Ag ⇔ K). Its material dispersion is given by the empirical relationship $n = p_0 - p_1 \ln\left(p_2\lambda^2 + p_3\lambda + p_4\right)$ with $p_0 = 1.50656$, $p_1 = 1.21158\times10^{-2}$, $p_2 = -1.52753/\text{nm}^2$, and $p_4 = -18.6382$; the thermooptic coefficient of BGG31 is 3.1×10^{-6}. Other substrate glasses, BGG21 (Cs ⇔ K), soda-lime glass (K or Ag ⇔ Na), BK7 (K or Ag ⇔ Na), permit the exchange of other ion species.

Process technologies based on the deposition of glass layers start with a silicon or quartz glass substrate, where silicon is mostly preferred due to its low cost and favorable mechanical and thermal properties. The substances used to dope the glass (generally silica) are boron (B_2O_3) to decrease the refractive index and

Table 15.6 Material parameters for the dispersion formulas (15.90) of SiO_2 with the dopants B_2O_2, GeO_2, and P_2O_5

	SiO_2	B_2O_3	GeO_2	P_2O_5
E_0 (eV)	13.38	12.63	9.80	13.84
$E_0^{(d)}$ (eV)	14.71	13.00	15.49	16.49
E_1 (eV)	0.1254	0.170	0.113	0.155
$\Delta E_1^{(d)}$ (eV)	0	4×10^{-4}	1.4×10^{-3}	2×10^{-4}
U	1	$3m/(m+2)$	m	$2m/(m+1)$
V	1	$2m/(m+1)$	m	$2m/(m+1)$

germanium (GeO_2) and phosphorus (P_2O_5) to increase it. The waveguide layers can be deposited by means of flame hydrolysis deposition (FHD) or in a reactor from the gas phase [chemical vapor deposition (CVD)].

In flame hydrolysis, which is related to preform fabrication for glass fibers, glass particles are deposited from the flame of a burner in the form of a porous glass layer onto the wafer's surface. Then the porous layers are sintered at 900–1300 °C to a compact glass. The refractive index of the glass layers is adjusted by means of the mixture of gases injected into the flame (e.g., $SiCl_4$, $TiCl_4$, $POCl_3$, BCl_3 or $GeCl_4$). In the various competing methods that rely on deposition from the gas phase (CVD), the waveguide layers are first deposited in a reactor at temperatures of 400–700 °C. Using plasma-enhanced chemical vapor deposition (PECVD), the process temperatures can be decreased to ≈ 300 °C at the cost of a subsequent annealing process to be carried out at ≈ 1000 °C. In addition to glass layers doped with germanium (GeO_2) and phosphorus (P_2O_5) ($\Delta n \approx 0.007-0.01$), PECVD allows also fabrication of silicon oxynitride (SiON) layers, whose refractive indices can be chosen within the range $n \approx 1.45-2$ [15.145, 146]. The lateral waveguide structures are fabricated for both technologies by means of contact or projection lithography and reactive ion etching (RIE) on the basis of fluorine compounds (e.g., CF_4, C_2F_6 or CHF_3). The material dispersion of quartz glass doped with B_2O_3, GeO_2, and P_2O_5 is given by the Sellmeier equation [15.147, 148]

$$n^2 = 1 + \frac{E_0 E_0^{(d)}}{E_0^2 - E^2} + \frac{E_1 E_1^{(d)}}{E_1^2 - E^2} \qquad (15.90)$$

with

$$\begin{aligned} E_0 &= E_0(SiO_2) + U\,[E_0(X) - E_0(SiO_2)]\,, \\ E_0^{(d)} &= E_0^{(d)}(SiO_2) + V\left[E_0^{(d)}(X) - E_0^{(d)}(SiO_2)\right], \\ E_1 &= E_1(SiO_2) + U\,[E_1(X) - E_1(SiO_2)]\,, \\ E_1^{(d)} &= E_1^{(d)}(SiO_2) - m\Delta E_1^{(d)}(X)\,, \end{aligned} \qquad (15.91)$$

and $E_1^{(d)}(SiO_2) = 0.11251\,\text{eV}$. In (15.91), m (in mol%) describes the level of dopants added to the silica glass, U is the bond and V is the cation fraction. Material parameters obtained in glass fibers are listed in Table 15.6. To describe integrated optical structures, the parameters need to be matched to the local technological conditions through nonlinear regression, since the refractive indices are also affected by the density and the internal structure of the waveguiding layers and thus by the process control parameters.

15.5.2 III–V Semiconductors

The following discussion focuses on the two most common material systems: the quaternary material system $In_{1-x}Ga_xAs_yP_{1-y}/InP$ for the wavelength ranges 1.3/1.5 µm, and the ternary material system $Al_xGa_{1-x}As/GaAs$ for the wavelength range around 0.8 µm. Unlike all other material systems, direct semiconductors allow (monolithic) integration of active and passive components, i. e., of waveguide structures, laser diodes, photodiodes, and optical switches, on one chip [15.9, 19, 20, 149, 150]. The available emission wavelengths of laser diodes determine the wavelength range in which a material system is applied preferentially. With respect to the field width of the fundamental mode the waveguide structures are normally matched to the active components, especially to laser diodes. Therefore, coupling to single-mode fibers requires (as in the case of laser diodes) coupling optics or tapers with spot magnification of $m = 3-5$.

In the III–V technologies, components are fabricated through lattice-matched epitaxial growth on a substrate, usually on indium phosphide (InP) or gallium arsenide (GaAs). Nowadays, the epitaxial layers are mostly grown by means of metalorganic vapor-phase epitaxy (MOVPE) or molecular beam epitaxy (MBE); the formerly widely used method of liquid-phase epitaxy (LPE) is only rarely used now, due to the large fluctuations in layer thickness. The lateral waveguide structures are fabricated using contact or projection

lithography, and in the case of high-resolution structures such as phase-shifted Bragg gratings also by direct writing using electron beam lithography. Due to their good reproducibility and the precise adjustability of the etching profile, reactive dry etching techniques such as reactive ion etching (RIE) or reactive ion-beam etching (RIBE) are used predominantly nowadays to etch the lateral structures [15.20], where mostly argon (Ar) is used as a nonreactive and nitrogen (N_2) as a reactive component for etching the quaternary and ternary layers. In addition, wet chemical etching still plays an important role, since it avoids defects of the crystal structure due to the etching process. Mostly, $H_2SO_4 : H_2O_2 : H_2O = 3 : 1 : 1$ etching solution is used for GaAs, and $HCl : H_3PO_4 = 1 : 1$ for InP and related ternary or quaternary layers. Bragg gratings are preferentially etched with an etching solution ($HBr : SBW : H_2O = 1 : 10 : 40$) based on saturated bromine water (SBW).

Semiempirical analytical models based on the band structure of the underlying III–V semiconductors have been developed to describe the material dispersion of $In_{1-x}Ga_xAs_yP_{1-y}$/InP and $Al_xGa_{1-x}As$/GaAs [15.149, 151, 152], and refined by taking into account the momentum dependence of the matrix elements [15.153]. As a result of this refinement, precision for energies in the region of the fundamental bandgap E_0, which are essential for the description of laser diodes, was improved significantly. For a given wavelength, the refractive index of $Al_xGa_{1-x}As$/GaAs decreases with increasing aluminum concentration; i. e., the refractive index of the GaAs substrate is greater than that of the grown ternary layers. The waveguide layers must therefore be separated from the substrate by a sufficiently thick buffer layer. In contrast, the refractive index of $In_{1-x}Ga_xAs_yP_{1-y}$/InP increases with increasing arsenic concentration; i. e., the refractive index of the InP substrate is always smaller than that of any quaternary layers.

15.5.3 Lithium Niobate ($LiNbO_3$)

Lithium niobate [15.154, 155] is a synthetic, ferroelectric crystal. Lithium niobate as a basic material for optical switches, modulators, and acoustooptic filters is of interest in integrated optics, since it exhibits the linear electrooptic (Pockels) effect and, in addition, has a large elastooptic coefficient and low attenuation of acoustic waves.

Numerous technological approaches – epitaxy, sputtering, ion exchange, and thermal in- and out-diffusion – have been pursued over the past 25 years for fabrication of optical waveguide layers in $LiNbO_3$. Two processes have become prevalent: thermal diffusion of titanium (Ti) and proton exchange ($H \Leftrightarrow Li$).

In the thermal inward diffusion of Ti, a structured Ti layer with thickness of 20–60 nm is first deposited by sputtering or electron beam evaporation on the chip's surface. The titanium is diffused in locally at $\approx 1000\,^{\circ}C$ from the lithographically structured layer. The refractive index step at the surface, which depends on the thickness of the Ti layer, is $\Delta n_o = 0.5{-}1 \times 10^{-2}$ for the ordinary and $\Delta n_e = 1{-}2 \times 10^{-2}$ for the extraordinary refractive index. Normally to the surface, the refractive index profile is described by a Gaussian distribution with typical diffusion depth of $d = 2{-}3\,\mu m$. To prevent lithium dioxide (LiO_2) diffusing out at the same time as the Ti diffuses in – which would result in a parasitic waveguide at the surface – the wafer is either bathed in a suitable gas atmosphere, e.g., a humid argon/oxygen mixture, or is housed in a gastight platinum container of minimum size.

In proton exchange, hydrogen is exchanged for lithium ($H \Leftrightarrow Li$) from molten benzoic acid (C_6H_5COOH) at 160–250 °C through apertures in a mask. To avoid scattering losses resulting from the high hydrogen concentration near the surface, proton-exchanged waveguides undergo a curing process lasting several hours at 400 °C. The proton exchange leads, after the curing process also, to considerably greater refractive index steps ($\Delta n_e = 2{-}5 \times 10^{-2}$) for the extraordinary refractive index than Ti diffusion, whereas the ordinary refractive index is decreased by the proton exchange ($\Delta n_o \approx -4 \times 10^{-2}$). The penetration depth of the protons, given an approximately step-like refractive index profile, is likewise greater ($d \approx 4\,\mu m$) than in Ti diffusion. When fabricating single-mode waveguides by means of proton exchange, the refractive index contrast can be significantly reduced by adding a small amount of lithium benzoate.

The material dispersion of lithium niobate is discussed in Chap. 5 and in [15.156].

15.5.4 Polymers

Polymers [15.157, 158] have been used for over 20 years in the fabrication of planar waveguide structures. For a long time, they suffered from a reputation of having poor resistance to aging. Consequently, the attitude of many system providers towards polymer technologies was cautious or even hostile. Nowadays, waveguide polymers with high aging resistance

are available on the market, and residual susceptibility to solvent vapors and UV radiation can be largely counteracted by employing suitable housing technology.

Polymers are characterized by low absorption in the red ($\lambda = 0.6–0.9\,\mu m$) and in the infrared range relevant to telecom applications ($\lambda = 1.3–1.5\,\mu m$); however, considerable absorption losses ($> 1\,dB/cm$) occur as a result of CH groups. These losses can be reduced through fluorination or deuteration of the monomers, at the cost of reduced adhesion of the waveguide layers to the substrate.

Polymer waveguides can be deposited on almost any substrate. Silicon substrates are used frequently, due to their good substrate quality and excellent mechanical properties. However, temperature changes lead to severe stresses and thus to strain-driven birefringence due to the different heat expansion coefficients of polymers and Si. Thus, many waveguide polymers are deposited on specially developed polymer substrates whose thermal properties are suitably tuned.

For a long time, polymers were applied almost exclusively for multimode waveguiding in the 0.6–0.9 μm wavelength range, since unlike most competing materials polymers can be deposited in thick layers ($> 10\,\mu m$) without difficulty. Moreover, polymers are of special interest for multimode applications due to their cost-reduction potential in mass production. With regard to the typical applications for interboard and intraboard wiring, polymers should be soldering-proof, i. e., tolerate short-term heating up to 150–250 °C. In addition, use in narrow housings involves permanently high temperatures (60–85 °C). The glass-transition temperature T_g is, therefore, often at the focus of discussion when assessing waveguiding polymers. More recently, in addition to multimode waveguide structures, single-mode waveguide structures and the associated components (e.g., optical phased arrays) for telecom applications at $\lambda = 1.3–1.5\,\mu m$ are being implemented as well.

Nowadays, essentially three processes and their combinations are used for fabrication of planar waveguide structures.

- *Casting, injection molding* [15.159]
  In casting, the liquid polymer is introduced into a previously prepared mold, usually by injection (injection molding). This process is well suited for mass production, since the cost of the mold is incurred only once and the waveguide components themselves can be fabricated in one or at least very few steps. So far, casting methods have not yet attained the dimensional stability of lithographically fabricated structures ($|\Delta\vec{r}| \approx 0.1–0.5\,\mu m$). Therefore, they are used preferentially for fabrication of multimode waveguide structures.
- *Spin-coating, dipping*
  Layers of polymers or monomers can be produced from suitable solutions through spin-coating (sometimes also by dipping). The achievable layer thicknesses ($d = 0.1–10\,\mu m$) cover a vast range. In direct fabrication with a mold, the introduction of polymers from solution is less suitable since as a result of the complicated geometry, usually solvent residues and material inhomogeneities are unavoidable.
- *In situ polymerization*
  In situ polymerization is an elegant method for introducing lateral waveguide structures into a previously deposited layer. Polymerization triggered by UV exposure is especially advantageous, since mostly it can be carried out at room temperature or at only slightly elevated temperatures. Shading must be avoided during the waveguide structures exposure, since the deposited monomers do not polymerize sufficiently in partly shaded areas.

As within other materials, two-photon absorption (TPA) processes can be used for direct writing of waveguide structures, intentionally permitting three-dimensional

Table 15.7 Typical material data for several polymers

Material	T_g (°C)	Absorption loss (dB/cm)		
		$\lambda = 0.8\,\mu m$	$\lambda = 1.3\,\mu m$	$\lambda = 1.5\,\mu m$
PMMA	104	< 0.1	0.3	0.8
Polyguide, MM	260	0.1	0.4	1.6
Polyguide, SM	260	0.1	0.2	0.6
BeamBox	> 180	?	0.3	0.5
BCB	280	< 0.1	0.2	1.5
FBCB	280	< 0.1	0.1	0.2
Ormocer	280	< 0.1	0.2	0.5

(3-D) waveguide paths. In polymers, TPA enables direct links of the waveguide and either the transmitter or the receiver [15.160].

Table 15.7 presents typical material data – glass-transition temperature T_g, and typical absorption losses at $\lambda = 0.8$, 1.3, and 1.5 μm – for several interesting material systems: PMMA, Polyguide [15.4], BeamBox [15.161], benzocyclobuten (BCB) [15.15], and fluorinated BCB (FBCB) [15.162], and ORMOCER [15.163]. Similarly to the glass-based material systems, all these systems allow purely passive waveguide structures and their control by means of the thermooptic effect.

Nonlinear optical (NLO) polymers that allow the refractive index to be controlled by means of electrooptic effects are made through the addition of directional polymers to host polymers (guest–host systems), through the incorporation of suitable side or main chains, through cross-linking, or through sol–gel methods [15.164–166]. Nonlinear optical polymers are currently still at the research stage.

15.5.5 Silicon on Insulator (SOI)

Silicon is the most widely used material for microelectronics, and it is a standard wafer material for waveguide optics in glass and polymer waveguide systems. It is transparent within the wavelength range used in telecom applications (1.25–1.6 μm), which should make it a well-suited candidate for economic fabrication of passive photonic circuits. Active devices will result in additional complexity, since Si is not a direct semiconductor.

First, in order to operate a silicon waveguide on a silicon wafer, optical isolation towards the substrate is indispensable. Such isolation is achieved using a buried silicon oxide (BOX) layer. It can be fabricated by implanting oxygen or by bonding and subsequent etch-back of oxidized wafers [15.167], thus facilitating the silicon-on-insulator (SOI) material system. With a BOX layer, the refractive index contrast is $\Delta n \approx 2$; i. e., the waveguide dimensions for a single-mode waveguides span from 3 μm × 2 μm for enlarged rib waveguides [15.168] to about 0.5 μm × 0.5 μm (Sect. 15.2) for a silicon strip waveguide. Thus, achievable dimensions and roughness of structures defined with the standard processes of microelectronics were an obstacle for the fabrication of integrated low-loss Si photonics until the end of the last millennium. Deep-UV lithography and related improvements within the standard semiconductor manufacturing processing [15.169] especially in the complementary metal–oxide–semiconductor (CMOS) process chain and the availability of high-quality SOI wafers have now changed that situation.

Today, low-loss waveguides (< 2 dB/cm) can be routinely fabricated using either a hard mask for the etch of the Si-waveguide layer or an oxidation step after a conventional etch [15.170]. In combination with the tight field confinement of Si wires, this allows for high-density integrated complex components as required for WDM applications [15.171, 172].

Field size and often also the shape of the eigenmodes of silicon waveguides differ significantly from those of fiber. Therefore, an appropriate fiber–chip coupling is crucial for SOI photonics. As for the III–V material system, waveguide tapers with typical insertion losses of ≈ 3 dB are integrated on SOI. The polarization diversity mode which is usually applied within Si photonic circuits requires special care regarding tapers as well as waveguide bends to avoid unwanted polarization rotation [15.173]. Grating couplers have also been used for fiber–chip coupling [15.172]. They may operate for both polarizations simultaneously and thus can connect polarization-diversity circuits directly to a fiber [15.174].

Within the SOI platform, active elements require specific integration schemes. Apart from a hybrid integration of photodiode chips, receivers may be bonded to the SOI wafer [15.175] or direct semiconductors can be grown onto the SOI wafer [15.176, 177], which however requires additional processing steps. Although Si has no intrinsic electrooptical effect, its absorption and refractive index can be influenced by the change of carrier densities [15.178], i. e., modulation can be achieved by operating *p-i-n* or *p-n* photodiodes to be integrated monolithically within the CMOS process into the SOI platform [15.176, 179], thus hybrid integration is not required. The integration of transmitters can also follow different approaches. Hybrid integration by flip-chip attachment of laser chips is routinely used [15.172]. The heterogenous and monolithic integration of lasers into Si platforms has made substantial progress between 2000 and 2010 [15.180].

15.5.6 Computer-Aided Design (CAD) for Integrated Optical Circuits

CAD systems are used in integrated optics as in other chip technologies to convert an integrated optical circuit into a physical description, usually a set of masks for the fabrication process. CAD systems are designed on the one hand to speed up the design process, and on

the other hand to help the designer to avoid mask defects as early as during the design process (correctness by construction).

For a number of years, therefore, special layout editors have been available for integrated optics. Their elementary structures (primitives) – straight waveguides, curved waveguides, Y-splitters, tapers, and Bragg gratings – are tuned to the requirements of integrated optics. They permit construction and modification of these structures by accessing their physical parameters (Fig. 15.33), e.g., waveguide widths, radii of curvature, or grating constants, rather than by accessing the vertices of complex polygons. In addition, they help to connect waveguide structures to each other without kinks, i. e., without corner defects, e.g., through the insertion of connecting waveguides (e.g., the pioneering CAD system SIGRAPH-Optic). Numerous integrated optical circuits consist of only a few elementary structures, and therefore can be fabricated interactively very well. Complex or compound structures such as optical phased arrays, Mach–Zehnder chains or chirped Bragg gratings consist of hundreds, sometimes even thousands, of elementary structures. In order to address this task, the CAD systems used in integrated optics have by now been equipped also with customized macro languages.

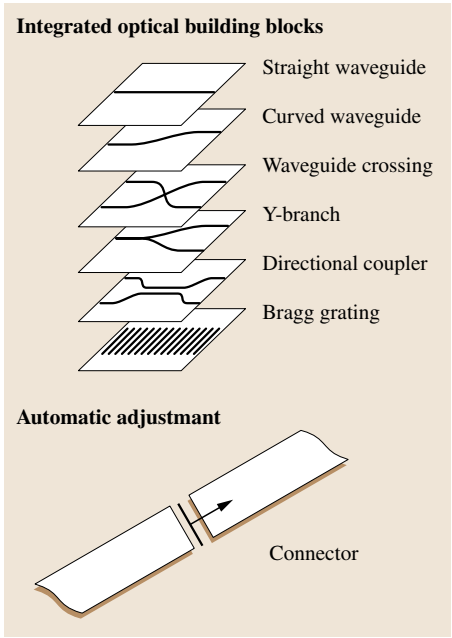

Fig. 15.33 CAD systems for integrated optics: primitives and layout strategies

15.5.7 Comparison of Integrated Optics with Microoptics

Almost every technology today has to prove itself by standing up to competing approaches. The toughest competitor of integrated optics is still microoptics. Even in recent times, the value of integrated optics was still doubted. By now, however, these voices have largely fallen silent in view of the successful entry of integrated optics into the splitter devices market [1 : 4, 1 : 8, 1 : 16, and 1 : 32 splitters (ion exchange)], the fast modulators market [10–40 GHz, Mach–Zehnder modulators ($LiNbO_3$)], and in particular the rapidly growing WDM market [optical phased arrays (SiO_2/Si)]. Pre-existing microoptical devices were completely driven out by the integrated optical solutions. Within the InGaAsP material system there is a commercially successful integrated waveguide component as well, the laser-electroabsorption modulator chip.

The question regarding the advantages of integrated optical solutions must, however, constantly be reconsidered (especially when they substitute for alternative components), in terms of the following four aspects.

1. *Performance data*
   Although the technologies of integrated optics have made great progress over the last few years, the low insertion losses of micro- and fiber-optical components have only been matched so far by glass-based components (ion exchange in glass or SiO_2/Si), and not even by them in every single case. On the other hand, often integrated optical components offer lower parameter scatter than the competing micro- and fiber-optical solutions; for example, integrated optical $1 : N$ branching devices ($N \geq 4$) in ion-exchanged glasses have achieved market leadership, especially due to their excellent uniformity of power distribution.
2. *Cost, yield, reproducibility*
   Integrated optical components are normally associated with higher upfront development costs and thereafter lower unit cost; i. e., they promise cost benefits with increasing unit numbers. In the case of the complex III–V technologies with several hundred process steps, however, this applies only for very large unit numbers. Cost leadership is reached much sooner with rising complexity (e.g., for switching matrices or spectrographs).
3. *Footprint, handling, complexity*
   The complexity of optical circuits has risen rapidly with the increasing significance of wavelength-division multiplexing (WDM) in optical communi-

cation technology; for example, an array of optical attenuators with complete performance monitoring for 16 wavelength channels consists of 16 attenuators and 32 tap couplers; i. e., in the case of hybrid construction it exhibits 32 external and 64 internal fiber interfaces. A fiber-optical 16×16 switching matrix, a more complex example, typically consists of 256 2×2 switches with 510 internal fiber connections. Evidently, the use of integrated optical chips permits significant reduction in internal construction complexity and at the same time in the component's size.

4. *Product lifetime, operating conditions*
   Due to weaknesses in packaging technologies, the product lifetime of lasers and integrated optical components was not always adequate in the early years of their marketing. Examples of such issues include the fiber–chip coupling when using hermetically sealed housings for active components, and the inadequate resistance to humidity of epoxy-based adhesive joints in fiber-matched integrated optical chips. The existence of components certified to Bellcore 12.09 and 12.21 standards, however, shows that these problems have now been overcome. However, as with computers based on vacuum tubes in their time, the lifetime of a complete component drops appreciably with increasing complexity of the microoptical superstructural elements compared with the lifetimes of its constituent parts. The same applies also to integrated optical chips when their area and especially the number of process steps increase significantly [15.181].

16. Interferometry

The intention of this chapter is to provide a fast and comprehensive overview of the principles of interferometry and the various types of interferometer, including interferogram evaluation and applications. Due to the age and the importance of the subject, you can find a number of monographs [16.1–4] and book chapters [16.5] in the literature. The number of original papers on optical interferometry is far too large to even attempt complete coverage in this chapter. Whenever possible, review papers are cited. Original papers are cited according to their aptness as starting points into the subject. This, however, reflects my personal judgment. Even if you do not share my opinion, you should find the references therein useful.

Section 16.1 presents a short introduction to the interference of light covering two-beam and multiple-beam interference, vector interference, and partial coherence. Section 16.2 is devoted to the various types of interferometry, divided into wavefront-division and amplitude-division interferometers, including polarization interferometry. The last Sect. 16.3 covers the various methods of obtaining quantitative phase values.

Optical interference is the manifestation of the wave property of light. The term "interference" was coined by Thomas Young in 1801 [16.6], meaning that the superposition of two or more waves results in amplification (interference maxima) or attenuation (interference minima) of the superposed fields. To that end it is required that the interfering waves be correlated with each other; i. e., they must be completely or partially coherent. Otherwise, the interference pattern is not stable in time and vanishes upon the time integration applied in conventional optical detectors.

Interferometry is the technical application of interference. Since the wavelength of light is in the range of several hundred nanometers, it is nowadays an indispensable tool for high-precision metrology. Applications include dimensional metrology, nondestructive testing, holographic interferometry, optical-system metrology, spectroscopy, and even encryption.

16.1 Interference of Light

Light is an electromagnetic wave. However, it is easier to understand the basic concepts in scalar notation. So, we start in scalar approximation and switch to full vectorial expressions afterwards.

In the following description of interference, we assume the superposition principle to be valid. The superposition principle states that, at each point and any time, the total field is the sum of the superposed partial

fields; i. e., each wave propagates as if the other waves were not there. It is a consequence of the linearity of Maxwell's equations in linear media.

16.1.1 Scalar Two-Beam Interference

Consider a quasimonochromatic scalar wave in complex representation

$$E_1 = A_1 \exp(\mathrm{i}\varphi_1) \exp(-\mathrm{i}\omega t) \ , \tag{16.1}$$

oscillating at frequency

$$\nu = \frac{\omega}{2\pi} \ , \tag{16.2}$$

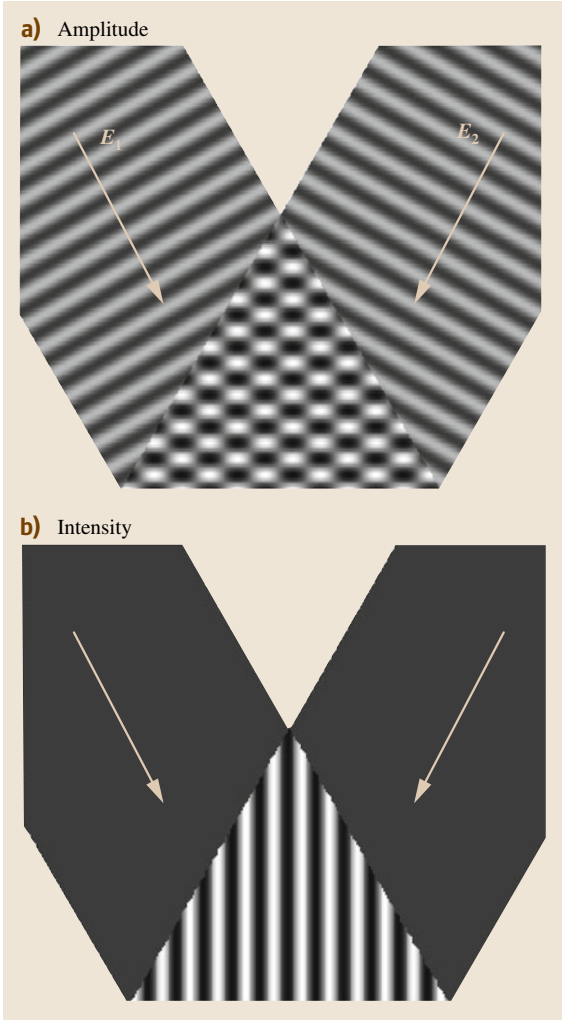

Fig. 16.1a,b Interference of two plane waves E_1 and E_2: **(a)** amplitude, and **(b)** intensity

with scalar amplitude A_1 and space-dependent phase offset φ_1.

The superposition with a coherent second wave $E_2 = A_2 \exp(\mathrm{i}\varphi_2) \exp(-\mathrm{i}\omega t)$ of identical frequency yields the intensity of the stationary, i. e., time-independent, total field (Fig. 16.1)

$$I = |E_1 + E_2|^2 = A_1^2 + A_2^2 + 2A_1A_2 \cos(\varphi_1 - \varphi_2) \ . \tag{16.3}$$

The spatial distribution of the intensity of the total field is called the interference pattern. The maxima of intensity in the interference pattern are called *fringes*. The interference equation can be written in terms of intensity and phase as

$$I = \underbrace{I_1 + I_2}_{\text{Added intensities}} + \underbrace{2\sqrt{I_1 I_2} \cos(\varphi_1 - \varphi_2)}_{\text{Interference term}} \ , \tag{16.4}$$

with $I = |A|^2$. A slight rearrangement of terms yields the interference equation

$$I = I_0 \left[1 + \gamma \cos(\Delta\varphi)\right] \ , \tag{16.5}$$

with

$$\text{mean intensity} \qquad I_0 = I_1 + I_2 \ , \tag{16.6a}$$

$$\text{contrast (modulation)} \qquad \gamma = \frac{2\sqrt{I_1 I_2}}{I_1 + I_2} \ , \tag{16.6b}$$

$$\text{phase-difference} \qquad \Delta\varphi = \varphi_1 - \varphi_2 \ . \tag{16.6c}$$

So, the interference pattern of two interfering waves consists of a background term, composed of the added intensities, an interference term dependent on the phase difference of both waves, and the contrast. The contrast is also called the modulation or visibility. It is related to the maxima and minima of the interference pattern by (Fig. 16.2)

$$\gamma = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}} \ . \tag{16.7}$$

The contrast γ can vary between one and zero. It equals one if $I_{\min} = 0$ and it equals zero if $I_{\max} = I_{\min}$. In (16.6b) we derive that a contrast of one requires that both waves have identical intensity while the contrast becomes zero if one wave has vanishing intensity. The contrast depends also on the mutual coherence and the polarization of the interfering waves.

The phase of the interfering waves depends on the traversed optical path in terms of the wavelength $\lambda = c/\nu$ (c is the speed of light), i. e.,

$$\varphi \propto \frac{nd}{\lambda} \ . \tag{16.8}$$

Because of this, interferometers are used for accurate measurement of the refractive index n (refractometry),

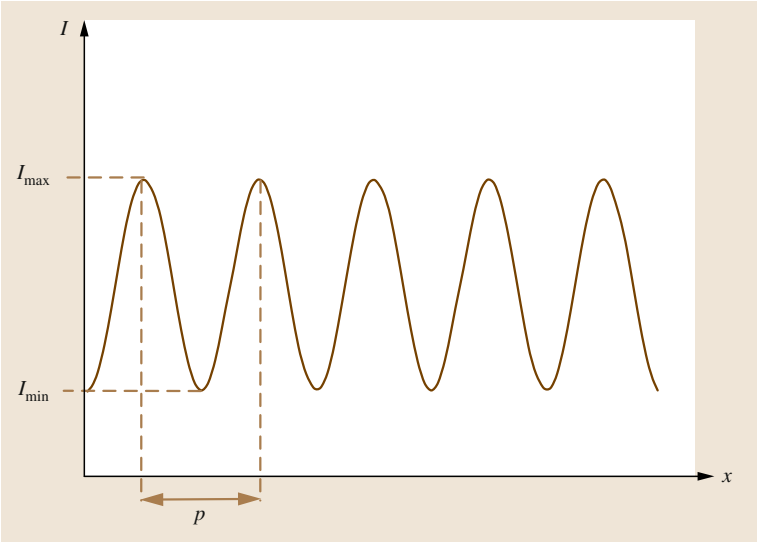

Fig. 16.2 Definition of maximum and minimum intensity of an interference pattern

distances d (length measurement), and wavelength λ (spectroscopy).

16.1.2 Fringe Period

The period of the interference fringes depends on the spatial distribution of the phase difference $\Delta\varphi$, which in turn depends on the shape of the interfering wavefronts. The simplest case is that of two plane waves (Fig. 16.3). For two plane wave enclosing an angle α we obtain a period

$$p = \frac{\lambda}{2\sin(\alpha/2)} \,. \tag{16.9}$$

The period is independent of the distance.

The second basic case is that of two point sources at distance s (Fig. 16.4). At a distance D, rays from both sources enclose an angle α with $\tan\alpha = s/2D$, i. e., they produce an interference pattern with period

$$p = \lambda\frac{D}{s} \,. \tag{16.10}$$

16.1.3 Vector Two-Beam Interference

Consider two quasimonochromatic electromagnetic waves in complex representation. Since conventional detectors are sensitive to the electrical field component only [16.7], it is sufficient for most applications to consider the electric field, i. e.,

$$\boldsymbol{E}_1 = \boldsymbol{A}_1 \exp(\mathrm{i}\varphi_1)\exp(-\mathrm{i}\omega t) \,, \tag{16.11a}$$

$$\boldsymbol{E}_2 = \boldsymbol{A}_2 \exp(\mathrm{i}\varphi_1)\exp(-\mathrm{i}\omega t) \,. \tag{16.11b}$$

Based on the superposition principle the intensity of the superposition is

$$\begin{aligned} I &= |\boldsymbol{E}_1 + \boldsymbol{E}_2|^2 \\ &= ||\boldsymbol{A}_1||^2 + ||\boldsymbol{A}_{21}||^2 + 2\boldsymbol{A}_1 \cdot \boldsymbol{A}_2^* \cos(\varphi_1 - \varphi_2) \,, \end{aligned} \tag{16.12}$$

where $\cdot$ denotes the inner product and $||\cdots||$ denotes the norm of the vector; i. e., the interference intensity is conveniently described by (16.5),

$$I = I_0\left[1 + \gamma\cos(\Delta\varphi)\right] \,, \tag{16.13}$$

but now with

mean intensity $$I_0 = ||\boldsymbol{A}_1||^2 + ||\boldsymbol{A}_{21}||^2 \tag{16.14a}$$

contrast (modulation) $$\gamma = \frac{2\boldsymbol{A}_1 \cdot \boldsymbol{A}_2^*}{||\boldsymbol{A}_1||^2 + ||\boldsymbol{A}_{21}||^2} \tag{16.14b}$$

phase-difference $$\Delta\varphi = \varphi_1 - \varphi_2 \,. \tag{16.14c}$$

The contrast of the vector interference pattern depends on the inner product of the two vectors. Because of this, we observe no interference pattern for two orthogonally polarized waves, and maximum contrast if both waves are of the same polarization (Fig. 16.5).

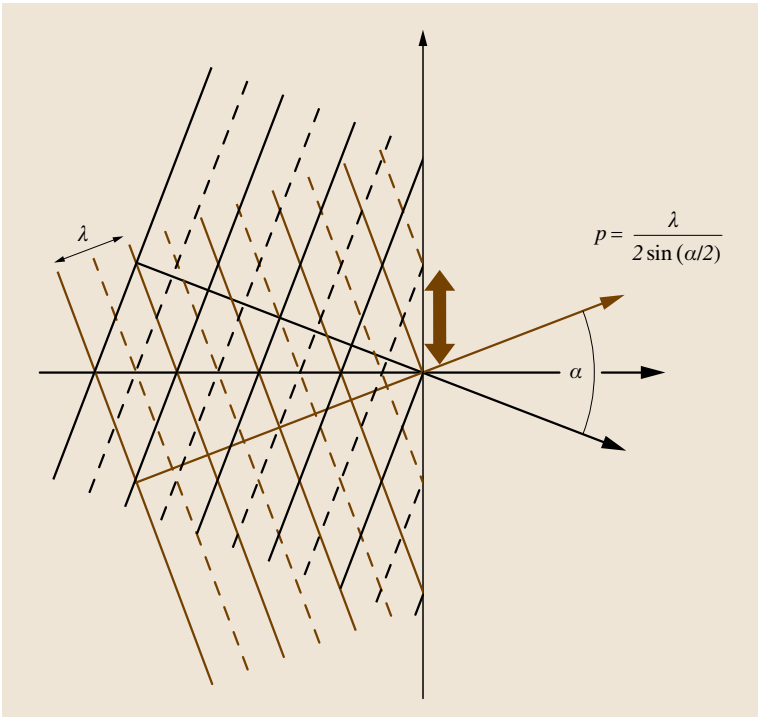

Fig. 16.3 Interference of two plane waves

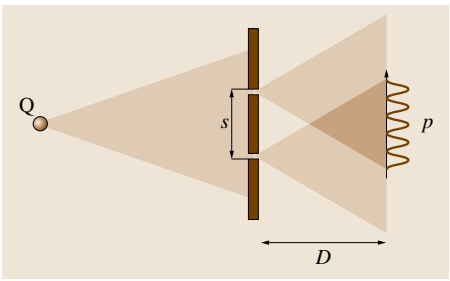

Fig. 16.4 Young interferometry

16.1.4 Partially Coherent Two-Beam Interference

In the previous sections we assumed completely coherent interfering waves; i. e., the light source would have been a point source of vanishing bandwidth. If we consider instead an extended, broadband light source, the resulting wave field is partially coherent. It is described mathematically by a partial degree of coherence $\gamma_{12}(\tau)$. It is immediately clear that partial coherence should re-

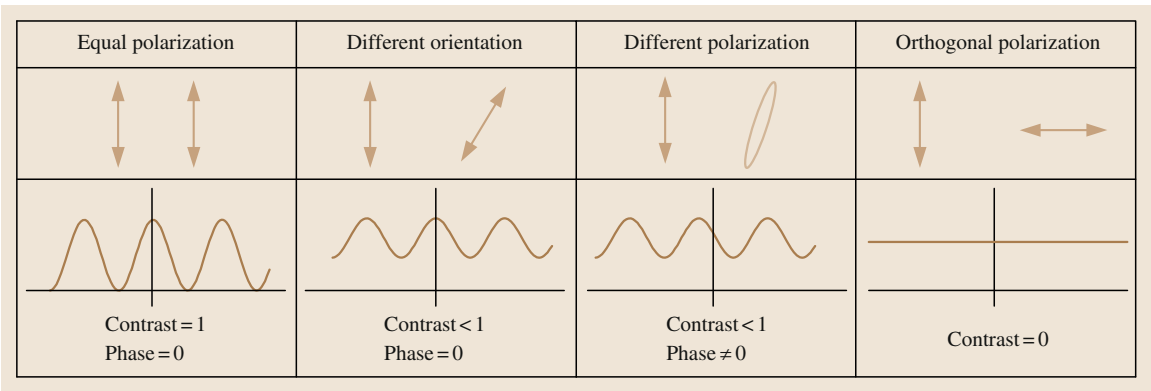

Fig. 16.5 Two-beam interference for different polarization states

duce the contrast of the interference pattern. In fact, the real part of $\gamma_{12}(\tau)$ yields the reduction of the contrast of the interference pattern

$$\gamma = \frac{2\boldsymbol{A}_2 \cdot \boldsymbol{A}_2^*}{||\boldsymbol{A}_1||^2 + ||\boldsymbol{A}_{21}||^2} \Re\{\gamma_{12}(\tau)\} \ . \tag{16.15}$$

The temporal coherence is given by $\gamma_{11}(\tau)$. It is just the Fourier transform of the spectrum of the light source, i. e.,

$$\gamma_{11}(\tau) = \int_0^\infty s(\nu) \exp(-\mathrm{i}2\pi\nu\tau) \, \mathrm{d}\nu \ . \tag{16.16}$$

A light source of frequency bandwidth $\Delta\nu$ yields a temporal coherence of width

$$\Delta t = \frac{1}{\Delta\nu} \ . \tag{16.17}$$

However, a limited temporal coherence Δt results in a limited coherence length of

$$\Delta L = c\Delta t \ , \tag{16.18}$$

with the speed of light c.

The spatial degree of coherence is $\gamma_{12}(0)$. According to the van Cittert–Zernike theorem, $\gamma_{12}(0)$ is equal to the diffraction pattern of an aperture of identical dimensions as the light source.

16.1.5 Two-Beam Interference of Waves of Different Frequency

The superposition of two quasimonochromatic scalar waves of frequency difference $\Delta\omega = 2\pi\Delta\nu$, i. e.,

$$\boldsymbol{E}_1 = \boldsymbol{A}_1 \exp(\mathrm{i}\varphi_1) \exp(-\mathrm{i}\omega t) \ , \tag{16.19a}$$

$$\boldsymbol{E}_2 = \boldsymbol{A}_2 \exp(\mathrm{i}\varphi_2) \exp[-\mathrm{i}(\omega + \Delta\omega)\, t] \ , \tag{16.19b}$$

yields the time-dependent total field

$$I = |\boldsymbol{E}_1 + \boldsymbol{E}_2|^2 = ||\boldsymbol{A}_1||^2 + ||\boldsymbol{A}_{21}||^2 + 2\boldsymbol{A}_1 \cdot \boldsymbol{A}_2^* \cos(\varphi_1 - \varphi_2 - \Delta\omega t) \ ; \tag{16.20}$$

i. e., the intensity becomes time dependent with beat frequency $\Delta\omega$. The phase of this beat signal is equal to the phase difference between the two waves. This is the basis for heterodyne interferometry.

16.2 Types of Interferometers

Interferometers can be classified along two axes: the method used to obtain coherent waves, and the number of interfering waves.

With the exception of frequency-stabilized lasers, two independent light sources are incoherent. Because of this, we need to derive the interfering waves from a single source. To do this, basically two principles are used (Fig. 16.6):

1. Amplitude division: For a given point, a part of the wave is directed along different paths, for instance, by use of a beam splitter.
2. Wavefront division: The interfering waves are derived from laterally displaced parts of the same wavefront.

Amplitude-division interferometers require that the amplitude of an incident wavefront be divided. This can be accomplished by diffraction (diffraction interferometer) or most commonly by a beam splitter that produces a transmitted and a reflected wavefront. The latter yields great flexibility in constructing the optical beam path, but it is impossible to build an amplitude-division interferometer from purely reflective elements or purely transmissive elements alone. However, for unusual wavelengths (extreme ultraviolet (EUV), x-ray), it is very difficult to realize a beam-splitting device, although mirrors do exist. For these wavelengths, wavefront-division interferometry is much easier to realize.

For the number of interfering waves we distinguish two cases, namely:

1. Two-beam interferometers
2. Multibeam interferometers.

Two other criteria are also important:

1. The complexity of the setup, i. e., how many optical components are needed to realize the interferometer. For unusual optical wavelengths, for instance, in the deep ultraviolet (UV), it is preferably to use simple types that need only a few elements. These include the Newton interferometer and the point-diffraction interferometer.
2. The length traversed by the interfering beams that is not common. If this length is large, the requirements on stability are much higher compared with an interferometer where this length is small. The latter are called common-path interferometers.

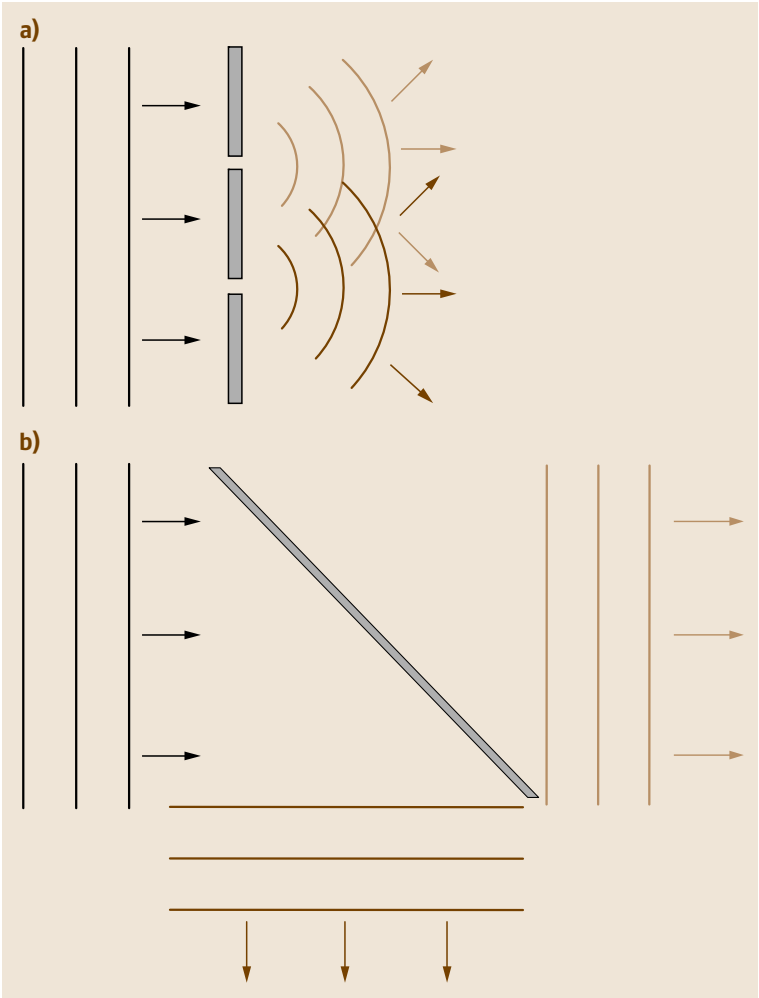

Fig. 16.6a,b Amplitude division (**a**) and wavefront division (**b**)

Table 16.1 Interferometer types according to amplitude division and wavefront division

Number of beams	Type of division	
	Amplitude division	**Wavefront division**
Two beam	Michelson interferometer Twyman–Green interferometer Mach–Zehnder interferometer Jamin interferometer Newton interferometer Fizeau interferometer Sagnac interferometer Gratig interferometer	Fresnel biprism interferometer Young interferometer Lloyd interferometer Rayleigh interferometer Point-diffraction interferometer
Multibeam	Fizeau interferometer Fabry–Pérot interferometer	*N*-Slit interferometer

Common-path interferometers include the Newton interferometer, the shearing interferometer, and the point-diffraction interferometer.

Table 16.1 provides a list of interferometer types according to the type of division and the number of beams.

16.2.1 Wavefront-Division Interferometry

In wavefront-division interferometers, the interfering waves are derived from laterally displaced parts of the same wavefront. The Fresnel biprism and mirrors, the Lloyd, the Rayleigh, the point-diffraction, the Young, and the N-slit interferometer are of this type. In the following, their basic working principles, typical realizations, and most important applications are discussed.

Young Interferometer

The Young interferometer is based on Young's interference of two slits illuminated by the same light source (Fig. 16.4).

Two slits at a distance s yield a fringe period of (16.10)

$$p = \lambda \frac{D}{s} \,. \tag{16.21}$$

An integrated optics variant can be used for optical sensing (Fig. 16.7) [16.9]. A Y-junction serves as an integrated optical beam splitter, sending light from a laser diode into the two arms. One arm contains a sensing region where environmental changes induce a phase shift. Both arms end in free space, acting as two point sources of which the interference pattern is imaged onto a charge-coupled device (CCD) array by a cylindrical lens ($2f$ setup). A phase shift in one arm results in a shift of the interference pattern on the CCD array.

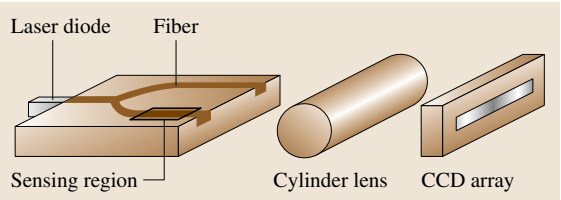

Fig. 16.7 Integrated Young interferometer

Point-Diffraction Interferometer

In the basic configuration of the point-diffraction interferometer, an optical system is illuminated with a coherent wavefront and the transmitted wavefront is focused on a membrane with an off-axis pinhole

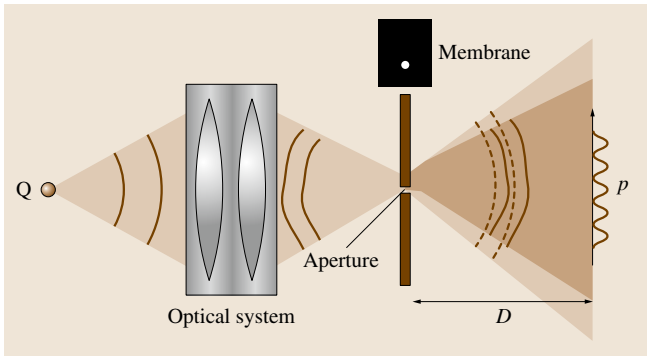

Fig. 16.8 Point-diffraction interferometer (after [16.8])

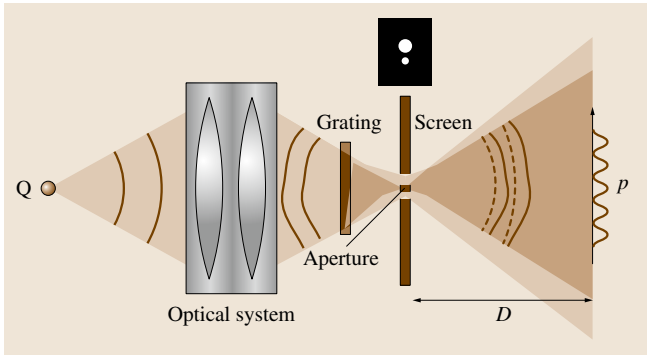

Fig. 16.9 Phase-shifting point-diffraction interferometer (after [16.8])

(Fig. 16.8). The membrane attenuates the aberration-containing main wave by a significant factor, for instance, down to 1%. The pinhole is small enough to produce a spherical reference wave that interferes with the attenuated main wave. The attenuation is needed to balance the intensity of both interfering waves to get high-contrast fringes. Analysis of the interferogram yields the aberrations of the optical system.

The main disadvantage of the basic configuration is the need for an attenuating transmitted wave and the lack of a phase-shifting capability, which is required for quantitative phase measurements. Both constraints are overcome in the phase-shifting point-diffraction interferometer (Fig. 16.9) [16.8]. Here, a grating or an object plane mask is used to yield a high-intensity reference wave and to shift the phase of the reference wave in discrete steps.

Because the point-diffraction interferometer involves no optical components (except of course the optical system and the illumination) and furthermore uses a common-path configuration, it is well suited for at-wavelength testing of optics for use at short wave-

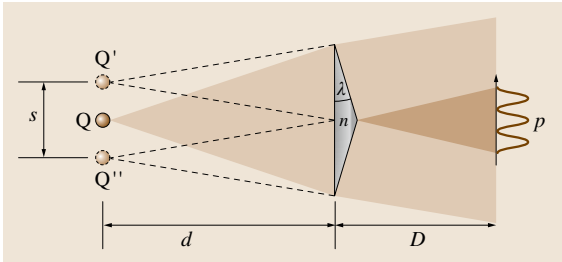

Fig. 16.10 Fresnel biprism

lengths such as deep ultraviolet (DUV) [16.10] and EUV [16.8].

Fresnel Biprism

A Fresnel!biprism of refractive index n and refracting angle γ produces from a point source Q at distance d two virtual point sources Q′ and Q″ of apparent distance (Fig. 16.10)

$$s = nd\tan(\gamma)\,. \tag{16.22}$$

Their interference results in a fringe period of

$$p = \lambda\frac{D+d}{nd\tan(\gamma)}\,. \tag{16.23}$$

The Fresnel biprism is used for measurement of the autocorrelation of short laser pulses by means of a simplified version of frequency-resolved optical gating (FROG), called GRENOUILLE [16.11].

The electrostatic biprism is a realization of the Fresnel biprism for electrons. It is applied for electron interferometry [16.12].

Fresnel Mirror

A Fresnel mirror consists of two plane mirrors that enclose an angle slightly different from 180° (Fig. 16.11). By this means, two virtual light sources are obtained

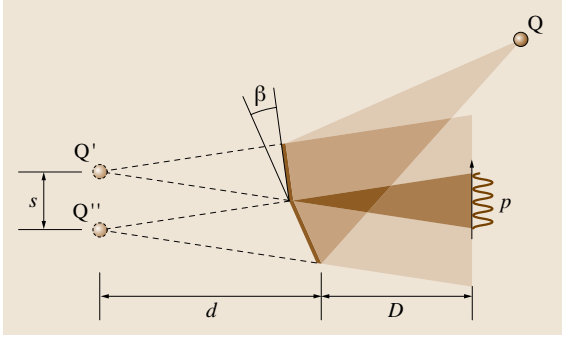

Fig. 16.11 Fresnel mirror interferometer

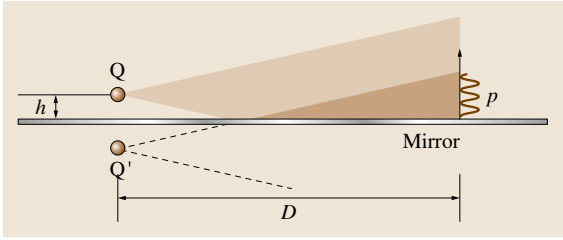

Fig. 16.12 Lloyd's mirror interferometer

from a single real one. Their distance s is given by [16.1]

$$s = 2d\beta\,, \tag{16.24}$$

yielding a fringe period

$$p = \lambda\frac{D+d}{2d\beta}\,. \tag{16.25}$$

Fresnel mirror interferometers are used for x-ray interferometry [16.13, 14].

Lloyd's Mirror

A Lloyd's mirror interferometer consists of a plane mirror and a point source (usually a focal spot) on top of it (Fig. 16.12). The mirror reflects a part of the wavefront emanating from the point source, producing a virtual point source near to the real one. Their distance s is given by $s = 2h$, yielding a fringe period

$$p = \lambda\frac{D}{2h}\,. \tag{16.26}$$

Applications of Lloyd's mirror interferometers include flatness tests [16.15], measurement of refractive index and thickness of thin films [16.16], phase imaging in the soft x-ray regime [16.17], and interferometry of boundary diffraction waves [16.18].

16.2.2 Amplitude-Division Interferometry

In amplitude-division interferometry, the interfering waves are derived from the same wavefront by division of its amplitude. The Michelson, Twyman–Green, Mach–Zehnder, Jamin, Newton, Fizeau, Sagnac, and Fabry–Pérot interferometers are of this type. In the following we discuss their basic working principles starting with the beam-splitter matrix, typical realizations, and their most important applications.

Shearing Interferometry Versus Interferometry with Reference

There are two principal methods for generation of an interferogram of a modulated wave (Fig. 16.13):

- In *interferometry with reference*, the sample wave U_S is superposed with a reference wave U_R of known phase structure, usually a plane wave

$$I(x, y) = |U_S(x, y) + U_R(x, y)|^2 . \qquad (16.27)$$

  From the interferogram we can determine the phase of the sample wave (Sect. 16.3).
- In *shearing interferometry*, the sample wave is superposed with a displaced version (vector (dx, dy) of itself

$$I(x, y) = |U_S(x, y) + U_S(x + dx, y + dy)|^2 . \qquad (16.28)$$

  The measured phase-difference is $\varphi(x + dx, y + dy) - \varphi(x, y)$, i. e., it is proportional to the derivative of the phase structure of the sample wave.

Types of Interferences at a Plane-Parallel Plate

A single plate is certainly the simplest interfering device. This could be, for instance, a thin film or an air gap between two plane-parallel plates. In both cases, incident light is reflected at both interfaces, yielding interference. If the reflection factor is small, we observe to a good approximation two-beam interference. Multibeam (Fabry–Pérot) interference occurs for large reflection factors, i. e., surfaces coated with a high-reflection (HR) coating (Fig. 16.14). The theory of the interaction of light with such a structure is described in detail in Chap. 6. Here, we recapitulate only the main formulas.

With a ray propagation angle of ϑ between the semitransparent mirrors, we get a phase difference of two neighboring rays of

$$\delta = \frac{4\pi}{\lambda} nd \cos\vartheta . \qquad (16.29)$$

The reflected and transmitted intensity are described by the Airy function

$$\text{transmission} \quad \frac{I_t}{I_i} = \frac{1}{1 + F \sin^2(\delta/2)} , \qquad (16.30a)$$

$$\text{reflection} \quad \frac{I_r}{I_i} = \frac{F \sin^2(\delta/2)}{1 + F \sin^2(\delta/2)} ; \qquad (16.30b)$$

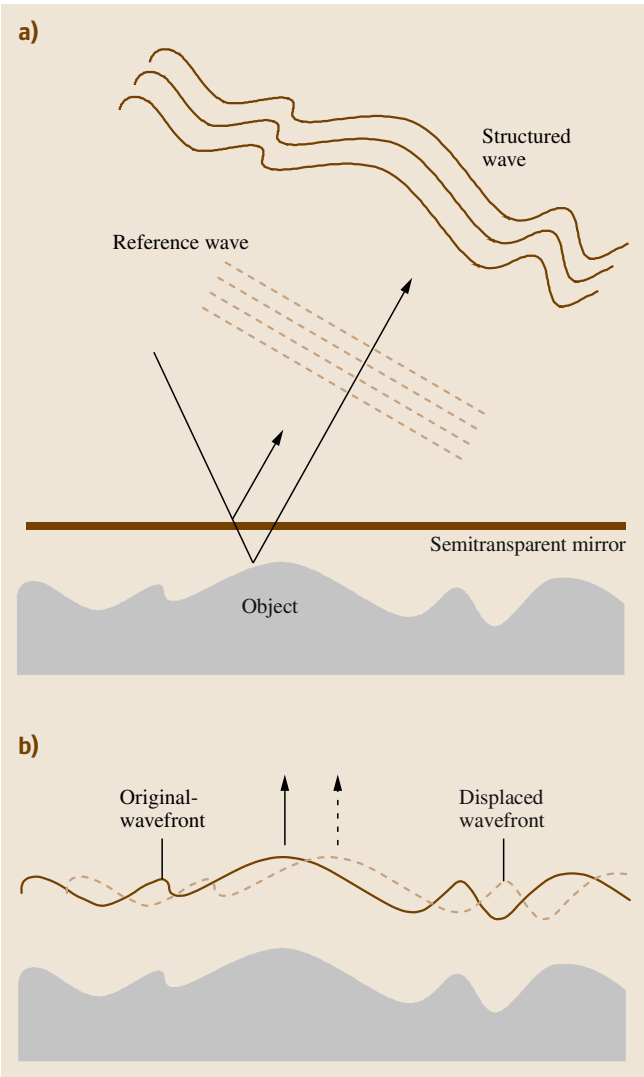

Fig. 16.13 **(a)** Interference with reference wave, **(b)** shearing interferometry

where F is determined by the reflection factor r of the semitransparent mirrors

$$F = \frac{4r^2}{(1 - r^2)^2} . \qquad (16.31)$$

The distance between two transmitted wavelengths is called the free spectral range of the interferometer

$$\Delta\lambda = \frac{\lambda^2}{1 + 2nd \cos\vartheta} . \qquad (16.32)$$

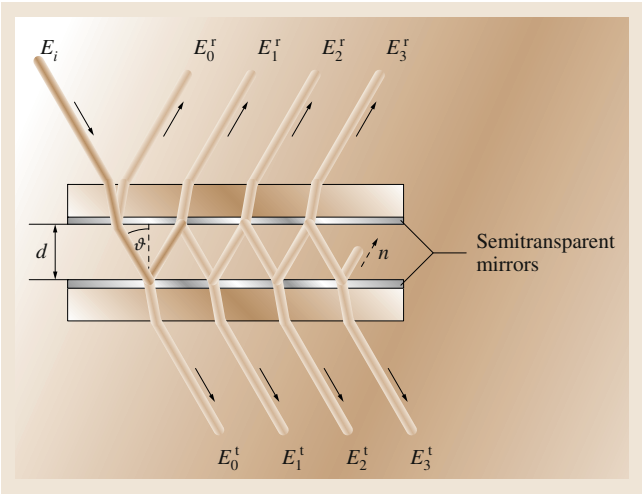

Fig. 16.14 Multibeam interference at two plane-parallel plates

The sharpness of the fringes is measured by the full-width at half-maximum (FWHM) of the intensity peaks. For large F it is given by [16.5]

$$\delta\lambda = \frac{4}{\sqrt{F}} \,. \tag{16.33}$$

The finesse $\mathfrak{F}$ of the interferometer is defined as the ratio of the separation of two adjacent fringes and their FWHM, i. e., for large F,

$$\mathfrak{F} = \frac{\Delta\lambda}{\delta\lambda} = \frac{\pi\sqrt{F}}{2} \,. \tag{16.34}$$

Fizeau fringes of equal thickness occur for a point source Q at a distance from the gap of thickness d (Fig. 16.15b). The reflection of Q at both interfaces yields two imaged point sources at axial distance $2d$. For a plane-parallel plate, circular fringes are observed. If the thickness varies in lateral direction, the fringes are distorted, allowing the local thickness to be gauged. With a collimated incident beam (point source at infinity) the fringes provide directly the height variation.

Haidinger fringes of equal inclination occur at infinity for an extended source and a plane-parallel plate (Fig. 16.15a). Rays in the same direction traverse the same path length and are imaged by the lens to the same spot.

Beam Splitter

The beam splitter is the basic component of any two-beam amplitude division interferometer. A beam splitter can be realized as the well-known beam-splitter cube, but also just as a surface of a dielectric plate, a metallized surface, a free-standing membrane, or even a grating (Fig. 16.14). The basic characteristic is that it produces from each point of an incident wavefront two samples, usually a transmitted and a reflected beam.

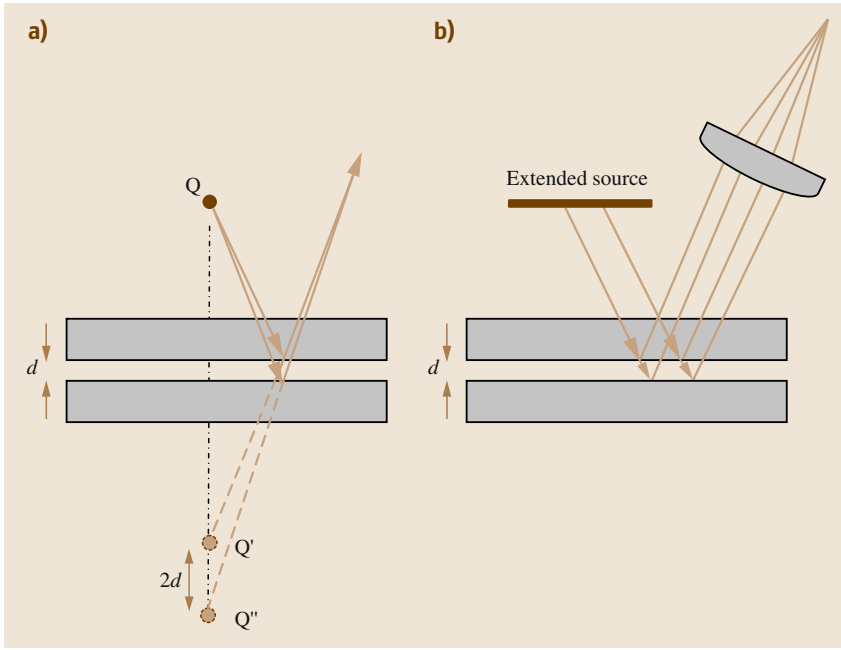

Fig. 16.15 **(a)** Fizeau interference (fringes of equal thickness), **(b)** Haidinger interference (fringes of equal inclination)

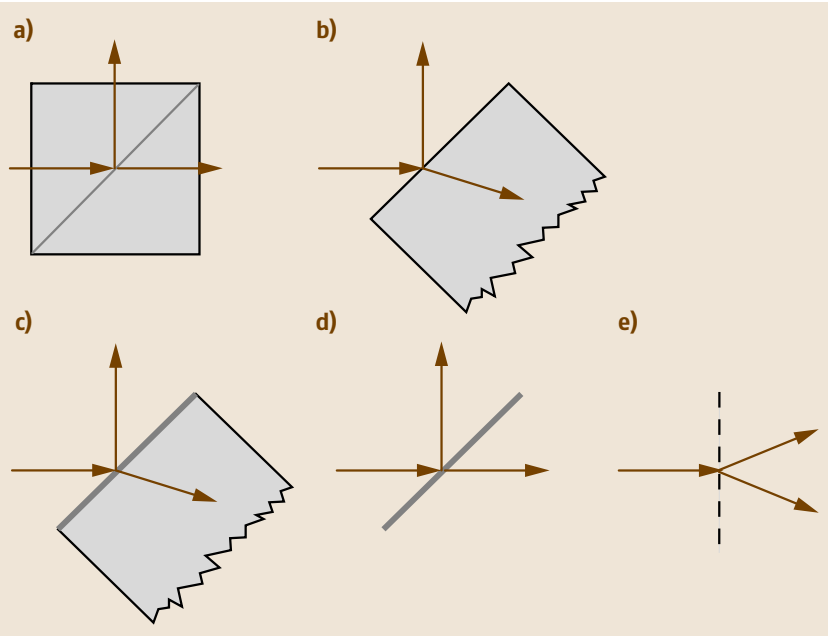

Fig. 16.16a–e Beam-splitting devices: **(a)** beam-splitter cube, **(b)** dielectric interface, **(c)** partially reflecting mirror, **(d)** pellicel, **(e)** grating

Detailed analysis of the path difference introduced by a beam splitter and the required accuracy can be found in [16.2, Chap. 2].

Beam-Splitter Matrix

An interface or thin-film beam splitter (Fig. 16.16a–e) has two input and two output ports, as indicted in Fig. 16.17.

The performance of a lossless beam splitter is described by a 2×2 *beam-splitter matrix*. Following [16.19], we denote the two input ports with 1 and 2, and the two output ports with 3 and 4:

$$\begin{pmatrix} E_3 \\ E_4 \end{pmatrix} = \begin{pmatrix} r_{31} & t_{32} \\ t_{41} & r_{42} \end{pmatrix} \begin{pmatrix} E_1 \\ E_2 \end{pmatrix} . \tag{16.35}$$

Energy conservation requires that

$$|E_1|^2 + |E_2|^2 = |E_3|^2 + |E_4|^2 . \tag{16.36}$$

Inserting (16.35) into (16.36), we find that the matrix of a general lossless beam splitter is unitary and the lossless symmetric beamsplitter can be expressed as

$$\begin{pmatrix} E_3 \\ E_4 \end{pmatrix} = \begin{pmatrix} r & t \\ t & r \end{pmatrix} \begin{pmatrix} E_1 \\ E_2 \end{pmatrix} , \tag{16.37}$$

with

$$|r|^2 + |t|^2 = 1 , \tag{16.37a}$$

$$rt^* + tr^* = 0 . \tag{16.37b}$$

In particular, a 50 : 50 beam splitter is described by the matrix

$$\begin{pmatrix} E_3 \\ E_4 \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & \mathrm{i} \\ \mathrm{i} & 1 \end{pmatrix} \begin{pmatrix} E_1 \\ E_2 \end{pmatrix} . \tag{16.38}$$

We get a more convenient form of (16.38) if we assume an offset phase between E_1 and E_2, and E_3 and E_4, respectively, i. e., writing

$$\begin{pmatrix} E_3 \\ \mathrm{i}E_4 \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \begin{pmatrix} E_1 \\ \mathrm{i}E_2 \end{pmatrix} . \tag{16.39}$$

So, apart from a phase offset of $\pi/2$ between both input and output ports and a constant amplitude factor,

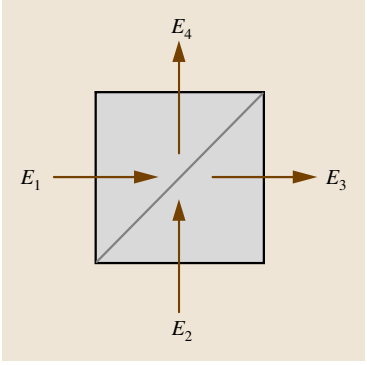

Fig. 16.17 The two input and output ports of a beam splitter

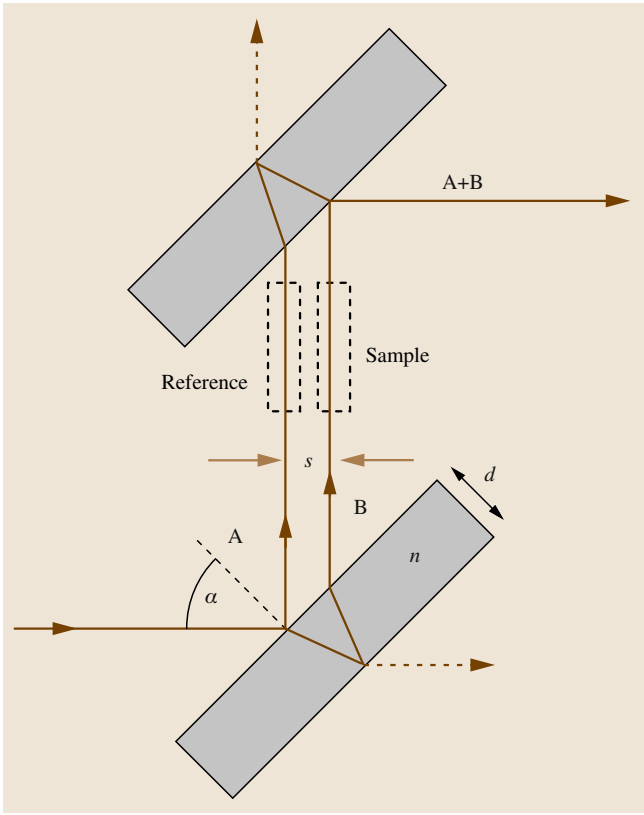

Fig. 16.18 Jamin interferometer ◀

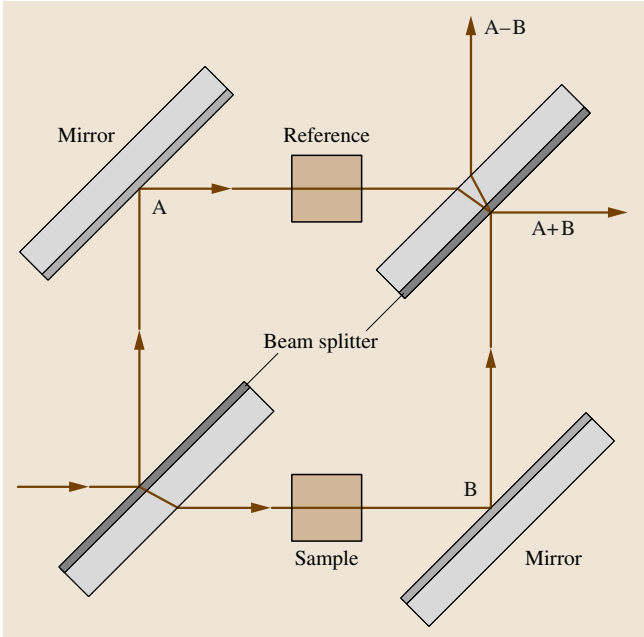
the output ports yield the sum and the difference of the input ports, i. e.,

$$E'_3 = E'_1 + E'_2 \,, \tag{16.40a}$$

$$E'_4 = E'_1 - E'_2 \,. \tag{16.40b}$$

Jamin Interferometer



The Jamin interferometer consists of two plane-parallel glass plates aligned parallel to each other (Fig. 16.16). Both surfaces of each plate act as partial reflecting mirrors. The interference occurs between the first beam A that is reflected from the front surface of the first and the back surface of the second plate, and the second beam B that is reflected from the back surface of the first and the front surface of the second plate. Between the plates, both beams are displaced by an amount proportional to the thickness of the plates.

This interferometer is not exactly common path, but the geometry allows both beams to be close to each other. In this way, its sensitivity to environmental disturbances becomes low. The distance s of both beams is

$$s = \frac{d}{n} \frac{\sin 2\alpha}{\sqrt{1 - \frac{1}{n^2} \sin^2 \alpha}} \,. \tag{16.41}$$

In the original experiment of Jamin, the interferometer was used to measure the refractive index of gases by arranging two cells, one filled with gas and one evacuated, between both plates so that each beam traverses a single cell [16.20] (as indicated by dashed lines in Fig. 16.18).

Fringes are observed when the plates are tilted with respect to each other. A phase measurement can be done by inserting a phase-shifting element into one path.

Mach–Zehnder Interferometer

The Mach–Zehnder interferometer consists in its basic configuration of two beam splitters and two mirrors (Fig. 16.19). It has the same topology as the Jamin interferometer, with the reflecting surfaces situated on different components. Compared with the Jamin interferometer, the displacement of the two beams with

Fig. 16.19 Mach–Zehnder interferometer. Note that, because of the arrangement of the beam splitters, the interferometer is already compensated for the path length in the substrate of the beam splitter. No compensating element is required ◀

respect to each other can be arbitrarily large, yielding great flexibility in terms of the setup.

The first beam splitter provides an amplitude division of the incoming beam into two subbeams A and B, while the second beam splitter combines them again. It should be kept in mind that a beam splitter acting as a beam combiner in fact has two exits. Due to the conservation of energy, the superposition of both beams has to differ by a factor of π between the two exits (16.40). So, if A and B denote the amplitudes, the amplitude at exit 1 is proportional to $A + B$ whereas the amplitude at exit 2 is proportional to $A - B$.

Compared with the Jamin interferometer, the Mach–Zehnder interferometer can host samples of large transverse dimension. However, because of this, the Mach–Zehnder interferometer is also far from being common path, which imposes stringent requirements on the stability of the setup.

The Mach–Zehnder interferometer was first constructed in 1891 by *Mach* and *Zehnder* [16.21, 22]. It is used to measure the phase shift of transparent samples in transmission, for instance, to determine the aberrations of an optical system in transmission [16.2]. For this purpose, the sample is inserted into one arm (dashed in Fig. 16.19), and an optional reference may be placed in the other.

Tilting of one mirror results in an angular displacement of both interfering beams A and B and therefore the observation of fringes. Transforming this basic configuration into a phase-shifting interferometer is usually done by changing the path length in the reference arm (the arm not hosting the sample) by use of a piezoactuator on one mirror.

Michelson Interferometer

The Michelson interferometer consists in its basic configuration of one beam splitters and two mirrors (Fig. 16.20). The incident beam is divided by a partially reflecting mirror – the beam splitter – into two beams. Both beams are directed into different paths and reflected at mirror 1 and 2, respectively. Finally they are recombined at the same, partially reflecting mirror. Whereas the Mach–Zehnder interferometer probes samples in transmission, the Michelson interferometer probes a sample either in a double-pass configuration (back and forth) or in reflection. For the latter, the object forms one mirror of the interferometer. The Michelson interferometer is easily converted into a phase-shifting interferometer by actuating one mirror.

The Michelson interferometer can be folded back to a plane plate: We can think of one mirror (M_1) as being reflected into the second mirror (M_2) by a plane

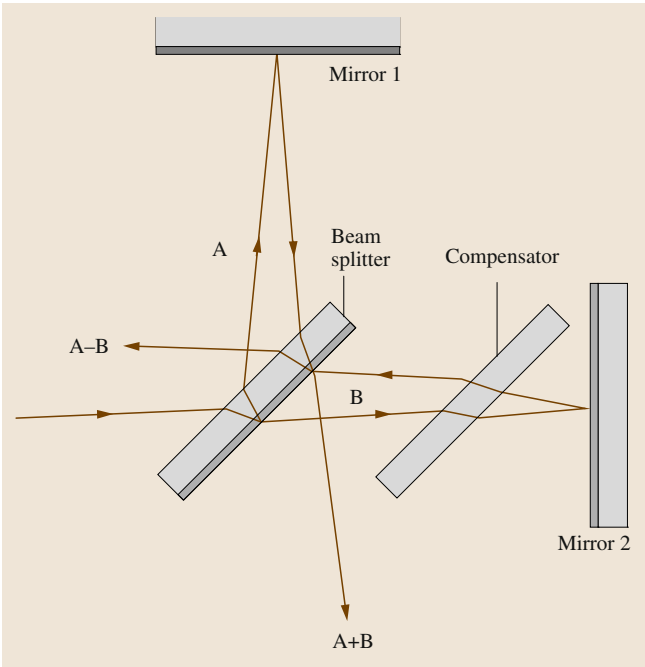


Fig. 16.20 Michelson interferometer (after [16.5])

defined by the beam splitter (BS in Fig. 16.21). Then, we have basically the same double-surface configuration as already presented in Fig. 16.13. One surface is real, while the other surface is not. Contrary to an ac-

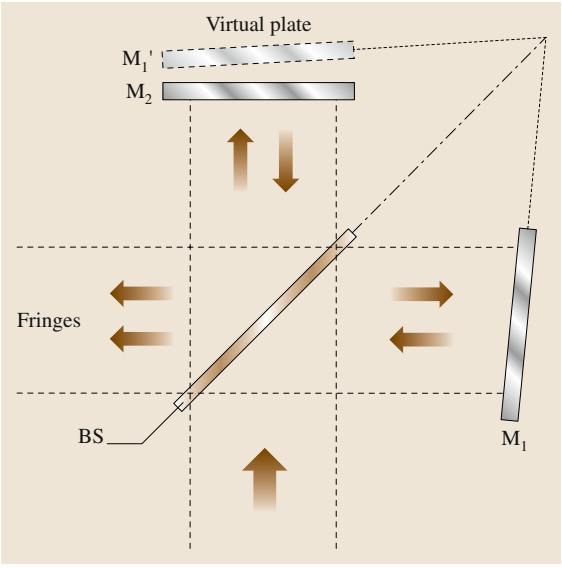

Fig. 16.21 The virtual plane plate in a Michelson interferometer

tual plane plate, where multiple-beam interference can be observed for highly reflecting surfaces, this virtual plane plate forms a strict two-beam interferometer. Depending on the illumination, we observe Haidinger or Fizeau fringes.

The Michelson interferometer is probably the best known interferometric configuration. It was originally used in 1887 by *Michelson* and *Morley* to prove the invariance of the velocity of light against the movement of the Earth [16.23].

The Michelson interferometer is the basic configuration for Fourier spectroscopy [16.24] and high-resolution length measurement for, e.g., gravitational wave detection [16.25], for the Twyman–Green interferometer used for testing of optical components, for the Kösters interferometer used for height measurements, and for interference microscopy of Michelson, Linnik, and Mirau type (see the following sections).

Twyman–Green Interferometer

The Twyman–Green interferometer is a Michelson interferometer with collimated beams (Fig. 16.22). It contains two lenses: lens 1 (L_1) collimates the light from a point source, and lens 2 (L_2) focuses the collimated light onto a detector. The Twyman–Green interferometer is equivalent to a Fizeau interferometer with clearly separated paths for the reference and the sample light.

As the Fizeau interferometer, the Twyman–Green interferometer is used to test optical systems: prisms, lenses, and mirrors (original literature is referenced in [16.1,2]). The basic idea underlying these tests is simple: the system under test together with the mirror must yield a reflected plane wave for an incident plane wave. The basic modification of the interferometer to achieve this is the adaptation of the reflection mirror after the sample. To test a system of focal optics, a spherical mirror is used as indicated in Fig. 16.22. To test optical systems that produce an aspherical wavefront, a so-called null lens is used to generate a wavefront that is exactly opposite to the one of the system under test. Of course, the role of the mirror and the optics under test can be exchanged, so that the mirror is the tested component.

The immediate application of the Twyman–Green interferometer is accurate measurement of height variations on a sample surface (Kösters comparator [16.5]).

Kösters Comparator

The Kösters comparator is a Twyman–Green interferometer adapted for the comparison of two length standards. It is based on a Kösters prism, enabling a very compact setup (Fig. 16.23). Inclusion of a vacuum chamber (indicated dashed in Fig. 16.23) enables correction for variations of the refractive index of air [16.26].

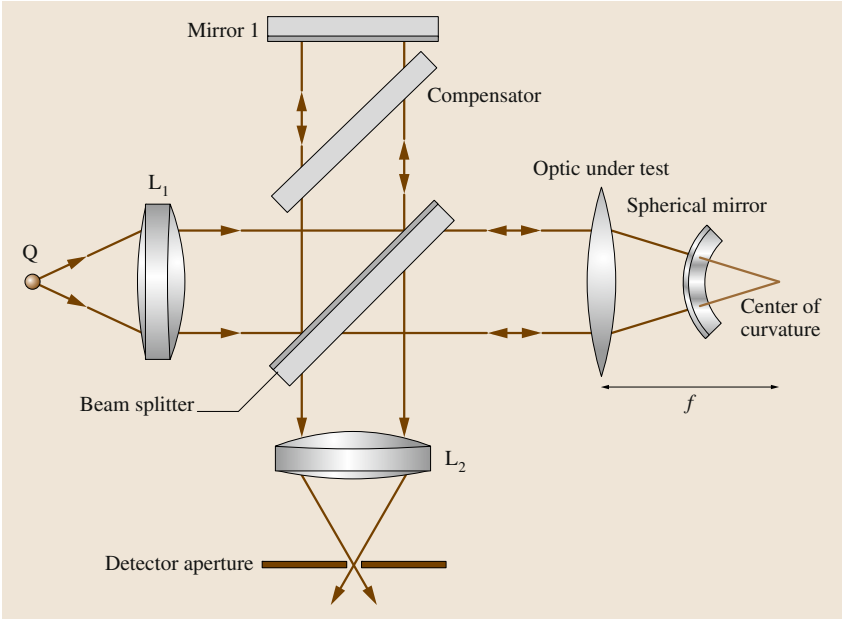

Fig. 16.22 Twyman–Green interferometer to test a focal optical system

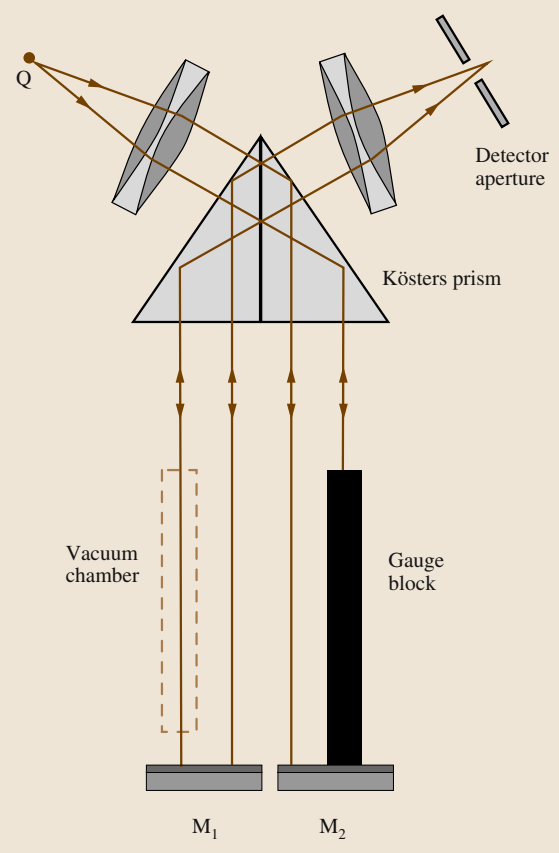

Fig. 16.23 Kösters comparator

Interference Microscopes Based on the Twyman–Green Design

Interference microscopes enable microscopic measurements of height variations. Three designs are derived directly from the Twyman–Green interferometer. The Michelson type is suitable for low numerical apertures (NA) only because of the rather bulky component below the microscope lens (Fig. 16.24b). The Mirau type can be used for NAs up to 0.8 (Fig. 16.24a). Even higher NAs are possible to reach with the Linnik interference microscope. Here, a second microscope lens is required; i. e., it is simply a Twyman–Green interferometer with two microscope lenses: one in the reference arm and one in the sample arm.

Fizeau Interferometer

Observation of fringes of equal thickness between two parallel plates for an extended source requires that the air gap between them be only a few micrometers thick. For larger gap widths, collimated, monochromatic light is needed. This is the basic principle of the Fizeau interferometer (Fig. 16.25). A lens collimates the light from a point source. The collimated light traverses a first plate (the *Fizeau plate*) and impinges on the surface under test. Interference occurs between the light reflected from the surface under test and the light reflected from the Fizeau plate. A beam splitter allows the observation of the interference fringes.

The Fizeau interferometer is used extensively for optical testing [16.2]. Compared with the Twyman–Green interferometer it has the advantage that large parts of the light path are common path, making it more stable against environmental fluctuations.

Fabry–Pérot Interferometer

The Fabry–Pérot interferometer [16.27] is a multiple-beam interferometer. The main component is a cavity composed of two highly reflecting mirrors, whose separation d is tunable (Fig. 16.26). It is called a Fabry–Pérot resonator or Fabry–Pérot cavity.

For an extended source, we observe fringes of equal inclination that satisfy

$$\cos\vartheta = m\frac{\lambda}{2nd}\,, \tag{16.42}$$

where m denotes the fringe order and n the refractive index in the cavity. A Fabry–Pérot cavity composed of a rigid plane plate with high-reflection coating is called an etalon. A dielectric plane plate illuminated under grazing incidence is called a *Lummer–Gehrcke plate* [16.28]. Here, the high reflectivity needed for multibeam interference is obtained from the angular dependence of the interface reflection coefficient (Fresnel's formulas).

Fabry–Pérot interferometers have a number of applications. In particular, laser resonators can be considered as Fabry–Pérot cavities. Because of the narrow transmission spectrum, Fabry–Pérot interferometers can be used for high-resolution spectroscopy. The etalon is used for the realization of single-mode laser resonators by suppressing all but one resonator modes.

Sagnac Interferometer

The Sagnac interferometer [16.29] is a ring interferometer, i. e., an interferometer where both interfering waves propagate along the same path but in opposite directions (Fig. 16.27a). A single beam splitter acts as beam divider and combiner.

Due to the Doppler shift, rotation of the interferometer at angular velocity Ω results in a phase difference

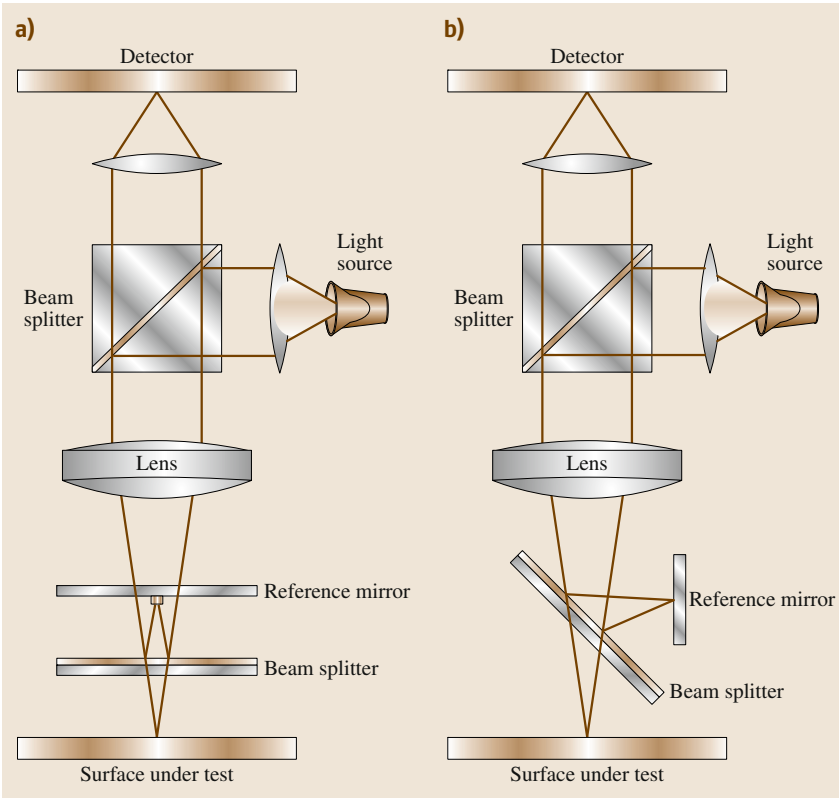

Fig. 16.24a,b Interference microscopes after Mirau **(a)** and Michelson **(b)**

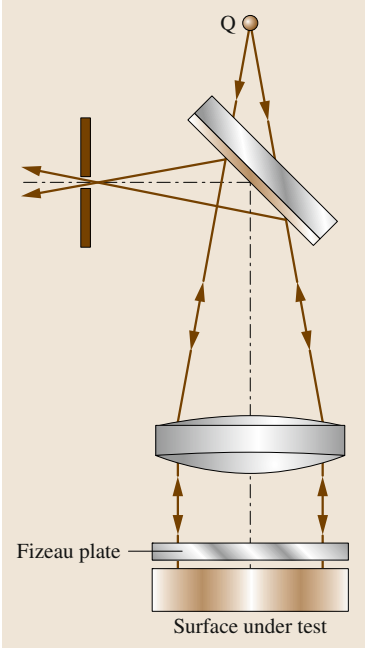

Fig. 16.25 Fizeau interferometer

of

$$\Delta\varphi = \frac{4A\Omega}{\lambda c}\,; \tag{16.43}$$

of both counterpropagating beams (A is the enclosed area). This is used in the fiber-optical version of the interferometer – the fiber-optic gyroscope – for rotation sensing [16.30] (Fig. 16.27b). To obtain a high-contrast interference signal, polarization-maintaining fibers have to be used.

The free-space version of the Sagnac interferometer is the basic component of ring lasers.

16.2.3 Polarization-Division Interferometry

In an amplitude-division interferometer in the strict sense, two exact replicas of the incident wavefront are produced, but with reduced amplitude compared with the incident wave. However, polarization state and spectrum are retained. The same applies for recombination of the wavefronts.

In contrast, a polarization-division interferometer does the amplitude division on a polarization basis, i. e.,

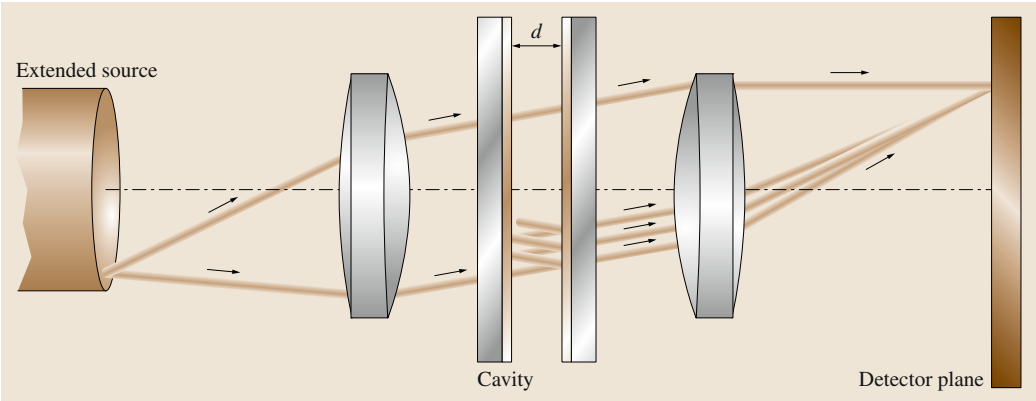

Fig. 16.26 Fabry–Pérot interferometer

the incident wavefront is divided into two (usually orthogonal) polarization states [16.31, 32]. These travel along different paths. They are recombined and brought into interference by a polarizer. So, the interference equation for a polarization interference of two orthogonal polarization states $\boldsymbol{E}$, $\boldsymbol{E}_{\text{orth}}$ at a polarizer with Jones matrix $\mathbf{P}$ is

$$I = ||\,\mathbf{P}\,(\boldsymbol{E} + \boldsymbol{E}_{\text{orth}})\,||^2\,, \tag{16.44}$$

which becomes, for x- and y-polarization, $\boldsymbol{E} = (E_x, 0)$, $\boldsymbol{E}_{\text{orth}}(0, E_y)$ and a polarizer under 45°

$$I = |E_x + E_y|^2\,. \tag{16.45}$$

We can even understand polarimeters as a kind of polarization-division interferometer. The main advantage of this kind of interferometers is that they are common-path interferometers; i. e., both the object and the reference beam travel along the same path. They are separated in terms of polarization and can be manipulated using this property.

Polarizing Beam Splitters

The polarization beam splitter is the central component of any polarization interferometer. It is realized as:

- Polarizing thin films [16.33], transmitting the p-polarized component and reflecting the s-polarized component (incident ray near the Brewster angle) (Fig. 16.28a).
- Wire-grid grating for infrared (IR) wavelengths and beyond [16.34] (Fig. 16.28b).
- Optimized gratings deflecting one polarization into the first diffraction order [16.35, 36] (Fig. 16.28c).
- Wollaston prism [16.37] (Fig. 16.28d) consisting of two right-angled prisms made of a birefringent crystal (quartz, calcite) with orthogonal axes parallel to a surface. They are cemented together at their hypotenuse. An incident ray is split at the interface of the two prisms into two orthogonal polarized rays of mutual angle (with Δn = birefringence = difference of extraordinary and ordinary refractive index)

$$\alpha = 2\Delta n \sin\vartheta\,. \tag{16.46}$$

- Nomarski prism [16.38] (Fig. 16.28e). It is similar to a lower than Wollaston prism with the difference that the optical axis of the first prism is not parallel to the interface, but at 45° to it. The Nomarski modification causes the light rays to come to a focal point

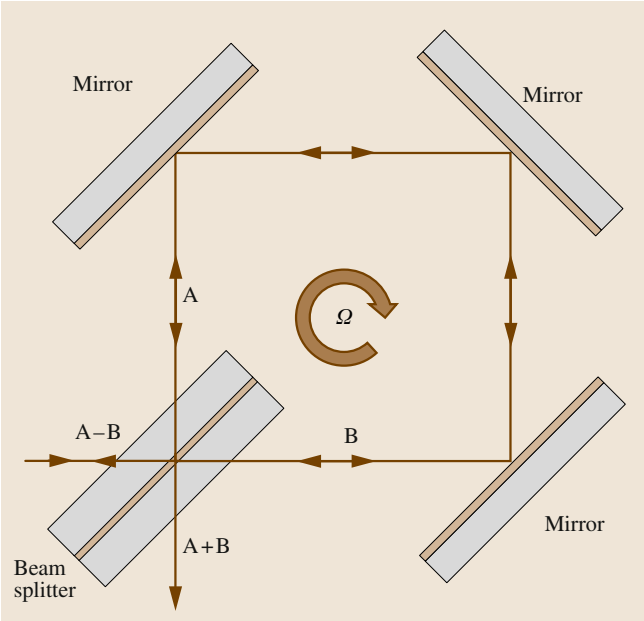

Fig. 16.27 Sagnac interferometer

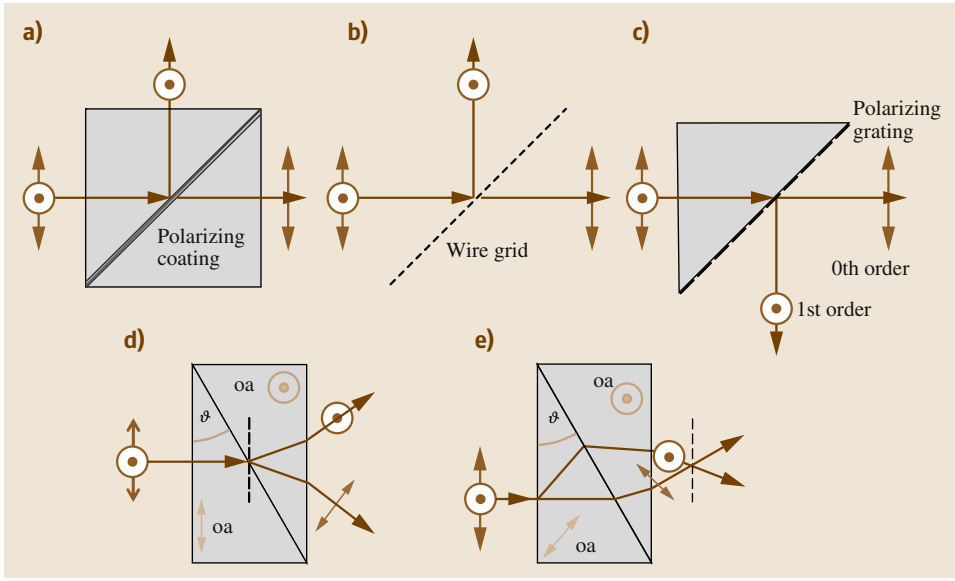

Fig. 16.28a–e Various types of polarizing beam splitters: **(a)** polarizing coating, **(b)** wire-grid polarizer, **(c)** polarizing diffraction grating, **(d)** Wollaston prism, and **(e)** Nomarski prism

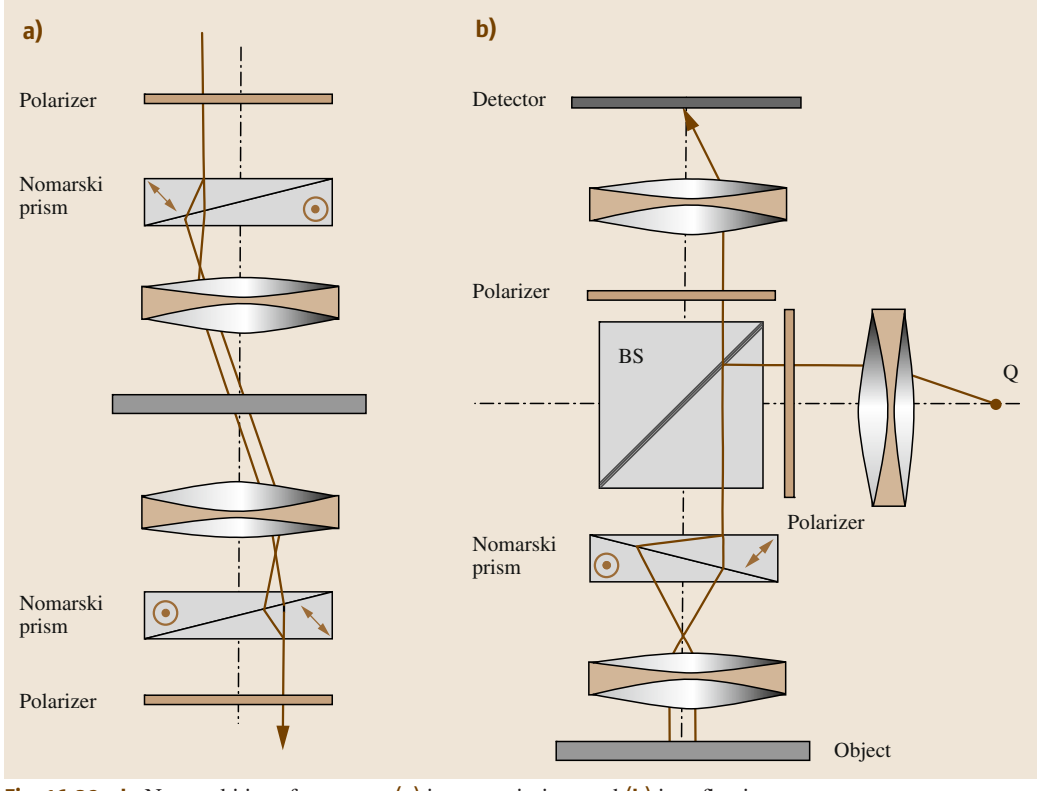

Fig. 16.29a,b Nomarski interferometer: **(a)** in transmission, and **(b)** in reflection

outside the prism itself (dashed interference plane in the figure). This yields a larger useful field.

Using a polarizing beam splitter, any of the above-mentioned amplitude-division interferometers can be transformed into a polarization-division interferometer. This is done, for instance, to use polarizing elements for wavefront manipulations, for instance, planar nematic liquid-crystal displays (LCDs) for phase shifting, as well as to get rid of the second output channel (using a polarizing beam splitter in combination with quarter-wave plates).

Nomarski Interferometer

The Nomarski interferometer [16.37] is a shearing interferometer using two Nomarski or Wollaston prisms for beam division and recombination, respectively. The illuminating light is polarized at 45° using a first polarizer and divided afterwards into two laterally displaced, orthogonal polarized subbeams by a first Nomarski prism. These beams impinge on the object and are recombined in second (Fig. 16.29a) or – in the reflection version – the first Nomarski prism (Fig. 16.29b). A second polarizer under 45° lets both beams interfere. The interference reveals the phase difference between the two orthogonal polarized beams and thereby the differential phase.

With a lateral shear of s in the x-direction the interference becomes

$$I(x, y) = |E_x(x+s, y) + E_y(x, y)|^2 \,. \tag{16.47}$$

The Nomarski interferometer is widely used for differential interference contrast (DIC) microscopy [16.38]. An important modification is to use it with circular polarized light instead of 45° linear polarized light. This enables adjustment of the shear direction by rotation of the Nomarski prism instead of the object itself (C-DIC [16.39]).

16.3 Quantitative Phase Measurement

Interferogram evaluation, i. e., extraction of the phase distribution from measured interferograms, is an intrinsic part of interferometry. While historically that was done by interpreting the interference as isophase lines (similarly to isoheight lines for topometry), the evaluation is now done almost solely by digital means, enabling real-time interferometry applications. Excellent in-depth discussions of evaluation techniques in interferometry are provided by *Schwider* [16.40] and *Schreiber* and *Bruning* [16.2, Chap. 14].

16.3.1 Homodyne Detection

Homodyne detection means interferometry at a single frequency, i. e., the interference happens between waves of identical frequency.

As discussed at the beginning of this chapter, an interferogram is composed of three quantities: intensity, contrast, and phase. In wavefront metrology, one is interested in the phase only and takes the contrast as a kind of quality gauge. In the application of interferometry to surface inspection, the 2π ambiguity of the phase becomes annoying: The phase does not represent the surface structure, but rather a mod $\lambda/2$ version of it. If the surface is continuous, proper phase unwrapping can be applied to resolve this. However, if the surface may be discontinuous, which is mostly the case, we need to find the actual fringe order. This can be done by detection of the contrast, as in white-light interferometry [16.41]

However, for inspection purposes the contrast itself is of interest. It has proved useful for inspection of semiconductor surface structures near the resolution limit [16.42].

Temporal Phase-Shifting Interferometry

The fringes of an interferogram denote the isophase lines. Historically, these have been interpreted directly. However, there are severe drawbacks to this. It is difficult to find the centers of the lines in the presence of noise, and intensity variations cannot be distinguished from phase variations.

Phase-shifting interferometry (PSI) is the state-of-the-art method to perform direct measurement of the phase map. Consider the two-beam interference equation (16.5), including a phase shift ψ_j. ψ_j is constant across the field, i. e., it is actually a phase-offset

$$I_j = (\boldsymbol{r}) = I_0(\boldsymbol{r}) \left[1 + \gamma(\boldsymbol{r}) \cos\left(\Delta\varphi(\boldsymbol{r}) + \psi_j\right)\right] \,. \tag{16.48}$$

The index $j = 1, \ldots, N$ indicates that several intensity maps are taken for different phase shifts. Since we have three unknown quantities (I_0, γ, $\Delta\varphi$) it is clear that

we need at least three independent images to reconstruct each of them unambiguously, i. e., $N \geq 3$.

Algorithms. PSI algorithms can be divided into four classes:

1. Constant and known phase shift
2. Constant but unknown phase shift
3. Known but arbitrary phase shift
4. Unknown and arbitrary phase shift.

Constant Phase Steps With Known Phase Shift

The case of constant and known phase shift is obviously the easiest to handle. In the following we state the most common algorithms. Several algorithms are discussed in [16.2, 40, 47].

Digital Fourier analysis provides an efficient way to understand the exact form of the algorithms and to construct new ones [16.45, 46, 48]. To that end, we consider a continuous and linear phase shift $\psi = 2\pi\nu_0 t$, yielding a pixelwise Fourier transform [16.45]

$$\tilde{I}(r, \nu) = \int_{-\infty}^{\infty} W(t) I(\boldsymbol{r}, t) \exp(-\mathrm{i}2\pi\nu t)\,\mathrm{d}t \,. \qquad (16.49)$$

A weighting function $W(t)$ is introduced to reduce the spectral leakage associated with finite observation intervals [16.45]. It determines the error contribution of the data acquisition process, as becomes clear when we compute the Fourier transform as defined in (16.48) for a linear phase shift

$$\tilde{I}(\boldsymbol{r}, \nu) = W(\nu) + \tfrac{1}{2}\gamma(\boldsymbol{r})\big[W(\nu - \nu_0) \times \exp(\mathrm{i}\Delta\varphi) + W(\nu + \nu_0)\exp(-\mathrm{i}\Delta\varphi)\big] \,. \qquad (16.50)$$

For $\nu = \nu_0$ we get the phase as

$$\Delta\varphi = \arctan\left(\frac{\Im\left\{\tilde{I}(\boldsymbol{r}, \nu)\right\}}{\Re\left\{\tilde{I}(\boldsymbol{r}, \nu)\right\}}\right) \,, \qquad (16.51)$$

provided $W(\nu_0) = 0$ and $W(2\nu_0) = 0$. So, we need a weighting function $W(\nu)$ that has broad zeros around ν_0 and $2\nu_0$. This problem is well known from digital filtering and signal processing. There, various window functions such as the Hamming, Parzen, and Von Hann window are used to minimize the influence of spectral leakage on the spectral evaluation of the data bounded by the window [16.49].

The various PSI algorithms can be related to different window functions. This approach was successfully applied to develop new algorithms [16.45, 46]. Other approaches to develop new PSI algorithms use recursion rules to generate a new algorithm from an old one, or least-squares methods to optimize the noise performance of an algorithm while constraining it to a desired set of properties [16.50].

The most popular algorithms are listed in Table 16.2. The construction of Table 16.2 makes use of the fact that the basic composition of the PSI algorithms is identical:

- The mean intensity is denoted by

$$I_0 = \sum_{j=1}^{N} I_j \,. \qquad (16.52)$$

- The phase is computed from

$$\Delta\varphi = \arctan\left(\frac{A}{B}\right) \,. \qquad (16.53)$$

- The contrast follows from

$$\gamma = \frac{\sqrt{A^2 + B^2}}{2I_0} \,. \qquad (16.54)$$

Error Sources

Phase Shifter Miscalibration. A miscalibration of the phase shifter results in a linear phase shift and thereby violation of $W(\nu_0) = 0$ and $W(2\nu_0) = 0$. It needs a smooth apodizing weighting function for error minimization. The three- and four-step algorithms are

Table 16.2 The quantities A and B for some popular PSI algorithms

No. of steps	Ψ_j	A	B	Remark
3	$(2j-1)\pi/4$	$I_3 - I_2$	$I_1 - I_2$	Very sensitive to errors
3	$(j-2)3\pi/2$	$\sqrt{3}^*(I_3 - I_2)$	$2I_1 - I_2 - I_3$	Very sensitive to errors
4	$(j-1)\pi/2$	$I_2 - I_4$	$I_3 - I_1$	[16.1]
5	$(j-1)\pi/2$	$I_2 - I_4$	$I_3 - 0.5(I_1 + I_5)$	[16.43, 44]
7	$(j-1)\pi/2$	$-(I_1 - I_7) + 7(I_3 - I_5)$	$4(I_2 + I_6) + 8I_4$	[16.45]
8	$(j-1)\pi/2$	$5I_2 - 15I_4 + 11I_2 - I_8$	$I_1 - 11I_3 + 15I_5 - 5I_7$	[16.46]

very sensitive to this error. The five- to eight-step algorithms are increasingly better. The eight-step algorithm, for example, yields (for phase shifter miscalibration of 20%) errors of $\approx 0.001°$.

Quadratic Nonlinearities of the Phase Shifter. These are critical up to the five-step algorithm. However, the seven- and eight-step algorithms show significantly reduced sensitivity in this regard, which enables use of inherently nonlinear phase shifters [16.45].

Detector Nonlinearities. These occur in particular when the detector is set to maximum gain. So, deliberately reducing the contrast is helpful here. As for phase shifter miscalibration, algorithms with a higher number of frames show better performance [16.2, table in Chap. 14].

Vibrations. They are a significant problem for all non-common-path interferometers. They are minimized by the mechanical design of the setups, which should be stable and rigid. Again, algorithms with more frames perform better. If the frequency spectrum of the vibration is known, it is of advantage to use or even design an algorithm that is insensitive to the main frequencies of the vibration [16.51]. For a known vibration spectrum it is also possible to design the mechanical setup such that its eigenfrequencies are far away from the main vibration frequencies.

Quantization Errors. This error stems from the analog-to-digital (AD) conversion. The analog signal of the detector is represented by Q steps of a quantized signal, resulting in a quantization error. Its standard deviation can be approximated for an N-step algorithm by [16.2, 52]

$$\sigma_N = \frac{1}{\sqrt{3N}Q} \,. \tag{16.55}$$

So, the phase error is inversely proportional to the modulated intensity. To reduce the phase error, the analog signal intensity should cover as much of the dynamic range of the AD converter as possible [16.53]. For an 8-bit signal, for instance, we have $Q = 256$, and for an eight-step algorithm, a standard deviation of < 0.001 waves.

Constant Phase Steps with Unknown Phase Shift

The PSI algorithm of *Carré* [16.54] assumes a constant phase shift, but the estimated phase is independent of the exact amount of phase shift. All it requires is that it is linear. Assuming a phase shift of α between two consecutive measurements we get four interferograms

$$I_j(\boldsymbol{r}) = I_0(\boldsymbol{r}) \left\{ 1 + \gamma(\boldsymbol{r}) \cos \left[\Delta\varphi(\boldsymbol{r}) + \frac{2j-5}{2}\alpha \right] \right\} . \tag{16.56}$$

The phase modulo π becomes

$$\Delta\varphi = \arctan \left\{ \frac{\sqrt{[3(I_2-I_3)-(I_1-I_4)][(I_2-I_3)+(I_1-I_4)]}}{(I_2+I_3)-(I_1+I_4)} \right\} , \tag{16.57}$$

and the contrast for $\alpha \approx \pi/2$ is approximately [16.47]

$$\Delta\varphi \approx \frac{1}{2I_0} \sqrt{\frac{[(I_2-I_3)+(I_1-I_4)]^2+[(I_2+I_3)-(I_1+I_4)]^2}{2}} . \tag{16.58}$$

The phase in (16.57) is modulo π. Because of the square root in the nominator, negative values cannot appear there. To extend the phase to a modulo 2π phase we have to consider the sign of

$$(I_1 - I_4) = 2I_0\gamma \sin\alpha \sin\Delta\varphi \,, \tag{16.59a}$$

$$(I_2 + I_3) - (I_1 + I_4) = 2I_0\gamma \cos\alpha \sin^2\alpha \cos\Delta\varphi \,, \tag{16.59b}$$

to determine in which quadrant the phase is placed [16.55].

Arbitrary Phase Steps with Known Phase Shift

If it is difficult or even impossible to calibrate the phase shifter accurately, but we still have the means to determine the amount of introduced phase shift exactly, we have the case of an arbitrary and known phase shift [16.56]. Based on a least-squares iterative procedure it is possible to reconstruct the phase even of randomly phase-shifted interferograms [16.57]. The basic idea is to write the interferogram as

$$I_{ij} = I_{0i} \left[1 + \gamma_i \cos\left(\Delta\varphi_i + \delta_j \right) \right] , \tag{16.60}$$

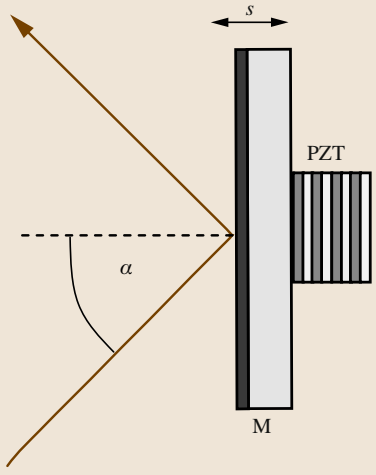
where $i = 1, \ldots, M$ denotes the pixel number and $j = 1, \ldots, N$ denotes the j-th phase-shifted image. If the δ_j are known, we have $3M$ unknowns and MN equations. The unknowns can be determined by use of a least-squares method.

Arbitrary Phase Steps with Unknown Phase Shift

Here the phase shift is completely arbitrary. Interferograms are taken with unequal phase steps of unknown phase shift. In the five-frame algorithm of *Stoilov* and

Dragostinov, the phase steps may be arbitrary but should be equal [16.58]. *Cai* et al. suggested a generalized phase-shifting interferometry with arbitrary unknown phase steps for diffraction objects based on their statistical properties [16.59].

Phase Modulators



To induce the phase required for phase-shifting interferometry a phase modulator is needed. In Table 16.3 a schematic sketch of these devices together with the equation governing the phase shift is given. We distinguish scalar phase shifters, which introduce a phase shift basically independent of the polarization, and polarization phase shifters, which introduce a phase shift that depends on the polarization. The latter are particular useful for common-path polarization interferometry.

The moving mirror (Table 16.3a) is easiest incorporated into an interferometer setup. All it needs is a piezo-actuator on a mirror. Problems are caused by drift of the actuator and its hysteresis. So, an actuator with independent control of the displacement (for instance, provided by a capacitive or inductive sensor) is preferred.

The tilted glass plate (Table 16.3b) is useful if we have a plane plate compensator anyway in the setup. Ghost reflections between its two surfaces may cause unwanted stray light, so you may consider to apply antireflection coatings to the surfaces.

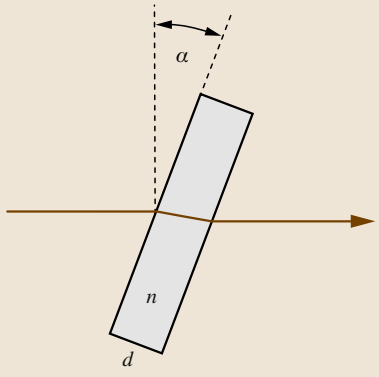


Table 16.3 Scalar phase shifters

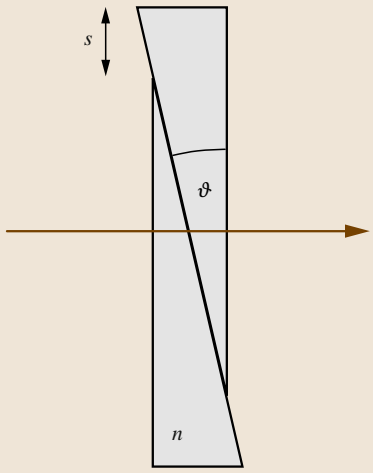
a) Moving mirror

$$\Delta\Psi = \frac{2\pi}{\lambda} 2s\cos\alpha \tag{16.61}$$



b) Tilted glass plate

$$\Delta\Psi = \frac{4\pi}{\lambda} d\left(\sqrt{n^2 - \sin^2\alpha} - \cos\alpha\right) \tag{16.62}$$

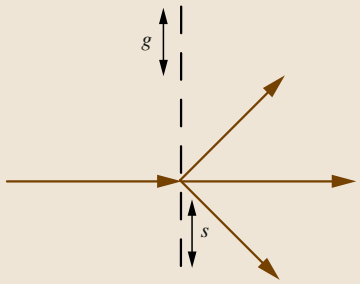


Table 16.3 (continued)

c) Sliding wedge

$$\Delta\Psi = \frac{2\pi}{\lambda}(n-1)s\tan\vartheta \qquad (16.63)$$

d) Translated diffraction grating

$$\Delta\Psi = \frac{ms}{g} \qquad (16.64)$$

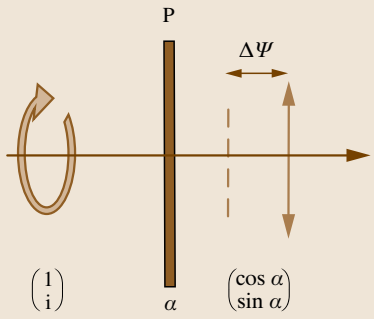
The sliding wedge (Table 16.3c) uses the same mechanics as the Babinet–Soleil compensator.

The translated diffraction grating (Table 16.3d) induces a phase shift proportional to the diffraction order, i. e., it induces a phase shift between the zeroth and first diffraction order in particular. This property is used in grating interferometry.

Polarization phase shifters use birefringent or polarizing materials to induce a phase shift of a polarized wave. They fall into two basic categories. The first category acts on circular polarized light by means of a rotating half-wave plate or rotating polarizer. The second category uses materials with externally adjustable birefringence to act on linearly polarized light. The mentioned polarization states are necessary only for the basic effects. Afterwards they can be transformed into other polarization states. In particular the transformation between linear and circular polarized light is done by a quarter-wave plate.

Because the phase shifting is less obvious here than for scalar phase shifters, we discuss the effect in more detail by use of Jones matrix calculus. Consider a rotating polarizer illuminated with circularly polarized light (Table 16.4a). The Jones matrix of a polarizer rotated to angle α with respect to the x-axis is

$$\mathbf{P} = \begin{pmatrix} \cos^2\alpha & \cos\alpha\sin\alpha \\ \cos\alpha\sin\alpha & \sin^2\alpha \end{pmatrix} . \qquad (16.65)$$



Multiplying with the Jones vector of left-circular light, we get

$$\boldsymbol{E} = \mathbf{P}\begin{pmatrix} 1 \\ \mathrm{i} \end{pmatrix} = \exp(\mathrm{i}\alpha)\begin{pmatrix} \cos\alpha \\ \sin\alpha \end{pmatrix} , \qquad (16.66)$$

i. e., linear polarized light which is oriented along the polarizer orientation and phase-shifted by α.

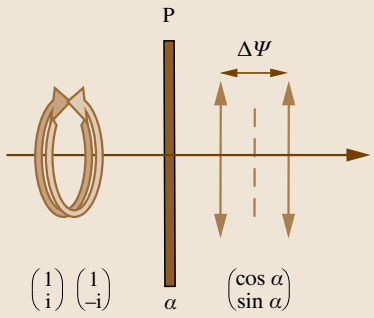


Table 16.4 Polarization phase shifters

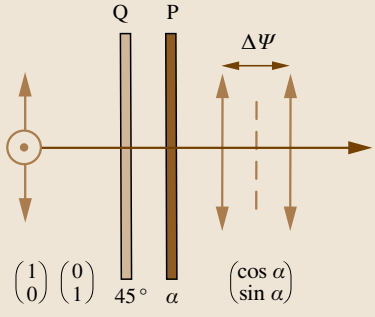
a) Rotating polarizer for left-circular polarized light



$$\Delta\Psi = \alpha \qquad (16.68)$$

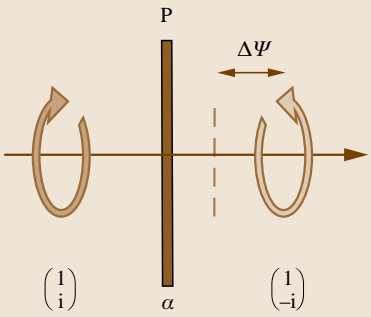
b) Rotating polarizer for left- and right-circular polarized light

$$\Delta\Psi = 2\alpha \qquad (16.69)$$

c) Rotating polarizer with quarter-wave plate

$$\Delta\Psi = 2\alpha \qquad (16.70)$$

Multiplying **P** by the Jones vector of right-circular light, we get



$$\boldsymbol{E} = \mathbf{P}\begin{pmatrix}1\\ -\mathrm{i}\end{pmatrix} = \exp(-\mathrm{i}\alpha)\begin{pmatrix}\cos\alpha\\ \sin\alpha\end{pmatrix}, \qquad (16.67)$$

i. e., linear polarized light which is oriented along the polarizer orientation and phase-shifted by $-\alpha$. So, left- and right-polarized light result in identically polarized light, but with a phase difference of 2α (Table 16.4b). A phase shifter of this type is called a geometric phase shifter because the induced phase shift does not depend on the wavelength.

Inserting a quarter-wave plate in front of the rotating polarizer enables the same effect for light, that is, oriented at 45° to its optical axis (Table 16.4c). The incident linear polarized light is transformed into circular polarized light, whereby the two orthogonal linear states are transformed into left- and right-circular polar-

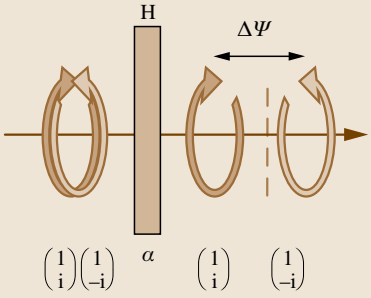


Table 16.4 (continued)

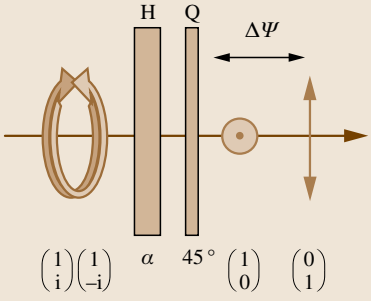
d) Rotating halfwaveplate



$$\Delta\Psi = 2\alpha \qquad (16.71)$$

e) Rotating half-wave plate with left- and right-circular polarized input

$$\Delta\Psi = 4\alpha \qquad (16.72)$$

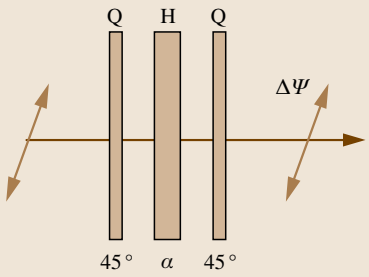
f) Rotating half-wave plate with fixed quarter-wave plate

$$\Delta\Psi = 4\alpha \qquad (16.73)$$

ized light, respectively. So, we get a phase modulator that acts on linear polarized light.

The rotating half-wave plate illuminated by circular polarized light is indicated in Table 16.4d. The Jones matrix of a $\lambda/2$ retarder rotated to angle α with respect to the x-axis is

$$\mathbf{H} = \begin{pmatrix} \cos 2\alpha & \sin 2\alpha \\ \sin 2\alpha & -\cos 2\alpha \end{pmatrix} . \qquad (16.74)$$



Multiplying by the Jones vector of left-circular light, we get

$$\boldsymbol{E} = \mathbf{H} \begin{pmatrix} 1 \\ \mathrm{i} \end{pmatrix} = \exp(\mathrm{i}2\alpha) \begin{pmatrix} 1 \\ -\mathrm{i} \end{pmatrix} ; \qquad (16.75)$$

i. e., left-circular polarized light is transformed into right-circular polarized light and phase-shifted by 2α. Right-circular polarized light is transformed into left-circular polarized light and phase-shifted by -2α.

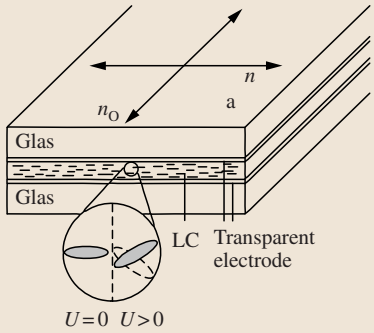


Table 16.4 (continued)

g) Rotating half-wave plate between two quarter-wave plates

$$\Delta\Psi = 2\alpha \qquad (16.76)$$

h) Liquid-crystal phase shifter

$$\Delta\Psi \propto n_e - n_0 \qquad (16.77)$$

Together, this yields a phase shift of 4α for incident left- and right-circular polarized light (Table 16.4e). A fixed quarter-wave plate provides a transformation into linear polarized light (Table 16.4f).

Inserting a second quarter-wave plate in front of the half-wave plate enables linear polarization also on the incident side (Table 16.4g).

There are a number of elements that yield an adjustable linear birefringence: The liquid-crystal phase shifter, as an example, is indicated in Table 16.4h. Other elements are electrooptical and elastooptical elements.

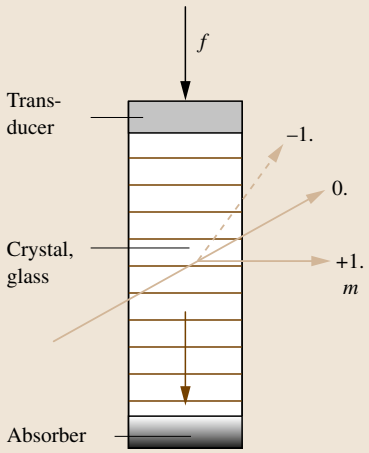
Spatial Phase-Shifting Interferometry

Instead of a temporal phase shift, a spatial phase shift can be applied. To this end, both interfering beams are inclined to each other so that high-density fringes appear [16.60]. If these fringes are adjusted such that two neighboring pixels see a phase difference of $\pi/2$, the PSI algorithms can be applied in a pixelwise manner. Of course, the spatial resolution is reduced.

Takeda introduced a direct spatial method that uses a Fourier transform of the image, then filters the first order, shifts it back to the origin, and finally does an inverse Fourier transform [16.61].

The dynamical interferometrical camera of *Wyant* et al. uses left- and right-circular polarized light for interference and a two-dimensional (2-D) array of linear polarizers at four orientations (0°, 45°, 90°, and 135°) matched to the CCD pixel to superpose them with phase shifts of 0°, 90°, 180°, and 270° [16.62]. So, at the expense of spatial resolution, four phase-shifted frames are captured simultaneously.

16.3.2 Heterodyne Detection



In heterodyne interferometry, a slight frequency shift $\Delta\nu$ is introduced between two interfering beams. After interference, a beat frequency at the difference frequency is observed in the detected signal

$$\begin{aligned} I(t) &= |E_1 + E_2|^2 \\ &= A_1^2 + A_2^2 + 2A_1A_2\cos(\Delta\varphi - \Delta\omega t)\ . \end{aligned} \qquad (16.78)$$

The phase of the beat signal is equal to the phase difference $\Delta\varphi$ between the two beams. It can be determined

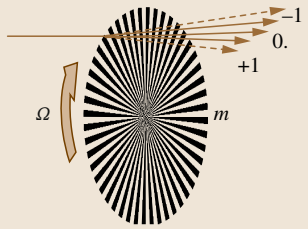


Table 16.5 Frequency shifter used for heterodyne interferometry

a) Acoustooptical modulator

$$\Delta\nu = m f \qquad (16.79)$$

b) Rotating grating

$$\Delta\nu = m\frac{\Omega}{2\pi M} \qquad (16.80)$$

by electronic means. To this end, a fast detector is needed. The phase is determined with respect to a reference that is taken either from the current driving the frequency modulator or from an external reference of constant optical path length. So far, heterodyne interferometry has been used with fast photodiodes as point detectors. A spatially resolved signal is obtained by scanning the beam.

All of the previously discussed interferometer concepts can be converted into a heterodyne interferometer. For this, we need to replace the phase shifter as needed for phase-shifting interferometry into a frequency shifter.

Indeed, each of the previously discussed phase shifters is at the same time a frequency shifter. This can be explained by use of the Doppler effect or very simply by use of a *phase change velocity*. Assume a continuous phase shifter that induces a phase linearly increasing in time

$$\psi = \nu_\varphi t \,. \qquad (16.81)$$

Inserting (16.81) into the interference equation yields

$$I(t) = |E_1 + E_2|^2 = A_1^2 + A_2^2 + 2A_1A_2\cos\left(\Delta\varphi - \nu_\varphi t\right) \,. \qquad (16.82)$$

Comparing with (16.75) we see that

$$\Delta\omega = \nu_\varphi \,; \qquad (16.83)$$

i. e., the wave's frequency has changed from $\nu = \omega/2\pi$ to $\nu + \Delta\nu$ with

$$\Delta\nu = \frac{\nu_\varphi}{2\pi} \,. \qquad (16.84)$$

For frequency conversion a fast, continuous phase shifter is needed. The most popular one is the acous-

tic optical modulator (AOM) (Table 16.5a), but also rotating gratings (Table 16.5b) as well as rotating polarization components are used. Table 16.5 gives an overview of the principles of application together with the basic equation governing the obtained frequency shift.

The frequency shift of the AOM is just the frequency of the acoustic wave times the diffraction order used.

The frequency shift of the rotating grating is the angular velocity divided by 2π times the number of grating lines M.

17. Frequency Combs

Much of modern research in the field of atomic, molecular, and optical science relies on lasers, which were invented some 50 years ago and perfected in five decades of intense research and development. Today, lasers and photonic technologies impact most fields of science and they have become indispensible in our daily lives. Laser frequency combs were conceived a decade ago as tools for the precision spectroscopy of atomic hydrogen. Through the development of optical frequency comb techniques, a setup of the size $1 \times 1\,m^2$, good for precision measurements of any frequency, and even commercially available, has replaced the elaborate previous frequency-chain schemes for optical frequency measurements, which only worked for selected frequencies. A true revolution in optical frequency measurements has occurred, paving the way for the creation of all-optical clocks with a precision that might approach 10^{-18}. A decade later, frequency combs are now common equipment in all frequency metrology-oriented laboratories. They are also becoming enabling tools for an increasing number of applications, from the calibration of astronomical spectrographs to molecular spectroscopy. This chapter first describes the principle of an optical frequency comb synthesizer. Some of the key technologies to generate such a frequency comb are then presented. Finally, a non-exhaustive overview of the growing applications is given.

17.1 The Frequency Comb Principle

An optical frequency comb is an optical spectrum, which consists of several millions of perfectly evenly spaced spectral lines with known frequencies. Several review articles [17.1–5] and books [17.6] describe optical frequency comb technology and its various applications.

Most of the time, the periodic pulse train generated by femtosecond mode-locked lasers is used for producing very broadband frequency combs; therefore the explanation of the generation of optical frequency combs concentrates on this aspect here.

17.1.1 Time- and Frequency-Domain Description of a Mode-Locked Laser

In the time domain (Fig. 17.1), the output of such lasers is a sequence of pulses that are essentially copies of the same pulse separated by the laser cavity round-trip time. In the frequency domain (Fig. 17.1), the separation between two modes or comb lines is just equal to the repetition frequency f_r. This remains true even if the pulses are not identical replicas but if a reproducible slip of the phase of the electromagnetic carrier wave rela-

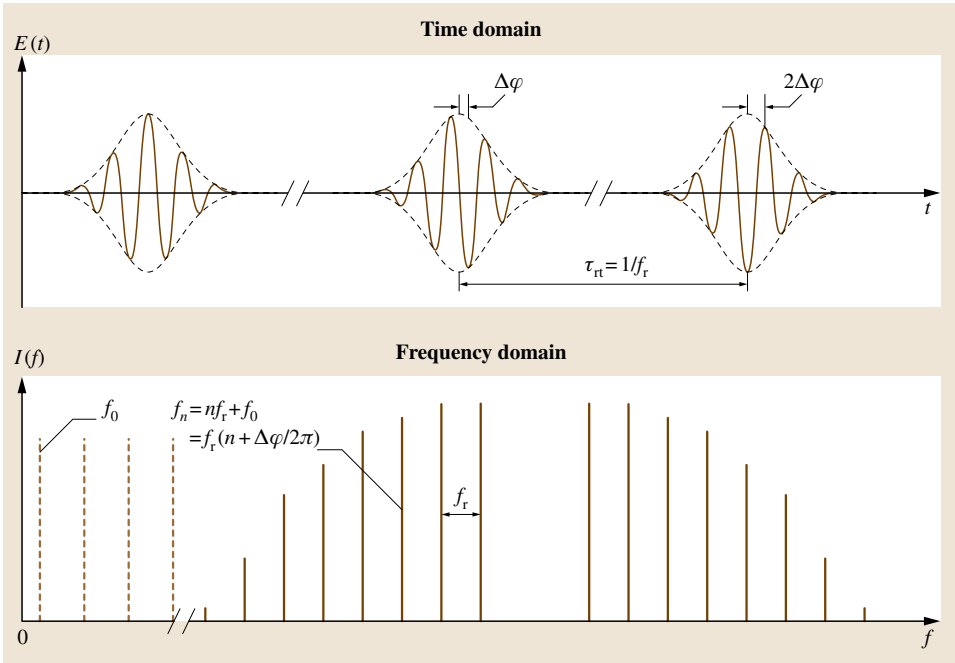

Fig. 17.1 Consecutive pulses of the pulse train emitted by a mode-locked laser and the corresponding spectrum. *Upper trace*: as the carrier wave moves with the phase velocity while the envelope moves with a different group velocity, the carrier wave shifts by $\Delta\phi$ after each round trip with respect to the pulse envelope. *Lower trace*: this continuous shift results in a frequency offset $f_0 = \Delta\phi/\tau_{rt}$, which prevents the comb from being comprised of exact harmonics of the pulse repetition frequency f_r

tive to the pulse envelope from pulse to pulse is allowed for [17.7]. Such phase slips occur in a laser because of dispersion in the cavity. The entire comb will then be shifted relative to the integer harmonics of the repetition frequency f_r by a carrier-envelope offset frequency f_0, which equals the net phase slip modulo 2π per pulse interval. The frequency of a comb line with integer mode number n is then given by $f_n = n f_r + f_0$. The frequency of any comb line can be calculated from the two radio-frequencies f_r and f_0 together with the integer mode number n. Such a comb acts like a ruler in frequency space and can, for instance, be used to measure a large separation between two different optical frequencies in terms of the pulse repetition frequency f_r. A rigorous mathematical description of the time- and frequency-domain behavior of a mode-locked laser may be found Chap. 4 of this handbook.

17.1.2 Frequency Control of the Comb Spectrum and Self-Referencing

For the comb generated by a mode-locked laser to be useful for applications, control of its spectrum, i. e., its two degrees of freedom, the absolute position and spacing of the comb lines, is often necessary. In terms of the above description of the output pulse train, this means control of the repetition frequency f_r and the pulse-to-pulse phase shift $\Delta\phi$.

As the spacing of the comb lines f_r is simply determined by the repetition rate of the laser, measuring and controlling f_r is a rather easy task. f_r can be measured with a fast photodiode and compared or phase-locked to a microwave reference. Alternatively, an optical mode of the comb can be heterodyned against an external stable continuous-wave laser. This second approach can take advantage of the extremely low noise of stabilized narrow-linewidth lasers, which may have fractional stability exceeding that available from microwave oscillators.

The detection of the pulse-to-pulse phase-shift $\Delta\phi$ or the carrier envelope frequency f_0 is more involved. In fact, generating f_0 became possible only in 1999 [17.8, 9] by beating different harmonics (3.5th and 4th) of different components of the comb. As considerable effort has been needed to generate the required harmonics, the task simplified [17.10–12] dramatically with the availability of octave spanning frequency combs. A simple way of self-referencing is indeed possible when an octave-spanning comb is produced e.g. with a photonic crystal fiber [17.13]. By frequency doubling the modes directly (Fig. 17.2), the carrier envelope-offset beat frequency $f_0 = 2f_n - f_{2n}$ is produced by a large number of modes depending on the bandwidth of the second har-

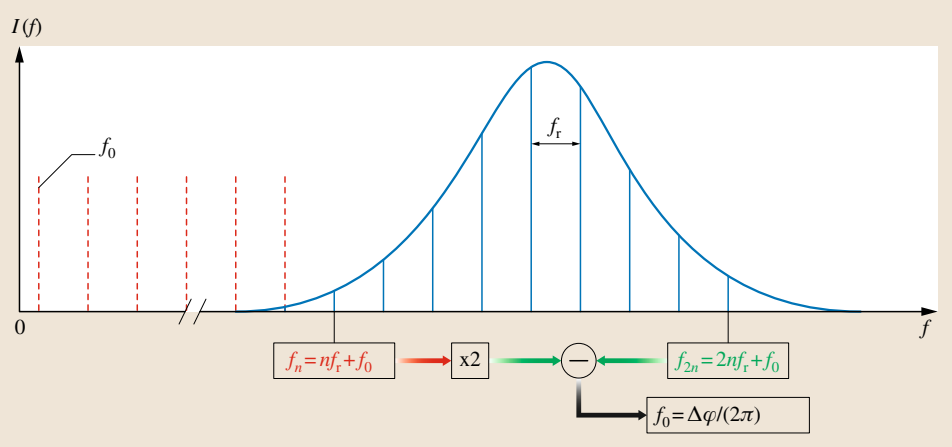

Fig. 17.2 Principle of the self-referenced optical frequency comb synthesizer. A mode with the mode number n at the low-frequency wing of the comb and whose frequency is given by $f_n = n f_r + f_0$ is frequency doubled in a nonlinear crystal. When the frequency comb covers a full optical octave, a mode with the number $2n$ oscillates simultaneously at $f_{2n} = 2n f_r + f_0$. The beat note between the frequency-doubled mode and the mode at $2n$ yields the carrier envelope offset frequency $2f_n - f_{2n} = f_0$

monic generation crystal. To bring all these beat notes in phase, both pulses, the original *high optical frequency* pulse and the frequency-doubled *low optical frequency* pulse must arrive at the f_0 detector at the same time. An optical delay line may accomplish this. With this setup, called a $f-2f$ interferometer, the two radio frequencies that set the degrees of freedom of a comb are determined. To obtain a stable comb for absolute optical-frequency measurements, it is advantageous to phase lock both f_r and f_0 to a precise radio-frequency reference such as a cesium atomic clock or GPS-controlled quartz oscillator. Alternatively, another optical mode of the comb can be also heterodyned and stabilized against an external stable continuous-wave laser. To complete the stabilization loop, the adjustment on the laser, that can be used to control f_0, has to be capable of changing the difference between the intracavity group and phase velocities. The mirror may be tilted at the dispersive cavity end for a prism dispersion-controlled laser [17.9]. Today, the most widespread technique consists of modulating the pump power with an acousto-optic modulator or electrooptic modulator.

17.2 Frequency Comb Generator Technology

17.2.1 Electrooptic Modulators

Optical frequency comb generators were initially constructed [17.14] by injecting a single frequency continuous-wave laser into a high-quality optical cavity that contains a strongly driven electrooptic modulator (EOM). Dozens of sidebands typically produce comb bandwidths of a few THz, nearly 10% of the optical carrier frequency. If the absolute optical frequency of the continuous-wave laser is known, then the resulting comb can be used to directly measure nearby frequencies [17.15]. Alternatively, when the absolute frequency of the continuous wave laser is not known, a comb generator can be used to span a frequency gap in a more complex chain. EOM-based frequency combs had an immediate impact on the field of optical frequency measurement [17.16]. However, the bandwidth achievable by this technique is limited by cavity dispersion and modulation efficiency. To achieve larger bandwidth, mode-locked lasers were introduced, thus producing a true revolution in optical frequency measurement.

17.2.2 Mode-Locked Lasers

The starting point [17.17–19] in the development of frequency comb techniques based on mode-locked lasers was as early as 1976. It was indeed shown that a synchronously pumped mode-locked picosecond dye laser can produce a stable phase coherent pulse train and that the resulting comb lines can serve as a frequency ruler to measure some atomic fine structure intervals [17.20]. However, the limited span of the picosecond lasers did not make it possible to determine the phase slips of the carrier wave relative to the pulse envelope and, therefore, to know the absolute positions of the comb lines.

The progress in ultrashort pulse laser technology led to the generation of the first self-referenced frequency combs [17.10, 11] in the late 1990s with solid-state Ti:sapphire lasers that emitted around 800 nm. In most cases, their output spectra were broad but not yet octave-spanning, as required for detecting the carrier envelope frequency with the usual $f-2f$ self-referencing scheme. Additional spectral broadening in a photonic crystal fiber was then used. Initially, there was concern that this method would not preserve the coherence and thus the comb structure, but it was found that the comb structure is usually well preserved. Dispersion-managed Ti:sapphire lasers are also capable of directly generating octave-spanning spectra without the use of nonlinear fibers [17.21, 22]. Erbium [17.23, 24] and ytterbium-doped [17.25, 26] fiber lasers, emitting around 1550 and 1040 nm, respectively, are also used in conjunction with a photonic crystal fiber or a highly nonlinear dispersion-flattened fiber for spectral broadening. Fiber sources [17.27] allow a more practical, robust, alignment-free and compact setup. However, titanium–sapphire-based systems usually exhibit better noise performance. Such laser frequency comb sources are now commercially available, so that the wavelength range from 400–2000 nm is well covered. In the past decade several other femtosecond lasers have also been employed as frequency combs. They involve gain media such as Cr:LiSAF [17.28], Cr:forsterite [17.29], Yb:KYW [17.30], etc.

Extensions of frequency comb techniques to new spectral regions from THz frequencies to the extreme ultraviolet are now under exploration. THz comb generation is still emerging [17.31]. THz combs have been produced from a photoconductive antenna excited by a femtosecond-pulse train or by optical rectification. To date, the most common approach to generate short pulses in the mid-infrared and ultraviolet regions relies on the down-conversion or up-conversion of near infrared or visible mode-locked lasers through nonlinear processes, such as optical parametric generation [17.32–34], difference- [17.35, 36] and sum-frequency [17.37] generation. Although several groups have already demonstrated convincing frequency comb sources, none of them are widespread nor commercially available yet. Some of the leading laboratories in ultrashort laser sources development are currently planning to develop alternative emerging technologies based on novel quantum cascade semiconductor lasers or new solid-state laser materials. This might open up additional horizons in the next few years.

While a choice of crystals for nonlinear frequency conversion is available in the mid-infrared and ultraviolet spectral regions, this is not the case in the vacuum and extreme ultra-violet. The strategy for very high repetition frequency ultra-short pulse laser sources in the XUV (extreme ultraviolet) spectral domain is high harmonics generation. Focusing intense femtosecond laser pulses on a gas target indeed leads to the generation of high-order harmonics (HHG) of the fundamental radiation, reaching into the XUV or even x-ray range [17.38–40]. External enhancement cavities were demonstrated [17.41, 42] to hold much promise for achieving high power XUV comb generation. In such experiments the equidistant modes of an infrared or visible frequency comb (in most case Ti:sapphire and Yb-laser based systems) are injected (Fig. 17.3) in a resonant passive cavity containing the focus for the gas target. After each pass through the focus, the nonconverted portion of the light pulse is coherently overlapped with the successive pulse from the laser. This way, a power enhancement of several hundred watt and intensities of $10^{13}\,\mathrm{W/cm^2}$ or more, which are necessary for HHG, can be reached in the cavity focus (Fig. 17.4).

The most recent Ti:sapphire enhancement cavity at 50 MHz repetition frequency could stably build up average powers of 750 W and peak intensities of $4.5\times10^{14}\,\mathrm{W/cm^2}$ [17.43]. With this, unprecedented conversion efficiencies of the order of 10^{-7} reached. High-reflectivity mirror designs enabling to manage dispersion in order to couple the full spectral bandwidth of the seeding comb to the resonator and to sustain the required high intra-cavity average circulating power are one of the technical challenges to generating XUV radiation via an enhancement cavity. Another one has been the lack of a suitable method [17.44] to couple the harmonic light out of the cavity. Since there is essentially no solid material that is sufficiently transparent at XUV wavelengths, the XUV radiation cannot pass through the cavity mirrors without being absorbed. Approaches

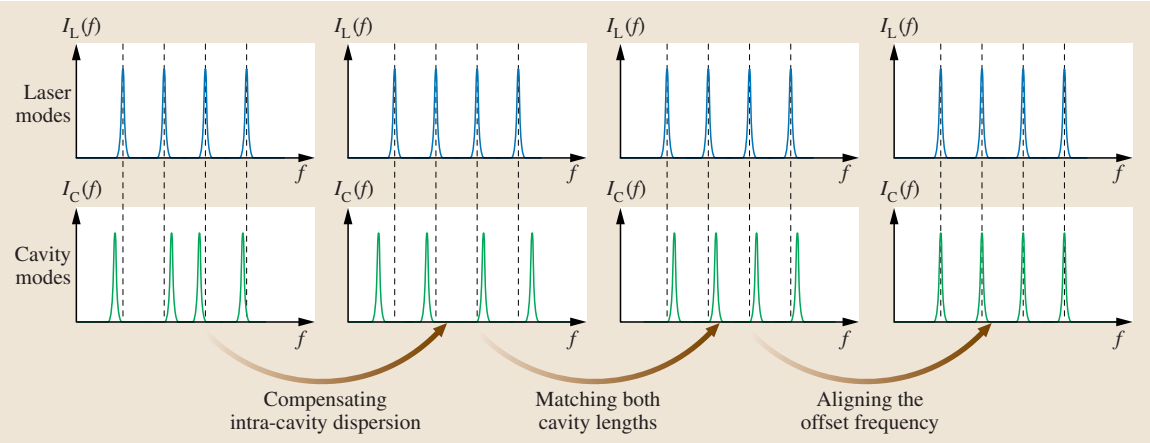

Fig. 17.3 Frequency domain picture of the injection of the modes of a frequency comb (*blue*) in a passive resonator (*green*). Three parameters have to be controlled to obtain broadband resonance: compensating the dispersion of the enhancement cavity results in equidistant cavity modes. Aligning the cavity length to the length of the laser matches the mode spacing. Adjusting the offset frequency of the seeding laser finally matches all the respective modes

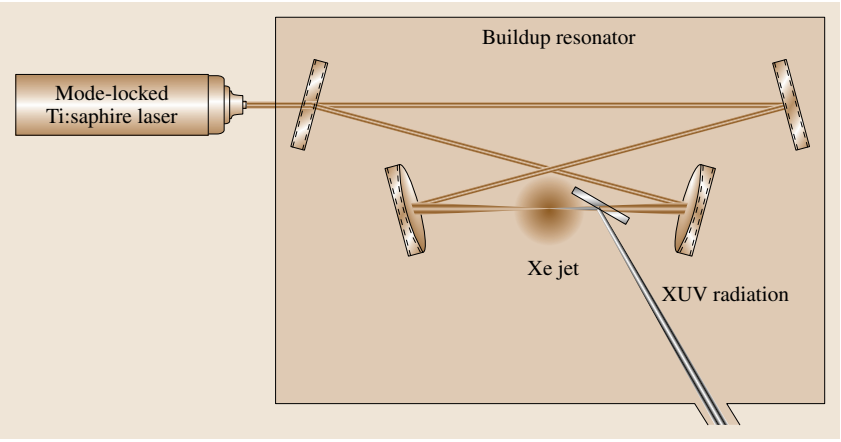

Fig. 17.4 Sketch of an experimental setup for XUV frequency comb generation in an enhancement cavity

to XUV output coupling include insertion [17.41, 42] of a plate at Brewster angle for the fundamental radiation inside the enhancement cavity, noncollinear high harmonic generation [17.45], designed cavity geometries (for instance drilling a small hole in the curved mirror after the intracavity focus, since the harmonic light will diverge less than the fundamental light), optimized design of output couplers (e.g., small period dispersion gratings [17.46]). Phase-matching effects that control the buildup of the harmonic signal over the interaction length must also be optimized with positioning the interaction region after the focus of the beam in the cavity or guiding the ultrashort fundamental pulses in waveguides. Extremely high power high repetition frequency amplifiers [17.47] may also allow an alternative approach to efficient direct high harmonic generation without the need of an enhancement cavity. Once the XUV radiation is generated, the frequency-comb structure must be characterized. As the HHG process is extremely nonlinear, it is a significant concern that frequency-comb coherence could not be maintained through HHG. So far, only the coherence between one pulse and the next one has been experimentally proven [17.48] in the seventh harmonic of the fundamental radiation from a high-power mode-locked femtosecond fiber laser at 1070 nm.

With the exception of Ti:sapphire and Yb:fiber lasers, which have been demonstrated with repetition frequencies up to 10 GHz [17.49] and 1 GHz [17.50], respectively, most frequency comb generators operate

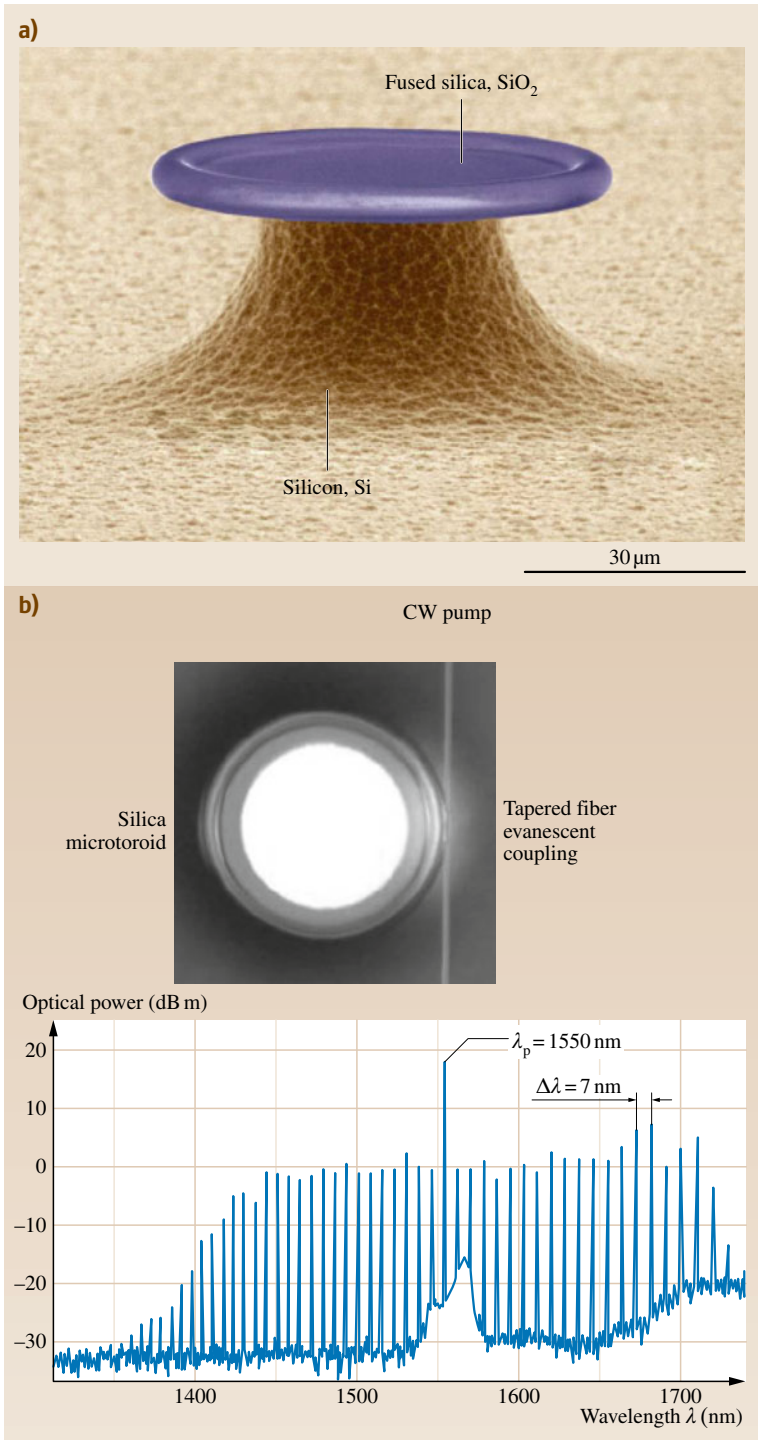

Fig. 17.5 **(a)** Scanning electron microscope image of a fused silica microtoroidal whispering gallery mode resonator (*colored*) (after [17.51]). **(b)** Top-view of a silica toroid and a spectrum measured at the output of the tapered optical fiber. The individual modes are spaced by the free spectral range of the resonator (after [17.51])

at repetition frequencies of a few hundred megahertz. The suitable repetition frequency is application dependent. For precision spectroscopy, the range of a few hundred megahertz up to a few gigahertz is often desirable, with some small tunability for the determination of the mode index. Direct resolution of individual modes with e.g., dispersive spectrometers is needed in applications related to astronomy or line-by-line pulse shaping. Alternatively high power per comb line is important for harnessing nonlinear phenomena in spectroscopy and in such cases repetition frequencies higher than 1 GHz are requested. On the other hand, high resolution molecular spectroscopy or nonlinear frequency conversion that reach mid-infrared or ultraviolet wavelengths involve low repetition frequencies (< 100 MHz) and high energy per pulse.

Frequency stability and noise issues are also strongly application driven. Most of the time it is desirable that the frequency comb does not add noise to the reference oscillator used to control f_r and f_0. On time scales longer than a few tens of milliseconds, it has been proven that the reference oscillator stability may indeed be transferred [17.52] on the comb emission and that the position of the comb lines may provide an accurate gear with residual uncertainty below 1×10^{-19} [17.53]. In other words, appropriate referencing and servo-control individual comb line widths, and frequency uncertainty at the 1 Hz level may be obtained of 100 THz of the comb spectral bandwidth. Any of the 10^5–10^6 individual modes of the comb acts as a frequency-stabilized continuous-wave narrow linewidth laser. On time scales shorter than 10 ms, intrinsic comb noise sources may, however, contribute substantially and may be challenging to eliminate, even with elaborated designs. These noise sources [17.27,54] include temperature and acoustic perturbations, amplified spontaneous emission, amplitude and frequency noise transferred by the pump source, and amplification of various noise in the nonlinear fiber used for spectral broadening [17.55].

17.2.3 Microresonators

Emerging novel techniques for frequency comb generation include microresonators [17.56]. Whispering gallery mode resonators such as microdiscs, microspheres, microtoroids, or microrings confine light by total internal reflection around the perimeter of an air–dielectric interface. Extremely high quality factors may be obtained, ($> 10^8$) resulting in long interaction lengths and extremely low thresholds for nonlinear optical effects.

When such a microresonator made from a third-order nonlinearity material is pumped with a continuous-wave laser, cascaded four-wave mixing leads to the generation of a frequency comb spectrum, as it has been first demonstrated in silica microtoroids in the near-infrared. In this process, two pump photons (frequency f_P) are annihilated to give rise to a pair of photons, whose frequencies are up-shifted (f_S) and down-shifted (f_I) by one cavity free spectral range with respect to the pump ($2f_P = f_S + f_I$). This process can cascade and thereby, as the parametric process is energy conserving, lead to the formation of an equidistant optical frequency comb [17.51] whose spectral properties (offset frequency and mode spacing) can be controlled [17.57]. It has also been shown that dispersion engineered microresonators enable direct octave spanning comb generation [17.58]. In and out coupling of the light to the resonator is accomplished using tapered optical fibers or total internal reflection prisms, via the overlap of the evanescent field of these devices and the evanescent portion of the whispering gallery modes. Several microresonator platforms based on this mechanism have demonstrated frequency comb generation in the near-infrared [17.51, 57–59] as well as the visible region [17.60], and more recently in the mid-infrared range [17.61]. Silica ([17.51, 57–59], Fig. 17.5), single crystals like quartz [17.62], MgF_2 [17.61, 63], or CaF_2 [17.64] or CMOS-compatible semiconductors such as InP, Ge, SiN, or Si are suitable materials [17.65–67] for frequency comb generation.

Microresonators are particularly interesting as their small diameter (typically 100 μm–10 mm) enables generation of frequency combs with large line spacing (10–1000 GHz), which have been needed for a number of recent applications. Such line spacings are difficult to obtain from mode-locked laser based frequency combs due to the short cavity length that would be needed. The compact miniaturized design, possible on-chip integration, direct fiber optical coupling, and high power per comb line also hold much promise for expanding the versatility of frequency combs and deploying them in practical applications.

17.3 Applications of Frequency Combs

The coherent nature of short pulses emitted by mode-locked lasers has hence led to a remarkable union of the two previously distinct fields of ultrafast optics and precision spectroscopy. Frequency combs can conveniently link optical and microwave frequencies, and they provide the long missing clockwork for optical atomic clocks. So far no fundamental limit of the accuracy of frequency combs has been discovered. The extension of the limits of time and frequency metrology has enabled new tests of fundamental physics laws. Precise comparisons of optical resonance frequencies of atoms, ions, and molecules with the microwave frequency of a cesium atomic clock are establishing sensitive limits for possible slow variations of fundamental constants. Extensions of frequency comb techniques to new spectral regions from THz frequencies to the extreme ultraviolet might open new spectral territories for precision spectroscopy. It was also quickly realized that important applications in many areas of science and technology could benefit from these exquisite laser sources. For instance, frequency comb techniques are providing a key to attosecond science by permitting control of the phase of the electric field of ultrashort laser pulses. The calibration of astronomical spectrographs with laser frequency combs will permit sensitive searches for earth-like planets, and precise interferometric distance measurements will allow new space missions with highly controlled formations of space vehicles.

17.3.1 Precision Spectroscopy

Spectroscopy is one of the areas where accurate frequency measurements, the physical quantities that can be determined with the highest precision, permit unique confrontations between experiment and theory. Precision spectroscopy of simple systems such as the hydrogen atom has, therefore, long played a central role in the history of atomic physics. Accurate measurements in hydrogen are, for instance, able to derive a new value of the Rydberg constant, the scaling factor for any spectroscopic transition, and the most precisely known of the fundamental constants. However, any statement about the absolute frequency of an optical transition must follow from a comparison with the time unit, the second, defined as the period during which a cesium atom oscillates 9 192 631 770 times on a hyperfine clock transition in the atomic ground state. The clockwork that would permit the phase coherent conversion of the extremely high optical frequency (hundreds of THz) to a countable signal in the microwave domain has for decades been the main impediment in this endeavor. One approach [17.68] was to build frequency chains that create successive harmonics of the cesium standard, which only worked for selected frequencies. This approach to frequency metrology proved to be very complicated and required the scale of investment that is generally found only at national research facilities. Through the development of optical frequency comb

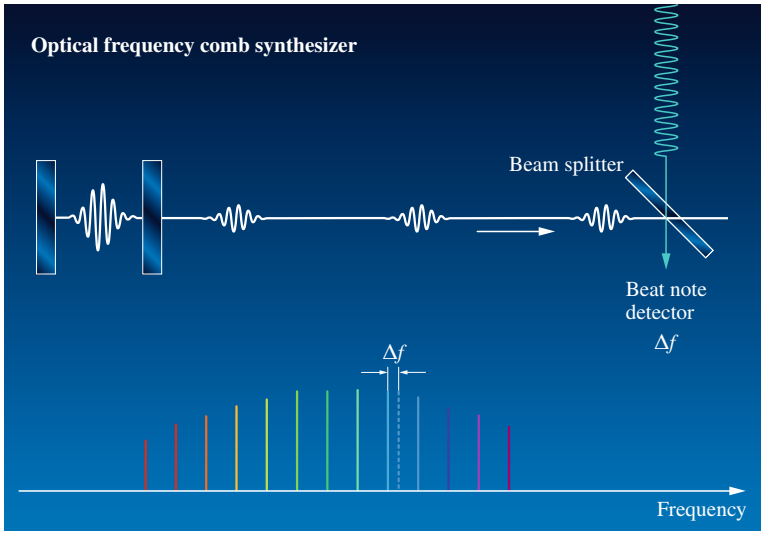

Fig. 17.6 Scheme of the measurement of the frequency of a continuous-wave laser by a femtosecond laser frequency comb synthesizer

techniques, the previous elaborate frequency chains have been replaced by a setup of the size $1 \times 1\,\mathrm{m}^2$, which is good for precision measurements of any frequency. Frequency combs have revolutionized the way the frequency of light is measured and are now common equipment in all frequency metrology-oriented laboratories.

In precision spectroscopy [17.69], the frequency comb is used (Fig. 17.6) as a frequency ruler. The unknown absolute frequency f_l of a continuous-wave laser is determined by creating a beat note f_b with the nearest mode: $f_\mathrm{l} = n f_\mathrm{r} + f_0 \pm f_\mathrm{b}$. The correct sign of f_b may be determined by a small change in either of the frequencies, and the mode number n may be determined by a coarse measurement of f_l, for example, with a wavemeter.

Frequency combs are now commonly used as tools for precision spectroscopy and they have enabled the measurement of an impressive number of frequency standards of various atomic and molecular lines. Frequency combs were initially conceived for precision spectroscopy of hydrogen, and the accurate measurement of the 1S–2S Doppler-free two-photon transition in hydrogen at 243 nm is perhaps the best illustration of the progress they enabled [17.69, 70]. Atomic hydrogen is arguably the most fundamental atomic system one can study, allowing accurate quantum electrodynamics (QED) theoretical calculations to confront precise experimental data. Precision laser spectroscopy of hydrogen enables accurate determinations of physical constants, stringent tests of fundamental theories, and searches for possible drifts of the fundamental constants. A precise determination of the absolute frequency of the sharp 1S–2S two-photon resonance is, moreover, of interest as a reference for future experiments with antihydrogen. Figure 17.7 shows the relative accuracy in optical spectroscopy of atomic hydrogen over the years. The introduction of Doppler-free laser spectroscopy in the 1970s and of optical frequency measurements in the 1990s led to major breakthroughs. Until a decade ago, the primary challenge in hydrogen spectroscopy was the precise measurement of the frequency of laser light. With the advent of frequency combs, the effort has shifted towards the assessment and control of systematic line shifts in spectroscopic measurements, as they are particularly important for very light atoms. The accuracy of such measurements will soon be limited by the performance of cesium atomic clocks. In 2010, a much improved measurement [17.71] has indeed set the fractional frequency uncertainty to 4.2×10^{-15}.

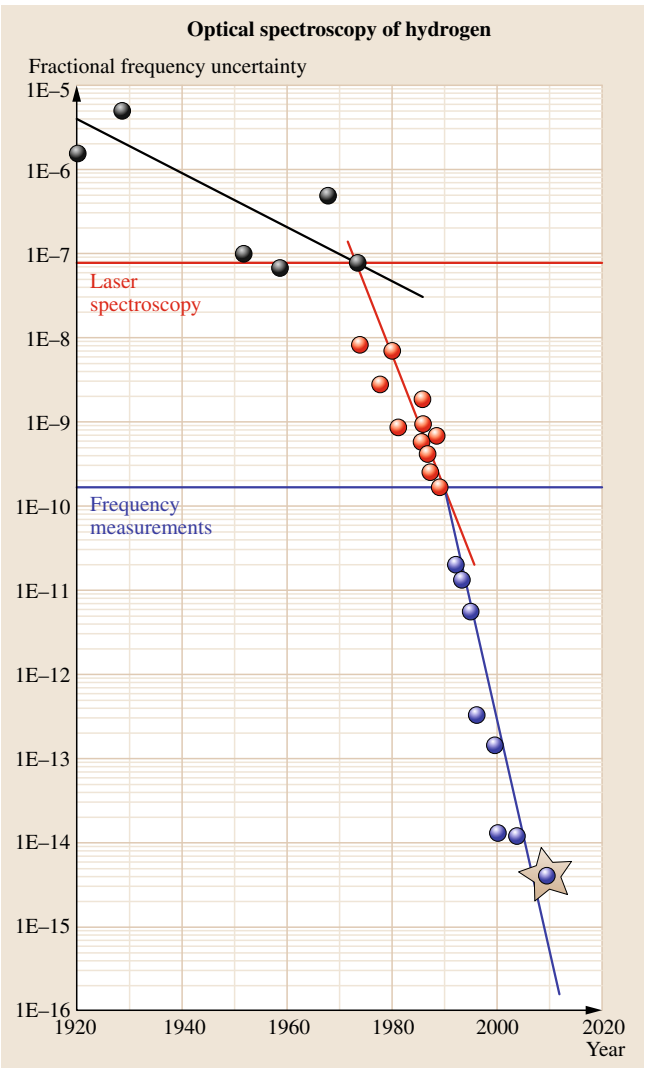

Fig. 17.7 Relative accuracy in optical spectroscopy of atomic hydrogen over years

17.3.2 Optical Clocks and Frequency Transfer

Optical Clocks

An optical clock consists, like any other clock, of an oscillator that defines the ticks in time and a counter that keeps track of these cycles. In a cesium clock, the oscillations are those of the electron precessing around the spin of the nucleus. An electronic counter advances the second hand every time the counter has completed 9 192 631 770 oscillations. This number was chosen when the SI (Système international d'unités)

second was redefined for the last time in 1967. Clocks become more accurate as the oscillation frequency increases, as a higher oscillation frequency divides time into smaller pieces. The perfection of optical frequency standards has been progressing at a much more rapid pace than that of microwave cesium clocks. With the femtosecond laser comb now available as a perfect clockwork mechanism, the efforts concentrate on ever more perfect laser frequency stabilization and on the management of systematic line shifts in precision spectroscopy of narrow optical resonances that serve as the pendulum of optical clocks. Much progress has already been made in experiments with cold trapped ions, notably Hg^+, Yb^+, In^+, and Sr^+. Cold neutral atoms such as Ca, or Sr are also appealing candidates because many atoms can be observed simultaneously without disturbing Coulomb repulsion, improving the signal-to-noise ratio and the speed with which a resonance frequency can be established. The best of these optical clocks are now surpassing (Fig. 17.8) the accuracy of even the best Cs fountain clocks. To demonstrate such a performance, a comparison with another optical clock is required. Scientists [17.72] have succeeded with such a measurement that shows the stability of two optical clocks based on single trapped Al ions. Their fractional frequency inaccuracy reaches 8.6×10^{-18} and their measured fractional frequency difference -1.8×10^{-17}. Furthermore, while it takes hours or days to compare two cesium clocks to a part in 10^{15}, two optical frequencies can be compared to this level within just seconds. Better atomic clocks will be enabling tools for many scientific and technical applications. They can extend the frontiers of precision spectroscopy and of time and frequency metrology. They will make it possible to precisely synchronize clocks over large distances. In astronomy, such synchronized clocks may allow an extension of large baseline interferometry to infrared and optical wavelengths. Better clocks can improve the performance of satellite navigation systems and the tracking of probes deep in space. Accurate clocks are also needed to synchronize optical telecommunication networks. In fundamental physics, more accurate clocks will permit more stringent tests of special and general relativity, as well as other fundamental laws.

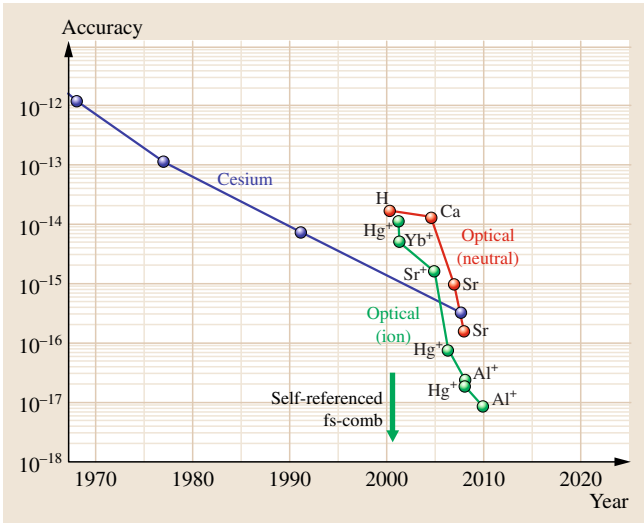

Fig. 17.8 Evolution of microwave and optical frequency clock relative uncertainty over the years. All optical measurements since 2000 have been performed with frequency combs. Now the best optical clocks are outperforming even the best cesium atomic clocks

Frequency Transfer

Frequency transfer across fiber networks [17.73–76] can take advantage of the phase coherence and broad optical bandwidths of frequency combs. A frequency comb can indeed phase-coherently link an optical clock frequency and a 1.5 μm continuous-wave laser. This continuous-wave laser is then transmitted over a fiber link containing e.g., intermediate amplifiers and active fiber noise cancelation. At the end of the link, another frequency comb translates the laser frequency to another optical frequency or the radio-frequency domain. Relative frequency uncertainties of reaching 10^{-19} are achievable over hundreds of kilometers. It then becomes possible to remotely reference precision spectroscopy experiments directly to the optical clocks of national metrology laboratories or to remotely compare two optical clocks. Frequency combs with large line spacing are also ideally suited for high-speed telecommunications. One such frequency comb generator can replace more than a hundred of conventional laser diodes to provide an absolutely referenced frequency grid for multiplexing/demultiplexing. Miniaturized combs may even create a new generation of chip-size frequency standards for space-based clock applications and long range frequency standard dissemination.

17.3.3 Waveform Synthesis

The optical synthesizer can be operated in reverse [17.77,78] to produce a countable radio-frequency output, the repetition frequency f_r, that is phase coherently linked to a sharp optical transition. Low-phase-noise microwave generation and arbitrary RF waveform generation may then be undertaken. For low-

phase-noise microwave generation, a self-referenced frequency comb is phase-locked to an ultrastable continuous-wave narrow-linewidth laser. The repetition frequency of the comb is then a fraction of the continuous-wave laser frequency, with the phase noise given by the intrinsic thermal cavity noise.

Microwave Synthesis

Photodetection of the comb repetition rate or its harmonics generates a microwave signal with a phase noise that may be lower than that achieved with room-temperature radio-frequency oscillators. Such low phase noise microwave signals may find use in technological applications such as radars, time distribution and synchronization, telecommunications, space navigation systems, and local oscillators for precise fountain atomic frequency standards.

Optical Waveform Synthesis

For several decades, electronic radio-frequency devices have been used to generate and measure arbitrary electric field waveforms. Because the frequencies involved are much higher, optical devices often generate and measure intensity waveforms, without control of the phase of the electric field. The advent of laser frequency combs has allowed the phase of an optical electric field to be measured and controlled, with respect to the corresponding intensity waveform. The development of such laser frequency combs has recently opened up [17.79] new horizons for the generation of arbitrary waveforms at optical frequencies and *line-by-line* pulse shaping [17.80]. Static *line-by-line* pulse shaping to a hyperfine spectral resolution of a few Hz on a 100 comb lines may benefit coherent control over quantum mechanical processes, such as high-sensitivity broadband spectroscopy techniques and ultrafast chemical reactions, by allowing the generation of interrogation fields optimized for the detection of a particular species. Generation of optical arbitrary waveforms has thus become conceivable and can also be used to generate an arbitrary radio-frequency waveform while avoiding the limitations imposed by digital-to-analog converters.

17.3.4 Distance Measurements

Frequency combs may be implemented through laser ranging approaches [17.81], most interestingly in a combination [17.82, 83] of multiwavelength interferometry and time-of-flight measurements. The precise time base of frequency combs indeed enable them to be employed as a spatial ruler, where the accuracy is only limited by the variations in the index of refraction over the measurement path. To date specular reflectors are needed because the power in each comb line is still too low to compete with a continuous-wave laser. Therefore, for LIDAR (light detection and ranging) applications to a diffuse target, conventional lasers using a frequency comb as a frequency ruler are still preferable.

17.3.5 Astronomy

In astronomy the need for ever more precise measurements of spectral lines has reached the degree where classical calibration sources – spectral lamps – are no longer sufficient. A direct measurement of the continuing expansion of the universe could be made by studying the Hubble flow in the forest of Lyman-alpha absorption lines of intergalactic atomic hydrogen clouds illuminated by distant quasars. However, this would require measurements of Doppler velocity drifts of $\sim 1\,\mathrm{cm\,s^{-1}\,yr^{-1}}$, and astronomical spectrographs have not yet been calibrated to such accuracy. Comparisons from different instruments in different locations, years or decades apart, also require high traceability of the spectrographs. Similarly, extrasolar Neptune-size planets can currently be detected with spectrographs, such as the high-performance échelle spectrograph high accuracy radial velocity planet searcher (HARPS) at the European Southern Observatory's (ESO) 3.6 m telescope at La Silla, Chile. HARPS achieves an accuracy of better than 1 m/s. Significantly improved performance is still necessary to discover Earth-like extrasolar planets. For the next generation of telescopes and spectrometers new calibration techniques need to be developed to improve the precision with which stellar light can be measured.

Calibration lamps with an accuracy of about 10^{-8} enable the determination of the Doppler shift of a spectral line down to a few m/s. A frequency comb locked to an atomic clock can have an accuracy of 10^{-14}, which would in theory enable a Doppler shift measurement of the order of μm/s. The real challenge is to transfer the accuracy of the comb to the spectrometer. For a frequency comb to enable precise online calibration of an astronomical spectrometer, the comb modes must be resolved by the spectrometer. For astronomical spectrographs a resolving power of 10^5 is the trade-off between resolution and detection efficiency. Frequency combs of sufficiently large mode spacing (> 10 GHz) over bandwidths of hundreds of nanometers are therefore needed [17.84]. Because a reliable frequency comb with such a repetition rate is hardly available, one ap-

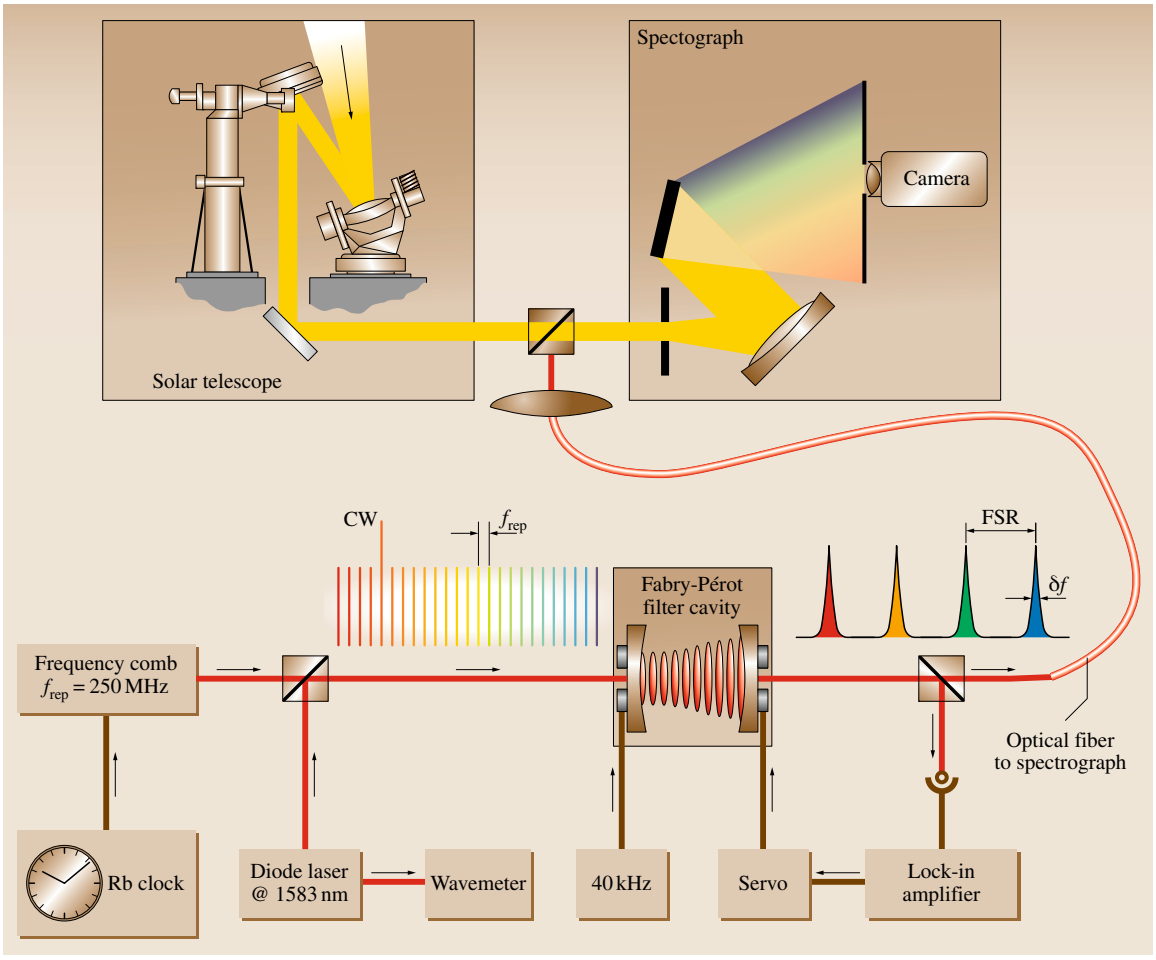

Fig. 17.9 Sketch of an astro-comb experimental setup, as developed at the Vacuum Telescope Tower at Tenerife. Superimposing the frequency comb with light from the Sun enables calibration of its emission or absorption spectrum against an atomic clock. An erbium-doped fiber frequency comb with 250 MHz repetition frequency is filtered with a Fabry–Pérot cavity (FPC) to increase the effective mode spacing, allowing it to be resolved by the spectrograph. The frequency comb is controlled by a rubidium atomic clock. A continuous-wave near-infrared laser is locked to one comb line and simultaneously fed to a wavemeter. Even though the wavemeter is orders of magnitude less precise than the laser frequency comb, it is sufficiently accurate to identify the mode number n. The FPC length, defining the final comb line spacing , is controlled by feedback from its output (after [17.86])

proach (Fig. 17.9) has been pulse rate multiplication in cascaded filter cavities [17.85–90]. Other alternatives include harmonically mode-locked lasers [17.91] or microresonators.

A number of experimental demonstrations have been reported in recent years at various telescopes including the Vacuum Telescope Tower at Tenerife [17.86], the Whipple Observatory at Amado, Arizona [17.89], and the 3.6 m telescope of the ESO at La Silla, Chile [17.88]. Covering one echelle order of the HARPS spectrograph of the ESO instead of all 72 was already sufficient [17.88] to calibrate the instrument with the same repeatability (15 cm/s in a single 80 s exposure) as with traditional spectral lamps, which need to be averaged over all 72 orders. In addition, irregularities in the pixels of the charge-coupled device (CCD) sensor array could be characterized, resulting in an improvement of the spectrograph's absolute calibra-

tion (reaching 5 MHz when averaging all acquisitions over a few hours) by more than one order of magnitude. Covering the whole visible range by spectral broadening of the frequency comb in a highly nonlinear fiber might, therefore, enable Doppler-shift measurements at the cm/s repeatability level within a few minutes-long acquisition.

17.3.6 Attosecond Science

The crucial impact of carrier envelope phase stabilization on attosecond science [17.92] has also paved the way to the stable and reproducible production of isolated attosecond pulses. The applications of ultrafast laser science require an ever higher control over the production of intense ultrashort laser pulses, e.g., for the development of compact, brilliant particle and x-ray sources. Techniques for adjusting spatial and temporal intensity pulse profiles and the sweep of carrier frequency across the electric field are already well established, as are methods for pulse diagnostics, which can fully characterize the envelope of the pulse and its chirp, that are an integral part of any control scheme. However, the time-dependent polarization state of the pulse field on the scale of a single optical cycle is a crucial requirement for strong-field applications sensitive to the strength of individual light-wave cycles within the laser pulse. As ultrashort-pulse laser systems approach the single-cycle regime, the electric-field strength of the pulses varies substantially from peak to peak of every optical half cycle. Control of the evolution of the electric field underneath the pulse envelope for ultrashort waveforms of light may be then achieved by detection and stabilization of the carrier-envelope phase. Therefore, there is currently a lot of activity aimed at the development of carrier envelope phase diagnostics. The detection and stabilization of the carrier envelope phase also allowed [17.93] complete recovery of the electric field transients of ultra short pulses. Measuring the pulses' autocorrelation together with the determination of the carrier envelope phase via spectral analysis of high harmonics permits the calculation of the field transient. A more direct measurement probes [17.94] the variation of the field strength with an attosecond electron burst. The field transient can then be sampled with a temporal resolution shorter than one optical cycle.

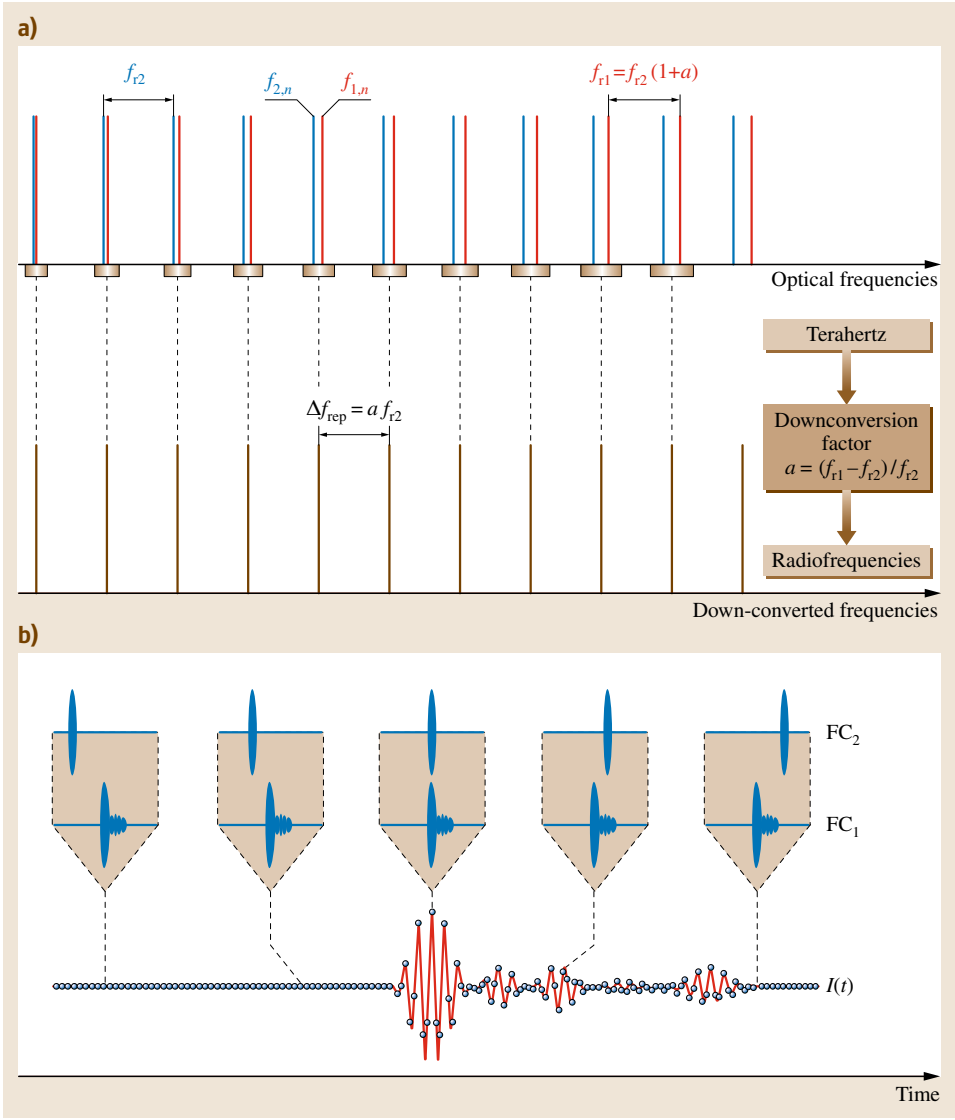
17.3.7 Molecular Spectroscopy

As for precision spectroscopy of simple atomic systems, in molecular spectroscopy the comb may serve [17.95] as a frequency ruler against which the frequency of a continuous-wave laser used to probe the sample is measured. Alternatively experiments where a frequency comb excites [17.96] the fluorescence of an atomic sample have also been performed and may be extended to molecules.

However in recent years, novel techniques have been developed in which the comb directly interrogates the sample. The promises held by such methods are such that dramatic advances in molecular science may also be foreseen. Direct absorption frequency comb spectroscopy results in short measurement time and high accuracy over a broad spectral bandwidth. Such advances have been demonstrated with dispersive [17.97] and Fourier transform spectrometers [17.98–101]. Fourier spectrometers record the spectroscopic signal on a single photodetector and, therefore, present the advantage of an almost unlimited spectral span in any spectral region with Doppler limited resolution.

The measurement sensitivity may additionally be significantly improved with the coherent coupling of a laser frequency comb to a high-finesse cavity containing the sample. Cavity-enhanced and cavity-ring-down spectroscopies are widely used for ultrasensitive spectroscopic absorption measurements [17.102] and for a long time they have led to remarkable progress in fundamental spectroscopy and nonintrusive trace-gas sensing when practiced with tunable narrow bandwidth lasers. In one approach to cavity-enhanced frequency comb spectroscopy, the spectral analysis of the light transmitted through the cavity is performed with dispersive spectrometers, usually equipped with detector arrays. This results in massively parallel spectra [17.103] recorded in a spectral span typically 10 nm broad with GHz resolution and ms acquisition time. Although dispersive spectrometers do not generally allow one to directly resolve the comb lines in a motionless short measurement, scanning the comb and cavity modes [17.104] and implementing Vernier techniques [17.105] has proved to be successful in improving the resolution, at the price of longer and sequential recordings. However, large detector arrays are not conveniently available in the mid-infrared molecular fingerprint spectral region, where most molecules have intense rovibrational signatures.

Furthermore, recent experiments [17.106–111] of multiheterodyne frequency comb Fourier transform (FT) spectroscopy (also called dual-comb spectroscopy) have demonstrated that the precisely spaced spectral lines of a laser frequency comb can be harnessed for



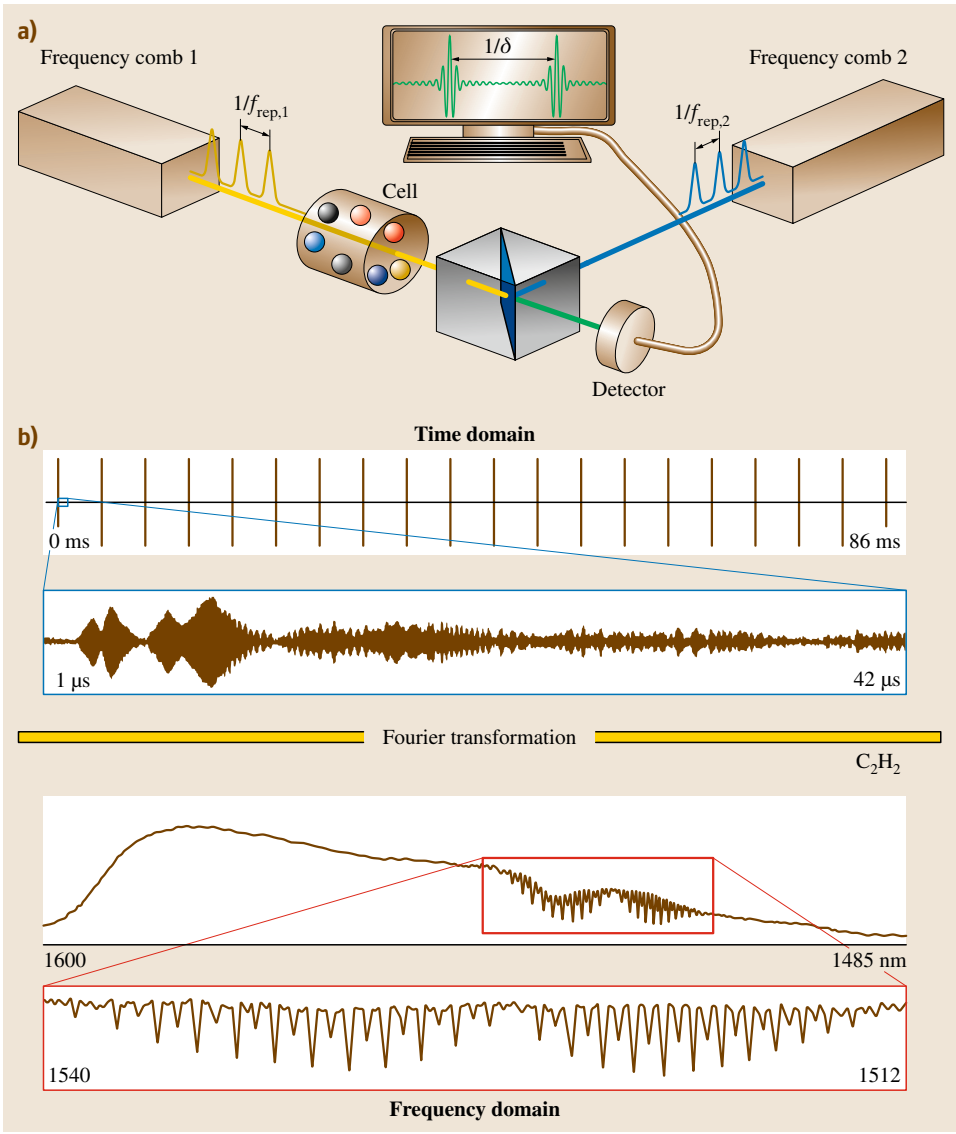


Fig. 17.10a,b Physical principle of dual comb spectroscopy. The repetition frequency of the two lasers is f_{r1} and f_{r2}, respectively, and they differ by $\Delta f_r \ll f_{r1}$. The technique requires that the differences $f_{r1} - f_{r2}$ and $f_{01} - f_{01}$ be kept constant during the measurement or to monitor their variations so as to make a posteriori corrections. **(a)** In the frequency domain, the reference comb 2 with f_{r2} line spacing acts as a highly multiplexed heterodyne receiver to generate a radio-frequency comb. **(b)** In the time domain, the reference comb FC2 pulse train slowly walks through the interrogating pulses from FC1 to generate a measurement $I(t)$ of the interrogating electric field

the rapid and sensitive acquisition of highly multiplexed spectra of molecules.

In one such experiment [17.106], an absorbing molecular gas was placed inside an optical cavity matched to the laser resonator so that it was simultaneously resonant for each comb line. The sensitivity for weak absorption was thus much enhanced because the effective path-length was increased, as in massively parallel cavity ring-down spectroscopy. The information encoded by this interrogating comb then needs to be retrieved

by a spectrometer. This is achieved by heterodyning the interrogating comb with a second comb, which serves as a reference. This provides simultaneous and accurate access to a broad spectral bandwidth within a short measurement time and can physically be equally understood in terms of time domain interferences, multiheterodyne detection, optical free induction decay, linear optical sampling, or cross-correlation between two electric fields. In practice, the light transmitted by the cavity is superimposed on a second frequency comb with a slightly different repetition frequency. A single fast photodetector then produces an output signal with a comb of radio frequencies due to interference between pairs of optical comb lines. In the frequency domain (Fig. 17.10a), the optical spectrum is thus effectively mapped into the radio frequency regime, where it becomes accessible to fast digital signal processing. In the time domain (Fig. 17.10b), the pulse train of the interrogating comb excites the absorbing sample at regular time intervals. A second pulse train of different repetition frequency interferometrically samples the transient response or *free induction decay* of the medium, akin to

Fig. 17.11 **(a)** Experimental setup for dual comb spectroscopy. Two frequency combs, 1 and 2, have slightly different line spacing. One of these combs (1) is transmitted through the cell (which may be a single-pass cell or an enhancement resonator) and heterodyned against the second comb (2) yielding a down-converted radio-frequency comb containing information on the absorption and dispersion experienced by each line of the comb 1. Other implementations allow the two combs to interrogate the sample. **(b)** The *upper part* shows an experimental interferogram. Due to the slight mismatch between the constant repetition frequencies of the pulses of the two combs, the interferogram repeats itself at a period that is the inverse of the difference in the repetition frequencies of the two lasers. Strong bursts occur when pulses from the two lasers overlap. On one side of these bursts, the modulation of the interferogram, zoomed on in the *second row* of **(b)**, is due to the molecular signatures. When a single comb interrogates the sample, the resulting interferometer can indeed be viewed as the equivalent of a dispersive Fourier transform Michelson interferometer, in which the sample is placed in one arm of the spectrometer. The Fourier transform of a small part of the interferogram time sequence reveals the spectrum recorded with Er-doped frequency combs. A spectrum of acetylene (C_2H_2) in the region of the $\nu_1 + \nu_3$ overtone band spanning 115 nm is measured within a single recording of 42 μs, which brings a unapodized resolution of 3 GHz. For comparison, recording such a spectrum with a conventional Fourier transform spectrometer requires more than 10 s. When compared to Michelson-based FT spectroscopy, the method indeed demonstrates a million-fold improvement in recording times at identical signal-to-noise ratio ◀

an optical sampling oscilloscope. Here the phase correlations between successive laser pulses are crucial for reproducible sampling, even if the free induction decay occurs on a time scale that is short compared to the time interval between two laser pulses.

Even the first proof-of-principle experiments (Fig. 17.11), carried out in the near-infrared region which is of limited interest to sensitive molecular spectroscopy, demonstrated a very exciting potential of dual-comb spectroscopy without moving parts for ultra-rapid and ultra-sensitive recording of complex molecular spectra. Compared to conventional Michelson-based Fourier transform spectroscopy, recording times were shortened from seconds to microseconds [17.106], with intriguing prospects for spectroscopy of short lived transient species or for hyperspectral imaging. The resolution improves proportionally to the measurement time. Therefore longer recordings allow high resolution spectroscopy of molecules with extreme precision [17.108, 109], since the absolute frequency of each laser comb line can be known with the accuracy of an atomic clock.

17.4 Conclusion

One decade after the first demonstration of frequency combs and the revolution they produced in optical frequency metrology, optical frequency synthesis, and optical atomic clocks, most frequency metrology laboratories around the world use frequency comb synthesizers as a common laboratory tool. The growing tree of applications of laser frequency combs ranging from attosecond science to telecommunications and satellite navigation, brings much confidence; in the fact there will be new unexpected discoveries in many areas of science and technology, as the frontiers of the development of these ground-breaking photonic tools are advanced. Applications beyond the laboratory are in progress and they also promise very exciting results in the near future.

18. Quantum Optics

Quantum optics is the study of the quantum theory of light at low energies and interactions with bound electronic systems. We discuss physically achievable states of the electromagnetic field, including squeezed states and single photons states, as well as schemes by which they may be generated and measured. Measured systems are necessarily open systems and we discuss how dissipation, noise and decoherence is treated in quantum optics in terms of Markov master equations, quantum trajectories and quantum stochastic differential equations. Quantum optics has recently proved a valuable test-bed to implement new communication protocols such as teleportation and quantum information processing and we discus some of these new schemes including ion traps and linear optics quantum computing.

18.1 Quantum Fields

Quantum optics is the study of the quantum theory of light at low energies. It is a special case of quantum electrodynamics (QED) for the electromagnetic field with frequencies ranging from microwave to ultraviolet and electrons bound in atomic systems. We consider first of all the free electromagnetic field described classically by the vector potential $\boldsymbol{A}(\boldsymbol{x}, t)$. As this obeys the wave equation it may be expanded in terms of plane wave states with two orthogonal transverse polarisations. If we assume the field is bound in a box of volume V, with Dirichlet boundary conditions, we find that

$$\boldsymbol{A}(\boldsymbol{x}, t) = \sum_{n,\nu} \sqrt{\frac{\hbar}{2\epsilon_o \omega_n V}} \times \boldsymbol{e}_{n,\nu} \left(\mathrm{e}^{\mathrm{i}(\boldsymbol{k}_n \cdot \boldsymbol{x} - \omega_{nt})} \alpha_{n,\nu} + \mathrm{e}^{-\mathrm{i}(\boldsymbol{k}_n \cdot \boldsymbol{x} - \omega_n t)} \alpha^*_{n,\nu} \right) , \quad (18.1)$$

where $\boldsymbol{e}_{n,\nu}$ are two orthonormal polarisation vectors ($\nu = 1, 2$) which satisfy $\boldsymbol{k}_n \cdot \boldsymbol{e}_{n,\nu} = 0$, as required for a transverse field, and the frequency is given by the dispersion relation $\omega_n = c|\boldsymbol{k}_n|$. The positive- and negative-frequency Fourier amplitudes are, respectively, $\alpha_{n,\nu}$ and $\alpha^*_{m,\nu}$. The corresponding electric field is given by

$$\boldsymbol{E}(\boldsymbol{x}, t) = \mathrm{i} \sum_{n,\nu} \sqrt{\frac{\hbar\omega_n}{2\epsilon_o V}} \times \boldsymbol{e}_{n,\nu} \left(\mathrm{e}^{\mathrm{i}(\boldsymbol{k}_n \cdot \boldsymbol{x} - \omega_n t)} \alpha_{n,\nu} - \mathrm{e}^{-\mathrm{i}(\boldsymbol{k}_n \cdot \boldsymbol{x} - \omega_n t)} \alpha^*_{n,\nu} \right) . \quad (18.2)$$

Canonical quantisation [18.1] is now carried out by promoting these Fourier amplitudes to the operators $\alpha_{n,\nu} \mapsto a_{n,\nu}$, $\alpha^*_{n,\nu} \mapsto a^\dagger_{n,\nu}$ with bosonic commutation relations

$$[a_{n,\nu}, a^\dagger_{n',\nu'}] = \delta_{\nu\nu'} \delta_{nn'} \quad (18.3)$$

with all other commutations relations zero (we are assuming Coulomb gauge quantisation). The canonical quantisation procedure then gives the Hamiltonian for the free field as

$$H = \sum_k \hbar\omega_k a^\dagger_k a_k , \quad (18.4)$$

where the subscript k stands for both the wave number index, n and polarisation index ν. We have explicitly omitted the constant shift due to the vacuum energy of $\hbar\omega_k/2$ per mode. Typically we now take the continuum limit by

$$\frac{1}{\sqrt{V}}\sum_k \mapsto \frac{1}{(2\pi)^{3/2}}\int \mathrm{d}^3k a_\nu(\boldsymbol{k})\,. \tag{18.5}$$

The canonical commutation relations then take the form

$$\left[a_\nu(\boldsymbol{k}), a^\dagger_{\nu'}(\boldsymbol{k}')\right] = \delta_{\nu\nu'}\delta^3(\boldsymbol{k}-\boldsymbol{k}')\,. \tag{18.6}$$

In the full theory of QED, the interaction between the electromagnetic field and charged matter is described by coupling between the vector potential and the Dirac spinor field. In quantum optics we only need the low-energy (nonrelativistic) limit of this interaction. This is given by the minimal coupling Hamiltonian [18.2]

$$H = \frac{1}{2m}(\boldsymbol{p}-e\boldsymbol{A})^2 + eV(\boldsymbol{x}) + H_{\mathrm{rad}}\,, \tag{18.7}$$

where $\boldsymbol{p}$ is the momentum operator for a particle of charge e moving in a Coulomb potential $V(\boldsymbol{x})$. The last term, H_{rad}, is the Hamiltonian of the free radiation field given in (18.4). We now use an occupation-number representation in the antisymmetric sector of the many body Hilbert space for the electronic system based on a set of single-particle states $|\phi_j\rangle$, with position probability amplitudes, $\phi_j(\boldsymbol{x})$, which we take as the bound energy eigenstates of the electronic system without radiation. They could for example be the stationary states of a atom, the quasi-bound states of a single Cooper pair on a mesoscopic superconducting metal island, or the bound exciton states of semiconductor quantum dot. We then define the electronic field operators

$$\hat\psi(\boldsymbol{x}) = \sum_j c_j\phi_j(\boldsymbol{x})\,, \tag{18.8}$$

where the appropriate commutations relations for the antisymmetric sector are the fermionic forms

$$c_k c_l^\dagger + c_l c_k^\dagger = \delta_{kl}\,, \tag{18.9}$$

$$c_k c_l + c_l c_k = c_k^\dagger c_l^\dagger + c_l^\dagger c_k^\dagger = 0\,. \tag{18.10}$$

In the occupation number representation the Hamiltonian may be written as the sum of three terms, $H = H_{\mathrm{el}} + H_{\mathrm{I}} + H_{\mathrm{rad}}$ where the electronic part is given by

$$\begin{aligned} H_{\mathrm{el}} &= \int \mathrm{d}^3\boldsymbol{x}\hat\psi^\dagger(\boldsymbol{x})\left[-\frac{\hbar^2}{2m}\nabla^2 + eV(\boldsymbol{x})\right]\hat\psi(\boldsymbol{x}) \\ &= \sum_j E_j c_j^\dagger c_j\,. \end{aligned} \tag{18.11}$$

The interaction part may be written as the sum of two terms $H_{\mathrm{I}} = H_{\mathrm{I},1} + H_{\mathrm{I},2}$, where

$$\begin{aligned} H_{\mathrm{I},1} = \int \mathrm{d}^3\boldsymbol{x}\hat\psi^\dagger(\boldsymbol{x}) \\ \times\left\{-\frac{e}{2m}[\boldsymbol{A}(\boldsymbol{x})\cdot\boldsymbol{p} + \boldsymbol{p}\cdot\boldsymbol{A}(\boldsymbol{x})]\right\}\hat\psi(\boldsymbol{x})\,, \end{aligned} \tag{18.12}$$

$$H_{\mathrm{I},2} = \int \mathrm{d}^3\boldsymbol{x}\hat\psi^\dagger(\boldsymbol{x})\left\{\frac{e^2}{2m}[\boldsymbol{A}(\boldsymbol{x})^2]\right\}\hat\psi(\boldsymbol{x})\,. \tag{18.13}$$

Unless we are dealing with very intense fields for which multi-photon processes are important, the second term $H_{\mathrm{I},2}$ may be neglected.

The dominant interaction energy may then be written as

$$H_{\mathrm{I}} = \hbar\sum_{\boldsymbol{k},n,m} g_{\boldsymbol{k},n,m}(b_{\boldsymbol{k}} + b_{\boldsymbol{k}}^\dagger)c_n^\dagger c_m\,, \tag{18.14}$$

where the interaction coupling constant is

$$\begin{aligned} g_{\boldsymbol{k},n,m} = -\frac{e}{m}\left(\frac{1}{2\epsilon_0\hbar\omega_k V}\right)^{1/2} \\ \times\int \mathrm{d}^3\boldsymbol{x}\phi_n^*(\boldsymbol{x})(\mathrm{e}^{\mathrm{i}\boldsymbol{k}.\boldsymbol{x}}\boldsymbol{p})\phi_m(\boldsymbol{x})\,. \end{aligned} \tag{18.15}$$

We now proceed by making the *dipole approximation*. The factor $\mathrm{e}^{\mathrm{i}\boldsymbol{k}\boldsymbol{x}}$ varies on a spatial scale determined by the dominant wavelength scale, λ_0, of the field state. At optical frequencies, $\lambda_0 \approx 10^{-6}$ m. However the atomic wave functions, $\phi_n(\boldsymbol{x})$ vary on a scale determined by the Bohr radius, $a_0 \approx 10^{-11}$ m. Thus we may remove the oscillatory exponential from the integral and evaluate it at the position of the atom $\boldsymbol{x} = \boldsymbol{x}_0$. Using the result

$$[\boldsymbol{p}^2, \boldsymbol{x}] = -\mathrm{i}2\hbar\boldsymbol{p} \tag{18.16}$$

we can write the interaction in terms of the atomic dipole moments

$$\begin{aligned} \int \mathrm{d}^3\boldsymbol{x}\phi_n^*(\boldsymbol{x})(\mathrm{e}^{\mathrm{i}\boldsymbol{k}.\boldsymbol{x}}\boldsymbol{p})\phi_m(\boldsymbol{x}) \\ = \mathrm{i}\frac{m}{e}\omega_{nm}\int \mathrm{d}^3\boldsymbol{x}\phi_n^*(\boldsymbol{x})(e\boldsymbol{x})\phi_m(\boldsymbol{x})\,, \end{aligned} \tag{18.17}$$

where $\omega_{nm} = (E_n - E_m)/\hbar$.

In the interaction picture the interaction Hamiltonian becomes explicitly time dependent,

$$\begin{aligned} \tilde H_{\mathrm{I}}(t) = \hbar\sum_{\boldsymbol{k},n,m} g_{\boldsymbol{k},n,m}\left(b_{\boldsymbol{k}}\,\mathrm{e}^{-\mathrm{i}\omega(\boldsymbol{k})t} + b_{\boldsymbol{k}}^\dagger\,\mathrm{e}^{\mathrm{i}\omega(\boldsymbol{k})t}\right) \\ \times c_n^\dagger c_m\,\mathrm{e}^{\mathrm{i}\omega_{nm}t}\,, \end{aligned} \tag{18.18}$$

where the tilde indicates that we are in the interaction picture. If the field is in a state for which the dominant frequency is such that $\omega(\boldsymbol{k}_0) \approx \omega_{nm}$, the field is resonant with a particular atomic transition and we may neglect terms rotating at the very high frequency $\omega(\boldsymbol{k}) + \omega_{nm}$. This is known as the *rotating wave approximation*. This assumes that the field strength is not too large and further that the state of the field does not vary rapidly on a time scale of ω_{nm}^{-1}, i. e. we ignore fields of very fast strong pulses. As a special case we assume that the field is resonant (or near-resonant) with a single pair of levels with $E_2 > E_1$. The interaction picture Hamiltonian in the dipole and rotating wave approximation is then given by

$$\tilde{H}_{\mathrm{I}} = \hbar \sum_{\boldsymbol{k}} c_1^\dagger c_2 b_{\boldsymbol{k}}^\dagger g_{\boldsymbol{k}} \, \mathrm{e}^{-\mathrm{i}(\omega(\boldsymbol{k})-\omega_{21})t} + \mathrm{h.c}\,, \tag{18.19}$$

where

$$g_{\boldsymbol{k}} = -\mathrm{i}\,[2\hbar\epsilon_0\omega(\boldsymbol{k})V]^{-1/2}\,\mu_{21}\,\mathrm{e}^{\mathrm{i}\boldsymbol{k}.\boldsymbol{x}_0} \tag{18.20}$$

and

$$\mu_{21} = \omega_a \langle\phi_n|e\boldsymbol{x}|\phi_m\rangle \tag{18.21}$$

with $\omega_a = \omega_2 - \omega_1$.

It is conventional to describe the operator algebra of a two-level system in terms of a peusdo-spin representation by noting that the Pauli operators may be defined as

$$\sigma_z = c_2^\dagger c_2 - c_1^\dagger c_1\,, \tag{18.22}$$

$$\sigma_x = c_2^\dagger c_1 + c_1^\dagger c_2\,, \tag{18.23}$$

$$\sigma_y = -i\left(c_2^\dagger c_1 - c_1^\dagger c_2\right), \tag{18.24}$$

$$\sigma_+ = \sigma_-^\dagger = c_2^\dagger c_1\,. \tag{18.25}$$

The operators $s_\alpha = \sigma_\alpha/2$ (with $\alpha = x, y, z$) then obey the SU(2) algebra for a spin-half system. In terms of these operators we may write the total Hamiltonian for the system of field plus atom in the dipole and rotating wave approximation as

$$H = \sum_{\boldsymbol{k}} \hbar\omega(\boldsymbol{k}) b_{\boldsymbol{k}}^\dagger b_{\boldsymbol{k}} + \frac{\hbar\omega_{\mathrm{a}}}{2}\sigma_z + \hbar \sum_{\boldsymbol{k}} g_{\boldsymbol{k}} b_{\boldsymbol{k}} \sigma_+ + \mathrm{h.c.} \tag{18.26}$$

If we further restrict the state of the field to include only a single mode, perhaps using a high-Q optical resonator, we arrive at the *Jaynes–Cummings* Hamiltonian,

$$H = \hbar\omega_0 b^\dagger b + \frac{\hbar\omega_a}{2}\sigma_z + \hbar\left(gb\sigma_+ + g^* b^\dagger \sigma_-\right) \tag{18.27}$$

coupling a single harmonic oscillator degree of freedom to a two-level system, which might well be called the standard model of quantum optics [18.3]. The coupling constant g can vary from a few kHz to many MHz. This needs to be compared with the linewidth of the cavity mode, κ, as well as the spontaneous emission rate, γ, of the excited state both of which we have thus far neglected but will discuss in Sect. 18.4. If we can arrange for $g > \kappa, \gamma$ we are in the *strong coupling limit*. This is typically achieved by using very small cavity mode volumes. The resulting physical system is often referred to as *cavity QED*. An example is provided by the experiment of *Aoki* et al. [18.4] in which a cesium atom interacts with the toroidal whispering gallery mode of a micro-resonator as it falls under the action of gravity from a magneto-optical trap. The atomic resonance at is the $6S_{1/2}$; $F = 4 \rightarrow 6P_{3/2}$; $F' = 5$ transition in cesium. A coupling constant as large as $g/2\pi = 50\,\mathrm{Mz}$ was achieved. The corresponding cavity and atomic decay rates were $(\kappa, \gamma)/2\pi = (17.9 \pm 2.8, 2.6)\,\mathrm{MHz}$.

18.2 States of Light

The simplest state of light is the ground state, or vacuum state of the free-field Hamiltonian in (18.4) defined by the tensor product of all states $|0\rangle_k$ such that $a_k|0\rangle_k = 0$. The excited states of the free field are the photon number states defined by the tensor product $|\boldsymbol{n}\rangle = \Pi_k |n_k\rangle_k$ where n_k is the kth component of $\boldsymbol{n}$ and

$$a_k^\dagger a_k |\boldsymbol{n}\rangle = n_k |\boldsymbol{n}\rangle\,. \tag{18.28}$$

These states are defined in terms of the plane-wave expansion of the free field in (18.1) and are thus very delocalised. We can of course expand the field in a completely different set of spatiotemporal modes and define photon-number states accordingly. The physical interpretation of the number states depends on what mode expansion we are using.

The interaction Hamiltonian for the classical electromagnetic field coupled to a classical current four-density $j^\mu(\boldsymbol{x}, t)$ is

$$H_{\mathrm{c}} = \int \mathrm{d}^3\boldsymbol{x} e A_\mu(\boldsymbol{x}, t) j^\mu(\boldsymbol{x}, t)\,. \tag{18.29}$$

In quantum optics this may be approximated by treating the current as classical and using the quantised form of the vector potential. The resulting interaction Hamiltonian takes the form

$$\tilde{H}_{\mathrm{I}}(t) = \mathrm{i}\hbar \sum_{\boldsymbol{k}} \left(E^*_{\boldsymbol{k}}(t) a_{\boldsymbol{k}} \, \mathrm{e}^{-\mathrm{i}\omega(\boldsymbol{k})t} - E_{\boldsymbol{k}}(t) a^\dagger_{\boldsymbol{k}} \, \mathrm{e}^{\mathrm{i}\omega(\boldsymbol{k})t} \right) . \tag{18.30}$$

If the source is a monochromatic plane wave at frequency $\omega_0 = c|\boldsymbol{k}|$ we can write this as

$$\tilde{H}_{\mathrm{I}}(t) = \mathrm{i}\hbar(\epsilon a^\dagger - \epsilon^* a) , \tag{18.31}$$

where $a = a_{\boldsymbol{k}_0}$. If the free field starts in the vacuum state at $t = 0$, the state at a later time is a vacuum state for all modes $\boldsymbol{k} \neq \boldsymbol{k}_0$ and for mode $\boldsymbol{k}_0$, the state is

$$|\psi(t)\rangle = \exp[t(\epsilon a^\dagger - \epsilon^* a)]|0\rangle . \tag{18.32}$$

Expanding the exponential and we see that this state may be written in the number state basis as

$$|\psi(t)\rangle = \mathrm{e}^{-|\epsilon t|^2/2} \sum_{n=0}^{\infty} \frac{(\epsilon t)^n}{\sqrt{n!}} |n\rangle_{\boldsymbol{k}_0} . \tag{18.33}$$

We are thus led to define the *coherent states* of a single mode of the field as

$$|\alpha\rangle = D(\alpha)|0\rangle , \tag{18.34}$$

where we have defined the *displacement operator*

$$D(\alpha) = \mathrm{e}^{\alpha a^\dagger - \alpha^* a} \tag{18.35}$$

the name of which is derived from the result

$$D^\dagger(\alpha) a D(\alpha) = a + \alpha . \tag{18.36}$$

Using this last result it is easy to see that $a|\alpha\rangle = \alpha|\alpha\rangle$.

Consider the field operator evaluated for convenience at $\boldsymbol{x} = 0$ and for now ignore the polarisation degree of freedom. We can express this in terms of sine and cosine amplitudes at a carrier frequency ω_{c} as

$$A(t) = A_1(t)\cos(\omega_{\mathrm{c}} t) - A_2(t)\sin(\omega_{\mathrm{c}} 0t) , \tag{18.37}$$

where in the interaction picture

$$A_1(t) = \frac{1}{2} \sum_k \sqrt{\frac{\hbar}{2\epsilon_0 \omega_k V}} \times \left[a_k(t) \, \mathrm{e}^{-\mathrm{i}(\omega_k - \omega_{\mathrm{c}})t} + a^\dagger_k(t) \, \mathrm{e}^{\mathrm{i}(\omega_k - \omega_{\mathrm{c}})t} \right] , \tag{18.38}$$

$$A_2(t) = \frac{-\mathrm{i}}{2} \sum_k \sqrt{\frac{\hbar}{2\epsilon_0 \omega_k V}} \times \left[a_k(t) \, \mathrm{e}^{-\mathrm{i}(\omega_k - \omega_{\mathrm{c}})t} - a^\dagger_k(t) \, \mathrm{e}^{\mathrm{i}(\omega_k - \omega_{\mathrm{c}})t} \right] . \tag{18.39}$$

We are thus led to define the *quadrature phase operators* for each mode of the field as

$$X = (a + a^\dagger) , \tag{18.40}$$

$$Y = -\mathrm{i}(a - a^\dagger) . \tag{18.41}$$

These operators have the commutation relation $[X, Y] = 2\mathrm{i}$, which is isomorphic to the Heisenberg–Weyl algebra of canonical position and momentum operators and so there is an equivalent uncertainty principle, $\Delta X \Delta Y \geq 1$, where $(\Delta A)^2 \equiv \langle A^2 \rangle - \langle A \rangle^2$. States that satisfy the lower bound in this relation are called minimum-uncertainty states. The vacuum state and coherent state are minimum-uncertainty states with $\Delta X = \Delta Y$. Minimum-uncertainty states for which the quadrature phase operator uncertainties are not equal are called *squeezed states*.

Single-mode squeezed states are generated from the vacuum state by a unitary transformation defined by

$$S^\dagger(\xi)(\tilde{X} + \mathrm{i}\tilde{Y})S(\xi) = \tilde{X}\mathrm{e}^r + \mathrm{i}\tilde{Y}\mathrm{e}^{-r} , \tag{18.42}$$

where $\tilde{X} + \mathrm{i}\tilde{Y} = (X + \mathrm{i}Y)\mathrm{e}^{-\mathrm{i}\phi}$. Thus the canonical pair $(\tilde{X}, \tilde{Y})$ are related by a rotation to the original canonical pair (X, Y). Clearly the uncertainty in the rotated canonical coordinates are $\Delta\tilde{X} = \mathrm{e}^r$, $\Delta\tilde{Y} = \mathrm{e}^{-r}$. The squeezed vacuum state is then defined as $|0, \xi\rangle = S(\xi)|0\rangle$, where

$$S(\xi) = \exp\left[\frac{1}{2} (\xi (a^\dagger)^2 - \xi^* a^2) \right] , \tag{18.43}$$

where $\xi = r\,\mathrm{e}^{2\mathrm{i}\phi}$. The corresponding transformation of the complex amplitude operators is

$$S^\dagger(\xi) a S(\xi) = a \cosh r + a^\dagger \mathrm{e}^{2\mathrm{i}\phi} \sinh r . \tag{18.44}$$

We may then add a coherent amplitude by displacing the squeezed vacuum state $|\alpha, \xi\rangle = D(\alpha)|0, r\rangle$.

Of more interest are the two-mode squeezed vacuum states which correlate two modes, a and b, of the field through a generalisation of (18.44),

$$S_2^\dagger(\xi) a S_2(\xi) = a \cosh r + b^\dagger \mathrm{e}^{2\mathrm{i}\phi} \sinh r , \tag{18.45}$$

$$S_2^\dagger(\xi) b S_2(\xi) = b \cosh r + a^\dagger \mathrm{e}^{2\mathrm{i}\phi} \sinh r , \tag{18.46}$$

where $S_2(\xi) = \exp[(\xi a^\dagger b^\dagger - \xi^* ab)]$. The two-mode squeezed vacuum state is then defined as

$$|\mathcal{E}\rangle_{ab} = \exp[(\xi a^\dagger b^\dagger - \xi^* ab)]|0\rangle_a \otimes |0\rangle_b . \tag{18.47}$$

The two-mode squeezed state is an entangled state of two modes of an optical field. To see this we note that,

for $\xi = r$, a real number, the expansion in number eigenstate basis for each oscillator is

$$|\mathcal{E}\rangle 2_{ab} = \sqrt{(1-\lambda^2)} \sum_{n=0}^{\infty} \lambda^n |n\rangle_a \otimes |n\rangle_b \,, \tag{18.48}$$

where $\lambda = \tanh r$ and $a^\dagger a|n\rangle_a = n|n\rangle_a$ and $b^\dagger b|n\rangle_b = n|n\rangle_b$.

The entanglement of this state can be viewed in two ways. Firstly as an entanglement between pairs of canonically conjugate physical quantities with a continuous spectrum, the quadrature phases, and secondly as an entanglement between number and phase. We will only discuss the former case here (see [18.5] for the latter case). We can easily show that this state approximates the entangled state first considered by Einstein, Podolsky and Rosen (an EPR state) in the limit $\lambda \to 1$ or $r \to \infty$. The correlation between quadrature phase in each mode is easily seen by calculating the variances in an appropriate set of joint observables. We first define the quadrature phase operators for the two modes

$$\hat{X}_a = a + a^\dagger \,, \tag{18.49}$$

$$\hat{Y}_a = -\mathrm{i}(a - a^\dagger) \,, \tag{18.50}$$

$$\hat{X}_b = b + b^\dagger \,, \tag{18.51}$$

$$\hat{Y}_b = -\mathrm{i}(b - b^\dagger) \,, \tag{18.52}$$

with canonical commutation relations, $[\hat{X}_\nu, \hat{Y}_\mu] = 2\mathrm{i}\delta_{\nu,\mu}$. Then

$$\mathrm{Var}(\hat{X}_a - \hat{X}_b) = 2\,\mathrm{e}^{-2r} \tag{18.53}$$

$$\mathrm{Var}(\hat{Y}_a + \hat{Y}_b) = 2\,\mathrm{e}^{-2r} \tag{18.54}$$

where $\mathrm{Var}(A) = \langle A^2\rangle - \langle A\rangle^2$ is the variance. Thus in the limit of $r \to \infty$ the state $|\mathcal{E}\rangle$ approaches a simultaneous eigenstate of $\hat{X}_a - \hat{X}_b$ and $\hat{Y}_a + \hat{Y}_b$. This is the analogue of the EPR state with position replaced by the real quadratures $\hat{X}$ and the momentum replaced by the imaginary quadratures, $\hat{Y}$.

The very strong correlations between the quadrature phase operators for the squeezed state can be seen in the diagonal basis of $\hat{X}_a$, $\hat{X}_b$

$$\begin{aligned}\mathcal{E}(x_a, x_b) &= \langle x_a, x_b|\mathcal{E}\rangle \\ &= (2\pi)^{-1/2} \\ &\quad \exp\left[-\frac{e^{2r}}{8}(x_a - x_b)^2 - \frac{e^{-2r}}{8}(x_a + x_b)^2\right]\end{aligned} \tag{18.55}$$

with $\hat{X}_\alpha|x_\alpha\rangle_\alpha = x_\alpha|x_\alpha\rangle_\alpha$ and $|x, y\rangle = |x\rangle_a \otimes |y\rangle_b$ and where $\alpha \to a, b$.

We now turn to multimode states of the field to describe more-complex states. To this end we assume that the only modes that are excited have the same plane polarisation and are all propagating in the in same direction, which we take to be the x-direction. All other modes are in the vacuum state. The positive-frequency components of the electric field for these modes are then

$$E^{(+)}(x,t) = \mathrm{i}\sum_{n=0}^{\infty}\left(\frac{\hbar\omega_n}{2\epsilon_0 V}\right)^{1/2} a_n\,\mathrm{e}^{-\mathrm{i}\omega_n(t-x/c)} \,. \tag{18.56}$$

In ignoring all the other modes, we are implicitly assuming that all our measurements do not respond to the vacuum state, an assumption which is justified below. Let us further assume that all excited modes of this form have frequencies centred on the *carrier frequency* of $\Omega \gg 1$. Then we can approximate the positive-frequency components by

$$E^{(+)}(x,t) = \mathrm{i}\left(\frac{\hbar\Omega_n}{2\epsilon_0 Ac}\right)^{1/2}\sqrt{\frac{c}{L}}\sum_{n=0}^{\infty} a_n\,\mathrm{e}^{-i\omega_n(t-x/c)} \,, \tag{18.57}$$

where A is a characteristic transverse area. This operator has dimensions of electric field. In order to simplify the dimensions we now define a field operator that has dimensions of $\mathrm{s}^{-1/2}$. Taking the continuum limit we thus define the positive-frequency operator

$$a(x,t) = e^{-\mathrm{i}\Omega(t-x/c)}\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}\mathrm{d}\omega' a(\omega')\,\mathrm{e}^{-\mathrm{i}\omega'(t-x/c)} \,, \tag{18.58}$$

where we have made a change of variable $\omega \mapsto \Omega + \omega'$ and used the fact that $\Omega \gg 1$ to set the lower limit of integration to minus infinity, and

$$\left[a(\omega_1), a^\dagger(\omega_2)\right] = \delta(\omega_1 - \omega_2) \,. \tag{18.59}$$

In this form the moment $n(x,t) = \langle a^\dagger(x,t)a(x,t)\rangle$ has units of s^{-1}. As we show in the next section this moment determines the probability per unit time (the count rate) to count a photon at the space–time point (x,t). The field operators $a(t)$ and $a^\dagger(t)$ can be taken to describe the field emitted from the end of an optical cavity, which selects the directionality.

A multimode coherent state is defined by a multimode displacement operator acting on the vacuum $D|0\rangle$, defined implicitly by

$$D^\dagger a(\omega) D = a(\omega) + \alpha(\omega) \,, \tag{18.60}$$

where consistent with proceeding assumptions, $\alpha(\omega)$ is peaked at $\omega = 0$, which corresponds to a carrier frequency $\Omega \gg 1$. The average field amplitude for this state is

$$\langle a(x,t)\rangle = \mathrm{e}^{-\mathrm{i}\Omega(t-x/c)}\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}\alpha(\omega)\mathrm{e}^{-\mathrm{i}\omega(t-x/c)} \equiv \alpha(x,t)\mathrm{e}^{-\mathrm{i}\Omega(t-x/c)} \quad (18.61)$$

which implicitly defines the average complex amplitude of the field as the Fourier transform of the frequency-dependent displacements $\alpha(\omega)$. We can also calculate the probability per unit time to detect a photon in this state at space-time point (x,t). This is given by $n(x,t) = |\alpha(x,t)|^2$. Note that in this case the second-order moment $\langle a^\dagger(x,t)a(x,t)\rangle$ factorises, a result characteristic of fields with first-order coherence. A coherent state is closest to our intuitive idea of a classical electromagnetic field.

The multimode single-photon state is defined by

$$|1\rangle = \int_{-\infty}^{\infty}\nu(\omega)a^\dagger(\omega)|0\rangle\,. \quad (18.62)$$

This state has zero average field amplitude but $n(x,t) = |\nu(t-x/c)|^2$, where $\nu(t)$ is the Fourier transform of $\nu(\omega)$. So while the state has zero average field amplitude there is apparently some sense in which the coherence implicit in the superposition of (18.62) is manifest. We discuss in the next section how this coherence is made explicit through fourth-order interference. For this state the function $\nu(\phi)$ is periodic in the phase $\phi = t - x/c$ and it is not difficult to choose a form with a well-defined pulse sequence. However care should be exercised in interpreting these pulses. They do not represent a sequence of pulses each with one photon, rather they represent a single photon coherently superposed over all pulses. Once a photon is counted in a particular pulse, the field is returned to the vacuum state. A single-photon state is a highly nonclassical state with applications to quantum information processing. A review of current efforts to produce such a state may be found in [18.6].

An important example of a multimode two-photon state is

$$|2\rangle_{ab} = \int_{-\infty}^{\infty}\mathrm{d}\omega_1\int_{-\infty}^{\infty}\mathrm{d}\omega_2\alpha(\omega_1,\omega_2)a^\dagger(\omega_1)b^\dagger(\omega_2)|0\rangle_{ab}\,, \quad (18.63)$$

where a and b are two distinguishable spatial or polarisation modes. This state is important in the theory of spontaneous parametric down conversion in which a pump photon at frequency 2Ω is absorbed and simultaneously two photons in each of the modes a and b are produced with frequencies ω_1 and ω_2, respectively, such that $\omega_1 + \omega_2 = 2\Omega$, the condition for energy conservation. A good approximation to the state produced can be written as $|0\rangle + \kappa|2\rangle_{ab}$ where κ is related to the down-conversion efficiency [18.7]. As we have shifted all frequencies by the carrier frequency Ω, we can impose energy conservation as $\omega_1 + \omega_2 = 0$, and choose

$$\alpha(\omega_1,\omega_2) = \alpha(\omega_1)\delta(\omega_1+\omega_2)\,. \quad (18.64)$$

In other words photons in the symmetric side bands around the frequency of Ω are correlated. Normalisation of the state in (18.63) requires

$$\int_{-\infty}^{\infty}\mathrm{d}\omega|\alpha(\omega)|^2 = 1\,. \quad (18.65)$$

If we ask for the probability per unit time to count a photon from either mode a or b independently it is easily seen to be a constant in time indicating that we will count a photon in either beam at completely random times. However if we count the coincidence correlation rate $C(t,t') = \langle a^\dagger(t)a(t)b^\dagger(t')b(t')\rangle$ we find

$$C(t,t') = |\alpha(t-t')|^2\,, \quad (18.66)$$

where $\alpha(t)$ is the Fourier transform of $\alpha(\omega)$. The quantum coherence implicit in the correlations of (18.63) appear as a two-photon correlation with a maximum for coincidence counting. To put it another way, the two photon correlation is a *fourth-order interference* effect as C depends on a fourth-order moment of the field amplitude operators.

18.3 Measurement

At optical frequencies, all measurements ultimately derive from how the field interacts with matter, and it is some property of the material which is ultimately measured. For example if the field is directed to a particular kinds of semiconductor material free carriers can be produced, either as electrons or holes, each refereed

to as a photoexcitation event. The resulting charge or current flow may then be amplified to produce a measurable electrical signal which is entirely classical and stochastic. There are two special cases. Firstly if we use light of such low intensity that individual photoexcitation events result in a distinct signal pulse. These pulses can then be counted and different counts recorded per count interval. The statistics of this counting process is ultimately conditioned on the photon-number distribution for the quantum state of the incident light. Secondly we may have light of a higher intensity so that individual counting events cannot be resolved. The classical measurement signal is then a fluctuating current. The noise power spectrum of this current is still conditioned on the quantum state of the input light. This last case occurs if a weak signal is first mixed with a strong coherent light beam by a beam splitter and then the reflected and transmitted beams individually give rise to distinct photocurrents on separate detectors. The strong coherent beam is usually called a *local oscillator*. The interference between the signal and local oscillator enables a phase-sensitive measurement of the field to be made. If it is resonant with the carrier frequency, the photocurrent has a direct current (DC) average signal and we refer to the process as homodyne detection. If the local oscillator is detuned from the signal the photocurrents acquire an alternating current (AC) frequency component equal to the detuning between the local oscillator and the signal carrier frequency. This is called heterodyne detection. We now show how these various classical stochastic signals are conditioned on different field quantities.

18.3.1 Photon Counting

If we assume that the interaction between the detector and signal field is weak, the probability of photoexcitation event per unit time may be calculated from the interaction Hamiltonian and Fermi's golden rule. Typically the interaction Hamiltonian, in the interaction picture takes the form of a dipole interaction in the rotating wave approximation

$$\tilde{H}_{\mathrm{I}} = \hbar\chi(E^{(+)}(\boldsymbol{x},t)\sigma_{+}(t) + E^{(-)}(\boldsymbol{x},t)\sigma_{-}(t)) \,, \tag{18.67}$$

where g is a typical coupling constant, $E^{(\pm)}(\boldsymbol{x},t)$ are the positive- and negative-frequency components of the field at space time point $(\boldsymbol{x},t)$, while $\sigma_{\pm}(t)$ are the dipole transition operators. We assume the dipole starts in the ground state $|g\rangle$ defined by $\sigma_{-}|g\rangle = 0$. The probability that the dipole, located at $\boldsymbol{x}$ is excited per unit time, i.e. the rate of excitation is given by perturbation theory (to second order in χ) [18.8] as

$$p_{\mathrm{e}}(\boldsymbol{x},t) \propto \langle E^{(-)}(\boldsymbol{x},t)E^{(+)}(\boldsymbol{x},t)\rangle \,. \tag{18.68}$$

Insofar as an excitation event results in a classical signal, the probability to detect a photon per unit time is then simply,

$$p_1(t) = \gamma\langle E^{(-)}(t)E^{(+)}(t)\rangle \,, \tag{18.69}$$

where $\gamma \propto \chi^2$ and the other factors that depend on the details of the detector (such as area and spectral sensitivity) and its ability to respond to a photoexcitation event with a detectable signal. The counting process is thus seen to be a classical stochastic random variables $\mathrm{d}N(t)$ which only takes the values $0, 1$ in a sufficiently small time interval $\mathrm{d}t$. This is a Poisson point process. The classical average of this process is $\mathcal{E}[\mathrm{d}N(t)] = p_1(t)$. If we now consider a count interval of duration T, the probability to count n photoexcitation events in that time is [18.9]

$$p_n(T) = \left\langle : \frac{[\gamma\bar{I}(T)T]^n}{n!} \exp[-\gamma\bar{I}(T)T] : \right\rangle , \tag{18.70}$$

where the operator $\bar{I}$ is defined by

$$\bar{I}(T) = \frac{1}{T}\int_0^T E^{(-)}(t)E^{(+)}(t)\,\mathrm{d}t \,, \tag{18.71}$$

where $: \ldots :$ indicates normal ordering, that is the power-series expansion is done by ordering all the negative-frequency components to the right of the positive-frequency components.

If the count rate is too large to resolve individual counting events, we need to consider a photocurrent. We then define the current as

$$i(t) = e\frac{\mathrm{d}n(t)}{\mathrm{d}t} \,, \tag{18.72}$$

where $n(t) = \sum_{n=0}^{\infty} n\,p_n(t)$ is the average number of counts in time t. In terms of the point process $\mathrm{d}N(t,\ n(t)) = \int_0^t \mathrm{d}N(t)$ so that the ensemble average of $i(t)$ is the average current

$$\overline{i(t)} = e\frac{\mathrm{d}\mathcal{E}(n(t))}{\mathrm{d}t} = \gamma\langle E^{(-)}(t)E^{(+)}(t)\rangle \,. \tag{18.73}$$

The stationary two-time correlation function of the current is then the classical ensemble average,

$$G(\tau) = \lim_{t\to\infty} \mathcal{E}\,[i(t+\tau)i(t)] - \mathcal{E}[i(t+\tau)]\mathcal{E}[i(t)] \,. \tag{18.74}$$

If we first consider the case $\tau > 0$, then we need to find $\mathcal{E}[\mathrm{d}N(t+\tau)\mathrm{d}N(t)]$. The only way this can be nonzero is for $\mathrm{d}N(t) = 1$ at time t. Thus we need the conditional average

$$\mathcal{E}[\mathrm{d}N(t+\tau)\mathrm{d}N(t)] = \mathrm{Prob}[\mathrm{d}N(t) = 1] \times \mathcal{E}[\mathrm{d}N(t+\tau)|_{\mathrm{d}N(t)=1}] \,. \tag{18.75}$$

The details may be fund in [18.10] The two-time correlation function is then seen to be

$$G(\tau) = e\bar{i}\delta(\tau) + \lim_{t\to\infty} e^2\gamma^2\langle E^{(-)}(t)E^{(-)}(t+\tau) \times E^{(+)}(t+\tau)E^{(+)}(t)\rangle \,. \tag{18.76}$$

The noise power spectrum is then defined by

$$S(\omega) = 2\int_{-\infty}^{\infty} \mathrm{d}\tau G(\tau)e^{-i\omega\tau} \,. \tag{18.77}$$

In the previous section we considered a special case in which almost all field modes were taken in the vacuum state except those propagating in the positive x-direction which could for example describe the directional emission from an optical cavity. We may write the average current and $G(\tau)$ in terms of the field operators $a(t)$ and $a^\dagger(t)$ defined in (18.58)

$$\overline{i(t)} = e\gamma\langle a^\dagger(t)a(t)\rangle \,, \tag{18.78}$$

$$G(\tau) = e\bar{i}\delta(\tau) + \lim_{t\to\infty} e^2\gamma^2 \times \langle a^\dagger(t)a^\dagger(t+\tau)a(t+\tau)a(t)\rangle \,. \tag{18.79}$$

The delta-correlated term in $G(\tau)$ represents the shot-noise component of the photocurrent.

18.3.2 Homo-/Heterodyne Detection

We now deal exclusively with the positive and negative field operators $a(t)$ and $a^\dagger(t)$ appropriate for directional emission from a cavity. Consider two spatially distinct field modes, $a_\mathrm{i}(t)$ and $b_\mathrm{i}(t)$, directed onto opposite sides of a dielectric interface, so that each field is partially transmitted and partially reflected. The interaction with the beam splitter is described by an effective unitary scattering process that couples the two input fields to two output fields, $a_\mathrm{o}(t)$ and $b_\mathrm{o}(t)$, as

$$\begin{pmatrix} a_o(t) \\ b_o(t) \end{pmatrix} = U^\dagger(\theta,\phi)\begin{pmatrix} a_\mathrm{i}(t) \\ b_\mathrm{i}(t) \end{pmatrix} U(\theta,\phi) \,, \tag{18.80}$$

$$= \begin{pmatrix} a_\mathrm{i}(t)\cos\theta + b_\mathrm{i}(t)\mathrm{e}^{\mathrm{i}\phi}\sin\theta \\ b_\mathrm{i}(t)\cos\theta - a_\mathrm{i}(t)\mathrm{e}^{-\mathrm{i}\phi}\sin\theta \end{pmatrix} \,. \tag{18.81}$$

The commutation relation for the output fields are the same as the input fields. Suppose now that the field $b(t)$ is prepared in a coherent state, so that we may simply replace $b(t) \mapsto \beta(t)$. We will further assume that $|\beta(t)|^2 \to \infty$ and that $\sin\theta \to 0$ such that $|\beta(t)|^2\sin^2\theta \equiv |\alpha(t)|^2 \gg 1$ is a finite average photon flux. The probability to detect a photon per unit time in the output field $a_0(t)$ is then given by

$$n(t) = \gamma\left\langle\left[a_\mathrm{i}^\dagger(t) + \alpha^*(t)\right]\left[a_\mathrm{i}(t) + \alpha(t)\right]\right\rangle \,. \tag{18.82}$$

As the coherent component is assumed to be large, we are in the limit of a photocurrent detection scheme. Let us now define a classical stochastic process by subtracting off the background current and normalising by the coherent flux,

$$h(t)\mathrm{d}t = \frac{\mathrm{d}N(t) - \gamma|\alpha(t)|^2\,\mathrm{d}t}{\gamma|\alpha(t)|^2} \,. \tag{18.83}$$

The ensemble average of the classical current process $h(t)$ is then well approximated by

$$\mathcal{E}[h(t)] = \langle a(t)\mathrm{e}^{\mathrm{i}(\theta+\omega_\mathrm{LO}t)} + a^\dagger(t)\mathrm{e}^{-\mathrm{i}(\theta+\omega_\mathrm{LO}t)}\rangle \tag{18.84}$$

where we have assumed that $\alpha(t) = |\alpha(t)|\exp[-\mathrm{i}(\phi + \omega_\mathrm{LO}t)]$ and ω_LO is called the *local oscillator* frequency. We may write this average current in terms of the quadrature phase amplitudes defined with respect to the local oscillator carrier frequency and its phase

$$\mathcal{E}[h(t)] = \langle X_\theta(t)\rangle\cos(\Delta t) + \langle Y_\theta(t)\rangle\sin(\Delta t) \,, \tag{18.85}$$

where we have defined the quadrature phase operators

$$X_\theta(t) = a(t)\mathrm{e}^{\mathrm{i}(\theta+\omega_\mathrm{s}t)} + a^\dagger(t)\mathrm{e}^{-\mathrm{i}(\theta+\omega_\mathrm{s}t)} \tag{18.86}$$

$$Y_\theta(t) = -\mathrm{i}(a(t)\mathrm{e}^{\mathrm{i}(\theta+\omega_\mathrm{s}t)} - a^\dagger(t)\mathrm{e}^{-\mathrm{i}(\theta+\omega_\mathrm{s}t)}) \tag{18.87}$$

where we have anticipated that the signal field has a carrier frequency of ω_s and we have defined $\Delta = \omega_\mathrm{LO} - \omega_\mathrm{s}$, which is typically a radio frequency. It is then apparent that the in-phase signal at frequency Δ is a measurement of the average quadrature phase amplitude, $\langle X_\theta(t)\rangle$, while the quadrature phase signal is a measurement of the complementary quadrature phase amplitude $\langle Y_\theta(t)\rangle$. Such a measurement is know as the *heterodyne* measurement. If we choose $\Delta = 0$, so that we are monitoring a DC signal, we have the case of *homodyne*

measurement [18.11]. The higher-order moments of the current also reveal corresponding higher-order moments of the signal-field quadrature phase amplitudes. For example, The stationary second-order correlation function of the homodyne ($\Delta = 0$) current $h(t)$ is easily seen to be given by the normally ordered correlation function of the quadrature phase operator:

$$G(\tau) = \lim_{t\to\infty} \langle : X_\theta(t), X_\theta(t+\tau) : \rangle \,. \tag{18.88}$$

The spectrum of this quantity is called the *spectrum of squeezing* as it can only fall below zero if the signal is in a squeezed state [18.12].

18.4 Dissipation and Noise

The interaction between a single mode of an intracavity field and the many modes external to the cavity can be modelled in terms of a local harmonic oscillator coupled to an environment of many harmonic oscillators [18.13, 14] Fig. 18.1. This model is valid when the cavity finesse is large, so that the line width of each cavity resonance is much less than the resonance frequency, and we can separate the total field into local discrete quasi-modes internal to the cavity and many modes outside. This is equivalent to a weak interaction between the cavity quasi-modes and the external field. We can then use second-order perturbation theory and, assuming the external field can be treated as a heat bath at temperature T, we can find a master equation for the dynamics of the density operator for the intracavity field in the Schrödinger picture as

$$\frac{\mathrm{d}\rho}{\mathrm{d}t} = -\frac{\mathrm{i}}{\hbar}[H, \rho(t)] + \kappa(\bar{n}+1)\mathcal{D}[a]\rho(t) + \kappa\bar{n}\mathcal{D}[a^\dagger]\rho(t) \,, \tag{18.89}$$

where we have defined the action of the super-operator for any operator A as

$$\mathcal{D}[A]\rho = A\rho A^\dagger - \frac{1}{2}(A^\dagger A\rho + \rho A^\dagger A) \tag{18.90}$$

and H is the Hamiltonian for the cavity mode plus any interactions with matter that may be present and $\bar{n}$ is the mean photon number in an external mode at frequency $\omega = \omega_\mathrm{c}$ at temperature T. For an empty cavity $H = \hbar\omega_\mathrm{c} a^\dagger a$. The average intracavity field amplitude and photon number obey the equations

$$\frac{\mathrm{d}\langle a\rangle}{\mathrm{d}t} = -\mathrm{i}\omega\langle a\rangle + \frac{\kappa}{2}\langle a\rangle \,, \tag{18.91}$$

$$\frac{\mathrm{d}\langle a^\dagger a\rangle}{\mathrm{d}t} = -\kappa\langle a^\dagger a\rangle + \kappa\bar{n} \,. \tag{18.92}$$

The solutions for which are

$$\langle a\rangle(t) = \langle a\rangle(0)\mathrm{e}^{-(\kappa/2+\mathrm{i}\omega_\mathrm{c})t} \,, \tag{18.93}$$

$$\langle a^\dagger a\rangle(t) = \langle a^\dagger a\rangle(0) + \bar{n}(1-\mathrm{e}^{-\kappa t}) \,. \tag{18.94}$$

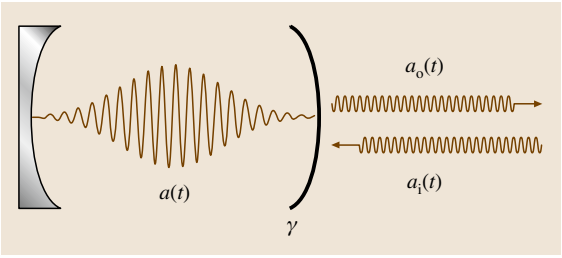

Fig. 18.1 An optical cavity with a single output mirror. The cavity is weakly coupled to many external modes, but a particular class of directional input/output modes are defined by the cavity, indicated as $a_\mathrm{i}(t), a_\mathrm{o}(t)$. The cavity quasi-mode has a field amplitude operator $a(t)$, while γ is the rate at which photons are lost through the end mirror

Taking the Fourier transform of the first of these equations we see that the cavity field amplitude has a Lorentzian spectrum centred at the cavity resonance frequency and with a linewidth of κ. The second equation indicates that in the steady state, while the mean field is zero, the mean photon number in the cavity is the same as the thermal photon number in the environmental mode at the cavity resonance. In fact is is easy to see that in the steady state, the field in the cavity is in the thermal state given by

$$\rho_\infty = \frac{1}{1+\bar{n}} \sum_{n=0}^{\infty} \left(\frac{\bar{n}}{1+\bar{n}}\right)^n |n\rangle\langle n| \,. \tag{18.95}$$

In the input/output theory of *Gardiner* [18.13], the external field modes are related to the internal mode through the boundary condition

$$a_0(t) = \sqrt{\gamma}a(t) - a_\mathrm{i}(t) \,. \tag{18.96}$$

Note that while $a_{\mathrm{i,o}}(t)$ are explicitly many-mode fields, the internal quasi-mode $a(t)$ is represented by a single harmonic-oscillator degree of freedom with frequency ω_c. In an alternative, but equivalent, formulation to the master equation we can represent the dynamics in the Heisenberg picture by a *quantum stochastic differential*

equation

$$\frac{\mathrm{d}a(t)}{\mathrm{d}t} = -\frac{\mathrm{i}}{\hbar}[H_\mathrm{S}, a(t)] - \frac{\gamma}{2}a(t) + \sqrt{\gamma}a_\mathrm{i}(t)\,. \quad (18.97)$$

In this formulation, the external field input to the cavity plays the role of a quantum noise term. If these equations are linear,

$$\frac{\mathrm{d}\boldsymbol{a}}{\mathrm{d}t} = A\boldsymbol{a} - \frac{\gamma}{2}\boldsymbol{a} + \sqrt{\gamma}\boldsymbol{a}_\mathrm{i}(t)\,, \quad (18.98)$$

where

$$\boldsymbol{a}(t) = \begin{pmatrix} a(t) \\ a^\dagger(t) \end{pmatrix}\,, \quad (18.99)$$

$$\boldsymbol{a}_{\mathrm{i,o}}(t) = \begin{pmatrix} a_{\mathrm{i,o}}(t) \\ a^\dagger_{\mathrm{i,o}}(t) \end{pmatrix}\,. \quad (18.100)$$

We can Fourier transform both sides and ignore initial-value terms, as we are primarily interested in the stationary statistics to obtain a linear system of algebraic equations for the frequency components of the various fields. Combining this with (18.96) we find that

$$\boldsymbol{a}_0(\omega) = -\left[A + \left(\mathrm{i}\omega + \frac{\gamma}{2}\right)I\right] \times \left[A + \left(\mathrm{i}\omega - \frac{\gamma}{2}\right)I\right]^{-1}\boldsymbol{a}_\mathrm{i}(\omega)\,. \quad (18.101)$$

In the case of an empty cavity we get an interaction picture defined with respect to some carrier frequency ω_i for the input external field,

$$a_\mathrm{o}(\omega) = \frac{\frac{\gamma}{2} + \mathrm{i}(\omega - \delta)}{\frac{\gamma}{2} - \mathrm{i}(\omega - \delta)}a_\mathrm{i}(\omega)\,, \quad (18.102)$$

where $\delta = \omega_\mathrm{c} - \omega_\mathrm{i}$. In other words there is simply a frequency-dependent phase shift of each field mode from input to output. Suppose we input a single-photon state defined by

$$|\psi\rangle_\mathrm{i} = \int_{-\infty}^{\infty} \nu(\omega)a_\mathrm{i}^\dagger(\omega)|0\rangle\,. \quad (18.103)$$

After interacting with the cavity this state is transformed to

$$|\psi\rangle_\mathrm{o} = \int_{-\infty}^{\infty} \nu(\omega)a_\mathrm{o}^\dagger(\omega)|0\rangle\,. \quad (18.104)$$

It is then easy to see that the probability per unit time to detect a single photon in the output field is

$$n(t) = \left|\int_{-\infty}^{\infty} \mathrm{d}\omega \left(\frac{\frac{\gamma}{2} + \mathrm{i}(\omega - \delta)}{\frac{\gamma}{2} - \mathrm{i}(\omega - \delta)}\right)\nu(\omega)\mathrm{e}^{-\mathrm{i}\omega t}\right|^2\,, \quad (18.105)$$

which is a delayed and broadened pulse.

If the quantum Langevin equations are nonlinear the standard procedure is to first find the semiclassical steady states. The semiclassical equations result by ignoring the noise and replacing the creation and annihilation operators by complex numbers, $a \mapsto \alpha$, $a^\dagger \mapsto \alpha^*$. If the steady state, (α_0, α_0^*) is stable fixed point, we write $a = \delta a + \alpha_0$, $a^\dagger = \delta a^\dagger + \alpha_0^*$. The dynamics is then expanded to linear order in δa and $\delta a^\dagger$ and then we proceed as above. An example of this approach is given in [18.15].

Spontaneous emission can also be treated using a master equation. In this case the system is a two-level electronic system, with ground state $|g\rangle$ of energy $\hbar\omega_1$ and excited state $|e\rangle$ with energy $\hbar\omega_2$, representing an electric dipole transition, coupled to the many modes of the radiation field in the dipole and rotating wave approximation. The master equation is

$$\frac{\mathrm{d}\rho}{\mathrm{d}t} = -\frac{\mathrm{i}}{\hbar}[H, \rho] + \gamma(\bar{n}+1)\mathcal{D}[\sigma_-]\rho + \gamma\bar{n}\mathcal{D}[\sigma_+]\rho\,, \quad (18.106)$$

where $\bar{n}$ is the thermal occupation of the radiation field mode at the atomic resonance frequency $\omega_a = \omega_2 - \omega_1$. We have neglected a small term which gives rise to a shift in the atomic transition frequency and which contributes to the Lamb shift. At optical frequencies, $\bar{n} \approx 0$. In the case of a free two-level atom, $H = \frac{\hbar\omega_\mathrm{a}}{2}\sigma_z$ the probability to find the atom in the excited state, $p_\mathrm{e}(t) = \langle e|\rho|e\rangle$ satisfies the equation

$$\frac{\mathrm{d}p_\mathrm{e}}{\mathrm{d}t} = -\gamma p_\mathrm{e}(t) \quad (18.107)$$

with the solution $p_\mathrm{e}(t) = p_\mathrm{e}(0)\mathrm{e}^{-\gamma t}$, which describes spontaneous emission. The dipole polarisation is proportional to the atomic coherence, $\langle e|\rho|g\rangle = \langle\sigma_-\rangle$, which obeys

$$\frac{\mathrm{d}\langle\sigma_-\rangle}{\mathrm{d}t} = -\left(\mathrm{i}\omega_\mathrm{a} + \frac{\gamma}{2}\right)\langle\sigma_-\rangle \quad (18.108)$$

with the solution

$$\langle\sigma_-(t)\rangle = \langle\sigma_-(0)\rangle\,\mathrm{e}^{-(\gamma/2+\mathrm{i}\omega_\mathrm{a})t}\,. \quad (18.109)$$

The dipole oscillates at the transition frequency and decays, as it radiates.

The radiated field is related to the input field and the local source through an input/output relation in analogy with the case of a cavity discussed above. The positive-frequency components of the field operator take the

form

$$E_{\rm o}^{(+)}(\boldsymbol{x},t)=E_{\rm i}^{(+)}(\boldsymbol{x},t)-\frac{\omega_a^2}{4\pi\epsilon_0 c^2 r}\left(\boldsymbol{\mu}\times\frac{\boldsymbol{x}}{r}\right)\times\frac{\boldsymbol{x}}{r}\sigma_-(t-x/c)\,, \tag{18.110}$$

where $r=|\boldsymbol{x}|$ is the distance from the course to the point $\boldsymbol{x}$ and $\boldsymbol{\mu}$ is the atomic dipole moment.

If the atom is driven by a classical radiation field, the Hamiltonian becomes [see (18.27) and replace $b\mapsto\beta$]

$$H=\frac{\hbar\omega_{\rm a}}{2}\sigma_z+\Omega(\sigma_+\,{\rm e}^{-{\rm i}\omega_L t}+\sigma_- e^{i\omega_L t})\,, \tag{18.111}$$

where Ω is the Rabi frequency and $\omega_{\rm L}$ is the carrier frequency of the driving field. The master equation in an interaction picture at the frequency $\omega_{\rm L}$ is

$$\frac{{\rm d}\rho}{{\rm d}t}=-{\rm i}\frac{\Delta\omega}{2}[\sigma_z,\rho]-{\rm i}\Omega[\sigma_++\sigma_-,\rho]+\gamma\mathcal{D}[\sigma_-]\rho\,, \tag{18.112}$$

where the detuning is $\Delta\omega=\omega_{\rm a}-\omega_{\rm L}$. The resulting *Bloch equations* for the atomic moments are linear

$$\frac{{\rm d}\langle\sigma_-\rangle}{{\rm d}t}=-\left(\frac{\gamma}{2}+{\rm i}\Delta\omega\right)\langle\sigma_-\rangle+{\rm i}\Omega\langle\sigma_z\rangle\,, \tag{18.113}$$

$$\frac{{\rm d}\langle\sigma_z\rangle}{{\rm d}t}=-\gamma\left(\langle\sigma_z\rangle+1\right)-2{\rm i}\Omega(\langle\sigma_+\rangle-\langle\sigma_-\rangle)\,. \tag{18.114}$$

The solutions for resonance ($\Delta\omega=0$) are

$$\langle\sigma_z(t)\rangle=\frac{8\Omega^2}{\gamma^2+8\Omega^2}\left[1-e^{-3\gamma t/4}\times\left(\cosh\kappa t+\frac{3\gamma}{4\kappa}\sinh\kappa t\right)\right]-1\,, \tag{18.115}$$

$$\langle\sigma_+(t)\rangle=2{\rm i}\Omega\frac{\gamma^2}{\gamma^2+8\Omega^2}\left\{1-{\rm e}^{-3\gamma t/4}\times\left[\cosh\kappa t+\left(\frac{\kappa}{\gamma}+\frac{3\gamma}{16\kappa}\right)\sinh\kappa t\right]\right\}\,, \tag{18.116}$$

where

$$\kappa=\sqrt{\frac{\gamma^2}{4}-16\Omega^2}\,. \tag{18.117}$$

Clearly there is a threshold at $\Omega=\gamma/8$ below which the solutions monotonically approach the steady state and above which they are oscillating. A similar threshold occurs in the solutions for the two-time correlation function $\langle\sigma_+(t)\sigma_-(t+\tau)\rangle_{t\to\infty}$ which determines the spectrum of the scattered light. For $\Omega\gg\gamma$ we find that this spectrum has three peaks at $\omega=\omega_{\rm a}$ and $\omega=\omega_{\rm a}\pm\Omega$. This is the *Mollow spectrum* [18.16].

The light scattered by a two-level atom also exhibits *photon anti-bunching*. Consider the conditional probability that given a photon is counted at time t another photon will be counted a time τ later. This is proportional to the second-order correlation function

$$G^{(2)}(t,\tau)=\langle a^\dagger(t)a^\dagger(t+\tau)a(t+\tau)a(t)\rangle\,. \tag{18.118}$$

Usually we are interested in a stationary source so we let $t\to\infty$ and we normalise this by the intensity squared to define

$$g^{(2)}(\tau)=\lim_{t\to\infty}\frac{G^{(2)}(t,\tau)}{\langle a^\dagger(t)a(t)\rangle^2}\,. \tag{18.119}$$

Using the result in (18.110) we can express this directly in terms of correlation functions for the atomic polarisation. As the equations of motion for the atomic variables are linear, the stationary correlation function $\langle\sigma_+(t)\sigma_+(t+\tau)\sigma_-(t+\tau)\sigma_-(t)\rangle_{t\to\infty}$ obeys the same equations [see below (18.143)]. We then find that

$$g^{(2)}(\tau)=1-{\rm e}^{-3\gamma t/4}\left(\cosh\kappa\tau+\frac{3\gamma}{4\kappa}\sinh\kappa\tau\right)\,. \tag{18.120}$$

The result $g^{(2)}(\tau=0)=0$ indicates *photon anti-bunching*, as the probability to count a second photon, immediately after a first one has been counted, vanishes. This is a direct result of the emission process of the source. Photons are emitted when an excited atom relaxes back to the ground state. If a photon is counted, the atom is likely to be in ground state and thus a finite time must elapse before it is re-excited and capable of emitting another one. This prediction, first made by *Carmichael* and *Walls* [18.17], was one of the earliest examples of how quantum optics would differ from a semiclassical description of light. This result has been seen in the resonance fluorescence of a single trapped atom.

18.4.1 Quantum Trajectories

The master equation describes the dynamics of a subsystem by averaging over (tracing out) the properties of the larger *bath* to which it is coupled. Solving the master equation typically results in a mixed state. Any mixed state admits infinitely many decompositions into convex combinations of (nonorthogonal) pure states. In a stochastic unravelling of a master equation we represent the solution at any time as a convex combination of pure states each evolving under a stochastic

Schrödinger equation such that if we average over the noise we obtain the solution to the original master equation. This approach leads to a powerful numerical simulation tool as much less memory is required to store a pure quantum state at each time step.

Consider a simple harmonic oscillator coupled to a zero-temperature heat bath. The dynamics, in the interaction picture, is given by the master equation, (18.89) with $\bar{n} = 0$. Solving this equation over a small time interval $\mathrm{d}t$ we can write

$$\rho(t+\mathrm{d}t) = \left\{\rho(t) - \frac{\gamma}{2}[a^\dagger a\rho(t) + \rho(t)a^\dagger a]\,\mathrm{d}t\right\} + \gamma a\rho(t)a^\dagger\,\mathrm{d}t\,. \tag{18.121}$$

We can think of this as describing photons leaking from a single-mode cavity at Poisson-distributed times. Suppose there were exactly n photons in the cavity at time t so that $\rho(t) = |n\rangle\langle n|$. Then (18.121) would become

$$\rho(t+\mathrm{d}t) = (1-\gamma n\,\mathrm{d}t)|n\rangle\langle n| + \gamma n\,\mathrm{d}t|n-1\rangle\langle n-1|\,. \tag{18.122}$$

We can think of this as follows. In a small increment of time $\mathrm{d}t$, two events are possible: either a single photon is lost or no photon is lost. If a photon is lost, the state of the field has one less photon so that it changes from $|n\rangle$ to $|n-1\rangle$ and this event will occur with probability $\gamma n\,\mathrm{d}t$. This form results from the last term of (18.121). On the other hand, if no photon is lost the state is unchanged, and this will occur with probability $1-\gamma n\,\mathrm{d}t$, which arises from the first term in (18.121). Thus (18.121) describes a statistical mixture of the two events that can occur in a small time step $\mathrm{d}t$: the first term in square brackets describes the change in the state of the cavity field given that no photon is lost in time interval $\mathrm{d}t$, while the second term describes what happens to the state of the field if one photon is lost in a time interval $\mathrm{d}t$.

If this interpretation is correct it suggests an answer to conditional questions such as: if no photon is lost from time t to $t+\mathrm{d}t$, what is the conditional state of the field? In this case we have no contribution from the last term in (18.121) so the conditional state is the solution to

$$\rho(t+\mathrm{d}t)_\mathrm{c} = \frac{\left\{\rho(t)_\mathrm{c} - \frac{\gamma}{2}[a^\dagger a\rho_\mathrm{c}(t) + \rho(t)_\mathrm{c}a^\dagger a]\,\mathrm{d}t\right\}}{\mathrm{tr}\left\{\rho_\mathrm{c}(t) - \frac{\gamma}{2}[a^\dagger a\rho_\mathrm{c}(t) + \rho_\mathrm{c}(t)a^\dagger a]\,\mathrm{d}t\right\}} \tag{18.123}$$

$$\approx \rho_\mathrm{c}(t) - \gamma\,\mathrm{d}t\left\{\frac{1}{2}\left[a^\dagger a\rho_\mathrm{c}(t) + \rho_\mathrm{c}(t)a^\dagger a\right] - \langle a^\dagger a\rangle_\mathrm{c}(t)\rho_\mathrm{c}(t)\right\} \tag{18.124}$$

to linear order in $\mathrm{d}t$, where the subscript c is to remind us that we are dealing with a particular conditional state conditioned on a rather special history of null events and $\langle a^\dagger a\rangle_\mathrm{c}(t)$ is the conditional average of the photon number in the state $\rho_\mathrm{c}(t)$.

We can now introduce a *classical* stochastic process, a conditional Poisson process, $\mathrm{d}N(t)$ which is the number of photons lost in time $\mathrm{d}t$. Clearly

$$\mathrm{d}N(t)^2 = \mathrm{d}N(t)\,, \tag{18.125}$$

$$\mathcal{E}[\mathrm{d}N(t)] = \gamma\langle a^\dagger a\rangle_\mathrm{c}(t)\,, \tag{18.126}$$

where $\mathcal{E}$ is an average over the classical stochastic variable. In terms of $\mathrm{d}N(t)$ we can now define a *stochastic master equation*

$$\mathrm{d}\rho_\mathrm{c}(t) = \mathrm{d}N(t)\mathcal{G}[a]\rho_\mathrm{c}(t) - \gamma\,\mathrm{d}t\,\mathcal{H}[a^\dagger a]\rho_\mathrm{c}(t)\,, \tag{18.127}$$

where we have defined two new super-operators (that map density operators to density operators),

$$\mathcal{G}[A]\rho = \frac{A\rho A^\dagger}{\mathrm{tr}[A\rho c^\dagger]} - \rho\,, \tag{18.128}$$

$$\mathcal{H}[A]\rho = A\rho + \rho A^\dagger - \mathrm{tr}[A\rho + \rho A^\dagger]\,, \tag{18.129}$$

for any operator A. Note that, if we take the classical ensemble average over the noise process $\mathrm{d}N(t)$, we recover the original master unconditional master equation in (18.121). The solution to (18.127) is the conditional state at time t conditioned on an entire fine-grained history of jump events (that is to say, the total number of jumps and the time of each jump event). Denote such a history as the sequence of jump times on the interval $[0, t)$ as $h[t] = \{t_1, t_2, \ldots, t_m\}$. The unconditional state is a sum over all such histories

$$\rho(t) = \sum_{h[t]} \Pr(h[t])\rho_\mathrm{c}(h[t])\,, \tag{18.130}$$

where we have explicitly indicated that the conditional state ρ_c is conditioned on the history of jump events, $h[t]$ in the time interval of interest and $\Pr(h[t])$ is the probability for each history. We have *unravelled* the solution to the master equation in terms of conditional stochastic events. For a point process as considered here the sum over histories has an explicit form in terms of time-ordered integrals [18.18]

$$\rho(t) = \sum_{m=0}^{\infty}\int_0^t \mathrm{d}t_m \int_0^{t_m}\ldots\int_0^{t_1} \mathcal{S}(t-t_m)\mathcal{J}\mathcal{S}(t_m - t_{m-1}) \ldots \mathcal{J}\mathcal{S}(t_1)\rho(0)\,, \tag{18.131}$$

where the super operators are defined by

$$\mathcal{S}(t)\rho = \mathrm{e}^{-\frac{\gamma}{2}ta^\dagger a}\rho\,\mathrm{e}^{-\frac{\gamma}{2}ta^\dagger a}\,, \tag{18.132}$$

$$\mathcal{J} = \gamma a\rho a^\dagger\,. \tag{18.133}$$

Clearly the probability of a specific jump history is given by

$$\Pr(h[t]) = \mathrm{tr}[\mathcal{S}(t-t_m)\mathcal{J}\mathcal{S}(t_m-t_{m-1}) \ldots \mathcal{J}\mathcal{S}(t_1)\rho(0)]\,. \tag{18.134}$$

The form of (18.131) indicates that, if we start in a pure state and have access to the entire history of photon loss events $h[t]$, the conditional state $\rho_\mathrm{c}(h[t])$ must still be a pure state. This implies that we can write a stochastic Schrödinger for the damped harmonic oscillator

$$\mathrm{d}|\psi_\mathrm{c}(t)\rangle = \left[\mathrm{d}N_\mathrm{c}(t)\left(\frac{a}{\sqrt{\langle a^\dagger a\rangle_\mathrm{c}(t)}}-1\right) + \gamma\,\mathrm{d}t\left(\frac{\langle a^\dagger a\rangle_\mathrm{c}(t)}{2}-\frac{a^\dagger a}{2}\right) - \mathrm{i}H\,\mathrm{d}t\right]|\psi_\mathrm{c}(t)\rangle\,, \tag{18.135}$$

where we have now included the possibility of a Hamiltonian part to the dynamics. We can show the equivalence between this equation and the stochastic master equation by considering the Ito-like expansion

$$\begin{aligned}\mathrm{d}\left[|\psi_\mathrm{c}(t)\rangle\langle\psi_\mathrm{c}(t)|\right] = {}& [\mathrm{d}|\psi_\mathrm{c}(t)\rangle]\,\langle\psi_\mathrm{c}(t)| + |\psi_\mathrm{c}(t)\rangle \\ & \times[\mathrm{d}\langle\psi_\mathrm{c}(t)|] + [\mathrm{d}|\psi_\mathrm{c}(t)\rangle|] \\ & \times[\mathrm{d}\langle\psi_\mathrm{c}(t)|]\end{aligned} \tag{18.136}$$

and retaining all terms to first order in $\mathrm{d}t$, noting that $\mathrm{d}N^2 = \mathrm{d}N$.

A point process with a large rate parameter γ can be well approximated on a time scale long compared to γ^{-1} by a white-noise process. This suggests that it must be possible to unravel the master equation in terms of white-noise processes as well as the point process $\mathrm{d}N(t)$. Such master equations give the conditional dynamics conditioned on homodyne and heterodyne measurements on the field leaving the cavity. Here we simply quote the result and show that averaging over the classical noise returns us to the unconditioned master equation.

In the case of the real valued Weiner process $\mathrm{d}W(t)$ we can write the *homodyne* stochastic master equation for a damped simple as

$$\begin{aligned}\mathrm{d}\rho_c(t) = {}& -\mathrm{i}[H,\rho_\mathrm{c}(t)]\,\mathrm{d}t + \mathcal{D}[a]\rho_\mathrm{c}(t)\,\mathrm{d}t \\ & + \mathrm{d}W(t)\mathcal{H}[a]\rho_\mathrm{c}(t)\,,\end{aligned} \tag{18.137}$$

where

$$\mathcal{D}[A]\rho = A\rho A^\dagger + \frac{1}{2}(A^\dagger A\rho + \rho A^\dagger A) \tag{18.138}$$

and $\mathcal{H}[a]$ is given by (18.129).

In terms of a complex-valued white-noise process, $\mathrm{d}W(t) = \mathrm{d}W_1(t) + \mathrm{i}\,\mathrm{d}W_2(t)$, where $\mathrm{d}W_i(t)$ are independent Winer processes, we can write the *heterodyne* stochastic master equation

$$\begin{aligned}\mathrm{d}\rho_\mathrm{c}(t) = {}& -\mathrm{i}[H,\rho_\mathrm{c}(t)]\,\mathrm{d}t + \mathcal{D}[a]\rho_\mathrm{c}(t)\,\mathrm{d}t \\ & + \frac{1}{\sqrt{2}}[\mathrm{d}W_1(t)\mathcal{H}[a]\rho_\mathrm{c}(t) \\ & + \mathrm{d}W_2(t)\mathcal{H}[-\mathrm{i}a]]\rho_\mathrm{c}(t)\,.\end{aligned} \tag{18.139}$$

There is a connection between the quantum jump process and the two-time correlation function discussed in above. We first define a new stochastic process, the rate or the current, as

$$i(t) = \frac{\mathrm{d}N}{\mathrm{d}t}\,. \tag{18.140}$$

This is a rather singular stochastic process, consisting of a series of delta functions concentrated at the actual jump times. In physical terms this is intended to model the output of an ideal photon counting detector, with infinite response bandwidth, that detects every photon that is lost from the cavity. Define the classical current two-time correlation function

$$G(\tau,t) = \mathcal{E}[i(t+\tau)i(t)]\,. \tag{18.141}$$

Given the nature of a Poisson jump process, $\mathrm{d}N(t)$ can only take the values 0 or 1, so it is easy to see that we can write the two-time correlation function in terms of the conditional probability to get $\mathrm{d}N(t+\tau) = 1$ given a jump at time t,

$$G(\tau,t)\mathrm{d}t^2 = \Pr(\mathrm{d}N(t+\tau) = 1\,|\,\mathrm{d}N(t) = 1)\,. \tag{18.142}$$

This conditional probability is given by

$$\begin{aligned}&\Pr[\mathrm{d}N(t+\tau) = 1\,|\,\mathrm{d}N(t) = 1] \\ &\quad = \gamma^2\mathrm{tr}\left[a^\dagger a\,\mathrm{e}^{\mathcal{L}\tau}a\rho(t)a^\dagger\right]\mathrm{d}t^2\end{aligned} \tag{18.143}$$

where $\mathrm{e}^{\mathcal{L}t}$ is the formal solution to the unconditional master equation evolution written in terms of the abstract generator $\mathcal{L}$ as $\dot\rho = \mathcal{L}\rho$. The two-time correlation function is then given by

$$G(\tau,t) = \gamma^2\mathrm{tr}\left[a^\dagger a\,\mathrm{e}^{\mathcal{L}\tau}a\rho(t)a^\dagger\right]. \tag{18.144}$$

Note that the so-called regression theorem follows directly from the definition of G,

$$\frac{\mathrm{d}G(\tau,t)}{\mathrm{d}\tau} = \mathcal{L}G(\tau,t)\,. \tag{18.145}$$

We usually deal with driven damped harmonic oscillators for which the system settles into a steady state, emitting photons according to the conditional Poisson process derived from the steady-state solution $\rho_\infty = \lim_{t\to\infty}\rho(t)$, so we define the *stationary* two-time correlation function for the current as

$$G(\tau) = \gamma^2 \mathrm{tr}\left[a^\dagger a\,\mathrm{e}^{\mathcal{L}\tau}a\rho_\infty a^\dagger\right]\,. \tag{18.146}$$

18.4.2 Simulating Quantum Trajectories

A mixed state for system with a Hilbert space of dimension N requires that we specify N^2 complex matrix elements. On the other hand a pure state requires that we specify only N complex numbers. For this reason numerically solving the master equation is more computationally difficult than solving the Schrödinger equation. We can use the unravelling of a master equation in terms of a stochastic Schrödinger equation to make the numerical solution of master equations more tractable. In this numerical setting, the method of quantum trajectories was independently developed as the *Monte Carlo wavefunction* method [18.19]. We will illustrate the method using the jump process.

Suppose the state at time t is $|\psi(t)\rangle$. Then in a time interval δt, sufficiently short compared to γ^{-1}, the system will evolve to the (unnormalised) state conditioned on no jump having occurred,

$$|\tilde{\psi}(t+\delta t)\rangle = \mathrm{e}^{-\mathrm{i}H\delta t-\gamma a^\dagger a\delta t/2}|\psi(t)\rangle\,. \tag{18.147}$$

To compute this we implement a routine to solve the Schrödinger equation with the effective non-Hermitian Hamiltonian

$$K = H - \mathrm{i}\frac{\gamma}{2}a^\dagger a\,. \tag{18.148}$$

The norm of this state is the probability that no jump has occurred in the time interval δt,

$$p_0 = \langle\tilde{\psi}(t+\delta t)|\tilde{\psi}(t+\delta t)\rangle \tag{18.149}$$

$$= 1-p\,, \tag{18.150}$$

where it is easy to see that

$$p = \gamma\delta t\langle\psi(t)|a^\dagger a|\psi(t)\rangle\,, \tag{18.151}$$

which we understand to be the probability that a jump takes place in this time interval. We need to ensure that $p \ll 1$.

Let us now chose a random number r uniformly distributed on the unit interval. At the end of the time interval, we compare p and r. If $p < r$ (usually the case) we normalise the state

$$|\psi(t+\delta t)\rangle = \frac{|\tilde{\psi}(t+\delta t)\rangle}{\sqrt{p_0}} \tag{18.152}$$

and continue the non-Hermitian evolution for a further time step. If however $p > r$, we implement a quantum jump via

$$|\tilde{\psi}(t+\delta t)\rangle \to |\psi(t+\delta t)\rangle = \frac{\sqrt{\gamma}a|\tilde{\psi}(t+\delta t)\rangle}{p/\delta t}\,. \tag{18.153}$$

Based on our previous discussions we see that $p/\delta t = \gamma\langle\psi(t)|a^\dagger a|\psi(t)\rangle$, and the jump operation is as described by the first term in (18.135). As the simulation proceeds we accumulate the record of times at which particular jump events occur. That is to say, we have access to a sample fine grained history of the jump process, $h[t]$. However we are primarily interested in solving the master equation. We thus run K trials up to time t, starting from an identical initial state each time, and then form the mixed state

$$\bar{\rho}(t) = K^{-1}\sum_{k=1}^{K}|\psi_k(t)\rangle \tag{18.154}$$

as a uniform average over the K trials. Strictly speaking the probability of each of the K trials is not uniform, however one can show that, for K sufficiently large, $\bar{\rho}(t)\approx\rho(t)$, with an error that scales as $K^{-1/2}$. In *Mølmer* et al. [18.19] more-general cases are discussed including how to simulate non-zero-temperature master equations or master equations with multiple jump processes.

18.5 Ion Traps

The ability to trap an individual ion and cool it close to the ground state of vibrational motion has enabled precise quantum control to be achieved together with very high-efficiency measurement. The technology originated some three decades ago in the effort to develop ultra-high-precision spectroscopy with particular appli-

cation to frequency standards. In recent years ion trap technology has led the field in efforts to implement quantum information processing following the seminal proposal of *Cirac* and *Zoller* in 1995 [18.20]. The technology is now entering an even more exciting phase with the development of smaller and more effective traps, ion trap arrays for coherently processing a large number of ions and the integration of traps and optical cavities.

One of the keys to the success of ion traps is the ability to detect the electronic state of a single ion with high efficiency. This is done by laser-induced fluorescence on a dipole-allowed transition, scattering millions of photons per second. The idea goes back to a proposal of *Dehmelt* in 1975 [18.21] and appears in various applications such as electron shelving, cycling transitions and quantum jumps [18.22]. Another key to the success of ion traps is the invention of sub Doppler cooling techniques, particularly resolved side band cooling. This makes it possible to prepare a single ion in a state with very few quanta of vibrational excitation, even so few as to reach the vibrational ground state. A single trapped ion is well approximated by a particle moving in a three-dimensional harmonic potential. It is possible to remove vibrational energy stochastically by laser-induced Raman transitions coupling electronic and vibrational degrees of freedom. In effect, heat is removed from the vibrational motion of of the ion and pumped into the very low temperature heat bath associated with the much higher frequency of the fluorescent radiation.

It is not possible to trap a charged particle in a static potential. This is because the Laplace equation implies there is always one unstable (not trapped) direction in the electrostatic potential. However a time-dependent electric potential can produce an effective harmonic potential for a charge particle.

The quantum description of the centre of mass motion of the ion is given in terms of the eigenstates of the Hamiltonian

$$H = \hbar\nu a_z^\dagger a_z + \hbar\nu_t\left(a_x^\dagger a_x + a_y^\dagger a_y\right) . \qquad (18.155)$$

The motion is thus separable into axial (ω_z) and transverse motion and, to be specific, we now concentrate on the axial motion alone, although much of the discussion can be applied to the transverse motion as well. Henceforth, as we neglect the transverse motion, we will drop the subscript on $a_z, a_z^\dagger$.

Many different kinds of ions can be trapped but availability of lasers limits the kinds of ions that can be easily laser cooled. For example, the Wineland group at NIST Colorado uses $^9Be^+$ while the Blatt group in Innsbruck uses $^{40}Ca^+$. When the ion is first trapped it is in a highly excited state of its vibrational motion, corresponding to a temperature of the order of 10^4 K. Cooling typically proceeds in two stages. The first stage is based on Doppler cooling and is very efficient, the second stage is based on resolved sideband cooling.

Ion traps are a remarkably versatile quantum devices for a number of reasons. Firstly, it is possible to coherently couple the vibrational motion and the internal electronic state using an external laser. Secondly, resolved sideband cooling enables the vibrational motion to be prepared in its ground state with probability approaching unity. This is done using an external laser to induce Raman transitions between the ground and excited internal electronic state which absorb one photon and one phonon of vibrational per excitation cycle. Finally, the method of fluorescence shelving enables the internal electronic state of a single trapped ion to measured with efficiency approaching unity. In order to understand these three features we need to begin with a description of how an external laser can couple the vibrational and electronic degrees of freedom.

We will assume that the external laser can couple two internal electronic states, the ground state $|g\rangle$ and the excited state $|e\rangle$. This might involve a direct dipole transition. However for quantum information applications it typically involves a Raman two-photon transition connecting the ground state to an excited metastable state. In either case the Hamiltonian describing the system is

$$H = \hbar\nu a^\dagger a + \frac{\hbar\omega_A}{2}\sigma_z + \frac{\hbar\Omega}{2}\left(\sigma_- \mathrm{e}^{\mathrm{i}(\omega_L t - k_L\hat{q})} + \sigma_+ \mathrm{e}^{-\mathrm{i}(\omega_L t - k_L\hat{q})}\right) , \qquad (18.156)$$

where $\hat{q}$ is the operator for the displacement of the ion from its equilibrium position in the trap, ν is the trap (secular) frequency, Ω is the Rabi frequency for the two-level transition, ω_A is the atomic transition frequency, and ω_L, k_L are the laser frequency and wave number. There are three frequencies in the problem: ν, ω_A and ω_L. A wide variety of processes can be made dominant by carefully choosing relationships between these three frequencies. Note that the phase of the laser field as seen by the ion is dependent upon the position of the ion. As the ion moves harmonically in the trap the phase is thus modulated at the trap frequency. As we shall see this leads to sidebands in the absorption spectrum for the two-level system.

The ion position operator, in terms of the vibrational raising and lowering operators, is

$$\hat{q} = \left(\frac{\hbar}{2m\nu}\right)^{1/2} (a + a^\dagger) \,. \tag{18.157}$$

We now define the Lamb–Dicke parameter, η

$$\eta = k_\mathrm{L} \left(\frac{\hbar}{2m\nu}\right)^{1/2} = 2\pi \Delta x_\mathrm{rms}/\lambda_\mathrm{L} \tag{18.158}$$

where the root-mean-square (r.m.s.) position fluctuations in the oscillator ground state is Δx_rms. Then moving to an interaction picture via the unitary transformation

$$U_0(t) = \exp(-\mathrm{i}\nu a^\dagger a\, t - \mathrm{i}\omega_\mathrm{A}\sigma_z t) \,, \tag{18.159}$$

the interaction Hamiltonian can be written as

$$\begin{aligned} H_I(t) = \frac{\hbar\Omega}{2} \big\{ & \sigma_- \exp[-\mathrm{i}\eta(a\,\mathrm{e}^{-\mathrm{i}\nu t} + a^\dagger \mathrm{e}^{\mathrm{i}\nu t})] \\ & \times \exp[-\mathrm{i}(\omega_\mathrm{A} - \omega_\mathrm{L})t] + \mathrm{h.c} \big\} \end{aligned} \tag{18.160}$$

The exponential of exponentials make this a complicated Hamiltonian system. However in most ion trap experiments the ion is confined to a spatial region that is significantly smaller than the wavelength of the exciting laser so that we may assume that the Lamb–Dicke parameter is small $\eta < 1$ (typically $\eta \approx 0.01$–0.1). Expanding the interaction to second order in the Lamb–Dicke parameter gives

$$\begin{aligned} H_I(t) = {} & \frac{\hbar\Omega}{2}(1 - \eta^2 a^\dagger a)\left(\sigma_- \mathrm{e}^{-\mathrm{i}\delta t} + \sigma_+ \mathrm{e}^{\mathrm{i}\delta t}\right) \\ & - \mathrm{i}\frac{\hbar\Omega\eta}{2}\left(a\,\mathrm{e}^{-\mathrm{i}\nu t} + a^\dagger \mathrm{e}^{\mathrm{i}\nu t}\right)\mathrm{e}^{-\mathrm{i}\delta t}\sigma_- \\ & + \mathrm{i}\frac{\hbar\Omega\eta}{2}\left(a\,\mathrm{e}^{-\mathrm{i}\nu t} + a^\dagger \mathrm{e}^{\mathrm{i}\nu t}\right)\mathrm{e}^{\mathrm{i}\delta t}\sigma_+ \\ & - \frac{\hbar\Omega\eta^2}{4}\left(a^2\,\mathrm{e}^{-2\mathrm{i}\nu t} + (a^\dagger)^2\,\mathrm{e}^{2\mathrm{i}\nu t}\right) \\ & \times \left(\mathrm{e}^{-\mathrm{i}\delta t}\sigma_- + \mathrm{e}^{\mathrm{i}\delta t}\sigma_+\right) \,, \end{aligned}$$

where the detuning of the laser from the atomic frequency is $\delta = \omega - \omega_\mathrm{L}$.

By carefully selecting δ to be positive or negative integer multiples of the trap frequency, various resonant terms may be extracted and all time dependent terms neglected. In the first case, known as the carrier excitation, $\delta = 0$, and the resonant terms are

$$H_\mathrm{c} = \hbar\Omega(1 - \eta^2 a^\dagger a)\sigma_x \quad \text{(carrier excitation)} \,, \tag{18.161}$$

where $\sigma_x = (\sigma_- + \sigma_+)/2$. If we choose $\delta = \nu$ so that the laser frequency is detuned below (to the red of) the carrier frequency by one unit of trap frequency, $\omega_\mathrm{L} = \omega_\mathrm{A} - \nu$, the resonant terms are

$$H_\mathrm{r} = \mathrm{i}\frac{\hbar\eta\Omega}{2}\left(a\sigma_+ - a^\dagger\sigma_-\right) \quad \text{(first red sideband excitation)} \,. \tag{18.162}$$

This is just the Jaynes–Cummings Hamiltonian except that it involves the absorption of a trap *phonon* as well as one laser photon. On the other hand we can choose $\delta = -\nu$ so that $\omega_\mathrm{L} = \omega_\mathrm{A} + \nu$ and the laser is detuned one unit of vibrational frequency to the blue of the carrier, the resonant interaction Hamiltonian is

$$H_\mathrm{b} = \mathrm{i}\frac{\hbar\eta\Omega}{2}\left(a^\dagger\sigma_+ - a\sigma_-\right) \quad \text{(first blue sideband excitation)} \,. \tag{18.163}$$

This describes an excitation process that absorbs one photon from the laser and *emits* one trap phonon. Continuing in this way we can define the second red sideband excitation $\delta = 2\nu$ and second blue sideband excitation $\delta = -2\nu$, and so on. Figure 18.2 shows an energy-level diagram that represents the carrier, red and blue sideband excitations.

Once excited to $|e\rangle$ the ion can spontaneously decay to the ground state. For a dipole-allowed transition this can be quite fast, thus enabling another excitation process to occur. In the case of red sideband excitation the net result is to remove one phonon per excitation cycle. This is the basis of sideband cooling. In effect the external laser has coupled the vibrational motion to a very-low-temperature heat bath: the vacuum radiation field at frequency ω_A. Of course it is only possible to address the sidebands if the laser can be accurately tuned to each. As each transition is homogeneously broadened by a width equal to the spontaneous emission rate, γ, we require that $\nu > \gamma$ for resolved sideband cooling. An explicit expression for the spectrum of resonance fluorescence for a single trapped ion follows from the

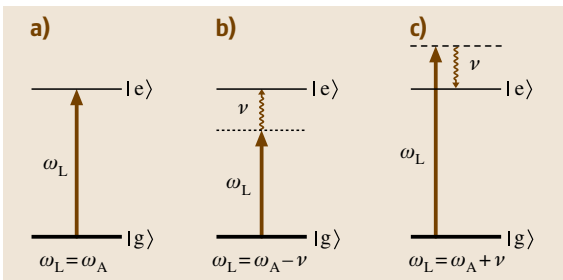

Fig. 18.2a–c Energy-level diagram for **(a)** carrier **(b)** first red sideband and **(c)** first blue sideband excitation

methods given in Sect. 18.4. A detailed calculation in the low intensity limit ($\Omega < \gamma$) for a traveling-wave field was given by *Cirac* et al. [18.23].

Resolved sideband cooling requires that the exciting laser be tuned one unit of trap frequency below the atomic transition frequency. The atom is then excited by the absorption of one laser photon and one trap phonon. In the Lamb–Dicke limit relaxation is dominated by spontaneous emission into the spectral peak at the carrier frequency ($\omega = \omega_A$). Thus on each excitation cycle one unit of vibrational energy is removed on average. A simple rate equation method suffices to understand this phenomenon. We find that the rate of change of the average phonon number is given by

$$\frac{d\bar{n}}{dt} = -\gamma \left(\frac{\eta^2 \Omega^2 \bar{n}}{2\eta^2 \Omega^2 \bar{n} + \gamma^2} \right) . \qquad (18.164)$$

Note that, as the cooling proceeds, the rate decreases until the vibrational ground state is a steady state. In a more careful treatment we need to consider heating mechanisms, for example off-resonant excitation of the blue sideband [18.24], and the probability of populating the vibrational ground state in the steady state is less than unity. Despite this, resolved sideband cooling care prepare an ion in the vibrational ground state with a probability greater than 99%. Ground state cooling in all three dimensions was first achieved by the NIST group in *Boulder* [18.25]. Other heating mechanisms due to experimental artifacts are often important. For example, fluctuating charge distributions on the trap electrodes lead to a stochastic displacement of the centre of the trap.

In order to read out the state of the ion, an additional auxiliary level can be coupled by a strong laser to one or the other of the ground or excited states, to be specific let us say the ground state Fig. 18.3. If the ion is in the ground state when the probe laser is turned on, fluorescent photons are scattered in all directions and can easily be detected. On the other hand if the ion is in the excited state, it is not resonant with the probe laser and no photons are scattered: the ion remains dark.

If we now apply a weak laser to couple the ground and excited states, incoherent transitions occur $|g\rangle \leftrightarrow |e\rangle$. The net result is that the fluorescent signal due to the probe laser blinks on and off in fashion of a random telegraph process. A typical signal is also shown in Fig. 18.3. In so far as fluorescence indicates that the ion is in the ground state, the random switching of the fluorescence is a direct indicator of *quantum jumps* between the ground and excited states.

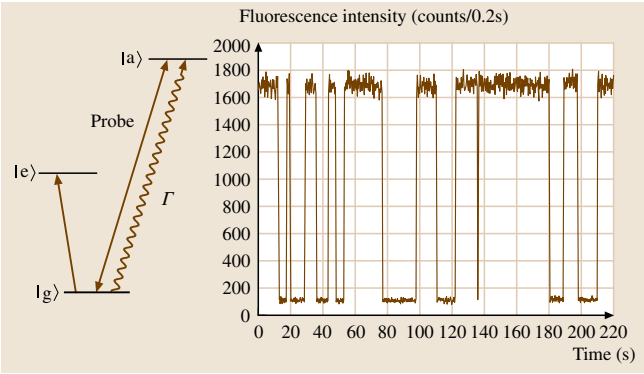

Fig. 18.3 Energy-level diagram showing fluorescence readout of the ground atomic state. A strong probe laser drives a dipole-allowed transition between the ground state $|g\rangle$ and an auxiliary state $|a\rangle$ which decays back to the ground state at a rate Γ scattering many many photons. Also shown (*right*) is the fluorescent signal on the probe transition when a weak laser couples the ground and excited state (after *Leibfried* et al. [18.24] with permission)

These jumps were first reported in a number of laboratories [18.22].

The efficiency of the readout is a function of the integration time of the fluorescence signal, that is to say, how long we need to monitor the fluorescence to be sure that we are in period of high intensity. This time must be at least of the order of the average time between photon emission events. In an experiment however there are other sources of error, such as dark counts in the detector and typically the minimum time to distinguish ground and excited states is of the order of 2 ms. We capture the quality of the readout in an overall efficiency is η which is the conditional probability for the ion to be detected in the ground state given that it was prepared in the ground state before the probe laser was turned on.

We now return to the experimental determination of the efficiency of sideband cooling. The objective is to determine the state of vibrational motion by coupling it to the internal state of the ion and then using the fluorescent readout technique described above. At the end of a cooling stage, the electronic state of the ion to is first coupled to its vibrational motion for a time T using the first red and blue sideband transitions. If we write the probability for the atom to found in the excited state after time T as $P_e^R(T)$ and $P_e^B(T)$ for red and blue sideband excitation respectively it can be shown that the mean phonon number $\bar{n}$ is given by $\bar{n}/(1+\bar{n}) = P_e^R(T)/P_e^B(T)$. Thus measurement of the ratio of excitation probability on the first red and blue sideband yields $\bar{n}$ directly.

18.6 Quantum Optomechanics

Ion traps opened up the possibility of directly controlling the quantum state of the mechanical degree of freedom of one or more ions. New fabrication techniques have now made it possible to extend this capability to bulk flexural modes of mesoscopic mechanical resonators, initiating the field of quantum optomechanics [18.26]. While the field has its roots in the development of gravitational wave interferometric detection [18.27], new experiments enable far greater control over quantum mechanical degrees of freedom, including the possibility of entangling gram scale mechanical systems separated by macroscopic distances. Applications include ultra precise measurement of weak forces and mass detection and offer a path to testing fundamental ideas on the quantum to classical transition and perhaps even the quantum effects of gravity.

While in many ways this field is similar to ion trap quantum control, for example it uses sideband cooling to approach the ground state of a vibrational degree of freedom, there is one significant difference. The quantum description of the mechanical degree of freedom in opto-mechanics begins with the classical continuum theory of elasticity in a bulk material. A wave equation is derived for classical mechanical deformation of, for example, a doubly clamped beam, and a modal decomposition of the deformation is then defined. The quantum description is then obtained by treating the amplitude functions of these modes as quantum mechanical operators. This is a kind of effective quantum theory is valid for sufficiently low temperatures where the bulk flexural mode dynamics largely factors out of the remaining microscopic degrees of freedom which are then treated as a source of dissipation and noise [18.28]. This approach to effective quantisation is very similar to the way in which collective electrical degrees of freedom are quantised in the description of superconducting circuits.

The scheme of a typical optomechanical system is shown in Fig. 18.4 based on the experiments of the Aspelmeyer group [18.29]. The field of a single mode optical cavity, described by creation and annihilation operators, $a, a^\dagger$ is coupled to a movable mirror subject to a restoring force. The mirror is thus described as a simple harmonic oscillator. The motional degree of freedom of the mirror is described by a displacement operator, $\hat{x}$, which can be written in terms of the raising and lowering operators $(b, b^\dagger)$ of a simple harmonic oscillator,

$$\hat{x} = \sqrt{\frac{\hbar}{2m\omega_\mathrm{m}}}\left(b + b^\dagger\right) \qquad (18.165)$$

where m is the effective mass of the mechanical resonator and ω_m is the frequency of the relevant vibrational degree of freedom. In the photograph in Fig. 18.4 the mirror is a Bragg reflection layer placed at the centre of a doubly clamped beam etched in silicon nitride. The Bragg mirror serves as one end mirror of a Fabry Perot cavity. The beam has dimensions $100\,\mu\mathrm{m} \times 50\,\mu\mathrm{m} \times 1\,\mu\mathrm{m}$, with a fundamental mode mechanical frequency of $\omega_\mathrm{m} = 2\pi \times 945\,\mathrm{kHz}$. The cavity decay rate $\kappa \approx 0.8\omega_\mathrm{m}$ while the decay rate of the mechanical vibrational mode $\mu = \omega_\mathrm{m}/30\,000$

The coupling between the optical field and the mechanical resonator is via radiation pressure force:

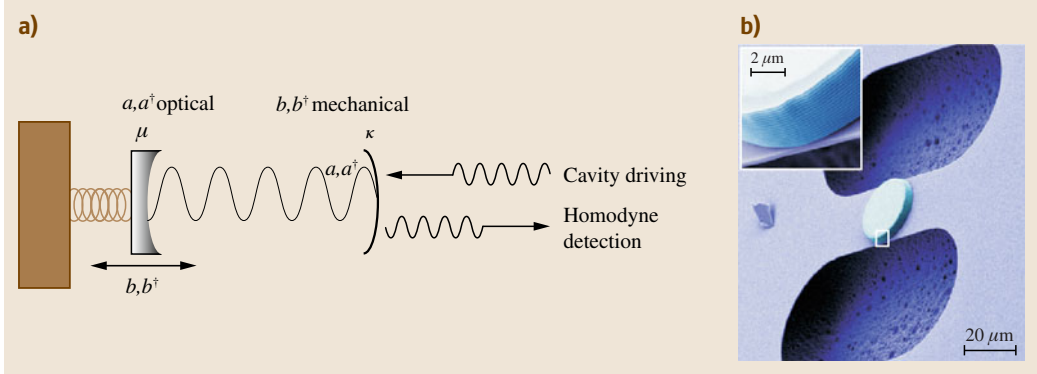

Fig. 18.4 **(a)** Schematic representation of an opto-mechanical system implemented in the group of Aspelmeyer. **(b)** A photograph of the doubly clamped mechanical resonator with Bragg reflection mirror. Reproduced with permission from Nature Physics **5**, 485 (2009). The mechanical resonator is damped at rate μ while the cavity is damped at rate κ

a linear force on the mechanical resonator proportional to the intensity of the light in the cavity [18.30]. The total Hamiltonian is

$$H = \hbar\omega_c a^\dagger a + \hbar\omega_m b^\dagger b + \hbar G a^\dagger a \hat{x} \,, \tag{18.166}$$

where $G = \omega_c/L$, where L is the length of the cavity. In typical experiments [18.29], G is of the order of one Hertz. In order to make this large, one needs to make L as small as possible. This will ultimately be limited by the wavelength of light, but some very innovative schemes have been suggested [18.31]. In many experiments, however, one drives the cavity coherently and linearises the opto-mechanical interaction around the steady state field amplitude. Under these circumstances the Hamiltonian, in an interaction picture at the frequency of the coherent driving laser ω_L, is

$$H_I = \hbar\Delta a^\dagger a + \hbar\omega_m b^\dagger b + \hbar g(a^\dagger + a)(b + b^\dagger) \,, \tag{18.167}$$

where $\Delta = \omega_c - \omega_L$, and the coupling constant is

$$g = G\alpha_0\sqrt{\frac{\hbar}{2m\omega_m}} \,, \tag{18.168}$$

where α_0 is the steady state field inside the cavity (assumed real) in the absence of the opto-mechanical coupling. In the experiment of [18.32] $g = 2\pi \cdot 325\,\mathrm{kHz}$, while $\kappa = 2\pi \cdot 215\,\mathrm{kHz}$ and $\mu = 2\pi \cdot 140\,\mathrm{Hz}$ which places this experiment in the strong coupling regime.

In close analogy to the case of a trapped ion we can now chose to drive the cavity on the red sideband, $\Delta = \omega_m$ or the blue side band, $\Delta = -\omega_m$. If the coupling is not too strong, and we are in the resolved sideband regime of $\omega_m > \kappa$, we can then make the rotating wave approximation and approximate the Hamiltonian in a new interaction picture as

$$H_I = \begin{cases} \hbar(ab^\dagger + a^\dagger b) & \text{red sideband} \,, \\ \hbar(ab + a^\dagger b^\dagger) & \text{blue sideband} \,. \end{cases} \tag{18.169}$$

Like the ion trap case we can use the red sideband driving to cool the mechanical resonator. In the experiment [18.29] the mechanical resonator was cooled to roughly 30 quanta on average, while in the experiment of *Riviere* et al. [18.33] it was cooled to on average 9 quanta. In the best case (i. e. no heating due to off-resonant blue sideband transitions and other unknown heating mechanisms), the steady state phonon number in the limit of a strongly damped cavity field is given by

$$\langle b^\dagger b\rangle_{ss} = \frac{\mu}{\Gamma}\bar{n}_m \,, \tag{18.170}$$

where $\bar{n}_m$ is the thermal mean phonon number in the bath evaluated at the temperature of the mechanical resonator.

$$\gamma_{om} = \frac{4g^2}{\kappa} \,,$$
$$\Gamma = \mu + \gamma_{om} \,.$$

Significant cooling will occur for $\gamma_{om} \gg \mu$.

The verification of cooling in these devices is done quite differently to the ion trap case. Typically one uses a transducer (e.g. homodyne detection of the output field) to monitor the long-time displacement of the mechanical resonator

$$x(t) = \sqrt{\frac{\hbar}{2m\omega_m}}\left[b(t) + b(t)^\dagger\right] \,. \tag{18.171}$$

If there is no driving force, $\langle x\rangle_{ss}$ is zero, however

$$\langle x^2\rangle_{ss} = \frac{\hbar}{2m\omega_m}(2\bar{n}_m + 1) \tag{18.172}$$

thus even at zero temperature, ($\bar{n}_m = 0$) there are fluctuations in the displacement. This is called *zero point noise*. If the transducer is quantum limited so that it does not add any additional noise to the signal, we can assume that the two-time correlation function for the measured signal is proportional to the two time correlation function,

$$G_x(\tau) = \langle x(t)x(t+\tau)\rangle_{t\to\infty} \tag{18.173}$$

and the corresponding noise power spectrum is

$$S_x(\omega) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathrm{d}\tau\, \mathrm{e}^{-\mathrm{i}\omega\tau} G_x(\tau) \tag{18.174}$$

in which case we find that

$$S_x(\omega) = \frac{\gamma(2\bar{n}_m + 1)\Delta_0^2}{\gamma^2/4 + (\omega_m - \omega)^2} \,. \tag{18.175}$$

The area under this curve is proportional to $(2\bar{n}_m + 1)$ which is a direct measurement of the average thermal occupation. On resonance and for zero temperature, this result gives the standard quantum limit (SQL)

$$S_x^{SQL} = \frac{2\hbar}{m\omega_m\gamma} \,. \tag{18.176}$$

18.7 Quantum Communication and Computation

Quantum teleportation is a new communication task enabled by quantum entanglement. It permits the transfer of an unknown quantum state from a *client* system (C) provided to a *sender* (A), to a remote *receiver* (B). The sender and receiver share a maximally entangled state, and they can communicate via a classical channel. The original proposal of *Bennett* et al. [18.34] was posed in terms of systems with a two-dimensional Hilbert space (qubits [18.35]). *Furasawa* et al. [18.36], using a proposal of *Braunstein* and *Kimble* [18.37], have demonstrated that the method can also be applied to entangled systems with an infinite-dimensional Hilbert space, specifically for harmonic oscillator states. In that work, a coherent state was teleported using an entanglement resource that consisted of a two mode squeezed vacuum state. The joint measurements required for teleportation are joint quadrature phase on the client system and that part of the entangled resource be shared by the receiver.

Teleportation of continuous variables is possible using a perfect quadrature phase quantum nondemolition (QND) measurement between two optical modes, A and B, to create the entanglement resource. The state that is produced is an optical analogue of the EPR state which had previously been shown by *Vaidman* [18.38] to enable teleportation of continuous observable. The EPR state is not a physical state because quadrature phase eigenstates are infinite-energy states. However we can use arbitrary close approximations to these states in terms of a squeezed vacuum state (18.177). This is essential feature exploited in the scheme of Furasawa et al.

Suppose that at some prior time a two-mode squeezed vacuum state is generated and that one mode is available for local operations and measurements at the sender's location A by observer Alice, while the other mode is open to local operations and measurements in the receiver's location B, by observer Bob. Alice and Bob can communicate via a classical communication channel. Thus Alice and Bob each have access to one of the two entangled subsystems described by

$$|\mathcal{E}\rangle_{\mathrm{AB}} = \sqrt{(1-\lambda^2)} \sum_{n=0}^{\infty} \lambda^n |n\rangle_{\mathrm{A}} \otimes |n\rangle_{\mathrm{B}} \qquad (18.177)$$

This state is generated from the vacuum state by the unitary transformation

$$U(r) = \mathrm{e}^{r(a^\dagger b^\dagger - ab)} , \qquad (18.178)$$

where $\lambda = \tanh r$ and where a, b refer to the mode accessible to Alice and the mode accessible to Bob, respectively.

The sender, Alice, has access to another quantum system, the client (C), in state $|\psi\rangle_{\mathrm{C}}$. Perfect (projective) measurements are made of the joint quadrature phase quantities, $\hat{X}_{\mathrm{C}} - \hat{X}_{\mathrm{A}}$ and $\hat{Y}_{\mathrm{C}} + \hat{Y}_{\mathrm{A}}$ on the client mode and the Alice's part of the entangled mode, A, with the results X and Y, respectively. The conditional state resulting from this joint quadrature measurement is described by the projection onto the state $|X, Y\rangle_{\mathrm{CA}}$ where

$$|X, Y\rangle_{\mathrm{CA}} = \mathrm{e}^{-\frac{\mathrm{i}}{2}\hat{X}_{\mathrm{A}}\hat{Y}_{\mathrm{C}}} |X\rangle_{\mathrm{C}} \otimes |Y\rangle_{\mathrm{A}} . \qquad (18.179)$$

The (unnormalised) conditional state of total system after the measurement is then seen to be given by

$$|\tilde{\Psi}^{(X,Y)}\rangle_{\mathrm{out}} =_{\mathrm{CA}} \langle X, Y|\psi\rangle_{\mathrm{C}} |\mathcal{E}\rangle_{\mathrm{AB}} \otimes |X, Y\rangle_{\mathrm{CA}} . \qquad (18.180)$$

The state of mode B at the receiver, denoted as Bob, is the pure state

$$|\phi^{(X,Y)}(r)\rangle_{\mathrm{B}} = [P(X, Y)]^{-1/2}_{\mathrm{CA}} \langle X, Y|\psi\rangle_{\mathrm{C}} \otimes |\mathcal{E}\rangle_{\mathrm{AB}} \qquad (18.181)$$

with the wave function (in the $\hat{X}_{\mathrm{B}}$ representation),

$$\phi_{\mathrm{B}}^{(X,Y)}(x) = \int_{-\infty}^{\infty} \mathrm{d}x' \, \mathrm{e}^{-\frac{\mathrm{i}}{2}x'Y} \mathcal{E}(x, x')\psi(X + x') \qquad (18.182)$$

where $\psi(x) =_{\mathrm{C}} \langle x|\psi\rangle_{\mathrm{C}}$ is the wavefunction for the client state we seek to teleport. The kernel is simply the wave function for the two-mode squeezed-state resource.

The state in (18.182) is clearly not the same as the state we sought to teleport. However in the limit of infinite squeezing, $r \to \infty$, we find that $\mathcal{G}(x_1, x_2; r) \to \delta(x_1 + x_2)$ and the state of mode B approaches

$$|\phi_{XY}(r)\rangle_{\mathrm{B}} \to \mathrm{e}^{-\frac{\mathrm{i}}{2}Y\hat{X}_{\mathrm{B}}} \mathrm{e}^{\frac{\mathrm{i}}{2}X\hat{Y}_{\mathrm{B}}} |\psi\rangle_{\mathrm{B}} \qquad (18.183)$$

which, up to the expected unitary translations in phase space, is the required teleported state.

For finite squeezing the state after Bob's conditional control is not an exact replica of the client state. We can quantify the fidelity of the reproduction by computing the probability that the state received by Bob, after displacement, is the same as the client state. This probability is called the *fidelity* and is given by

$$F = |\langle\psi| \mathrm{e}^{\frac{\mathrm{i}}{2}\mu\hat{X}_{\mathrm{B}}} \mathrm{e}^{-\frac{\mathrm{i}}{2}\nu\hat{Y}_{\mathrm{B}}} |\phi^{(X,Y)}\rangle|^2 \qquad (18.184)$$

with $\mu = gY$ and $\nu = gX$, which allows for some flexibility in the choice of displacements in the nonideal case. The quantity g is called the *gain*. In the limit of infinite squeezing we expect $g \to 1$.

In the experimental context, imperfections in the measurements, noise in the classical communication channel, degradation of the entanglement, and imperfections in the local unitary transformations, mean that Bob's state is not precisely the same as the state of the client C. A final step in any teleportation protocol is to check to see to what extent the state is teleported. In other words we need to determine the probability that the teleported state is the one we want, that is we need the fidelity. This of course requires knowledge of the actual state of the mode C. As the fidelity is a probability it must be adequately sampled, so the verification stage requires repeated measurements upon the output state of the teleportation scheme at mode B. The previously mentioned errors act independently from trial to trial which means we must describe the teleported state as a mixed state ρ_{B} in general. In this case the fidelity is given by

$$F = \langle\psi|\rho_{\mathrm{B}}|\psi\rangle\,. \tag{18.185}$$

We can also define an overall measure of performance in terms of the average fidelity $\bar{F}$ obtained by averaging the fidelity over all possible client states $|\psi\rangle$ with some appropriate measure on the set of pure states. We first need to specify the class of client states and the ensemble from which they are drawn. In the case of client states drawn from an ensemble of coherent states we can obtain an explicit result. If A and B share no entanglement $\bar{F} = \frac{1}{2}$. This is the classical boundary for teleportation of a coherent state. A quantum protocol would need to give an average fidelity greater than 0.5.

Quantum teleportation using squeezed states has been demonstrated by the group of *Kimble* at Caltech [18.36]. Related experiments have been performed by the group of di Martini in Rome [18.39] and *Zeilinger* in Innsbruck [18.40]. In order to understand the Caltech experiment we need to explain how some of the formal steps in the preceding analysis are done in the laboratory. We will also need to understand how imperfections, such as photon loss, and noise are included.

In order to effect a joint measurement of the combined quadratures $\hat{X}_C - \hat{X}_A$, $\hat{Y}_C + \hat{Y}_A$, the experiment first combined the client and sender field amplitudes on a 50/50 beam splitter, followed by direct homodyne measurements of the output fields after the beam splitter. After the beam splitter we then make a homodyne measurement of X-quadrature on mode C and the Y-quadrature on mode A. In the case of homodyne detection, the actual measurement records are two photocurrents (I_X, I_P). For unit efficiency detectors, this is an optimal measurement of the corresponding quadratures $\hat{X}_C$, $\hat{Y}_A$. In reality however efficiency is not unity and some noise is added to the measurement results. We shall return to this point later.

The measured photocurrents are a classical stochastic processes and may be sent to the receiver B over a standard communication channel. On receipt of this information the receiver must apply the appropriate unitary operator, a displacement, to complete the protocol. Displacement operators are quite easy to apply in quantum optics. To displace a mode, say B, we first combine it with another mode, prepared in a coherent state with large amplitude, $\alpha \to \infty$, on a beam splitter with very high reflectivity, $R \to 1$, for mode B. If $|\phi\rangle_{\mathrm{B}}$ is the state of B, then after the combination at the beam splitter the state of B is transformed by

$$|\phi\rangle_{\mathrm{B}} \to D(\beta)|\phi\rangle_{\mathrm{B}}\,, \tag{18.186}$$

where $D(\beta) = \exp(\beta b^{\dagger} - \beta^* b)$ is the unitary displacement operator, and

$$\beta = \lim_{R\to 1}\lim_{\alpha\to\infty} \alpha\sqrt{1-R}\,. \tag{18.187}$$

In terms of the quadrature operators for B the displacement operator can be written

$$D(x, y) = \mathrm{e}^{\mathrm{i}y\hat{X}_{\mathrm{B}} + \mathrm{i}x\hat{Y}_{\mathrm{B}}} \tag{18.188}$$

with $\beta = x + \mathrm{i}y$. A suitable choice of β will produce the required displacements to complete the teleportation protocol. This was achieved by using the measured photocurrents to control the real and imaginary components of the displacement field using electrically controlled modulators. As the measurement records, the photocurrents, are classical stochastic processes they can be scaled by a gain factor, g, to produce the required β.

The experiment included an additional step to verify to what extent the state received by Bob faithfully reproduced the stat of the client field. In this experiment the state of the client was a coherent state. In essence another party, Victor, is verifying the fidelity of the teleportation using homodyne detection to monitor the quadrature variances of the teleported state.

The key feature that indicates success of the teleportation is a drop in the quadrature noise seen by Victor when Bob applies the appropriate unitary operator to his state. This is done by varying the gain g. If Bob simply does nothing to his state ($g = 0$), then Victor simply gets one half of a squeezed state. Such a state has a quadrature noise level well above the vacuum level of

the coherent state. As Bob varies his gain, Victor finds the quadrature noise level fall until, at optimal gain, the teleportation is effected and the variance falls to the vacuum level of a coherent state. In reality of course extra sources of noise introduced in the detectors and control circuits limit the extent to which this can be achieved.

In a perfect system the fidelity should be peaked at unit gain. However photon loss in the shared entanglement resource and detector inefficiencies reduce this. In the experiment, the average fidelity at unit gain was found to be $F = 0.58 \pm 0.002$. As discussed previously, this indicates that entanglement is an essential part of the protocol.

18.7.1 Linear Optical Quantum Computing

In 1982 *Feynman* [18.41] suggested there were certain problems that would be difficult to preform on a computer running according to classical mechanics but which would be easy to do on a computer running according to quantum principles. In 1985 *Deutsch* [18.42] showed in more detail what would be required for a quantum computer (QC) and gave examples of problems that might be solved more efficiently on such a machine compared to a classical machine. The promise of quantum computation suggested by Feynman and elaborated by Deutsch was made very apparent in the factoring algorithm of *Shor* in 1994 [18.43]. Shor's algorithm is an efficient factoring algorithm for a quantum computer, while all known algorithms for factoring on a classical computer require an exponentially increasing number of steps as the size of the integer to be factored increases.

How does a quantum computer achieve this enormous increase in efficiency? The answer lies in the quantum superposition principle. Suppose we wish to evaluate a function f on some binary input string x to produce a binary output string $f(x)$. We can code the input and output binary string as the product state of N qubits. The output qubits however are preset to zero. Now we set up a machine so that under unitary quantum evolution the state transforms as

$$|x\rangle|0\rangle \rightarrow |x\rangle|f(x)\rangle \,. \tag{18.189}$$

Why do we demand that the transformation be unitary? Consider what happens when we prepare the input qubits in a uniform superposition of all possible input states;

$$\sum_x |x\rangle|0\rangle \rightarrow \sum_x |x\rangle|f(x)\rangle \,. \tag{18.190}$$

If the dynamics is unitary the linearity of quantum mechanics ensures that (18.189) implies (18.190). It would appear that in a single run of the machine we have evaluated all possible values of the function.

This is not quite as interesting as it seems. If we measure the output qubits we will get one value at random. That does not seem very useful. To see why it is useful to do this let us ask; when would we ever want to evaluate every value of a particular function? The answer, is when we are not so much interested in a particular value of the function as a *property* of the function. How can we use the superposition state in (18.190) to determine properties of functions? To see this consider a function f that maps the binary numbers $\{0, 1\}$ to $\{0, 1\}$. There must be four such functions, two of which are constant functions with $f(0) = f(1)$, and two have $f(0) \neq f(1)$, so called balanced functions. Suppose now the problem involves determining if a function is balanced or constant. On a classical computer to answer this we need to make two evaluations of the function, $f(0)$ and $f(1)$. We would then need to run the computer twice. However a quantum computer can determine this property in only a single run.

Suppose we have two qubits. One qubit will be used to encode the input data and the other qubit, the output qubit, will contain the value of the function after the machine is run. The output qubit is initially set to 0. The machine might then run according to (18.189). However there is a problem with this expression. If f is a constant function we have two distinct input states unitarily transformed to the same output state. Clearly this is not a reversible transformation and thus cannot be implemented unitarily. The problem is easily fixed however by setting up the machine to evolve the states according to

$$|x\rangle|y\rangle \rightarrow |x\rangle|y \oplus f(x)\rangle \,, \tag{18.191}$$

where the addition is defined modulo two and we have allowed all possible settings of both qubits. The unitary transformation which realises this operation has been called the f-controlled NOT gate [18.44]. The input qubit x is the control qubit while the output qubit y is the target. If the value of f on the control qubit is one, the bit on the target is flipped; thus the name. Every unitary transformation on qubits can be realised as suitable networks of simple one- and two-qubit gates using primitive gate operations.

The quantum algorithm that solves this problem is a version of a quantum algorithm first proposed by Deutsch. It proceeds as follows. In the first step we prepare the output qubit in the state $|0\rangle - |1\rangle$ (we ignore

normalisation in what follows for simplicity). This can be done using a single-qubit rotation $|1\rangle \to |0\rangle - |1\rangle$. Such a rotation is called a Hadamard transformation. In the second step the input qubit is prepared in the 0 state and is then subjected to a Hadamard gate as well, which immediately produces a superposition of the two possible inputs for the function f. In the third step we couple the input and output qubit via the f-controlled NOT gate. The transformation is

$$(|0\rangle + |1\rangle)(|0\rangle - |1\rangle) \to [(-1)^{f(0)}|0\rangle + (-1)^{f(1)}|1\rangle](|0\rangle - |1\rangle) . \tag{18.192}$$

In the last step we apply a Hadamard gate to the input qubit so that

$$[(-1)^{f(0)}|0\rangle + (-1)^{f(1)}|1\rangle](|0\rangle - |1\rangle) \to (-1)^{f(0)}|f(0) \oplus f(1)\rangle(|0\rangle - |1\rangle) . \tag{18.193}$$

Thus the input qubit is in state 0 if f is constant and is in state 1 if f is balanced and measurement of the qubit will determine if the function is balanced or constant with certainty in a single run of the machine.

There is a simple quantum optical realisation of this algorithm based on a Mach–Zehnder interferometer, see Fig. 18.5. The interferometer couples two modes of the field, labelled upper (U) and lower (L). A single photon in mode U encodes logical 1 while a single photon in mode L encodes logical 0. At the input a single photon in mode U is transformed by the first beam splitter into a superposition state in which it is in either mode 1 or mode 0. If we encode our qubits so that a $|1\rangle$ corresponds to the photon in mode 1 and a $|0\rangle$ corresponds to a photon in mode 0, the first beam splitter performs a Hadamard transformation. Now we insert into each arm a phase shift ϕ_i which can only be set at 0 or π phase shift. We encode the value of the functions as $\phi_0 = f(0)\pi$ and $\phi_1 = f(1)\pi$. Set the interferometer so that in the absence of the phase shift the photon emerges with certainty at the upper detector, which encodes a 1. The lower detector encodes a zero. It is then clear that if $f(0) = f(1)$ a single photon will emerge at the upper detector, while if $f(0) \neq f(1)$ the photon will be detected at the lower detector, that is the result is a 0.

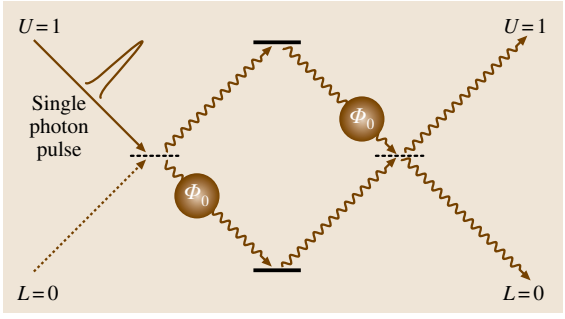

Fig. 18.5 An optical realisation of the Deutsch algorithm in terms of a Mach–Zehnder interferometer. The phase shifts are chosen according to the values of a binary function f as $\phi_0 = f(0)\pi$, $\phi_1 = f(1)\pi$

The previous example illustrates the key features of a quantum algorithm. Firstly it involves unitary transformations of pure quantum states. Secondly we need both single qubit and two qubit interactions to produce entangled states. These were the Hadamard transformation (H-gate) and a controlled NOT transformation (CNOT gate). It turns out that suitable networks of an arbitrary single qubit rotations, together with a controlled NOT gate, can perform any computation involving arbitrarily many qubits.

In the interferometric implementation of Deutsch algorithm we used a simple physical qubit based on a single-photon excitation of one of a pair of spatial modes. This is know as a *dual-rail* logic. The relationship between logical states and the physical photon number state is

$$|0\rangle_L = |1\rangle_1 \otimes |0\rangle_2 , \tag{18.194}$$

$$|1\rangle_L = |0\rangle_1 \otimes |1\rangle_2 . \tag{18.195}$$

The modes could be two input modes to a beam splitter distinguished by the different directions of the wave vector, or they could be distinguished by polarisation. In the case of a beam splitter a single qubit gate is easily implemented by the linear transformation

$$a_i(\theta) = U(\theta)^\dagger a_i U(\theta) \tag{18.196}$$

with $U(\theta) = \exp\left[\theta(a_1 a_2^\dagger - a_1^\dagger a_2)\right]$. Thus

$$a_1(\theta) = \cos\theta a_1 - \sin\theta a_2 , \tag{18.197}$$

$$a_2(\theta) = \cos\theta a_2 + \sin\theta a_1 . \tag{18.198}$$

The description in the logical basis becomes,

$$|0\rangle_L \to \cos\theta_1|0\rangle_L - \sin\theta_1|1\rangle_L , \tag{18.199}$$

$$|1\rangle_L \to \cos\theta_1|1\rangle_L + \sin\theta_1|0\rangle_L . \tag{18.200}$$

While single-qubit gates are readily implemented by linear optical devices such as beam splitters, quarter-wave plates, phase shifters etc., two-qubit gates are difficult. In order to implement the controlled phase gate (CSIGN) defined by

$$|x\rangle_L|y\rangle_L \to U_{CP}|x\rangle_L|y\rangle_L = (-1)^{x.y}|x\rangle_L|y\rangle_L . \tag{18.201}$$

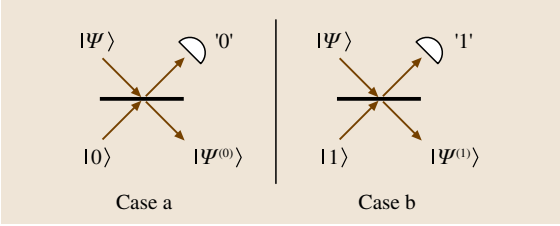

Fig. 18.6 A conditional state transformation conditioned on photon counting measurements

In a dual-rail single-photon code, this can be implemented using a two-mode Kerr nonlinearity. The two-mode generalisation is described by the Hamiltonian

$$H = \hbar\chi a_1^\dagger a_1 a_2^\dagger a_2 \,. \tag{18.202}$$

At the level of single photons this Hamiltonian produces the transformation, $|x\rangle|y\rangle \rightarrow \mathrm{e}^{-\mathrm{i}xy\chi t}|x\rangle|y\rangle$ and it is a simple matter to implement the CSIGN gate in the logical basis for the dual-rail single-photon code.

There are at least two problems in pursuing this approach: (a) the difficulty of realising number states in the laboratory, and (b) the difficulty of producing one-photon phase shifts of the order of π. The second difficulty is very considerable. Third-order optical nonlinearities are very small for a field with such a low intensity as a single photon. However experimental advances may eventually overcome this [18.45, 46].

A quite different approach to achieve large single-photon conditional phase shifts is based on the nonunitary transformation of a state that results when a measurement is made. Consider the situation shown in Fig. 18.6. Two modes of an optical field are coupled via a beam splitter. One mode is assumed to be in the vacuum state (a) or a one-photon state (b), while the other mode is arbitrary. A single-photon counter is placed in the output port of mode 2. What is the conditional state of mode 1 given a count of n photons?

Consider two modes, a_1 and a_2, coupled with a beam-splitter interaction, described by the one-parameter unitary transformation, given in (18.197), (18.198) We now assume that photons are counted on mode a_2 and calculate the conditional state for mode a_1 for two cases: no count and also for a single count at mode a_2. The conditional state of mode a_1 is given by (unnormalised),

$$|\tilde{\psi}^{(i)}\rangle_1 = \hat{\Upsilon}(i)|\psi\rangle_1 \,, \tag{18.203}$$

where

$$\hat{\Upsilon}(i) =_2 \langle i|U(\theta)|i\rangle_2 \,, \tag{18.204}$$

with $i = 1, 0$. The probability to observe each event is given by

$$P(i) = \langle\psi|\Upsilon^\dagger(i)\hat{\Upsilon}(i)|\psi\rangle_1 \tag{18.205}$$

which fixes the normalisation of the state,

$$|\psi^{(i)}\rangle_1 = \frac{1}{\sqrt{P(i)}}|\tilde{\psi}^{(i)}\rangle_1 \,. \tag{18.206}$$

We find that

$$\hat{\Upsilon}(0) = \sum_{n=0}^{\infty} \frac{(\cos\theta - 1)^n}{n!}\left(a_1^\dagger\right)^n a_1^n \,,$$

$$\hat{\Upsilon}(1) = \cos\hat{\Upsilon}^{(0)} - \sin^2\theta a_1^\dagger \hat{\Upsilon}^{(0)} a_1 \,.$$

This can be written more succinctly using normal ordering,

$$\hat{\Upsilon}(0) =: \mathrm{e}^{\ln(\cos\theta)} : \,. \tag{18.207}$$

In order to see how we can use these kind of transformations to effect a CSIGN gate, consider the situation shown in Fig. 18.7. Three optical modes are mixed on a sequence of three beam splitters with beam splitter parameters θ_i. The *ancilla* modes, a_1 and a_2 are restricted to be in the single-photon states $|1\rangle_2$ and $|0\rangle_3$, respectively. We will assume that the *signal* mode a_0 is restricted to have *at most* two photons, thus

$$|\psi\rangle = \alpha|0\rangle_0 + \beta|1\rangle_0 + \gamma|2\rangle_0 \,. \tag{18.208}$$

This captures the fact that in the dual-rail encoding a general two-qubit state can have at most two photons. The objective is to chose the beam splitter parameters so that when the two detectors at the output of modes 2 and 3 detect 1 and 0 photons respectively (that is detect no change in their occupation), the signal state is transformed as

$$|\psi\rangle \rightarrow |\psi'\rangle = \alpha|0\rangle + \beta|1\rangle - \gamma|2\rangle \tag{18.209}$$

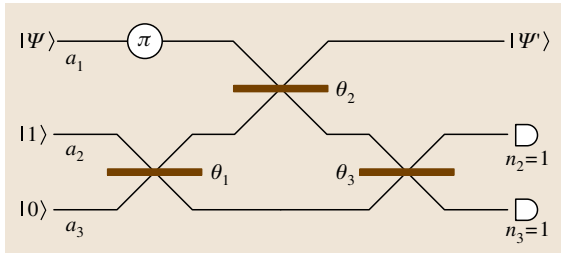

Fig. 18.7 A conditional state transformation on three optical modes, conditioned on photon counting measurements on the ancilla modes a_2, a_3. The signal mode a_1 is subjected to a π phase shift

with a probability that is *independent* of the input state $|\psi\rangle$. This last condition is essential as, in a quantum computation, the input state to a general two-qubit gate is completely unknown. We will call this transformation the NS (for nonlinear sign shift) gate. This can be achieved using: $\theta_1 = -\theta_3 = 22.5°$ and $\theta_2 = 65.53°$. The probability of the conditioning event $(n_2 = 1, n_3 = 0)$ is $1/4$. Note that we cannot be sure in a given trial if the correct transformation will be implemented. Such a gate is called a *nondeterministic* gate. However the key point is that success is heralded by the results on the photon counters (assuming ideal operation).

We can now proceed to a CSIGN gate in the dual-rail basis. Consider the situation depicted in Fig. 18.8. We first take two dual-rail qubits encoding for $|1\rangle_L|1\rangle_L$. The single-photon components of each qubit are directed towards a 50/50 beam splitter where they overlap perfectly in space and time and produces a state of the form $|0\rangle_2|2\rangle_3 + |2\rangle_2|0\rangle_3$,a effect known as the Hong-Ou-Mandel (HOM) interference [18.47]. We then insert an NS gate into each output arm of the HOM interference. When the conditional gates in each arm work, which occurs with probability $1/16$, the state is multiplied by an overall minus sign. Finally we direct these modes towards another HOM interference. The output state is thus seen to be $-|1\rangle_L|1\rangle_L$. One easily checks the three other cases for the input logical states to see that this device implements the CSIGN gate with a probability of $1/16$ and successful operation is heralded.

Clearly a sequence of nondeterministic gates is not going to be much use: the probability of success after a few steps will be exponentially small. The key idea in using nondeterministic gates for quantum computation is based on the idea of gate teleportation of *Gottesmann* and *Chuang* [18.48]. In quantum teleportation an unknown quantum state can be transferred from A to B provided A and B first share an entangled state. Gottesmann and Chuang realised that it is possible simultaneously teleport a two-qubit quantum state and implement a two-qubit gate in the process by first applying the gate to the entangled state that A and B share prior to teleportation.

We use a nondeterministic NS gate to prepare the required entangled state, and only complete the teleportation when the this stage is known to work. The teleportation step itself is nondeterministic but, as we see below, by using the appropriate entangled resource the teleportation step can be made near-deterministic. The near deterministic teleportation protocol requires only photon counting and fast feedforward. We do not need to make measurements in a Bell basis.

A nondeterministic teleportation measurement is shown in Fig. 18.9. The client state is a one-photon state in mode 0 $\alpha|0\rangle_0 + \beta|1\rangle_0$ and we prepare the entangled ancilla state

$$|t_1\rangle_{12} = |01\rangle_{12} + |10\rangle_{12}\,, \tag{18.210}$$

where mode 1 is held by the sender A and mode-2 is held by the receiver B. For simplicity we omit normalisation constants wherever possible. This an ancilla state is easily generated from $|01\rangle_{12}$ by means of a beam splitter.

If the total count is $n_0 + n_1 = 0$ or $n_0 + n_1 = 2$, an affective measurement has been made on the client state and the teleportation has failed. However if $n_0 + n_1 = 1$, which occurs with probability 0.5, teleportation succeeds with the two possible conditional states being

$$\alpha|0\rangle_2 + \beta|1\rangle_2 \quad \text{if } n_0 = 1, n_1 = 0\,, \tag{18.211}$$

$$\alpha|0\rangle_2 - \beta|1\rangle_2 \quad \text{if } n_0 = 0, n_1 = 1\,. \tag{18.212}$$

This procedure implements a partial Bell measurement and we will refer to it as a nondeterministic teleportation protocol, $T_{1/2}$. Note that teleportation failure is detected and corresponds to a photon-number measurement of the state of the client qubit. Detected number

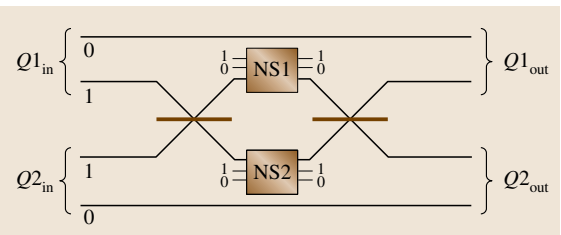

Fig. 18.8 A conditional state transformation conditioned on photon counting measurements. A CSIGN gate that works with probability of $1/16$. It uses HOM interference and two NS gates

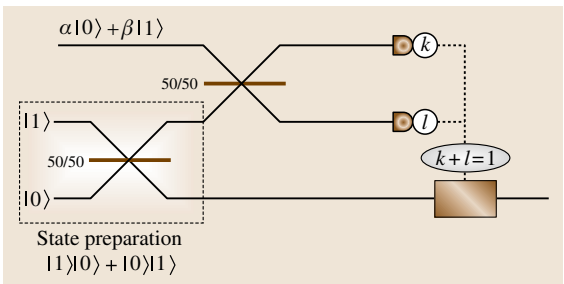

Fig. 18.9 A partial teleportation system for single-photons states using linear optics

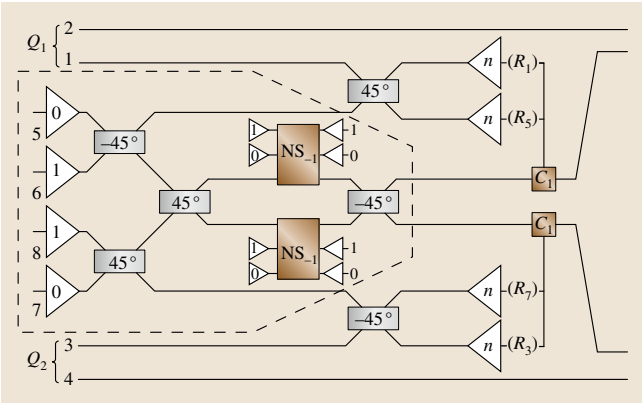

Fig. 18.10 A CSIGN two-qubit gate with teleportation to increase the success probability to 1/4. When using the basic teleportation protocol (T_1), we may need to apply a sign correction. Since this commutes with CSIGN, it is possible to apply CSIGN to the prepared state before performing the measurements, reducing the implementation of CSIGN to a state-preparation (outlined) and two teleportations. The two teleportation measurements each succeed with probability 1/2, giving a net success probability of 1/4. The correction operations C_1 consist of applying the phase shifter when required by the measurement outcomes

measurements are a very special kind of error and can be easily corrected by a suitable error correction protocol. For further details see [18.49]

The next step is to use $T_{1/2}$ to effect a conditional sign flip $\text{csign}_{1/4}$ which succeeds with probability 1/4. Note that to implement csign on two bosonic qubits in modes 1, 2 and 3, 4 respectively, we can first teleport the first modes of each qubit to two new modes (labelled 6 and 8) and then apply csign to the new modes. When using $T_{1/2}$, we may need to apply a sign correction. Since this commutes with csign, there is nothing preventing us from applying csign to the prepared state before performing the measurements. The implementation is shown in Fig. 18.10 and now consists of first trying to prepare two copies of $|t_1\rangle$ with csign already applied, and then performing two partial Bell measurements. Given the prepared state, the probability of success is $(1/2)^2$. The state can be prepared using $\text{csign}_{1/16}$, which means that the preparation has to be retried an average of 16 times before it is possible to proceed.

To improve the probability of successful teleportation to $1-1/(n+1)$, we generalise the initial entanglement by defining

$$|t_n\rangle_{1\ldots 2n} = \sum_{j=0}^{n} |1\rangle^j |0\rangle^{n-j} |0\rangle^j |1\rangle^{n-j} \,. \qquad (18.213)$$

The notation $|a\rangle^j$ means $|a\rangle|a\rangle\ldots$, j times. The modes are labelled from 1 to $2n$, left to right. Note that the state exists in the space of n bosonic qubits, where the kth qubit is encoded in modes $n+k$ and k (in this order).

To teleport the state $\alpha|0\rangle_0 + \alpha|1\rangle_0$ using $|t_n\rangle_{1\ldots 2n}$ we first couple the client mode to half of the ancilla modes by applying an $n+1$ point Fourier transform on modes 0 to n. This is defined by the mode transformation

$$a_k \to \frac{1}{\sqrt{n+1}} \sum_{l=0}^{n} \omega^{kl} a_l \,, \qquad (18.214)$$

where $\omega = \mathrm{e}^{\mathrm{i}2\pi/(n+1)}$ This transformation does not change the total photon number and is implementable with passive linear optics. After applying the Fourier transform, we measure the number of photons in each of the modes 0 to n. If the measurement detects k bosons altogether, it is possible to show [18.49] that, if $0 < k < n+1$, then the teleported state appears in mode $n+k$ and only needs to be corrected by applying a phase shift. The modes $2n-l$ are in state 1 for $0 \le l < (n-k)$ and can be reused in future preparations requiring single bosons. The modes are in state 0 for $n-k < l < n$. If $k = 0$ or $k = n+1$ an effective measurement of the client is made, and the teleportation fails. The probability of these two events is $1/(n+1)$, regardless of the input. Note that again failure is detected and corresponds to measurements in the basis $|0\rangle, |1\rangle$ with the outcome known. Note that both the necessary correction and the receiving mode are unknown until after the measurement.

The linear optics quantum computing (LOQC) model described above can be drastically simplified by adopting the cluster state method of quantum computation [18.50]. The cluster state model was developed by *Raussendorf* and *Breigel* [18.51] and is quite different from the circuit models that we have been using. In cluster state QC, an array of qubits is initially prepared in a special entangled state. The computation then proceeds by making a sequence of single-qubit measurements. Each measurement is made in a basis that depends on prior measurement outcomes. Nielsen realised that the LOQC mode of [18.49] could be used to efficiently assemble the cluster using the nondeterministic teleportation t_n. As we saw the failure mode of this gate constituted an accidental measurement of the qubit in the computational basis. The key point is that such an error does not destroy the entire assembled cluster but merely detaches one qubit from the cluster. This enables a protocol to be devised that produces a cluster that grows on average. The LOQC cluster state method

dramatically reduces the number of optical elements required to implement the original LOQC scheme. Of course if large single-photon Kerr nonlinearities were available, the optical cluster state method could be made deterministic [18.52].

A number of LOQC protocols have been implemented in the laboratory. The first was experiment was performed by *Pittmann* and *Franson* [18.53]. This used entangled ancillas that are readily produced as photon pairs in a spontaneous parametric down conversion process. A simplified version of the LOQC model was implemented by *O'Brien* et al. [18.54], based on a proposal of *Ralph* et al. [18.55] for a CNOT gate. The simplification results by firstly setting the beam splitter parameters θ_1 and θ_3 to zero in the NS gate implementation and secondly only detecting photon coincidences at the output. This gate performs all the operations of a CNOT gate but requires only a two-photon input. Detecting only coincidences means that the device must be configured so that correct operation leads to a coincidence detection of both photons at the output. The gate is nondeterministic but gate failures are simply not detected at all. In essence, the control (C) and target (T) qubits act as their own ancilla.

In the University of Queensland (UQ) experiment the two modes of each qubit are distinguished by orthogonal polarisations. This may be converted to spatial mode encoding by using polarising beam splitters and a half-wave plate. The key advantage in using a gate based on two-photon coincidence detection is that spontaneous parametric down-conversion (SPDC) may be used in place of true single-photon sources. An SPDC produces a photon pair in two distinct spatiotemporal modes at random times. There is a small probability of producing more than two photons, but this can be neglected.

On the other hand, the four photon state produced at higher order, or by multiple passes, can be used to directly implement the gates of [18.49] if the rate is high enough. An NS gate close to the original proposal, was implemented in the Zeilinger group, using a polarisation encoding and the four photon state emitted by spontaneous parametric down conversion [18.56]. As in the experiment of [18.54], a coincidence detection configuration was used to signal correct operation of the gate. The experimentally observed conditional phase shift was $1.05 \pm 0.06)\pi$. A four-photon realization of the original LOQC gate was first demonstrated by *Okamoto* et al. [18.57]. This experiment used the four-photon state, generated via type-I spontaneous parametric down-conversion, in a network of interferometers based on a displaced Sagnac interferometer and several partially polarising beamsplitters. It directly implemented the two-photon interference at the core of the LOQC scheme proposed in [18.49].

A diagnostic of the fidelity of gate operation is provided by state tomography, a reconstruction of the full density matrix of the output state [18.58], when the output is entangled. State tomography requires sampling the statistics for the measurement outcomes of 16 different two qubit projections. Given these statistics data inversion can be devised to reconstruct the density matrix for the output state. Given the density matrix, we can then compute its overlap, or fidelity, with respect to the pure ideal entangled state $|\psi^-\rangle$ that the ideal gate would produce. In the case of $|\psi^-\rangle$ the fidelity obtained in the experiment of [18.54] was 0.87 ± 0.08. This is sufficiently high that such a state were it not destroyed in the detection process, would violate a Bell inequality test. The four-photon experimental realisation by *Okamato* et al. [18.57] of the heralded CNOT gate achieved average gate fidelity of 0.82 ± 0.01.

Future progress on linear optical quantum computing schemes will most likely be based on cluster state implementations. A four-photon cluster state implementation was first implemented by the Zeilinger group [18.59]. A very elegant approach based on fusion gates was proposed by *Browne* and *Rudolph* [18.60]. A four-photon and six-qubit cluster state CNOT gate has been demonstrated by *Gao* et al. [18.61].

19. Nanooptics

Nanooptics deals with optical near fields, the electromagnetic fields that mediate the interaction between nanometric particles located in close proximity to each other. The optical near field mediates this interaction, whose energy is localized around the nanometric particles like an electron cloud around an atomic nucleus. Its decay length is proportional to the particle size. This chapter is primarily a review of nanophotonics, a leading branch of nanooptics, which is the technology utilizing the optical near field. The true nature of nanophotonics is to realize qualitative innovation in photonic devices, fabrications, and systems by utilizing novel functions and phenomena caused by optical near field interactions, which are impossible as long as conventional propagating light is used. As evidence of such qualitative innovation, this chapter describes novel nanophotonic devices, fabrication techniques, energy conversions, systems, and extensions related to science.

19.1 Basics

Nanooptics deals with the light generated in or on nanometer-sized particles. It has been applied to open an innovative field of technology, i. e., *nanophotonics*, in order to develop novel photonic devices, fabrication techniques, energy conversions, and systems, as proposed by *Ohtsu* [19.1]. Nanophotonics is a means, for example, to reduce the size of photonic devices, improve the resolution of optical fabrications, and increase the storage density of optical disc memories. However, the diffraction limit of light impedes the attainment of these improvements.

Considering photonic devices, the technologies listed below have recently been developed, which bear some resemblance to nanophotonics. Nevertheless, they cannot reduce the size of these devices beyond the diffraction limit.

19.1.1 The Photonic Crystal

This is a filter device [19.2] used to control optical interference and light scattering by installing a subwavelength-sized periodic structure in the device

material, as is the case of a diffraction grating. Constructive interference between the scattered light takes place at the center of the material, concentrating the optical energy. In contrast, at the edge of the material, the scattered light interferes destructively. In order to maintain the destructive interference, the rim must be sufficiently larger than the wavelength of light; otherwise the constructive interference is not maintained, and light concentrated at the center leaks to the rim. This means that a photonic crystal involves conventional wave-optical technology and the minimum size of the device is limited by diffraction.

19.1.2 Plasmonics

This technology utilizes the resonant enhancement of the light in a metal by exciting free electrons [19.3]. The optical energy can be concentrated as a plasmon on the metal surface as a result of the strong interaction with free electrons. However, this technology is based on wave optics in the metal, which is again limited by diffraction. Related technologies, such as metaoptics [19.4] and optics in materials with a negative refractive index [19.5], are also limited by diffraction.

19.1.3 Silicon Photonics

This technology [19.6] involves developing narrow-stripe optical waveguides using high-refractive index silicon crystals to confine the light effectively. This is also an application of wave optics in silicon, and is limited by diffraction.

19.1.4 Quantum Dot Laser

This is a laser device that uses nanometer-sized semiconductor quantum dots as the gain media [19.7]. Since the quantum dots are much smaller than the wavelength of light, the light cannot be confined in an individual quantum dot efficiently due to scattering and diffraction. To solve this problem, a large number of quantum dots are installed in a conventional laser cavity, which means that the device size is limited by diffraction.

Although the four examples listed above have been popular subjects of study in recent years, they are all based on diffraction-limited wave optics. Even if novel or nanometer-sized materials are used in the future, the size of a photonic device cannot be reduced beyond the diffraction limit as long as propagating light is used for its operation. This also applies to improvements in the resolution of optical fabrication and for increasing the storage density of optical disc memories. To go beyond the diffraction limit, one needs a non-propagating nanometer-sized light to induce primary excitation in a nanometer-sized material in such a manner that the spatial phase of excitation is independent of that of the incident light.

19.2 Principles of Nanophotonics

Nanophotonics is a promising candidate technology to decrease the size of light. If a nanometer-sized particle is illuminated by propagating light, it generates scattered light, which propagates to the far field and exhibits diffraction. However, also generated at the surface of the particle is an *optical near-field*, which is non-propagating light whose energy is localized at the particle surface. Furthermore, the extent of localization is equivalent to the particle size, which is independent of the incident light wavelength, and thus, in the case of a nanometric particle, it is much smaller than the wavelength. Therefore, if the optical near-field is utilized, novel technologies that can break through the bounds imposed by the diffraction-limit can be realized, thus enabling *quantitative innovations* in optical technology.

The optical near-field is a *virtual cloud of photons* that always exists around an illuminated nanometric particle. Its energy fluctuation δE and duration of the fluctuation τ are related by the Heisenberg uncertainty relation, $\tau\delta E \cong \hbar$, where $\hbar$ is Planck's constant divided by 2π. From this relation, the linear dimension of the virtual cloud of photons (the *virtual photons* for short) is given by $r \cong c\tau \cong \hbar c/\delta E$, where c is the speed of light. In the case of visible light illumination (photon energy $\approx 2\,\mathrm{eV}$), r is estimated to be about 100 nm. This means that the effect of the virtual photons at the surface of the illuminated particle is important if the particle is smaller than 100 nm. In other words, the optical properties of submicron-sized matter are not free from the effects of virtual photons.

This feature of the optical near-field, i. e., the virtual photons, can be most appropriately described by using a Feynman diagram (Fig. 19.1), popularly employed for elementary particle physics. In this figure, a photon is emitted from an electron in the illuminated nanometric

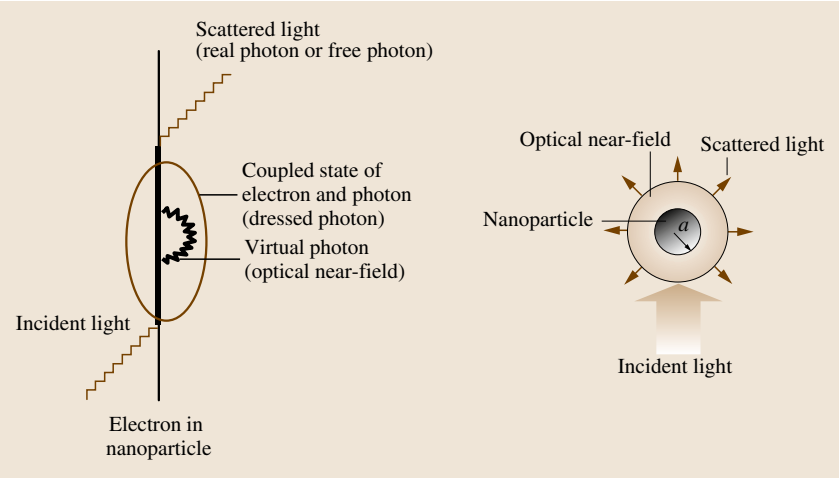

Fig. 19.1 Feynman diagram representing the generation of optical near-fields

particle and can be re-absorbed within a short duration. This photon is nothing more than a virtual photon, and its energy is localized at the surface of the nanometric particle. Independently of this virtual photon, a real photon (also called a free photon) can also be emitted from the electron. This photon is conventional propagating scattered light. Since the virtual photon remains in the proximity of the electron, it can couple with the electron in a unique manner. This coupled state, called a *dressed photon*, is a quasi-particle from the standpoint of photon energy transfer. It is the dressed photon, not the free photon, that carries the material excitation energy. Therefore, the energy of the dressed photon $h\nu_{\mathrm{dp}}$ is larger than that of the free photon $h\nu$ due to contribution of the material excitation energy.

To detect the dressed photon, a second nanometric particle should be placed in close proximity to the first particle in order to disturb the dressed photon on the first particle. This disturbance generates a free photon, which propagates scattered light that can be detected by a conventional photodetector installed in the far field. This detection scheme suggests that the dressed photon energy is exchanged between the two particles.

The dressed photon is theoretically described by assuming a multipolar quantum electro-dynamic Hamiltonian in Coulomb gauge and single-particle states in a finite nanosystem [19.8]. Its annihilation and creation operators are, respectively, expressed as

$$\tilde{a}_{\boldsymbol{k}\lambda} = a_{\boldsymbol{k}\lambda} - \mathrm{i}N_{\boldsymbol{k}} \sum_{\substack{\alpha>F \\ \beta<F}} \left[\rho^{*}_{\beta\alpha\lambda}(\boldsymbol{k})A^{\dagger}_{\alpha\beta} + \rho^{*}_{\alpha\beta\lambda}(\boldsymbol{k})A_{\alpha\beta}\right] \tag{19.1}$$

and

$$\tilde{a}^{\dagger}_{\boldsymbol{k}\lambda} = a^{\dagger}_{\boldsymbol{k}\lambda} + \mathrm{i}N_{\boldsymbol{k}} \sum_{\substack{\alpha>F \\ \beta<F}} \left[\rho_{\alpha\beta\lambda}(\boldsymbol{k})A^{\dagger}_{\alpha\beta} + \rho_{\beta\alpha\lambda}(\boldsymbol{k})A_{\alpha\beta}\right], \tag{19.2}$$

where $\boldsymbol{k}$ is the wavenumber of the free photon, λ is the polarization of a free photon, $N_{\boldsymbol{k}}$ is the normalization constant, α and β represent the electronic energy states above and below the Fermi energy level F, $\left(a_{\boldsymbol{k}\lambda}, a^{\dagger}_{\boldsymbol{k}\lambda}\right)$ and $\left(A_{\alpha\beta}, A^{\dagger}_{\alpha\beta}\right)$ are the annihilation and creation operators of the free photon and an electron–hole pair, respectively, and $\rho_{\alpha\beta\lambda}(\boldsymbol{k})$ is the Fourier transform of the spatial distribution of the transition dipole, $\rho_{\alpha\beta\lambda}(\boldsymbol{r})$, of the nanometric particle.

The real system is more complicated because the nanometric subsystem (composed of the two nanometric particles and the dressed photons) is buried in a macroscopic subsystem composed of the macroscopic substrate material and the macroscopic incident and scattered light fields. The macroscopic subsystem is expressed as an exciton–polariton, which is a mixed state of material excitation and electromagnetic fields. Since the nanometric subsystem is excited by an electromagnetic interaction with the macroscopic subsystem, the projection operator method is effective for describing the quantum mechanical states of these systems [19.9]. As a result of this projection, the nanometric subsystem can be treated as being isolated from the macroscopic subsystem, where the magnitudes of effective interaction energy between the elements of the nanometric subsystem are influenced by the macroscopic subsystem. This local electromag-

netic interaction can take place within a sufficiently short duration in which the uncertainty relation allows the exchange of dressed photons non-resonantly, as well as the exchange of a free photon resonantly. The interaction due to the non-resonant process is expressed by a screened potential using a Yukawa function $\exp(-r/a)/r$, which represents the localization of the optical near-field around the nanometric particles. Its decay length a is equivalent to the particle size, which means that the extent of localization of the optical near-field is equivalent to the particle size, as was described above.

Because the extent of localization of the dressed photon is equivalent to the nanometric particle size, the long-wavelength approximation, which has always been employed for conventional light–matter interaction theory, is not valid. This means that an electric dipole-forbidden state in the nanometric particle can be excited as a result of the dressed photon exchange between closely placed nanometric particles, which enables the operation of novel nanophotonic devices. Details of such devices will be reviewed in Sect. 19.3.

A real nanometric material is composed not only of electrons but also of a crystal lattice. In this case, after a dressed photon is generated on an illuminated nanometric particle, its energy can be exchanged with the crystal lattice. By this exchange, the crystal lattice can excite the vibration mode, creating a coherent phonon state. As a result, the dressed photon and the coherent phonon can form a coupled state. The creation operator $\hat{a}_i^\dagger$ of this novel form of elementary excitation is expressed as

$$\hat{a}_i^\dagger = \tilde{a}_i^\dagger \exp\left[-\sum_{p=1}^{N} \frac{\chi_{ip}}{\Omega_p}\left(b_p^\dagger - b_p\right)\right] , \tag{19.3}$$

where $\tilde{a}_i^\dagger$ is the creation operator of the dressed photon (19.2) localized on the ith site of the crystal lattice, N is the number of sites, χ_{ip} is the phonon–photon coupling in mode p at site i, and Ω_p is the eigenfrequency of the phonon mode p. The exponential function in this equation is called a displacement operator, composed of the photon creation and annihilation operators $\left(b_p^\dagger, b_p\right)$. This is an operator representing the creation of the coherent phonon state [19.10, 11]. This coupled state (*the dressed photon carrying the coherent phonon energy* (DP-CP)) is a quasi-particle and is generated only when the particle size is small enough to excite the crystal lattice vibration coherently. If not, the vibration is incoherent, and thus, its energy is dissipated, heating the particle.

It is easily understood that the energy of DP-CP, $h\nu_{\text{DP-CP}}$, is higher than that of the dressed photon, $h\nu_{\text{DP}}$. It is also higher than the free photon energy, $h\nu_{\text{FP}}$, incident on the nanometric particle. The relation between these energies is represented by

$$h\nu_{\text{FP}} < h\nu_{\text{DP}} < h\nu_{\text{DP-CP}} . \tag{19.4}$$

The first and second inequalities originate from the contribution of the electron and coherent phonon energies, respectively. Novel fabrication techniques allowing qualitative innovations can be developed by utilizing the DP-CP. Several examples of such innovations will be reviewed in Sect. 19.5.

19.3 Nanophotonic Devices

The size and energy consumption of electronic and optical devices must be reduced to improve the performance of information processing systems and energy conversion systems. It should be noted that conventional electronic devices can hardly meet these requirements because they need electrical wires for connection with external devices in order to fix the direction of the energy flow and the transmitted signal intensity. This means that they dissipate a large amount of energy in the external macroscopic wires. Furthermore, these electronic wires are susceptible to non-invasive attacks [19.12]. Conventional optical devices also need connecting lines, such as optical fibers and dielectric optical waveguides, as long as propagating light is used as a signal carrier. Even macroscopic free space in vacuum may play the role of the connecting line here.

Nanophotonics is a promising candidate for meeting the above requirements for two reasons: (1) a signal can be transferred by the dressed photon exchange between nanometric particles without using any wires, and (2) a non-invasive attack is impossible because the signal intensity is fixed by the energy dissipation inside the nanometric particles [19.13]. This section reviews the principles, operations, and applications of these nanophotonic devices.

19.3.1 Basic Devices

Because long-wavelength approximation is not valid due to the localized nature of the dressed photon (Sect. 19.2), an electron in the nanometric particle can be excited even to an electric dipole-forbidden energy level as a result of the dressed photon exchange between closely spaced nanometric particles, which enables novel nanometer-scale wireless optical devices with dimensions beyond the diffraction-limit, low energy consumption, and resistance to non-invasive attacks.

Figure 19.2 explains the principle of operation. Two semiconductor cubic quantum dots (QD) of different sizes are placed in close proximity to each other. The small and large QDs are used as input and output ports of the device, respectively. Quantized energy levels of excitons that are relevant to the device operation are also illustrated in this figure. The (1, 1, 1) exciton energy level in the small QD and the (2, 1, 1) energy level in the large QD are resonant with each other when the ratio of their sizes is $1 : \sqrt{2}$. However, it should be noted that these levels are electric dipole-allowed and -forbidden, respectively. If the input optical signal is applied to the small QD, an exciton can be excited to the (1, 1, 1) energy level resulting in the generation of a dressed photon. Then, this dressed photon can excite the exciton to the electric dipole-forbidden (2, 1, 1) energy level in the large QD because the long-wavelength approximation is not valid. After this excitation, the subsequent fast relaxation from the (2, 1, 1) to the (1, 1, 1) energy level in the large QD can block energy back-transfer to the small QD, guaranteeing unidirectional signal transfer from the input to the output port. It should be noted that such energy transfer to the electric dipole-forbidden level has never been realized in conventional optical devices and thus, Fig. 19.2 represents a qualitative innovation in device operation.

Based on this operating principle, novel nanophotonic devices and their associated integrated circuits have been proposed [19.14].

An optical switch (an AND gate) (Fig. 19.3) is the first example of the basic devices [19.15]. Three different-sized QDs are used as input, output, and control ports. By fixing their size ratio to $1 : \sqrt{2} : 2$, they satisfy the resonant condition of Fig. 19.2. When the input signal is applied to the input QD in order to excite the exciton to the (1, 1, 1) energy level, the dressed photon exchange allows resonant energy transfer to the electric dipole-forbidden (2, 1, 1) energy level of the output QD. After subsequent relaxation from the (2, 1, 1) to (1, 1, 1) energy level in the output QD, the energy is then resonantly transferred to the (2, 1, 1) energy level of the control QD. Similar transfer is possible also from the (1, 1, 1) energy level of the input QD to the (2, 2, 2) energy level of the control QD. Finally all the energies are transferred to the control QD, and the exciton relaxes to the (1, 1, 1) energy level to be dissipated to the external heat bath. This means that the output QD does not generate any output signals, which corresponds to the off-state of the switch (Fig. 19.3). To turn the switch on, the control signal is applied to the control QD in order to excite an exciton to its (1, 1, 1) energy level (Fig. 19.3). This excitation prohibits any energy transfers from the other QDs to the control QD due to the shifts of the energy levels of the control QD originating from the many-body effect of the exciton. As a result, an output signal is generated from the (1, 1, 1) energy level of the output QD.

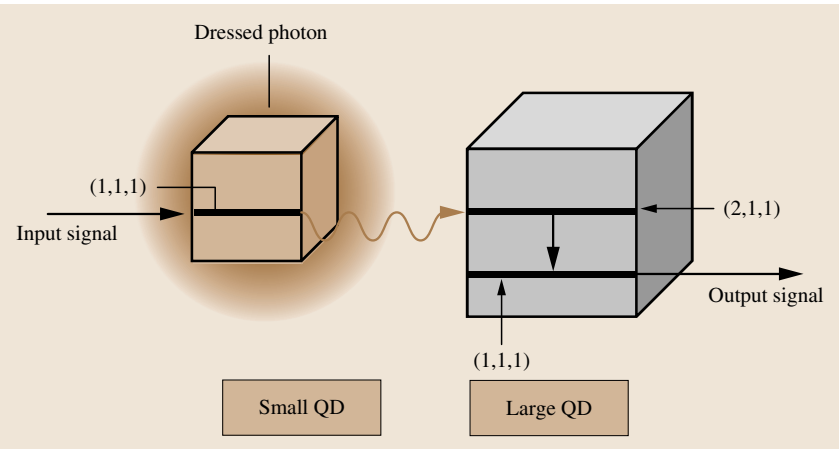

Fig. 19.2 Operating principle of a nanophotonic device

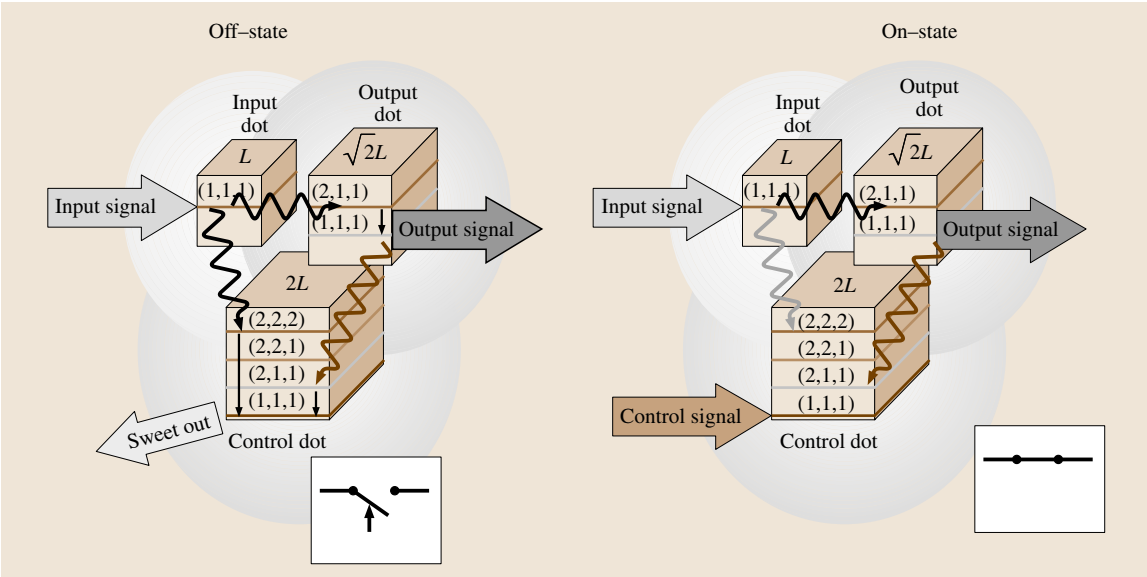

Fig. 19.3 The structure of a nanophotonic switch. L is the size of the quantum dot used as the input terminal

A switching operation has been experimentally confirmed by using cubic CuCl QDs with sizes 4 nm, 6 nm, and 8 nm separated from each other by 3 nm. They were grown in a self-assembled manner in an NaCl crystal. Experimental results were obtained at a temperature of 5 K. The output pulse shape in Fig. 19.4 represents a 25 ps rise time, determined by the time constant T of the dressed photon exchange, which is inversely proportional to the optical near-field interaction energy represented by the Yukawa function. The fall time is 4 ns, which is determined by the carrier lifetime τ_c, i. e., the time constant of the energy dissipation from the (1, 1, 1) energy level of the control QD to the heat bath. The fall time can be decreased by extracting the energy of the (1, 1, 1) energy level of the control QD into the other energy levels in additional QDs to be placed adjacent to it. The solid curve of the magnified output pulse profile in Fig. 19.4 represents the value calculated by the dressed photon theory, which agrees well with the experimental values. The oscillatory behavior in the solid curve is due to the residual bi-directional energy transfer by the dressed photon exchange between the input and output QDs.

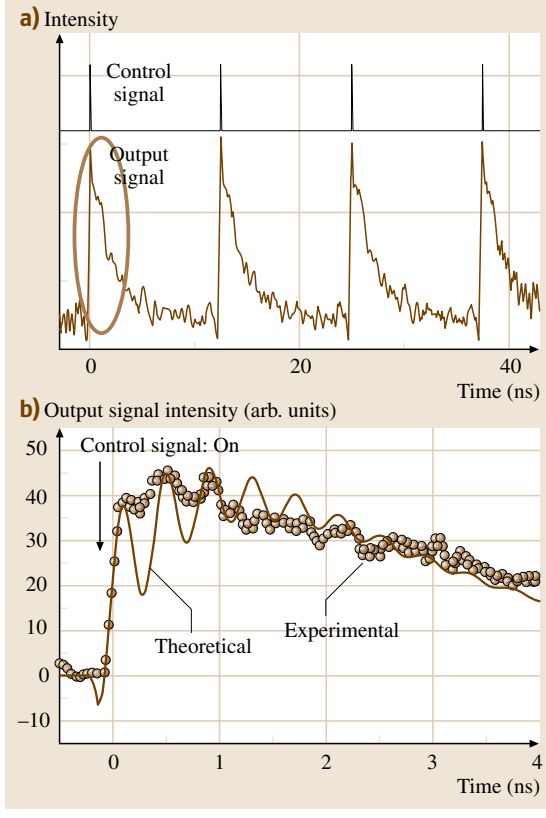

Fig. 19.4a,b Dynamic behavior of the output signal of a nanophotonic switch. **(b)** The experimental and theoretical curves of the part of the output signal identified by the ellipse in **(a)**▶

To demonstrate the room-temperature operation necessary for practical industrial applications, three layers of InAs QDs were grown in a size- and position-controlled manner by a molecular beam epitaxy method. After the growth, the sides of the layered structure were removed by phonon-assisted photolithography (Sect. 19.4.2) in order to form a switching device module. Device operation at a wavelength of 880 nm has been confirmed at a temperature as high as 210 K. Recently fabricated InAs QDs exhibited a very strong photoluminescence signal at 273 K, showing the potential for room-temperature operation for practical switching devices. By slight modification of the device structure, the switching operation was confirmed also by using two closely spaced ZnO quantum wells in a ZnO nanorod [19.16].

The second example is a NOT gate, illustrated in Fig. 19.5 [19.17]. Small and large QDs are used as output and input ports, respectively. Since their size ratio deviates slightly from $1 : \sqrt{2}$, the energy levels of the two QDs are off-resonant. Continuous wave (CW) optical energy, serving as a power supply for the device, is applied to the (1, 1, 1) energy level of the output QD in order to generate the dressed photon. However, due to the off-resonant condition, the generated dressed photon is not transferred to the (2, 1, 1) energy level of the input QD. As a result, the dressed photon is directly extracted as an output signal from the output QD (Fig. 19.5a). This represents output signal generation in the absence of the input signal.

By applying an input signal to excite an exciton to the (1, 1, 1) energy level of the input-QD, the linewidth of the (2, 1, 1) energy level of the input QD is broadened due to the decrease in the phase-relaxation time of the exciton induced by carrier–carrier scattering. This broadening allows this energy level to be made resonant with the (1, 1, 1) energy level of the output QD, by which the dressed photon, generated by the CW light, is transferred from the (1, 1, 1) energy level of the output QD to the (2, 1, 1) energy level of the input QD. After this transfer and subsequent relaxation to the (1, 1, 1) energy level in the input QD, the energy is dissipated to the heat bath, resulting in no dressed photon generation from the output QD. This means that no output signal is extracted even though the input signal is applied to the input QD (Fig. 19.5b). Such mutually anti-correlated relation features between the input and output signals, as shown by Fig. 19.5a,b, represent a NOT gate operation.

The NOT gate operation was experimentally confirmed by using CuCl QDs, as in the case of the nanophotonic switch. Figure 19.5c shows the temporal behavior of the output signal intensity, which decreases

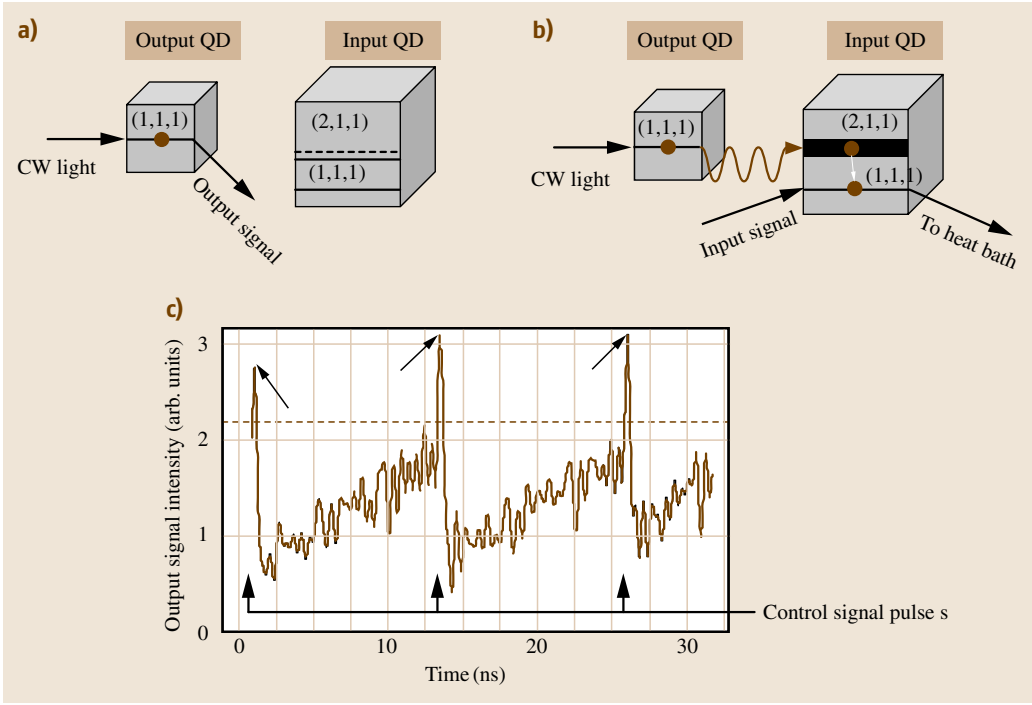

Fig. 19.5a–c A NOT gate. **(a,b)** Principles of operation. **(c)** Experimental results obtained using cubic CuCl QDs. Three peaks indicated by *arrows* represent artifact signals induced by the pulsed laser used as an input signal source

with application of the input signal pulse. For room-temperature operation, two layers of InAs QDs were grown in a size- and position-controlled manner, as in the case of the nanophotonic switch. After the growth, the sides of the layers were removed by phonon-assisted photolithography in order to form a two-dimensional array of NOT gate modules [19.17]. A two-dimensional array of more than one hundred NOT gate devices has been fabricated within a substrate area of $5\,\mu m \times 5\,\mu m$.

By combining AND and NOT gate operations, NOR, OR, and NAND gates can be assembled, allowing a complete set of logic gates to be realized for application to future information processing systems.

In addition to the basic logic gate devices reviewed above, a variety of novel devices is made possible by nanophotonics. A light emitting device, namely, an optical pulse generator, has been invented by using a chain of closely spaced QDs. Cooperative behavior of the induced electric dipoles in these QDs has been used to realize Dicke's superradiant photon emission [19.18]. An optical buffering device has also been invented by utilizing bi-directional energy transfer due to the dressed photon exchange. Its operation has been experimentally confirmed by using a multiquantum well in the ZnO nanorod [19.16]. Furthermore, optical buffering operation has also been confirmed by utilizing a time-delayed energy concentration feature of a so-called optical nanofountain [19.19]. For connecting nanophotonic devices in the integrated, a nanodot coupler has been invented based on the dressed photon exchange, and its successful operation has been confirmed by using a chain of CdSe QDs [19.20]. A novel method of fabricating a chain of ZnO QDs has been developed by utilizing DNA as a template [19.21].

19.3.2 Input and Output Terminals

Input and output terminals are used to connect the nanophotonic device in the integrated circuit with external macroscopic photonic devices. The input terminal is used to convert the incident propagating light (free photons) to the optical near-field (dressed photons). A novel device called an *optical nanofountain* has been invented for such conversion; its operation is similar to that of the light-trapping antennae in light-harvesting bacteria [19.22]. As illustrated in Fig. 19.6, it utilizes the dressed photon exchange between QDs of different sizes and subsequent fast relaxation. Finally, all of the energy of the incident propagating light is concentrated to the largest QD located at the center, resulting in the generation of dressed photons. The conversion efficiency from the free to the dressed photon energies is high because the energy is dissipated only through relaxation from upper to lower quantized energy levels in each QD.

Proper device operation has been experimentally confirmed by using CuCl QDs at low temperature, as with the nanophotonic switch and the NOT gate. Figure 19.6 shows an output optical spot with a diameter of less than 10 nm; in contrast, the spot size of the incident light (wavelength: 325 nm) was as large as 150 nm. This means that the equivalent numerical aperture of focusing is much larger than unity.

For room-temperature operation, multilayered InAs QDs were grown by molecular beam epitaxy in a size- and position-controlled manner [19.23, 24], as with the basic devices reviewed in Sect. 19.3.1. A layer of large QDs was sandwiched by 30 layers of small QDs. The dressed photons generated by applying the input propagating light to the small QDs were transferred to the large QDs. The resultant photoluminescence intensity emitted from the large QDs (wavelength: 1581 nm) was confirmed to be 40 times larger than that from a solitary layer of large QDs.

An output terminal can be easily realized by fixing a metallic nanometric particle in close proximity to the output QD of a nanophotonic device. The dressed photon is transferred from the output QD to the metallic nanometric particle in order to generate a scattered free photon, as a result of the large electric dipole and the fast relaxations of phase and energy in the metallic nanometric particle. This device operation was confirmed by fixing a gold nanometric particle on the top of a cap layer of InAs QDs. An increase in the photoluminescence intensity from the InAs QDs is due to the gold nanometric particles. This is because the impedance due to the fast relaxations of phase and energy are matched

to that of free space, resulting in efficient energy conversion from the dressed photon to the free photon.

19.3.3 Unique Features and Application to Information Processing Systems

Nanophotonic devices have several unique features, by which their predominance over conventional photonic devices has been established for application to next-generation information processing systems. One feature is undoubtedly their nanometer-scale dimensions beyond the diffraction limit, which is an example of a quantitative innovation of optical technology. However, it should be noted again that the true nature of nanophotonic devices involves their ability to realize qualitative innovations, originating from their unique features.

Low Heat Generation and Low Energy Dissipation

A nanophotonic device dissipates energy only through the relaxation from an upper electric dipole-forbidden energy level to a lower electric dipole-allowed energy level. The value of the relaxation rate Γ depends on the size and structure of the QD. Typical values are, for example, 10 and 50 meV for CuCl and InAs QDs, respectively. For more detailed estimation of the energy dissipation, the relation with the error ratio (the bit error rate) should be discussed. By referring to Fig. 19.2, the output signal is correctly generated only when the input signal is transferred from the (1, 1, 1) energy level of the small QD to the (2, 1, 1) energy level of the large QD, with subsequent relaxation to the (1, 1, 1) energy level of the large QD. An invalid output is generated if the input signal is transferred directly to the (1, 1, 1) energy level in the large QD without going through the (2, 1, 1) energy level. The possibility of this direct transfer depends on the value of the relaxation rate Γ. Based on a master-equation analysis, it was found that the error ratio due to this invalid output remained lower than 10^{-6} if the magnitude of the energy dissipation due to Γ in the large QD was larger than 25 μeV [19.25]. This small value of energy dissipation suggests that the heat generation of nanophotonic devices could be substantially lower than that of conventional electronic logic devices [19.26]. In fact, this low energy dissipation could be as low as that of the computational operations in biological systems [19.27].

Single Photon Operation

The single photon operation capability of nanophotonic devices has been confirmed by the Hanbury Brown and Twiss method [19.28], where two closely spaced CuCl QDs were used at 019 K [19.29]. Numbers of emitted photons were counted with different electric time-delays, which were acquired by using two synchronous photodetectors. The value of the synchronous count is very small at the time origin ($t = 0$). This clear anti-bunching feature indicates that the two QDs were acting as a single photon emitter. A 99.3% plausibility of single-photon emission was confirmed with 99.98% accuracy.

Resistance to Non-Invasive Attacks

Conventional electronic and optical devices need electrical or optical wires to dissipate their energies toward the external macroscopic wires in order to fix the output signal intensity. Since it is straightforward to monitor the signals transmitted through these wires by using conventional electrical or optical sensing probes, non-invasive attacks are possible [19.12]. In contrast, a nanophotonic device dissipates the energy only through the relaxation from the higher to the lower energy levels in the QD. Because the energy is dissipated by non-radiative relaxation to the crystal lattice vibration (phonon) in the QD and also because its magnitude is very low, non-invasive attacks are extremely difficult, and thus, the tamper resistance is high [19.13, 30]. This is advantageous for maintaining security in information processing systems.

In addition to the unique features outlined above, further advantages of nanophotonic devices over conventional optical devices include the possibility of novel logic operations and correlation functions. Additionally, for application to information transmission systems, their operating wavelengths are compatible with WDM systems. Although the operating speed of current WDM systems is about 10 Gbps, higher speeds are expected in the near future by decreasing the fall time. Based on these advantages, nanophotonic devices have already been employed for demonstrating prototype novel highly integrated content addressable memory (CAM) of an optical router system [19.31], which is much more effective than the huge, high power consumption conventional optical router systems.

19.4 Nanophotonic Fabrication

The unique phenomena originating from dressed photon exchange have been applied also to the development of novel high-resolution fabrication techniques. As was described in Sect. 19.2 ((19.3) and (19.4)), the principle of fabrication utilizes the dressed photon, which carries the coherent phonon energy (DP-CP). Several examples are reviewed in this section.

19.4.1 Photochemical Vapor Deposition

Photochemical vapor deposition (PCVD) involves depositing particles or films on a substrate by photodissociating organic molecules. For reviewing a novel PCVD method using the DP-CP, metallic Zn deposition is taken as an example. For this deposition, a popularly employed metal-organic molecule is gaseous diethylzinc (DEZ), whose photoabsorption energy E_{abs} and dissociation energy E_{dis} are 4.59 and 2.26 eV, respectively. The molecule stably remains in the lowest energy state $|E_g; el\rangle \otimes |E_l; vib\rangle$, where $|E_g; el\rangle$ and $|E_l; vib\rangle$ represent the ground electronic state and the lowest molecular vibrational energy state, respectively.

The DP-CP generated at a fiber probe tip enables a novel PCVD because the molecule can transit from $|E_g; el\rangle \otimes |E_l; vib\rangle$ to $|E_g; el\rangle \otimes |E_h; vib\rangle$ (where $|E_h; vib\rangle$ is a higher molecular vibrational energy state) by absorbing the DP-CP energy even though the transition is electric dipole-forbidden. If the DP-CP energy $h\nu_{DP\text{-}CP}$ is higher than E_{dis}, transfer of a single DP-CP from the fiber probe tip to the molecule is sufficient for dissociation, as is schematically explained by the Feynman diagram of Fig. 19.7a. When $h\nu_{DP\text{-}CP} < E_{dis}$, multiple DP-CP transfer is required for dissociation, by which the molecule can be excited to the excited electronic state $|E_{ex}; el\rangle \otimes |E_l; vib\rangle$. Figure 19.7b shows the case where two DP-CPs are transferred, i. e., two-step excitation of the molecule for dissociation. These processes are named *phonon*-assisted. One technical advantage of these processes is that a high power consumption short wavelength light source is not required. In principle, one can use a longer wavelength light source even if its photon energy is lower than E_{dis}, which represents a qualitative innovation of this novel PCVD.

Figure 19.8a–c shows AFM images of the nanometric Zn particles deposited on a sapphire substrate as a result of dissociating DEZ molecules by the phonon-assisted PCVD using ultraviolet ($h\nu_{FP} = 3.81$ eV; wavelength $= 325$ nm), blue ($h\nu_{FP} = 2.54$ eV; wavelength $= 488$ nm), and red ($h\nu_{FP} = 1.81$ eV; wavelength $= 684$ nm) light sources, respectively, for generating the DP-CP at the fiber!probe tip [19.32]. On the other hand, Fig. 19.8d is an image of a nanometric Zn particle deposited by dissociating $Zn(acac)_2$ molecules [19.33]. It should be noted that this molecule is optically inactive, i. e., adiabatic dissociation is not possible; however, it was successfully dissociated by the phonon-assisted process.

The relation between the photon flux I of the incident light and the deposition rate R of the Zn nanometric particles can be expressed as $R = aI + bI^2 + cI^3 + \cdots$, where the first, second, and third terms rep-

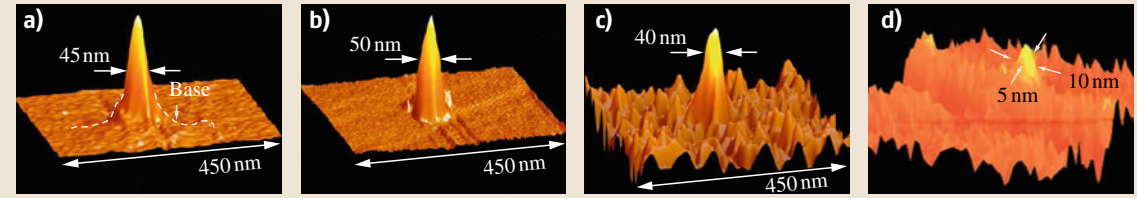

Fig. 19.8a–d AFM images of nanometric Zn particles deposited on a sapphire substrate by phonon-assisted PCVD using **(a)** ultraviolet, **(b)** blue, and **(c)** red light sources. **(d)** Image of a nanometric Zn particle deposited by dissociating optically inactive $Zn(acac)_2$ molecules

resent single-, two-, and three-step excitation by the DP-CP, respectively. Since its photon energy $h\nu_{FP}$ of the ultraviolet light is higher than E_{dis}, single-step excitation is sufficient to dissociate the DEZ molecules. The experimental results are fitted by the solid line $R = aI$. Since the photon energy $h\nu_{FP}$ of the blue light is still higher than E_{dis}, single-step excitation is sufficient here, too. However, by increasing the incident light intensity I, two-step excitation becomes possible. The experimental results are fitted by the solid curve $R = aI + bI^2$. In the case of the red light, the photon energy $h\nu_{FP}$ is lower than E_{dis}; thus, two-step excitation is essential for dissociation. By increasing I, even three-step excitation becomes possible. The experimental results are fitted by the solid curve $R = bI^2 + cI^3$.

On the basis of the dressed photon theory and the important role of electric dipole-forbidden molecular vibrational excitations, recent theoretical studies have proposed a simple model to describe atom or atom-cluster desorption due to the dressed photons from a nanometric particle deposited on a substrate [19.33]. This model could potentially lead to a novel fabrication method, in addition to controlling the size and position of nanostructures [19.34].

19.4.2 Photolithography

The phonon-assisted process can be applied also to photolithography in order to pattern widely available commercial photoresists by using a visible light source even though such photoresists are sensitive only to UV light. To confirm this patterning ability, a film of commercial photoresist (OFPR) was coated on a substrate, and a photomask having a subwavelength sized aperture was mounted on it. Applying visible light to the photomask, low-intensity propagating light passes through aperture. However, the photoresist was not patterned by this propagating light because it is sensitive only to the UV propagating light. In contrast, a DP-CP is generated at the edge of the photoresist, and its energy is transferred to the photoresist, by which the photoresist is activated and patterned by the phonon-assisted process [19.35]. Figure 19.9 shows an AFM image of the linear pattern formed on the OFPR photoresist with an exposure time longer than the threshold. The linewidth of the fabricated pattern was as narrow as 90 nm, which is equivalent to the width of the aperture and is much narrower than the wavelength (550 nm) of the incident visible light. For comparison with the conventional photolithography based on the adiabatic process, the same OFPR photoresist and the same photomask were used.

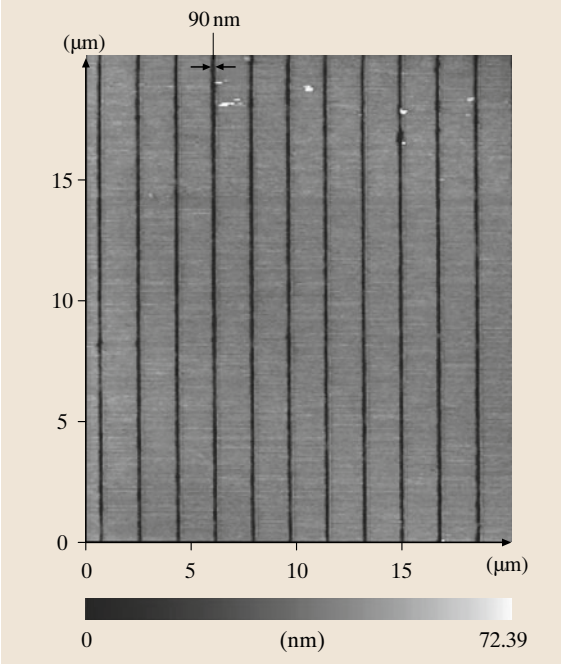

Fig. 19.9 Top view of a photoresist with a corrugated pattern that was fabricated non-adiabatically using optical near fields

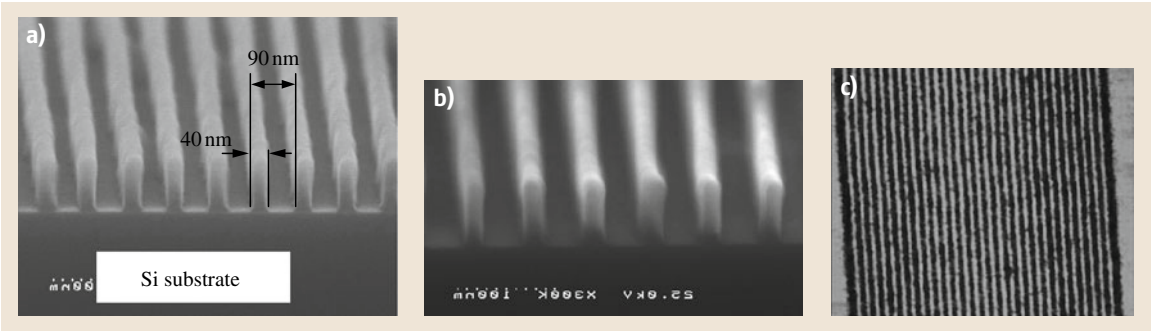

Fig. 19.10a–c Examples of patterns fabricated by a machine. **(a)** A linear pattern of 40 nm width lines at 90 nm intervals. **(b)** High-aspect-ratio patterns with a half pitch of 32 nm. **(c)** The minimum linewidth (22 nm) of the linear patterns

However, they were illuminated by UV light to which the OFPR photoresist was sensitive. The resultant linewidth of the pattern was as wide as 300 nm, which is much broader than that of Fig. 19.9. Such a broader linewidth was due to the diffraction of the propagating UV light passing through the aperture, to which the photoresist is sensitive. By comparing these results, it is concluded that higher resolution was obtained by using a longer-wavelength light source, which is longer than the absorption band edge wavelength of the photoresist. This means that large, expensive, high power consumption, short-wavelength x-ray, EUV, and UV light sources are not required for phonon-assisted photolithography. In addition to the high resolution obtained with a visible light source, this method based on the phonon-assisted process has several advantages, including multiple exposure and patterning of optically inactive film [19.35].

Based on the results outlined above, a prototype machine for producing commercial products has been constructed in collaboration with industry [19.36]. It occupies an area as small as 1 m^2. It uses a conventional Xe lamp as a light source and is operated by computer-controlled robotics. A resolution of 20–50 nm is guaranteed for a substrate area of 50 mm × 60 mm. A wider patterned area is expected by employing a mechanical stepper system. A two-layer resist film is employed to fabricate a high-aspect-ratio pattern and a lubricant is coated to remove the photomask from the photoresist without damaging the photomask surface. Although photomasks were fabricated by electron beam lithography in the early stages of the present study, it has become possible to fabricate them by phonon-assisted photolithography. It should be pointed out that a metallic photomask may sacrifice the resolution due to diffraction of the plasmonic wave. To solve this problem, the plasmonic wave on the photomask surface must be suppressed, for which it is advantageous to use Si as a photomask material.

Examples of the patterns fabricated by this machine are: a 40 nm-linewidth linear pattern (Fig. 19.10a), a high-aspect-ratio pattern (Fig. 19.10b), a pattern with a minimum linewidth of 22 nm realized by making high-resolution photoresist (Fig. 19.10c), two-dimensional arrays of rings and discs, and so on [19.36]. This machine has been made available for public use. Examples of its use include the fabrication of a two-dimensional array of room-temperature operated nanophotonic NOT gates composed of InAs QDs, linear and curved Si optical waveguides, and so on. Other examples of fabricated structures include diffraction gratings and Fresnel zone plates for soft x-rays with a wavelength of 0.5–1.0 nm. It should be pointed out that these devices were fabricated by using green light, whose wavelength is more than 500 times longer than that of soft x-rays. For the diffraction gratings, corrugations of 7600 lines/mm were patterned on a Si substrate, which were coated with Mo/SiO_2 multilayer films. The evaluated diffraction efficiency is as high as 3% in the wavelength range of 0.5–1.0 nm. This is higher than that of a commercially available diffraction grating using the crystal lattice of KAP [19.37]. This high efficiency confirms the high resolution and high reproducibility of the prototype lithography machine. For Fresnel zone plates, concentric circular patterns were fabricated on a Ta film [19.38]. Figure 19.11 shows a high-contrast SEM image of a fabricated Fresnel zone plate. The outer diameter, linewidth on the rim, and number of rings were 400 μm, 420 nm, and 230, respectively. The thickness of the Ta was 65 nm. The present phonon-assisted photolithography realized higher contrast than the conventional adiabatic photolithography, especially for rings of higher order.

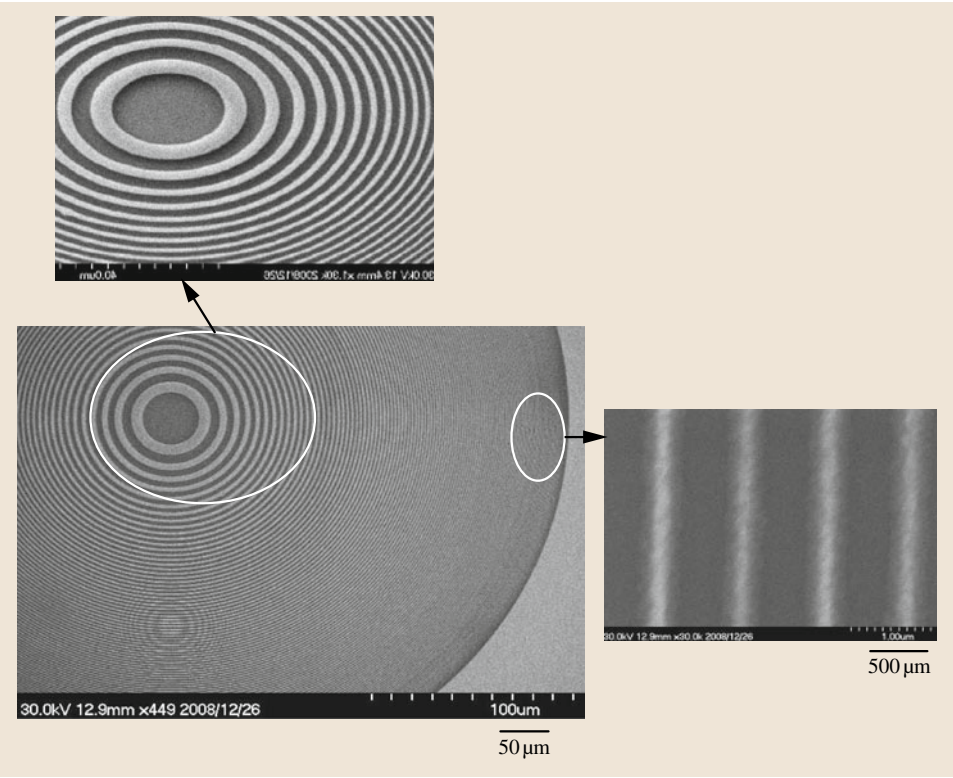

Fig. 19.11
Fabricated Fresnel zone plate (SEM image)

A notable advantage of this method of fabricating soft x-ray optical devices is its mass-production capability. For example, a two-dimensional array of Fresnel zone plates prepared on the photomask were transferred to the photoresist with an exposure of several minutes, and thus, 49 Fresnel zone plates were simultaneously fabricated. This process demonstrates that the fabrication throughput is much higher than that of raster-scanned electron beam lithography, which has been conventionally used for fabricating Fresnel zone plates. This demonstrates that dressed photon technology shows the possibility of mass-producing even devices for soft x-rays, from which novel applications are expected, such as portable soft x-ray fluorescence spectrometers for analyzing items of cultural heritage and security inspection systems.

Although the prototype machine is fully automatic and can be used to fabricate a variety of devices, a more compact and simple machine is sufficient for the purpose of fabricating a limited species of devices. A compact, desk-top machine has a footprint of only $0.03\,m^2$. A single light emitting diode (LED) emitting green light with a power of 30 mW and driven with input electrical power of 4.5 W was used as a light source. Even such a simple machine can fabricate a two-dimensional array of room-temperature operated nanophotonic NOT gates, linear and curved Si optical waveguides, diffraction gratings, and Fresnel zone plates for soft x-rays. Such machines have many benefits compared with conventional photolithography stepper systems, which are large and expensive and have high power consumption because they need short-wavelength light sources.

19.4.3 Self-Organized Smoothing

For further increases in the throughput of patterning, maskless methods are reviewed in this section. The key to these methods is to exploit the fact that DP-CPs can always be generated on a nanometrically rough material surface when it is illuminated with light. Even if the surface is flat, DP-CSs are also generated at the parts at which the structure or component is nanometrically singular. The generated DP-CPs cause smoothing of locally rough parts or make the sizes of individual parts uniform. After they become flat or homogeneous,

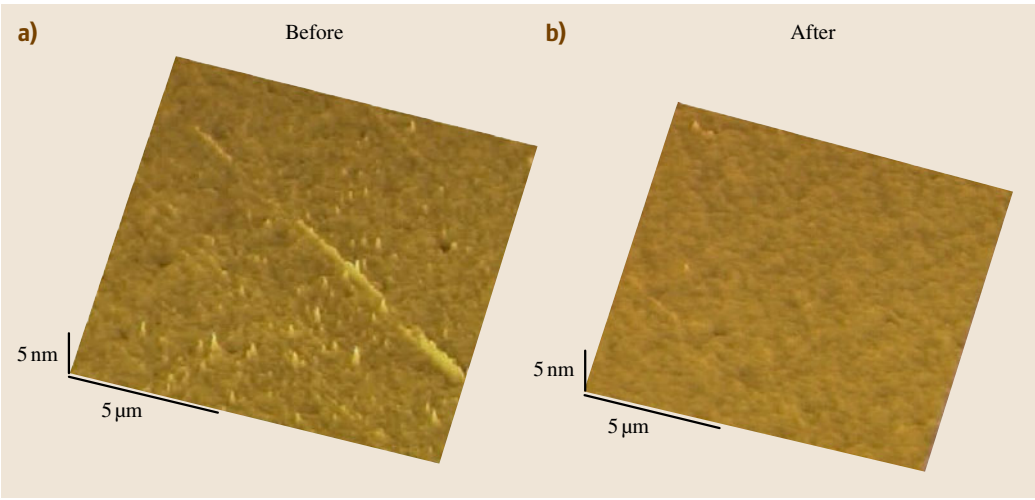

Fig. 19.12a,b Results of phonon-assisted photochemical etching of a glass substrate surface. AFM images of the glass surfaces before **(a)** and after **(b)** the etching

the smoothing or homogenizing stops automatically because the DP-CPs are no longer generated. Thus, they are called self-organized processes.

It should be noted that the methods reviewed below can be applied not only to a planar substrate but also to convex and concave substrates. They can also be applied to an inner wall surface of a cylinder if it can be illuminated by propagating light. Furthermore, they can be used for a variety of materials, such as glasses, crystals, ceramics, metals, plastics, and so on.

(1) Repairing Surface Roughness

Phonon-assisted photochemical etching was developed for smoothing the surface of glass, with the goal of fabricating high-quality mirrors for high-power, short-pulse laser systems [19.39]. A glass substrate with nanometric surface roughness is installed in a vacuum chamber filled with gaseous Cl_2 molecules. Although the absorption band edge wavelength of these molecules is 400 nm, a propagating light with a wavelength as long as 532 nm is used for photochemical etching. The Cl_2 molecules remain stable above the flat glass surface because of the absence of DP-CPs. However, DP-CPs are generated at the tips of bumps on the illuminated rough surface, and by exchange of DP-CPs between the bumps and the Cl_2 molecules, the Cl_2 molecules are dissociated to produce radical Cl atoms, which etch the tips of the bumps. By this phonon-assisted process, the photochemical etching spontaneously starts to remove the bumps when the glass surface is illuminated with incident propagating light, and it stops spontaneously when the glass surface becomes so flat that DP-CPs are no longer generated. Thus, it is a self-organized method of smoothing the surface. As shown in Fig. 19.12, the magnitude of the roughness decreased from 0.23 to 0.13 nm after 60 min of photochemical etching. This figure shows that the scratches, bumps, and digs formed in the process of preliminary mechano-chemical polishing were successfully removed by the phonon-assisted photochemical etching.

Phonon-assisted desorption was developed for smoothing the surface of transparent alumina (Al_2O_3), which is a hard polycrystalline ceramic, with the aim of fabricating low-loss gain media for ceramic lasers to be used in laser-driven spark plugs for ignition systems in automobile engines [19.40,41]. It was expected that surface roughness, including the scratches formed in the preliminary grinding by diamond abrasive grains, would be repaired by sputtering Al_2O_3 particles and phonon-assisted desorption. An alumina substrate is placed in a vacuum chamber, and Al_2O_3 particles are deposited on the substrate by RF sputtering. The substrate is illuminated with visible light (400 mW/cm^2 power density) whose wavelength (473 nm) is longer than that of the absorption band edge wavelength (260 nm) of the Al_2O_3 particles. By this illumination, DP-CPs are generated on the ridges of the scratches, which causes the Al_2O_3 particles to be activated, increasing the migration length, or which causes them to be desorbed from the ridge. On the other hand, on the flat areas and the slopes of the scratches, the Al_2O_3 particles are deposited with the same deposition rate because of the absence of DP-CPs. By this phonon-assisted process, the deposition at the ridges is suppressed, whereas the bottoms of the scratches are filled by the Al_2O_3 particles, and finally, the scratches

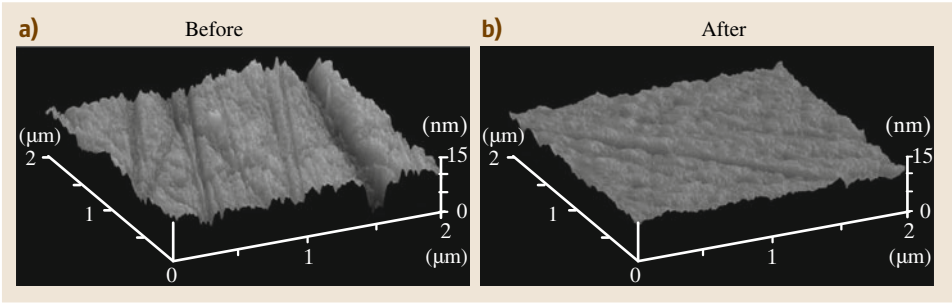

Fig. 19.13a,b Experimental results of RF sputtering. AFM images of the alumina substrate surface **(a)** before and after **(b)** RF sputtering under visible light illumination

are repaired. It is a self-organized method of smoothing the surface, as in case (1). Experimental results are shown in Fig. 19.13, which shows a drastic change in the surface profile.

(2) Homogenizing Mole-Fraction Ratio

The spatial distribution of the mole-fraction ratio x of indium (In) in an $In_xGa_{1-x}N$ film was homogenized by phonon-assisted desorption in a self-organized manner [19.42]. The motivation for this homogenization is to increase the color-rendering index of an $In_xGa_{1-x}N$ LED by controlling the spectral profile of the emitted light for applications to high-quality lighting, displays, and so on. It is possible to control this index because the emission wavelength λ_e, increases from 400 nm to 1.50 μm by increasing x from 0 to 1, as a result of the decrease in the bandgap energy E_g from 3.10 to 0.83 eV.

While the TEI, TMG, and NH_3 source gases are supplied for doping In, Ga, and N, respectively, in $In_xGa_{1-x}N$ on the substrate, the film surface is illuminated with visible light. Due to this illumination, DP-CPs are generated on the film surface with a spatial profile that depends on the local singularities, i. e., on the mole-fraction ratio x. In an area of larger mole-fraction ratio x_0 and bandgap energy E_{g0} lower than the energy $h\nu_{DP\text{-}CP}$ of the DP-CPs, the $In_xGa_{1-x}N$ film absorbs the DP-CP energy and transfers it to the doped In for desorption. As a result, the mole-fraction ratio x_0 decreases. On the other hand, in an area of lower mole-fraction ratio x_1 and bandgap energy E_{g1} higher than the energy $h\nu_{DP\text{-}CP}$, the $In_xGa_{1-x}N$ film does not absorb the DP-CP energy, and thus, the In can be steadily doped into the substrate without desorption. As a result, the mole-fraction ratio x_1 increases. The decrease and increase continue until the bandgap energies E_{g0} and E_{g1} reach $h\nu_{DP\text{-}CP}$. Finally, both mole-fraction ratios x_0 and x_1 reach a value $x_{DP\text{-}CP}$, which is determined by $h\nu_{DP\text{-}CP}$. This means that the mole-fraction ratio can be spatially homogenized in a self-organized manner. Further, the photon energy of the incident light can determine the value $x_{DP\text{-}CP}$ of the homogenized mole-fraction ratio and the wavelength of the light emitted from the $In_xGa_{1-x}N$ film.

For experimental confirmation of this effect, room-temperature PCVD was employed to grow an $In_xGa_{1-x}N$ film on a sapphire substrate [19.43] while visible light was made incident on the film surface for desorbing In. Figure 19.14 shows the spectral profiles of the photoluminescence emitted from the $In_xGa_{1-x}N$ film grown in this way. Spectral narrowing is seen in the area of the photon energy lower than that of the incident light ($h\nu_{FP} = 2.71$ eV; wavelength = 457 nm; power = 200 mW).

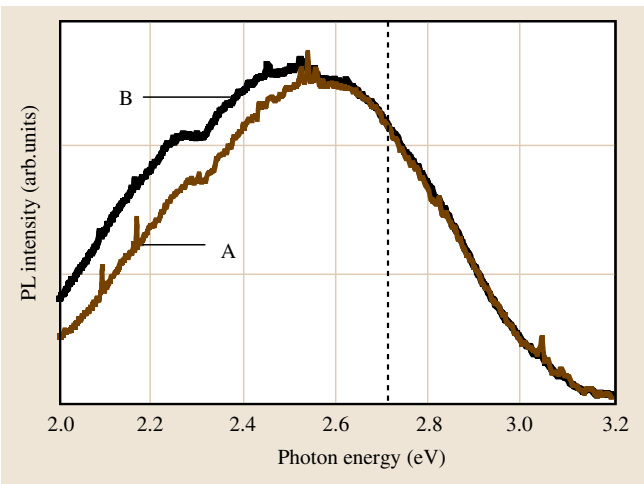

Fig. 19.14 Spectral profiles of the photoluminescence emitted from the $In_xGa_{1-x}N$ film. *Curves* A and B represent the spectra from the film grown by the present and by the conventional method, respectively. The *broken vertical line* represents the photon energy of the incident light (= 2.71 eV)

19.5 Nanophotonic Energy Conversion

Noting that (19.4) represents energy up-conversion, this section reviews novel methods of optical/optical energy conversion and optical/electrical energy conversion.

19.5.1 Optical/Optical Energy Up-Conversion

Powdery grains of DCM organic dye molecules were used as a test material [19.44]. Although the absorption band-edge wavelength of the DCM is as short as 670 nm, the grains were illuminated by near infrared light of 805 nm wavelength. This illumination generated the DP-CPs at the edges of grains, which were then exchanged between the adjacent grains. As a result of this exchange, an electron in the adjacent grain was excited by a phonon-assisted process, and then, it emitted light whose photon energy was higher than that of the incident light due to the contribution of the phonon energy. Figure 19.15 shows an optical microscopic image of the 650 nm-wavelength spectral component of the emitted light. The spatial distribution of the emitted light intensity in this figure is inhomogeneous because the light was emitted selectively from the edges of the grains, which demonstrates the phonon-assisted process due to the DP-CPs generated at the edges of the grains. For comparison, conventional 650 nm fluorescence is emitted as a result of the frequency down-conversion under illumination with 402 nm-wavelength light. The spatial distribution of the fluorescence intensity is homogeneous, in contrast to that of Fig. 19.15.

Figure 19.16 shows the relation between the incident light intensity I used for excitation and the frequency up-converted light intensity I_{uc} emitted from the powdery grains of the DCM organic dye molecules. Experimental results are presented for the wavelength components of 650 nm and 690 nm, to which the curve $I_{uc} = aI + bI^2$ was least-squares fitted. The fitted results are represented by solid curves. The fitted curves show that the frequency up-conversion is due to the two-step excitation by the DP-CP, as described in the following: $|E_\alpha; \mathrm{el}\rangle$ and $|E_\beta; \mathrm{vib}\rangle$ represent molecular electronic and vibration (phonon) states, respectively, and E_α ($\alpha = \mathrm{g}, \mathrm{ex}$) and $E_{\beta\mu}$ ($\beta = \mathrm{i}, \mathrm{a}, \mathrm{b}, \mathrm{thermal}, \mathrm{em}$) represent the molecular electronic and vibrational energies, respectively: After the excitation light generates a DP-CP at the edge of the DCM grain, the DP-CP induces the first-step transition from $|E_\mathrm{g}; \mathrm{el}\rangle \otimes |E_\mathrm{i}; \mathrm{vib}\rangle$ to $|E_\mathrm{g}; \mathrm{el}\rangle \otimes |E_\mathrm{a}; \mathrm{vib}\rangle$ due to the phonon-assisted excitation. After the first-step excitation, the excited coherent phonon relaxes to the thermal equilibrium state $|E_\mathrm{g}; \mathrm{el}\rangle \otimes |E_\mathrm{thermal}; \mathrm{vib}\rangle$ with a relaxation rate of about 100 meV/ps. If the energy of the re-distributed phonon in the $|E_\mathrm{g}; \mathrm{el}\rangle \otimes |E_\mathrm{thermal}; \mathrm{vib}\rangle$ state exceeds the energy difference of 0.34 eV between the electronic excited state in a molecule and the photon energy of the incident light, the excitation occurs via two possible routes. One route (I) is from $|E_\mathrm{g}; \mathrm{el}\rangle \otimes |E_\mathrm{thermal}; \mathrm{vib}\rangle$ to $|E_\mathrm{ex}; \mathrm{el}\rangle \otimes |E_\mathrm{c}; \mathrm{vib}\rangle$ due to the conventional adiabatic photoexcited process. The other (II) is from $|E_\mathrm{g}; \mathrm{el}\rangle \otimes |E_\mathrm{thermal}; \mathrm{vib}\rangle$ to $|E_\mathrm{g}; \mathrm{el}\rangle \otimes |E_\mathrm{b}; \mathrm{vib}\rangle$. After the excitation (I) or (II),

Fig. 19.15 Optical microscopic image of the frequency up-converted light emission from powdery grains of DCM organic dye molecules (wavelength 650 nm)

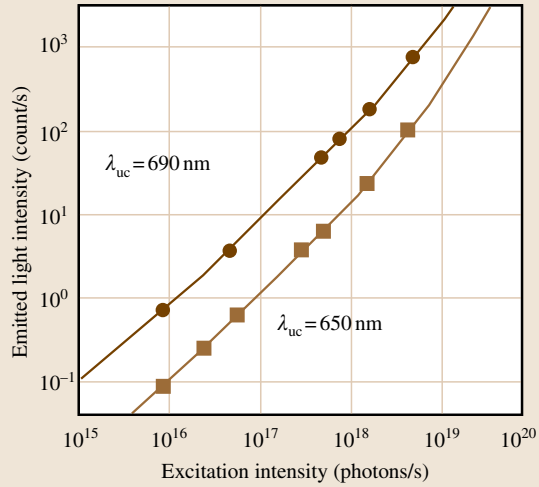

Fig. 19.16 Relation between the incident light intensity and the frequency up-converted light intensity

both $|E_{ex}; el\rangle \otimes |E_c; vib\rangle$ and $|E_g; el\rangle \otimes |E_b; vib\rangle$ relax to $|E_{ex}; el\rangle \otimes |E_{em}; vib\rangle$ due to cooling or the coupling of the phonon and electronic states, respectively.

After the two-step transition described above, visible light is emitted by the transition from $|E_{ex}; el\rangle \otimes |E_{em}; vib\rangle$ to $|E_g; el\rangle \otimes |E_i; vib\rangle$. Since the excitation (I) is a conventional adiabatic process, its probability of occurrence is more than 10^6 times that of the first-step excitation. Furthermore, the probability of visible light emission by the infrared excitation is governed only by the phonon-assisted excitation of the first step because the second-step transition saturates easily. This is the origin of the linear intensity dependence. Because the excitation (II) is phonon-assisted, its probability of occurrence is equal to that of the first-step transition. This is the origin of the squared dependence. As a whole, the relation between I and I_{uc} is represented by a quadratic function [19.45]. It was found that the efficiency of the frequency up-conversion is more than 100 times higher than that of the second harmonics generated from a KDP crystal for an incident light power density lower than $1\,W/cm^2$.

As an application, a novel system for optical pulse shape measurement has been developed [19.46]. Several experiments using DCM dye molecules have confirmed that the optical pulse shape of the 800 nm wavelength was measured with a temporal resolution of 0.8 ps, which was limited by the lifetime of the intermediate state involved in the two-step excitation. It should be noted that the measured optical pulse shape has low jitter because the present measurement system employs only an optical process, unlike the conventional streak-camera system employing an electro-optical process. By using other commercially available dye molecules, the measurable wavelength range can be extended to 1.3–1.55 μm with a temporal resolution of 0.8 ps, which enables optical pulse shape measurement for optical fiber transmission systems.

Instead of the powdery grains of organic dye molecules, a variety of materials can be used for optical frequency up-conversion as long as the DP-CPs are efficiently generated on their surfaces.

19.5.2 Optical/Electrical Energy Up-Conversion

Frequency up-conversion can extend the photodetection bandwidth of a photovoltaic device [19.47]. For confirming this, a poly(3-hexylthiophene) (P3HT) organic thin film was used as a p-type semiconductor, whereas a ZnO film was used as an n-type semiconductor. They were sandwiched by a transparent ITO film and an Ag film to be used as electrodes. It should be noted that no photocurrent is generated from this device if it is illuminated by light whose wavelength is longer than the absorption band-edge wavelength λ_c ($= 570$ nm), which is governed by the bandgap energy E_g of P3HT.

It is possible to excite electrons by a two-step phonon-assisted process for creating electron-hole pairs. The first step is the transition from the initial state in the HOMO ($|E_g; el\rangle \otimes |E_{ex,thermal}; phonon\rangle$) to the intermediate state ($|E_g; el\rangle \otimes |E_{ex}; phonon\rangle$) by the DP-CP. Here, $|E_g; el\rangle$ represents the ground state of the electron, $|E_{ex,thermal}; phonon\rangle$ represents the thermal equilibrium state of a phonon whose energy is determined by the lattice temperature, and $|E_{ex}; phonon\rangle$ represents the excited state of a phonon whose energy depends on the energy of the DP-CP. The DP-CP is indispensable for this transition because it is electric dipole-forbidden. The second step is the transition from the intermediate state to the final excited state in the LUMO ($|E_{ex}; el\rangle \otimes |E_{ex'}; phonon\rangle$) by the DP-CP or the free photon (conventional propagating light). Here, $|E_{ex}; el\rangle$ represents the excited state of the electron, and $|E_{ex'}; phonon\rangle$ represents the excited state of a phonon whose energy depends on the photon energy used for the transition. Since this transition is electric dipole-allowed, it can be brought about not only by the DP-CP but also by the free photon. After this transition, the excited phonon relaxes to the thermal equilibrium state $|E_{ex',thermal}; phonon\rangle$.

The phonon-assisted process is used twice: once for efficient photocurrent generation in the wavelength range beyond the one limited by E_g and once for fabricating a metallic electrode for the device, in which the morphology of the electrode surface can be controlled in a self-organized manner so that the phonon-assisted process is efficiently induced for photocurrent generation. For this self-organized control, Ag is deposited by RF-sputtering under light illumination on the previously deposited Ag thin film while the P3HT/ZnO pn-junction is reversely biased with a DC voltage V_b. Here, V_b was fixed to -1.5 V, and the wavelength λ_0 of the incident light was 660 nm, which is longer than λ_c of the P3HT. It is expected that this deposition with light illumination controls the morphology of the Ag film as a result of the phonon-assisted process induced by the DP-CP. When the Ag film with this controlled morphology is used as an electrode of the device, it is also expected that a conspicuous phonon-assisted process will be induced for photocurrent generation.

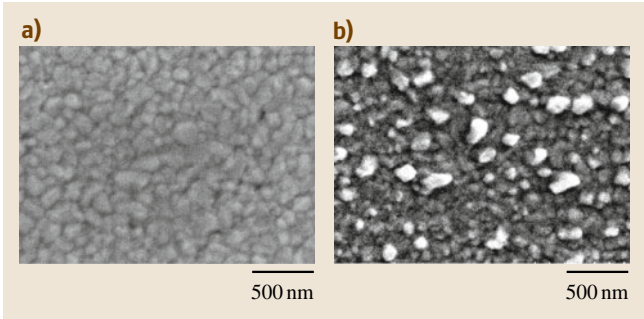

Fig. 19.17a,b SEM images of Ag film surfaces. **(a)** and **(b)** are for Device 1 and Device 2, respectively

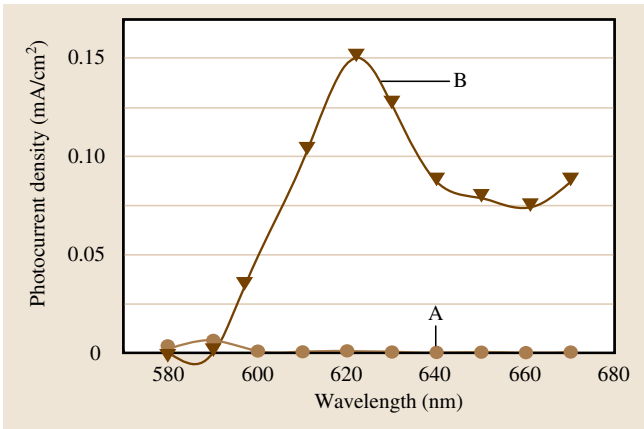

Fig. 19.18 Dependence of the generated photocurrent densities on the wavelength of the incident light. *Curves* A and B are for Devices 1 and 2, respectively

By using this morphology-controlled Ag film as an electrode of the device and by applying the incident light from the rear surface of the sapphire substrate, it is expected that the DP-CP can be efficiently generated on the electrode. Thus, electron–hole pairs can be created efficiently by the phonon-assisted process if the photovoltaic device is illuminated by light with the same wavelength λ_0 as the one used for controlling the morphology of the Ag film. Thus, this device should exhibit wavelength-selectivity in the photocurrent generation, which should take a maximum at the wavelength λ_0. Furthermore, since this wavelength is longer than λ_c, the working wavelength becomes longer than that limited by E_g.

Ag was deposited on the previously fabricated Ag film by RF sputtering. Device 1 was fabricated without applying V_b and the incident light power P, which was used as a reference to evaluate the performance of Device 2. For Device 2, V_b and P were -1.5 V and 70 mW, respectively. Figure 19.17a,b shows SEM images of the Ag film surfaces of Devices 1 and 2. By comparing them, it is clear that the Ag surface of Device 2 (Fig. 19.17b) was very rough, with larger grains than those of Device 1 (Fig. 19.17a). The average and standard deviation of the diameters of the grains of Fig. 19.17b were 86 and 32 nm, respectively. The sum of the thicknesses of Ag and P3HT was estimated to be less than 70 nm. Therefore, it is expected that the DP-CP generated on the Ag grains of Fig. 19.17b can extend to the pn-junction because the average diameters of these grains were 90 nm and 86 nm, respectively. As a result, it is expected that this DP-CP efficiently creates electron–hole pairs at the pn-junction by the phonon-assisted process.

The detailed wavelength dependences of the photocurrent generation in the longer wavelength range beyond E_g of P3HT were evaluated, and the experimental results are shown in Fig. 19.18 for the wavelength range 580 nm $\leq \lambda_i \leq$ 670 nm. The photocurrent density from Device 1 was also very low, but it is shown by curve A as a reference. Curve B represents the measured photocurrent densities from Device 2, generated by incident light with wavelengths up to $\lambda_i = 670$ nm, which clearly demonstrates the extension of the working wavelength range beyond that limited by E_g of P3HT. This curve also indicates the possibility of photocurrent generation even in the wavelength range longer than 670 nm. The photocurrent of curve B was the highest at $\lambda_{ip} = 620$ nm. Thus, Device 2 is effectively a wavelength-selective photovoltaic device for incident light with a wavelength beyond that limited by E_g. This wavelength λ_{ip} (= 620 nm) is 40 nm shorter than λ_0 (= 660 nm) used for controlling the morphology of the Ag film. This difference is attributed to the DC Stark effect induced by the reverse bias voltage V_b (= -1.5 V) applied in the process of controlling the morphology of the Ag film. The photocurrent density was 0.15 mW/cm^2 at the peak of curve B ($\lambda_{ip} = 620$ nm), which corresponds to a quantum efficiency of 0.24%. This efficiency is as high as that of a conventional hetero-junction photovoltaic device using P3HT [19.48]. However, it should be pointed out that Device 2 realized such high quantum efficiency even for wavelengths longer than the one limited by E_g of P3HT.

It is expected that this method can be applied not only to P3HT but also to other organic and inorganic semiconductors because the phonon-assisted process was induced merely by controlling the morphology

of the electrode while the semiconductor materials remained untreated.

There are at least two methods of increasing the conversion efficiency of photodetecting devices, including photovoltaic devices and solar cell batteries. For solar cell batteries, the first method is to increase the efficiency within the visible range, i. e., the wavelength range shorter than that of the absorption band edge of the material to be used as an active medium. Conventionally, this method has been employed; however, it is reaching fundamental and technical limits. The second method is to utilize the infrared component of the solar energy whose wavelength is longer than the absorption band edge. This method is effective to increase the conversion efficiency because sunlight contains large numbers of photons in the infrared region. Since most of the materials to be used as the active media (Si, P3HT, and so on) for solar cell batteries are active only in the visible region, they must be replaced by other exotic materials, e.g., compound semiconductors, in order to utilize the infrared photons. However, they are often toxic or rarely excavated. Instead, the examples reviewed above demonstrated that the infrared photons can be utilized, even by using non-toxic and commonly produced conventional materials, if a nanometric structure is formed on the electrode, while the semiconductor materials remain untreated. Due to this technological advantage, nanophotonics can enable novel device functions by using conventional materials, which can realize qualitative innovations in optical technology. In the other words, nanophotonics is not a conventional material technology but a novel *size- and conformation-controlling technology* to enable novel device functions even by using conventional materials.

19.6 Hierarchy in Nanophotonics and Its Applications

Another unique attribute in nanophotonics is the inherent hierarchy in optical near-field interactions [19.49, 50]. There are multiple layers associated with the physical scale between the macro-scale world and the atomic-scale world, which are primarily governed by propagating light and electron interactions, respectively. Between those two extremes, typically in scales ranging from a few nanometers to wavelength-scale, optical near-field interactions play a crucial role and they exhibit hierarchical properties. They are applied in information and communications applications [19.49–57] and also for nanofabrications [19.58].

19.6.1 Propagating Light and Optical Near-Field Interactions

We can make use of physical differences in optical near-field and far-field effects for a wide range of applications. The behavior of conventional optical elements, such as diffractive optical elements, holograms, or glass components, is associated with their optical responses in optical far-fields. Nanostructures can exist in such optical elements as long as they do not affect the optical responses in far-fields. Therefore, designing nanostructures accessible only via optical near-fields provides additional, or hidden, information recorded in those optical elements while maintaining the original optical responses in far-fields. A *hierarchical hologram* or *hierarchical diffraction grating* has been experimentally demonstrated [19.51, 52].

19.6.2 Hierarchy in the Subwavelength Regime

There is hierarchy *within* the scales smaller than the optical wavelengths. A simple theoretical model behind is the one based on dipole-interactions [19.49]. The electromagnetic interactions between two spheres are maximized when these radii are given by the same value. This suggests that, for instance, a larger-size probe cannot resolve detailed nanostructures but it can resolve structures with a resolution comparable to the probe size. Based on such a principle, a hierarchical memory retrieval was demonstrated based on an array of Au nanoparticles, each with a diameter of 80 nm, distributed over a SiO_2 substrate in a 200 nm radius ring. With a near-field optical microscope with a diameter aperture comparable to the size of the ring of the nanoparticles (500 nm), the output signal increased linearly corresponding to the *number* of the nanoparticles, validating hierarchical memory retrieval from nanostructures via near-field optical interactions.

19.6.3 Shape-Engineered Nanostructures for Hierarchy

Shape-engineering of metal nanostructures is a promising asset in realizing hierarchical optical responses in optical near-fields due to the progress of technologies in fabricating fine nanostructures. For example, it has been theoretically and experimentally demonstrated that two

triangular-shaped nanostructures exhibit different scattering cross sections depending on the arrangement of those triangles, whereas they exhibit strong electric field enhancement at the tip of the triangles independent of the arrangement of triangles. This provides a two-layer optical system where it exhibits two different signals in a coarser scale, while yielding a constant signal in a finer scale; which could be useful in realizing *traceability* for security applications [19.53, 54].

More generally, we can have a unified understanding of optical near-field and far-field responses from metal nanostructures by noticing induced electric currents in individual nanostructures and their associated optical near-fields between the nanostructures [19.55]. Based on this picture, the *quadrupole-dipole transform* has been theoretically and experimentally demonstrated by two stacked layers of nanostructures. Each layer works as a quadrupole when it is isolated, but it works as a dipole when they are closely stacked and connected via optical near-field interactions [19.56, 57]. Such functionality is useful in ensuring product authentication or certification, where a system should work only when the two nanostructures match, just like a lock and key.

19.7 Industrial Applications of Nanophotonics

Nanophotonics has realized both quantitative and qualitative innovations. For example, novel architectures have been proposed for optical signal transmission systems, and their performance has been confirmed experimentally. They include computing using nanophotonic switches and an optical nanofountains [19.59], as well as data broadcasting using multiple nanophotonic switches [19.60].

Quantitative innovations have already been realized by breaking the upper limit of optical/magnetic hybrid disc storage density. The upper limit of the storage density of conventional magnetic storage systems is about $0.3\,\mathrm{Tb/in^2}$, which is limited by the thermal instability of the magnetic domains on the disc. In order to break this limit, an optical near-field was used to locally heat a magnetic domain in order to decrease the coercivity, followed by immediately applying a magnetic field to the domain to write a pit. With this technique, a storage density as high as $1\,\mathrm{Tb/in^2}$ is expected, which meets the requirements of the technology roadmaps of future magnetic storage systems. To realize such a high-density magnetic storage system, near-field storage media technology, recording technology, and nanomastering technology have been developed [19.61–64]. By assembling these technologies, isolated pits of 20 nm diameter at 30 nm pitch were successfully written on a storage disc, corresponding to a storage density of $1.5\,\mathrm{Tb/in^2}$. These technical developments realized a storage density higher than that dictated by the fundamental limits due to thermal fluctuations. Furthermore, with the recent progress of EB lithography, a track pitch as small as 3.5 nm was achieved in 2010 [19.65], from which a storage density reaching $10\,\mathrm{Tb/in^2}$ can be expected in the near future. A technology roadmap predicting a future storage density as high as $1\,\mathrm{Pb/in^2}$ by the year 2025 has also been published [19.66]. To achieve such quantitative innovations in storage density, this roadmap predicts that conventional memory systems using moving devices (such as flying heads and rotating discs) will be completely replaced by novel solid-state elements using various kinds of nanophotonic devices and their associated integrated circuits. Qualitative innovations have also been proposed by applying the hierarchy inherent in optical near-fields to memory retrieval [19.49].

An example of evolution to a related science is atom photonics, in which the thermal motions of neutral atoms in a vacuum are controlled using optical near-fields [19.67]. Theoretical studies have examined single-atom manipulation based on the dressed photon model [19.68], and experimental studies have involved the first successful guidance of an atom through a hollow optical fiber [19.69]. Recent studies have examined atom-detecting devices [19.70], atom deflectors [19.71], and an atomic funnel [19.72]. Atom photonics will open up a new field of science that examines the interactions between dressed photons and single atoms.

From both fundamental and applied perspectives, the role of spin degrees of freedom in excitation energy transfer driven by optical near-fields is an intriguing and important issue. A new approach has been proposed to discuss spin information achieved by energy transfer in a quantum dot pair and the effects of spin relaxation due to interactions with the environment [19.73–75].

19.8 Summary

By combining the concepts of quantum field theory, optical science, and condensed-matter physics, a theoretical picture of dressed photons was obtained. Based on this picture, the exchange of dressed photons was studied, revealing energy transfer to electric dipole-forbidden energy levels. Furthermore, the possibility of coupling a dressed photon with a coherent phonon was found, revealing a novel phonon-assisted process in light–matter interactions in nanometric space. These discoveries were applied to develop novel technologies, such as devices, fabrication techniques, energy conversion, information systems, architectures and algorithms.

Fundamental concepts such as the behavior of photons in nanometric space, excitation transfer and relaxation in a nanometric space, and the primary mechanisms of the phonon-assisted process should be delved into more deeply. Such fundamental studies are expected to bring about further discoveries involving the coupling of dressed photons with various elementary excitations besides coherent phonons, leading to the discovery of novel applications. This marriage of basic studies and technological applications is expected to establish a new field of dressed photon science and technology in the near future.

Dressed photons can be utilized to establish fundamental new technologies that can replace a wide range of conventional optical technologies. Even though users will not notice their existence, it is expected that technologies exploiting dressed photons will be widely used in everyday life in the near future. This is because dressed photons can be generated universally on the surface of illuminated nanometric materials.

The name *nanophotonics* is occasionally used for photonic crystals, plasmonics, metamaterials, silicon photonics, and quantum dot lasers using conventional propagating light. Here, one should consider the stern warning by *Shannon* on the casual use of the term *information theory*, which was a trend in the study of information theory during the 1950s [19.76]. The term *nanophotonics* has been used in a similar way, although some work in nanophotonics is not based on optical near-field interactions. For the true development of nanophotonics, one needs deep physical insight into the behavior of virtual photons and the nanometric subsystem composed of electrons and photons.

20. Optics Far Beyond the Diffraction Limit

New developments in far-field light microscopy made possible to radically overcome the diffraction limit (ca. 200 nm laterally, 600 nm along the optical axis) of conventional far field microscopy. Here, three principal *nanoscopy* families are presented: *Nanoscopy* based on highly focused laser beams, such as 4 Pi-, and STED (stimulated emission depletion) microscopy; nanoscopy based on structured illumination excitation (SIE); and nanoscopy allowing superresolution even in the case of homogeneous excitation (spectrally assigned localization microscopy/SALM): With such techniques, it has become possible to analyze the spatial distribution of fluorescent molecules with a greatly increase light optical resolution down to a few nanometers (≈1/100 of the exciting wavelength).

References 1393

The development of laser technology in combination with novel optical and photophysical approaches, highly sensitive and fast detection systems, and computer-based evaluation procedures have made it possible to radically overcome the diffraction limit (ca. 200 nm laterally, 600 nm along the optical axis) of conventional far-field fluorescence microscopy. Since the 1980s, a number of *superresolution* light microscopy techniques have been developed to allow an optical resolution beyond that magic threshold. Presently, three main *nanoscopy* families have been established: Nanoscopy based on highly focused laser beams, such as 4Pi, STED, and GSD microscopy; nanoscopy based on structured illumination excitation (SIE), such as standing wave (SW), spatially modulated illumination (SMI), structured illumination (SI) and patterned excitation microscopy (PEM); and nanoscopy allowing superresolution even in the case of homogeneous excitation (spectrally assigned localization microscopy (SALM)). With such techniques, it has become possible to analyze the spatial distribution of fluorescent molecules with a greatly increased light optical resolution down to a few nanometer; presently, nanoscale images can be obtained that were previously reserved for electron microscopy.

In his famous contribution on the fundamental limits of optical resolution achievable in (far field) light microscopy [20.1], *Ernst Abbe* stated that the resolution limit of about half the wavelength used for imaging is valid only ... so lange nicht Momente geltend gemacht werden, die ganz ausserhalb der Tragweite der aufgestellten Theorie liegen ... (... as long as no arguments are made which are completely beyond the theory stated here...).

Since the 1980s, this prophecy of Abbe has become true: using conditions not included in the assumptions made by Abbe or by *Rayleigh* [20.2], a variety of light optical techniques surpassing this limit in a very substantial manner have been developed, i. e., far-field microscopy approaches in the visible light range which allow *superresolution*. Here, this term will be defined to include any optical resolution considerably beyond the Abbe/Rayleigh limit of ca. 200 nm laterally (object plane) and/or 600 nm axially (along the optical axis) obtained with nanoscopy systems at a working distance between the object plane and the front lens of the optical system of at least several hundred wavelengths, in contrast to the very short working distances allowing superresolution in near-field scanning optical microscopy (NSOM) [20.3, 4].

The first practicable approach to overcome the Abbe limit was confocal laser scanning fluorescence 4Pi microscopy, [20.5–9] a variant of focused nanoscopy [20.10, 11]. In the focused nanoscopy mode of superresolution, the object is scanned *point-by-point* and the resulting fluorescence signal is registered point-by-point. The *sharper* the scanning laser beam (i. e., the smaller the full-width at half-maximum (FWHM) of the point spread function (PSF) of the system, the better the achievable optical resolution. By increasing the numerical aperture (NA) beyond the limits imposed by a single objective lens, the FWHM can be decreased below the value for a single lens system, and hence the optical resolution can be improved. First ideas about the principal possibility of such a 4π(4Pi) microscopy may be traced back to the 1970s [20.5, 12]; a successful realization demonstrating superresolution (around 100 nm) in the direction (z) along the optical axis was first obtained in the beginning of the 1990s [20.7–9]. In this 4Pi microscopy approach, two opposing high NA lenses were used to focus counter-propagating laser beams to narrow the FWHM in the direction of the optical axis and thus to obtain a 3-D observation volume ($V_{obs} = (4/3)\pi(\mathrm{FWHM}_x/2)(\mathrm{FWHM}_y/2)(\mathrm{FWHM}_z/2)$) about 5–7 times smaller than in conventional fluorescence microscopy (at the same wavelength and refraction index).

However, the lateral optical resolution in the object plane (x, y) was only minimally improved by this two-lens-based type of 4Pi microscopy. This improvement became possible by a second type of focused nanoscopy, namely, stimulated emission depletion (STED) microscopy [20.10, 13, 14]. Here, the PSF is narrowed even in the x, y-plane by the interplay of two laser beams: A first, highly focused beam at a wavelength λ_1 excites the fluorescence at a given object site; a second, typically doughnut-shaped beam of suitable intensity at a wavelength λ_2 centered around the intensity maximum of the first beam is used to suppress the registered fluorescence of molecules in the vicinity of the center of the exciting beam by the induction of stimulated emission. As a general consequence, the molecules in the vicinity of the focal center of the exciting beam can be transferred into a dark state (with respect to a certain detection mode) in such a way that only the molecules in the focal center of the exciting beam (λ_1) contribute to the registered signal and thus may be called to be in a bright state. These signals are registered by a point detector. Since the position of the exciting beam focus is given by the mechanics of the system and thus can, in principle, be determined with any accuracy desired (down to subnanometer precision), the image of the object can be composed point-by-point with a highly improved optical x, y resolution. This method presently allows a lateral (x, y) optical resolution of about 15–20 nm in biological specimens [20.15–17] and about 6–8 nm in material science applications [20.18]. Since the only condition required for superresolution in focused nanoscopy is to suppress the registration of fluorescence of molecules not in the center of the focus of the scanning excitation beam, this approach has been generalized to the concept of reversible saturable optical fluorescence transitions (RESOLFT) microscopy [20.19]. In RESOLFT microscopy, in *addition* to the STED mode other ways may be used to achieve the same effect. For example, instead of first exciting the molecules in a focal region with a diameter (FWHM) of about $0.5\lambda_{exc}/\mathrm{NA}$ (where λ_{exc} is the vacuum wavelength used for excitation of fluorescence and NA the numerical aperture) and then to deplete the S_1 states of the molecules not directly in the focal center of this area by a STED beam, one may use a doughnut-shaped second laser beam of high intensity to transfer these molecules in a nonfluorescence triplet (T_1) state; triplet–singlet transition times of the order of a few µs are sufficient to allow *ground state depletion* (GSD) of these molecules during the dwell time of the scanning excitation beam [20.20].

A second major approach to superresolution is structured illumination excitation (SIE) nanoscopy [20.21–25]. In SIE imaging, instead of scanning the object point-by-point by a single highly focused laser beam (or multiples of it), the illumination intensity in object space is modulated in a certain way, usually by a sinusoidal pattern; the fluorescence of the object is registered not with a point detector but with an array detector, typically a highly sensitive CCD camera; to obtain superresolution, the object is registered multiple times by moving the patterns (or the objects) with respect to each other. From the individual images obtained in this way from the same object, an image with an increased structural resolution can be calculated. According to the way the illumination pattern is realized, various methods have been described, such as the standing wave (SW), spatially modulated illumination (SMI), structured illumination (SI), structured illumination interference (SIIM), or patterned excitation microscopy (PEM). In this way, the optical resolution (in terms of the spatial cut off frequency) can be doubled compared to the conventional case, i. e., about 100 nm can be achieved in the (x, y)-direction and about 250 nm in the z-direction.

The present third major approach to superresolution is spectrally assigned localization microscopy (SALM). In principle, the SALM mode can be used in any type of fluorescence microscopy to allow a substantial further improvement in optical resolution, down to a presently achieved optical resolution (x, y) in the range of few nm, or $\approx 1/100\lambda_{exc}$ (in special cases down to ≈ 1 nm). From the conceptual point of view, it is particularly interesting that SALM can achieve such a superresolution even if the illumination intensity in the object plane is homogeneous; a wide-field detector like a sensitive CCD camera is applied for registration; and standard fluorophores are used. In this case, SALM may be denominated as a method of homogeneous illumination-based nanoscopy. In this mode, the optical isolation and hence localization of closely adjacent single fluorescent molecules is assigned by spectral signature differences between the molecules where spectral signature means any way to assign the photons detected to a specific single molecule [20.26–30]. While first concepts and proof-of-principle experiments date back to the 1990s [20.26, 27, 31–35], within recent years a variety of SALM methods has been developed to allow a broad range of biomedical applications, with the prospect to extend this range to the materials sciences [20.18, 36].

20.1 Basic Principles

20.1.1 Focused Nanoscopy

In light microscopy, an object may be considered as an arrangement of a number of point sources at given spatial positions (x, y, z) absorbing, emitting, or scattering light. The ultimate goal of light microscopic structure analysis is to identify the point sources and to determine their positions as precisely as possible. In conventional microscopy, for each of these point sources the Abbe sine condition must be fulfilled in order to produce a sharp image from each of these object points, and hence a sharp image of the entire object. In terms of geometrical optics, it relates the angles α_1, α_2 of any two rays of light emitted by an object point source P to the angles β_1, β_2 of the same rays reaching the image plane (all angles relative to the optical axis of the microscope system) by the relation $\sin\alpha_1/\sin\alpha_2 = \sin\beta_1/\sin\beta_2$). A further basic idea in the Abbe/Rayleigh theory of optical resolution is the assumption that all point sources are registered simultaneously. Consequently, two neighboring, stably emitting point sources of the same spectral signature (e.g., the same fluorescence absorption/emission spectrum, the same fluorescence life time and luminescence behavior, etc.) can be separated from each other only if their diffraction patterns (with their maxima positions fulfilling the Abbe sine condition) are separated in such a way that the maxima of the two diffraction patterns can be identified independently from each other. In terms of the object, in fluorescence microscopy this leads to a minimum resolvable distance (optical resolution power or simply optical resolution) of $d_{min} = 0.61\lambda_{exc}/NA$ using the Rayleigh criterion ($d_{min} = 0.51\lambda_{exc}/NA$ using the FWHM of the corresponding PSF). These conditions, however, are not absolutely necessary to obtain an image of an object, i. e., information about the positions (x, y, z) of its light-emitting/absorbing/scattering elements. As an alternative to the simultaneous registration of the light-emitting elements of the object, one may reconstruct the image in a sequential manner point by point. In this case, a given small region of the object p_1 (point) at a start position (x_1, y_1, z_1) is illuminated by a highly focused beam of coherent light, and the optical response $I(x_1, y_1, z_1)$ is registered by a detector, e.g., a photomultiplier tube, or an avalanche diode; then either the object or the beam is moved in such a way that the next object point p_2 at a position $(x_2 = x_1 + \Delta x, y_2 = y_1 + \Delta y, z_2 = z_1 + \Delta z)$ is illuminated by the focused beam, and the new response $I(x_2, y_2, z_2)$ is again registered by the detector; the procedure is repeated until the entire object is scanned in x, y, z (x, y object plane, z-coordinate along the optical axis of the microscope system). The responses I assigned to the coordinates x_i, y_i, z_i $(i = 1, 2, \ldots, n)$ form the image; in the case of $z = \text{const}$ (e.g., object plane), a 2-D image is obtained; if the scan involves variation of z, a 3-D image is formed, like in confocal laser scanning fluorescence microscopy [20.5, 37–41]. In these approaches of laser scanning microscopy, the positional information (x_i, y_i, z_i) is obtained from the mechanics of the system (e.g., the piezoelectrical control of the position of the object stage, or of the mirror positions changing the focal positions of the scanning beam). Since this mechanical positioning is independent of the illumination wavelength λ_{exc}, positioning accuracies down to the subnanometer scale can be obtained.

For each of the sequentially imaged point sources, the Abbe conditions might be fulfilled one after the

other; it might even be possible that for a single point source, that the Abbe condition is not necessary to obtain information about its position. For example, one might use a focused beam of light for transmission, scattering, or fluorescence excitation and register the transmission/scattering/fluorescence signal obtained in any way convenient with or without the Abbe sine condition [20.5]. As outlined above, in this case, the positional information is given by the knowledge about the position of the illuminating spot; the optical resolution achievable is then essentially given by the diameter (D_{ill}) of the illuminating spot. Hence the optical resolution (i. e., the smallest resolvable distance between two fluorescent point sources A, B) will become the better the smaller this diameter can be made. Focusing coherent light uniformly through a single objective lens with a given aperture NA $= n \sin\alpha$ (n refraction index, α half aperture angle) gives for (D_{ill}) a value (FWHM) around $0.5\lambda_{exc}/NA$; for the maximum value possible for α ($180°/2$), $\sin 90° = 1$ and hence $(D_{ill}) \approx 0.5\lambda_{exc}/n$ is obtained [20.2]. To obtain a higher optical resolution, one possibility is to find a way to somehow increase the numerical aperture NA. Since in practical light microscopy, the maximum refraction index n is typically around 1.5, one would have to increase the full aperture angle (2α) beyond 180° to diminish (D_{ill}).

In principle, even the diameter of the illuminating spot (D_{ill}) is not absolutely decisive for the achievable optical resolution; instead, a way might be found to register the fluorescence emission first only from an area with $D_{fluor} \ll D_{ill}$ from an object A and then register the fluorescence emission only from an area with $D_{fluor} \ll D_{exc}$ from a point object B, with a distance $d_{AB} \ll D_{ill}$ [20.13, 20]. The maximum signal intensity in the point detector obtained for an object position x_A, y_A of the beam focus (derived, e.g., from the mechanical position of a scanning mirror) would give the position of A while the maximum signal intensity in the point detector obtained for an object position x_B, y_B of the beam focus would give the position of B; hence, a distance $d_{AB} = [(x_A - x_B)^2 + (y_A - y_B)^2]^{1/2} \ll D_{ill}$ and hence smaller than $0.5\lambda_{exc}/NA$ would be determined. Such a distance measurement $d_{AB} \ll 0.5\lambda_{exc}/NA$ would be equivalent to a corresponding improvement of the optical resolution. In this scheme, the condition to register in a first step *only* the fluorescence signal from A, and to register in a second step *only* the fluorescence signal from B is a decisive one. If, e.g., two molecules A, B with a diameter of 1 nm and closely adjacent to each other (distance $d_{AB} \ll D_{ill}$) are excited to fluorescence but the detection procedure cannot distinguish between fluorescence photons emitted from A and fluorescence photons emitted from B, the registered diffraction patterns of both molecules overlap, and the smallest resolution possible is not substantially smaller than $\approx D_{ill}$.

In the following, several approaches of this basic concept of *focused nanoscopy* will be discussed.

4Pi Microscopy

First ideas to overcome the Abbe limit of ≈ 200 nm for optical resolution using a confocal laser scanning fluorescence microscopy approach with an extension of the aperture angle (2α) beyond 180° were discussed already in the 1970s [20.5, 12]. In this early 4π microscopy concept (Fig. 20.1) based on experimental experience with diffraction limited focusing of coherent light in the sub-micron range and fluorescence excitation [20.42], the object is illuminated point-by-point by a focused laser beam using a 4π geometry; i. e., instead of focusing the light through a single high NA objective lens ($\sin\alpha_{max} = \sin 90° = 1$; full spatial aperture angle 2π), the coherent light is focused from all sides (sterical angle 4π) by constructive interference. The fluorescence emitted from each object point is registered via a detection pinhole in the image plane which excludes contributions outside the central maximum of the diffraction pattern produced in the image plane by a point source; the individual fluorescence signals obtained from object sites (x, y, z) are then used to electronically construct an image with improved optical resolution by assigning the signals to image sites (Mx, My, Mz), where M is the magnification factor. It was suggested that by 4π focusing, the focal diameter could be reduced to a minimum below the Abbe limit at least in one direction [20.5]. To realize a full 4π geometry, it was proposed to generate a 4π point hologram, either experimentally from a source with a diameter much below the wavelength of the light emitted from such a source, or to produce it synthetically on the basis of calculations. This 4π hologram should replace a (single) conventional optical lens (maximum numerical aperture NA ≈ 1.5) which allows focusing only down to about the Abbe limit. In *addition*, the use of plane point-holograms for focusing the exciting beam in the laser scanning microscope was suggested to be advantageous at least with respect to the much larger working distance available.

In the original 4π concept [20.5], a hologram was generally defined as a device to produce the boundary conditions which together with appropriate illumination yields the reconstructed waves, leaving open questions such as production, material problems, or direction,

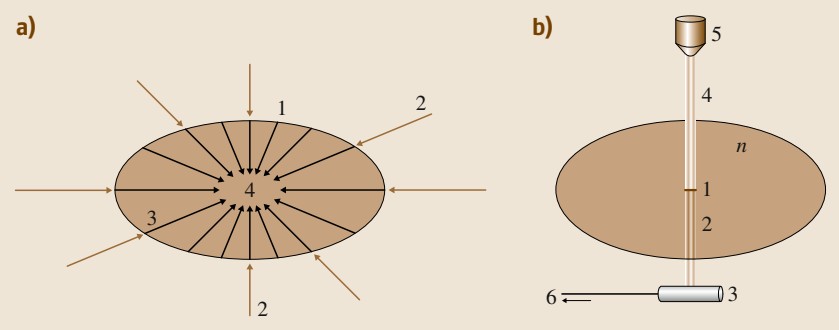

Fig. 20.1a,b Principle of superresolution in a confocal laser scanning fluorescence 4π microscope. **(a)** Coherent light is constructively focused from all sides (spatial angle 4π) to achieve a focal diameter smaller than possible by focusing through a single high numerical aperture objective lens. This is thought to be realized by means of a 4π point hologram. 1) surface of the 4π point-hologram (ideally a closed envelope), 2) incident waves, 3) reconstructed waves, 4) focus of the 4π point-hologram. **(b)** Application of a 4π point-hologram in a laser-scanning microscope: 1) specimen with a fluorescent surface located in the *focus* of a 4π point-hologram, 2) holding device (same refractive index n as the specimen and the immersion fluid), 3) scanning stage to displace the specimen, 4) light conductor, 5) microscope objective for the collection of the fluorescence light, 6) connection to the scan generator and to the automated focusing system (Fig. 1 in [20.5], equivalent to axial contrast generation as in a confocal laser scanning fluorescence microscope), n, refractive index of the immersion fluid (after [20.5])

amplitudes, and coherence of the incident and the reconstructed waves. Furthermore, is was assumed that the amplitudes and the incident angles of the coherent waves falling on the 4π-point-hologram can be varied almost independently from each other, i. e., the concept was not limited to the classical assumptions [20.43] used to calculate focal intensities.

Since in the electromagnetic theory of light, the consequences of complex boundary conditions can be solved only numerically, it still appears to be difficult to make valid conclusions on the ultimate physical limits of focusing possible by such a full 4π approach. However, in the special case that for fluorescence excitation a hypothetical continuous wave, monochromatic spherical wavefront of constant intensity is focused in a full 4π geometry, theoretically in the far field (distance r from focusing device $(2\pi/\lambda)r \gg 2$ [20.44]) a limiting focus diameter of about one-third to one-fourth of the wavelength (measured in the medium where the focusing occurs) may be obtained [20.11, 45]. Assuming a wavelength $\lambda_{exc} = 488\,nm$ and a refraction index of $n = 1.5$, this would result in a focal diameter $D_{ill} = 0.33\lambda_{exc}/n = 0.22\lambda_{exc} = 107\,nm$, i. e., considerably smaller than the typical minimum spot size for fluorescence of $D_{ill} = 0.5\lambda_{exc}/NA \approx 0.5\lambda_{exc}/1.4 = 0.36\lambda_{exc} = 175\,nm$. Numerical calculations [20.46] suggested that for a specific polarization mode [20.47] assuming ≈ 200 constructively interfering coherent light sources arranged homogeneously in a 4π geometry, even a somewhat smaller focus diameter of $0.25\lambda_{exc}/n$ might be obtained. Assuming $\lambda_{exc} = 488\,nm$, this would result in minimum focal diameter of $D_{ill} = (0.25/1.5)\ 488\,nm = 0.17\lambda_{exc} = 81\,nm$. For the (vacuum) excitation wavelength $\lambda_{exc} = 257\,nm$ used in the first studies on fluorescence excitation by diffraction limited focusing with continuous wave ultraviolet light [20.42], 4π focusing would have resulted in $D_{ill} = (0.33/1.5)\ 257\,nm = 57\,nm$, and $D_{ill} = (0.25/1.5)\ 257\,nm = 43\,nm$, respectively. In terms of the 3-D observation volume V_{obs} used as a measure for the overall spatial resolution ($V_{obs} = 4/3\pi$ (FWHM$_x$/2) (FWHM$_y$/2) (FWHM$_z$/2)), such a full 4π/4Pi approach would have provided an overall 3-D resolution improvement (for the same wavelength and refraction index) of about $(250\times250\times600\,nm^3)/(107\times107\times81\,nm^3) = 40$ times. In the confocal registration mode assumed, still somewhat smaller FWHMs of the 4Pi PSF would be obtained.

The first experimental confocal laser scanning 4Pi microscope attaining 3-D superresolution was designed and realized in the beginning 1990s [20.6–9]. Instead of holograms with 4π geometry, two single opposing high numerical aperture objective lenses were used to concentrate two opposing laser beams constructively in a joint focus (Fig. 20.2). Although in this arrangement the sterical angle covered by the focusing light was con-

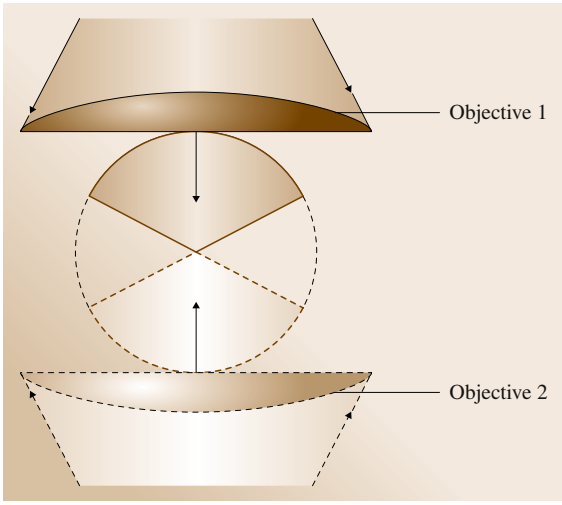

Fig. 20.2 Principle of 4π/4Pi microscopy. In conventional far-field light microscopy only a segment of a spherical wave front is focused into or collected from an object point. A higher spatial resolution is achieved when not only a segment but a complete spherical wavefront is used. Thus, focusing or collecting is improved when a second lens provides another segment of the complete spherical wave front thus increasing the angles of the focused and/or collected wave fronts (after [20.8])

siderably smaller than 4π, the designation ($4\pi = 4$Pi) was maintained to indicate the basic principle of extending the spatial aperture angle beyond 2π.

In Fig. 20.3, the design of two basic experimental 4Pi setups are presented which use either one photon excitation (in this case combined with the registration of scattered light), or two photon excitation of fluorescence.

Presently, confocal laser scanning 4Pi fluorescence microscopy applying either continuous wave visible laser light or femtosecond pulsed infrared laser wavelengths for excitation [20.8, 9] has become an established light optical nanoscopy method, which has been made also commercially available [20.10, 48–51]. An axial optical resolution down to the 100 nm

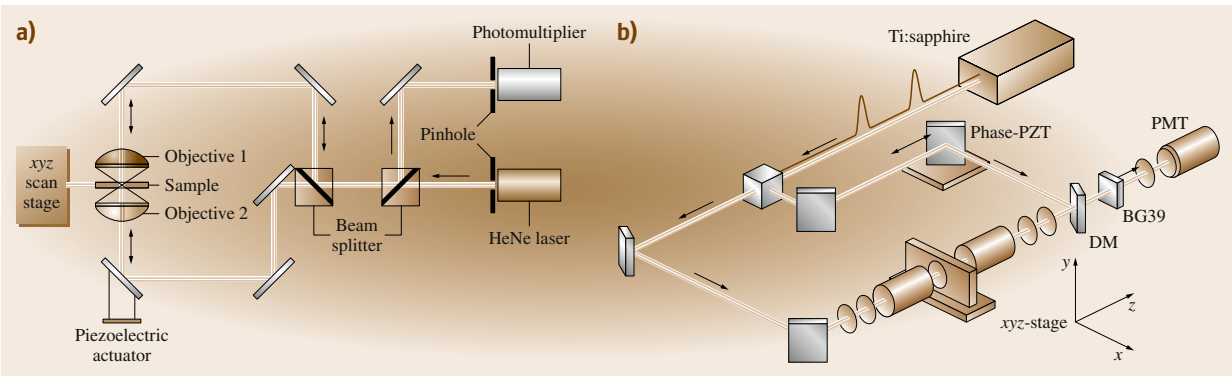

Fig. 20.3a,b Basic optical setups for 4Pi confocal microscopy. **(a)** Single photon excitation. Two high aperture lenses (NA = 1.4) with a common focus are used to increase the aperture of illumination and collection. To achieve the common focus one of the lenses is adjusted with a piezoelectric stage. The wave front coming from the illumination pinhole is split with a beam splitter to illuminate each of the lenses. The light collected from both lenses is combined with the same beam splitter and directed toward the detection pinhole. The 4Pi confocal microscope setup was used in the scattering light mode using polarized light for illumination and a crossed polarizer in front of the detector for registration. The axial full width at half-maximum of the main maximum was 75 nm in the 4Pi confocal case as opposed to 520 nm in the confocal case. The lateral extent was 160 nm in the 4Pi case and 200 nm in the confocal one (after [20.8]). **(b)** Two-photon excitation. The sample is mounted between two cover slips and attached to a precision XYZ-scanning stage capable of positioning the sample with an accuracy of 10 nm in all three directions. Two opposing lenses of high numerical aperture focus the light to the same point inside the sample. For two-photon excitation a mode-locked Ti:sapphire laser providing a stream of 130 fs pulses with a repetition rate of 76 MHz is used. The pulses are split and guided along two paths of equivalent length to ensure interference in the common focus of the lenses. The relative phase of the wave fronts is adjusted by a piezoelectrically driven mirror. The fluorescence light from the sample is collected via one of the lenses, separated through a dichroic mirror and focused onto a pinhole placed in front of a photomultiplier tube operated in the photon counting mode. The axial FWHM of the 4Pi confocal response was measured to be 140 nm as opposed to 630 nm of the conventional two photon excitation response (after [20.9])

regime was experimentally realized, i. e., about 6–7 times better than in conventional confocal laser scanning fluorescence microscopy (CLSM). Although due to the sterical angle used ($\approx 2.7\pi$ instead of 4π), the optical resolution in the lateral direction was improved only slightly, the observation volume V_{obs} used as a measure for 3-D resolution was decreased substantially compared with the conventional case ($V_{obs[CLSM]}/V_{obs[4PiHell]} = 250\times250\times600\,nm^3)/(250\times250\approx100\,nm^3) = 6\times$. By combination of such a 4Pi microscope with microaxial tomography (μtom) techniques [20.52–54] where the object is imaged from different directions, even an isotropic optical resolution substantially below the Abbe limit might be possible, with an expected increase in the observation volume ($V_{obs[CLSM]}/V_{obs[4PiHell\mu tom]} = (250\times250\times600\,nm^3)/(100\times100\times100\,nm^3)\approx 40\times$.

Stimulated Emission Depletion (STED) Microscopy

In experimental 4Pi microscopy using two opposed objective lenses, so far a 3-D optical resolution around $200\times200\times100\,nm^3$ has been realized. This means that objects with spatial features below about 100 nm would still remain unresolved. The first successful concept to achieve a lateral optical resolution far below 100 nm in a far-field arrangement using a single objective lens was stimulated emission depletion (STED) microscopy conceived by *Hell* and *Wichmann* [20.13] and realized in the following decade (for a related concept see [20.55]). This focused nanoscopy method is again based on scanning the object with a focused laser beam [20.14].

However, in spite of increasing the spatial aperture angle beyond 2π as in 4π/4Pi microscopy, in this case the basic idea was to realize superresolution by an optical device which allowed one to register the fluorescence emission from a much smaller object region than given by the diameter (D_{ill}) of the illuminating focused laser beam. This was achieved by an appropriately shaped second laser beam of wavelength λ_{STED} (the STED beam) producing an illumination pattern around the excitation beam (λ_{exc}) by which excited molecules (S_1 state) in the vicinity ($d \ll D_{ill}$) of the center of the focus of the excitation beam were induced to stimulated emission of radiation from the lowest S_1 state to the highest S_0 state. By appropriate excitation/detection arrangements, this emission was separated from the spontaneous fluorescence emission (at wavelengths λ_{fluor}) of the molecules in or close to the focal center of the excitation beam; these were not subjected to the – typically doughnut-shaped – STED beam producing a zero intensity point just in the center of the focus of the exciting beam. In consequence, the stimulated emission of these molecules was not registered by the detector system set to detect the spontaneous fluorescence only. In the next step, either the object or the two coupled beams are moved to a neighboring site, and the procedure is repeated. In this case, the molecules previously positioned in the center of the exciting beam (λ_{exc}) are now stimulated to emission by the STED beam (λ_{STED}) and thus do not contribute to the spontaneous fluorescence signal λ_{fluor}; the molecules previously stimulated to emission by the STED beam are now in the center of the exciting beam, and their fluorescence signal λ_{fluor} is registered. This is a first example for a general spatially scanning nanoscopy concept (see later) involving focused or structured illumination with zero intensity positions in which the fluorescence emission (λ_{fluor}) is registered first only from an area A with $D_{fluor} \ll D_{ill}$ and then the fluorescence emission is registered only from an area B with $D_{fluor} \ll D_{ill}$ with a distance $d_{AB} \ll D_{ill}$; and the object positions A, B are obtained by the mechanics of the scanning procedure.

An example for this basic STED effect is given in Fig. 20.4. On/off switching of the STED beam in a STED microscope arrangement allowed on/off switching of the fluorescence signal at a given position in the vicinity of the scanning laser focus.

By appropriate saturation intensities, the fluorophores in a doughnut-shaped annulus around the center of the exciting laser focus are induced to emit photons by stimulated emission of radiation at a red-shifted wavelength compared to the fluorescence emission maximum. The remaining fluorescence, which can be spectrally separated from the high intensity STED beam, can thus only stem from the very center where (in the ideal case) the doughnut-shaped STED beam has a zero intensity point. As a consequence, fluorescence photons of a given energy are detected from a much smaller region than D_{ill}. Since due to the scanning mechanism, the position of this smaller fluorescent region can be known with an accuracy of few nm, the fluorescence signal obtained can now be assigned to this smaller region; hence the optical resolution may be improved further. STED microscopy was the first implementation of utilizing nonlinear response in lateral superresolution fluorescence microscopy.

Later implementations of the STED microscopy concept allowed superresolution imaging in the object plane (x, y) down to the 10 nm range and presently have found numerous applications [20.16, 56–58]. The best (lateral) optical resolution values obtained by STED

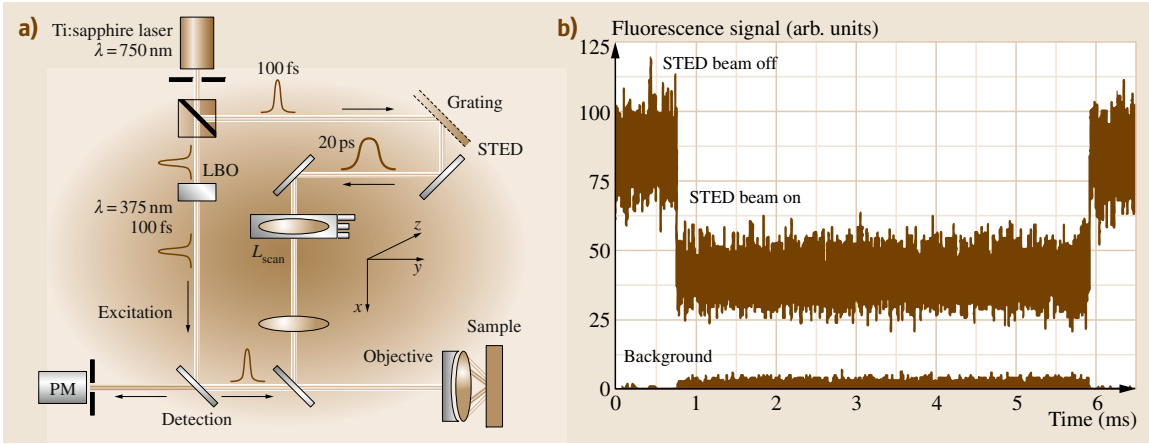

Fig. 20.4a,b Stimulated emission depletion microscopy. **(a)** Laser optical setup to study stimulated emission on a microscopic scale. The pulse from a Ti:sapphire laser is split by the cube, partly directed to a grating where it is dispersed to about 20 ps duration. The other part is frequency doubled by a LBO crystal. The fluorescence light from the sample is collected by the objective lens and focused onto a pinhole in front of the photomultiplier. The lens L_{scan} scans the 750 nm light across the focus formed by the 375 nm excitation light. **(b)** Induction of dark states by a STED beam. The fluorescence signal measured between 600–700 nm when exciting with 375 nm and switching on and off a stimulating STED beam at a wavelength of 750 nm. The background signal is obtained when switching off the UV excitation and illuminating with the STED laser (after [20.14])

microscopy are presently around 15–20 nm in biomedical applications [20.15] and ≈ 6 nm in solid-state physics [20.18]. In combination with the 4Pi method, a 3-D optical resolution of few tens of nm has been achieved [20.59].

Recently, commercial versions of the STED microscope have become available, featuring about 70–80 nm optical resolution, both in the two-photon excitation mode or in a continuous-wave single photon excitation setup; the resolution along the optical axis, however, is the same as in a conventional confocal microscope (axial FWHM ≈ 600 nm). The 3-D observation volume of these commercial STED microscopes may hence be compared with the 3-D observation volume of 4Pi microscopy: V_{obs}(4Pi commercial)/V_{obs}(STED commercial) = $(200\times200\times110\,nm^3)/(70\times70\times600) = 1.5\times$; i. e., the 3-D resolution of the commercial STED microscope is similar to that of the commercial 4Pi microscope; a full 4π angle 4Pi microscope (isotropic optical resolution around 100 nm in all directions, see before), would result in a ratio V_{obs} (full 4π microscope)/V_{obs} (STED commercial) = $(100\times100\times100\,nm^3)/(70\times70\times600) = 0.3\times$, i. e., the 3-D resolution of such a full 4π angle 4Pi microscope would even be several times superior to that of a present commercial STED superresolution microscope (although still considerably inferior to the 3-D resolution of a 4Pi-based iso-STED device as recently realized, e.g., by *Schmidt* et al. [20.59]).

Ground-State Depletion (GSD) Microscopy

In STED-based focused nanoscopy, the improvement in optical resolution is accomplished by reducing the spatial extent of the effective focus of the scanning laser beam by depleting the excited state (S_1) of the fluorescence molecules in the outer region of the focus. Another, very elegant alternative is to use the same general principles as in STED microscopy but instead of depleting the excited state (S_1), the ground state (S_0) of the fluorescence molecules in the outer region of the excitation focus (λ_{exc}) is depleted [20.20]: The illumination conditions (i. e., the intensity of the depletion beam) are set up in such a way that there, the density (n_0) of molecules in an S_0 state is greatly diminished in the outer region of the focus; hence these molecules cannot the transferred to an S_1 state and hence they cannot emit photons by a S_1 to S_0 transition. To allow imaging by this method, it is essential that by moving the scanning laser focus to another site, by reducing the intensity of the depletion beam the molecules are quickly relaxed to the S_0 state; that means that the depletion process must be reversible on a sufficiently fast

time scale. To show the feasibility of such a focused nanoscopy approach of GSD fluorescence microscopy, the transition parameters for S_0 to S_1 to T_1 (triplet state) and back from S_1/T_1 to S_0 were calculated for fluoresceine as an example [20.20]. The population densities for the various energy states were determined as a function of the illumination intensity ($\lambda_{exc} = 488$ nm). With average lifetimes for the energy states for the S_1 to S_0 transition of 4.5 ns, S_1 to T_1 transition of 100 ns, and 1 µs for the T_1 to S_0 transition, at sufficiently high illumination intensities ($I_{depl} \geq 10\,MW/cm^2$), 87% of the fluorophore molecules were predicted to reside in the relatively long lived triplet state (T_1), 13% in the S_1 state, while the ground state was almost completely depleted. Consequently, in an area A_{GSD} with intensely illuminated molecules most of them would be in T_1, and a T_1 to S_0 transition would occur on average (half time) only once in 1 µs = 1000 ns; in another area A_{fluor} with low illumination intensity, most of the molecules would be in S_0; hence, these molecules would be easily excited to the S_1 state from which they return on average (half time) every few ns to S_0 to be excitable again. Compared to this area A_{fluor}, the ground-state-depleted molecules in A_{GSD} would have a very low fluorescence emission and hence practically be shut off, i. e., in a *dark state*. To use this effect for optical resolution improvement, a similar optical device may be used as realized in STED microscopy: A first low intensity beam (I_{exc}) is used to excite the molecules in a region of the size of the Airy intensity distribution; a second offset beam I_{depl} (like the STED beam in STED microscopy but operated at the same wavelength as the exciting beam) at high illumination intensities transfers the molecules in the outer region of the geometric focus to the relatively long lived triplet state (compared with the S_0 to S_1 transition); the molecules in the inner region of the focal area subjected only to low illumination intensities can rapidly cycle between S_0 and S_1, emitting a photon at every S_1 to S_0 return (on the mean every few ns, in contrast to the 1000 ns range for the T_1 to S_0 transitions). Consequently, the effective area from which photons are registered by the detector is highly diminished compared to D_{ill}. The next step of GSD microscopy described by *Hell* and *Kroug* [20.20] is to switch off the depletion beam after about 1 µs during which time the fluorescence emission has been registered; the molecules caught in the T_1 state are relaxed and return to S_0. After all the molecules are in the ground state again ($\approx 5T_1$ to S_0 transition life times, in this case ≈ 5 µs) and the exciting beam and the depletion beam has been moved to a new neighboring site, the scanning procedure is repeated pixel for pixel. With a dwell time of 5 µs per pixel, the maximum recording speed was estimated to be of the same order as in a standard confocal laser scanning fluorescence microscope. Assuming an excitation/depletion wavelength of 400 nm and a numerical aperture of NA = 1.4, [20.20] estimated a lateral optical resolution (FWHM of the effective PSF) of about 15 nm.

The concept of the single point scanning GSD microscope outlined above was experimentally realized in 2007 [20.60]. In the proof-of-principle experiment using a confocalized stage scanning microscope, relatively modest depletion intensities ($\lambda_{exc} = 532$ nm; $I_{depl} \approx 10^2\,kW/cm^2$) in a focal distribution featuring a local intensity zero were sufficient to confine the fluorescence emission of rhodamine-like fluorophore (Atto532) molecules to a very small region around the local intensity zero; a lateral optical resolution (FWHM of the effective PSF) down to ca. 50 nm was achieved. As a first application example for this type of scanning GSD microscopy, Atto532-stained microtubules, and membrane bound protein clusters were presented, featuring a clear improvement compared to confocal images of the same structure.

Reversible Saturable Optical Fluorescence Transitions (RESOLFT) Microscopy

The concepts outlined above for STED microscopy and GSD microscopy were generalized for an entire class of scanning nanoscopy approaches, called RESOLFT microscopy. This principle states that superresolution by any kind of scanning device can be obtained if illumination conditions can be realized with focal spots (or other intensity distributions) featuring central intensity zeros which allow one to inhibit transiently the reversible fluorescence emission of molecules outside this zero region, e.g., by stimulated emission, or by GSD.

To achieve superresolution in the RESOLFT scheme, the fluorophore molecules used must generally allow light induced reversible transitions between two states A and B at any point in space [20.11, 12]. In the simplest case, A and B are ordinary energy states of this entity, such as a ground and an excited state. Other examples are molecular conformational states, photochromic and isomerization states, binding and protonation states, etc. A → B is assumed to be photoinduceable while no specific further restrictions are needed about B → A. In the most general case, B → A may have a spontaneous component together with a component which is triggered externally through light, heat, by a chemical reaction, etc. To be practi-

cally useful, the reversible dark–bright transition cycle A → B, B → A must be fast enough to allow efficient point-by-point or line-by-line scanning, i. e., it has to be of the order of μs to ms.

On the laser optical side, the essential requisite of the RESOLFT concept described is that scanning is used, i. e., either the object is moved in a specific way, or the position of the illumination pattern relative to the object is changed to move the focal spots featuring central zeros to different sites of the object [20.61].

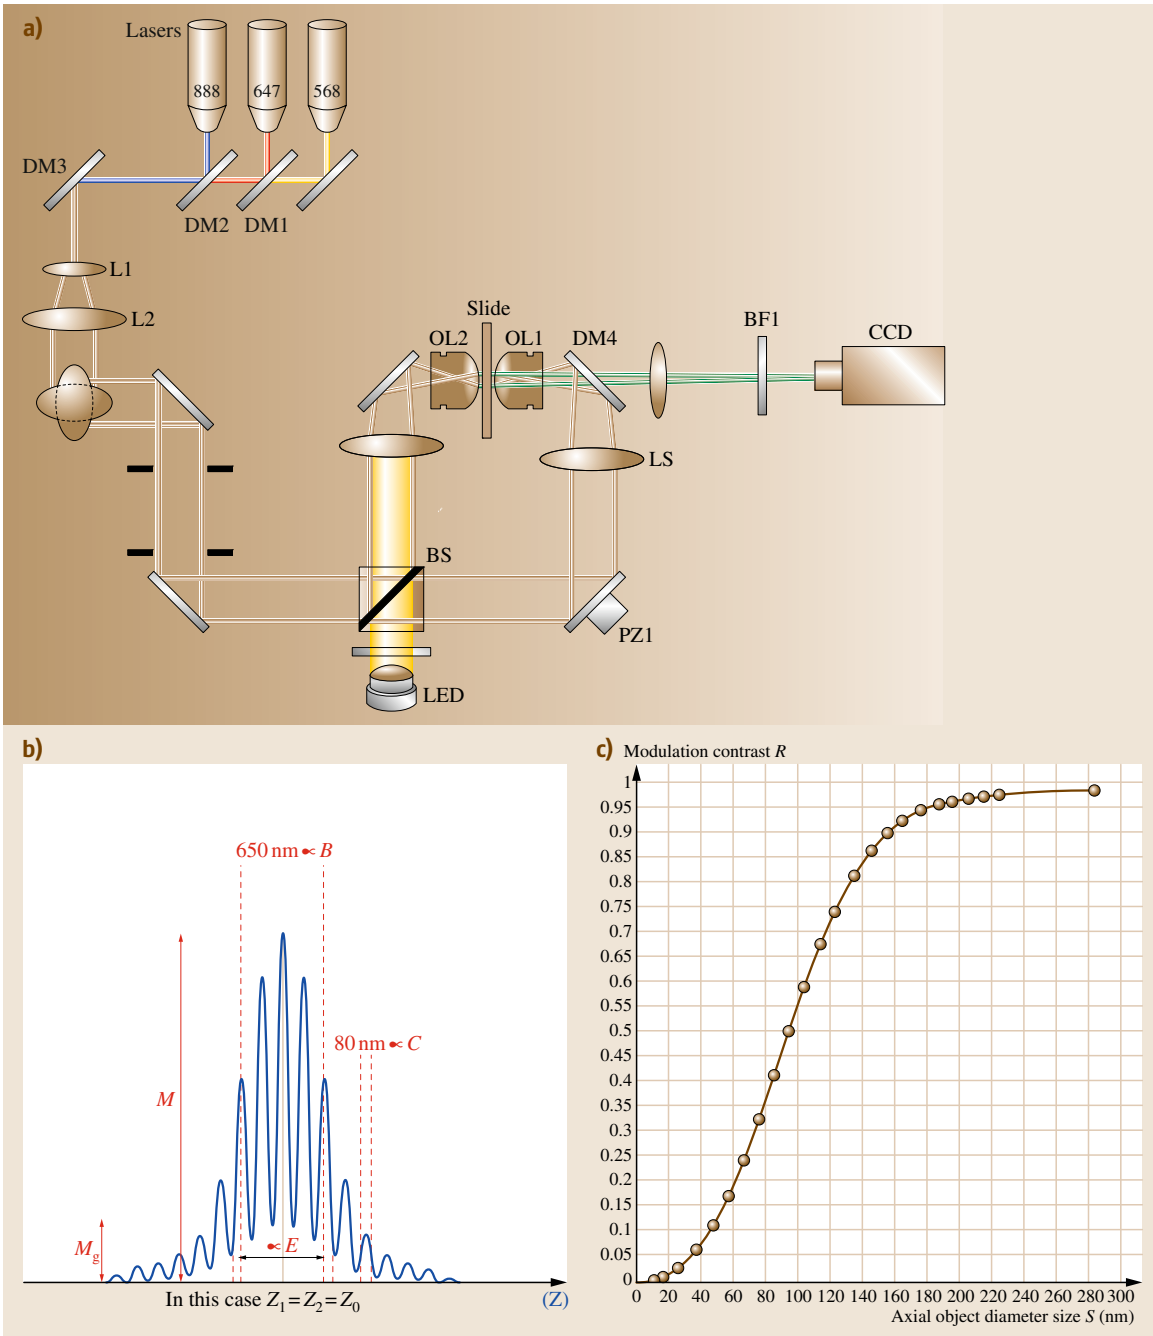
As a general formula for the resolution, *Schwentker* et al. [20.63] give the relation

$$\Delta x \approx \lambda \Big/ \left(2n \sin\alpha \sqrt{1+\xi}\right) ,$$

where Δx is the smallest distance detectable (optical resolution) with a point scanning system featuring central zeros, λ the excitation wavelength, $n \sin\alpha$ the numerical aperture (NA), $\xi = P/P_{\text{sat}}$ the saturation factor given by the applied power P driving the reversible, light-driven transition between a fluorescent and a nonfluorescent state of the dye label with a focal intensity distribution featuring a local zero divided by the saturation power P_{sat} that classifies the magnitude of the power necessary to attain 50% of the according transition.

For $\xi = 0$ (high saturation power compared to the applied power), i. e., for linear excitation conditions, the well-known Abbe formula is obtained. The higher the saturation factor becomes, the more the optical resolution is improved.

The RESOLFT concept of far field superresolution can be applied not only to single point scanning systems (one focal spot featuring a central zero as in the basic concepts of STED [20.13] and GSD microscopy [20.20]) but to any other scanning schemes based on illumination conditions creating intensity distributions that feature zero intensity sites, e.g., multiple spots or zero intensity lines as realized, e.g., in saturated patterned excitation microscopy [20.63, 64].



20.1.2 Structured Illumination Excitation (SIE) Microscopy

Spatially Modulated Illumination Microscopy (SMI)

Spatially modulated illumination (SMI) microscopy is a method of wide-field fluorescence microscopy using axially structured illumination to obtain additional high resolution information about sizes and relative positions of fluorescently labelled target regions. To generate the illumination pattern, two counter-propagating laser beams are brought to coherent interference, establishing a standing-wave field [20.65]. In contrast to focused laser light techniques [20.8, 10, 11, 48] or other types of structured illumination with excitation intensity modulation along the object plane [20.21–25, 64, 66], the SMI method as originally described was not suited for the generation of optically superresolved images of photostable fluorescence emitters, due to a range of missing

Fig. 20.5a–c Experimental setup of an SMI microscope and principle of nanosizing. **(a)** For illumination, three laser sources are available for excitation at $\lambda_{\text{exc}} = 488$ nm, 568 nm and 647 nm, which additionally can be independently switched with shutters before being combined with the dichroic mirrors DM1 and DM2. The dichroic DM3 works as a clean-up and reflects the three laser lines into the collimator, consisting of two achromates (L1 and L2) to expand the beam to a diameter of approximately 20 mm. The expanded laser is split by a 50 : 50 beam splitter (BS) to yield two coherent counter-propagating and collimated laser beams which are focused into the back focal plane of two opposing oil immersion objective lenses (OL1 and OL2) (100×, NA = 1.4). This results in a collimated laser beam leaving each objective lens. Interference between these two beams leads to a standing-wave field in the space between the two objective lenses, and hence a $\cos^2$ shape of the intensity distribution along the optical axis. Samples prepared on ordinary object slides/coverslips are placed between the two objective lenses and moved along the optical axis in precise steps with a piezoelectric stage, thus allowing 3-D data stacks of the specimens to be obtained. The emission light from the fluorescently labeled target regions, collected by the detection objective lens (OL1), is then separated from the excitation light by a dichroic mirror (DM4) and focused with the help of a tube lens onto a highly sensitive black-and-white CCD camera used for detection. In front of the CCD chip, a blocking filter (BF1) blocks any remaining laser light (after [20.61]). **(b)** Principle of axial size determination. A small fluorescent object (diameter < 150–200 nm) is moved through the $\cos^2$-shaped standing wave intensity field; at each step the maximum intensity of the diffraction pattern obtained is plotted as a function of the z-position. The modulation depth $R = M_{\text{G}}/M$ ($M_{\text{G}} = M_{\text{g}}$) can be obtained by comparing the experimental axial intensity distribution to a fitting function AID(z) as described in the text. For a given excitation wavelength, the modulation depth $R = M_{\text{G}}/M$ is a measure for the axial extension (size) of the fluorescent object (after [20.62]). **(c)** Example for calibration function $R(S)$ for fluorescent objects with N equally spaced point emitters (axial extension $S = N \times 10$ nm for $\lambda_{\text{exc}} = 488$ nm, $n = 1.515$ (after [20.62]) ▶

intermediate spatial frequencies. However, in combination with high-precision axial positioning [20.67–70] this technique of far-field light microscopy allows the nondestructive high precision localization analysis of complex spatial arrangements inside relatively thick transparent specimens such as the cell nucleus and enables size measurements at molecular dimensions of a few tens of nanometers [20.71–74] and 3-D position

measurements down to the 1 nm range [20.62, 67–70]. SMI microscopy is now an established method for the analysis of topological arrangements of small protein clusters and and chromatin domains [20.71–74]. It has even been shown to allow nanosizing measurements in the living cell nucleus [20.61].

For example, the size of a specific chromatin region in a cell is regarded to have a decisive influence on its genetic activity; thus, size measurements may provide key information towards a better understanding of the regulation of gene activity. Another example is the identification of functional biomolecular machines by analyzing the co-localization of its constituents: It is obvious that a necessary requirement for the proper functioning of a biomolecular machine is that its constituents are sufficiently close together; i. e., the diameter of the minimum volume enveloping these elements must meet certain limits.

Figure 20.5a presents the typical optical setup of an SMI microscope. In this case, the optical axis is positioned horizontally, and the object slide with the fluorescent object between the two opposing objective lenses is arranged vertically. It is also possible to position the optical axis vertically with the object slide arranged horizontally [20.61]. The principle of axial size determination (nanosizing) is shown in Fig. 20.5b,c. To convert the contrast ratio $R = M_G/M$ into a size estimate, one may either use fluorescent calibration objects of known diameter D, or one may directly calculate the correlation between D, r, and the excitation wavelength λ_{exc}. A direct approach to this is to numerically simulate the SMI imaging procedure by SMI virtual microscopy (VIM). Such a VIM model can be briefly summarized in the following way [20.62]:

1. An extended fluorescent object with an axial diameter D_0, $\lambda/40 < D_0 < \lambda/2$, is represented as the superposition of several point-like fluorescence emitters $P_1, P_2, \ldots, P_N$ (e.g., individual fluorescent molecules with a diameter of few nm at given x, y, z positions, each one emitting light independently from the others.
2. The diffraction image of each of the fluorescence emitters $P_1, \ldots, P_N$ of the fluorescent object (diameter D_0) is characterized by the PSF (SMI) of its fluorescent intensity distribution; for a given emitter P at an axial position z_1 it may be described by the normalized function

$$M_1 \mathrm{sinc}^2\left(\frac{z-z_1}{A}\right)\left(\cos\frac{z-z_0}{C}\right)^2 ,$$

where z is the axial coordinate, A and C are constants that depend on λ_{exc}.

3. The measured axial fluorescence intensity distribution (AID) of the fluorescent object (composed of the contributions of the single point emitters $P_1, \ldots, P_N$) is the sum of the PSF (SMI)s of each point emitter. For a given number of emitters (e.g., assumed to be located at various positions, with x_i, $y_i = \mathrm{const}$) this sum may be calculated for any given spatial distribution of point emitters, excitation wavelength, refraction index, fluorescence photon statistics, detector noise, etc., and fitted to the experimentally determined AID (z); this fit function may be described by

$$\begin{aligned}\mathrm{AID}(z) = (M - M_G)\mathrm{sinc}^2\left(\frac{z-z_1}{B}\right)\\ \times\cos^2\left(\frac{z-z_0}{C}\right) + M_G\\ \times\mathrm{sinc}^2\left(\frac{z-z_2}{E}\right) + L ,\end{aligned}$$

where M is the total intensity maximum of the AID, M_G is the maximum of the background part of the AID, B is proportional to the FWHM of the enveloping AID profile, z_1 is the position of the maximum of the enveloping AID profile, E is proportional to the FWHM of the internal background AID profile produced by the influence of the object size, z_2 is the position of the maximum of the internal background AID profile, C is a parameter derived from the $\cos^2$-shaped standing wave field present between the two objective lenses, z_0 is the position of one reference maximum of the standing wave field, and L is a constant related to the overall background in the region of interest (residual noise). For a given excitation wavelength, the calculated modulation depth $R = M_G/M$ is a measure for the axial extension (size) of the fluorescent object. An example of the dependence of R on size as calculated by VIM is shown in Fig. 20.5b. The relation between the axial object size S and the AID depends strongly on the excitation wavelength used.

For sizes smaller than 20 nm, the modulation contrast R is close to zero, i. e., the size in this range cannot be accurately determined. Increasing S also increases the modulation contrast and allows size measurements with an error (standard deviation) in the 10 nm range, see below; for $S > 160$ nm, R approaches values > 0.9, making a precise size determination again difficult to

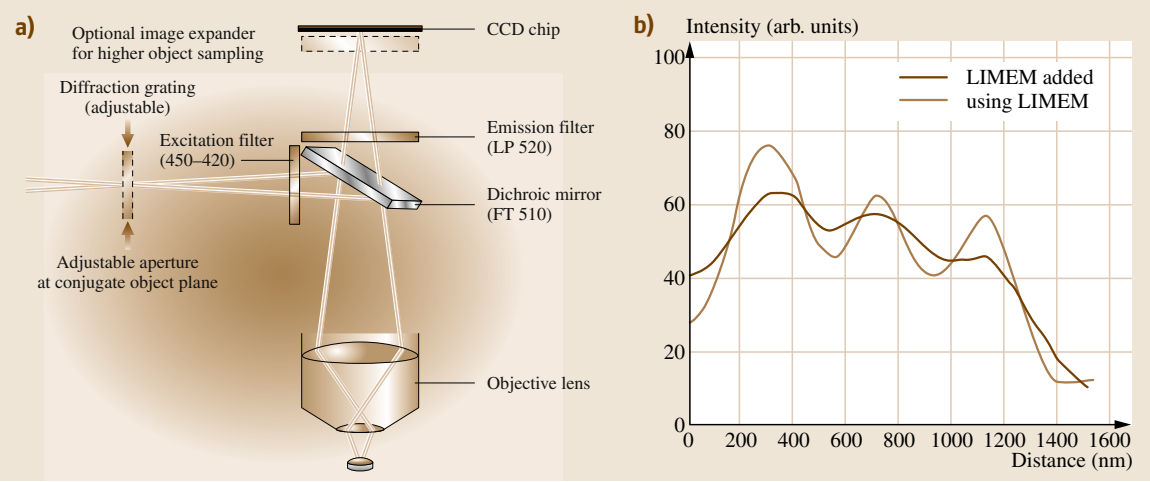


Fig. 20.6a,b Structured illumination microscopy using one objective lens (PEM/SIM). **(a)** The illumination pathway of a standard epifluorescence microscope is modified by inserting a diffraction grating at the conjugate object plane (position of the adjustable aperture). It is imaged into the object by the objective lens system (here 63×, NA = 1.4). In this proof-of-principle device, the grating constant was 30 μm using a conventional Hg-vapor light source) resulting in a 476 nm fringe distance in the object. **(b)** Experimental intensity line scans through RITC quartz beads ($D = 416$ nm) being attached to each other [20.35]. The LMEM added line (*solid line*) represents the result equivalent to the conventional epifluorescence image; the broken LMEM line (*dashed line*) presents the result obtained by using the reconstruction process obtained from several shifted images (after [20.21])

nonpractical. However, for size measurements in this range and larger, conventional microscopy methods may be used [20.75].

Patterned/Structured Illumination Excitation Microscopy (PEM/SIM)

First concepts to overcome the conventional optical resolution limit in the lateral direction (object plane) by a single objective lens approach and wide-field detection (e.g., using CCD cameras, in contrast to point detectors like photomultipliers or avalanche diodes) were developed by the end of the 1990s [20.21–23] and have found a variety of biomedical applications [20.76, 77]. The basic principle of these approaches was to create a spatially modulated illumination pattern not in the direction (z) along the optical axis as in standing wave microscopy [20.65] or in SMI microscopy [20.78, 79] but in the object plane (x, y). This can be done, e.g., by inserting a diffraction grating in the illumination beam at the conjugate object plane and projecting it through the objective lens into the object. The object and the illumination pattern are then moved relative to each other in precise steps. At each step a widefield detection image is taken, e.g., by a CCD camera. The images obtained are used to calculate an image with increased resolution using an algorithm based on the structure of the Fourier space. Principally, the effective optical resolution can be improved up to a factor of 2 compared with conventional widefield microscopy (a more detailed description of algorithms will be given later).

Figure 20.6 shows a typical optical setup for such a microscope system, and a first experimental proof-of-principle example for its use (for a recent biomedically relevant application see below).

Structured Interference Illumination Microscopy (SIIM)

Instead of a diffraction grid which is projected into the object plane, one may create the desired illumination pattern also by the interference of two or more laser beams. In the following, the basic underlying theory is summarized; this theory is applicable for all optical procedures for optical resolution improvement which generate an illumination pattern in the object space, whether by projection of a pattern, or by interference.

Since in this case, the resolution improvement is based on two or three interfering excitation beams, the impact of the periodically distributed excitation intensity must to be considered in the process of image

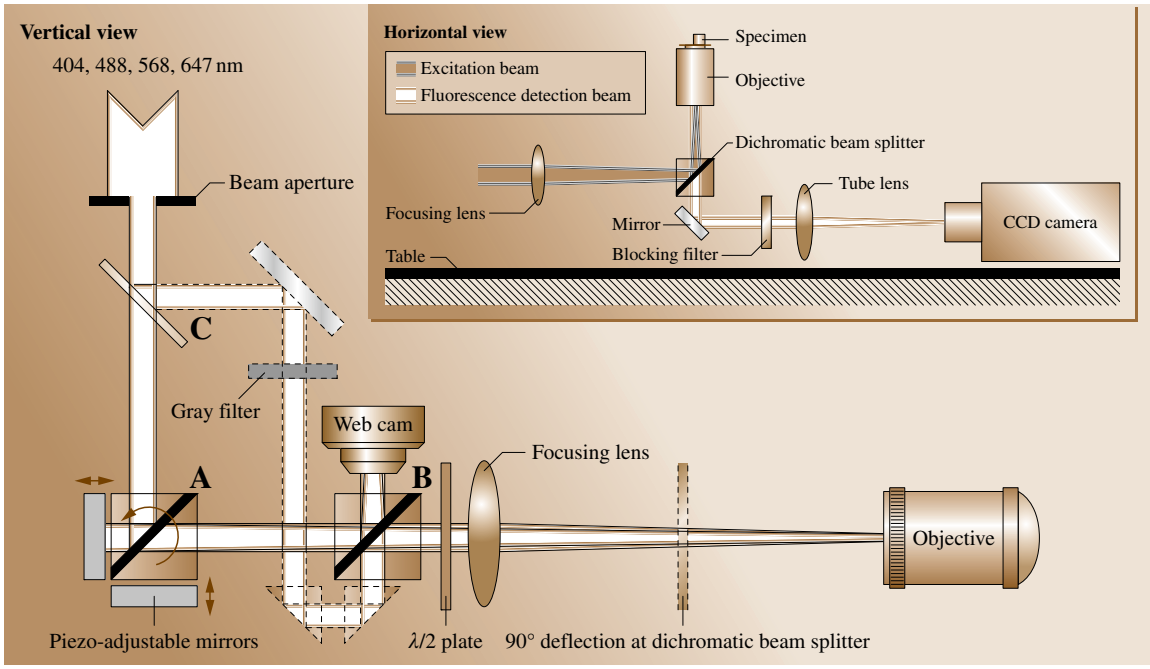

Fig. 20.7 Schematic design of an interferometer-based structured illumination microscope. The excitation beams (in this case $\lambda_{exc} = 404, 488, 568, 647\,nm$) are deflected by 90° onto the vertically positioned objective lens (NA = 1.4) by a dichroitic beam splitter. The *dashed elements* (indicated by C, Gray filter) are used for the optional three-beam interference mode.The objects labeled with A, B, and C are beam splitters. The *arrows* indicate movable elements (after [20.80])

formation. Figure 20.7 shows the optical setup of such a microscope.

In the conceptual outline given here, the description will be restricted to the case of two-beam interference. While the optical resolution improvement in the case of focused nanoscopy (once established) is almost intuitively understandable from the point of optical physics, it appears to be less obvious in the case of two or three interfering excitation beams. Its practical use became possible only with the advent of fast calculating personal computers (PCs). Both reasons might have contributed to the fact that this way to improve the optical resolution was designed and realized only in the late 1990s [20.21–23]. Therefore, the arguments for this approach are given here somewhat more formally, following the presentation given in [20.81].

Assuming (for simplicity of argument) a linear relation between fluorescence molecule distribution ρ, the image g is given by a convolution with the point spread function (PSF) (in the following noise effects are not considered)

$$g = \mathrm{PSF} \otimes \rho \,.$$

Transformation into Fourier space, abbreviated to FT, leads to

$$\mathrm{FT}[g] = \mathrm{OTF} \cdot \mathrm{FT}[\rho] \,.$$

During image formation, multiplication by the optical transfer function (OTF) acts like a low pass filter; only frequencies smaller than Abbes cut-off frequency limit are transmitted by the optical system (e.g., the microscope, mainly the objective lens). Moreover, the OTF decreases in transfer strength from the origin to the cut-off frequency, which results in reduced contrast transmission. The reduced contrast can be compensated by an appropriate weighting, only limited by image quality (signal to noise ratio, SNR).

In contrast to a homogeneous widefield illumination, the fluorescence molecule distribution must be multiplied by an intensity distribution (I) of illumination.

In the case of structured illumination

$$g = \mathrm{PSF} \otimes (\rho \cdot I)$$

is obtained.

This assumes that the fluorescence molecule emits photons at a rate proportional to the local excitation

irradiance. In Fourier space, respectively,

$$\mathrm{FT}[g] = \mathrm{OTF} \cdot (\mathrm{FT}[\rho] \otimes \mathrm{FT}[I])$$

is obtained.

For further calculations, an expression for the intensity distribution (I) of the illumination is required. Typically, the intensity distribution (I) of the illumination is generated by the interference of two or three beams coupled through a single objective. To achieve maximum interference at different interferometer planes, the polarization of the incoming linear polarized beams must always be azimuthal.

The intensity distribution (I) of the illumination generated by a two-beam interference can be calculated assuming the interference of two planar coherent waves each described by a wave vector of size k at an angle $\pm\alpha$ to the optic axis.

According to the linearity of the Maxwell equations, which implies that the sum of two amplitude distributions also constitutes a solution of the Maxwell equations, plane light waves can simply be added. Hence the y-component of the electric field is written as

$$E = E_{-1}\,\mathrm{e}^{-\mathrm{i}[k(-\sin\alpha\cdot x+\cos\alpha\cdot z)-\varphi_1]} + E_{+1}\,\mathrm{e}^{-\mathrm{i}[k(\sin\alpha\cdot x+\cos\alpha\cdot z)-\varphi_2]}\,.$$

Here E_{-1} and E_{+1} are amplitudes of incident plane light waves, respectively, and φ is a phase shift as would be obtained by translating a grating that generates these beams. To achieve the highest signal to noise ratio, an optimal intensity contrast is required and achieved by interfering beams of equal intensity I_0. Thus,

$$E_{-1} = E_{+1} = \sqrt{I_0}\,.$$

For the squared absolute value ($*$ indicates complex conjugation) of the electrical field, using the identity $\cos x = \frac{1}{2}(\mathrm{e}^{\mathrm{i}x} + \mathrm{e}^{-\mathrm{i}x})$, one obtains the intensity distribution

$$I = E \cdot E^* = 2I_0[1 + \cos(2k \cdot \sin\alpha \cdot x + \varphi)]\,,$$

with

$$\varphi = \frac{\varphi_1}{2} - \frac{\varphi_2}{2}\,.$$

By application of structured illumination, the total information transferred by the objective lens increases. Additional information is transmitted in a sum and must be separated and shifted to the correct position in Fourier space, before obtaining a high resolution image. To separate the components, the acquisition of a few images of the same region of the object with different positions of the illumination pattern is required. Different positions mean different phases of the periodic modulation: using two-beam interference, three images with different phase positions, regarding three-beam interference five, are necessary to accomplish reconstruction.

It is possible to determine the illumination pattern and phases from the images measured via cross-correlations between the separated components. With this knowledge, a more detailed version of the fluorescence molecule distribution can be reconstructed, as compared to homogeneous widefield illumination.

By introducing φ_i as different phase positions of the periodic illumination intensity distribution, a linear system of equations is obtained. If the values of φ_i are chosen such that the equation system is nonsingular, it can be inverted to unmix the overlapping components in Fourier space. In the case of three-beam interference, the Fourier transformed images $\tilde{B}_{\mathrm{camera}}(\varphi_i)$ of a series with different phase positions φ_i can be written as

$$\begin{aligned}\tilde{B}_{\mathrm{camera}}(\varphi_i) &= \int_{-\infty}^{\infty} \mathrm{d}k_z \mathrm{FT}[\rho(x,y,z)\cdot I(\varphi_i)]\cdot \mathrm{OTF} \\ &= \tilde{A} + \tilde{B}_+\,\mathrm{e}^{+\mathrm{i}\cdot\varphi_i} + \tilde{B}_-\,\mathrm{e}^{-\mathrm{i}\cdot\varphi_i} \\ &\quad + \tilde{C}_+\,\mathrm{e}^{+2\mathrm{i}\cdot\varphi_i} + \tilde{C}_-\,\mathrm{e}^{-2\mathrm{i}\cdot\varphi_i}\,.\end{aligned}$$

The five unknown components $\tilde{A}$, $\tilde{B}_+$, $\tilde{B}_-$, $\tilde{C}_+$, and $\tilde{C}_-$ can be determined by measuring five images with different phase positions. Two methods are commonly used to solve the linear system of equation: inverting the associated coefficient matrix or by a discrete Fourier transformation. The latter is the solution of the inversion problem for the special case of all phase steps being of equal size and sampling the coarsest nonzero spatial frequency once over the experiment.

An almost isotropic resolution improvement can be achieved, if the periodic illumination intensity distribution is rotated and image series are taken at different angles.

Saturated Patterned Excitation Microscopy (SPEM)

In the wide-field-based superresolution schemes presented so far, a linear relation between excitation intensity and fluorescence emission was assumed. This is the typically desired condition in conventional fluorescence microscopy, where nonlinear effects like saturation and photobleaching usually are avoided. Nonlinear effects, however, cannot only be used to increase the optical

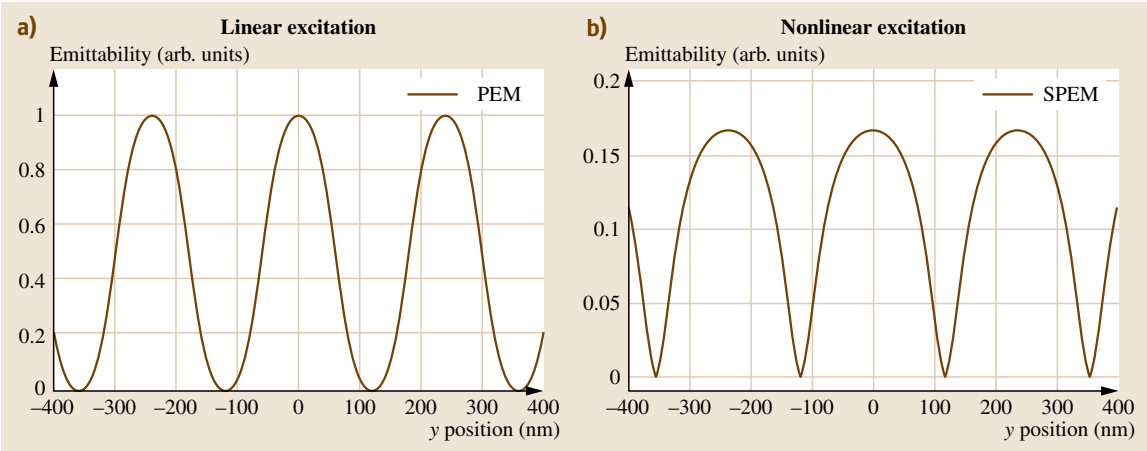

Fig. 20.8a,b Fundamental concept of SPEM implemented by fluorophore saturation. **(a)** Pattern of the sinusoidal emittability distribution generated by low-intensity patterned excitation (linear patterned excitation microscopy). **(b)** Emittability distribution generated by high-intensity illumination leading to fluorophore saturation (after [20.64])

resolution in point spread function engineered focused scanning methods like in STED or GSD microscopy but give highly interesting possibilities also in structured illumination excitation approaches. Nonlinear patterned excitation schemes can be used to achieve a substantial further improvement in optical resolution by deliberate saturation of the fluorophore excited state [20.64]. The postacquisition manipulation of the acquired data is computationally more complex than in STED or GSD, but the experimental optical requirements are simple. The fundamental illumination concept is shown in Fig. 20.8. The nonlinearity leads to the generation of higher spatial harmonics in the pattern of emittability, i. e., components in Fourier space beyond the frequency limit defined by the Abbe condition are created.

Computer simulations [20.82] have shown that by appropriate extension of the algorithms presented before for the case of linear structured illumination excitation, a further improvement of optical resolution is possible in SPEM. It is interesting to note that the sharp zeros created by nonlinear illumination patterns (Fig. 20.8b) might be used as virtual pinholes at the positions of the emittability minima in the original SPEM image. This opens an avenue to extend the RESOLFT concept to nonlinear pattern based scanning devices; instead of realizing illumination conditions with focal spots featuring central zeros to inhibit transiently the reversible fluorescence emission of molecules outside this zero region, e.g., by stimulated emission, or by ground-state depletion, in SPEM-based RESOLFT scanning microscopy lines with central emittability zeros are created [20.63]. In this way, in principle, an unlimited optical resolution should be possible not only in focused nanoscopy techniques with point-by-point fluorescence registration (e.g., by a photomultiplier or an avalanche diode) but also in nonlinear structured illumination excitation (SIE) scanning approaches using wide-field registration (e.g., a sensitive CCD camera). However, in practical applications noise, in particular originating from the Poisson distribution of the limited number of photons detected, is a limiting factor.

20.1.3 Spectrally Assigned Localization Microscopy (SALM)

Principles of SALM

The nanoscopy concepts described so far (4π/4Pi, STED, GSD, SMI/SIIM, PEM, SPEM, RESOLFT microscopy, etc.) were based either on diffraction-limited focusing or on structured illumination excitation schemes, which allowed a substantial improvement of the spatial resolution in far-field light optical microscopy; depending on the method, values between 100 nm (laterally, axially) and a few nm (laterally) were realized, the latter value corresponding to ca. 1/100 of the exciting wavelength. However, they require either complex laser optical systems, or sophisticated evaluation algorithms. So far, this has restricted a broad application in various fields of the life and the material sciences. In the following, a further nanoscopy approach (SALM, or simply localization microscopy) will be outlined which allows one to implement super-

resolution modes in various conventional microscopic techniques, e.g., in conventional confocal laser scanning microscopy, and to substantially further improve the optical resolution also in 4Pi microscopy and structured illumination excitation microscopy. The most striking feature of SALM methods, however, is the possibility to achieve superresolution down to the 1–5 nm range (1/500–1/100 of the exciting wavelength) even under homogeneous far-field illumination conditions and with wide-field detection. In principle, any mechanically stable epifluorescence microscope equipped with a sensitive CCD camera can be turned into a superresolving SALM device.

In contrast to the zero featuring intensity distributions required in STED, GSD, SPEM, and generally in RESOLFT microscopy, the basic principle of SALM allowing homogeneous illumination schemes does not require any more information about the spatial scanning positions of zero line intensity distributions like in the scanning-based nanoscopy methods described so far. The information about the position of point emitters (e.g., single fluorescent molecules) is derived directly from the diffraction pattern produced by such point emitters in the image plane which may be registered by any means, in particular including wide-field detectors without scanning.

During the last years, a large variety of SALM concepts has been developed and realized, denoted as BLINKING, FPALM, GSDM, PALM, RPM, SPDM, STORM, dSTORM, d^{4}STORM, etc.

Very general ideas on strategies for attaining superresolution using spectroscopic data as constraints may be dated back to the 1980s. For example, *Burns* et al. [20.31] considered the problem of precision localization of two-point objects within the Rayleigh distance of each other, possessing different spectral characteristics. Assuming linear superposition of the spectral characteristics, they showed by computer simulations that by appropriate, rather complex algebraic methods and assuming an SNR of 15 dB, two-point objects within a distance of 1/30−1/50 of the Rayleigh distance were still spatially resolvable. It was not clear, however, to what extent these arguments were practical to achieve superresolution in far-field fluorescence light microscopy, especially if the number of point objects located in an area smaller that the diameter of the Airy disc was increased to significantly higher values.

This problem was treated by *Betzig* [20.32] who discussed possibilities to realize localization microscopy of multiple point sources situated within the Airy disc (i. e., with distances below the Rayleigh distance = conventional optical resolution) in a near field scanning microscope at helium temperatures. Under these conditions, absorption cross sections would be sharp enough to achieve by appropriate laser-based absorption line tuning of the necessary optical isolation of adjacent molecules, i. e., the clear separation of their diffraction patterns. In contrast to the deconvolution procedure in [20.31], the independent evaluation of the diffraction patterns would allow localization of any number of point sources with mutual distances smaller than the conventional resolution. Experiments performed some years later by *van Ojen* [20.34] showed that this concept indeed allowed superresolution of multiple single molecules in low-temperature far-field microscopy. Due to the technical restrictions of cooling the specimen down to a few kelvin, only numerical apertures < 1.0 were used.

Hell and *Kroug* [20.20] discussed optical isolation and localization of molecules in the vicinity of a focused laser beam in a far-field scanning microscope around 300 K operating temperature by intensity induced reversible transitions between the ground state (S_0), the first excited state (S_1), and the triplet state T_1 (later integrated into the context of the RESOLFT concept), indicating a possible mechanism for light induced reversible transitions between dark and bright states.

Cremer et al. [20.26, 27] proposed to implement a localization-based mode of superresolution applicable to any far-field microscopy method, including for the first time also fluorescence excitation of multiple point sources by homogeneous illumination, allowing the use of high NA (> 1.0) objective lenses and operating temperatures around 300 K. To enable the detection of multiple point sources, in addition to differences in the fluorescence emission spectrum they proposed the use of differences in fluorescence lifetime, in luminescence, or in any other characteristics (*spectral signature*) useful for optical isolation (i. e., the independent registration of the diffraction patterns of the individual point sources).This included the explicit introduction of the time domain, i. e., in these cases the superresolution was not obtained by scanning in space (as in the previous nanoscopy approaches) but by scanning in time.

For brevity and simplicity of argument, the following description concentrates on the SALM mode developed in the laboratory of the author, called spectral precision distance or position determination microscopy. Like other SALM concepts, SPDM [20.26, 27, 35, 83, 84] is based on precision position distance measurements of objects optically isolated from each other by appropriate spectral signatures. In this case,

the definition of the optical resolution (smallest resolvable distance between two fluorescent point emitters) is based on the localization accuracy of the individual point sources [20.85]; the estimate of the attainable structural resolution must take into account also the density of optically isolated point emitters [20.86–88]. With this method, cellular and other biological nanostructures labeled with fluorescent markers can presently be analyzed down to the molecular optical resolution range, even in the case of homogeneous illumination conditions and using one laser frequency for a given molecule type. An additional essential feature of SPDM and related approaches (see below) is that it includes the use of standard fluorophores, like synthetic dyes and conventional fluorescent proteins.

Figure 20.9 schematically shows the SPDM principle; the example is based on numerical calculations using scalar wave theory, assuming a numerical aperture $\mathrm{NA} = n \cdot \sin\alpha = 1.4$ (α = half aperture angle, n = refraction index) and different emission wavelengths λ. Imagine that the first three, point-like self-luminous points (e.g., single molecules) have the same spectral signature (i. e., the same absorption/emission spectrum, fluorescence lifetime, luminescence characteristics, etc.. Furthermore, let us assume a next neighbor distance of only 50 nm (Fig. 20.9a), that is four times smaller than the conventional limit of optical resolution. From each of these molecules, an Airy disc like diffraction pattern is formed in the image plane by the microscope optics, with a diameter (FWHM) of about $D = 0.51 \cdot \lambda/(n \cdot \sin\alpha) \cdot M = 200\,\mathrm{nm} \cdot M$ (numerical aperture: $n \cdot \sin\alpha = 1.4$; excitation wavelength: $\lambda = 500\,\mathrm{nm}$, magnification factor M). With the same spectral signature all signals overlap additively in the image plane (Fig. 20.9b). An intensity cross-section horizontally through the center of this diffraction pattern is shown in Fig. 20.9c. In this case, it is not possible to determine where the three molecules are located precisely and by what distance they are separated from each other.

If to each of the closely spaced molecules, however, a different spectral signature B, G, R is assigned (Fig. 20.9d), localization of the individual molecules and a determination of their distances is possible. From the Airy disc center positions (X_B; Y_B) in the image plane, the corresponding molecule localizations ($x_\mathrm{B} = X_\mathrm{B}/M$, $y_\mathrm{B} = Y_\mathrm{B}/M$) are determined. It is possible to determine the center (X_B, Y_B) of the diffraction pattern (Airy disc) in the image plane with a positioning error $\sigma_{XY} = \sigma_\mathrm{loc} \cdot M$, which is much smaller than the diameter $D \approx 200\,\mathrm{nm} \cdot M$ of the Airy disc. With appropriate good photon statistics and after careful correction of all errors due to optical/chromatic aberrations and mechanical shifts the position of the corresponding molecule can be determined with a localization accuracy down to $\sigma < 1\,\mathrm{nm}$, the limits depending on the photon emission statistics [20.68, 69, 89, 90]. The achievable optical resolution defined as the smallest detectable distance between two point-like objects/fluorescent molecules can be estimated in this case to be about twice the localization precision σ_loc.

The basic experimental feasibility of SPDM (and related approaches) was shown already a decade ago [20.34, 35, 83, 84, 91–93]. Different fluorochromes (two or three) were used, with spectral signatures differing in the absorption and emission spectrum. From the positions of the diffraction image centers in the image plane, the corresponding object plane localizations were determined and from these localizations, distances in the object plane (x, y) were measured down to a distance of about 30 nm ($\approx 1/16$ of the excitation wavelength used); in 3-D (x, y, z), the smallest resolvable distances were approximately 50 nm [20.84]. In these early proof-of-principle experiments, confocal laser scanning fluorescence microscopy (CLSM) was applied to register the optically isolated diffraction pattern in three dimensions. Since differences in the excitation/emission spectrum were used, calibration of chromatic aberrations was performed.

Proof-of-principle experiments showed the feasibility of using time dependent fluorescence emission of molecules, such as fluorescent life times, for their discrimination [20.28]. Closely adjacent single molecules (distances $\ll 0.5 \cdot \lambda/(n \cdot \sin\alpha)$) were localized separately from each other even when they differed neither in the absorption nor in the emission spectrum from each other but were distinguished by time dependent features. Here, the fluorescence lifetime of excited states of single molecules (nanosecond range) was used as the spectral signature. The fluorescence excitation lifetimes of single molecules were determined by time-correlated single photon counting using a laser scanning device. This has been a first example how temporal variations in the fluorescence emission following simultaneous excitation can be used to determine the Airy discs produced by each individual molecule and thus to optically isolate them.

Since in an object to be studied, all point emitters of a given spectral signature can be resolved that have a mutual distance larger than the conventional resolution, already two or three spectral signatures allow highly relevant applications to nanostructure analysis [20.27, 35, 83, 84, 89, 94, 95]. It is evident, however,

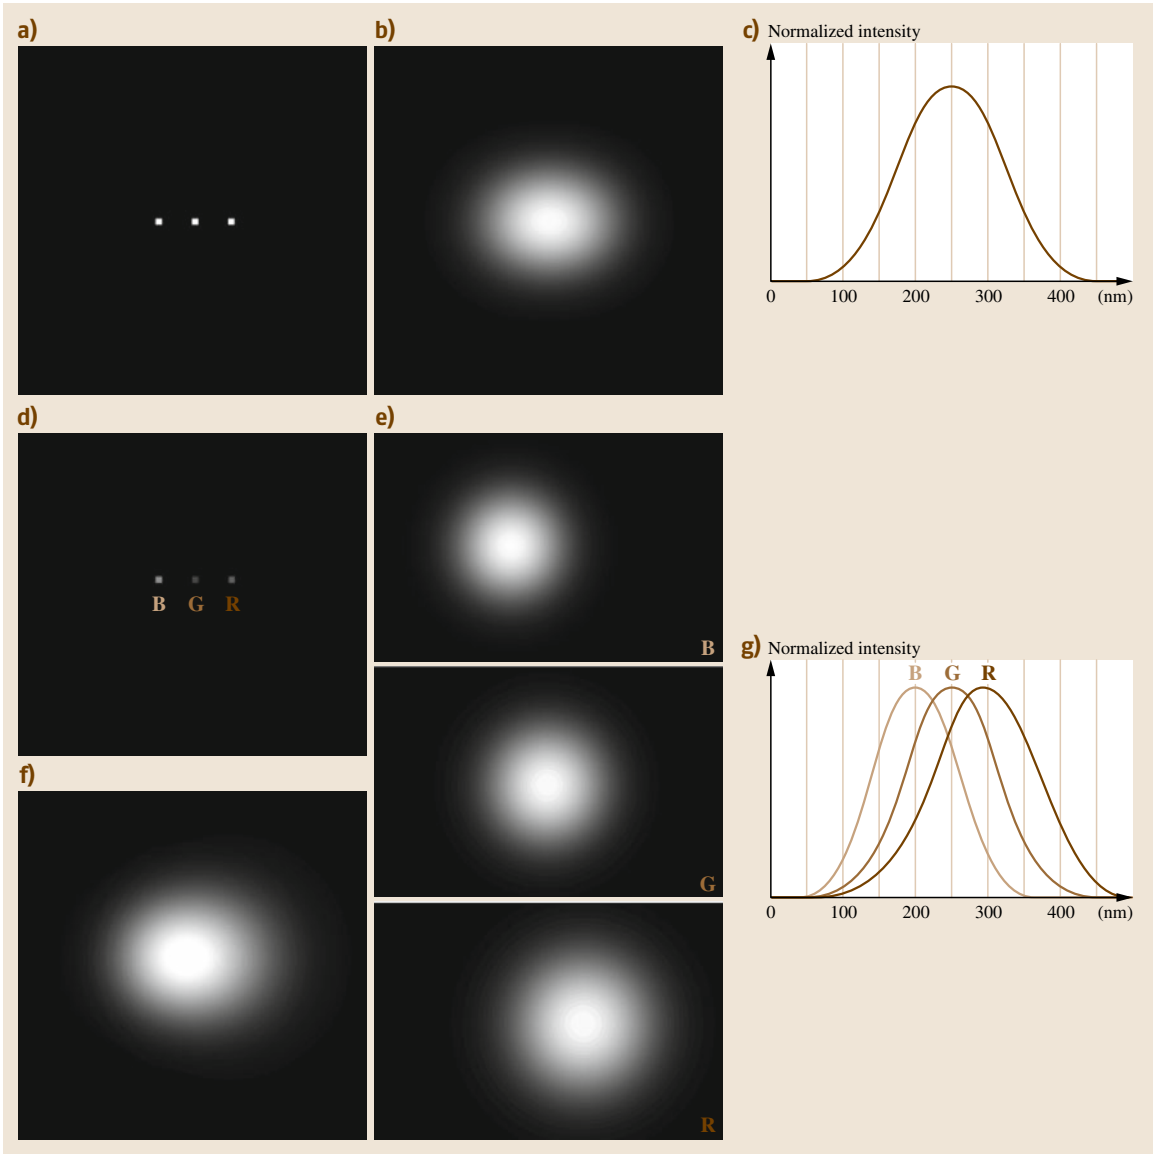

Fig. 20.9a–g Principle of spectral precision distance microscopy (SPDM). **(a)** Three point-like objects of the same spectral signature at a distance of 50 nm. **(b)** The diffraction pattern produced. **(c)** Intensity distribution across the center of the diffraction pattern of **(b)**. **(d)** Three point-like objects at a distance of 50 nm with three different spectral signatures B, G, R. **(e)** Optically isolated diffraction patterns of B, G, R. **(f)** Diffraction pattern of all three signals if not optically isolated. **(g)** Intensity distribution through the center of each optically isolated diffraction pattern of B, G, R. The abscissa and the diffraction image dimensions are normalized to object plane coordinates. Detailed explanation in the text (after [20.87] based on [20.26, 27])

that the higher the number of spectral signatures, the better small structures can be analyzed. The use of fluorescence life times provided the possibility to increase the number of useful spectral signatures. Assuming 5–7 spectral signatures based on differences in the fluorescence absorption/emission spectrum (at ≈ 300 K)

and a few additional spectral signatures based on fluorescence lifetimes of the S_1 state, around 10 spectral signatures would have been useful for the SPDM technique described so far [20.27].

Although these early proof-of-principle experiments were performed by using scanning devices, the application of the SPDM concept to superresolution using homogeneous illumination conditions was explicitly recognized [20.26, 27]. In addition, the concept to use the SPDM method to obtain high resolution images by stochastic optical reconstruction schemes using random labeling procedures was acknowledged [20.29]. First experiments to use point sources induced to emit fluorescent flashes distributed stochastically in time to realize high resolution localization microscopy have been described by [20.96]. Here, the intermittent fluorescence or blinking of quantum dots was registered and analyzed using an independent component analysis so as to identify the light emitted by each individual nanoparticle, localize it precisely, and thereby resolve groups of closely spaced ($< \lambda/30$) quantum dots. It became difficult, however, to reliably separate in the way described more than five emitters within a 200 nm diameter. Another setback for a wide spread application of this blinking approach was the use of nanoparticles as fluorescent emitters. It was stated, however, that this limitation should be taken as a limitation of the present approach and not of the blinking-based separation procedure in general.

Within recent years, localization microscopy approaches using both time-independent, e.g., [20.83, 84, 94, 95] and time-dependent optical isolation ([20.28]; see below) of the detected molecules using one or other scheme of time dependent blinking have been developed to allow a broad spectrum of applications. Presently they allow the localization of up to several to many thousand individual molecule signals/μm^2, corresponding to about 60 molecules in an area as small as an individual Airy disc. Using homogeneous, spatially nonscanning illumination schemes photoactivation/photoswitching transitions of organic fluorochromes between a dark state and a bright state can be achieved by the application of appropriate illumination sources (e.g., one wavelength for photoactivation/photoswitching and another one for fluorescence excitation of the molecules, or one wavelength only, or one laser frequency only for two given molecule types simultaneously) in combination with appropriate physicochemical conditions. Dark and bright in this case do not necessarily mean emission/nonemission of photons but may refer to the registration status of the detector for a particular spectral signature (e.g., shift of fluorescence emission to another wavelength [20.97]). Various methods using this principle for single molecule superresolution have been realized during the last few years and successfully applied to a variety of biological nanostructures, from bacteria to tissue sections. In particular, it is worth mentioning PALM (photoactivated localization microscopy) [20.97–100]; FPALM (fluorescence photoactivable localization microscopy) [20.101, 102], stochastic optical reconstruction microscopy (STORM) [20.103, 104], PALM with running acquisition (PALMIRA) [20.105–107], spectral precision distance microscopy (SPDM) using photobleached single molecule states (also denominated as $SPDM_{Phymod}$ [20.36, 61, 86, 87, 108], direct STORM (dSTORM) [20.109, 110], ground-state depletion imaging microscopy (GSDIM) [20.111], dual-color localization microscopy (2CLM) [20.112], reversible photobleaching microscopy (RPM) [20.75, 113, 114], or 4-D STORM (d^4STORM) [20.115]. For example, in the PALM approach a UV laser beam is used at very low illumination intensities to induce sparsely distributed conformational changes in photoactivatable green fluorescent proteins (PA-GFP), leading to a change in the fluorescence emission spectrum (activation) and producing a bright state. Here the basic idea has been to activate only very few of the fluorophores, to have not more than one of these per diffraction volume. The fluorescence emission of the individual, optically isolated molecules is registered until they are bleached (converted into an irreversibly dark state) [20.116]. After this first cycle all fluorophores are again in the dark state. Now a new subset of the PA-GFP molecules is activated, detected, and bleached. This procedure is repeated many times to detect a large amount of single molecules. In STORM, the required optical isolation of single fluorescent molecules has been achieved by using two laser frequencies to photoswitch pairs of molecules.

Another way to realize the appropriate conversion between dark and bright states under homogeneous illumination conditions (with respect to the region of interest) without needing special molecules or pairs of molecules which have to be photoactivated or photoswitched by two different wavelengths is to take advantage of the fact that under certain illumination conditions combined with specific physicochemical conditions, in many types of fluorescent molecules two types of dark states may be induced using one wavelength alone: one irreversibly bleached state M_{irb} and one reversibly bleached state M_{rbl} [20.117]. After excitation with a suitable single wavelength and

illumination intensity, they can either pass to the irreversibly bleached dark state M_{irb} or they can pass to the reversibly bleached dark state M_{rbl}. From this dark state they can stochastically re-enter the fluorescent state M_{fl} in which they emit in a few tens of milliseconds a flash of thousands of photons before they pass into either the irreversibly bleached dark state M_{irb} or are again transferred to the reversibly bleached state M_{rbl}. At appropriately long time constants for the transitions of the fluorophores from the reversibly bleached state M_{rbl} to the fluorescent state M_{fl}, the distances between the diffraction images of the molecules are large enough ($> 0.61\lambda/\mathrm{NA} * M$) to allow the desired optical isolation [20.88]. Thus the positions of the individual detected fluorophores can be determined according to the basic principles of SPDM outlined above: In this case, the spectral signature (according to the general definition of this term given, e.g., in [20.26, 27]) is the transition time of the individual molecule from the reversible bleached state M_{rb} to the fluorescent state M_{fl}. Interestingly, this transition can be achieved by using only a single laser frequency at constant illumination intensity (in space and time) for both the induction of reversible bleaching transitions and fluorescence registration [20.61, 86]. Since this superresolution technique is based on the general principles of SPDM using molecular states modified by appropriate illumination intensities and environmental conditions, it was also denominated as SPDM with physically modifiable fluorophores ($\mathrm{SPDM_{Phymod}}$) [20.36, 87, 112]. Typically, a few thousand frames registered at a frame rate of 20 fps or more are sufficient to render an image with a structural resolution down to the 20 nm range.

An especially intriguing consequence of the $\mathrm{SPDM_{Phymod}}$ approach and related methods like 2CLM, RPM, dSTORM, $\mathrm{d^4STORM}$, or GSDIM is the possibility to use standard fluorescent dyes as well as conventional fluorescent proteins in a microscope setup even at homogeneous illumination conditions (with respect to the field of view chosen), which makes this technique particularly useful for a broad spectrum of applications in the biosciences. Theoretical considerations [20.88] indicated that at the registration speeds presently realized, the dark (reversibly bleached) to bright (fluorescent state) transition times have to be of the order of many seconds to allow the desired optical isolation: i. e., two adjacent molecules must emit their photon flashes at different times so that the diffraction patterns produced by these photon emissions can be distinguished from each other and thus used for the localization of the individual molecules.

Comparing the $\mathrm{SPDM_{Phymod}}$ method in detail to other single molecule high-resolution imaging approaches using standard fluorophores, various similarities but also major differences may be noted. For example, in the technique of single molecule high-resolution imaging with photobleaching (SHRImP), *Gordon* et al. [20.116] localized pairs of single Cy3 molecules with nm precision and determined their separation with 5 nm precision, using their quantal photobleaching behavior. However, so far this method did not allow true imaging because it could only be used to measure distances with well separated pairs of molecules, not multiple molecule positions within the conventional resolution limit like in $\mathrm{SPDM_{Phymod}}$ and other more recent SALM techniques like PALM, FPALM, STORM, dSTORM, GSDIM, etc. This restriction probably is due to the fundamental difference how the photobleaching behavior of single molecules was used: while in SHRImP, the basic photophysical effect used was the stepwise, bleaching induced decrease in the total fluorescence intensity measured from a pair of adjacent dye molecules, the above mentioned single molecule localization microscopy approaches use the induction of either short unique short (e.g., in certain modes of $\mathrm{SPDM_{Phymod}}$ or GSDIM), or long (e.g., in PALM, FPALM), or repetitive fluorescence emissions (e.g., in STORM, dSTORM, or $\mathrm{d^4STORM}$). Hence, in these methods an arbitrary high number of molecule signals may be localized within the conventional resolution limit as long as the basic conditions of all SALM methods, the optical isolation due to an appropriate (in this case time dependent) spectral signature is maintained.

Comparing $\mathrm{SPDM_{Phymod}}$ and related approaches (see above) to the GSD concept and generally to the RESOLFT approach, fundamental similarities as well as fundamental differences may be noted: both methods rely on the use of nonlinear light induced reversible transitions between dark and bright molecular states; however, in contrast to the GSD/RESOLFT techniques, the $\mathrm{SPDM_{Phymod}}$ approach achieves superresolution down to the molecular level even at homogeneous illumination (in the region of interest selected). Furthermore, the dark to bright transition times are several orders of magnitude higher in $\mathrm{SPDM_{Phymod}}$ than in GSD/RESOLFT microscopy. This difference is decisive. In GSD/RESOLFT, appropriately short transition times (typically µs to ms) are necessary to allow a sufficiently fast scanning for image formation, while in $\mathrm{SPDM_{Phymod}}$ (and related methods) substantially longer transition times (typically many seconds to several minutes) are required to achieve the optical isolation of

the point emitters of high density with relatively low frame rates (presently up to ≈ 100 frames/s). These differences might have contributed to the relatively late discovery of this mode of superresolution. Another important difference is that in SPDM and especially in $SPDM_{Phymod}$ (and related techniques) spatial scanning procedures may be used but are not necessary to obtain superresolution.

Although the technical conditions (high mechanical stability, highly sensitive CCD cameras to detect single molecule fluorescence emission) for these highly simplified and robust modes of localization microscopy on the basis of homogeneous illumination schemes have existed at least for a decade, accounts of their realization for a variety of conditions and targets have been published only recently, within a few months independently of each other by a variety of groups. For example, [20.61] (manuscript received February and published 8 May 2008) described superresolution of nuclear pore complexes using the standard dye Alexa 488 (homogeneous illumination at $\lambda_{exc} = 488\,nm$) in combination with a standard embedding medium, to be followed shortly afterwards by [20.109] (received 21 May 2008 and published 22 July 2008) and [20.110] (received 19 August and published 24 November 2008) describing the use of Cy5/Alexa 647 in combination with certain specially made switching buffers to perform superresolution of DNA and cellular Actin filaments. *Lemmer* [20.86] (received 8 June and published 1 September 2008) described the extension of $SPDM_{Phymod}$ to standard fluorescent proteins (YFP), achieving a lateral optical resolution down to the 10–20 nm regime; in combination with SMI microscopy, an effective 3-D-resolution of thin cellular structures (axial thickness $< 150\,nm$) of 40–50 nm ($\approx 1/10$ of λ_{exc}) was achieved.

Another early report of SALM using homogeneous illumination in combination with standard fluorochromes called ground state depletion imaging microscopy (GSDIM) was published by *Fölling* [20.111] (received 24 July, 2008 and published 15 September, 2008), featuring an optical resolution of microtubules and peroxisomes immunostained with standard fluorophores Atto 532/565 in the $< 30\,nm$ range. In this latter case, the term scheme (S_0 to S_1 to T_1 to S_0) presented previously for relatively fast reversible transitions between dark and bright states (µs to ms) in GSD microscopy was extended to include an additionally assumed very long lived dark state D (transition times D–S_0 in the required order of seconds, i. e., several orders of magnitudes higher than the T_1–S_0 transitions of GSD microscopy). This state D was conceived to be accessible via a S_0–S_1–T_1 transition.

From the formal point of view this general scheme appears to be compatible with mechanisms proposed previously for reversible photobleaching [20.86, 117]. Compared to the dSTORM concept as published originally [20.109], the major differences between $SPDM_{Phymod}$ and dSTORM are the molecule types and biostructures studied, the chemical environment used, as well as the two laser excitation schemes used originally by *Heilemann* et al. [20.109].

The various denominations given to the novel localization microscopy approaches having it made possible to include even standard fluorochromes in a straightforward way are not only justified by the many differences in the optical setup, the molecule types, and physicochemical environments used; in addition they stress various elements of the entire SALM concept. For example, in PALM and FPALM the importance of using photoswitchable molecules is put forward; in STORM, dSTORM, and d^4STORM the optical isolation by stochastically distributed spectral signatures is highlighted; in GSDIM the focus is put on the quantum physical necessity to realize very long lived excited states for S_0 depletion; in RPM the effect of reversible photobleaching is denoted; in 2CLM the possibility to extend SALM to the simultaneous superresolution of multiple molecule types is envisaged; and in $SPDM_{Phymod}$ the aspect to perform highly precise position/distance measurements of single molecules under specific physicochemical conditions (e.g., illumination intensity, chemical environment) is regarded.

The exact photophysical mechanisms underlying the blinking effects used in 2CLM, GSDIM, RPM, dSTORM/d^4STORM, etc. are still widely unknown; it might well be assumed that they are different for different types of molecules including reversible or irreversible conformation changes [20.12, 97]. From the formal point of energy terms, they might include a transition through a T_1 state as assumed by *Fölling* et al. [20.111] but the molecular mechanisms to proceed from there to the required very long dark states are most probably highly complex (as an example see [20.97, 117]); they are expected to constitute a promising field for future photophysics of organic molecules.

The results reported here show that $SPDM_{Phymod}$/dSTORM/GSDIM, and related methods allow superresolution imaging of biological structures also for a variety of standard fluorescent molecules and a vari-

ety of biological nanostructures, including conventional fluorescent proteins.

The combination of localization microscopy with confocal microscopy/structured illumination schemes may be highly advantageous to obtain such a superresolution not only in the object plane but even in three dimensions [20.118]. For example, the combination of SPDM/localization microscopy with confocal laser scanning fluorescence microscopy allowed 3-D distance measurements down to 50 nm range [20.83] while the combination with 4Pi microscopy [20.119] permitted 3-D distance measurements of intracellular targets with a localization accuracy around 10 nm, corresponding to an optical resolution around 20 nm; the combination of $SPDM_{Phymod}$ and spatially modulated illumination (SMI) microscopy presently allows generation of images of (thin) biological structures with a 3-D effective optical resolution in the 30–50 nm range [20.86, 120]. Numerical simulations [20.67, 69] suggested that in the case of detected photon counts in the 10^3–10^4 range, even a 3-D optical resolution in the 1 nm range, eventually might become feasible for single molecule-based localization microscopy.

The following application examples are only intended to give an idea of the present possibilities of light optical superresolution microscopy; they are taken from work performed in the laboratory of the author or published in the context of direct collaboration projects (for the equally valuable contributions of other laboratories see earlier).

Experimental Realization of 2-D Localization Microscopy

The experimental setup of a typical localization microscope for $SPDM_{Phymod}$ (in the following also abbreviated by its basic concept, SPDM) as used in a variety of applications [20.61, 86, 87, 112, 120–123] is shown in Fig. 20.10. The specimen located on the slide is excited by a laser with a wavelength appropriate for the fluorophore used. A mechanical shutter S1 and a manually retractable intensity filter S2 allow blocking the beam or decreasing its intensity to

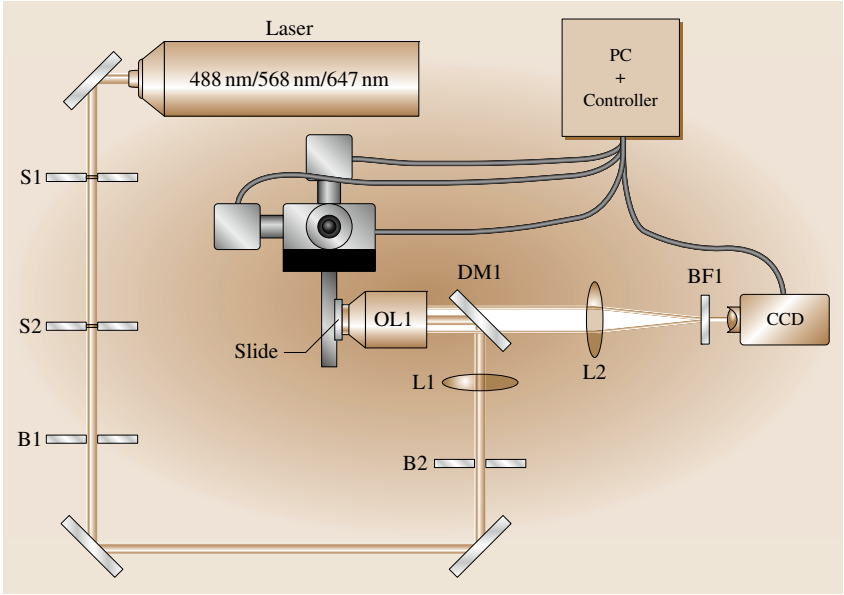

Fig. 20.10 Schematic design of an epifluorescence localization microscope with (ideally) homogeneous illumination of the region of interest (SPDM approach using conventional fluorochromes) developed to perform nanoscopy of two or more different types of molecules (compare the following examples). Laser excitation is possible at 488, 568, or 647 nm. The sample is illuminated through the lenses L1 and OL1. Additionally, the beams can be focused slightly by an additional lens (not shown) of long focal length (typically illuminated visual field $15 \times 15\ \mu m^2$). Coupling of the illuminating beams into the detection beam path is performed by a dichroic mirror (DM1). The fluorescence emission of the object is collected by the objective lens (OL1) and passes through a tube lens (L2) and a bandpass filter (BF1) to the chip of a sensitive CCD camera. The registered CCD frames (total number for a SPDM image typically several thousand) with a frame rate of about 20 frames/s are stored for further analysis in the computer. For further details see [20.86, 87]

1.68%. The sample is illuminated by lens L1 and an oil-immersion objective lens OL1 with a magnification of 100× and a numerical aperture of 1.4. The exciting beam is coupled into the detection beam path by a dichroic mirror DM1. The focus beam power can be increased at the expense of the illumination diameter by a retractable lens (not shown) with a long focal length in the exciting beam path. The emitted, Stokes shifted fluorescence light transmits the dichroic mirror DM1 and is focused by the ocular lens L2 onto a CCD camera (PCO, sensicam qe, Kelheim, Germany). Previously, the fluorescence beam is purified from any remaining excitation light by a blocking filter BF1, mounted in a filter wheel. This filter wheel allows interchanging of several filters and enables fluorescence light detection of spectral different fluorophores. The specimen is vertically located on a slide which can be positioned, to the slide by a stepping motor in x, y (object plane), and z-directions (optical axis). Furthermore, the focal position (z-direction) is precisely adjustable by a piezo element. Both the readout of the CCD camera and the control of the piezo element, and the stepping motor are implemented by a program written in python.

The raw data of a localization measurement is provided as an image stack typically consisting of several thousand frames. For many biological applications (e.g., SPDM measurements of proteins located deep in the cell interior) the algorithm must be able to deal with high background noise and bleaching gradients.

The positions of the detected single molecules may be determined in different ways, e.g., by fitting a model function to the segmented signals. For the lateral position fitting often a two-dimensional Gaussian is used with an estimation of a linear background signal. The localization is given by (p_2, p_3); the localization accuracy σ_{loc} is proportional to $1/\sqrt{N}$ (N is the number of detected, poisson distributed photons), limiting the achievable resolution [20.35, 90, 124], and furthermore depends on parameters of the optical detection system [20.90, 124]

$$f(x,y) = p_1 \exp\left[-\left(\frac{(x-p_2)^2}{2p_4^2} + \frac{(y-p_3)^2}{2p_5^2}\right)\right] + p_6 + p_7(x-p_2) + p_8(y-p_3)\,.$$

After the appropriate choice of start parameters for $p_1 - p_8$, the positions are optimized by a Levenberg–Marquardt fitting algorithm.

The output file of such localization procedures contains the position and localization accuracy of each detected molecule and additional information, like e.g., anisotropy of the signal (for further methodological details, see [20.88, 122]). Depending on the experimental conditions used (e.g., type of fluorophore and chemical environment, excitation wavelength, and intensity, etc.), the fluorescence emission may continue for more than one frame time Δt_{fr} (typical values are presently $\approx$ 20–100 frames/s corresponding to $\Delta t_{\mathrm{fr}} = 50\,/10$ ms. In this case, in the algorithm published in [20.87] it was assumed that the fluorescence emission originated from the same molecule. In case there was a clear intensity gap between two consecutive signals (i. e., one or several frames with a much lower intensity at a given site), the two signals were counted separately. While, under the conditions used, this posed no problem in localization microscopy of standard fluorescent proteins (usually just one blinking event), in the case of synthetic organic fluorophores like Alexa dyes, several to multiple blinking events may be registered from presumably the same molecule, depending on the conditions [20.75, 115]. Concerning structural resolution, in this case a density-based imaging algorithm [20.115] may be used. The problem becomes more difficult if images based on the positioning of individual molecules are to be obtained, e.g., for counting purposes [20.108, 120] or for numerical modeling applications [20.121]. However, in addition to structural analyses at least a relative count may be achieved.

Experimental Realization of 3-D Localization Microscopy

The 2-D localization microscopy approach outlined before allowed a localization accuracy of single molecules down to $\sigma_{\mathrm{loc}} \approx 2$ nm in the object plane [20.36, 98] and hence an optical resolution power down to $d_{\mathrm{min}} = 2.35\,\sigma_{\mathrm{loc}} = 5$ nm.

In the axial direction (z), the molecules can be localized by the epifluorescence setup shown in Fig. 20.10 with a localization accuracy $\sigma_{\mathrm{loc}}(z) \approx 300$ nm [20.87, 112]. It is highly desirable, however, to further increase the z-localization accuracy and hence the 3-D resolution, i. e., to diminish $\sigma_{\mathrm{loc}}(z)$. This can be achieved, e.g., by introducing a cylindrical lens in the optical pathway, resulting in as light distortion of the axial PSF. This distortion allows a z-localization accuracy of single molecules of the order of few tens of nm [20.104, 115] and hence an optical z-resolution of $d_{\mathrm{min}}(z) \approx 50$–$70$ nm.

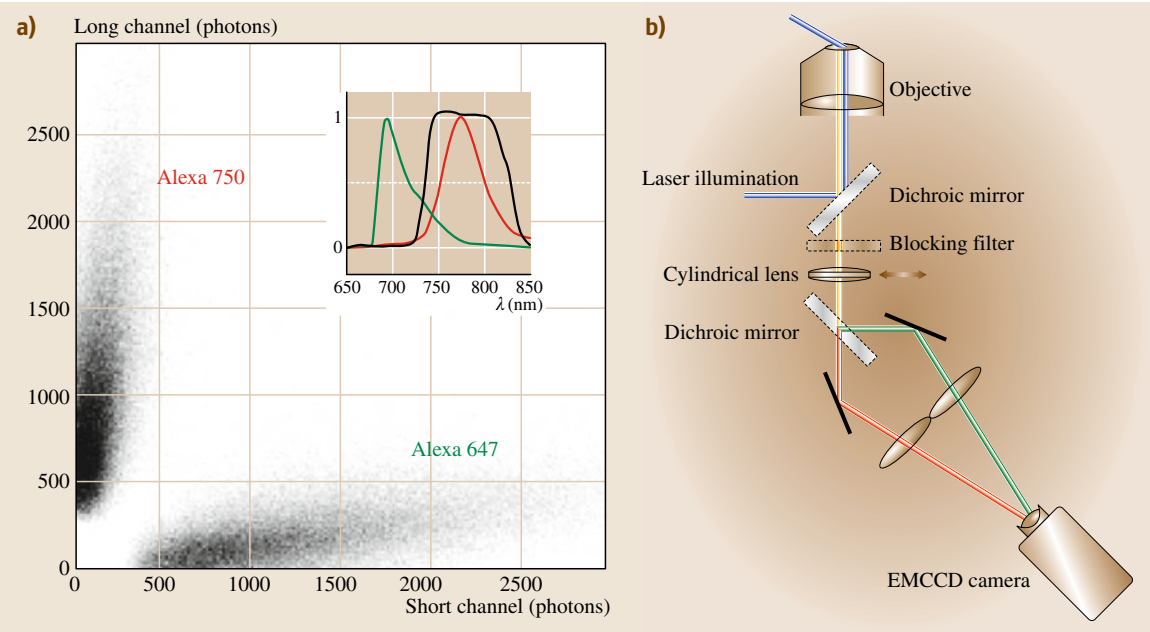

Fig. 20.11a,b Schematic design of a 3-D localization microscope with single wavelength excitation and dual-color detection. **(b)** A single diode laser at 671 nm is used to provide excitation and the collected light is split into two bands using a dichroic mirror. The bands are imaged side by side on an electron multiplying CCD (EMCCD). An optional cylindrical lens allows astigmatism-based 3-D localization. **(a)** Single molecule events (Alexa 647/750) are observed as flashes with an intensity component in each channel. When these intensities are plotted against each other, discrete populations emerge corresponding to each fluorochrome in the sample, Alexa 647 and Alexa 750. (*Insert*) Recorded emission spectra of Alexa 647 (*green*) and Alexa 750 (after [20.115])

As an example, Fig. 20.11 shows the setup of such a 3-D localization microscope. In addition to the single molecule 3-D positioning mode, only one laser frequency is used to excite and detect the fluorescence by two infrared dyes (Alexa 647/750) simultaneously.

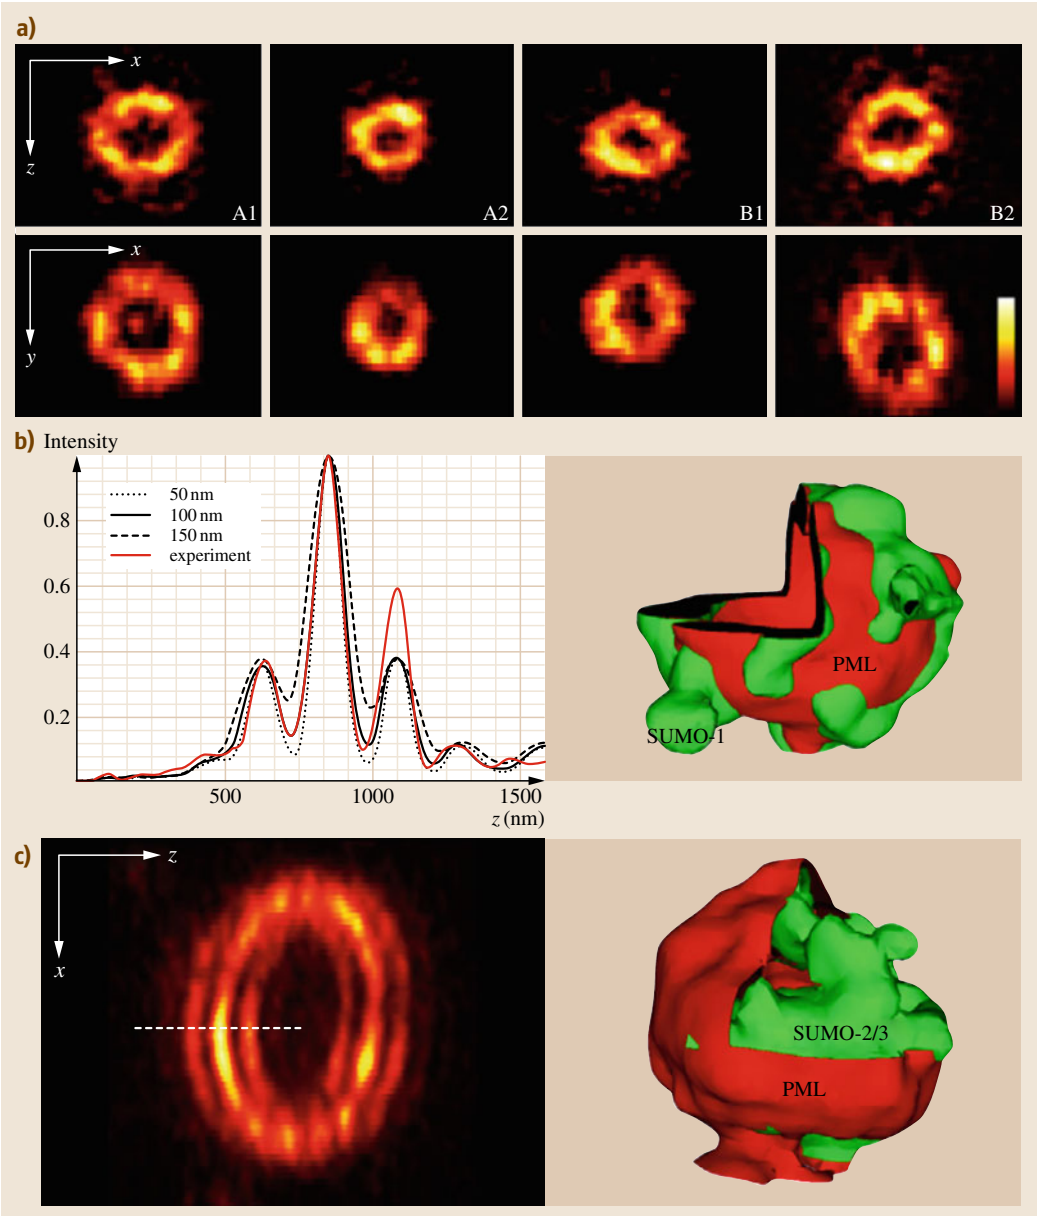
Still better single molecule target localization accuracies and hence optical 3-D resolution values have been achieved by using an optical setup with two high NA objective lenses opposed to each other, like in 4Pi/SMI microscopy [20.67, 93, 119]. However, in contrast to these techniques, a homogeneous wide-field illumination can be used. The fluorescence emission from a single molecule is transmitted through both objective lenses and subjected to interference in such a way that small phase shifts due to different z-positions are measured and translated to z-position values [20.118]. By this method, an optical resolution in 3-D in the 10 nm range has been realized. However, due to the very small tolerances in the optical path lengths and hence in refraction index variation, so far the method is restricted to thin structures (a few hundred nm).

Combination of 2-D Localization and Spatially Modulated Illumination Microscopy

An optically robust approach to an improved 3-D resolution is the combination of 2-D localization and structured illumination microscopy [20.86, 108]. For example, to obtain spatial 3-D information of an object with local z-dimensions in the < 150 nm range, in a first step the z-extension of the object (e.g., a group/cluster of proteins) and its x, y, z-position is measured in a spatially modulated illumination microscope (for optical design see above). In this way, the x, y, z-position of the cluster can be determined with localization accuracies down to the 10 nm range (or better) by a fitting procedure [20.68, 70, 73]; the extension of the molecules around the x_C, y_C, z_C position of the cluster can be determined with a halfwidth in the 30–50 nm range. In a second step, the object plane (x, y) coordinates of the single molecules in the clusters identified by their (x_C, y_C) positions are determined by localization microscopy ($SPDM_{Phymod}$); the two images are combined to a 3-D image [20.86, 120].

20.2 Nanoscale Imaging Applications

The light optical enhanced resolution (nanoscopy) methods described so far have already found numerous applications, from biology and medicine to materials sciences. It is to be expected that they will become a major research and diagnostics tool wherever structure on the nanoscale is studied. In comparison to electron microscopy, light optical nanoscopy provides an overlapping optical resolution range (down to the 1 nm range) with the possibility to directly resolve single fluorescent point emitters, from single proteins and small organic molecules to color centers in solid state physics; it allows identification of such point emitters with high efficiency due to electronic transitions in the 1 eV range; presently, up to five types of molecules can be identified simultaneously even if the distance between them is $\ll \lambda_{exc}/2$ [20.115]. It is to be expected that the advent of new, highly sensitive and ultrafast multichannel detectors will allow full use of small differences in fluorescence life times and will permit a substantial further increase of the number of emitter types. Furthermore, light optical nanoscopy can be performed with 3-D intact specimens (presently up to 10–100 µm thickness, depending on the method) at room temperature and with minimum preparation requirements; even physiological conditions and life cell nanoimaging is possible. Another advantage might be that in comparison to modern high-performance electron microscopes featuring subnanometer resolution and energy filtering down to the eV range for single molecule discrimination, light optical nanoscopy approaches, especially those based on spectrally assigned localization microscopy (SALM) and structured illumination excitation (SIE) are relatively economical and user friendly. It appears to be feasible to construct a basic, laser-diode illuminated localization microscope with single molecule resolution in the sub 100 nm range at construction costs not exceeding 30 000 €. On the other hand, the higher the desired resolution power, the more complex light optical nanoscopy becomes; an absolute resolution limit is given by the number of photons detectable from a single source and by the size of the emitter (for small organic fluorophores about 1 nm). The limitation of present light optical nanoscopy methods to fluorescent emitters does not allow direct determination of other important contrast features, e.g., the distribution of atoms (e.g., N, P); where fluorescent markers are not available or cannot be used, electron microscopy or other types of ultramicroscopy like x-ray microscopy [20.125] must be applied. As a consequence, the further development of correlative light and electron/x-ray microscopy will allow to combine the advantages of both approaches to the nanoscale.

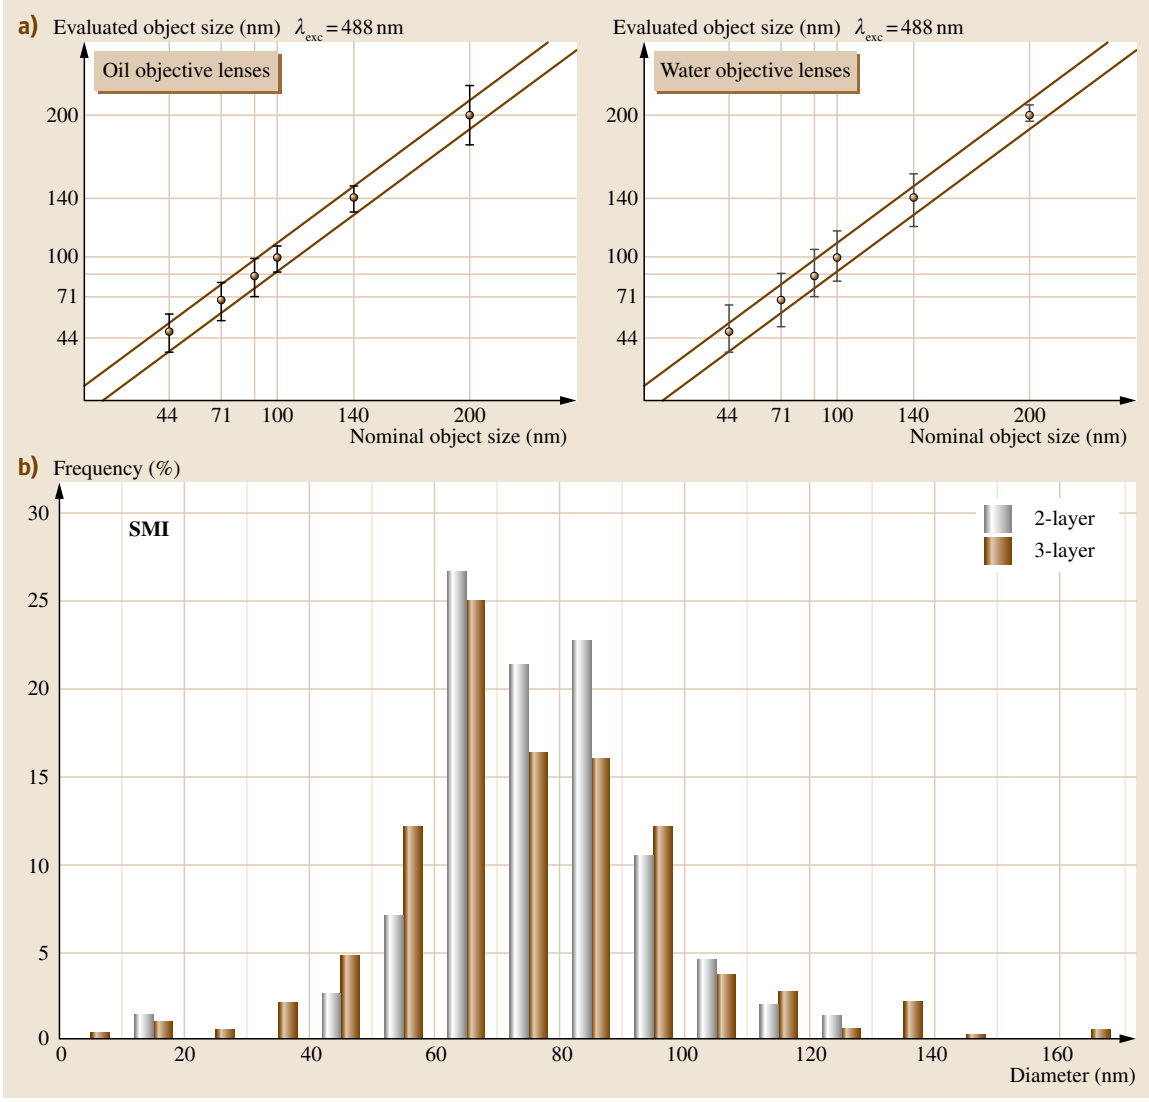


The following few examples for nanoscale imaging applications are taken from work in the laboratory of the author and his direct cooperation partners. They provide only a small selection of the wide range presently realized in a steadily growing number of laboratories, including in particular

Fig. 20.12a–c 4Pi microscopy (two-photon excitation) of an intracellular nanostructure (PML-bodies in U2OS and HeLa cell nuclei). **(a)** PML bodies were visualized by immunostaining with an antibody against PML and an Alexa-Fluor-568-coupled secondary antibody. The 4Pi microscopy images of x–z and x–y sections reveal that the PML protein is localized in the outer shell of a sphere of variable diameter in human U2OS (A) and HeLa cells (B). *Scale bars* ($x-z$, $x-y$): 500 nm. Note the clear resolution of the outer shell even in z-direction for PML bodies with a diameter around the axial resolution limit ($\approx$ 600 nm) of conventional confocal laser scanning fluorescence microscopy. **(b)** *Left*: Intensity distribution (direction along the optical axis z) through a promyelocytic leukemia nuclear body (PML) in a human cancer cell nucleus (U2OS). The z-line profile was evaluated on the 4Pi raw data depicted below **(c)**. From the modulation depth of the 4Pi line profile, the true object dimensions were estimated. Calculated intensity line profiles for shells with the same diameter as the PML-body (i. e., 1.2 µm) are shown for three different values for the wall thickness (50 nm, 100 nm, 150 nm). Good agreement with the theoretical curve for a body with $\approx$ 100 nm shell thickness was obtained. **(c)** *Left*: A 4Pi x–z section through a PML body in a U2OS nucleus. Note the ghost images due to the side lobes due to the imperfect 4π geometry of the two-lens 4Pi microscope [20.7, 8, 103]. While such ghost images can be removed by appropriate algorithms, e.g., Fourier filtering [20.9, 50], they can also be used to estimate the thickness of small structures (in this case the shell) by calculating the expected response (on the basis of a 4Pi PSF). **(b–c)** *Right*: Two-color 4Pi microscopy 3-D image reconstructions of PML and various SUMO proteins. Immunostaining was conducted with a secondary antibody labeled with Alexa Fluor 568 (PML, *red color*) and Atto 647 (*green color*) against a SUMO-1 or against a SUMO-2/3 primary antibody (after [20.51]) ▶

groups at Harvard University (X. Zhuang), Howard Hughes Medical Institute (E. Betzig, H. Hess), the Max-Planck-Institute Göttingen (S. Hell), Yale University (J. Bewersdorf), University of Maine (S. Hess), Stanford University (J. Biteen), Universities of Jena (R. Heintzmann), Würzburg (M. Sauer, M. Heilemann), Auckland (D. Baddeley, C. Soeller), and many others.

20.2.1 Focused Nanoscopy



Focused nanoscopy techniques (4Pi/STED microscopy) have found numerous biomedical applications, e.g., in the analysis of cell membranes, mitochondria, synapses, repair cluster size determination, etc. As an example, an application [20.51] is presented here for the 4Pi microscopic 3-D analysis of promyelocytic leukemia nuclear

bodies (PML-NBs). These nanostructures (diameter between 0.3 μm to ≈ 1 μm) found in the cell nucleus are mobile nuclear organelles formed by PML and Sp100 proteins. They have been reported to have a role in transcription, DNA replication and repair, telomere lengthening, cell cycle control, and tumor suppression. High-resolution 4Pi fluorescence laser-scanning microscopy studies showed that PML-NBs adopt a spherical organization characterized by the assembly of PML and Sp100 proteins into patches within a 50 to 100 nm thick shell. Combined with other approaches (correlative electron microscopy, mobility measurements), this allowed to derive a model that explains how the three-dimensional organization of PMLNBs serves to concentrate different biological activities while allowing for an efficient exchange of components (Fig. 20.12).

20.2.2 Structured Illumination Excitation (SIE) Microscopy

At the present state, SIE microscopy approaches (such as SIM, SMI) have found applications basic in cell biological research, e.g., in the analysis of the relationship

between nuclear pores and nuclear membrane structures [20.76], or in the determination of the size of the highly complex nanostructures involved in the replication of DNA [20.75]. Examples for other applications involve the analysis of features of age dependent macula degeneration, or the nanosizing of transcription factories which are essential for the transcription of genomic information from DNA into RNA.

Nanosizing by SMI Microscopy

Spatially modulated illumination (SMI) microscopy has been shown to allow accurate size measurements of individual fluorescent objects with a diameter ranging between few tens of nm and 200 nm. Figure 20.13a gives an example (calibration beads with nominal object diameters between 40 and 200 nm) obtained with an SMI microscope device where the optical axis of the two opposing high NA objective lenses was placed vertically, i. e. here the object plane was positioned horizontally (*Vertico*-SMI [20.61]); apart from that, the optical configuration was very similar to that shown in Fig. 20.5a. The *nanosizing* results turned out to be very similar for both oil and water immersion objective lenses. This indicates that nanosizing by SMI microscopy is not only possible for fixed specimens but even under live cell conditions (water).

As an example for biological applications, Fig. 20.13b presents SMI-based size measurements of transcription complexes in the nucleus of fixed human cancer (HeLa) cells containing the active, hyperphosphorylated form of RNA polymerase II. The RNA Pol II molecules were fluorescence labeled by using different methods of antibody binding (*2-layer*, *3-layer* protocol [20.71]). Both labeling methods yielded very similar results for the size of these transcription complexes, with a broad distribution and a mean around 80 nm. Recent measurements of such complexes using advanced electron spectroscopic imaging [20.126], structured illumination and localization microscopy [20.77] (compare Fig. 20.17e) indicated similar values, thus confirming the usefulness of the SMI approach.

Fig. 20.13a,b SMI measurements of subwavelength sized objects. **(a)** Evaluated object sizes (mean and standard deviation, indicated by *bars*) plotted against the nominal size of calibration beads using an excitation wavelength of $\lambda_{exc} = 488$ nm for oil (*left*) and water (*right*) immersion objective lenses (NA = 1.4). The two *lines* indicate a 10 nm error interval (after [20.61]). **(b)** Axial sizes of fluorescence-labeled Polymerase II (Pol II) sites in cryosections ($\approx$ 140 nm) of human cancer cells (HeLa) were measured by SMI microscopy. Sizes were grouped together into 10 nm ranges and frequencies expressed as a percentage of the total. The Pol II sites were labeled either with a two-layer protocol or with a three-layer protocol by using H5, rabbit anti-Ig antibodies and Alexa Fluor 488. Size measurements with the two-layer and three-layer protocols gave average (weighted) diameters of 82 nm (*open bars*) and 81 nm (*solid bars*), respectively (after [20.71]) ◀

Structured Interference Illumination Microscopy (SIIM) of Autofluorescent Aggregations in Human Tissue

As an example for the application of structured illumination in medical research, the SIIM method described above was applied to the investigation of the retinal pigmentepithelium (RPE) in human eye tissue samples [20.80]. The RPE, which supports the functioning of the retina, is a cell monolayer between the rod outer segments and the so-called Bruch's membrane. Age-related macula degeneration is primarily caused by a degeneration of the RPE. This degeneration (affect-

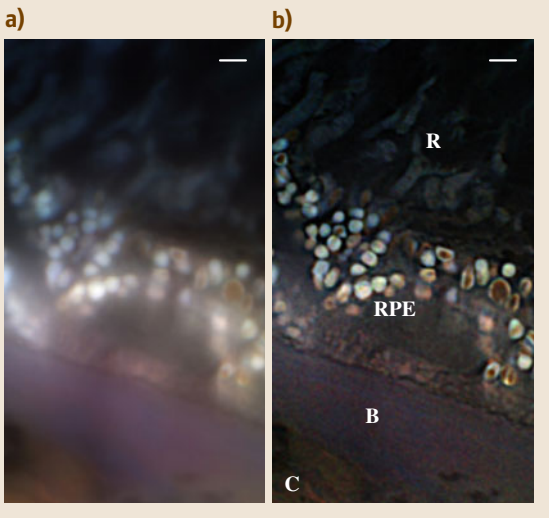


Fig. 20.14a,b Structured illumination microscopy of autofluorescent protein deposits on retina epithelium. The SIIM image **(b)** shows more details and less out of focus light than the wide-field image **(a)**. The background of each channel is subtracted and each channel is stretched to full dynamic range. The Bruch membrane (B) is located between the choroid (C) and the retinal pigment epithelium (RPE). On the *top* of the image endings of retinal rod cells (R) can be seen. The *scale bar* is 2 µm. The achievable optical lateral SIIM resolution is about 100 nm (after [20.80])

ing millions of people worldwide) is accompanied by excessive aggregations of lipofuscin. Lipofuscin consists of a variety of fluorescent and nonfluorescent proteins and lipids and exhibits autofluorescence across the visual spectrum, making fluorescence microscopy an attractive method to investigate the deposits of these pigments [20.127]. Structured illumination imaging at three different wavelengths (488, 568, 647 nm) has made it possible to study the distribution of lipofuscin at a level of detail not accessible to conventional fluorescence microscopy and to attain additional spectral information about the aggregations (Fig. 20.14).

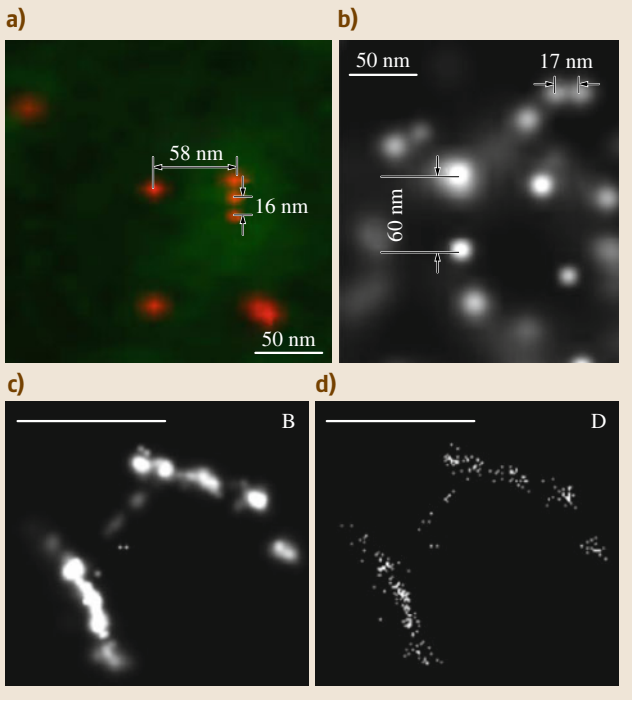

Fig. 20.15a–d Spectrally assigned localization microscopy ($SPDM_{Phymod}$) of individual fluorescent molecules. **(a)** Single Alexa 647 molecules; $\lambda_{exc} = 647$ nm, NA = 1.4 (after [20.128], with kind permission). **(b)** Histone H2B molecules in a 3-D conserved human fibroblast cell nucleus tagged with a standard green fluorescent protein (emGFP). $\lambda_{exc} = 488$ nm, NA = 1.4. *Scale bars*: 50 nm (after [20.87]). **(c–d)** $SPDM_{Phymod}$ images of *Tobacco mosaic virus* (TMV) particles with coat proteins labeled with the fluorophore Atto488 ($\lambda_{exc} = 488$ nm, NA = 1.4) (after [20.128]). **(c)** $SPDM_{Phymod}$ image after Gaussian blurring corresponding to the individual localization accuracy σ_{loc}. **(d)** $SPDM_{Phymod}$ image. Same data as in **(c)** but distribution of the detected individual molecule positions is shown without Gaussian blurring. *Scale bars*: 300 nm (after [20.129])

20.2.3 Spectrally Assigned Localization Microscopy (SALM)

In recent years, the wide scope of applications of various SALM methods for the investigation of biological nanostructures has been shown. 2-D single color imaging [20.61, 86, 87, 98–103, 105, 106, 108, 109, 121], multicolor imaging, and 3-D spatial resolution down to the 10–40 nm range has been realized [20.86, 107, 111, 112, 115, 118]. In addition, the single molecule information provided by localization microscopy can be used for statistical analyses of protein distributions [20.112, 120, 121]. It was even possible to use such methods for the analysis of completely label-free cells and gather structural information of autofluorescent molecules within these cells with a resolution far below the Abbe limit [20.108]. The following SALM examples are taken from our experience with a special SALM method, $SPDM_{Phymod}$.

Localization Microscopy of Single Molecules

One of the major advantages of SALM methods is the possibility to identify and localize individual molecules even if their mutual minimum distances are substantially below the conventional optical resolution limit (as, e.g., given by the FWHM of the PSF of the microscope system used), e.g., $\ll 200$ nm laterally. Figure 20.15 shows a few examples. Figure 20.15a presents single organic fluorescent molecules deposited on a glass slide. To indicate the resolution power, the individual molecule positions were blurred with a Gaussian corresponding to the individual localization accuracy σ_{loc}. Two molecule signals with a distance of 16 nm ($\approx 1/40\ \lambda_{exc}$) were still clearly discriminated from each other, suggesting in this case an optical resolution power around $d_{min} = 10$ nm. Possible applications of such single molecule distributions on surfaces might be found, e.g., in the quantitative analysis of the distribution of specific molecules on biofilms, in the analysis of environmentally relevant organic molecules attached to surfaces, or in material sciences to investigate molecule-surface interactions on the single molecule level.

Figure 20.15b gives an example how to use localization microscopy to study the spatial distribution of single histone molecules in 3-D intact cell nuclei. Such analyses may be used to test numerical models of genome structure and function, e.g., in relation to cancer induced changes [20.121].

Figure 20.15c,d presents an $SPDM_{Phymod}$ application to detect and analyze the structure of individual viruses. In this case, *Tobacco mosaic virus* (TMV) par-

ticles were used. TMV particles are important not only in plant research but are also an example for a class of most promising biomolecule complexes exhibiting a high potential for nanotechnology applications. TMV is a robust, self-assembling tube-shaped plant virus of 300 nm natural length and 18 nm diameter, with an inner longitudinal channel 4 nm in width. Its protein shell consists of 2130 identical, helically arranged coat protein (CP) monomers, interacting with a single buried RNA molecule determining the final length of the viral particle. For many decades, viral structures were thought to be resolvable only by electron microscopy and other ultrastructure techniques; due to their small dimensions (typically < 100 nm) they were thought not to be accessible by far-field light microscopy approaches. To highlight the optical resolution, Fig. 20.15c shows SPDM images of individual TMV particles after blurring with σ_{loc}. The progress achieved is visually indicated by the scale bar (300 nm). In quantitative terms, best localization values of ≈ 2 nm and mean 2-D molecule signal distances on the virus (projection area of a cylinder of 18 nm D_{ill} and length 300 nm) were around 6 nm [20.36].

Dual-Color Localization Microscopy

So far, localization microscopy images of individual molecules of one specific type were shown. In many cases, however, it is highly desirable to analyze the spatial location of several molecules types with respect to each other. This is of particular importance in biomedical research applications where the interaction between different molecule types is decisive. In Fig. 20.16, an example is shown how to use dual-color localization microscopy to study the functional organization of the genome in human cancer cell nuclei [20.112]. In the cell nucleus the DNA is compacted by histone proteins into a nucleoprotein complex termed chromatin. The central building block of chromatin is the cylindrically shaped nucleosome (11 nm diameter, 5.5 nm height). It comprises an octamer core of two copies each of histones H2A, H2B, H3, and H4 around which the DNA is wrapped in 1.67 turns. In this example, dual-color localization microscopy ($\text{SPDM}_{\text{Phymod}}$) was used to determine the intracellular location of chromatin remodeling complexes with respect to chromatin. Chromatin remodelers are molecular machines that can translocate nucleosomes along the DNA sequence. By making use of autofluorescent constructs of histone H2A as a nucleosome/chromatin marker and the ATPase subunit Snf2H that defines a certain class of chromatin remodeling complexes, their nuclear localization was analyzed with an estimated mean localization accuracy in the range of about 20 nm (ca. 1/25 of the excitation wavelength). The results indicate the feasibility to reveal details on the interaction of remodeling complexes with chromatin at unprecedented optical resolution.

Figure 20.17 shows a second example of how to use dual-color localization microscopy ($\text{SPDM}_{\text{Phymod}}$) to study functional nuclear organization [20.77]. In this case, the nuclear topography of RNA transcription and DNA replication in mammalian cell types was studied with ($\text{SPDM}_{\text{Phymod}}$) in specimens with polymerase II (Pol II) proteins and histone proteins immunolabeled with antibodies with two fluorophore types attached (Alexa488/Alexa568). While on the scale studied, conventional epifluorescence microscopy did not allow to resolve the spatial relationship between transcription complexes (highlighted by Alexa 568-Pol II molecules) and chromatin (highlighted by Alexa 488-H2B molecules), $\text{SPDM}_{\text{Phymod}}$ permitted a detailed study of the lateral (object plane, x, y) size of the Pol II clusters, the number of molecule signals detected within them, as well as the size of the transcription complexes. The graph in Fig. 20.17e presents a quantitative evalu-

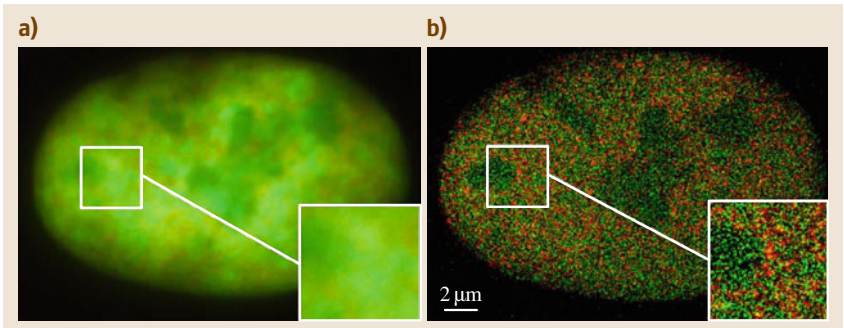

Fig. 20.16a,b Dual-color localization microscopy ($\text{SPDM}_{\text{Phymod}}$) of intracellular proteins I. **(a)** Conventional wide-field fluorescence image of nuclear histone (H2A) proteins (*red*) and chromatin remodeling (Snf2H) proteins (*green*) in the nucleus of a human cancer cell (U2OS). **(b)** Localization microscopy (SPDM) of the same nucleus; a total of $\approx 120\,000$ proteins was counted and localized in an optical section of ≈ 600 nm axial thickness (after [20.112])

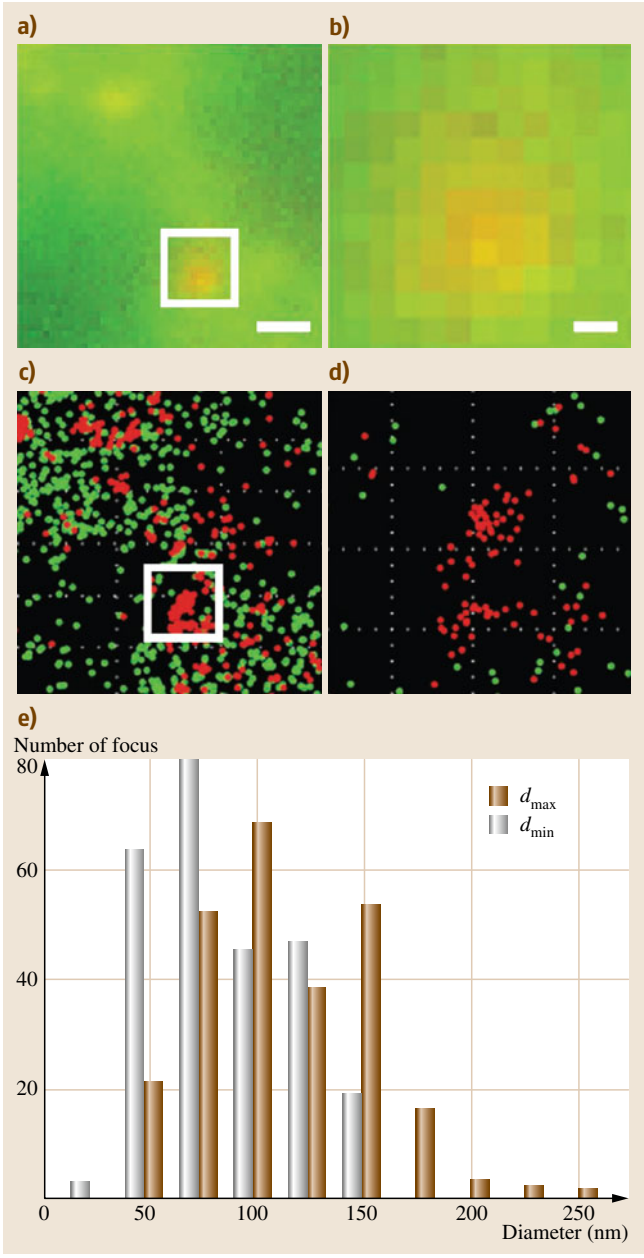

Fig. 20.17a–e Dual-color localization microscopy of intracellular nanostructures II. The figure shows a small fraction of the nucleus of a human cancer cell (HeLa) to study the nuclear topography of proteins involved in the transcription of DNA (Ser5P-RNA polymerase II), with respect to the location of histone H2B proteins to indicate chromatin (DNA-histone complexes). Ser5P-RNA Pol II was detected with specific primary and secondary antibodies conjugated to Alexa 568 (*red*). H2B was detected with antibodies conjugated to Alexa 488 (*green*). These images allow a comparison of the resolution obtained with conventional wide-field epifluorescence microscopy (**(a)**, **(b)** *insert*) and with SPDM **(c)**, **(d)**. **(a)**, **(b)** Conventional epifluorescence image. *Scale bar* **(a)**: 500 nm (valid also for **(c)**); *scale bar insert* **(a)**: 100 nm (valid also for **(d)**). **(c)**, **(d)** Localization microscopy (SPDM) image indicating the positions of single molecule signals (*green*: H2B; *red*: polymerase II positions (after [20.77]. For clarity of presentation, in **(c)** the size of the dots indicating single molecule positions was chosen to be several times larger than the mean localization accuracy ($\sigma_{loc} \approx 20$ nm) while in the *insert* **(d)**, the size of the dots indicating single molecule positions in **(c)** is somewhat smaller than σ_{loc}. **(e)** The estimated minimum (d_{min}, *blue*) and maximum (d_{max}, *red*) diameters of detected Pol II clusters. Only clusters exhibiting a normal signal distribution were included in these measurements. Mean d_{min} value: 87 nm (±30 nm); mean d_{max} value: 112 nm (±39 nm). The data indicate an average size of 100 nm (±33 nm) for these clusters with a range of 40–198 nm (after [20.77]) ◀

ation of the lateral size; very similar results were obtained for Pol II clusters as for the axial size determined by SMI microscopy [20.71]; compare Fig. 20.13b. This suggests that the 3-D structure of such transcription factories is globular/ellipsoidal, with a mean diameter around 80–100 nm. These results obtained by far-field light nanoscopy may be compared with data on transcription complexes obtained by electron microscopy. While the transmission electron microscopy (EM) yielded a mean diameter of 45 nm only [20.71], *Eskiw* et al. [20.126] using advanced EM methods (electron spectroscopic imaging (ESI)) found that the size of transcription complexes ranged between 60 and 120 nm with an average of 87 nm, i. e., a value very similar to the figures obtained by SMI and $SPDM_{Phymod}$.

Regarding the profound methodological differences between the various approaches of light optical nanoscopy and electron microscopy, the results obtained are very similar, indicating a common size overlap for transcription complexes ranging from 40–85 nm.

Dual-Color 3-D Localization Microscopy

So far, examples for the application of localization microscopy were restricted to 2-D images (object plane). By not including molecule signals with distorted Gaussian shapes from the analysis, molecule signals above

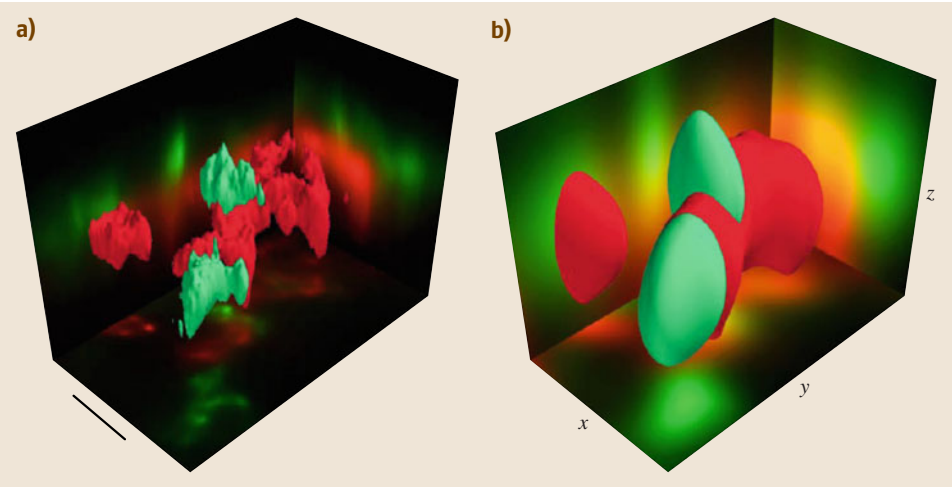

Fig. 20.18a,b 3-D localization microscopy of synapses. GFP-alpha-SAP97 (antibody labeled with an Alexa 647 secondary, *green*) and synapsin (with an Alexa 750 secondary, *red*) in a primary hippocampal culture. 4-D imaging was performed using dual-color 3-D localization based on astigmatism in conjunction with a ratiometric multicolor approach. **(a)** 3-D localization image. **(b)** Corresponding conventional diffraction-limited image of the two proteins. *Scale bar*: 500 nm (after [20.115])

or below the object plane (±300 nm), such signals can be excluded from the SALM image; hence, the $SPDM_{Phymod}$ images shown present an optical section of about 600 nm thickness. By comparing these images with 3-D images obtained by conventional microscopy for different axial (z) positions, it is even possible to estimate the z-position of such optical sections.

To realize an increased optical resolution in 3-D (x, y, z) also with localization microscopy, various approaches may be used. In Fig. 20.18, a recent example from neurobiology is presented to combine ratiometric localization microscopy of standard infrared dyes with z-positioning by using the distortion introduced by an astigmatic lens into the axial diffraction pattern [20.115]. It shows a 3-D localization microscopy image where synapses between axially adjacent processes have been clearly resolved in the 3-D localization data, while they are difficult to discern at conventional resolution. Using this method of dual-color 3-D superresolution, in tissue samples an axial resolution of better than 65 nm (std. dev.) could be routinely achieved with an observation volume ≈ 300 times smaller than in conventional optical microscopy.

Combination of Dual-Color $SPDM_{Phymod}$ with Structured Illumination

In addition to 3-D localization microscopy using single lens setups and z-positioning by astigmatism [20.104, 115] or a biplanar registration configuration [20.130], or using a two lens configuration and wide-field excitation combined with interferometric detection of fluorescence, a combination of localization microscopy/SPDM with structured illumination (SMI microscopy) has been used which also offers 3-D resolution far beyond the conventional resolution limit (Fig. 20.19).

Conclusions and Perspectives

In this chapter, we have described the principles of various approaches to far-field fluorescence superresolution microscopy. Since its first beginnings a few decades ago, it has developed into an entire class of approaches, which might be referred to as light optical biostructure analysis at enhanced resolution (LOBSTER). A first LOBSTER subspecies (or class) is formed by focused nanoscopy methods such as 4π/4Pi, STED, GSD, and (focused) RESOLFT microscopy. A second class, which might be denoted as structured nanoscopy, is formed by approaches using structured illumination excitation, such as SMI, SIM and SIIM microscopy using standard fluorophores by high precision localization of optically isolated individual molecules. A third class of nanoscopy, which may be denoted as spectrally assigned localization microscopy (SALM, abbreviated as *localization microscopy*), comprises a variety of approaches like BLINKING, 2CLM, FPALM, GSDIM, PALM, RPM,

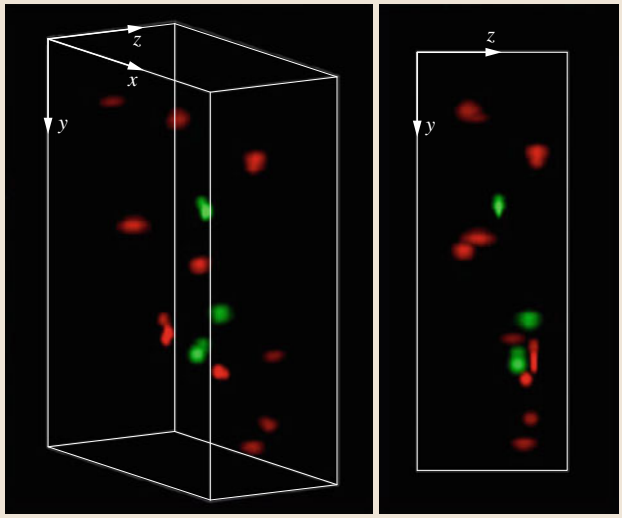

Fig. 20.19a,b Improved 3-D resolution by combination of SPM and SMI microscopy. 3-D reconstruction of dual-color acquisition of breast cancer related membrane proteins Her2/neu and Her3 in a human cell (AG11132)cell. Her3 was immunolabeled with Alexa 488 (*green*) and Her2/neu with Alexa 568 (*red*). The two images show a 3-D reconstruction of the protein clusters using the combination of SPDM and SMI microscopy. The localization accuracy for both channels was about 25 nm in all three directions. Clusters with z-extensions as small as 40 nm ($1/14\lambda_{exc}$) were determined. *Scale bars* in **(a)** and **(b)** are 500 nm in each direction (after [20.120])

SPDM, STORM, dSTORM, d^4STORM, etc. In these fast evolving LOBSTER subspecies, closely adjacent (distance $< 0.61\,\lambda_{exc}/NA$) point-like fluorescence objects are optically isolated by different spectral signatures (including time domain features like fluorescence life times, dark-bright, and bright-dark transitions) and independently localized from each other; the individual positions determined are then assigned to a joint localization map.

The application examples presented from this broad spectrum of LOBSTER methods range from *nanoimaging* of membrane structures and age-dependent protein depositions in the retina epithelium to the analysis of the distribution of single, closely neighbored individual proteins in individual cells, such as histone proteins, chromatin remodeling proteins, polymerases, or cancer related membrane proteins. Other applications in the material sciences, or in the analysis of individual viruses are emerging. Each of the methods presented has its advantages and its setbacks. What method is the best depends on the application envisaged.

From the viewpoint of optics, the approaches with the highest optical resolution so far realized in far-field fluorescence microscopy are STED microscopy and SALM microscopy. While STED microscopy so far has made possible an optical resolution of about 6 min in the material sciences [20.18], an optical resolution of 1.3 nm (ca. 1/400 of the exciting wavelength) between two single adjacent fluorescent molecules of the same type deposited on a surface has been reported [20.89]; for biostructures comprising multiple fluorescent molecules within an Airy disc sized area, an optical resolution in the range down to 10–20 nm may be regarded to become almost routine; under optimum conditions, even in this case values below 10 nm have been reported [20.122].

To allow a comprehensive presentation, the present review concentrated on typical examples of the various methods; an attempt was made to quote at least some key publications from all the major groups presently involved in this fast growing field of optical science, with respect to technical developments, optical insight, and ever broadening applications.

Methods of nanoscale superresolution microscopy in three dimensions have now been extended far beyond the classical, focused nanoscopy approaches, like 4Pi or isoSTED (combination with 4Pi microscopy) approaches [20.59]. For example, wide-field excitation-based localization microscopy has been combined with interferometric detection of fluorescence [20.118]. Another way towards the same goal is the combination of localization microscopy/SPDM with SMI [20.86, 120], which also offers the possibility of 3-D resolution far beyond the conventional resolution limit but does not require the very small coherence lengths required for interferometric fluorescence detection. Such 3-D superresolution methods open an avenue towards a highly improved understanding of biological nanostructures even on the three-dimensional scale, from viruses and bacteria to the highly organized system of life processes on the single cell/single intracellular nanostructure level, with profound implications also for medical applications and drug development, as well as for techniques using nanostructured biomaterials.

To summarize, it is anticipated that the novel developments in laser optical nanoscopy will eventually bridge the gap in resolution between ultrastructural methods (nm resolution) and conventional light mi-

croscopy (resolution of about 200 nm) in such a way that the same structure can be imaged and quantitatively analyzed at molecular resolution [20.131]; this will provide an essential extension to the nanosciences, from the life sciences to the analysis of materials and environmental research.

21. Ultrafast THz Photonics and Applications

Ultrafast THz photonics the topic of this chapter describes the union of optical and ultrafast laser capability with electronics to achieve frequency performance and bandwidths extending well into the THz frequency range. With the demonstrated capability to create and to measure subpicosecond electrical signals that are much faster than those produced and measured by any other method, THz photonics will help determine the direction for the development of new materials and ultra high performance technologies of the future.

In Sect. 21.1 the generation, measurement and applications of these very short electrical pulses are described. They can be used as probes for short electrical pulse studies and the consequent characterization of transmission lines is described, including the measurement of Cherenkov radiation. The performance of transmission lines is compared with metal THz waveguides, whose characterization is also presented. Results for superconducting transmission lines and dielectric THz waveguides are given.

In Sect. 21.2 recent work demonstrating the generation of freely propagating THz radiation (1 THz = 33.3 cm^{-1} = 4.1 meV) via material and electronic excitation by ultrashort laser pulses is presented. The generation of short pulses of THz radiation, by the passage of a short optical pulse through a nonlinear optical material, is also described. A CW photomixer capable of producing tunable radiation by beating together two laser beams is presented. The most developed THz application is THz time-domain spectroscopy (THz-TDS) which is described in detail (Sects. 21.2.4–21.2.6).

References 1452

The combination of THz-TDS with THz beams will be shown to have some powerful advantages compared to traditional CW spectroscopy. The efficacy of THz-TDS is demonstrated by the presented characterizations of water vapor, flames, sapphire, high-resistivity silicon, n- and p-type semiconductors, normal and high T_c superconductors, molecular vapors and liquids.

Ultrafast THz photonics describes the union of optical and ultrafast laser capability, for which the elementary excitation is the photon, with electronics to achieve frequency performance and bandwidths extending well into the THz frequency range. Optoelectronics, which is a subfield of photonics, has demonstrated the capability to create and to measure electrical signals that are much faster than those produced and measured by any other method. The subpicosecond electrical pulses produced optoelectronically are more than ten times faster than today's most advanced transistors, which have switching times on the order of 10 ps. The generation of short electrical pulses via optical methods has for some time been accomplished by shorting photoconductive

gaps with very short laser pulses [21.1]. The same optical methods can measure the generated electrical pulses by sampling techniques. An alternate measurement approach has been to use the electrooptic effect in a crystal [21.2, 3]. In this case, the field of the electrical pulse is sampled through the rotation of the polarization of the short optical sampling pulse. Both the photoconductive and polarization rotation techniques have been extended into the subpicosecond regime [21.2–11].

Given the capability of generating and measuring these very short electrical pulses, they can be used as probes for short electrical pulse studies. For example, the study of the propagation of such pulses on transmission line structures is an important concern for future ultra-high-performance VLSI (very large scale integration) technologies. In addition to the considerable amount of work that has been done with these short pulses to understand the high-frequency behavior of transmission line structures, they are now being put to use in other areas as well. Because these pulses are much faster than the fastest transistors, they provide a powerful means of studying their switching transients. They can be used to directly measure the impulse response of ultra-high-performance silicon and gallium-arsenide devices [21.7–9, 12–19]. They can be used to evaluate the high-frequency behavior of semiconductor package connectors essential to future generations of computers. In summary, optoelectronic techniques are providing the capability to generate and measure electrical signals in the subpicosecond regime. This optoelectronic capability provides a tool to better understand the properties of existing materials and the components of existing high-performance VSLI technologies. Clearly, this capability will help determine the direction for the development of new materials and ultra-high-performance technologies of the future.

Recently, there has been a great deal of work demonstrating the generation of THz radiation ($1\,\mathrm{THz} = 33.3\,\mathrm{cm}^{-1} = 4.1\,\mathrm{meV}$) via material and electronic excitation by ultrafast laser pulses. Modern integrated circuit techniques have made possible the precise fabrication of micron-sized dipoles, which when photoconductively driven by fs laser pulses, can radiate well into the THz regime [21.20–22]. An alternative and complimentary approach has been to extend radio and microwave techniques into the THz regime through the use of optoelectronic antennas [21.23–32]. The generation of short pulses of THz radiation, by the passage of a short optical pulse through a nonlinear optical material, was demonstrated many years ago [21.33]. A related source is based on the emission of an electromagnetic shock wave due to a volume dipole distribution moving faster than the phase velocity, i. e., electrooptic Cherenkov radiation [21.34, 35]. THz radiation has been generated by photoconductively driving the surface field of semiconductors [21.36, 37] and the intrinsic region of large aperture silicon p-i-n diodes [21.38] with ultrafast laser pulses. A CW photomixer capable of producing tunable radiation has been demonstrated by beating together two laser beams with frequencies above the band gap of a semiconductor [21.39–43].

One type of these sources is based on an optical-type approach, whereby a transient point source of THz radiation is located at the focus of a dielectric collimating lens, followed by an additional paraboloidal focusing and collimating mirror [21.21, 22, 29, 31, 44]. This type of source produces well collimated beams of THz radiation. Matched to an identical receiver, the resulting system has extremely high collection efficiency, a time resolution of less than 150 fs and a frequency range from 0.2 THz to more than 5 THz. This optoelectronic THz system is presently one of the most highly developed and will be the one described in most detail in this chapter, although the alternative systems will also be presented.

Applications of THz optoelectronic systems include THz imaging [21.45–47], THz ranging [21.48, 49] and THz time-domain spectroscopy (THz-TDS) [21.50–52]. Presently, THz-TDS is the most developed and has been shown to be the technique of choice for many research measurements. Consequently, THz-TDS will be the major application described in this article, by means of selected examples of significant measurements. The THz-TDS technique measures two electromagnetic pulse shapes, the input pulse and the propagated pulse, which has changed shape due to its passage through the sample under study. Consequently, via numerical Fourier analyses of the input and propagated pulses, the frequency-dependent absorption and dispersion of the sample can be obtained. The useful frequency range of the method is determined by the initial pulse duration and the time resolution of the detection process. Therefore, with each reduction in the generated electromagnetic pulse width, and/or the time resolution of detection, there is a corresponding increase in the available frequency range.

The combination of THz-TDS with THz beams will be shown to have some powerful advantages compared to traditional continuous wave (CW) spectroscopy. Firstly, the coherent detection of the THz radiation is extremely sensitive. In terms of average power this

sensitivity exceeds that of the incoherent liquid-helium-cooled bolometers, by more than 1000 times [21.53]. Secondly, because of the gated and coherent detection, the thermal background, which plagues traditional measurements in this frequency range, is observationally absent [21.53–56].

21.1 Guided-Wave THz Photonics

In this section we will initially present an overview of experimental efforts to obtain a THz ultra-wideband transmission channel. The importance of ultrafast optoelectronics will be shown to be paramount in this effort, whereby the combination of optics, ultrafast laser pulses and electronics has enabled bandwidth and performance increases of as much as 100 times when compared to purely electronic techniques. We will describe in detail how subpicosecond electrical pulses are generated and detected using the photoconductive and electrooptic approaches and go on to discuss how such pulses can be used to study the high-frequency behavior of transmission line structures. The importance of complete characterization of transmission lines and waveguides will be illustrated by select examples, where the characterization was achieved by THz time-domain spectroscopy. For these characterizations it was imperative that single-mode excitation and propagation was achieved. Sliding contact excitation of coplanar transmission lines will be shown to be such a single-mode excitation method. For the THz waveguide investigations, quasioptical coupling techniques were shown to be capable of exciting only a single mode of both metal and dielectric waveguides, even though the many THz bandwidth of the incoming pulse covered as much as 30 waveguide modes. Applications to the study of materials and devices will also be mentioned.

21.1.1 Subpicosecond Electrical Pulses

A typical experimental arrangement for the photoconductive generation and measurement of the subpicosecond electrical pulses is shown pictorially in Figs. 21.1 and 21.2 [21.5, 6]. The pulses are generated on a transmission line structure consisting of two parallel aluminum lines of micron dimensions on a thin silicon layer. As indicated in the diagram, an incoming laser beam consisting of a continuous stream of 0.1 ps (or less) ultrafast light pulses at a repetition rate of typically 100 MHz is divided into two synchronized beams P1 and P2, by a partially transparent mirror. Because the beams follow different paths, the relative timing between P1 and P2 can be precisely adjusted by movement of the prism: 0.15 mm corresponds to 1 ps. The initial (excitation) light pulse P1 strikes the photoconductive substrate (silicon) between the two aluminum lines, shorting them for a fraction of a ps and creating electrical pulses that travel in both directions on the transmission line. The sampling light pulse P2 drives the photoconductive gap at the detection electrode, sampling the electrical pulse as it propagates

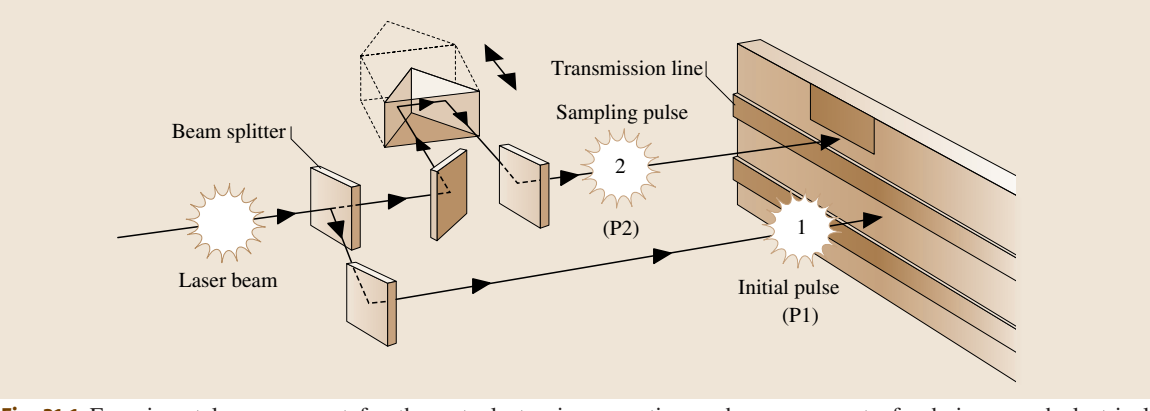

Fig. 21.1 Experimental arrangement for the optoelectronic generation and measurement of subpicosecond electrical pulses

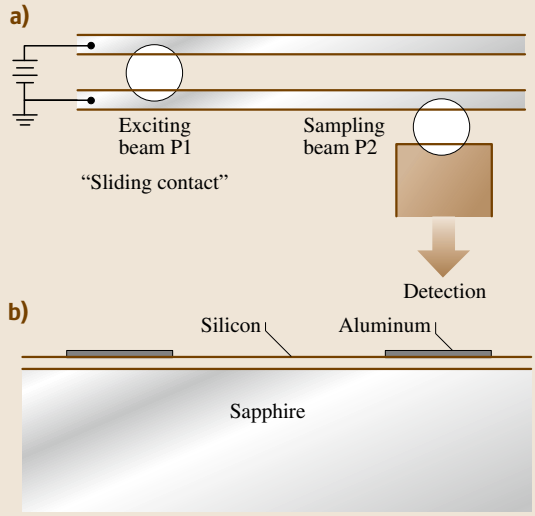

Fig. 21.2 **(a)** Experimental geometry, **(b)** cross section of SOS wafer

down the transmission line. The electrical pulse is characterized by measuring the collected electrical charge as a function of the time delay between P1 and P2. Representative electrical pulses measured in this way are shown in Fig. 21.3, where the ps time scale of the phenomena is indicated.

21.1.2 Sample Fabrication

The aluminum transmission line structures are fabricated using techniques similar to those used to form the interconnect wiring on semiconductor logic and memory chips. The starting substrate is a commercially available insulating silicon-on-sapphire (SOS) wafer with a 0.5 μm layer of pure undoped silicon epitaxially grown on top, as shown in the cross section in Fig. 21.2b. Typical linewidths are in the range of 0.5–10.0 μm. The metal thickness is in the range of 0.2–1.0 μm, and the length of the line structures varies from 5–25 mm. Numerous contact pads are fabricated along with the line structures to permit attachment of leads. Many different line dimensions and geometries can be fabricated simultaneously on a single 76 mm diameter wafer, since the area occupied by a single line structure is very small compared to the total surface area of the wafer.

At room temperature there are very few free electrons or holes in the silicon layer, and it behaves like an insulator. When an area of the film is struck by

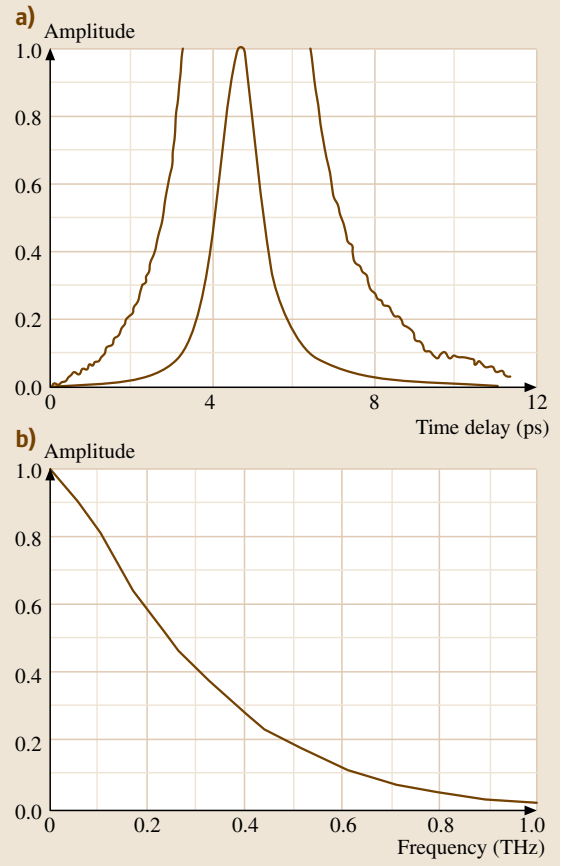

Fig. 21.3 **(a)** Measured ultrafast electrical pulse (*lower trace*), 10× expanded scale (*upper trace*). **(b)** Amplitude spectrum of **(a)**

an ultrafast 0.1 ps laser pulse, a large number of photocarriers, electrons and holes, are generated almost instantaneously, rendering the area conductive for some length of time thereafter. This time can be made very short by bombarding the film with high-energy oxygen ions to produce crystal damage throughout the 0.5 μm thick silicon layer [21.57].

21.1.3 Generation and Measurement of the Pulses

Once fabrication is complete, chips with one or more transmission line structures are cut from the wafer. The chip to be measured is mounted on a fixture and wire bond connections are made to the contact pads to allow biasing of the transmission line at a voltage V, typically a few volts, and collection of the charge transferred to

the detection electrode. The sample is then positioned on an optical table together with the laser, and the beams P1 and P2 are carefully aligned so as to strike the sample as shown in Figs. 21.1 and 21.2. The spot size of the laser is typically 5 μm.

The optoelectronic method of generation of the ultrafast electrical pulses is more precisely illustrated in Fig. 21.2a. This electrical arrangement was driven by 70 fs ultrafast optical laser pulses from a compensated, colliding-pulse, passively mode-locked dye laser producing pulses at a 100 MHz repetition rate. During operation, the P1 pulses short the transmission line by producing carriers in the silicon. These carriers are then trapped (disappear) in less than 600 fs [21.57]. The light pulses essentially turn on and off; they act as a very fast switch. When off, the resistance of the switch is many MΩ, but when on, its resistance is on the order of 1 kΩ. This transient shorting of the line produces an approximately 0.5 ps electrical pulse, which propagates down the transmission line. The generated pulses are measured by the P2 sampling pulses at the detection gap. As the electrical pulse traverses the line adjacent to the detection gap a voltage appears across this gap. If this gap is then photoconductively connected to the line by the P2 pulse, current will flow during the time of this connection. The amount of collected charge will be proportional to the voltage across the gap during the sampling interval. Consequently, the collected charge is measured against the relative time delay between the P1 and P2 pulses, which is mechanically scanned by moving an air-spaced retro-reflector with a computer-controlled stepper motor.

This sampling technique enables measurements down to the subpicosecond regime even though the wires bonded to the chip are low-frequency connections. All of the important time information is contained in the relative time delay between the two laser beams, which can be controlled with great precision. Because the excitation and sampling pulses come at a rate of one every 10 ns, while the relative timing between P1 and P2 is typically swept at a rate of 0.1 ps/s, the consequent slowly varying current reading represents an average of a large number (10^9) of identical events. Although the generated electrical pulses reflect off the end of the transmission line and then echo back and forth on the line, the 10 ns between events allows time for about 100 reflections for complete dissipation due to resistive losses. Thus, the system is electrically quiet prior to being excited with each P1 pulse.

For the generated pulse shown in Fig. 21.3a, the excitation site was very close to the sampling gap so that propagation effects were absent. This measurement illustrates the exceptionally clean pulses and high signal-to-noise ratios that can be obtained with this technique. This short electrical pulse had an amplitude of about 10 mV, and a measured half-width of less than 1 ps. The same pulse is shown on a 10× expanded scale, where the signal-to-noise ratio (S/N) of 500 : 1 (in a single scan) can be seen. In Fig. 21.3b, the Fourier transform (amplitude spectrum) of this pulse illustrates the bandwidth available for spectroscopic measurements.

21.1.4 Electrooptic Sampling of Pulses on Transmission Lines

Another measurement technique known as electro-optic sampling [21.2, 3, 7–12], can measure repetitive electrical transients with subpicosecond resolution and microvolt sensitivity. The technique is based on an electric field coupling between the electrooptic *sampling gate* and the circuit under evaluation and does not require that charge be removed from the circuit. Consequently, electrooptic sampling is a minimally interfering technique that, in certain configurations, can sample electrical signals with micron spatial resolution without making physical contact.

In the example presented in Fig. 21.4, electrooptic sampling was used to measure an electrical transient on a coplanar transmission line generated by photoconductively shorting a 50 μm gap biased at 50 V with the excitation pulse [21.8]. The Cr:GaAs and $LiTaO_3$ crystals were mounted side by side on a glass plate and were ground and polished together to a thickness of 500 μm in order for later fabrication. The transmission line was made by evaporating 0.5 μm of aluminum onto the smooth surface and then using standard photolithographic techniques to define the pattern. The measured 460 fs rise time (10–90%) is shown in Fig. 21.4b for which the 50 μm excitation gap was located 200 μm from the sampling point. The probe beam was aligned perpendicularly to the substrate and was focused to a 11 μm diameter between the two 50 μm wide lines separated from each other by 50 μm. The amplitude of the switched signal was 30 mV; the good signal-to-noise ratio indicates the sensitivity of the technique.

Electrooptic sampling reached the impressive combination of a demonstrated rise time of 290 fs and a 40 μm square footprint in the 1 THz bandwidth probe-station developed by *Valdmanis* [21.9]. In other work, a 260 fs rise time electrical transient was measured using electrooptic sampling with a thin lithium tantalate crystal plate overlying a coplanar transmission

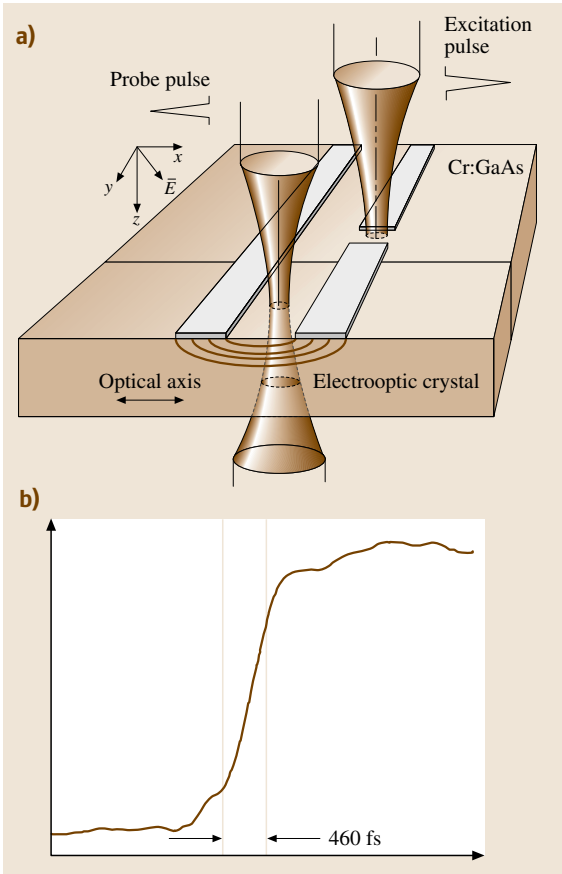

Fig. 21.4 **(a)** Electrooptic sampler arrangement. **(b)** Measured electrical response of the Cr:GaAs photoconductive switch. The 10–90% rise time is 460 fs (after [21.2,3])

line [21.10]. An impressive rise time of 150 fs has been demonstrated using a combination of photoconductive excitation and electrooptic sampling together with the total internal reflection probe [21.11]. Using the approach of [21.12] for GaAs circuitry, the chip itself can be used as the nonlinear crystal.

21.1.5 THz Shockwave Generation on Nonlinear Transmission Lines

The phenomenon of shockwave generation on a fully distributed nonlinear transmission line (NLTL) was first discussed by *Landauer* [21.59] with respect to its use as a parametric amplifier. The shockwave properties were later more fully analyzed [21.60] and the case of periodically loaded [21.61] NLTLs were discussed. Previous studies [21.62] have demonstrated the generation of 3.5 ps shockwaves on a GaAs NLTL having Schottky diodes with uniform doping. In this section the fabrication and results from NLTLs with hyperabrupt varactor diodes will be discussed [21.58]. The increased capacitance variation in hyperabrupt diodes permits using lower loss NLTL designs, that result in a shockwave with higher amplitude and decreased fall time.

The monolithic GaAs NLTL circuit consists of a high-impedance coplanar waveguide (CPW) transmission line with characteristic impedance Z_1 that is periodically loaded at spacing τ (in units of time), by Schottky varactor diodes, producing a synthetic transmission line whose propagation velocity is voltage dependent. Several variations of this mixed structure (Fig. 21.5a) having different numbers of large-scale diodes were fabricated with a minimum feature size of 2 μm on GaAs molecular beam epitaxy material with a total active layer thickness of 0.3 μm and a 1.0 μm buried n^+ layer (6×10^{18} /cm^3 doping) for the diode cathode connection.

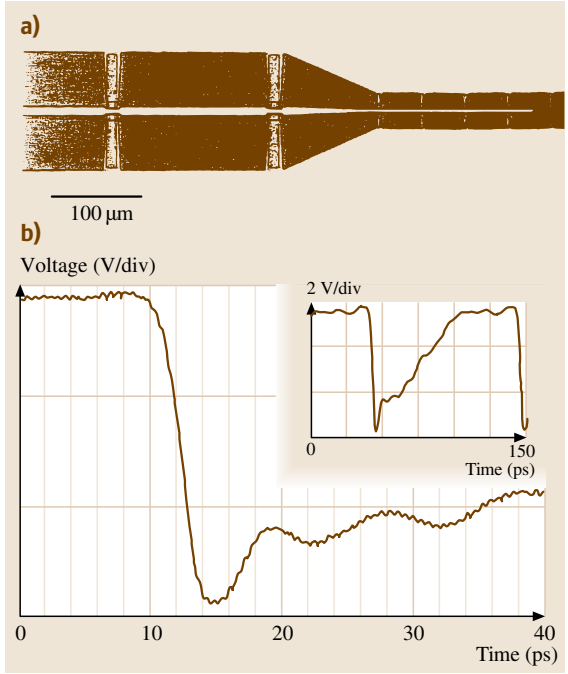

Fig. 21.5 **(a)** Photomicrograph of part of a hyperabrupt-diode nonlinear transmission line showing the taper between the larger-scale and final small-scale sections. **(b)** A 2.5 ps measured fall time shockwave generated on an NLTL with a 25 dBm, 10 GHz sinusoidal input. In the *insert*, the full 100 ps period saw tooth waveform is shown (after [21.58])

As a negative-going input voltage transition, with initial voltage V_h, final voltage V_f, and initial fall time t_{in}, propagates along the line, the fall time will decrease with distance due to the differential group delay, $\Delta t = t(V_h) - t(V_f)$, along the wavefront. As the fall time decreases, dispersion arising from the varactor cutoff frequency and the periodic-line cutoff frequency competes with the compression arising from the voltage-dependent propagation velocity. An asymptotic final fall time t_{min} is reached, at which point the fall time compression per line section is equal to the fall time broadening per section so that the resulting shockwave then propagates unchanged.

The circuit performance was evaluated by direct electrooptic (EO) sampling [21.12] of the voltage waveforms launched onto the line through microwave wafer probes. Figure 21.5b shows a measured waveform for 25 dBm sine wave excitation of a NLTL consisting of 30 large diodes and 40 small diodes with a measured $\Delta t = 49$ ps and a total length of 7.8 mm. The 10 GHz input had a 10–90% fall time of 30 ps, while the output shock wave had a measured 2.5 ps fall time. The shock amplitude was determined to be about 6 V by calibration of the optical signal to a reference electrical signal.

The first subpicosecond shockwaves generated and measured by entirely electronic means are shown in Fig. 21.6 [21.63]. This measurement was performed with a monolithic NLTL/sampler chip. At room temperature, an approximately 1 V, 1.8 ps fall time was observed with less than 20 fs of jitter for a 25 dBm, 6.56 GHz input. The packaged assembly was then lowered into a dewar flask of liquid nitrogen. Steady improvement in both amplitude and fall time was noted until the packaged circuit was completely immersed, resulting in the minimum fall time of 880 fs with a 3.5 V amplitude. The liquid nitrogen did not significantly load the circuits because of its relatively low permittivity $\varepsilon_r = 1.4$.

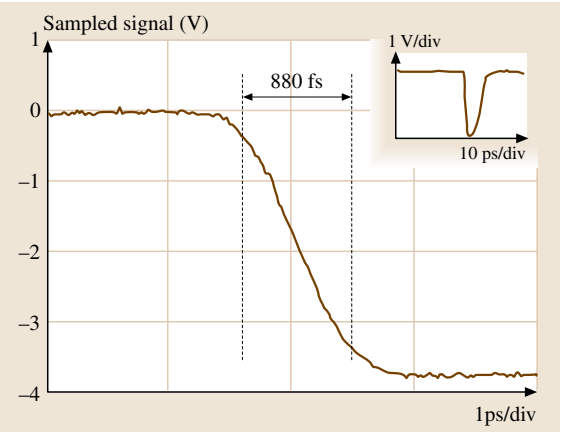

Fig. 21.6 An 880 fs measured-fall-time shockwave generated on a nonlinear transmission line and measured by an on-chip diode sampler at $T = 77$ K. The *inset* is a quarter period of the waveform (after [21.63])

21.1.6 Transmission Line Theory

We will now discuss some general aspects of transmission line theory in the quasistatic limit for which the wavelengths involved are large compared to the transverse dimensions of the line [21.64, 65]. For this case the number of transverse electromagnetic (TEM) modes is one less than the number of metal lines making up the transmission line. Consequently, a two line transmission line has a single propagating TEM mode, for which the electric field distribution (Fig. 21.7) is the same as for the static case when the lines are equally and oppositely charged. Any pulse propagating on this line can be described mathematically as a Fourier sum of single frequency components, all with this same TEM modal distribution.

Consideration of the sliding contact excitation site shows that, to first order, charge is simply transferred from one line to the other creating a symmetrical field distribution with respect to the two lines. During the excitation process a current flow is induced between the lines. Localized charge accumulations of opposite sign build up on the segments of the two metal lines under the laser excitation spot, creating a dipolar field distribution similar to that illustrated in Fig. 21.7 and thereby efficiently coupling the sliding contact excitation to the TEM mode.

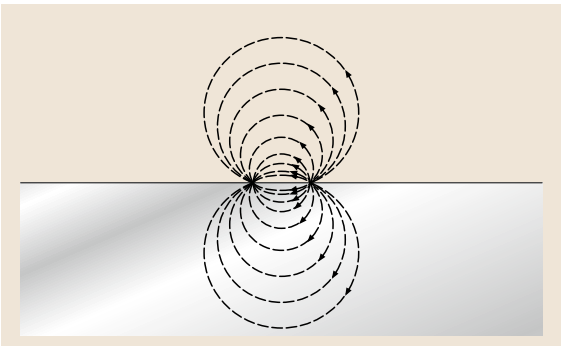

Fig. 21.7 Electrical field lines for the propagating TEM mode

A most important feature of coplanar transmission lines (of negligible thickness) on an infinite dielectric half-space is that for a constant voltage between the two conducting lines, the electric field lines are the same as for the lines immersed in free space. This result is due to the geometric symmetry with respect to the dielectric boundary and is a consequence of the fact that no electric field lines cross this boundary.

For this simple situation, it has been shown that the phase velocity is given by

$$v_p = c\,\{2/[\varepsilon(\omega)+1]\}^{1/2}\ . \tag{21.1}$$

If we define the effective index $n_e = c/v_p$, the expression for the group velocity becomes

$$v_g = c/[n_e + \omega(\mathrm{d}n_e/\mathrm{d}\omega)]\ . \tag{21.2}$$

The power absorption coefficient α for the transmission line can be written as the sum of the absorption due to the metal lines α_{ml} and that due to the dielectric α_{dl}

$$\alpha = \alpha_{ml} + \alpha_{dl}\ . \tag{21.3}$$

The dielectric loss of the line can be written in the very general form for guided waves

$$\alpha_{dl} = f_f \alpha_d v_{gd}/v_g\ , \tag{21.4}$$

where the filling factor f_f is defined as the ratio of the energy per unit length in the dielectric to the total energy per unit length on the coplanar line; α_d is the power absorption coefficient in the bulk dielectric and v_{gd} is the group velocity in the dielectric. For the simple case of the coplanar waveguide with the same field pattern in the air and in the dielectric, f_f is given by $f_f = \varepsilon/(1+\varepsilon)$; $v_{gd} = c/\varepsilon^{1/2}$, and α_{dl} is evaluated to be

$$\alpha_{dl} = \alpha_d[\varepsilon/(2+2\varepsilon)]^{1/2}\ . \tag{21.5}$$

21.1.7 THz-TDS Characterization of Transmission Lines

The powerful technique of THz time-domain spectroscopy (THz-TDS) is especially appropriate for characterizing dielectrics, ultra-wideband transmission lines and waveguides [21.52, 66]. With this technique, two electromagnetic pulse shapes are measured, the input pulse and the propagated pulse, which has changed shape due to its passage through the sample under study. Consequently, via Fourier analyses of the input and propagated pulses, the frequency dependent absorption and dispersion of the sample can be obtained.

The subpicosecond electrical pulses generated on coplanar transmission lines can be used for THz-TDS characterization of the transmission line itself. For the layout shown in Figs. 21.1 and 21.2, the point at which the pulse is generated can be moved with respect to the detection electrode by repositioning the exciting laser beam. This separation can be continuously adjusted and is the equivalent of a *sliding contact*. For THz-TDS studies it is important that the pulses propagate as a single mode of excitation on the transmission line. This feature is enabled due to the micron-sized dimensions of the coplanar line and to the sliding contact method of excitation, [21.5], which matches the TEM transverse electromagnetic mode of the transmission line. Thus, as the ultrafast electrical pulse propagates down the transmission line, its pulse shape will only change due to the frequency dependent electrical and magnetic properties of the transmission line, e.g., the metal of the line and the dielectric substrate and radiation processes. Consequently, via THz-TDS, the absorption and dispersion vs. frequency of the line can be obtained [21.67].

The performance of lithographically defined planar transmission lines will be shown to be limited by the resistive loss of the metal lines, Cherenkov radiation loss from the propagating pulse, and absorption by the underlying dielectric. Typically, for THz bandwidth pulses, Cherenkov radiation is the dominant loss process, which can be so severe that after propagating only 1 mm, power at 0.8 THz is reduced to $1/e$ of its original value. Various techniques have been demonstrated to reduce this radiation. The most straight-forward approach, which is compatible with VLSI processing, is to reduce line dimensions (linewidths and separations) to below 1 μm. However, for such dimensions resistive loss of the lines restricts the bandwidth. Normal superconductors can solve this problem for low frequency applications typically up to a band gap frequency of 0.7 THz, above which the line shows severe loss. As an added benefit, cryogenic temperatures usually lower the THz absorption loss of crystalline substrates. To achieve high-frequency response with submicron linewidths, the high-T_c superconductors with band gaps above 15 THz appear as a possible solution. Early attempts to achieve THz bandwidths with high-T_c transmission lines were limited by the extremely high absorptive loss of the lattice matched YSZ substrate [21.68]. Later investigations used lattice matched lanthanum aluminate substrates with much lower loss and achieved significantly lower propagation loss up to 1 THz at cryogenic temperatures for a high-T_c coplanar transmission line

compared to an identical transmission line with gold lines [21.69]. However, a more recent investigation of high-T_c coplanar transmission lines fabricated on a lattice matched MgO substrate gave the disappointing result that at 77 K the attenuation was higher for the high-T_c line than for an identical gold line [21.70]. This situation must be resolved if high-T_c lines are going to realize their promise as the future material for the VLSI interconnect with dimensions below 1 μm and with THz bandwidths.

Cherenkov Radiation

By studying the frequency dependent loss on an Al transmission line on SOS, where the coplanar lines were separated by 15 μm, a powerful radiation process was observed due to a type of Cherenkov radiation [21.71]. When charges move faster than the phase velocity for electromagnetic radiation in a material, Cherenkov radiation is emitted as an electromagnetic shock wave [21.72]. The initial analysis of this effect was for electric monopoles, but the physical picture holds true for higher-order moments as well. The electrical pulses were produced by transferring approximately 2000 electrons between the two lines at the generation site. Consequently, two dipoles with charges of 1000 e and separations of 15 μm move down opposite directions of the line at the measured group velocity of $c/2.45$, significantly faster than the phase velocity of approximately $c/3.3$ for THz radiation in sapphire. Thus, in the dielectric, the situation shown in Fig. 21.8 occurs, which generates radiation of an electromagnetic shock wave in the form of a Cherenkov-type cone.

THz-TDS measurements have characterized this loss process, which is so severe that after propagating only 1 mm the power at 0.8 THz is reduced to $1/e$ of its original value. Previous frequency domain studies have calculated the radiative loss for single-frequency transmission on coplanar metal lines on dielectrics [21.73]. These results have been confirmed by experimental measurements up to 1 GHz [21.73], where the radiation loss is only 10^{-9} of that presented here. The observed frequency-dependent absorption remains in good agreement with this calculation, even though the THz-TDS measurement extends up to 1 THz. At these high frequencies, the time-domain Cherenkov picture provides a simple intuitive description of the generation of the electromagnetic shock wave and of the radiation process associated with the propagating ultrafast electrical pulse.

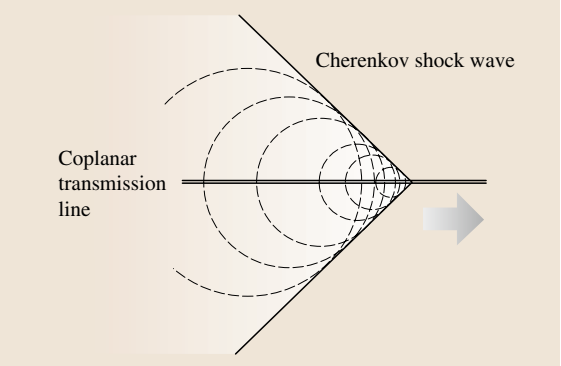

Fig. 21.8 The Cherenkov cone in the dielectric half-space

In Fig. 21.9a, the measured initial subpicosecond electrical pulse is shown [21.71]. In this case, the spatial separation between the exciting and sampling beams was approximately 50 μm, while the laser spot diameters were 15 μm. When the sliding contact was moved 6 mm from the optical sampling gap the pulse propagation effects shown in Fig. 21.9b were observed. The Fourier analyses of these pulses are shown in Fig. 21.9c, where it is seen that the amplitude spectrum of the initial pulse extends beyond 1 THz and that the transmitted pulse has suffered a significant frequency-dependent loss. From these spectra it is straight-forward to obtain the absorption coefficient as a function of frequency, as shown in Fig. 21.9d.

Evaluating the predicted loss (*absorption*) for these conditions [21.71, 73, 74], the amplitude absorption coefficient is obtained as $\alpha = (0.4\,\mathrm{mm}^{-1})f^3$, where f is the frequency in THz. This result should be compared with the measurements in Fig. 21.9d. The solid line fit to the data in Fig. 21.9d is given by the relationship $\alpha = (0.2\,\mathrm{mm}^{-1})f^{1/2} + (0.65\,\mathrm{mm}^{-1})f^3$. The first term gives the frequency-dependent loss due to the resistive skin effect for the Al lines, while the second term with the f^3 dependence describes the loss due to the radiation. The measured loss due to the radiation is approximately 1.5 times the calculated value. This good agreement, and especially the cubic-frequency dependence, definitely confirms the nature of the effect.

Methods to Eliminate Cherenkov Radiation from Transmission Lines

The Cherenkov radiation loss has been eliminated by the use of silicon-on-insulator materials with a microstrip geometry [21.75] and thin-film microstrip lines [21.76], but the total observed loss owing to the dielectric and the metal was still approximately the same as for the coplanar transmission line. A variety of transmission line structures have been designed to

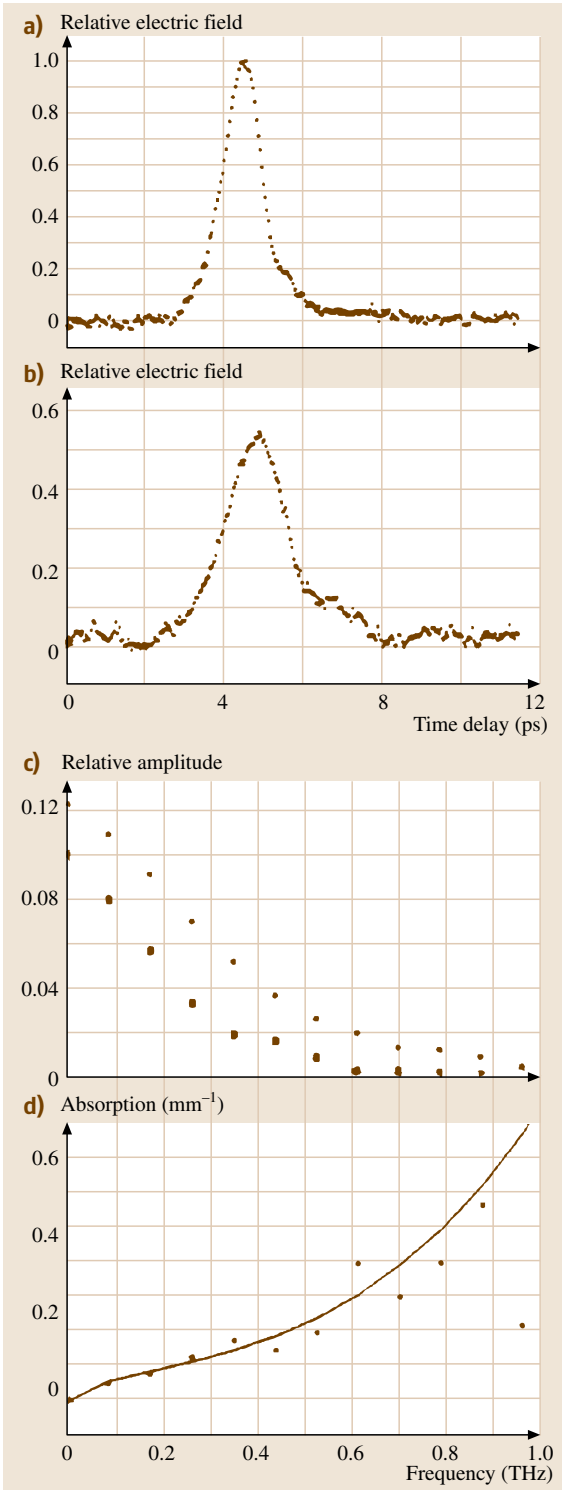

Fig. 21.9 **(a)** Measured initial pulse. **(b)** Measured pulse after 6 mm propagation. **(c)** Amplitude spectrum of pulse (*dots*) compared to propagated pulse (*squares*). **(d)** Experimental amplitude absorption coefficient (*dots*) compared with theory (after [21.71]) ◀

reduce the permittivity mismatch responsible for the Cherenkov radiation [21.77–80]. The ideal transmission line would have no substrate/superstrate mismatch. Along these lines, coplanar air transmission (CAT) lines have been fabricated [21.77]; these coplanar striplines are edge supported by a 200 nm layer of SiO_2 on GaAs. The GaAs below the transmission line is etched away leaving the striplines supported in free space. Rise times as short as 0.8 ps after a propagation length of 2.8 mm were obtained [21.77]. Coplanar striplines have also been fabricated on low permittivity substrates and membranes, on the order of microns thick, demonstrating significantly reduced loss and higher bandwidths [21.78–80].

A new approach to the reduction of radiative loss from transmission lines has been demonstrated [21.74]. Instead of reducing the permittivity mismatch, the mode characteristics of a three line stripline were utilized to generate a quadrupole electrical pulse with significantly reduced loss and dispersion compared to that of the dipole pulse. As shown in Fig. 21.10a, through appropriate bias of the striplines, either the even mode, where the electric fields are parallel between each gap with a dipole field pattern, or the odd mode, which has the antiparallel electric fields in the gaps with a quadrupole field pattern, can be exclusively excited.

Using THz-TDS analysis, the amplitude absorption coefficient $\alpha(f)$ for the quadrupole pulse and dipole pulse are shown in Fig. 21.10b. The absorption for the quadrupole is dramatically reduced over that of the dipole; at 0.8 THz a factor of two difference between the two coefficients is observed. Both curves are fit with the relationship $\alpha(f) = A_{\text{res}} f^{1/2} + A_{\text{rad}} f^3$, where the resistive A_{res} and the radiative A_{rad} loss coefficients are adjustable parameters. For the dipole pulse A_{res} is $6\,\text{cm}^{-1}$, compared to $7\,\text{cm}^{-1}$ for the quadrupole. For the dipole pulse, the strong f^3 dependence is seen with a radiative coefficient $A_{\text{rad}} = 32\,\text{cm}^{-1}$, whereas the quadrupole pulse has the much smaller coefficient $A_{\text{rad}} = 3\,\text{cm}^{-1}$. This order of magnitude reduction clearly demonstrates that the radiative loss for an electric quadrupole pulse is significantly less than that of a dipole pulse. It is instructive to compare the measured $A_{\text{rad}} = 32\,\text{cm}^{-1}$ for the 30 μm-sized dipole with that expected from the measurements of Fig. 21.9,

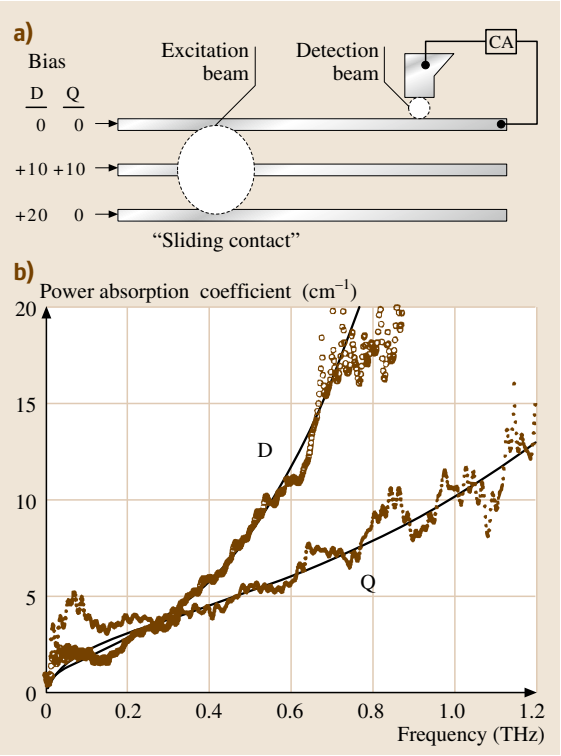

Fig. 21.10 **(a)** Three line coplanar transmission line. The aluminum lines are 4 μm wide separated by 15 μm. Quadrupole electrical pulses are generated with bias Q, dipole pulses with bias D. **(b)** Measured power absorption coefficient compared to theory (Q) quadrupole (odd mode) and (D) dipole even mode pulses (after [21.74])

where $A_{rad} = 6.5\,cm^{-1}$ for a 15 μm dipole. Because the radiation loss is proportional to the square of this length, Fig. 21.9 would predict an $A_{rad} = 28\,cm^{-1}$ for a 30 μm-sized dipole in good agreement with observation.

Superconducting Transmission Lines

One of the early applications of THz-TDS was the study of superconducting niobium metal lines [21.81]. Niobium has a superconducting transition temperature of 9.4 K and was cooled in a cryostat to temperatures in the range of 2–8 K. The cryostat had optical windows that allowed for the laser beams to pass through. For the experiment, the same pattern was fabricated in niobium metal on an SOS wafer, which was then ion implanted as before.

With the exciting beam striking very close to the detection electrode, the results are much the same as for aluminum at room temperature. Above the superconducting transition temperature $T_c = 9.4\,K$ for niobium, the propagated pulse was severely broadened by the highly resistive Nb transmission line. Figure 21.11a shows the pulse shape at 2.5 K and 0.5 mm from the point of excitation. The pulse broadens with propagation and develops a distinct oscillation at the leading edge, as shown in Fig. 21.11b. This oscillatory behavior is characteristic of a superconductor. While a superconductor has no losses at low frequencies, it has significant loss at and above the superconducting gap frequency, corresponding to the energy with which pairs of electrons are bound in the superconducting state. For niobium at 2.6 K this onset is at about 0.7 THz, which is close to the oscillation frequency shown in Fig. 21.11b. When the input and propagated pulses are frequency analyzed, the absorption coefficient has a sharp step at 0.7 THz, corresponding to the superconducting band gap. This result clearly identifies the band gap and illustrates the power of the method. The fact that for frequencies above the band gap, the line behaves as a normal metal has the important technical implication that ordinary superconducting lines cannot be used to propagate 1 ps pulses.

21.1.8 Guided-Wave THz-TDS Characterization of Dielectrics

The frequency-dependent dielectric properties of a material may be measured by placing the material on the transmission line and into the field lines of the propagating pulses. For a typical line composed of 5 μm lines separated by 10 μm, this requires that the material be brought within several microns of the line. For paths several mm long, this is not an easy task. An optoelectronic test that indicates the quality of the optical contact is the measured group velocity v_g of the pulse in the section of the transmission line covered by the dielectric sample. With no sample in place for an SOS chip $v_g = c/2.45$. The expression for the group velocity is easily generalized to the two dielectric case as $v_g = c/[2/(\varepsilon_1 + \varepsilon_2)]^{1/2}$, where ε_1 refers to the substrate and ε_2 refers to the dielectric under study. Consequently, with typical high dielectric constant ($\varepsilon_2 = 10$) samples v_g should be approximately $c/3$. An estimate of the contact with the transmission line is given by a comparison between this calculated value and the measured value. The result can be used to estimate a *filling factor* for the absorption measurement.

An early example of a THz-TDS measurement of a material brought into contact with the transmission

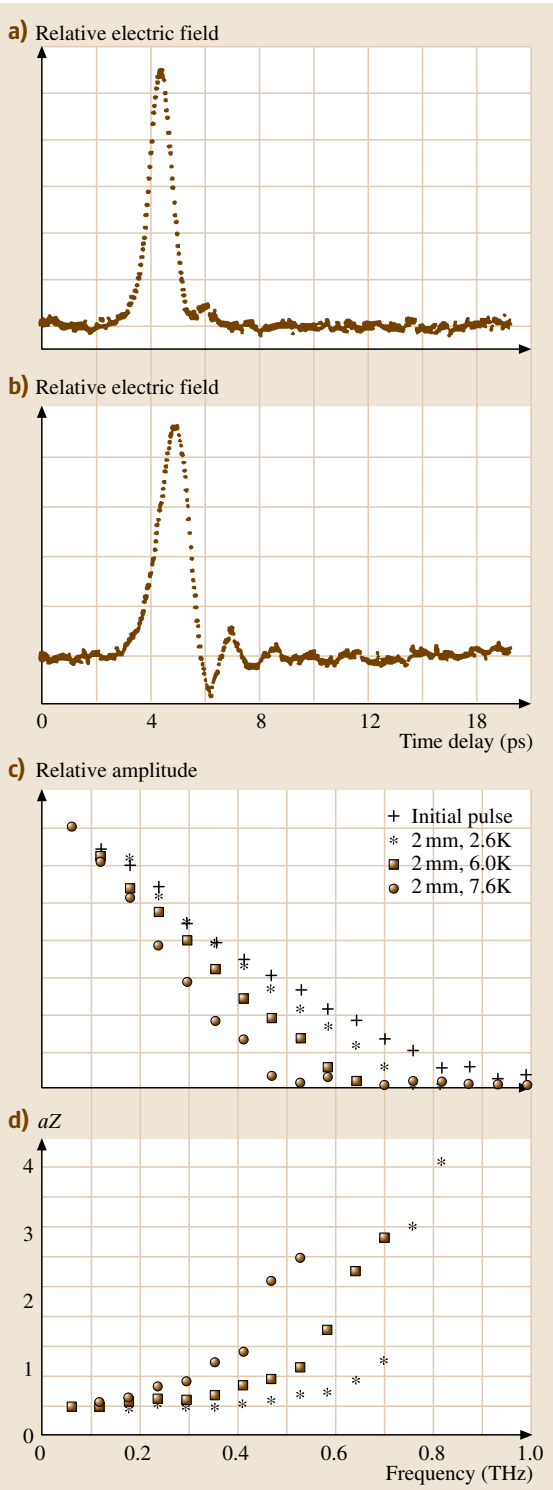

Fig. 21.11 **(a)** Initial electrical pulse. **(b)** Electrical pulse after 2 mm propagation on Nb superconducting transmission line at 2.6 K. **(c)** Fourier transforms of initial and propagated pulses at different temperatures. **(d)** Absorption spectra of transmission line versus temperature ◀

line was the observation of some magnetic resonances in erbium iron garnet (ErIG) [21.82]. It is of interest to note here that the interaction is with the magnetic field of the propagating electrical pulse in contrast to the usual case where it is the electric field responsible for the observed effects. For this study, an approximately 3 mm section of the line was covered with fine garnet powder. When the ultrafast pulse was propagated through this powder a new dramatic os-

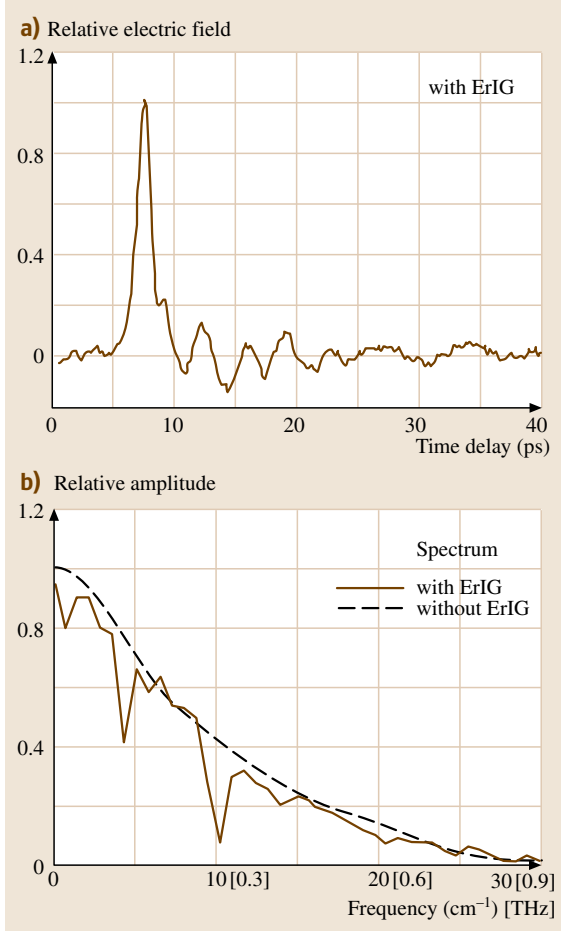

Fig. 21.12 **(a)** Electrical pulses after 4 mm propagation on the line covered with EIG powder. **(b)** Spectrum of propagated pulse with and without ErIG (after [21.82])

cillatory time dependence was observed on the output pulse shown in Fig. 21.12a. When this output pulse was frequency analyzed, two well-defined absorption lines appeared as shown in Fig. 21.12b. The line at $10\,\mathrm{cm}^{-1}$ had been measured earlier by more traditional spectroscopic techniques and identified as the exchange resonance [21.83], while the line at $4\,\mathrm{cm}^{-1}$ had previously not been observed. Earlier measurements using YbIG showed a line at $3\,\mathrm{cm}^{-1}$ due to the ferrimagnetic resonance [21.84]. By extrapolating these results to ErIG, the newly observed line appears to be the corresponding ferrimagnetic resonance.

21.1.9 THz Waveguides

THz waveguides have been recently demonstrated to be an alternative to transmission lines [21.85–90]. For bandwidths up to 3.5 THz the attenuation coefficient of metal waveguides has been shown to be less than 1/10 that of lithographically defined transmission lines on dielectric substrates. Within the passband of the waveguide, the measured power coupling into the waveguide was typically 40% of the incoming THz power. Although these waveguides should be quite useful for narrow band or THz-TDS applications, they have very high group velocity dispersion (GVD), which precludes subpicosecond pulse propagation. For the single conductor circular and rectangular metal waveguides the excessive THz pulse broadening is caused by the extreme GVD near the cutoff frequency. This pulse broadening would not occur for the TEM modes of a two-wire coplanar line, a coaxial line, or a parallel-plate metal waveguide, that do not have a cutoff frequency. The group and phase velocities of such TEM modes are determined solely by the surrounding dielectric. Quasioptic coupling techniques are not effective for the complex field patterns of the TEM mode of the two-wire coplanar line or the coaxial line, but are effective for the simple field pattern of the TEM mode of the parallel-plate metal waveguide.

Recent experiments have shown efficient quasioptic coupling of freely propagating subpicosecond pulses of THz radiation into a parallel-plate metal waveguide and the subsequent low-loss, single TEM mode propagation exhibiting negligible GVD [21.89, 90]. Consequently, the ideal THz interconnect [21.66], capable of propagating subpicosecond pulses with minimal loss and no distortion, has been realized.

A promising application of THz metal waveguides appears to be surface-specific frequency-dependent absorption measurements using THz-TDS. For an air-filled waveguide, the observed frequency-dependent absorption coefficient determines the frequency-dependent conductivity, which is difficult to obtain by other techniques. Long-path surface-specific measurements of molecular adsorption to the metal waveguide walls is another area of promise. From experimental measurements made on the absorption of water, we believe that for similar polar molecules, THz-TDS has the sensitivity to characterize the absorption of nanogram quantities of samples of toxic or precious gases contained in a tubular, single conductor THz waveguide. Such enclosed waveguides would also make excellent low-volume sample cells for high-pressure, long-path spectroscopic measurements of toxic or reactive gases and liquids. THz waveguides could enable the observation of nonlinear effects with relatively modest powers, due to the small diameters combined with the long-path, low-loss propagation.

In addition to the above possibilities, THz pulses propagating in the TEM mode open the door to other new research applications. The metal plates could be easily coated with films of other metals and alloys to measure their conductivities. Superconducting plates could be easily characterized. Shorter length waveguides could be constructed of highly doped semiconductors that are typically opaque to THz radiation, thereby enabling the measurement of their frequency-dependent complex conductivity. Simple thin films, more complex Langmuir–Blodgett films, and conducting polymers could coat the waveguide and be characterized by THz-TDS. A unique application for high-power TEM THz pulses would be the study of nonlinear pulse propagation, demonstrating nonlinear coherent effects of samples filling the space between the metal plates. Here, for the first time, a THz pulse can maintain its spatial focus for arbitrarily long paths without temporal broadening, thereby enormously increasing the effects of nonlinear interactions. This situation is similar to the nonlinear enhancement obtained with optical fibers.

Dielectric waveguides do not have the sharp low-frequency cutoff of metal waveguides and thereby extend the low-frequency limit. The initial demonstration [21.87] used single crystal sapphire fibers and achieved single HE_{11} mode propagation with large GVD caused by the extent of the fringing fields increasing with wavelength. The waveguide absorption was that of bulk sapphire. Given a suitable low loss dielectric, such as high-resistivity silicon with a power absorption coefficient of less than $0.05\,\mathrm{cm}^{-1}$, dielectric waveguides could have much less absorption than

metal waveguides. Such dielectric single-mode THz waveguides would have the promise of an extremely low-loss, flexible interconnect and communications channel, with advantages similar to that of single-mode optical fiber.

Planar dielectric waveguides appear to be especially well adapted for the proposed THz-TDS characterization of surface layers, due to the extensive fringing fields of the propagating THz waves outside the waveguide. For guided wave propagation there is an enormous increase in sensitivity to a thin sample layer, compared to a simple reflection or transmission. Appropriate easily applied samples would include adsorbed molecules, surface layers, thin films, Langmuir–Blodgett films, films of metals, alloys, and conducting polymers.

Metal Waveguides

Experimental investigations using quasioptical methods to efficiently couple freely propagating subpicosecond pulses of THz radiation into single-conductor, submillimeter metal waveguides and to consequently measure the transmitted pulses from these waveguides have been recently reported [21.85, 86]. Dispersive propagation with low-loss over the frequency band from 0.65 to 3.5 THz was observed with frequency dependent group velocities v_g ranging from $c/4$ to c and phase velocities v_p from $4c$ to c, where ($v_g v_p = c^2$). Even though the input spectrum overlapped the cutoff frequencies of more than 25 waveguide modes, the linearly polarized incoming THz pulses only significantly coupled into the TE_{11}, TM_{11} and the TE_{12} modes for observations using 24 mm long and 4 mm long stainless steel (SS) tubes with inside diameters of 240 μm and 280 μm, respectively. As shown in Fig. 21.13 [21.91–93], at 1 THz the power absorption coefficient for the dominant TE_{11} mode is $\alpha = 0.7\,\mathrm{cm}^{-1}$ for a 240 μm diameter. The SS waveguide is approximately 1/10 of the loss compared to lithographically defined coplanar transmission lines [21.66].

The experimental setup for THz waveguides is similar to that of the optoelectronic THz beam system described in the next section, except that at the beam waist centered between the two parabolic reflectors a lens–waveguide–lens system is placed as shown in Fig. 21.14a. For the waveguide system the silicon lens focuses the THz beam to a frequency-independent 1/e-waist diameter of approximately 200 μm, which is coupled into and propagated through the waveguide and is coupled out with the second silicon lens. The reference THz pulse is measured by removing the waveguide and then moving the two silicon lenses to their common

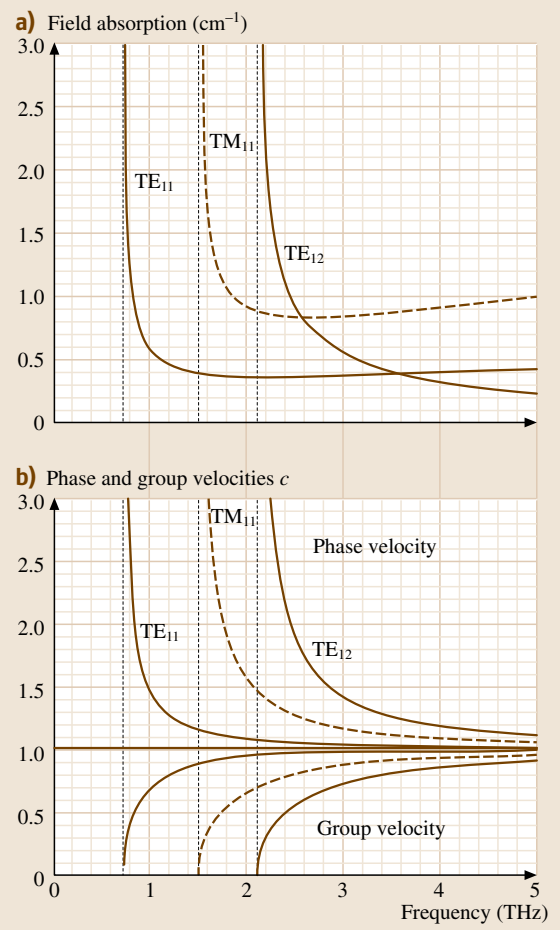

Fig. 21.13 **(a)** Field absorption and **(b)** phase and group velocities for the coupled three modes in a 240 μm diameter stainless steel waveguide (after [21.86])

focus (the confocal position). Such a reference THz pulse is shown in Fig. 21.14b, where the corresponding amplitude spectrum shown Fig. 21.14c extends from 0.1–4 THz.

The observed transmitted signal from the 24 mm long waveguide dramatically demonstrated the strong group velocity dispersion of the waveguide [21.85, 86]. The 1 ps input pulse was stretched to about 70 ps, with the high frequencies arriving earlier in time corresponding to negative chirp. The transmitted pulse from a 4 mm long waveguide displays comparatively less cumulative dispersion in Fig. 21.15a (dots). The pulse is spread over 30 ps and shows fewer oscillations. The spectrum of this pulse, Fig. 21.15b (dots), shows the lowest frequency cutoff at about 0.65 THz, which is also

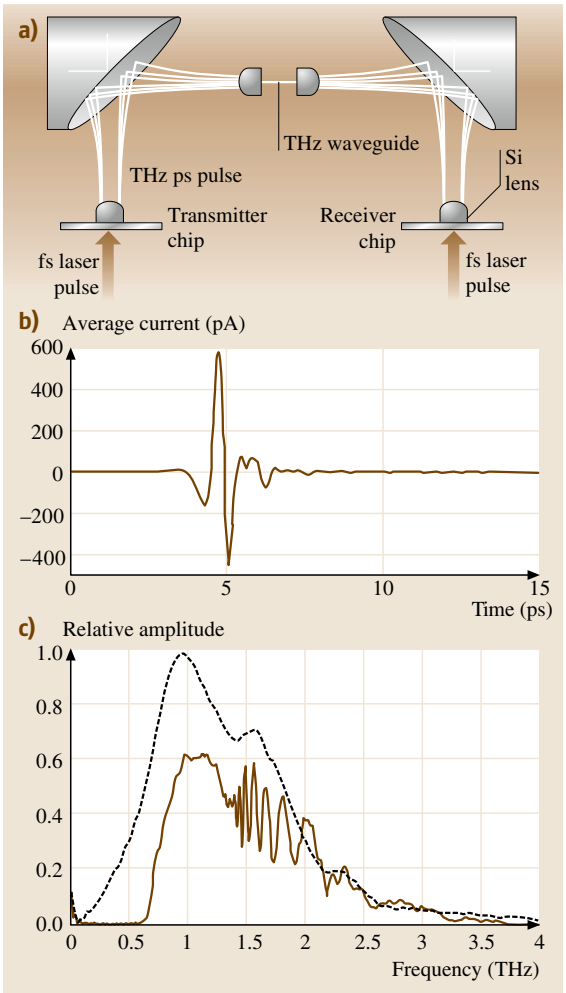

Fig. 21.14 **(a)** Schematic diagram of the optoelectronic THz-TDS system incorporating quasioptical coupling to the THz waveguide. **(b)** Measured reference THz pulse. **(c)** Relative amplitude spectrum of the reference pulse compared to that of the transmitted pulse (after [21.85])

The *inset* shows the THz pulse on an expanded time scale. **(b)** Amplitude spectrum (*dots*) of the measured transmitted pulse from **(a)**. The *inset* shows the amplitude spectrum on an expanded frequency scale. The *solid curves* are from theory (after [21.85])

calculated to be 0.65 THz for the TE_{11} mode. The comparison of the relative amplitude spectrum of this pulse with that of the reference pulse in Fig. 21.14c, where they both have the same normalization, illustrates the excellent amplitude coupling of the freely propagating THz pulse into the waveguide. Multimode interference was observed to be stronger in the shorter waveguide, starting at about 1.3 THz. The dominant TE_{11} mode has a cutoff frequency of 0.65 THz (77%); the coupled TM_{11} mode has a cutoff at 1.31 THz (20%), and the weakly TE_{12} coupled mode has a cutoff at 1.81 THz (3%). The percent of the total coupled power into each mode is in parentheses.

Using the spectrum of the reference pulse, the output spectrum from the 4 mm waveguide was calculated including the three coupled modes, their respective complex amplitude coupling, as well as their frequency-dependent complex propagation vectors, obtainable as from Fig. 21.13. This calculation overlays as the solid

line the measured spectra in Fig. 21.15b; good agreement is obtained for the interference oscillations and the other features of the spectra. The calculated time-domain output pulse (solid line) is given by the inverse Fourier transform of the calculated complex output amplitude spectrum $E_{out}(\omega, z)$ and is compared favorably with the experiment in Fig. 21.15a.

TEM THz Parallel-Plate Metal Waveguide

In the initial observation [21.89] shown in Fig. 21.16, a freely propagating beam of 0.3 ps FWHM THz pulses was efficiently coupled into a parallel-plate copper waveguide (with a plate separation of 108 μm), and low-loss, single TEM mode undistorted pulse propagation was observed within the bandwidth from 0.1–4 THz for a length of 24.4 mm. The experimental setup incorporated planocylindrical lenses to couple the energy into and out of the guide. The lens at the input of the guide is used to focus the beam only along one dimension producing an approximately Gaussian beam having an elliptic cross-section with a frequency-independent 1/e-amplitude minor axis of 200 μm at the beam waist, where the entrance face of the guide is located. An identical arrangement is used at the output face.

A more recent demonstration [21.90] is shown in Fig. 21.17, where the FWHM was 0.22 ps for the input reference pulse, 0.25 ps for the output pulse after $L = 125$ mm of TEM propagation, and 0.39 ps for the output pulse after $L = 250$ mm of TEM propagation. Characteristic of TEM propagation, the output pulses exhibit no dispersive pulse broadening [21.89, 90]. The minimal broadening of the output pulses is due to the relative loss in the high-frequency content as seen in the amplitude spectra. As shown in Fig. 21.17d, the FWHM of the amplitude spectra are 1.62 THz, 1.14 THz, and 0.74 THz for the reference, $L = 125$ mm, and $L = 250$ mm pulses, respectively. The smoothness of the output spectra revealing no low-frequency cutoff, confirms single TEM mode propagation [21.85–90]. The associated low loss for this TEM propagation is presented in Fig. 21.18, which gives the measured amplitude attenuation constant compared with theory.

Dielectric Waveguides

An alternative approach to low-loss, guided wave, THz propagation would be to use dielectric waveguides. Such waveguides do not have the sharp low-frequency cutoff of metal waveguides and would thereby extend the low-frequency limit. Dielectric waveguide propagation of subpicosecond THz pulses (in single-crystal sapphire fibers) has now been achieved [21.87]. An incident THz pulse of approximately 0.6 ps duration was observed to undergo considerable reshaping due to the absorptive and dispersive waveguide propagation, resulting in transmitted chirped pulse durations of 10–30 ps. Good agreement between theory and experiment was obtained by analyzing the propagation in terms of the single HE_{11} waveguide mode.

The THz dielectric waveguide work has been extended to planar waveguides based on films, such as

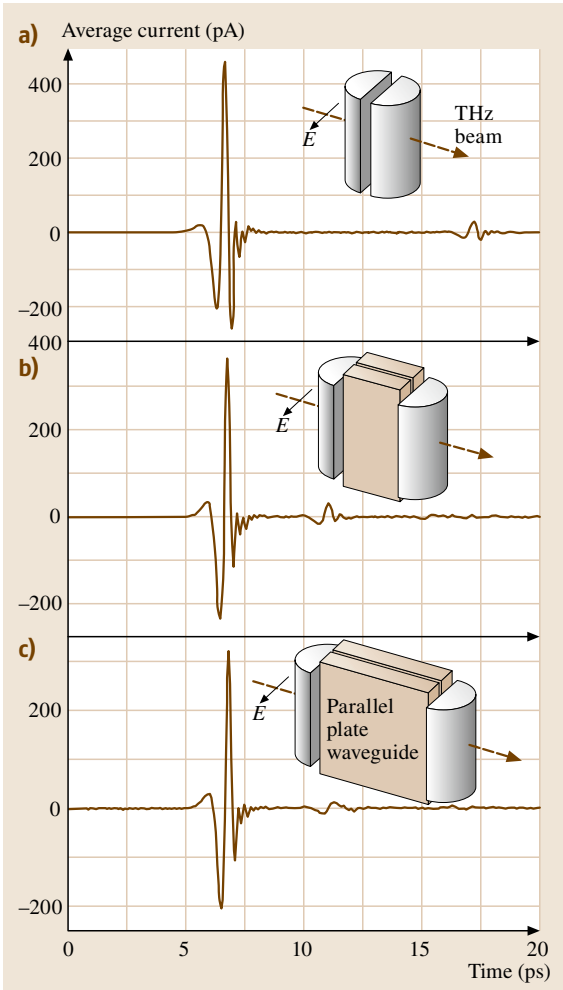

Fig. 21.16 **(a)** Scan of the reference pulse with the confocal cylindrical lens system shown in the *inset*. **(b)**,**(c)** Scans of the propagated pulse through the **(b)** 12.6 mm and **(c)** 24.4 mm long waveguides with the lens waveguide lens systems shown in the *insets*. high-density polyethylene. This material has low THz absorption and gives very low-loss propagation. Dispersive, low-loss propagation was observed for 2 cm wide by 150 μm thick ribbon waveguides made of high-density polyethylene (HDPE) [21.88]. The large GVD caused extensive THz pulse reshaping and broadening, resulting in positively chirped output pulses. The measured propagated THz pulse through a 10 mm long HDPE waveguide broadened to over 15 ps and showed strong reshaping indicating a frequency chirp. In contrast, the corresponding amplitude spectrum shows much less change. The reference pulse was a half-cycle pulse with a peak to peak pulse width of less than 1 ps; its amplitude spectrum extended from 0.1 to about 3 THz. The amplitude spectrum of the propagated pulses, compared to the spectrum of the reference pulse, clearly exhibits efficient wave-guiding characteristics.

This study demonstrated the feasibility of the plastic ribbon waveguide as a low-loss, single-mode transmission channel for the THz region, capable of utilizing efficient quasioptic coupling. Ultralow loss lines are possible by reducing the thickness of the ribbon such that most of the guided wave energy propagates outside the core region. The performance could be further enhanced by the use of a very low-loss material, such as high-resistivity silicon with a power absorption coefficient of much less than 0.05 cm^{-1} up to 2 THz [21.51].

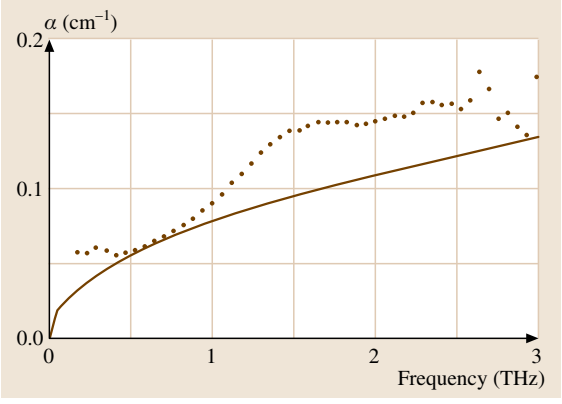

Fig. 21.18 The experimental values (*dots*) compared to theory (*solid line*) for the amplitude attenuation constant α. (after [21.90])

Consequently, dielectric waveguides could have much less absorption than metal waveguides. Due to the ability to change the group velocity dispersion (GVD) by changing the thickness of the ribbon waveguide, large-frequency regions with essentially no GVD can be obtained.

21.2 Freely Propagating Wave THz Photonics

Recently, there has been a great deal of work demonstrating the generation of THz radiation via material and electronic excitation by ultrafast laser pulses. Modern integrated circuit techniques have made possible the precise fabrication of micron-sized dipoles, which when photoconductively driven by fs laser pulses can radiate well into the THz regime [21.20–22]. An alternative and complimentary approach has been to extend radio and microwave techniques into the THz regime through the use of optoelectronic antennas [21.23–30, 32]. The generation of short pulses of THz radiation by the passage of a short optical pulse through a nonlinear optical material was demonstrated many years ago [21.33]. A related source is based on the emission of an electromagnetic shock wave due to a volume dipole distribution moving faster than the phase velocity, i. e., the electrooptic Cherenkov radiation [21.34, 35], and the electromagnetic shock wave radiated by a surface-dipole distribution propagating faster than the phase velocity [21.71]. THz radiation has been generated by photoconductively driving the surface field of semiconductors [21.36, 37] and the intrinsic region of large aperture silicon p-i-n diodes [21.20] with ultrafast laser pulses. A quite efficient source of broadband THz radiation involves the generation of photocarriers in trap-enhanced electric fields with ultrafast laser pulses [21.44, 94]. A CW photomixer capable of producing tunable radiation has been demonstrated by beating together two laser beams with frequencies above the band gap of a semiconductor [21.39–43].

Some of these sources are based on an optical type approach whereby a transient point source of THz radiation is located at the focus of a dielectric collimating lens, followed by an additional paraboloidal focusing and collimating mirror [21.21, 22, 29, 31, 95]. Although this system will be the one described in most detail, alternative approaches will also be presented. One of the most useful versions of the system is based on repetitive, subpicosecond optical excitation of a Hertzian dipole antenna imbedded in a charged coplanar transmission line structure [21.21, 22, 29, 31, 95]. The burst of radiation emitted by the resulting transient dipole is collimated by a THz optical system into a diffraction-limited beam and focused onto a similar receiver structure, where it induces a transient voltage and is detected. The THz optical system gives exceptionally tight coupling between the transmitter and receiver, while the excellent focusing properties preserves the subpicosecond time dependence of the source.

The combination of THz optics with the synchronously-gated, optoelectronic detection process has exceptional sensitivity for repetitively pulsed beams of THz radiation. Via two stages of collimation, a THz beam with a frequency-independent divergence is obtained from the THz transmitter. The THz receiver with identical optical properties collects essentially all of this beam. The resulting tightly coupled system of the THz transmitter and receiver can give strong reception of the transmitted pulses of THz radiation after many meters of propagation. Another reason for the exceptional sensitivity is that the THz receiver is gated. The gating window of approximately 0.6 ps is determined by the laser pulse width and the carrier lifetime in ion-implanted silicon-on-sapphire (SOS). Thus, the noise in the comparatively long time interval (10 ns) between the repetitive THz pulses is not seen by the receiver. A final important feature of the detection method is that it is a coherent process; the electric field of a repetitive pulse of THz radiation is directly measured. Because a repetitive signal is synchronously detected, the total charge (current) from the signal increases linearly with the number of sampling pulses, while the charge (current) from noise increases only as the square root of the number of pulses.

21.2.1 An Optoelectronic THz Beam System

This section describes the optoelectronic generation and detection of freely-propagating femtosecond pulses of THz electromagnetic radiation. Via optoelectronic excitation, a transient point source of THz radiation is generated at the focus of a dielectric collimating lens, followed by an additional paraboloidal focusing and collimating mirror. This source produces well-collimated beams of subpicosecond pulses of THz radiation. Matched to an identical receiver, the resulting system has extremely high collection efficiency. With

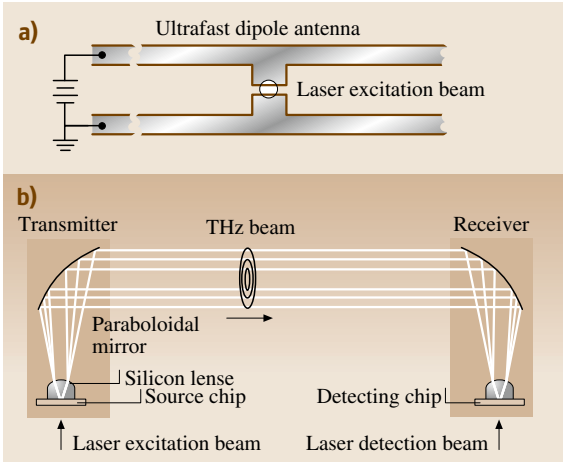

Fig. 21.19 (**a**) Ultrafast dipolar antenna. (**b**) THz transmitter and receiver

a demonstrated signal-to-noise ratio of 1000, a time resolution of less than 150 fs, and a frequency range from 0.2 THz to more than 6 THz, the performance of this optoelectronic THz system is limited only by the ballistic acceleration of the photocarriers.

The setup used to generate and detect beams of short pulses of THz radiation is presented in Fig. 21.19. For this example, the transmitting and receiving antennas are identical, each consisting of the antenna imbedded in a coplanar transmission [21.31], as shown in Fig. 21.19a. The antenna is fabricated on an ion-implanted SOS wafer.

The Experimental Setup

The 20 μm wide antenna structure is located in the middle of a 20 mm long coplanar transmission line consisting of two parallel 10 μm wide, 1 μm thick, 5 Ω/mm, aluminum lines separated from each other by 30 μm. In the initial demonstration of this system a colliding-pulse mode-locked (CPM) dye laser, produced 623 nm, 70 fs pulses at a 100 MHz repetition rate in a beam with 10 mW average power. The 5 mW excitation beam was focused onto the 5 μm wide photoconductive silicon gap between the two antenna arms. The 70 fs laser creation of photocarriers causes subpicosecond changes in the conductivity of the antenna gap. When a DC bias voltage of typically 10 V is applied to the transmitting antenna, these changes in conductivity result in pulses of electrical current through the antenna and consequently bursts of electromagnetic radiation are produced. A large fraction of this radiation is emitted into the sapphire substrate in a cone normal to the interface with the radiation pattern presented in [21.95]. The radiation is then collected and collimated by a dielectric lens attached to the backside (sapphire side) of the SOS wafer [21.31]. The dielectric lenses were made of high-resistivity (10 kΩ cm) crystalline silicon with a measured absorption of less than 0.05 cm^{-1} in the presented frequency range [21.51]. The silicon lens is a truncated sphere with a 10 mm diameter and a focal point located at the antenna gap when attached to the back side of the chip. As shown in Fig. 21.19b, after collimation by the silicon lens, the beam diffracts and propagates to a paraboloidal mirror, where the THz radiation is recollimated into a highly directional beam, with beam diameters (10–70 mm) proportional to the wavelength. Thereafter, all of the frequencies propagated with the same 25 mrad divergence. After a typical 50 cm propagation distance this THz beam is detected by the THz receiver, where the paraboloidal mirror focuses the beam onto a silicon lens, which focuses it onto a SOS antenna chip, similar to the one used in the emission process. The electric field of the focused incoming THz radiation induces a transient bias voltage across the 5 μm gap between the two arms of this receiving antenna, directly connected to a low-noise current amplifier. The amplitude and time-dependence of this transient voltage is obtained by measuring the collected charge (average current) versus the time delay between the THz pulses and the delayed CPM laser pulses in the 5 mW detection beam. These pulses synchronously gate the receiver, by driving the photoconductive switch defined by the 5 μm antenna gap.

Measurements of Signal-to-Noise Ratio

An early time-resolved measurement [21.31] is shown in Fig. 21.20a. The clean pulse shape is a result of the fast action of the photoconductive switch at the antenna gap, the broadband response of the ultrafast antennas, the broadband THz optical transfer function of the lenses and paraboloidal mirrors, and the very low absorption and dispersion of the silicon lenses. The measured pulse width of 0.54 ps (FWHM) is only an upper limit to the true pulse width, because no deconvolution has been applied to the measurement to take out the response time of the antenna gap. This time-response will be determined in the next section of this article. In Fig. 21.20b, the Fourier transform of the measured signal (Fig. 21.20a) is shown to stretch from about 0.1 to 2.0 THz. This only represents a lower limit to the true extent of the emitted radiation as it contains the frequency response of the receiver. At the

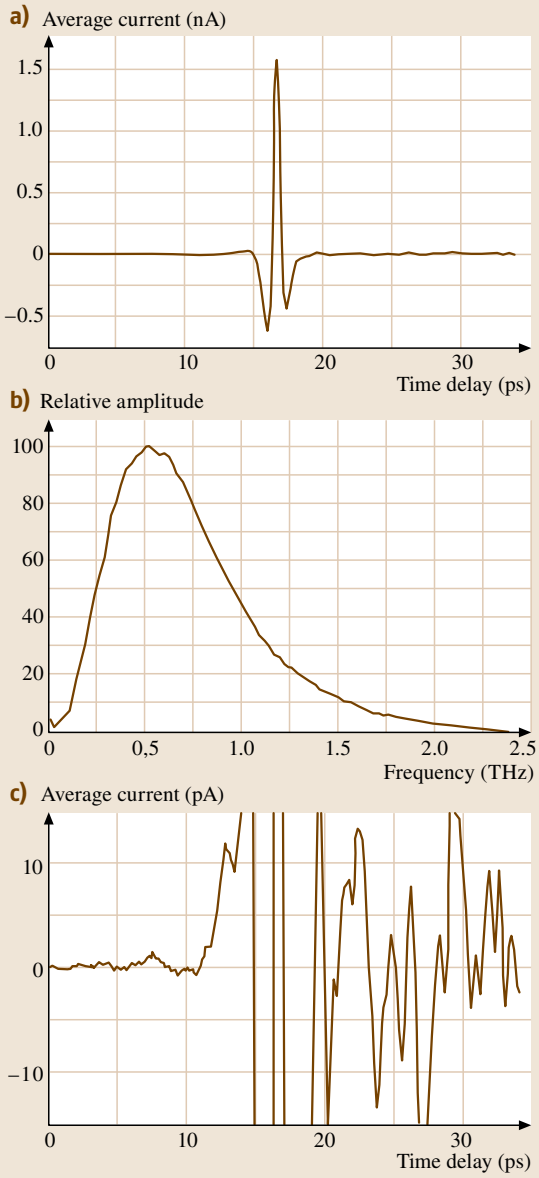

Fig. 21.20 **(a)** THz pulse measured to 35 ps. **(b)** Amplitude spectrum to 2.5 THz of the measured pulse shape. **(c)** THz pulse on a vertical scale expanded by a factor of 100. (after [21.31])

low-frequency end, the efficiency of both the emitter and receiver has been shown to be proportional to the length of the antenna, i. e., proportional to the separation between the two lines of the coplanar transmission line. For extremely low frequencies the size of the

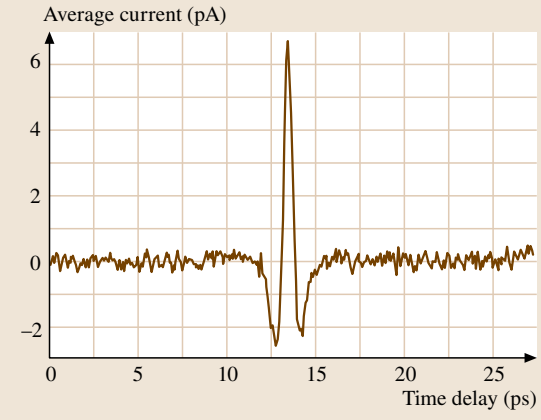

Fig. 21.21 Measured THz pulse to 27.5 ps with a 100 000 times reduction (compared to Fig. 21.20a) of the THz beam power. (after [21.31])

paraboloidal mirrors will also limit the efficiency. For the high-frequency limit the efficiency of the antenna is strongly reduced when half the wavelength (in the dielectric) of the emitted radiation is no longer small compared to the antenna length. The high-frequency part of the spectrum is also limited by the finite rise time of the current transient and the non-ideal imaging properties of the THz optics.

In Fig. 21.20c the time-resolved signal is shown on a vertical scale expanded by a factor of 100. The structure observable after the main pulse is reproducible and is due to reflections of the electrical pulse on the transmission line, reflections of the THz pulse from the various dielectric interfaces, and absorption and dispersion of residual water vapor. The signal-to-noise ratio in this 4 min scan is more than 10 000 : 1. Another 4 min scan is shown in Fig. 21.21, for which the intensity of the excitation laser beam was reduced to only 15 μW from the 5 mW normally used. The consequent 320-fold reduction in photocurrent indicates a reduction in the power of the THz beam by the factor 1/100 000. However, despite this enormous reduction in power, the peak amplitude is still more than 30 times larger than the rms noise. Based on previous calculations [21.31], the average power in the THz beam during this measurement was about 10^{-13} W. If the power of the THz beam were even further reduced, the detection limit of the THz receiver would be reached at 10^{-16} W, for a signal-to-noise-ratio of unity and a 125 ms integration time. Because the generation and detection of the THz (far-infrared) radiation is coherent, the THz receiver is approximately 1000

times more sensitive than an incoherent helium cooled bolometer [21.53].

The Semiconductor Time-Dependent Response Function

In the small antenna limit corresponding to the Hertzian dipole, the generated radiation field is proportional to the time-derivative of the current pulse, which is mainly determined by the intrinsic response of the semiconductor itself. The intrinsic time-domain response function will now be derived for a semiconductor described by the simple Drude formalism. The free carriers are considered as classical point charges subject to random collisions, for which the collision damping is independent of the carrier energy. The frequency-dependent complex conductivity $\sigma(\omega)$ is given by

$$\sigma(\omega) = \sigma_{\mathrm{DC}} \frac{\mathrm{i}\Gamma}{\omega + \mathrm{i}\Gamma} , \tag{21.6}$$

where $\Gamma = 1/\tau$ is the damping rate and τ is the average collision time. The DC conductivity is given by $\sigma_{\mathrm{DC}} = e\mu_{\mathrm{DC}}N$, where e is the electron charge, μ_{DC} is the DC mobility and N is the carrier number density. According to Drude, $\mu_{\mathrm{DC}} = e/(m^*\Gamma)$, where m^* is the effective mass. This relationship (21.6) is in good agreement with recent time-domain spectroscopy measurements [21.31] on lightly doped silicon from low frequencies to beyond 2 THz. The following procedure is similar to that of [21.96]. It is helpful to recast the formalism into a frequency-dependent mobility as

$$\mu(\omega) = \mu_{\mathrm{DC}} \frac{\mathrm{i}\Gamma}{\omega + \mathrm{i}\Gamma} . \tag{21.7}$$

This relationship shows the fundamental limit to the frequency response of the photoconductive switch. It is important to note that at high frequencies compared to Γ, the imaginary part dominates and falls off with frequency as $1/\omega$. Surprisingly, this allows useful material response to reach up to tens of THz. For example if $\tau = 200\,\mathrm{fs}$, $\Gamma/2\pi = 0.8\,\mathrm{THz}$ and the response at 8 THz is 0.10 that at low frequencies, similarly, the response at 16 THz is 0.05 that at low frequencies. The DC current density is given by $J_{\mathrm{DC}} = \sigma_{\mathrm{DC}}E$, or equivalently $J_{\mathrm{DC}} = eE\mu_{\mathrm{DC}}N$, where E is a constant electric field. Because of the linearity of the current in N, for a time-dependent carrier density $N(t)$, the time-dependent current density can be written as

$$J(t) = eE \int_{-\infty}^{t} \mu\left(t - t'\right) N\left(t'\right) \mathrm{d}t' , \tag{21.8}$$

where $\mu(t - t')$ is the time-domain response function for the mobility. This function is determined by the inverse transform of the frequency-dependent mobility to be the causal function

$$\mu\left(t - t'\right) = \mu_{\mathrm{DC}}\Gamma\, \mathrm{e}^{-\Gamma(t-t')} \tag{21.9}$$

which vanishes for negative $(t - t')$.

In order to facilitate the understanding of the photoconductive switch it is useful to rewrite the basic equation (21.8) in the equivalent form,

$$J(t) = eEA \int_{-\infty}^{t} \mu\left(t - t'\right) \int_{-\infty}^{t'} R_{\mathrm{c}}\left(t' - t''\right) I\left(t''\right) \mathrm{d}t'' \, \mathrm{d}t' , \tag{21.10}$$

where $I(t'')$ is the normalized intensity envelope function of the laser pulse, A is a constant giving the conversion to absorbed photons/volume and R_{c} is the response function describing the decay of the photogenerated carriers. By defining a new photocurrent response function $j_{\mathrm{pc}}(t - t')$, we can rewrite (21.10) to become

$$J(t) = \int_{-\infty}^{t} j_{\mathrm{pc}}\left(t - t'\right) I\left(t'\right) \mathrm{d}t' , \tag{21.11}$$

where $j_{\mathrm{pc}}(t - t')$ is obtained by evaluating (21.10) with a delta function $\delta(t'')$ laser pulse. Assuming the causal function $R_{\mathrm{c}}(t' - t'') = \exp[-(t' - t'')/\tau_{\mathrm{c}}]$, describing a simple exponential decay of the carriers with the carrier lifetime τ_{c} (significantly longer than the average collision time τ) for positive $(t' - t'')$ and vanishing for negative $(t' - t'')$, and that $\mu(t - t')$ is given by the Drude response of (21.9), the causal response function $j_{\mathrm{pc}}(t^*)$ is then evaluated to be

$$j_{\mathrm{pc}}(t^*) = \frac{\mu_{\mathrm{DC}}eEA\Gamma}{\Gamma - 1/\tau_{\mathrm{c}}} \left(\mathrm{e}^{-t^*/\tau_{\mathrm{c}}} - \mathrm{e}^{-t^*/\tau} \right) \tag{21.12}$$

for positive $t^* = (t - t')$ and shown to vanish for negative t^*. In the short-pulse limit of the ultrafast excitation pulses, the time dependence of the photocurrent $J(t)$ is approximately equal to that of the photocurrent response function $j_{\mathrm{pc}}(t^*)$ for positive t^*. For a long carrier lifetime, the time dependence of $j_{\mathrm{pc}}(t^*)$ is described by a simple exponential rise with a rise time on the order of $\tau = 1/\Gamma$, which is equal to 270 fs and 150 fs for the electrons and holes, respectively, in lightly doped silicon as previously measured [21.97,98]. As these results show, the material response can be slow compared to the

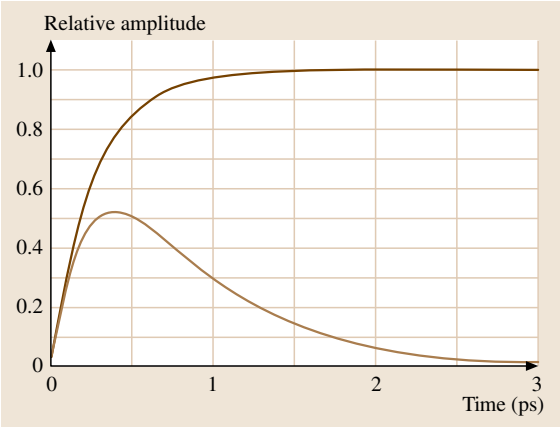

Fig. 21.22 Calculated photoconductive response function to 3 ps with the scattering time $\tau = 270$ fs and infinite carrier lifetime τ_c (*upper curve*) and with $\tau_c = 600$ fs (*lower curve*)

duration of the ultrafast laser excitation pulses, which can be as short as 10 fs, but is more typically on the order of 60 fs.

The time-dependent response function described by (21.12) is displayed in Fig. 21.22 for the two cases: $\tau = 270$ fs and $\tau_c = \infty$, and $\tau = 270$ fs and $\tau_c = 600$ fs. The result for infinite carrier lifetime has the following intuitive interpretation. After the instantaneous creation of carriers, the initial current and mobility are zero. The carriers then accelerate ballistically, as determined by the applied electric field, their charge and effective mass. This acceleration continues for a time approximately equal to the scattering time τ, after which the velocity and current equilibrate to their steady-state value. This discussion will now be shown to accurately describe the mathematical dependence of (21.12). With $\tau_c = \infty$, (21.12) is equal to

$$j_{pc}(t^*) = \mu_{DC} eEA \left(1 - e^{-t^*/\tau}\right) \qquad (21.13)$$

which, for times that are short compared to τ, reduces to

$$j_{pc}(t^*) = \mu_{DC} \frac{eEAt^*}{\tau} . \qquad (21.14)$$

Remembering that for Drude theory $\mu_{DC} = e/(m^*\Gamma)$, (21.14) is equivalent to

$$j_{pc}(t^*) = Aet^* \left(\frac{eE}{m^*}\right) \qquad (21.15)$$

which describes the ballistic acceleration eE/m^*.

Measurements of the Time-Dependent Response Function

Here the performance of a new type photoconductive receiver with a measured response exceeding 6 THz is described and analyzed by the above Drude [21.99]. This receiver used a prototype composite optoelectronic chip shown in Fig. 21.23. By using an identical receiver in a high-performance optoelectronic THz beam system as the transmitter, we were able to characterize the receiver with exceptional precision. The antenna structure, used for both the transmitter and receiver, is the same as shown in Fig. 21.19a, but with the reduced size of two parallel 5 μm wide lines separated from each other by 10 μm. A colliding-pulse mode-locked (CPM) dye laser provided the 5 mW focused beams of 623 nm, 80 fs excitation and sampling pulses. Excellent agreement with the Drude theory model was obtained for the photoconductive response.

Using this receiver, a source spectrum was measured with a FWHM bandwidth almost twice as broad as the initial experimental characterization of a similar system using SOS chips [21.96]. The improved performance was due to the following changes. Firstly, the positions of the paraboloidal mirrors were set to have a unity transfer function for the THz radiation [21.100]. Secondly, exceptional care was taken to match the foci of the silicon lenses to the antenna positions. For on-axis focusing, a series of observations were made using lenses of the same curvature, but with thicknesses varying in steps of 50 μm. In the plane of the chip, the position of the focus was adjusted to ±20 μm. Thirdly, the new composite chip was used to eliminate the absorption of the incoming THz radiation by the sapphire substrate of the previously used SOS detection chip. The 0.5 μm thick active layer of LPCVD polysilicon of the composite chip was annealed at 1000 °C for 1 h in a nitrogen atmosphere and was later implanted with 200 keV and 100 keV oxygen ions both at a dose of 10^{13} /cm^2. The underlying 0.7 μm thick thermal oxide layer was grown on a high resistivity silicon substrate.

The THz pulse measured with the ultrafast receiver is shown in Fig. 21.24a. The fall-time (90–10%) from the peak of the pulse to the minimum is only 127 fs,

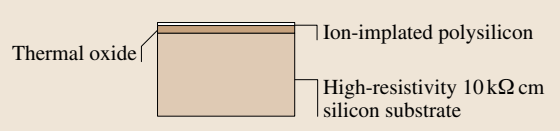

Fig. 21.23 Cross section of the composite chip

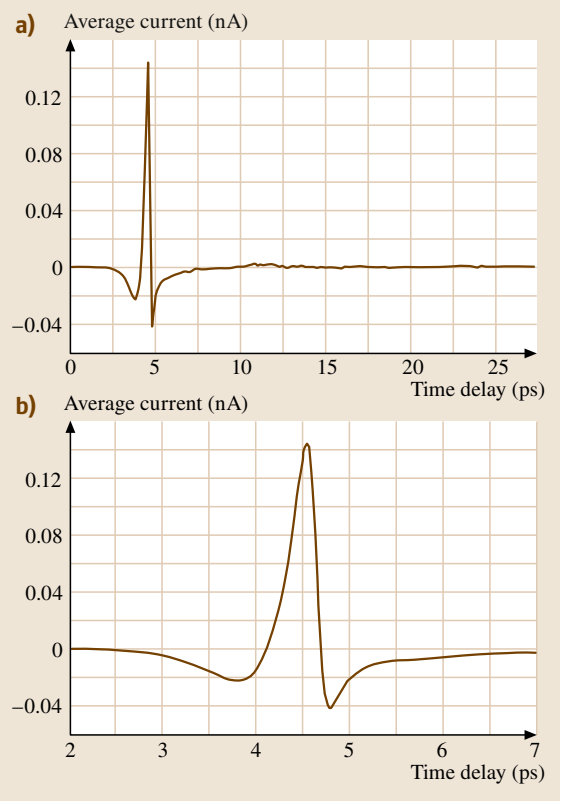

Fig. 21.24 **(a)** THz pulse measured by the ultrafast receiver. **(b)** Measured THz pulse on an expanded time scale (after [21.99])

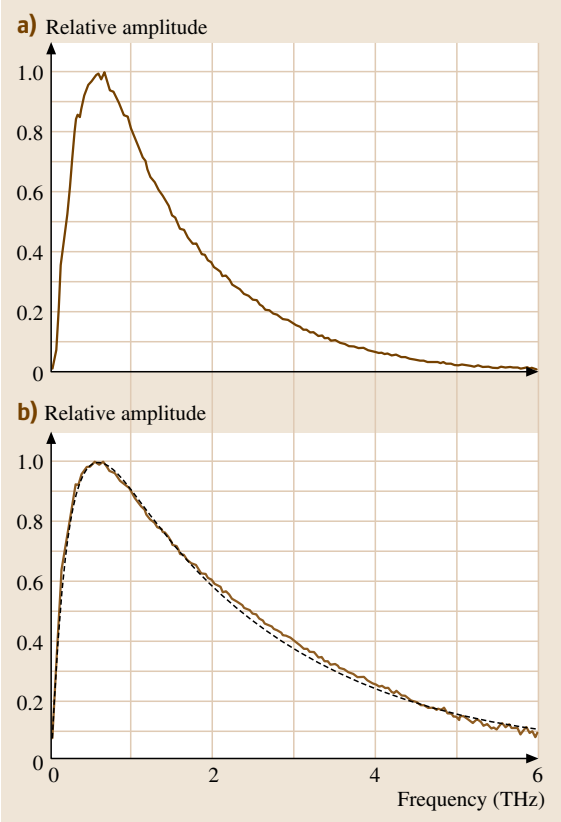

Fig. 21.25 **(a)** The numerical Fourier transform of Fig. 21.24a, equal to the receiver power spectrum. **(b)** Comparison of the calculated receiver amplitude spectrum (*dashed line*) with the measured amplitude spectrum (square root of **(a)**) (after [21.99])

as shown in the expanded view of Fig. 21.24b. This exceptional time resolution demonstrates that a photoconductive receiver can be much faster than is generally realized [21.99], but is consistent with the earlier prediction (for SOS chips) of a 150 fs time resolution [21.96]. The numerical Fourier transform of this pulse peaks at approximately 0.5 THz and extends to 6 THz, as shown in Fig. 21.25a. Because the measured spectrum is the product of the identical transmitter and receiver amplitude spectra, the receiver amplitude spectrum shown in Fig. 21.25b is simply the square root of the measured spectrum of Fig. 21.25a.

The theoretical understanding of the above results will now be presented. Because of the extremely fast electrical response, the current in the ultrafast antenna follows the current $J(t)$ in the semiconductor, where $J(t)$ is determined by the convolution of the photoconductive response function and the 80 fs (FWHM) sech^2-shaped laser driving pulse. Following the preceeding theoretical procedure, the response function is derived from simple Drude theory with a scattering time of 120 fs and a carrier lifetime of 600 fs.

The time-domain response function $j_{\text{pc}}(t^*)$ is assumed to be given by (21.12). This response function is then convolved with the laser pulse, as prescribed by (21.11). Using the above parameters the calculated shape of the current pulse in the photoconductive switch and the Hertzian dipole antenna is presented in Fig. 21.26a. The time derivative of this pulse is given in Fig. 21.26b, where an extremely fast transient, corresponding to the rising edge of the current pulse, is seen. Quantitative evaluation of this time-derivative shows that the Hertzian dipole antenna generates a 150 fs FWHM pulse of THz radiation. Conversely, by the reciprocity principle, 150 fs is also the time resolu-

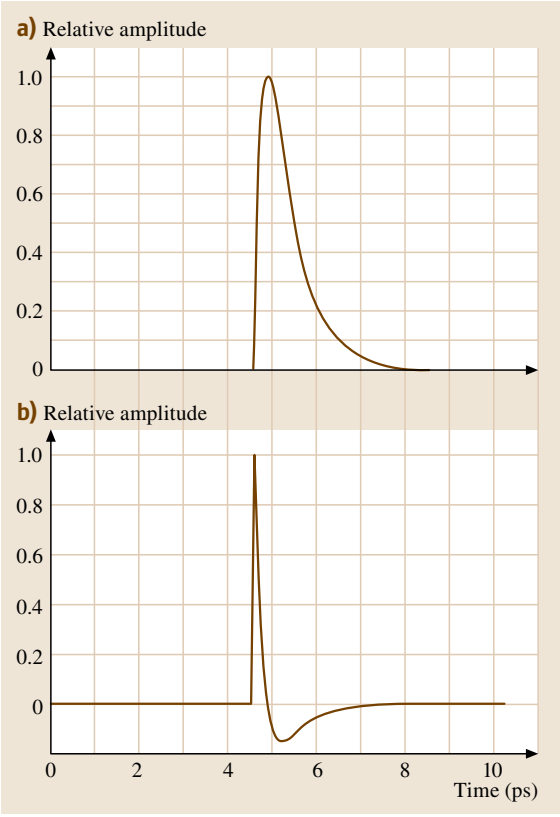

Fig. 21.26 **(a)** Calculated current pulse (11 ps timescale) in semiconductor and antenna. **(b)** Time derivative of the current pulse

tion of the photoconductive receiver. The numerical Fourier transform of Fig. 21.26b is the predicted amplitude spectrum of the transmitter. In Fig. 21.25b, this spectrum is compared with the measured amplitude spectrum of the receiver. The excellent agreement with experiment shows that, to a very good approximation, the semiconductor response follows Drude theory and that the resulting response time is limited by the ballistic acceleration of the photocarriers. As expected, the calculated amplitude spectrum falls off faster than the intrinsic material response of $\mu(\omega)$ defined by (21.7), due to the 80 fs optical pulsewidth compared to the delta function response.

It has also been shown that the 10 μm long antenna imbedded in the coplanar transmission line has electrical properties much faster than the semiconductor itself. Consequently, the performance is completely determined (and limited) by the intrinsic response time of the semiconductor.

21.2.2 Other THz Transmitters

Because essentially all of the existing and proposed THz applications are constrained by the limiting S/N ratio, any improvement in S/N would provide faster data acquisition rates and would improve the quality of the experimental comparisons. Large increases in S/N would make new applications possible. The most important approach to increase S/N is to increase the transmitter power, while at the same time maintaining or extending the THz bandwidth. This has become particularly appropriate because typical, ultrafast Ti-sapphire mode-locked lasers can produce 500 mW of beam power, compared to the previously used CPM lasers, which produced only on the order of 20 mW of beam power. For example, the GaAs TEF transmitter chip [21.44, 94, 100] (described below) is limited by optical damage to GaAs to a maximum average laser power of only 20 mW in the ultrafast Ti-sapphire driving laser pulse stream. A THz research group at the University of Bath (UK) has attained a 100-fold increase in transmitter power levels from the GaAs TEF chip by focusing a more powerful laser beam (well above the usual operating limits) with a cylindrical lens to produce a highly elliptical focus to minimize saturation and material damage.

A Bell Labs group [21.101], using a field-singularity emitter and a 50 μm dipole receiver antenna fabricated on low-temperature (LT) GaAs, has observed signal strengths of more than 100 times larger than typical results using GaAs or SOS transmitters, and SOS receivers. Although their THz conversion efficiency was essentially the same as for the GaAs TEF transmitter, the increase in THz power and S/N for the Bell Labs work were obtained by driving the LT-GaAs transmitter and the LT-GaAs receiver with optical powers almost an order of magnitude above the allowable operating power levels of the above-described GaAs and SOS transmitter and receiver chips. As shown by this example and earlier work, LT-GaAs has significant potential to extend both the output power and frequency response of photoconductive switches, transmitters and receivers, due to its high resistivity, high carrier mobility and short carrier lifetime [21.41–43, 102–107]. LT-GaAs is much more resistant to optical breakdown than GaAs and is also more resistant to electrical breakdown. In addition, the carrier lifetime can be controlled by annealing temperature and can be made to be lower than 300 fs [21.106, 107]. Currently, the main problem preventing widespread utilization of LT-GaAs is that the

commercial LT-GaAs wafer cost is about five times that of either GaAs or SOS.

GaAs Trap Enhanced Field (TEF) THz Source

A different type of high-performance optoelectronic source chip [21.44] is shown in Fig. 21.27d. The simple coplanar transmission line structure consists of two 10 μm wide metal lines separated by 80 μm fabricated on semi-insulating GaAs. Irradiating the metal–semiconductor interface (edge) of the positively biased line with focused ultrafast laser pulses produces synchronous bursts of THz radiation. This occurs because each laser pulse creates a spot of photocarriers in a region of extremely high electric field, called the trap-enhanced field [21.94]. In the initial demonstration of this source, a CPM dye laser provided 60 fs excitation pulses with an average power of 5 mW at 5 μm diameter excitation spot. This GaAs trap-enhanced field (TEF) source chip is completely compatible with the previously described optoelectronic THz beam system. However, this chip is limited only to the transmitter, because of its long carrier lifetime.

The measured THz pulse emitted from the laser excited GaAs TEF source chip with +60 V bias across the transmission line is shown in Fig. 21.27a, and on an expanded time scale in Fig. 21.27b. The measured pulse width with no deconvolution is seen to be 380 fs. At the time these results were obtained [21.44], they were the shortest directly measured THz pulses; the dip on the falling edge was the sharpest feature ever observed with an ion-implanted detector and indicated a response time faster than 190 fs. The amplitude spectrum (numerical Fourier transform) of the pulse extends beyond 3 THz, as presented in Fig. 21.27c. The sharp line structure is due to residual water vapor present in the system.

The GaAs TEF source remains one of the most efficient THz sources today and is the main THz transmitter chip used by the Oklahoma State University Ultrafast THz Research Group. In Fig. 21.28a we show a recent THz pulse measurement using the same type of GaAs TEF transmitter chip shown in Fig. 21.27d together with a low-noise, ion-implanted SOS receiver chip with the same antenna pattern as Fig. 21.19a, but with two parallel 5 μm wide lines separated from each other by 10 μm. To achieve a lower noise level,

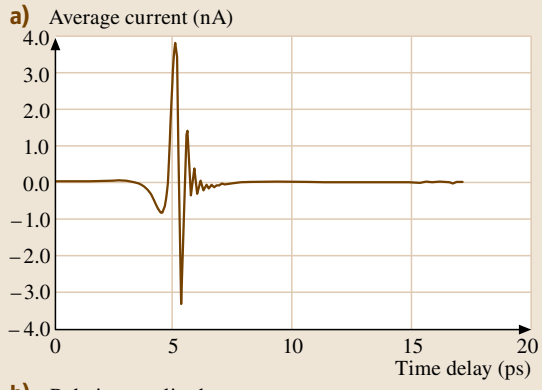

Fig. 21.28 **(a)** Measured THz pulse. **(b)** Amplitude spectrum of the THz pulse

the silicon layer was stripped off the SOS chip, except for the active photoconductive switch. The RMS noise level on the leading edge of the pulse is 0.1 pA, thereby giving an amplitude signal to noise ratio of more than 10 000. A Ti:sapphire mode-locked laser producing 60 fs, 780 nm pulses at a 100 MHz repetition rate provided the 10 mW excitation and 10 mW detection beams. As shown in Fig. 21.28b, the amplitude spectrum of this pulse extends from 0.2 to beyond 4.5 THz, allowing THz-TDS measurements in this frequency range.

Large Aperture Planar Photoconductor

In contrast to the Hertzian dipoles and micron-sized transmitter antennas described above, a THz transmitter approach based on large planar photoconductive apertures on the semiconductor surface has been demonstrated [21.108], as illustrated in Fig. 21.29. Here the biasing electrodes are separated by many millimeters

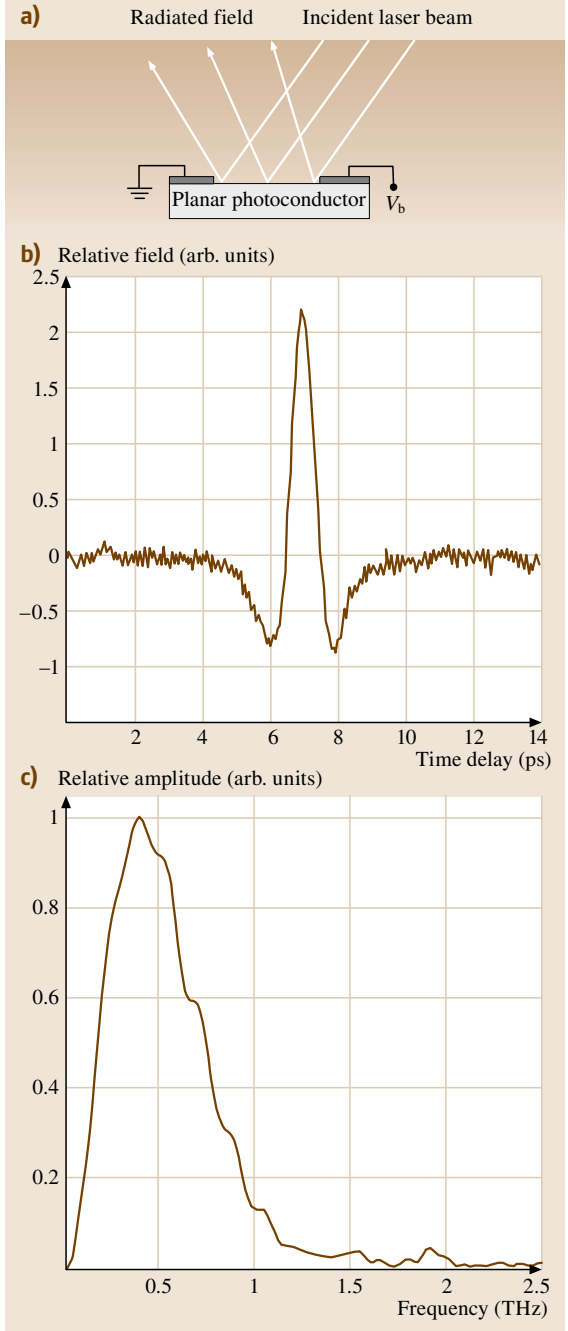

Fig. 21.29 **(a)** Schematic diagram of the large-aperture planar photoconductor. **(b)** Measured THz pulse. **(c)** Amplitude spectrum of the THz pulse (after [21.108])

and the bias voltages can be many kilovolts. The spot illuminated by the ultrafast exciting laser pulses is many millimeters in diameter, equivalent to many wavelengths of the radiated THz signal. For the experiment described by Fig. 21.29 the optical driving beam had a 4 mm diameter, and the photoconductive material was ion-implanted SOS. The CPM dye laser provided 75 fs pulses at 625 nm at a repetition rate of 100 MHz with approximately 10 mW of average optical power in the pump beam and 5 mW in the probe beam. The resulting radiated THz pulse was detected with a 100 μm photoconductive dipole antenna on SOS at the focus of a 3 mm sapphire ball lens.

The detected THz pulse is shown in Fig. 21.29b, and the corresponding amplitude spectrum is shown in Fig. 21.29c. The detector was placed 7 mm from the transmitter and was aligned in the specular direction for maximum signal. When the distance between the THz transmitter and detector was increased, the signal decreased as the inverse of the separation, and the pulse shape changed from the unipolar shape of Fig. 21.29b to a bipolar shape. The important possibility demonstrated by this experiment is the ability to scale up the optical power to very high levels, and thereby obtain very high power beams of THz pulses.

This possibility was realized in the later experimental demonstration of the scaling of these THz pulses to high energy (0.8 μJ), while maintaining both high bandwidth and short pulse duration (450 fs) [21.109]. This work achieved focused peak THz fields greater than 150 kV/cm. Such high-power THz pulses can be used for nonlinear quasioptics, multiphoton spectroscopy and ionization. An important feature of these THz pulses is the large asymmetry of at least 5 : 1 in the magnitude of the positive and negative components. Thus, to a reasonable theoretical approximation, these pulses can be considered to be half-cycle pulses, a situation very important to their utilization to ionize Rydberg atoms [21.110].

The GaAs wafers used to generate the high-power THz pulses were illuminated at normal incidence by 120 fs, 770 nm pulses from a Ti:sapphire chirped-pulse amplifier system, while a pulsed electric field was applied across the surface [21.109]. The aluminum electrodes, separated from each other by 1 cm, were connected to the GaAs surface with silver paint. Although THz radiation was observed in both the transmitted and reflected directions, only the transmitted radiation was used. The THz pulse energy was measured both with a helium cooled bolometer and a room-temperature pyroelectric detector.

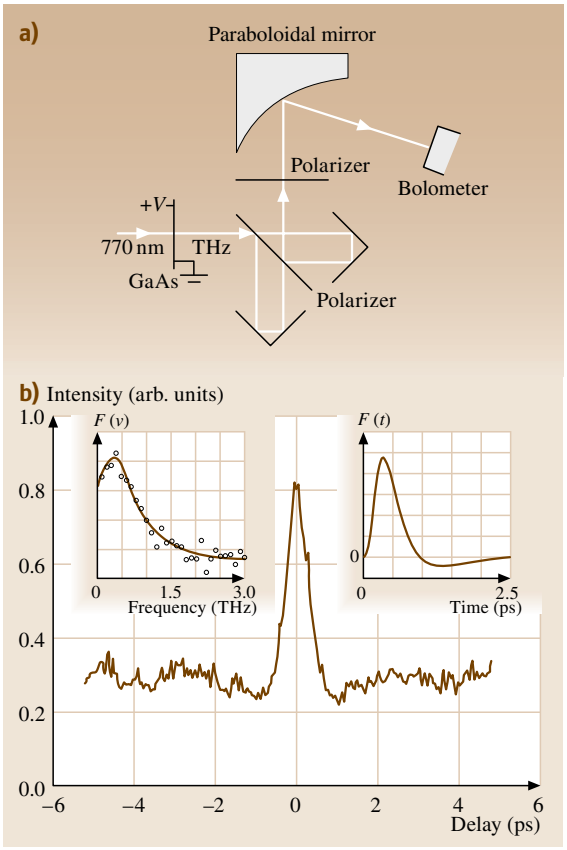

Fig. 21.30 **(a)** The interferometer. **(b)** The interferogram obtained by measuring the total THz energy as a function of delay in one arm of the interferometer. The *left inset* is the spectrum of the THz pulses obtained from the interferogram. The *right inset* indicates the asymmetric THz pulse shape (after [21.109])

The power spectrum of the generated THz pulses was obtained by Fourier transform spectroscopy using the interferometer shown in Fig. 21.30a. Typical interferograms measured with the bolometer were 600 fs wide, as shown in Fig. 21.30b, independent of the driving laser intensity, laser polarization, and bias field. The Fourier transform of the interferogram yields the spectral width of 1 THz as shown in the inset of Fig. 21.30b.

High-Surface Field Photoconductors

Another photoconductive THz source that has found significant use and interest requires no external bias voltage and no lithography, because it uses the static internal field at the semiconductor surface, which is perpendicular to the surface [21.36]. Consequently, when

such a bare semiconductor wafer is illuminated by femtosecond optical pulses, THz pulses are emitted from the surface in the form of freely propagating electromagnetic beams in the inward and outward directions. The amplitude and phase of the radiated THz pulse depend on the carrier mobility, and the strength, direction and polarity of the internal field.

Figure 21.31a shows the semiconductor illuminated by an unfocused optical beam together with the reflected optical beam and the consequent outward THz radiation and transmitted THz radiation. The CPM dye laser produced 2 nJ, 70 fs, 720 nm output pulses at a 100 MHz repetition rate. The CPM optical beam was split into two beams (30 and 70%), where the stronger excitation beam was modulated by a mechanical chopper at 2 kHz. The weaker sampling beam passed through a variable time delay and was used to gate a dipole antenna fitted with a sapphire lens for detection of the radiated THz pulse. Figure 21.31b shows a THz pulse from semi-insulating InP, detected by the dipole antenna in the outward direction (45° relative to the normal) with a 4 mm diameter laser excitation beam. The measured time response is limited by the dipole detector, which has an optimum frequency of 0.6 THz. The transmitted THz pulse through a 0.4 mm thick semi-insulating InP wafer was measured as a function of the angle of incidence of the excitation beam, by rotation of the wafer. These results are shown in Fig. 21.31c and indicate that the direction of current flow is along the direction of the surface field perpendicular to the wafer surface. Using this surface field technique, THz radiation pulses were generated from InP, GaAs, GaSb, InSb, CdTe, CdSe, and Ge, but not from Si [21.36]. Semi-insulating InP showed the strongest THz radiation; the radiation strength of ⟨100⟩ InP is 2.5 times larger than ⟨111⟩ InP.

It was demonstrated some time ago that the application of an external magnetic field could enhance the THz pulse generation from the surface field [21.111, 112]. Renewed interest in this effect was stimulated by claims that very large enhancements in the average-power of the THz pulse generation result with the application of a large magnetic field [21.113]. Although later investigations showed that these claims were overstated by approximately 100 times, many investigations were performed to characterize all the attributes of the enhancement effect [21.114–116].

Recently, a relatively simple explanation of the B field enhancement has been provided by two groups [21.117, 118]. Firstly, the application of the

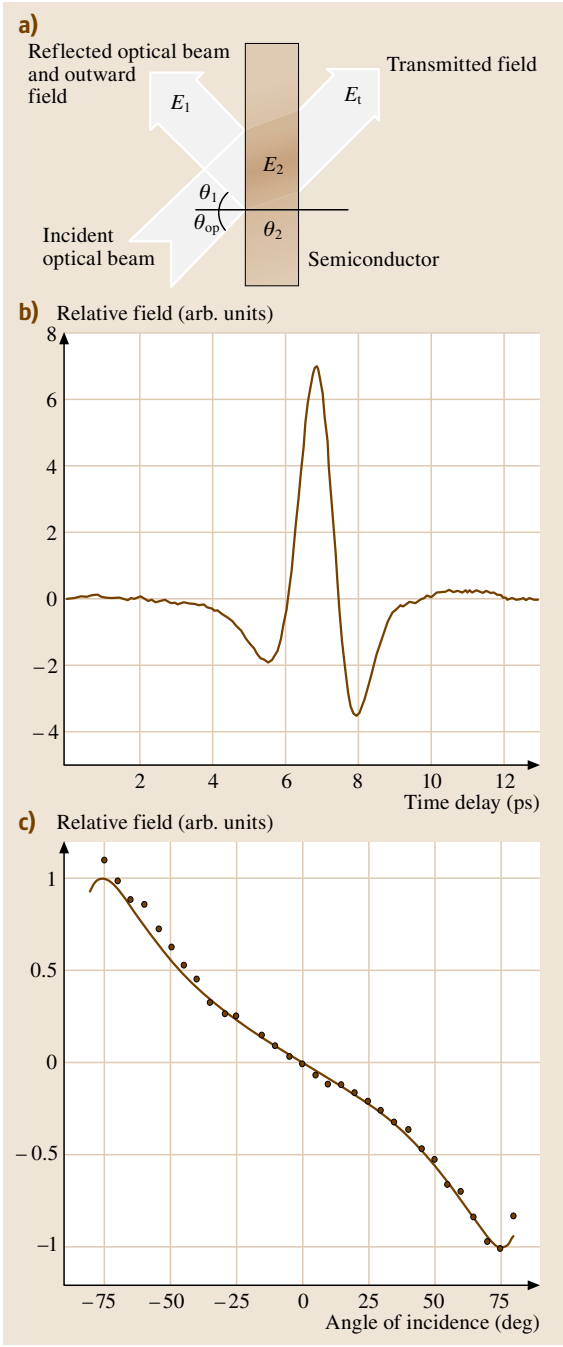

Fig. 21.31 **(a)** Electromagnetic beams generated from the semiconductor surface. **(b)** Measured THz pulse. **(c)** Transmitted THz pulse amplitude as a function of the incident angle (after [21.36])

B field does not increase the transient dipole responsible for the THz radiation. Secondly, the transient dipole and the consequent radiation pattern are reoriented by the *B* field, with respect to the surface boundaries of the semiconductor crystal. This reorientation of the radiation pattern can dramatically increase the output coupling from the crystal to free space. The coupling problem is quite important because of the high index of refraction of the crystal, which can lead to trapping of the THz radiation in the crystal.

Tunable CW THz Generation by PhotoMixing

A CW photomixer capable of producing tunable radiation can be realized by beating together two laser beams with frequencies above the band gap of a semiconductor [21.39, 40]. Depending upon the generated photocarrier lifetimes and the techniques used to couple out the generated radiation, this method can produce tunable THz radiation at the difference frequency between the two lasers [21.41–43]. The experimental demonstration of CW coherent output over the frequency range from 0.2 to 3.8 THz utilized a low-temperature-grown GaAs (LTG-GaAs, more commonly designated as LT-GaAs) photomixer [21.41–43]. The advantages of LT-GaAs are its short photocarrier lifetime, determined to be 0.27 ps, and the high electrical breakdown field. As shown in the inset of Fig. 21.32a, the LT-GaAs wafer was fabricated with a pattern of interdigitated electrodes covering an area of $20 \times 20\,\mu m$ and connected to opposite $20 \times 20\,\mu m$ bonding pads. After electron-beam lithography, the pads were connected to a three-turn self-complimentary spiral antenna shown in Fig. 21.32a, for which the low frequencies radiate from the outer extent of the spiral and the high

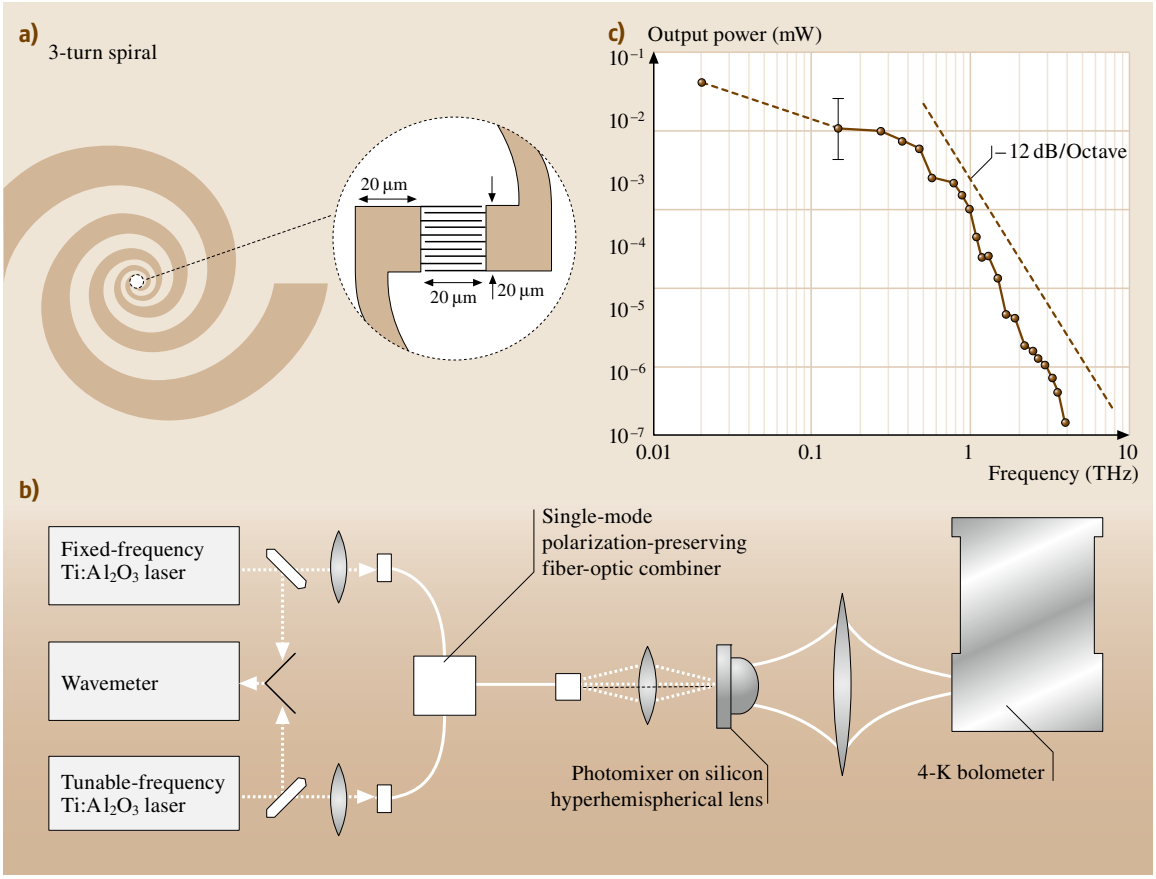

Fig. 21.32 **(a)** Three-turn self-complimentary spiral antenna. The *inset* shows an expanded view of the interdigitated-electrode photomixer structure. **(b)** Experimental setup for the LT-GaAs photomixer. **(c)** Measured output power from the photomixer (after [21.43])

frequencies from the inner extent. For the inner radius (40 μm) and outer radius (1.8 mm) of the actual antenna, the operating range was estimated to be approximately 60 GHz to 1.0 THz. The photomixer was characterized by the setup shown in Fig. 21.32b, for which the tunable optical pump power was provided by two Ti:Al_2O_3 lasers operating near 780 nm and with 25 mW in each laser beam. The photocurrent generates THz radiation at the tunable difference frequency between the two lasers from the antenna with a bias voltage of 25 V. The emitted radiation propagates predominantly into the GaAs substrate and then into a high-resistivity silicon lens in contact with the backside of the substrate. The THz output beam from the lens is subsequently focused by a plastic lens onto a liquid-helium-cooled Si bolometer. The measured THz output power is shown in Fig. 21.32c.

Electrooptic THz Generation

The generation of pulses of THz (far-infrared radiation) by the passage of a short optical pulse through a nonlinear optical material was demonstrated many years ago [21.33]. For this pioneering experiment 2 ps optical pulses from a mode-locked Nd:glass laser were focused onto and transmitted through millimeter-thick $LiNbO_3$ crystals. The resulting THz radiation was split into two beams. One beam was used for spectral analysis by either a Michelson or a Fabry–Pérot interferometer; the other beam was used for normalization. Both beams were separately detected by two n-type InSb (Putley) detectors at 1.5 K in a magnetic field of 5.4 kG. The resultant signals were displayed on an oscilloscope. An example of these early results is shown by the measured far-infrared power spectrum in Fig. 21.33. The experimental points were obtained from the Michelson interferogram and the solid curve is from a theoretical calculation assuming Gaussian laser pulses with a 1.8 ps pulse width. The spectrum can be understood as a product of (1) the spectral content of the mode-locked pulses, (2) a radiation efficiency curve, and (3) a phase-matching curve centered at zero frequency.

The propagation of fs optical pulses in electrooptic materials is also accompanied by the radiation of an extremely fast electromagnetic transient [21.34, 119, 120]. This phenomenon, arising from the inverse electrooptic effect, produces a Cherenkov cone of pulsed radiation having a duration of approximately one cycle and a frequency in the THz range. Although closely resembling classical Cherenkov radiation from relativistic charged particles in dielectric media, it is due to a nonlinear optical effect. The charge state of the effective source is

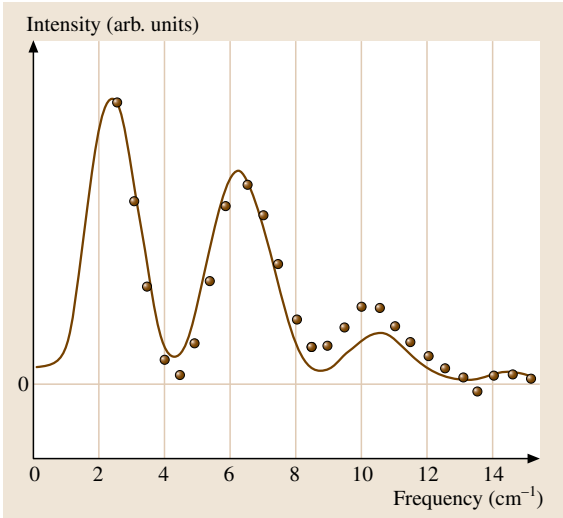

Fig. 21.33 Far-infrared (THz) power spectrum generated by mode-locked pulses in $LiNbO_3$ (after [21.33])

neutral, being an extended dipole moment, rather than a point charge; the velocity of the source significantly exceeds the radiation velocity. This situation, indicated in Fig. 21.34a, produces the characteristic Cherenkov conical shock wave. Because the spatial extent of the radiation source is proportional to the intensity envelope of the optical pulse, the radiation field depends on both the time duration and the beam waist of the optical pulse.

As indicated in Fig. 21.34a, two optical pulses were used, one to generate the radiation field, and the other to detect it. The 100 fs, 625 nm optical pulses were obtained from a CPM mode-locked dye laser, with a relatively low pulse energy of 0.1 nJ at a repetition rate of 150 MHz. The configuration of Fig. 21.34a uses electrooptic sampling [21.2, 3, 7–12] to measure the small birefringence produced by the electric field of the radiation pulse. A unique feature of the experiment is the automatic synchronism of the velocities of the radiation field and the probing pulse. As indicated in Fig. 21.34a, the probing pulse *surfs* along the Cherenkov wavefront enabling it to measure the electric field at a stationary point in the waveform by integrating the birefringence along the entire path through the crystal. To obtain the measured waveform, the timing of the probing pulse was slowly swept relative to the generating pulse by a computer controlled variable path length. The measured Cherenkov waveform shown in Fig. 21.34b is extremely fast and approximates a single cycle of frequency of 1.5 THz. The correspond-

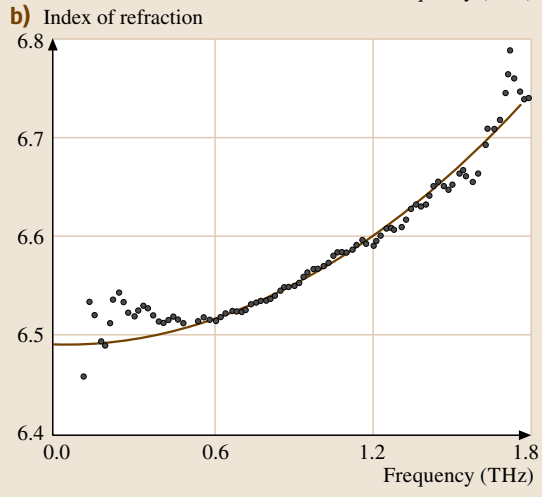
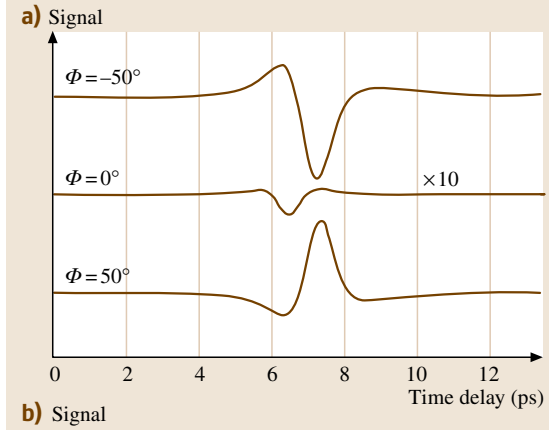
ing amplitude spectrum of this waveform is shown in Fig. 21.34c.

The coherent nature of the detection process enables the measurement of the far-infrared properties of materials by observing the change in the waveform due to their dispersion and absorption. Since the time reference is accurately known, phase information is measured as well, and consequently both the real and the imaginary parts of the dielectric function can be obtained [21.121, 122]. Such measurements of the absorption and index of refraction of lithium tantalate are presented below in Fig. 21.35 [21.122].

When a semiconductor is illuminated by an ultrafast laser pulse the sample can emit a THz radiation pulse, as shown in Fig. 21.31. This radiation can be due to the acceleration of the photocarriers in the surface field and for some semiconductors can be also due to optical rectification. It is possible to distinguish between the two processes by directing the incoming light beam at normal incidence to the semiconductor surface. For this case, the radiation from the photocarriers is not coupled out of the semiconductor, and the observed THz pulse radiated in the forward direction is due only to the optical rectification effect. This situation is demonstrated by the results shown in Fig. 21.36 [21.123]. For these results, the mode-locked Ti:sapphire laser illuminating the ⟨111⟩ GaAs sample had output pulse energies greater than 10 nJ, pulse durations of less than 200 fs and a repetition rate of 76 MHz. The laser beam was split into two parts by a beam splitter with a 0.05/0.95 reflection/transmission ratio. The stronger optical beam passed through a variable time delay stage and illuminated the semiconductor sample with a spot diameter of approximately 6 mm. The weaker optical beam, typically < 20 mW was used for optical gating a photoconducting 50 μm dipole antenna for detection of the emitted THz pulse.

The optical rectification signal was observed to change dramatically when the laser energy was tuned near the GaAs band gap. A more than 100-fold in-





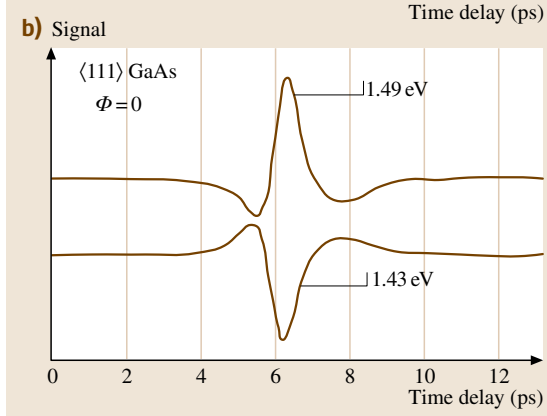


Fig. 21.35 **(a)** Absorbance of lithium tantalate. **(b)** Index of refraction. The *dots* are the measurements and the *solid lines* are the results of fitting the experimental points to a classical single-oscillator model (after [21.122])

crease in the signal was measured when the laser energy was tuned from 1.40 to 1.46 eV. The peak signal is reached when the laser energy is just above the band gap. As proof of the nonlinear nature of the effect, the THz signal was measured as a function crystal orientation with respect to the polarization of the laser beam and the expected threefold rotation symmetry was observed as shown in Fig. 21.36c. This work demonstrates the importance of optical rectification as a source of very short THz pulses, whose pulse widths are fundamentally limited only by the driving laser pulse width [21.123].

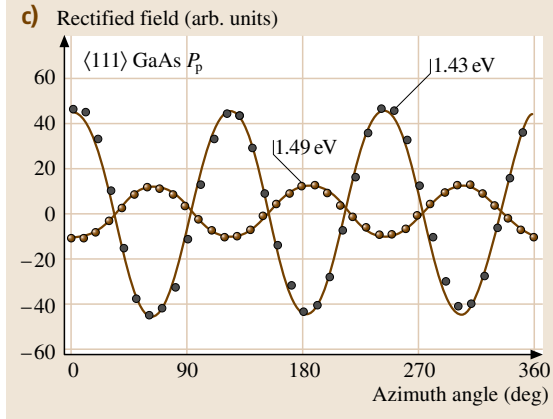

Fig. 21.36 **(a)** THz radiation from ⟨111⟩-oriented GaAs with normal (*center trace*) and ±50° (*upper* and *lower traces*) optical incident angles. **(b)** Emitted THz pulses with incident photon energies of 1.49 eV and 1.43 eV. **(c)** Generated THz pulse amplitude versus crystal azimuth angle. The *open* and *solid circles* are the experimental data at the two photon energies 1.43 eV and 1.53 eV, respectively. The *solid lines* are from theory (after [21.123])

In another demonstration of optical rectification of ultrafast laser pulses by GaAs, coherent far-infrared THz pulses were generated with a measured spectrum extending from 7 to 15 μm [21.124]. A Ti:sapphire laser, delivering 10–15 fs pulses at a 100 MHz repetition rate, was focused at normal incidence to a spot size of typically 20 μm diameter using a spherical mirror onto a 0.1 mm thick ⟨110⟩ GaAs plate. The resultant THz emission in the forward direction (transmitted through the sample) was directed onto a nitrogen-cooled HgCdTe detector sensitive to wavelengths up to 15 μm. A maximum THz power of 30 nW was measured for an incident laser power of 175 mW. The far-infrared THz spectra were obtained using a modified Michelson interferometer setup, synchronous detection, and numerical Fourier transforms. Figure 21.37a presents the THz power spectrum obtained for the generated THz pulse. The observed strong cutoff at 15 μm originates from the drop off of the spectral sensitivity. Figure 21.37b shows the electric field amplitude constructed from the spectrum of Fig. 21.37a, assuming a constant spectral phase. This work demonstrated that single-cycle THz generation can be extended to the near-infrared [21.124].

Using optical rectification and electrooptic sampling in ⟨110⟩ ZnTe for both the generation and coherent detection of freely propagating pulses of THz radiation, a wideband coherent THz-TDS system has been demonstrated [21.125], as shown in Fig. 21.38a. A mode-locked Ti-sapphire laser producing 130 fs pulses at 800 nm with a 76 MHz repetition rate was used to generate and detect the THz pulses. The 2 mm diameter pump beam, with an average power of 350 mW, was chopped and drove a 0.9 mm thick ⟨110⟩ ZnTe crystal at normal incidence. The pump beam was polarized at an angle of 60° to the ⟨110⟩ crystallographic direction in order to maximize the nonlinear response. The generated THz pulse was incident on an identical ZnTe crystal, after passage through a blocking Teflon filter. The incoming THz field was polarized parallel to the ⟨001⟩ axis of the ⟨110⟩ ZnTe sampling crystal. A 5 μm thick pellicle beam splitter in the THz beam line enabled the co-propagation of the optical probe and the THz beams through the sampling crystal. The probe beam was optically biased at the quarter wave point by a Soleil–Babinet compensator and a crossed polarizer arrangement was used to improve the sensitivity.

The measured 270 fs (FWHM) THz electric field pulse is shown in Fig. 21.38b. The small oscillations after the main peak were due, in part, to the free induction decay of the ambient water vapor excited by passage of the THz beam. In this geometry, both beams

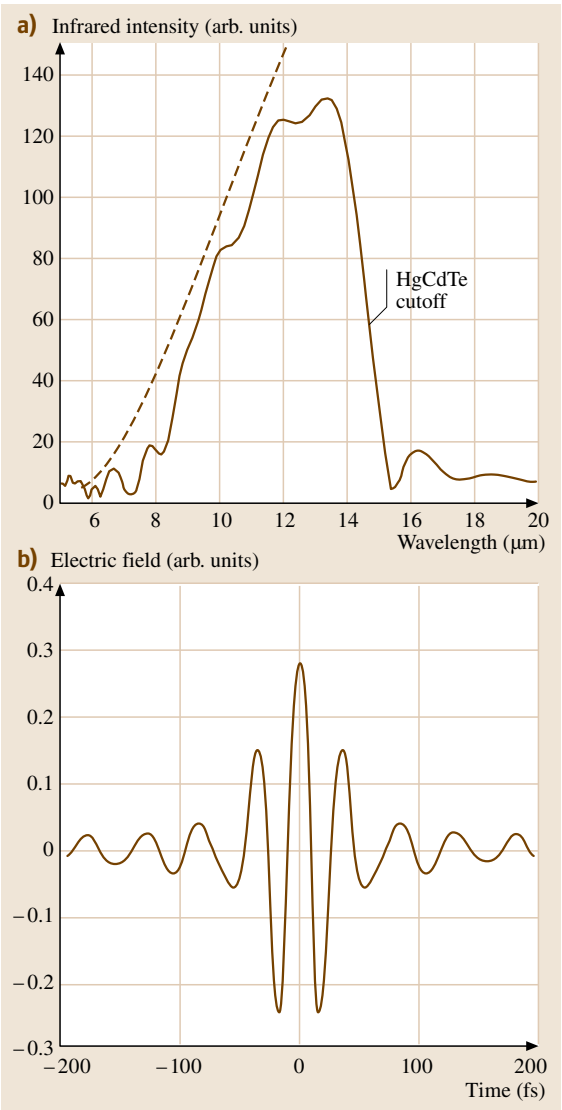

Fig. 21.37 **(a)** Power spectrum of the far-infrared THz emission obtained at normal incidence through the GaAs sample, as measured by the HgCdTe detector. **(b)** THz pulse electric field deduced from the spectrum assuming a negligible dispersion in the thin sample (after [21.124])

underwent multiple internal reflections within the sampling crystal, which were excluded from the data. The amplitude spectrum of the temporal waveform shown in Fig. 21.38c, demonstrates the wideband capability of the system. For this experiment the coherence length decreased rapidly beyond 2 THz due to the THz crystal dispersion.

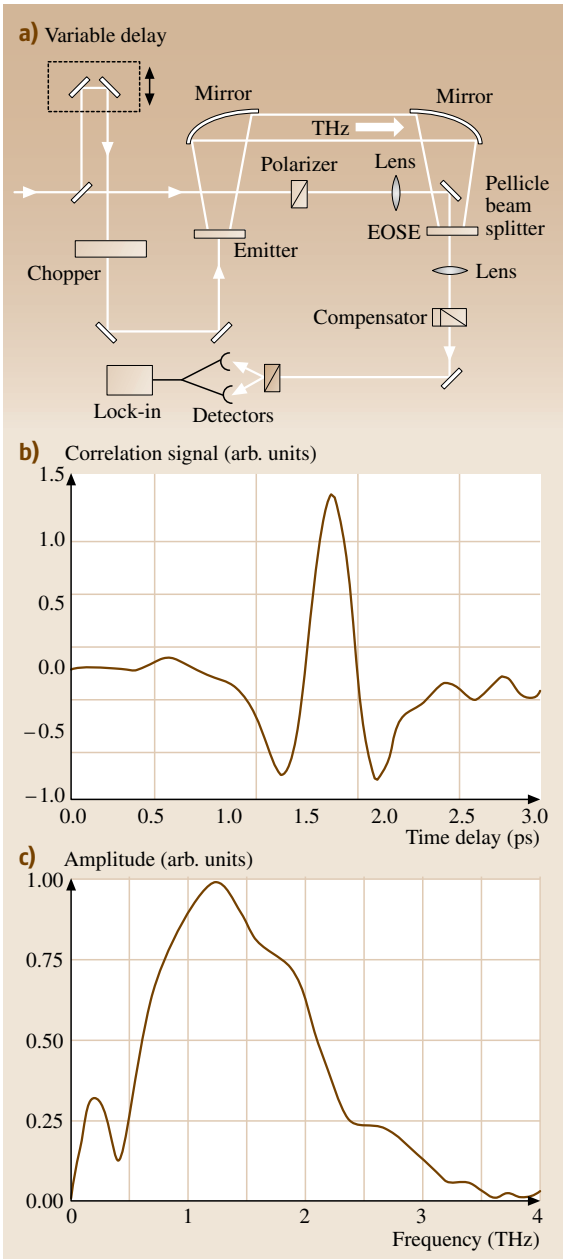

Fig. 21.38 **(a)** Schematic diagram of the experimental setup. **(b)** Measured THz pulse. **(c)** Amplitude spectrum of the measured THz pulse (after [21.125])

Another all-optical THz generation and detection system with a bandwidth of 7 THz has been reported [21.126], as shown in Fig. 21.39a. The ultrabroadband THz radiation was generated via optical rectification from ⟨110⟩ oriented GaAs, and coherently detected via free-space electrooptic sampling using a 150 μm thick, ⟨110⟩ GaP crystal. The Ti:sapphire laser source had an output power of up to 2 W and a minimum pulse width of 45 fs. An uncoated 2 μm thick pellicle

beam splitter, transparent to the THz beam was used to reflect about 50% of the optical probe beam collinearly along the THz beam into the GaP sensor. An optical chopper modulated the pump laser beam at 1.5 kHz for phase sensitive detection by a lock-in amplifier. Excess common-mode laser noise was effectively canceled by using a pair of identical photodetectors in a balanced detection scheme, so that the detection is primarily shot-noise limited. The laser pump beam with an average power of 1.5 W and 50 fs pulses was focused at normal incidence with a 25 cm focal length lens onto a ⟨110⟩ oriented GaAs crystal directly attached to the flat surface of a 12 mm diameter silicon collimating lens. The peak intensity at the emitter was about 1 GW/cm^2, limited by optical damage to the emitter surface.

Figure 21.39b displays the measured THz pulse. After an average of four consecutive scans, the peak-to-peak noise floor $\Delta I/I$ was below 10^{-8} as shown in the inset. The measured 185 fs THz pulse width (FWHM) was the shortest directly measured pulse duration at that time. The corresponding Fourier transform in Fig. 21.39c shows a 3 dB bandwidth of 3.6 THz with the upper frequency response reaching 7 THz.

21.2.3 Other THz Receivers

The bandwidth of the photoconductive THz receiver is limited most fundamentally by the ballistic acceleration of the generated carriers. In addition, the antenna response can be another limitation. An attractive alternative is based on electrooptic detection, where the receiver response is determined by the very fast electronic nonlinearity. Consequently, the THz receiver bandwidth could in principle be extended to tens of THz.

Electrooptic Detection

The first two demonstrations of electrooptic detection of freely propagating THz radiation were submitted for publication within a few days of each other [21.127, 128]. The Columbia group [21.128] used a 10 μm thick poled polymer film in their electrooptic sampling element and achieved an approximate 1 ps time resolution with a signal-to-noise ratio of 10. The RPI group [21.127] used a 500 μm thick $LiNbO_3$ crystal as their nonlinear element also achieving an approximate 1 ps rise time with a S/N = 10. These initial observations have been markedly improved upon by the same groups, as illustrated by their complete electrooptic THz systems shown in Figs. 21.38 and 21.39. Electrooptic (EO) detection of pulses of THz radiation [21.126, 129] has now demonstrated impressive bandwidths out to 70 THz [21.130]. However, as shown by the recent THz-TDS characterization of the important EO crystal ZnTe [21.131] and another THz-TDS characterization of other EO crystals [21.132], the EO technique is constrained by the THz absorption of the EO crystal, group-velocity matching between the measured THz pulse and the optical probing pulse, and the frequency-dependent nonlinearity [21.130,131,133]. This situation requires very thin EO crystals to obtain high-frequency response, concomitant with a reduction in S/N.

An example of these considerations is shown in Fig. 21.40, which describes the THz receiver of the system indicated in Fig. 21.39. Figure 21.40a shows the calculated frequency-dependent efficiency of the electrooptic THz measurement as a function of the GaP crystal thickness. The experimentally measured THz pulses using crystals of different thicknesses are shown in Fig. 21.40b and the corresponding amplitude spectra are shown in Fig. 21.40c.

A very high bandwidth, completely electrooptic system is shown in Fig. 21.41. Here, the measured frequency response extends to 37 THz. For these results the 12 fs Ti:sapphire laser delivered an average power of nearly 500 mW at 800 nm. A 0.45 mm thick ⟨110⟩ oriented GaAs wafer was used as the emitter and a 30 μm thick ⟨110⟩ oriented ZnTe crystal as the electrooptic receiver. A laser power of 350 mW was focused on the GaAs emitter by a gold-coated off-axis parabolic mirror with a 5 cm effective focal length. The resultant THz pulse generated by optical rectification in GaAs was collimated and then focused by the off-axis paraboloidal mirrors. The measured THz pulse is shown in Fig. 21.41b, where the shortest period of oscillation is 31 fs. Figure 21.41c shows the measurement on a longer time scan, and Fig. 21.41d shows the corresponding amplitude spectrum. The highest frequency response reaches to 37 THz. The strong absorption between 5 and 10 THz was caused by the Restrahlen bands of ZnTe and GaAs. The dip around 17 THz was explained in terms of velocity mismatching.

Interferometric Techniques Using Power Detection

An alternative method of source characterization is shown in Fig. 21.30a, which bypasses the problems of receiver bandwidth, and is based on far-infrared interferometric techniques using a power detector. This approach was first demonstrated for THz radiation sources [21.134] by measuring autocorrelation signals with a full-width-at-half-maximum (FWHM) of 230 fs for the THz radiation pulse from laser created carriers

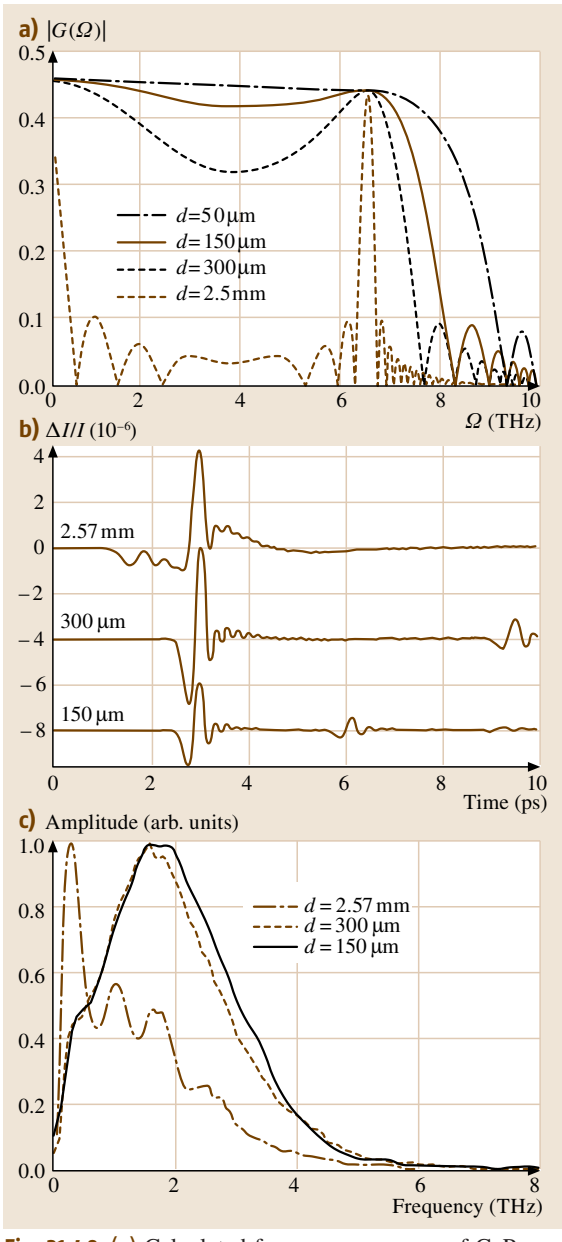

Fig. 21.40 **(a)** Calculated frequency response of GaP sensors with different thickness. **(b)** Measured THz pulses with 2.57 mm, 300 µm, and 150 µm thick ⟨110⟩ GaP detector. **(c)** Amplitude spectra of measured THz pulses. (after [21.126])

accelerated by the surface field of a photoconductive semiconductor. This approach used a single THz radiation source, illuminated by a 10 Hz repetition rate, amplified, 100 fs pulses from a CPM dye laser, together with a Martin–Puplett interferometer and a liquid-helium cooled bolometer. A different interferometric approach, using unamplified, 100 MHz repetition rate, CPM dye laser pulse excitation of a two-source interferometer has since been demonstrated [21.100]. Via this approach, together with fast, scanning-delay-line averaging, orders of magnitude improvements in the signal-to-noise ratio of the measured interferograms were obtained. Using this method, the THz radiation source described in Fig. 21.27d was shown to produce radiation to 6 THz. In addition, a 230 fs FWHM autocorrelation signal and an average power of 30 nW for 4 mW of laser excitation power were measured for this source [21.100]. Other work has used interferometric techniques together with incoherent bolometric detection to study THz emission from cold plasma oscillations [21.135].

21.2.4 THz-TDS with Freely Propagating THz Pulses

The combination of the THz-TDS technique with THz beams has some powerful advantages compared to traditional CW spectroscopy. Firstly, the coherent detection of the far-infrared radiation is extremely sensitive. Although the energy per THz pulse is very low (0.1 fJ), the 100 MHz repetition rate and the coherent detection measures the electric field of the propagated pulse with a S/N ratio of about 10 000 for an integration time of 125 ms [21.31]. In terms of average power this sensitivity exceeds that of liquid-helium-cooled bolometers, by more than 1000 times [21.53]. Secondly, because of the gated and coherent detection, the thermal background, which plagues traditional measurements in this frequency range, is observationally absent. Comparing time-domain spectroscopy with Fourier-transform spectroscopy (FTS), it should be clear that the frequency resolution of the two techniques are similar, as they are both based on a scanning delay line, where to first order the frequency resolution is determined by the reciprocal of the time scan. However, the fact that THz-TDS scans a delay line with a well collimated optical beam does present some experimental advantages. Although for now FTS is superior, being above 4 THz (133 cm^{-1}), the limited power of the radiation sources and the problems with the thermal background favor THz-TDS below 4 THz.

We will now describe several different measurement types that illustrate the generality and usefulness of THz-TDS.

THz-TDS Characterization of Water Vapor

The first THz-TDS measurements with the now standard THz optoelectronic system shown in Fig. 21.19 was the characterization of water vapor from 0.25 THz to 1.5 THz, for which the cross-sections of the nine strongest lines were measured with the best accuracy to date [21.50]. For these early measurements 30 μm long source and detector antennas on ion-implanted SOS substrates were used together with MgO [21.68] lenses instead of the currently used, more optimal high-resistivity silicon [21.51]. Figure 21.42a displays the detected THz radiation pulses after propagating

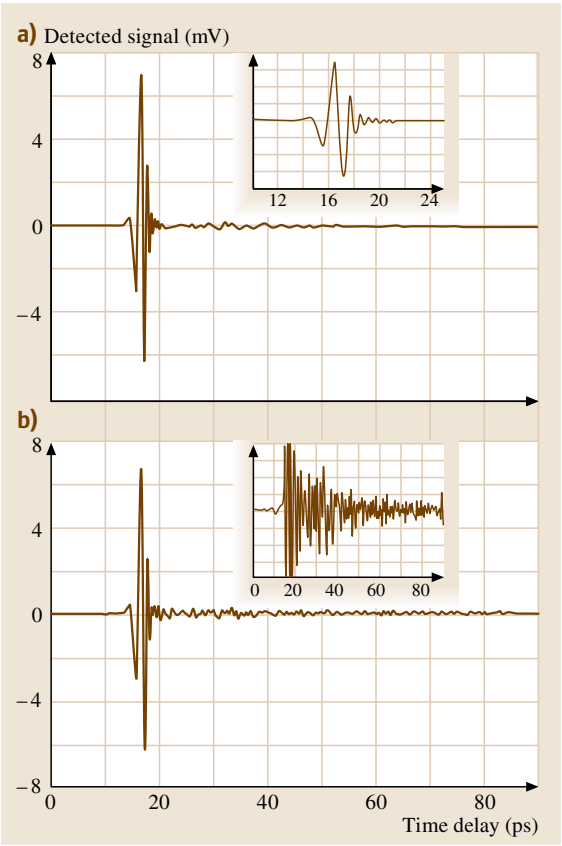

Fig. 21.42 **(a)** Measured freely propagating THz beam in pure nitrogen. *Inset* shows pulse on an expanded time scale. **(b)** Measured THz pulse with 1.5 Torr of water vapor in the enclosure. *Inset* shows pulse on a 20× expanded vertical scale (after [21.50])

through pure nitrogen. This measurement was made in a single 10 min scan of the 200 ps relative time delay between the excitation and detection pulses. When 1.5 Torr of water vapor, corresponding to 8% humidity at 20.5 °C, was added to the enclosure, the transmitted pulse changed to that shown in Fig. 21.42b. The additional fast oscillations are caused by the combined action of the dispersion and absorption of the water vapor lines. The slower and more erratic variations seen in Fig. 21.42a,b result from reflections of the main pulse. They are reproducible and divide out in the data analysis. The inset shows the data on a 20× expanded vertical scale. Here, the oscillations are seen to decay approximately exponentially with an average coherent relaxation time T_2.

The amplitude spectra of Fig. 21.42a,b are compared in Fig. 21.43a, where the strong water absorption lines are clearly observable. The additional structure on both spectra is not noise but results from spurious reflections of the main pulse. At each line the measured frequency with an estimated error of ± 0.001 THz and, in parentheses, the literature value are indicated. The corresponding absorption coefficients are displayed in Fig. 21.43b as the negative of the natural logarithm of the ratio of the two amplitude spectra in Fig. 21.43a. Because the electric field is directly measured, the relative phase shift between the two spectra is also obtained as plotted in Fig. 21.43c, without the need for the Kramers–Kronig relations. As expected for a Lorentzian line, the magnitude of the jump in phase, experienced at each resonance, equals the peak absorption.

THz-TDS Characterization of Flames (Hot Water Vapor)

The first comprehensive THz (far infrared) absorption measurement of flames, covering the region from 0.2 to 2.65 THz (7–88 cm^{-1}) has been accomplished by THz-TDS [21.54]. Such measurements have not been possible with the alternative method of Fourier-transform spectroscopy, because the incoherent bolometric (liquid-helium cooled) detection is overwhelmed by the copious amounts of far-infrared radiation emitted by flames. In contrast, the THz-TDS system is blind this incoherent thermal radiation. For flames, many of the expected constituents, H_2O, CO, OH, NO, and NO_2, have permanent electric-dipole moments and can thereby be simultaneously probed by THz-TDS with approximately 2 GHz spectral resolution. In this THz-TDS observation of a premixed propane–air flame, a large number of absorption lines were initially identified as those of water, CH, and NH_3 [21.54]. The flame temperature of 1300 K was determined by comparing the relative strengths of the water-vapor lines. It was later shown that, except for the one remaining line at 2.865 THz, all of the observed THz spectral, absorption lines in the propane–air flame are from water vapor, and

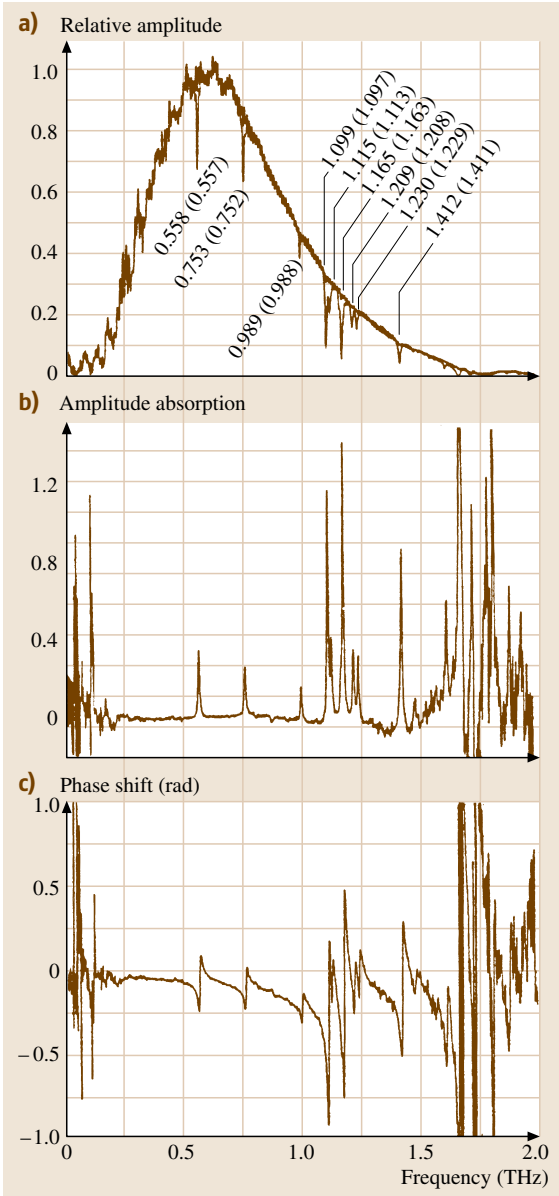

Fig. 21.43 **(a)** Amplitude spectra of Fig. 21.42a,b. **(b)** Amplitude absorption coefficient obtained from **(a)**. **(c)** Relative phase of the spectral components of **(a)**(after [21.50])

that previously unidentified lines in the flame are due to pure rotational transitions in the ν_2 (010) vibrational state of hot water vapor [21.55].

Later, via THz-TDS and a propane–air flame, measurements of the collisionally broadened pure rotational linewidths of water vapor at high temperatures were performed [21.56]. More than 40 rotational lines were observed in the ground and $\nu_2 = 1$ vibrational levels over the spectral bandwidth from 1 to 2.5 THz ($33-83\,\mathrm{cm}^{-1}$). The measured linewidths agree in magnitude with calculated values at the measured temperature of 1490 K; however, contrary to predictions, a pronounced energy dependence was observed. No temperature shift of line centers was observed, and line strengths were in reasonable agreement with tabulated values. The demonstrated ability of THz-TDS to measure linewidths of pure rotational transitions in hot samples can be extended to other samples and gas mixtures. Dopants can be added to the incoming fuel stream to look for important free radicals, transient species and reactants.

The experimental configuration used in this investigation is shown in Fig. 21.44. The path length through the flame was 20.7 cm, and the premixed flame was supported on a 24.8 cm × 17.8 cm sintered bronze water-cooled burner. The burner assembly was enclosed to prevent contamination from room air. The THz transmitter and receiver were enclosed in separate chambers isolated from the burner. The THz beam was coupled into the burner enclosure through 100 μm thick quartz windows fused to 5 cm diameter quartz tubes, permitting the windows to be inserted directly into the flame.

A representative measurement of the flame is shown in Fig. 21.45a; the inset shows the main THz pulse in detail. As illustrated in Fig. 21.45b, there was no increase in background noise with the flame on. Despite the high temperature within the flame, the gated coherent detection and the small acceptance of the THz optics are effective in blocking the incoherent THz radiation that is incident upon the receiver. The normalized amplitude spectrum of the pulse in Fig. 21.45a is shown in Fig. 21.45c. The 0.75 THz oscillatory structure in the spectrum is due to etalon effects of the 100 μm thick quartz windows. The power absorption spectrum, measured by taking the ratio of an average of three scans with the 1 : 30 propane–air flame on to that with the flame off and the burner enclosure purged with dry air, is shown in Fig. 21.46. The measurements fit the calculated line positions to an accuracy of 1 GHz. Twenty-two rotational absorption lines in the ν_2 band were observed; the measured strengths and linewidths agree well with calculations.

THz-TDS Characterization of Sapphire and Silicon

The early THz-TDS measurements [21.51] on single crystal sapphire and silicon were motivated at that time by the need to find the best material for THz lenses in contact with the emitting and detecting chips. The available published data were inadequate for this. Absorption of the THz radiation by the lens material (initially sapphire) imposed an upper limit on the bandwidth of the entire system. The use of silicon lenses, inspired by these measurements of unusually low absorption and dispersion, immediately increased the system bandwidth from 2 to 3 THz and gave smoother THz pulses with less ringing structure.

The single crystal sapphire sample was a polished, 57 mm diameter disc, 9.589 mm thick, and with the *c*-axis in the plane of the disc. A typical THz input pulse incident upon the sample is shown in Fig. 21.47a, and the output pulse (normalized to the input pulse) after propagation through the sample is shown in Fig. 21.47b for which the *c*-axis of the crystal was perpendicular to the polarization. The reduction in amplitude is due to the reflective loss at both surfaces and to the absorption during passage through the sapphire. The pulse at 73.4 ps delay is the ordinary pulse, while the smaller pulse at 85.1 ps delay is the extraordinary pulse. The ratio of the peak of the ordinary pulse to that of the extraordinary pulse is approximately 25 : 1 and gives the polarization sensitivity of the system. In terms of amplitude, the polarization ratio of the generated THz beam is 5 : 1. The 11.8 ps separation between the two pulses is a measure of the birefringence of sapphire

and, neglecting the correction to group velocity due to dispersion, directly gives the difference in the index of refraction between the extraordinary and ordinary ray to be $n_o = 0.37$ compared to the literature value of 0.34 [21.136, 137]. When a full frequency analysis is performed, excellent agreement is obtained with the literature value. The 73.4 ps time delay of the ordinary pulse with respect to the 7.1 ps time delay of the pulse with no sample in place gives the ordinary index of refraction $n_o = 3.07$ in agreement with the literature value [21.136–138]. The absorption coefficient versus frequency determined from these pulses is shown in Fig. 21.48a. Here, we see a monotonic increase in absorption with increasing frequency with the expected quadratic dependence. Due to excessive attenuation caused by the sample being too thick for the weak higher frequency components, the data is considered to be accurate only up to 1.75 THz. Some of the previous work [21.136–138] has been indicated on the curve, and shows rough agreement (within a factor of 2) with the THz-TDS measurement. The relative phases of the Fourier components determine the index of refraction versus frequency as presented in Fig. 21.48b, which compares reasonably well with the indicated earlier results [21.136–138].

Crystalline silicon is optically isotropic eliminating concern about the polarization of the incident THz beam and crystal orientation. Although there is significant literature concerning the far-infrared properties of silicon below 2 THz there are noteworthy discrepancies among the published data with variations in the measured absorption coefficients of up to 10 times. The main reason for this confusion is that below 2 THz the results are extremely sensitive to the presence of carriers. THz-TDS measurements [21.97, 98] have shown that for 1 Ω cm, n-type silicon the peak absorption is 100 cm^{-1}, and that for 10 Ω cm, n-type, the absorption is 12 cm^{-1}. Extrapolating these values to 100 Ω cm, $\alpha = 1\ cm^{-1}$, at 1 kΩ cm, $\alpha = 0.1\ cm^{-1}$, and at 10 kΩ cm, $\alpha = 0.01\ cm^{-1}$. Consequently, unless high-purity, high-resistivity material is used, what is measured is not the properties of the intrinsic semiconductor but that of the carriers due to residual impurities. This problem is most prevalent in the earlier work on silicon with resistivities of 10 Ω cm [21.136] to 100 Ω cm [21.138].

The above TDS measurements were made on a 50 mm diameter, 20.046 mm thick single crystal of high-resistivity (greater than 10 kΩ cm), float-zone silicon. For this material an unprecedented transparency was measured together with a remarkably flat dispersion curve. Throughout the range from low frequencies up to 2 THz the measured absorption coefficient is less than 0.05 cm^{-1}, while the index of refraction changes by less than 0.001.

THz-TDS Characterization of n-Type and p-Type Silicon

A THz-TDS measurement of device-grade, doped silicon wafers [21.97, 98] showed that the frequency-dependent absorption and dispersion were completely due to the carriers and not to the host crystal. Consequently, the complex conductance could be characterized over the widest frequency range to date. The samples used were a 283 μm thick wafer of 1.15 Ω cm; n-type and a 258 μm thick wafer of 0.92 Ω cm p-type silicon. The measured absorptions shown in Fig. 21.49a are more than 2000 times greater than that of the host crystal. The clear difference between the n- and p-type material is due to the different dynamic behavior of the electrons and holes. For these measurements the oscillations due to the etalon effects of the sample geometry have been removed numerically. As shown in Fig. 21.49b, the index of refraction is strongly frequency dependent. The agreement with the Drude theory (solid line) is exceptional.

As the THz optical properties of the samples are essentially completely determined by the carrier dynamics, the complex electric conductivity of the doped silicon has also been measured independently of conduction theory and relying on only very general assumptions [21.97,98]. The electric conductivity is obtained (without any fitting parameters) from the data of Fig. 21.49a,b; the real part of the conductivity is shown in Fig. 21.49c and the imaginary part in Fig. 21.49d. The extrapolated DC conductivities are 0.89 Ω cm for the p-type material and 1.13 Ω cm for the n-type, compared to the directly measured values of 0.92 Ω cm (p-type) and 1.15 Ω cm (n-type).

The final agreement with Drude theory (solid line) is quite acceptable with the two Drude parameters, the plasma angular frequency ω_p and the damping rate Γ, determined within 5% accuracy from the fits to the data. For 0.92 Ω cm p-type silicon $\omega_p/2\pi = 1.75$ THz and $\Gamma/2\pi = 1.51$ THz, while for 1.15 Ω cm n-type silicon $\omega_p/2\pi = 1.01$ THz and $\Gamma/2\pi = 0.64$ THz. The

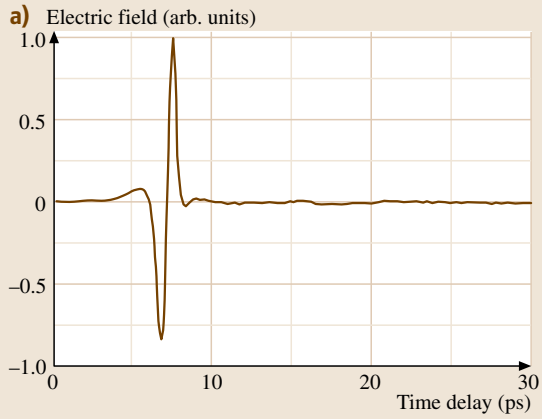

Fig. 21.47 **(a)** Measured input THz pulse. **(b)** Measured THz pulse transmitted through the sapphire crystal (after [21.51])

measured damping rates and the known effective carrier masses [21.97, 98], determine mobilities of $1680\,\mathrm{cm}^2/(\mathrm{V\,s})$ for the electrons and $500\,\mathrm{cm}^2/(\mathrm{V\,s})$ for the holes. The measured plasma frequencies and effective carrier masses determine the carrier number densities of $1.4\times10^{16}\,\mathrm{cm}^{-3}$ for the p-type and $3.3\times10^{15}\,\mathrm{cm}^{-3}$ for n-type silicon.

More recent definitive THz-TDS measurements of the complex conductivity $\sigma(\omega)$ from DC to 2.5 THz on

doped silicon have been recently performed [21.139], as displayed in Fig. 21.50. Compared to the above earlier experimental studies of doped silicon [21.97, 98], these new results have sufficient frequency range and precision to test alternative theories [21.140–143] for the conductivity. However, for both n-type and p-type silicon and over a measured range of more than two orders of magnitude of the carrier density N, agreement was not found with any standard theory, including Drude, lattice-scattering and impurity-scattering theories [21.97, 98, 140–143]. For the first time, a modified $\sigma(\omega)$ of Drude theory to include the Cole–Davidson (C–D) fractional exponent β [21.144], achieved an exceptional fit to all of the measurements. This first application of a C–D type distribution [21.144] to fit $\sigma(\omega)$ of well-ordered crystalline semiconductors extends the demonstrated frequency range of this type distribution by more than three orders of magnitude and demonstrates that fractal conductivity is not just found in disordered material. A later THz-TDS characterization of a very low carrier density sample of n-type neutron-doped float zone silicon obtained an excellent fit with the complex conductivity described by the C–D distribution with $\beta = 0.83$ [21.145].

THz-TDS Characterization of n-Type Gallium Nitride

The THz-TDS characterization of the complex electric conductivity and dielectric response of n-type GaN over the frequency range from 0.1 to 4.0 THz has recently been performed [21.146]. The measured conductivity is well fit by the simple Drude model.

The GaN sample was an unintentionally doped, n-type, 5 mm × 5 mm × 180 μm freestanding crystalline plate. Originally grown on *c*-plane sapphire by the hydride-vapor-phase epitaxy technique (HVPE), the GaN layer was removed from the sapphire substrate by laser liftoff [21.147, 148]. The *c*-axis is perpendicular to the main planes of the sample. The sample was attached to a thin brass plate and centered over a 4 mm diameter hole in the plate, which defines the optical aperture. Another identical clear hole is used to take reference signal designated as the input pulse. For this measurement the standard THz-TDS system was realigned into a $4f$ confocal geometry that enabled excellent beam

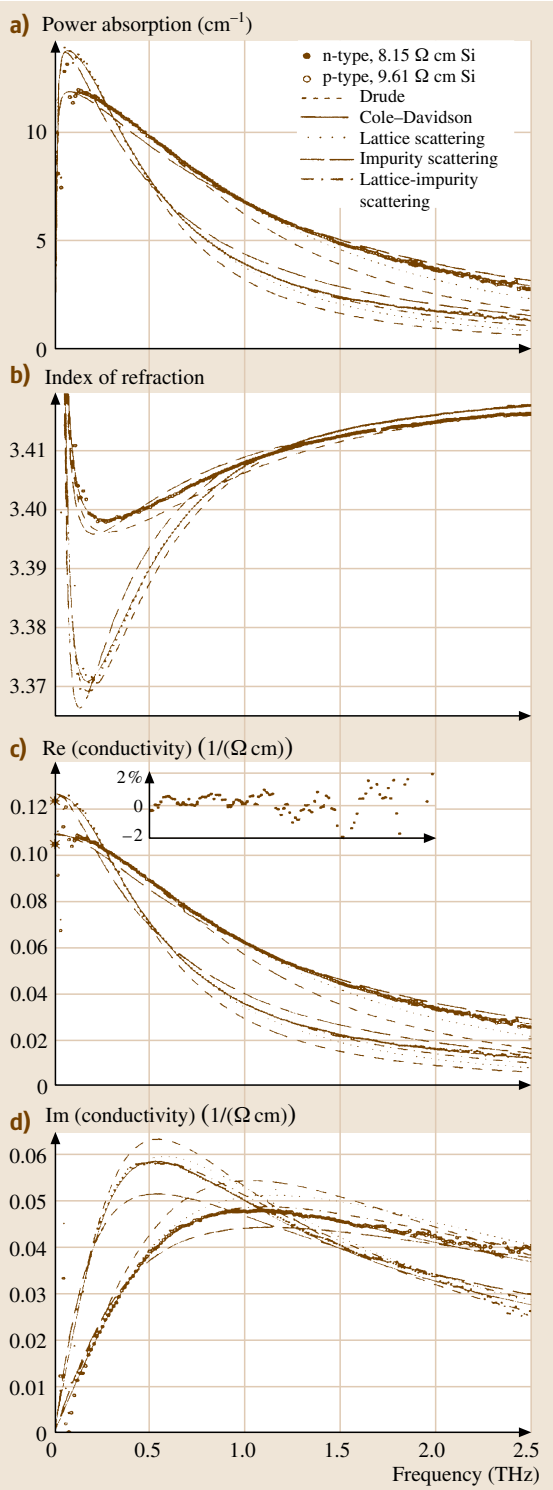

Fig. 21.50a–d THz-TDS measurements for n-type (*dots*) and p-type (*open circles*) silicon compared with five alternative theories. **(a)** Power absorption coefficient. **(b)** Index of refraction. **(c)** Real part of the conductivity. **(d)** Imaginary part of the conductivity (after [21.139]) ◀

coupling between the THz transmitter and receiver. In order to compress the THz beam to a diameter comparable to the size of the GaN sample while preserving the low-frequency components, a pair of 25 mm focal length, high-resistivity, silicon lenses, separated by the confocal distance of 50 mm, were placed on the axis of the THz beam between the two paraboloidal mirrors. As a result, midway between the two lenses, a frequency independent 2.8 mm diameter THz beam waist was obtained, on which the 4 mm sample clear aperture was centered.

The resulting measured power absorption coefficient of the sample is shown in Fig. 21.51a, and the measured index of refraction in Fig. 21.51b, as the open circles. The real and imaginary conductivity shown in Fig. 21.51c were obtained from the experimentally determined α and n curves shown in Fig. 21.51a,b.

The measured absorption, index of refraction and complex conductivity were then theoretically fit using the simple Drude model [21.97, 98]. Three parameters were used to obtain a good fit to the experimental data: $\omega_p/2\pi = 1.82\,\text{THz}$, $\Gamma/2\pi = 0.81\,\text{THz}$ and the real part of dielectric constant $\text{Re}(\varepsilon_d) = 9.4$. Given the reduced mass $m^* = 0.22\,m_0$ for electrons in GaN [21.149], these parameters correspond to a number density of $N = 0.91 \times 10^{16}\,/\text{cm}^3$ and a mobility $\mu = 1570\,\text{cm}^2/(\text{V s})$. In Fig. 21.51a, the material absorption of intrinsic GaN, is responsible for the difference between the Drude fitting curve and the measurement of power absorption at frequencies higher than 2 THz.

THz-TDS Characterization of Normal and High-T_c Superconducting Films

An important subject area is the complex conductivity of normal metal, and normal and high-T_c superconducting films. Here, the large dynamic range of the THz systems is the key to transmission measurements with extremely large attenuations from low frequencies up to approximately 6 THz. Consequently, thicker films can be measured and thereby results are obtained which are closer to the desired bulk properties of these materials. With THz-TDS it becomes possible to measure, by non-contact means, the complex conductivities of normal metal and superconducting films. It is to be noted

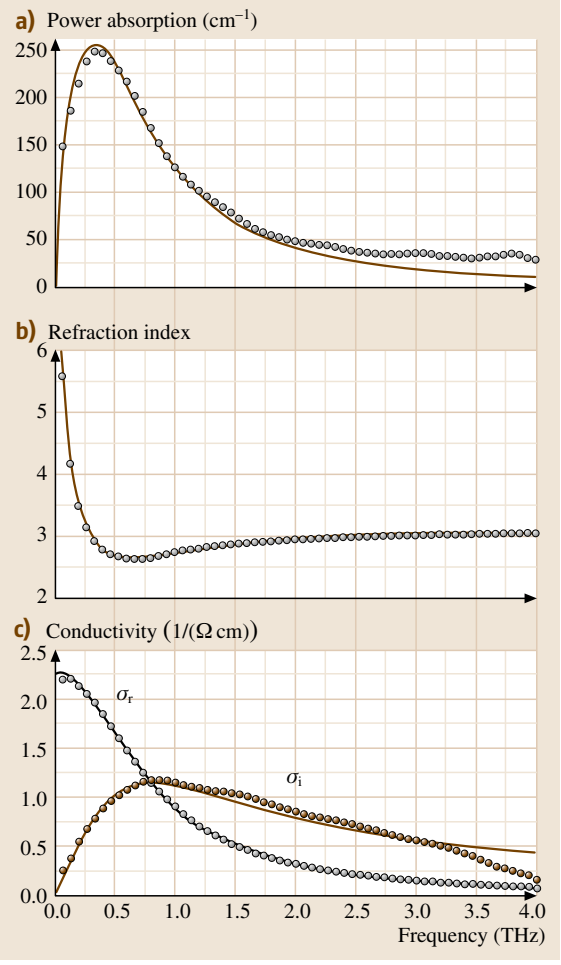

Fig. 21.51a–c THz-TDS measurements of GaN (*open circles*) compared with Drude model (*solid lines*). **(a)** Power absorption coefficient α; **(b)** real part of refractive index n_r; **(c)** complex electric conductivity σ_r and σ_i (after [21.146])

that the THz beams are easily focused to millimeter and even submillimeter spot sizes and thereby can be passed through the windows of optical dewars capable of cooling to cryogenic temperatures.

Direct measurements of the energy gap of normal superconductors have been performed on thin films of niobium [21.150] and lead [21.151]. In the early investigations of high-T_c films, the complex conductivity [21.152] and the real and imaginary parts of the surface impedance [21.153] were measured in both the normal and superconducting states. In another work [21.154], where the real and imaginary parts of the sub-bandgap conductivity σ of $YBa_2Cu_3O_7$ films were directly measured in the frequency range from 0.45 to 2.4 THz (15–80 cm^{-1}), a peak was observed in the real part σ_1 similar to the coherence peak expected in an s-wave BCS superconductor. More recent measurements have extended both the accuracy and frequency range of these measurements [21.155–165].

THz-TDS Characterization of High-T_c Substrates, Nonlinear Crystals and Polymers

The THz transparency of the underlying dielectric substrate is essential to realize the goal of a high-speed coplanar transmission line capable of transmitting a subpicosecond electrical pulse a distance on the order of 10 mm. These considerations become especially important with respect to the realization of a high-bandwidth coplanar transmission line fabricated out of the new high-T_c superconducting materials. The THz-TDS characterization at both room temperature and 85 K of three dielectric substrates used with high-T_c coplanar transmission lines, namely, magnesium oxide, yttria-stabilized zirconia (YSZ), and lanthanum aluminate provided limits on the realizable bandwidths obtainable [21.68]. More recent measurements have characterized another high-T_c substrate [21.166].

Although ZnTe has been the primary EO detection crystal, and even though detailed simulations have been compared with experimental results, the frequency dependent absorption and dispersion of ZnTe had not been measured. Recently, via THz-TDS, extensive measurements of the index of refraction and absorption of ZnTe from low frequencies to 4.5 THz were performed [21.131]. In contrast to what has been previously assumed, it was found that the absorption below 4.5 THz is not dominated by the strong TO-phonon line at 5.3 THz, but instead the measured absorption shows several new phonon lines. In fact, below 3.5 THz no significant absorption from the low frequency wing of the TO-phonon line was observed. However, as previously expected, the behavior of the index of refraction is dominated by the TO-phonon resonance. Another group has reported the THz-TDS characterization of the important electrooptic crystals: $LiNbO_3$, $LiTaO_3$, ZnTe and CdTe [21.132]. This same group has more recently reported the THz-TDS characterization of the nonlinear organic crystal DAST [21.167].

THz-TDS Characterization of Molecular Vapors

Early studies of coherent transients excited by THz pulses involved the use of THz-TDS techniques with N_2O vapor [21.168, 169] and methyl chloride vapor [21.170]. Using a subpicosecond pulse of THz

radiation to excite the vapor, the subsequent emission from the vapor of coherent THz pulse trains extending as long as 1 ns was observed. THz-TDS, rotational line-shape investigations have been performed to gain insight into the actual collision process [21.171–173], by measuring the far-wing absorption line profile of ensembles of collision broadened ground state rotational lines of methyl halide vapors out to more than 200 linewidths from resonance, corresponding to frequency offsets as much as 5× the resonant frequency. These observations extend from the regime of the van Vleck–Weisskopf theory to the regime of the Lorentz theory. These measurements have experimentally established the new molecular response theory, which explicitly includes the molecular orientation time during a collision [21.173].

More recent work has studied collision induced tunneling in the methyl halides [21.172] and ammonia [21.174]. In other work the use of THz-TDS for gas sensing has been presented and discussed [21.175, 176]. A gas filter correlation instrument for the THz monitoring has been developed [21.177], and an all electronic THz absorption spectrometer has been demonstrated [21.178].

21.2.5 THz-TDS of Liquids

The efficacy of THz-TDS measurements on liquids has been demonstrated in a series of measurements of the absorption and index of refraction of acetone [21.179], acetonitrile [21.179, 180], liquid ammonia [21.181], benzene [21.182, 183], carbon tetrachloride [21.182, 184], cyclohexane [21.182], ethanol [21.181], methanol [21.179, 181], 1-propanol [21.181], water [21.179, 181, 185–188], and heavy water [21.188]. In addition, nonaqueous mixtures of dipolar liquids have been characterized [21.189], as well as solvated HCl [21.190],and mixtures of water with acetone, acetonitrile, and methanol [21.179]. The obtained spectra typically covered the region from 0.1 to 2 THz, where the dielectric response of the nonpolar liquids is dominated by collision-induced dipole moments. The complex dielectric behavior of liquids in the THz region is different for polar and nonpolar molecules. The absorption in polar molecules is due to the electronic interaction of the incoming field with the molecular permanent dipole moments. The dipoles are aligned by the incoming THz field, while at the same time this alignment is opposed by collision processes. The collision induced relaxation of the polarization has a time constant in the picosecond range, ideal for the THz probing pulses. The much smaller absorption of nonpolar molecules originates in the transient dipole moments induced by collisions in the liquid. The complex dielectric constant can be measured by THz-TDS for both types of liquid samples and useful information thereby obtained.

21.2.6 Waveguide THz-TDS

The efficient coupling of broadband THz pulses into waveguides of different configurations, by quasi-optics incorporating hyper-spherical or plano-cylindrical silicon lenses, has allowed for many possibilities, as discussed in Sect. 21.1.9. In particular, the low-loss non-dispersive single TEM mode propagation in the metal parallel plate waveguide (PPWG) shown in Fig. 21.16, has made possible waveguide THz time-domain spectroscopy (THz-TDS), which can be used to measure the absorption and dielectric constant of thin layers of material on a waveguide plate of the waveguide.

For a metal PPWG with a thin dielectric layer, the total loss comes from both the metal walls and the dielectric layer. By comparing the signal from the empty guide with that from the waveguide containing the dielectric layer, the amplitude and phase change caused by the layer can be extracted. Thus, the absorption and index of refraction of the layer material can then be obtained. The sensitivity of this measurement is proportional to the ratio between the length and the plate separation of the waveguide, so that when properly configured, this method can be used to characterize extremely thin layers of low-loss materials.

The initial demonstration of the sensitivity and applicability of this technique was the measurement of nm water layers on the plates of a PPWG [21.191]. The water layer had a thickness of 25 nm, equivalent to approximately 80 molecular layers, and showed a similar index of refraction and absorption to that of bulk water.

Waveguide THz-TDS Compared with THz-TDS (Part 1)

A more recent application of waveguide THz-TDS for the study of thin microcrystalline film samples of organic and bio-organic materials, discovered a line narrowing phenomenon due to the alignment of the microcrystals on the waveguide plate [21.192]. Here, the initial goal of the waveguide THz-TDS measurements was to demonstrate the expected 100 times increase in sensitivity of waveguide THz-TDS compared to the

standard pellet technique. This work will now be described in detail.

For the first waveguide THz-TDS characterization of a solid organic thin film, the material 1,2-dicyanobenzene (12DCB) was studied because of its relatively strong vibrational lines in the THz region. The major finding of the study was that the measured THz waveguide film spectrum displays significantly sharper vibrational linewidths than found in the corresponding THz pellet spectrum [21.192]. For measurements performed near 77 K using the experimental setup shown in Fig. 21.52, a dramatic line narrowing was observed for the waveguide film, yielding linewidths as much as five times sharper than found in the pellet sample [21.192–194]. The line narrowing reveals additional vibrational structure in the waveguide film, which is not apparent in the pellet. The line narrowing was attributed to a reduction of inhomogeneous broadening for the 12DCB film drop-cast on the metal waveguide surface. The high sensitivity of the waveguide technique made possible by the subwavelength gap and long propagation length, was also demonstrated.

Waveguide THz-TDS Compared with THz-TDS (Technical Details)

A schematic of the experimental apparatus with liquid nitrogen (LN_2) cryogenic capability for waveguide THz-TDS is shown in Fig. 21.52 [21.191, 192]. The PPWG assembly consists of two copper plates with identical dimensions of 27.9 mm (width) × 30.5 mm (length) × 9.5 mm (thickness). A plate separation of 50 μm was achieved by four 50 μm thick spacers. A free-space THz beam is coupled into and out of the waveguide using two identical plano-cylindrical Si lenses at the input and exit faces of the PPWG. The waveguide assembly is placed inside a vacuum chamber with straight through optical access and is mechanically attached to a liquid nitrogen container.

A standard method for measuring the THz (far-infrared) absorption spectra of organic solids is to form a disc shaped compressed pellet that contains a small finely ground quantity of the sample solid, dispersed in a much larger quantity of a powder of a low absorbance host material such as polyethylene. A wide range of organic and bio-organic materials in the form of such pellets have been studied in the THz region, including explosive materials [21.195–198] and their by-products [21.199], conjugated organic oligomers [21.200], amino acids [21.201], and DNA [21.202, 203]. While much spectroscopic information can be obtained from pellet samples, in many cases their THz spectra exhibit broad line shapes due to intrinsic line broadening mechanisms, and to effects related to pellet preparation [21.204]. Such pellet samples are easily measured by THz-TDS.

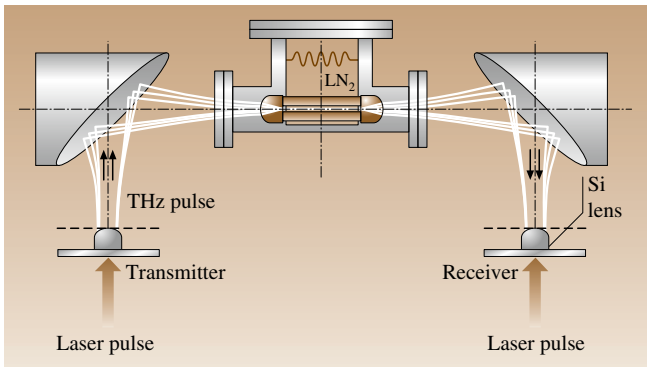

Fig. 21.52 Experimental setup for cryogenic waveguide THz-TDS [21.192]

The THz properties of organic solids can also be investigated by waveguide THz-TDS. For these investigations an important additional feature is that the PPWG is easily opened, and the exposed flat inner surfaces are ideal for coating with a thin film of the investigated material. These features stimulated the initial comparison study between standard THz-TDS using pellet samples and waveguide THz-TDS measurements on the same sample [21.192]. The comparison samples had been processed in the usual way into a powdered mixture with polyethylene, and pressed into pellets of 10 mm diameter by 1 mm thick. These pellets were characterized by the standard THz-TDS system. The same chemical compounds were also dissolved in an appropriate solvent such as chloroform, and a thin microcrystalline film was formed by drop-casting the solution onto one plate of a 30 mm long parallel plate waveguide (PPWG). The waveguide was then reassembled.

In the initial comparison [21.192], thin films of 12DCB were made by drop-casting from a 2 mg/ml solution of 12DCB in toluene onto the inner surface of one plate of an opened PPWG. Following evaporation, the thicker areas of the film along the perimeter were removed using a solvent-soaked swab to leave a visually uniform film that was 15 mm (width) ×25 mm in (length). The mass of the film was estimated by dissolving a similarly prepared film into a solution of chloroform and comparing the UV absorption spectrum to that of a 12DCB solution with a known concentra-

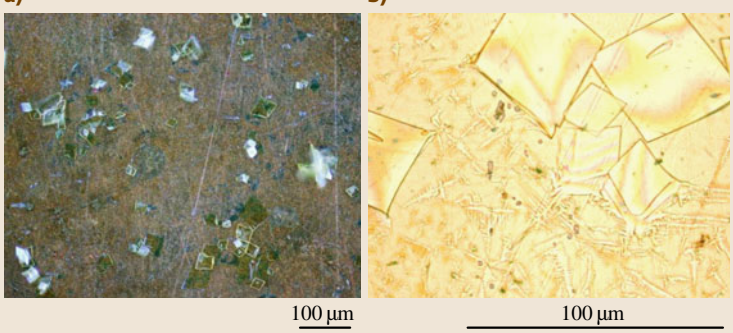

Fig. 21.53a,b Optical micrographs of TCNQ planar crystals on the Cu plate. Frame sizes: **(a)** 550 μm × 700 μm, and **(b)** 112 μm × 140 μm [21.194]

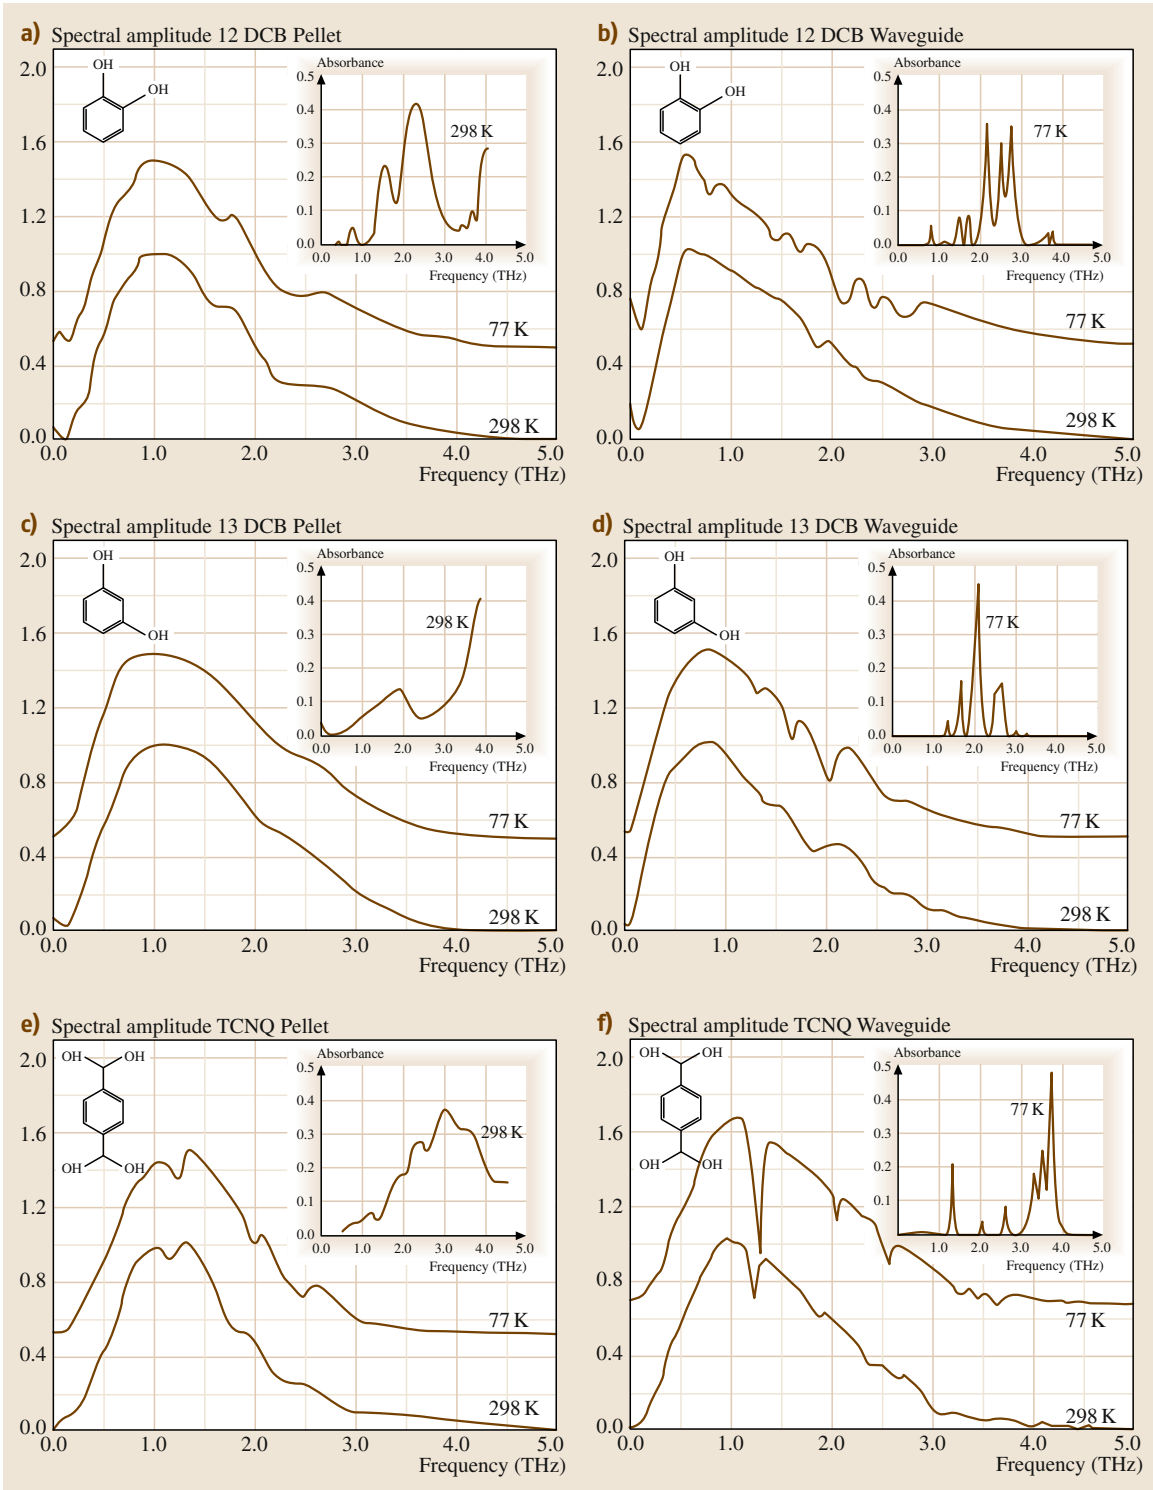
tion. A typical film mass was approximately 50–60 μg, compared with the 100× greater mass for the pellet. The pellet samples were made by mixing 4.8 mg of 12DCB powder in 100 mg of polyethylene powder, and then pressing the mixture to yield a 1 cm diameter pellet with a thickness of 1 mm.

In the early demonstrations, two other samples were also characterized [21.193, 194], the 1,3 isomer of DCB (13DCB) and tetracyanoquinodimethane (TCNQ), an important electron-accepting molecule in conductive organic solids. The thin polycrystalline films were made by drop casting of 13DCB from a toluene solution (2 mg/ml) and TCNQ from an acetone solution (2 mg/ml) onto waveguide plates. To date the most effective technique has been to drop-cast a small amount of a solution containing the sample (via a hand-held microsyringe) onto the waveguide plate. After evaporation of the solvent, in the successful cases, a thin film of partially ordered microcrystals forms on the metal surface. Typical film masses were approximately 80 μg. An inspection of these films under a microscope revealed polycrystalline structures on the surface of the metal waveguide plate, as shown below in Fig. 21.53.



This crystalline order is easily seen with an optical microscope, and optical micrographs of our most successful sample TCNQ are shown above in Fig. 21.53. There is quite a variety in surface morphology over the surface of the plate, as shown in Fig. 21.53a. Here, the flat platelet microcrystals are shown oriented on the plate surface. It is considered that the best experimental results are from the thin square platelets, shown with a higher magnification view in Fig. 21.53b. For this example a 2 mg (TCNQ)/ml (acetone) solution was directly drop-cast onto the optically polished Cu waveguide plate.

Waveguide THz-TDS Compared with THz-TDS (Part 2)

THz-TDS Characterization of Pellet Samples. Figure 21.54 shows the amplitude transmission spectra of 12DCB, 13DCB and TCNQ at room tempera-ture and at 77 K [21.193], where the 77 K spectra have been raised for clarity. The left column (Fig. 21.54a,c,e) shows pellet spectra and the right column (Fig. 21.54b,d,f) shows the corresponding waveguide film spectra. For each material the pellet spectra show relatively broad spectral lines due to both intra and intermolecular (phonon) vibrational transitions. The FWHM of the spectral features vary between about 0.15–1.0 THz (5.0–33 cm^{-1}). Upon cooling the pellet samples to 77 K the line shapes show relatively little narrowing, some line positions shift to higher frequencies, and new lines are not observed.

In contrast, the corresponding THz spectra of the waveguide films, shown in the right column of Fig. 21.54b,d,f, display much sharper lines, more pronounced temperature dependence, and reveal additional lines not evident in the pellet spectra. The effect of the waveguide surface is seen most clearly by comparing the pellet and waveguide spectra for TCNQ at 77 K (Fig. 21.54e,f). For the TCNQ pellet the linewidth of the lowest frequency mode at 1.3 THz is about 140 GHz (4.5 cm^{-1}), whereas for the waveguide film, the linewidth has narrowed to 26 GHz (0.85 cm^{-1}). Furthermore, the broad spectral features of the pellet

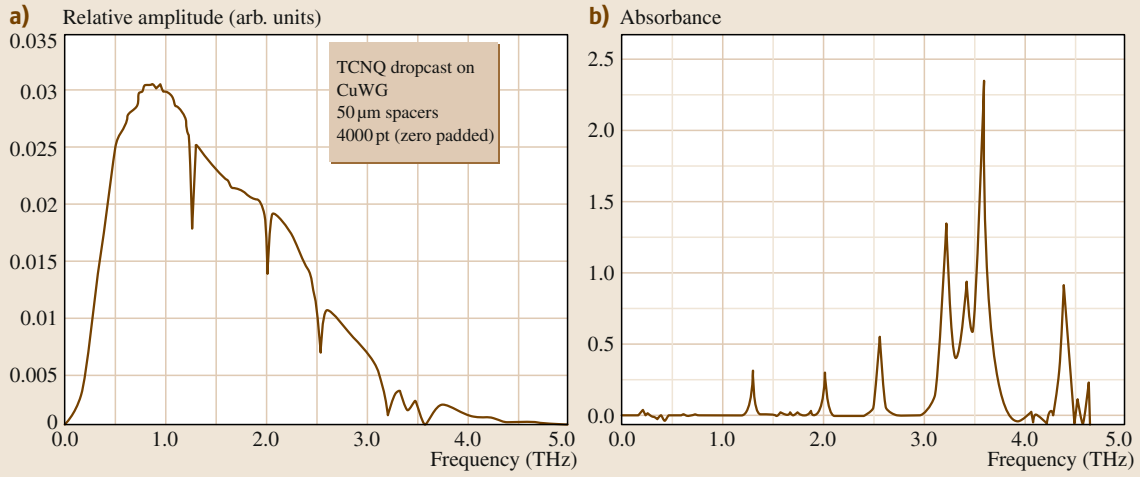

Fig. 21.55 (a) Amplitude spectrum of a THz pulse transmitted through the waveguide with a microcrystalline layer of TCNQ (shown in Fig. 21.53) at LN_2 temperature (77 K). (b) Corresponding absorbance (after [21.194])

between 3.0–4.0 THz have resolved into three distinct lines in the waveguide film. Similar observations are found for 12DCB and 13DCB.

The waveguide THz-TDS characterization of the excellent TCNQ sample of Fig. 21.54 is presented in Fig. 21.55a and shows a correspondingly high quality narrowing effect at 77 K. Notice the broad spectrum and the exceptionally narrow absorption lines. The associated absorbance is given in Fig. 21.55.

A reasonable explanation for these line-narrowing observations is that the pellet contains a static distribution of microcrystals, that are randomly oriented within the polyethylene host, giving rise to strong inhomogeneous broadening. Only minor temperature dependence of the linewidths may be expected in this limit. In contrast, the significant line narrowing upon cooling indicates that the lines of the waveguide film are dominated by a homogeneous broadening mechanism, which may be expected if the drop-cast polycrystalline film has a high degree of orientation on the waveguide surface. A microscopic inspection of these drop cast films showed that they were composed of microcrystals randomly distributed over the waveguide surface, but showing significant planar orientation with respect to the surface.

It should be clear that the demonstrated sample sensitivity increase of 100× of waveguide THz-TDS, compared to THz-TDS with pellets, is a general feature that applies to essentially all materials that can be formed into thin films. However, this is not necessarily the case for the line-narrowing effect, which requires an oriented microcrystalline layer of the sample material on the surface of the waveguide plate. Consequently, it was important to demonstrate that such spectral line-narrowing occurs for a wide range of materials. Line-narrowing has since been demonstrated for the biological materials of deoxycytidine, adenosine, D-glucose monohydrate, L-alanine, glycine, and tryptophan [21.205], and for TRIS an important amino alcohol in biochemistry and molecular biology [21.206]. Line narrowing has also been demonstrated for the pharmaceutical related materials of aspirin and aspirin precursors [21.207].

An important and simple extension of the technique was to cool the waveguide and sample to much lower temperatures than for LN_2 at 77 K, using a mechanical cryocooler as shown in Fig. 21.56.

It was indeed found that for a wide class of materials that many of the waveguide THz-TDS absorption lines continued to narrow with decreasing temperature all the way down to 11 K, where linewidths as narrow as 7 GHz were observed. Such was the case for the explosives related solids of 2,4-DNT and 2,6-DNT [21.208], which showed many well resolved new features. After this observation, all new samples with well resolved lines at LN2 at 77 K were further cooled to 11 K with much success.

An important demonstration of the power of the line-narrowing effect of waveguide-THz-TDS was the measurement of the explosive solids, RDX and

TNT [21.209]. This waveguide THz-TDS measurement resolved the previously observed broad absorption features into many well resolved new absorption lines and thereby, increased the accuracy of THz fingerprinting of these materials by an order of magnitude.

An informative paper with good descriptions of the experimental techniques of waveguide THz-TDS and the attainable accuracy of 1 GHz to locate the peak of a spectral line, which can be as much as 10 times less than the measured linewidth, has been recently published [21.210]. This work again showed that the previously observed broad features of an explosive material (here RDX) consist of a large number of well resolved absorption lines.

One of the most dramatic comparisons between the pellet THz-TDS spectrum and that attained by waveguide THz-TDS was that for the material 4-iodo-4-nitrobiphenyl (4INBP) shown in Fig. 21.57 [21.210].

Figure 21.58 [21.210] shows the remarkable reproducibility for the line-center measurements, where the obtained center positions are determined to ± 0.5 GHz, even though the FWHM linewidth of the absorbance was 8.4 GHz. As discussed earlier [21.211] and in [21.210], the spectra of the transmitted THz pulses were calculated after zero padding, i.e., the 150 ps data pulse was extended to 2667 ps by adding a train of zeros at the end of the pulse. Zero padding is often used in THz-TDS, whereby extending the time domain data with zeros causes the subsequent Fourier transform to perform an interpolation in the frequency domain between the linearly independent real data points, here separated from each other by 6.67 GHz, as determined by the 150 ps scan length. The determination of the line centers are from the interpolated amplitude spectrum of the zeropadded pulses.

With respect to zero-padding, an important measurement consideration is that, a too early truncation of the time domain pulse and starting the zero-padding before the pulse has damped out, results in a broadened line shape accompanied by small spectral shifts. However, when a time pulse signal has disappeared in the noise (as in the experiments discussed here), subsequent zero-padding should not affect the lineshape and not produce observable frequency shifts [21.212].

Because the line narrowing effect of waveguide THz-TDS is so much surface related, there has been a lingering question, whether surface interactions could shift the line positions or even result in new resonances. In order to answer these concerns, there have been several waveguide THz-TDS measurements on the same sample material but with different metal plates and/or

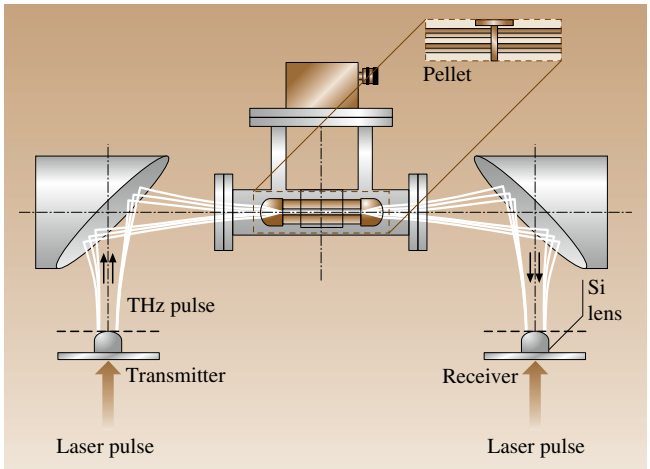

Fig. 21.56 Waveguide THz-TDS with mechanical cryocooler. *Inset* indicates replacement of waveguide with pellet for conventional THz-TDS (after [21.208])

with different surface treatments. None of these results have shown line shifting or new resonances. For example, Fig. 21.59 shows the comparison spectra measured for the microcrystalline layer of 4INBP on an Al waveguide plate and on a Cu waveguide plate and illustrates the reproducibility and independence to the metal substrate. More recent results with the sharp line structure of salicylic acid [21.207] have shown a remarkable

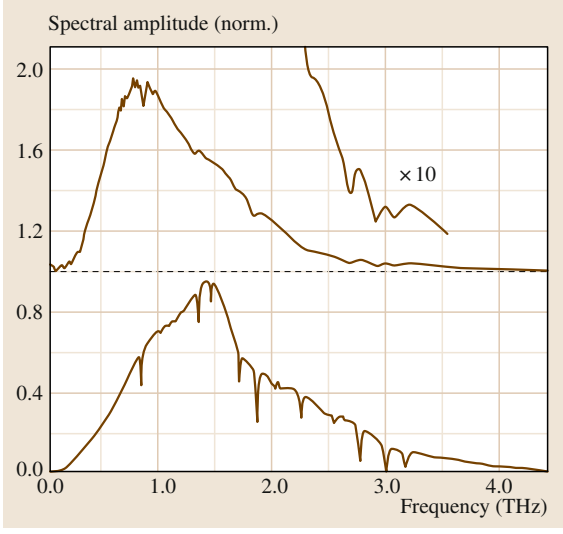

Fig. 21.57 Comparison of the spectral amplitudes for 4INBP in pellet form (*top curve*) and the 4INBP/Al film (*bottom curve*), both measured at 11 K (after [21.210])

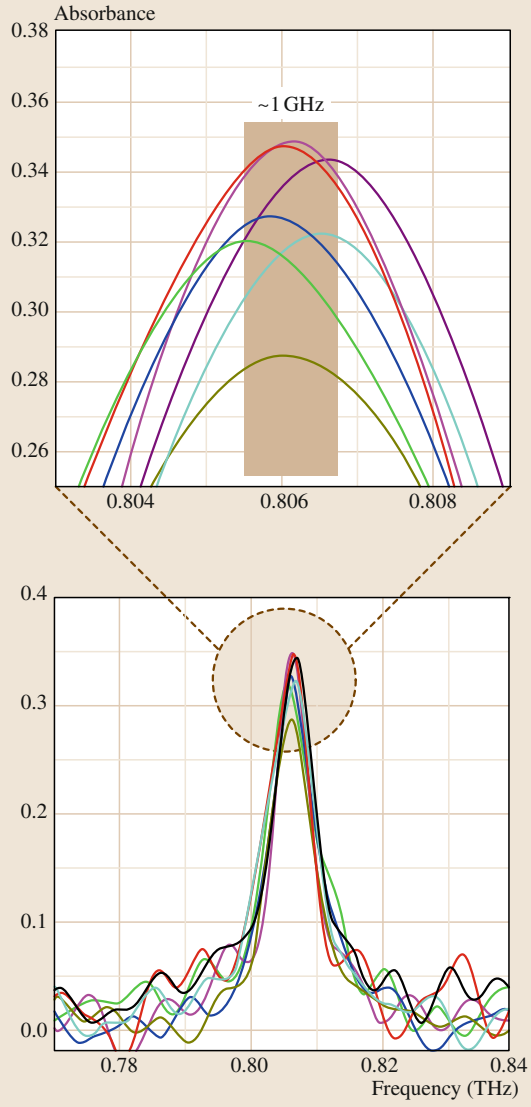

Fig. 21.58 Absorbance spectra of the lowest frequency mode of the 4INBP/Al film generated from seven independent zero-padded waveforms. The uncertainty of ± 0.5 GHz about the zero-padded average of 0.061 THz is the spectral region that contains all of the line-center frequencies of the 7 individual zero-padded absorption spectra (after [21.210])

reproducibility for the narrow-line structure with the sample waveguide plates of Al, Cu, Au coated Cu, and with a 2.5 m mylar film covering the Al waveguide plate. The conclusion is that the line structure for the

published measurements have been independent of the metal or metal covered waveguide plate.

21.2.7 CW THz Photomixing Spectroscopy

A tunable CW far-infrared (THz) difference-frequency spectrometer has been developed and demonstrated by mixing two single-mode visible dye lasers separated by THz frequencies in an ultra-high-speed photoconductor [21.213]. The photomixer device was fabricated with submicron interdigital electrodes driving a broadband spiral antenna on epitaxial low-temperature-grown GaAs [21.41–43]. The coherent far-infrared radiation was coupled out the backside of the GaAs substrate using an aplanatic Si lens and was detected by a Si-composite bolometer at $T = 4.2$ K. Usable S/N ratios were obtained for radiation from 0.1 to 1.0 THz, using two 584 nm dye lasers. The instrumental linewidth was about 2 MHz, limited by the frequency jitter of the dye lasers. Baseline normalization was necessary to compensate for the laser amplitude fluctuations and for the strong fringes due to standing waves between the source and detector and within the detector dewar. The schematic of the entire system is shown in Fig. 21.60a. The generated THz radiation traverses a 50 cm sample vapor cell using Teflon lenses as windows, from which it is detected by a Si-composite bolometer operated at $T = 4.2$ K. All of the obtained

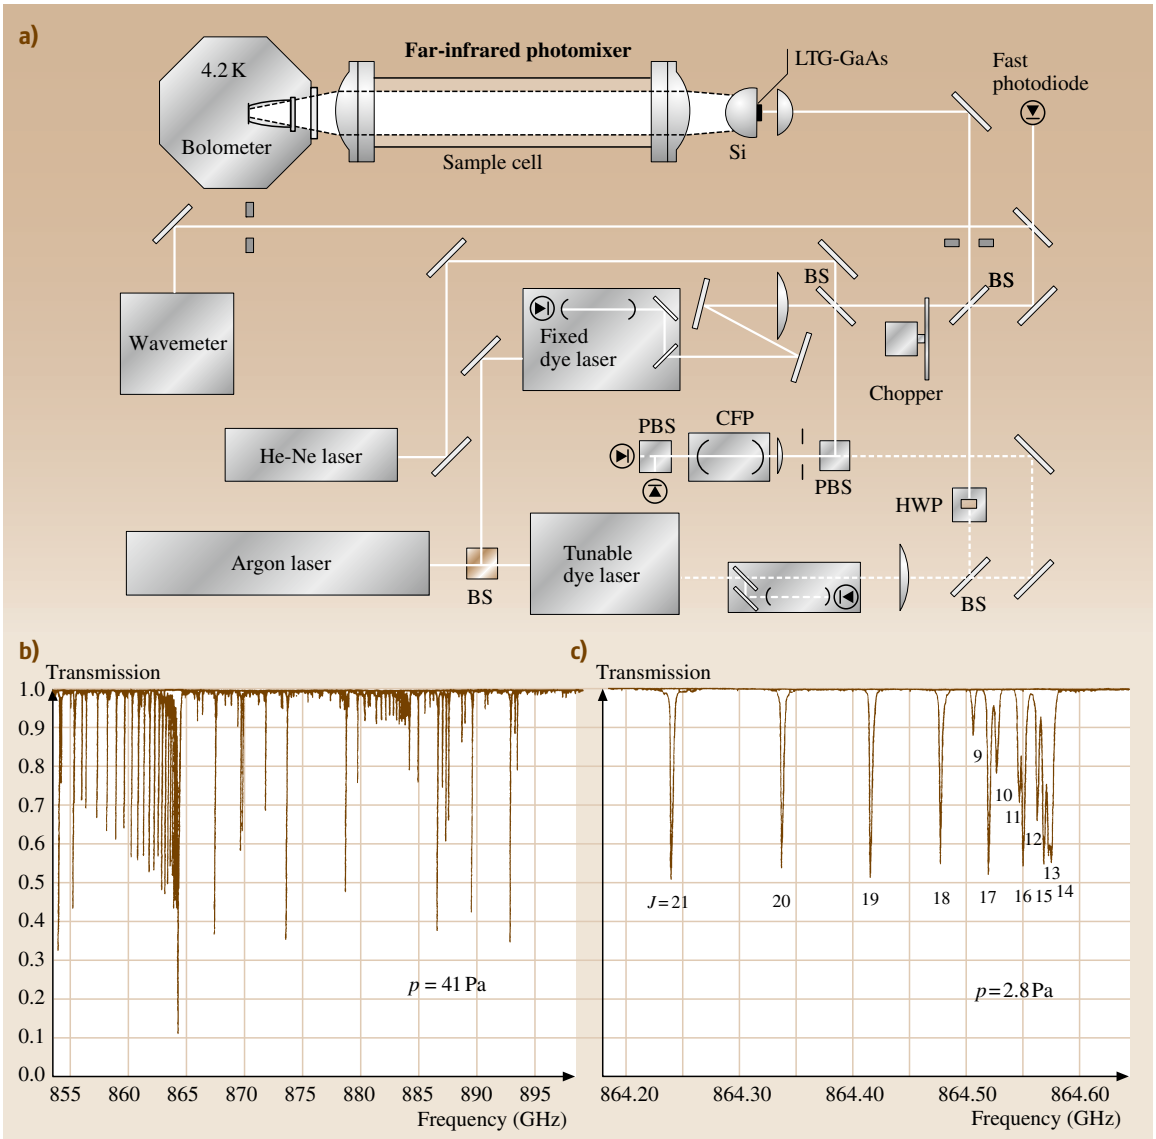

Fig. 21.60 **(a)** Schematic diagram of the photomixer spectrometer (BS: beam splitter, PBS: polarizer beam splitter, CFP: confocal Fabry–Pérot, HWP: half-wave plate). **(b)** Survey scan of SO_2 near the ${}^{r}Q_8$ subbranch. **(c)** High-resolution scan of ${}^{r}Q_8$ subbranch head (after [21.213])

spectra were normalized against laser amplitude fluctuations by dividing the bolometer signal from the THz radiation by the product of the incident laser powers.

The instrument was used to obtain SO_2 self-broadening coefficients for pure rotational transitions in several Q branches. Figure 21.60b shows a 45 GHz scan of the SO_2 ($p = 41$ Pa) ${}^{r}Q_s$ subbranch region near 865 GHZ normalized to an empty cell trace, each recorded in 5 min with 6000 sample points. Since each point represented 7.5 MHz, it was necessary to pressure broaden the lines slightly to increase the instrumental response because of the 40 ms lock-in time constant. The Doppler width for SO_2 at this frequency is only 1.3 MHz FWHM. Along the zero transmission baseline, the detector noise level in this trace when the

lasers are blocked is also shown. The $^{r}Q_{s}$ subbranch head is shown expanded in Fig. 21.60c at lower pressure and with a slower scan rate. A turn around is observed at $J = 14$, whose spacing from the $J = 13$ line of approximately 2.5 MHz is clearly resolved with the instrumental linewidth of 2 MHz.

22. X-Ray Optics

Due to the weak interaction of hard x-rays with matter it is generally difficult to manipulate x-rays by optical components. As a result, there have been many complementary approaches to making x-ray optics, exploiting refraction, reflection, and diffraction of x-rays by matter. In this chapter, we describe the physics that underly x-ray optics and explain the working principles and performances of a variety of x-ray optics, including refractive x-ray lenses, reflective optics, such as mirrors and waveguides, and diffractive optics, such as multilayer and crystal optics and Fresnel zone plates.

In the last decade outstanding progress has been made in x-ray optics. This development has been triggered by the availability of high-brilliance synchrotron radiation sources. Well-known optical schemes have been improved and new ones have been invented. Important fields of application for these optics are collimation and focusing, both at laboratory and synchrotron radiation sources, and hard x-ray microscopy, which is a growing field mainly at synchrotron radiation sources.

Although there is a large variety of x-ray optics with very different designs, they are all based on the same physical principles, i. e., elastic scattering of x-rays in matter. Refractive x-ray lenses make use of refraction inside the lens material, while mirror optics, capillaries, and waveguides use total external reflection, closely related to the refraction inside the optic's material. Diffractive optics, such as Fresnel zone plates, make use of attenuation and refraction to reduce and shift the amplitudes of the x-rays to generate a desired interference pattern, e.g., a small focal spot in the focal plane. Multilayer or crystal optics exploit Bragg reflection to focus x-rays. These physical mechanisms that underlie x-ray optics are reviewed in Sect. 22.1.

At laboratory x-ray sources, e.g., x-ray tubes, x-ray optics are mostly used to capture the radiation from a large solid angle and concentrate it either on the sample or on a detector. For this purpose very efficient optics are required that capture a large solid angle, such as for example polycapillary, multilayer or crystal optics. At modern synchrotron radiation sources, hard x-ray microscopy has developed quickly over the past decade. Both full-field and scanning techniques find a growing number of applications, requiring both imaging and focusing optics. The most important x-ray optics are reviewed in this chapter (Sect. 22.2).

For imaging, i. e., in full-field microscopy, Fresnel zone plates and refractive x-ray lenses are most commonly used. They are used as objective lens, generating a magnified image of the specimen on the detector. In this way, spatial resolutions down to 40 nm in the hard and to below 20 nm in the *soft x-ray* range can be achieved. The key strength of this type of microscopy is the large penetration depth of x-rays in matter, which allows one to image the interior of an object without destructive sample preparation. By combining this technique with tomography, the three-dimensional inner structure of an object can be reconstructed at high spatial resolution.

Scanning microscopy, on the other hand, allows one to perform with high spatial resolution hard x-ray analytical techniques, such as diffraction, fluorescence analysis, or absorption spectroscopy, that yield the local (nano-)structure, the elemental composition, or the chemical state of an element in the sample, respectively. When combined with tomography, spectroscopic information from inside a specimen can be obtained. The small beam for these scanning techniques is often generated by means of an x-ray optic, such as zone plates, refractive lenses, or curved total reflection or multilayer mirrors. Currently, all these optical schemes

are capable of generating intensive beams with a lateral extension well below 100 nm at third-generation synchrotron radiation sources. Recently, *hard x-rays* have been focused down to 7 nm in one dimension by curved mulilayer mirrors. In addition to scanning microscopy applications, the small beam can also be used as a small source for magnified projection microscopy. This scheme is recently used in full-field microscopy to obtain magnified high-resolution images of a specimen using Kirkpatrick–Baez mirrors or waveguides.

Currently, all x-ray optics are technology limited in their performance, but significant technological advances have been made, approaching physical limits. Recently, these limits have been addressed theoretically for several x-ray optics, such as waveguides, refractive lenses, and Fresnel zone plates. While beams in the range from 1–10 nm are conceivable with ideal optics, atomic resolution, e.g., at 1 Å seems to be out of reach.

As smaller and smaller x-ray beams are produced, their characterization becomes more and more difficult. Usually, well-characterized test patterns or sharp knife-edges are used to determine the beam size. Their fabrication and characterization become increasingly difficult, potentially introducing systematic errors. Recently, *scanning coherent diffraction microscopy* (SCDM), also known as ptychography, has been introduced for nanobeam characterization. As this method gives full access to the complex wave field in a reference plane and does not require any prior knowledge of a test object, it has revolutionized *nanobeam characterization*. A brief introduction to this method is given in Sect. 22.3.

22.1 Interaction of X-rays with Matter

A hard x-ray photon interacts with an atom mainly through scattering at its electrons or by absorption. Scattering can be both elastic or inelastic. In the cases of inelastic scattering, also called Compton scattering, and photoabsorption the photon is lost for image formation, while elastic scattering is responsible for refractive and diffractive effects.

The refraction of hard x-rays in matter is typically expressed by the index of refraction given in the form

$$n = 1 - \delta + i\beta, \tag{22.1}$$

where δ describes the deviation of the real part of the refractive index from unity and is referred to as the *index of refraction decrement*. As (22.1) suggests (with positive δ), the refractive index of hard x-rays in matter is smaller than unity, i. e., the vacuum is x-ray optically denser than matter. Figure 22.1b illustrates this effect as compared to the refraction of visible light in glass (Fig. 22.1a).

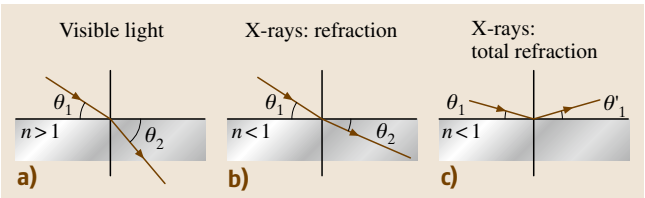

Fig. 22.1 **(a)** For visible light, the refractive index n in matter is larger than one. Therefore, light rays are refracted toward the surface normal when entering matter from the vacuum. **(b)** For hard x-rays, the refractive index n of matter is smaller than one. Therefore, x-rays impinging from vacuum onto a surface are refracted away from the surface normal. **(c)** If the angle of incidence θ_1 falls below the critical angle of total reflection, the x-rays do not propagate deeply into the material but are totally reflected at the surface

For a given atomic species, δ is given by [22.1]

$$\delta = \frac{N_a}{2\pi} r_0 \lambda^2 \rho \frac{Z + f'(E)}{A}, \tag{22.2}$$

where N_a is Avogadro's constant, r_0 is the classical electron radius, λ and E are the wavelength and energy of the x-rays, respectively, ρ is the mass density of the material, $Z + f'(E)$ is the real part of its atomic form factor in the forward direction, and A is the material's atomic mass. Figure 22.2a shows δ/ρ for different materials as a function of x-ray energy. Away from absorption edges, $f'(E)$ is small and δ is proportional to $\lambda^2 \sim E^{-2}$ and ρ. Since Z/A does not vary much between most elements, δ/ρ varies very little as a function of the atomic species away from absorption edges. As compared to that of visible light in glass, the refraction of hard x-rays is several orders of magnitude weaker. While δ/ρ is of the order of $10^{-6}\,\mathrm{cm}^3/\mathrm{g}$ for hard x-rays between 10 and 20 keV (Fig. 22.2a), that of visible light in glass is about $-\delta/\rho \approx 0.2\,\mathrm{cm}^3/\mathrm{g}$.

Due to this extremely small refraction, the reflectivity at a surface or interface is extremely low. Therefore, there are no mirrors for hard x-rays reflecting at large angles. However, when an x-ray beam impinges on

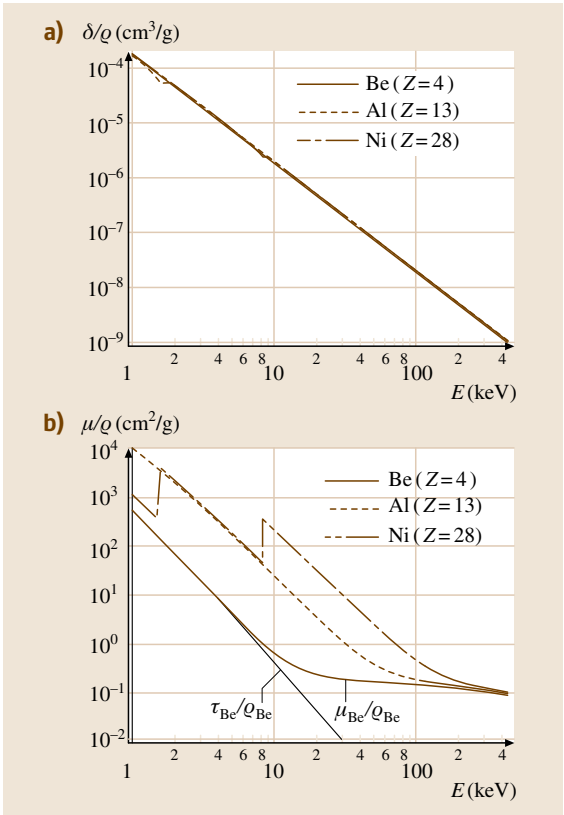

Fig. 22.2 **(a)** δ/ρ (the index of refraction decrement divided by the density of the material) for Be, Al, and Ni as a function of x-ray energy. **(b)** *Mass attenuation coefficient* μ/ρ for the same elements. After [22.2]

a plane interface between vacuum (or air) and a medium of index n under a sufficiently small angle θ_1, it is totally reflected (Fig. 22.1c). This total external reflection occurs for θ_1 smaller than the critical angle for total reflection θ_c, i. e.,

$$\theta_1 < \theta_c = \sqrt{2\delta}. \tag{22.3}$$

For hard x-rays, this angle lies below about 0.5° for all materials. In other words, total reflection occurs only at grazing incidence.

The imaginary part β of the refractive index in (22.1) describes the attenuation of x-rays in matter and is related to the linear attenuation coefficient μ by

$$\beta = \frac{\mu\lambda}{4\pi}. \tag{22.4}$$

Lambert–Beer law

$$I(z) = I_0 \cdot \mathrm{e}^{-\mu z} \tag{22.5}$$

describes the transmitted intensity $I(z)$ through a homogeneous piece of material of thickness z, given an incident intensity I_0. The linear attenuation coefficient μ is the inverse of the characteristic length of this exponential decay.

β and μ include photoabsorption as well as the attenuation of the incident beam by elastic (Rayleigh) and inelastic (Compton) scattering. The dependence of μ/ρ on the x-ray energy is shown in Fig. 22.2b. At low energies, photoabsorption τ dominates μ/ρ. As opposed to refraction, photoabsorption is strongly dependent on the atomic number. Between absorption edges it scales approximately like $\tau \sim Z^3/E^3$. With increasing x-ray energy, Compton scattering contributes increasingly to μ/ρ. Compton scattering is only weakly dependent on the atomic species and limits the mass attenuation coefficient from below to about $\mu/\rho > 0.1\,\mathrm{cm}^2/\mathrm{g}$ in the energy range from a few keV to several hundred keV. As a consequence, there is no material that is as transparent for hard x-rays as is glass for visible light. For comparison, the attenuation of visible light in glass can be as small as $\mu_{\text{ silica}} \approx 10^{-7}\,\mathrm{cm}^{-1}$ for pure silica used for fiber optics [22.3].

In the general case, elastic scattering contributes little to the attenuation of the transmitted beam. In some cases, however, when for example a Bragg reflection is excited in a crystalline material, elastic scattering can significantly attenuate the transmitted beam. In that case, the x-ray beam can be efficiently diffracted away from the forward and into another direction. Fig-

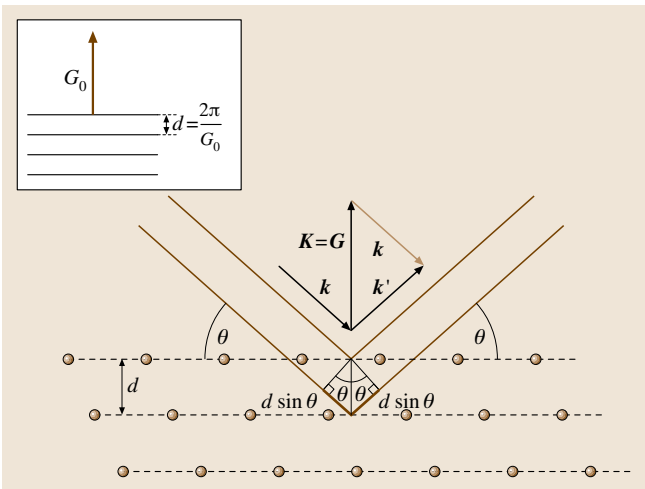

Fig. 22.3 Bragg scattering of hard x-rays from a crystalline material. The lattice planes have a spacing d and the x-rays impinge on the lattice planes under the angle θ

ure 22.3 illustrates this situation, in which the scattered amplitudes from a large number of atoms interfere constructively. This is the case when the path length difference $2d\sin\theta$ between amplitudes reflected from neighboring lattice planes is an integer multiple m of the wavelength λ of the x-rays, i. e.,

$$m\lambda = 2d\sin\theta. \tag{22.6}$$

While elastic scattering preserves the wave number ($k = 2\pi/\lambda$), the wave vector changes its direction

$$\boldsymbol{k}' = \boldsymbol{k} + \boldsymbol{G}, \tag{22.7}$$

where $\boldsymbol{G} = m\boldsymbol{G}_0$ is the reciprocal space vector associated with the lattice planes and the reflection order m (Fig. 22.3). For arbitrary alignment of a monocrystalline sample in a monochromatic beam, this virtually never occurs. However, some x-ray optics, such as crystal or multilayer optics, exploit this effect to monochromatize and focus the x-rays.

22.2 X-ray Optical Components

A large number of x-ray optical components are described in literature. One reason for this is the difficulty in manipulating x-rays due to their weak interaction with matter. There have been many complementary approaches to this problem, but none has proven significantly superior to the others. Indeed, as technology advances, approaching the physical limits, the performances of different optics become very similar. In this chapter, the most common x-ray optics are described.

22.2.1 Refractive Optics

Rotationally Parabolic Refractive X-ray Lenses

While refractive optics are most common for visible light, the interplay between weak refraction and relatively strong absorption inside the lens material makes the design of refractive lenses for hard x-rays difficult (Sect. 22.1). For instance, at 45°, the angular deviation of the refracted beam is δ, which is typically of the order of 10^{-6} rad, compared to some 17° for visible light at an air–glass interface. From the discovery of x-rays to the 1990s it was therefore believed that refractive lenses for hard x-rays could not be made [22.4–7]. In 1996 it was first demonstrated experimentally that refractive lenses can be fabricated and work despite this weak refraction and relatively strong absorption [22.8]. Since then, a variety of refractive x-ray lenses have been designed [22.9–18].

As the refractive index of hard x-rays is smaller than one ($n < 1$) in any lens material, a focusing lens has to have a concave shape (Fig. 22.4a), and since the refraction of hard x-rays in matter is about six orders of magnitude weaker than that of visible light in glass, the effective lens curvature must be accordingly stronger. For example, a biconvex lens for visible light with a radius of curvature of $R = 1\,\mathrm{m}$ for both surfaces has a focal length of about $f = R/2(n-1) \approx 1\,\mathrm{m}$. A single x-ray lens with the same focal distance would need to have a radius of curvature R in the micrometer range. It is difficult to fabricate such a lens, in particular with a sufficiently large aperture. This difficulty can be overcome by making the radius of curvature R of an

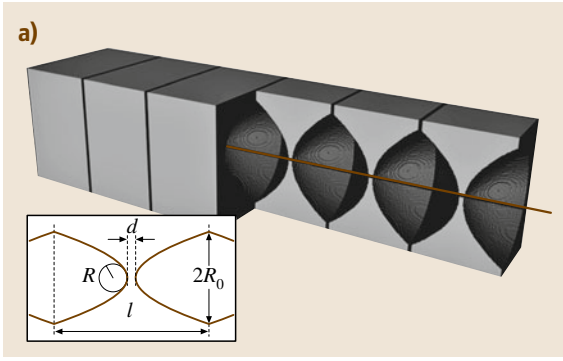

Fig. 22.4 (**a**) Parabolic refractive x-ray lenses. A large number of individual lenses is stacked behind each other to form a refractive x-ray lens. (**b**) Partially assembled parabolic refractive x-ray lens made of beryllium

individual lens larger and compensating the lack of refraction by stacking many of these lenses behind each other, as shown in Fig. 22.4a.

As the radius of curvature R has to be as small as possible to limit the number of single lenses, the spherical-lens approximation that is successfully applied in visible light optics does not apply to most x-ray lens designs. It would limit the aperture $2R_0$ of the lens to be much smaller than the radius of curvature R (Fig. 22.4a). To avoid spherical aberration and to allow for apertures that are as large as possible, the lens surfaces have to have a parabolic shape [22.9, 10, 15]. In the paraxial approximation this is the optimal aspherical lens shape. For parabolic lenses the aperture $2R_0$ can be chosen independently of the radius of curvature R (Fig. 22.4a).

Attenuation inside the lens is significant for all lens materials (Sect. 22.1), as there is no material that is as transparent in the hard x-ray range as glass is for visible light. Besides a reduction of the transmitted radiation, the attenuation inside the lens material reduces the aperture of the lens, since the thicker material in the outer parts of the lens (Fig. 22.4a) absorbs the x-rays more strongly than the thin material on the optical axis. In order to optimize the transmission and aperture it is thus important to choose the lens material carefully. As μ/ρ increases strongly with increasing atomic number Z ($\mu/\rho \sim Z^3$), atomic species with low Z, such as Li, Be, B, C, and compounds thereof, are good lens materials [22.8, 10]. In addition, the lenses should be made as thin as possible, reducing the distance d (Fig. 22.4a) between the apices of the parabolas to a minimum.

Ideal for imaging applications, in particular in x-ray microscopy, are rotationally parabolic lenses. At Aachen University, they are made by embossing the lens shape from both sides into the lens material, such as beryllium, aluminum, or nickel. These lenses are available with different radii of curvature R, ranging from 50 to 2500 μm and apertures $2R_0$ between 0.4 and 3.1 mm. Typical focal distances lie in the range 0.3–10 m, depending on the application. Figure 22.4b shows a partly assembled beryllium lens. A single lens is held and centered by a hard metal ring of well-defined diameter. These coin-like single lenses are stacked along two parallel polished shafts or in a V groove to align their optical axes. In this design, the number of lenses can be adjusted starting from a single lens up to several hundred lenses in one stack, allowing one to control the optical properties, e.g., focal length, within a wide range in a large energy interval (2 to > 100 keV). The lens is kept in an inert gas atmosphere or in vacuum to avoid corrosion of the beryllium in the intensive x-ray beam.

As the attenuation increases towards the outer parts of the lens, the rays passing the lens in these parts do not contribute as much to the image as those traveling through the lens close to the optical axis. Therefore, the effective aperture D_{eff} describing diffraction at the lens is smaller than the geometric aperture $2R_0$. It typically lies in the range of a few hundred micrometers to more than a millimeter. Attenuation inside the lens material also reduces the transmission T_p of the optic. Details about these quantities can be found in [22.10, 19].

These optics are ideal for imaging applications with hard x-rays above 5 keV, such as hard x-ray microscopy. They are free of spherical aberration. 100 nm spatial resolution has been achieved with beryllium lenses at 12 keV in an x-ray microscope [22.20]. Potentially, the diffraction limit of these optics can be pushed to below 50 nm. The lenses can be used to generate a small and intensive microbeam, by imaging the x-ray source onto the sample in a strongly reducing geometry. Besides for x-ray microscopy, these optics are commonly used for beam conditioning at third-generation synchrotron radiation sources, since they can withstand the high heat load of modern undulator sources and match their beam size very well. In addition, they find wide application in scanning microscopy, where they are used to generate intensive hard x-ray microbeams.

According to (22.2) the refractive index depends on the x-ray energy, leading to chromatic aberration. For the many experiments carried out with monochromatic synchrotron radiation, chromatic effects are irrelevant. In order to keep the focal length approximately constant at different energies, the number of lenses can be varied. This has been automated at several synchrotron radiation beamlines at the ESRF [22.21] and PETRA III (positron-electron tandem-ring accelerator). There are, however, also many experiments which require a broad x-ray spectrum or scanning the energy while keeping the focus unchanged. If the energy range is sufficiently small, a slight defocusing of the lenses can be tolerated in some cases [22.22]. In others, one should resort to genuinely achromatic optics, such as total reflection mirrors (Sect. 22.2.2).

Nanofocusing Refractive X-ray Lenses

To generate beams with a lateral extension well below one micrometer, the geometric image of the source must be made sufficiently small. This is possible by reducing the focal length f of a refractive lens, thus increasing the demagnification ratio. In addition, the diffraction

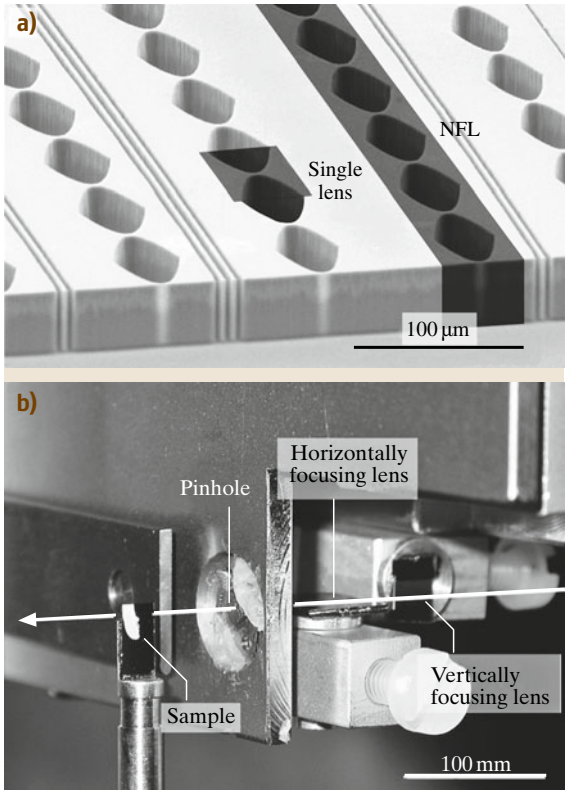

Fig. 22.5 **(a)** Scanning electron micrograph of nanofocusing lenses. A single lens and a nanofocusing lens are outlined by *dark shaded areas*. **(b)** *Nanoprobe* setup: the x-ray beam is focused onto the sample by two crossed nanofocusing lenses

limit decreases with decreasing focal length for refractive lenses. As it is difficult to reduce the focal length of the rotationally parabolic lenses to well below 0.3 m, a new type of parabolic lenses with extremely short focal distance was developed [22.23].

In order to achieve focal lengths in the centimeter range at hard-x-ray energies, the radii of curvature of the individual single lenses (Fig. 22.5a) need to be in the range of a few micrometers. This can for example be achieved with nanofabrication techniques for planar lenses, such as those shown in Fig. 22.5a. They are made of silicon by electron-beam lithography and subsequent deep reactive-ion etching. These planar structures only focus in one dimension. Thus, in order to obtain a point focus, two such lenses with appropriate focal lengths need to be crossed. Figure 22.5b shows a nanoprobe setup based on two crossed nanofocusing lenses (NFLs). With this setup, hard-x-ray beams down to about $50 \times 50\,\mathrm{nm}^2$ have been generated at the European Synchrotron Radiation Facility (ESRF) in Grenoble, France [22.24].

With optimized parameters, these optics are expected to generate beams with a lateral size between 10 and 20 nm. This is a physical limit for the given lens design. There are more-complicated lens designs that will in principle allow one to overcome this limit and focus hard x-rays down to below 5 nm [22.25].

22.2.2 Reflective Optics

Mirrors

The reflectivity of a surface or interface is negligible for large angles. Only in grazing incidence below the critical angle of total external reflection θ_c are high reflectivities possible (Sect. 22.1). This makes x-ray mirrors and capillaries very slender, i. e., much longer than wide. According to (22.2) and (22.3) θ_c depends mainly on the x-ray wavelength λ and on the density ρ of the mirror material. The higher the x-ray energy ($E = hc/\lambda$) the smaller the critical angle θ_c. In order to have sufficiently large reflection angles, materials with high density, such as palladium or platinum, are often used.

Two effects reduce the ability of a mirror to reflect x-rays without losses: absorption and surface roughness. X-rays penetrate into the mirror surface to a depth of a few nanometers. Here, they are partially absorbed, so that just below the critical angle the reflectivity is often far below 50%. For heavy elements and just above absorption edges this is particularly strong.

The second detrimental effect to the reflectivity is surface roughness. Due to the short wavelength of hard x-rays roughness brings the reflection amplitudes of a photon in the different areas inside each Fresnel zone out of phase, so that the total amplitude and hence the reflectivity are reduced. For high-quality mirror optics, the surface roughness must be in the 0.1 nm range. This effect and the high requirements on form fidelity make x-ray mirrors very expensive optical components.

For a given grazing incidence geometry with reflection angle θ_1, total-reflection mirrors reflect x-rays up to the energy where $\theta_1 = \theta_c$. They act like a low-pass filter for x-rays and are therefore often used to remove the high-energy content from the beam. In conjunction with a crystal monochromator, this allows one to strongly reduce higher harmonic radiation ($m \geq 2$ in (22.6)) and generate a clean monochromatic beam.

To focus or collimate x-rays, mirrors can be curved. To focus the x-rays, i. e., to image the source from point to point, the mirror surface needs have ellipsoidal shape

(Fig. 22.6a). For collimation, i. e., generating a parallel x-ray beam, the mirror surface needs to be parabolic (Fig. 22.6b). To achieve focusing or parallelization in two dimensions with a single reflection, the mirror must have the shape of an ellipsoid or paraboloid of rotation, respectively. Due to the very small reflection angle, this rotational body is very elongated (needle-like) having extremely different curvatures in the sagittal and meridional direction. Since such a mirror is extremely difficult to fabricate with high accuracy, there are only a few realizations. These optics are also referred to as elliptical or parabolic monocapillaries.

To avoid strong sagittal curvature, two reflections from flat mirrors are often used to obtain two-dimensional focusing. Figure 22.7 illustrates this scheme, which was first described by *Kirkpatrick* and *Baez* in 1948 [22.26]. Today, this technique is widespread as a focusing optic for scanning microscopy at synchrotron radiation sources. While it is relatively difficult to align, it has the great advantage of being achromatic for x-rays below a critical energy given by the maximal angle of incidence. This makes these optics particularly useful for white-beam microdiffraction techniques [22.27] and for absorption spectroscopy studies.

Today, these mirrors can be fabricated with extremely small surface roughness and excellent form fidelity, generating hard x-ray beams with a lateral size as small as 25 nm [22.28]. Since the reflection angles are limited by θ_c, the numerical aperture and thus the diffraction-limited focus size is limited, too. It is expected that beam sizes down to below 20 nm can be reached with total reflection mirrors. One way to overcome this limit is to use multilayer mirrors (Sect. 22.2.3) or use more-complicated multiple-reflection schemes.

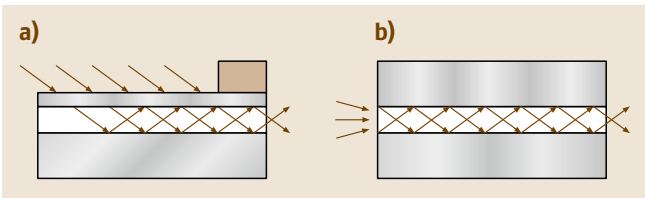

Fig. 22.8 X-ray waveguide. (a) The x-rays are coupled into the waveguide through the cap layer. (b) Focused x-rays are directly coupled into the waveguide

Waveguides

Another optical component which is based on total reflection and which has been developed recently are x-ray waveguides. They consist of a substrate made of a material with high density (e.g., nickel), a light-element (e.g., carbon) layer on top of it and a cap layer made of a dense material again (Fig. 22.8). The middle layer is the guiding layer, which is typically a few tens of nm thick. The x-rays are confined inside the waveguide by total external reflection at the side walls defined by the denser materials. The device works in analogy to a waveguide for microwaves.

There are two ways to couple x-rays into a waveguide. A well-collimated plane wave can be coupled into the waveguide through the thin cap layer [22.29] or a focused beam can be directly coupled into the waveguide from the side [22.30], as shown in Fig. 22.8a,b, respectively. Only those modes that survive by constructive interference can propagate in the waveguide. Depending on the illumination, different modes can be systematically excited, corresponding to different standing waves in the transverse direction. The first waveguides were planar structures, confining the beam only in one direction. Today, using nanofabrication techniques, two-dimensionally confining waveguides can be made [22.30].

Waveguides are mostly used for two types of applications: to illuminate a sample confined inside the waveguide [22.31] or to generate a very fine beam that is emerging from its exit. At the exit, the beam size is comparable to the dimensions of the waveguide. Lateral dimensions of 25 nm × 45 nm can be generated [22.30]. Recently, more efficient *planar waveguides* making use of a more sophisticated stack of materials were introduced, generating confined beams below 20 nm [22.32].

This beam can be used for projection microscopy and has a high degree of lateral coherence. If a single mode is excited inside the waveguide, the exiting beam is perfectly coherent. This can be exploited for coherent imaging experiments and holography. The smallest size that x-rays can be confined to by waveguides is also limited by total-reflection effects and is expected to lie slightly below 10 nm [22.33]. Until now, these components are in the stage of development and have not yet found widespread application.

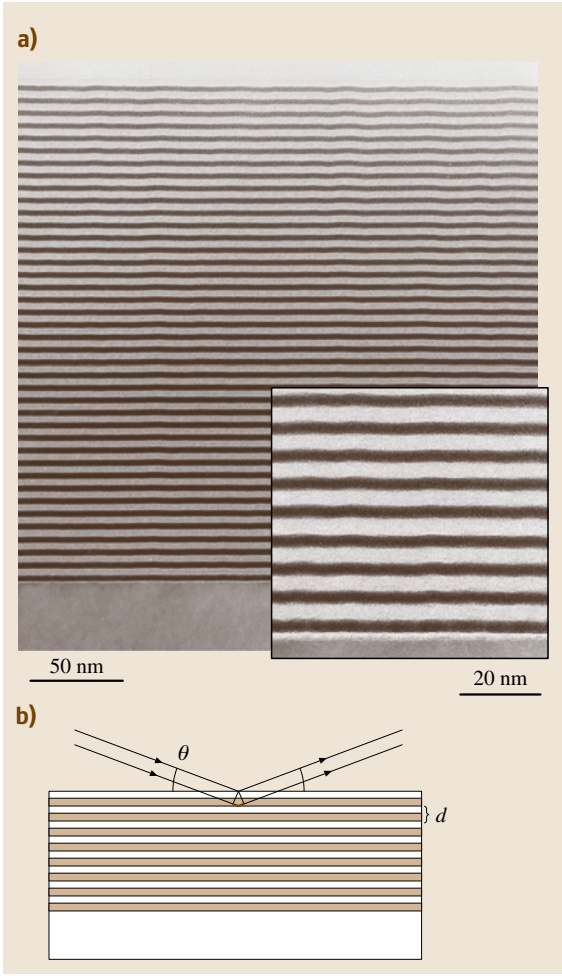

Fig. 22.9 **(a)** High-resolution transmission electron micrograph of a multilayer optic consisting of $N = 40$ double layers of Mo and Si. The lattice spacing is $d = 7$ nm. The *inset* shows a detail of the multilayer including the interface with the monocrystalline substrate (courtesy of S. Braun, Fraunhofer IWS, Dresden [22.34]). **(b)** Schematic drawing of a multilayer optic. The x-rays are reflected from the multilayer if the Bragg condition (22.6) is fulfilled, i. e., the *dark brown segment* of the lower optical path is an integer multiple of the x-ray wavelength λ

22.2.3 Diffractive Optics

Multilayer Optics

Multilayer optics consist of a series of alternating layers of high- and low-density materials. Figure 22.9a shows a transmission electron micrograph of a multilayer made of 40 double layers of Mo and Si. Figure 22.9b shows the operating principle of these optics: the x-rays impinging at the angle θ are reflected from the multilayer if the Bragg condition (22.6) for the multilayer is fulfilled, i. e., the path-length difference marked in dark brown in Fig. 22.9b is an integer multiple of the wavelength λ. Here, d is the period of the multilayer, which can be chosen freely and typically lies in the range from about 2 to 20 nm, and the resulting Bragg angles lie in the range of degrees for hard x-rays. The reflectivity can be close to one (70–90%) for hard x-rays. It depends on the number of layers and the difference in electron density between the two multilayer materials. As for total-reflection mirrors, the reflectivity is also deteriorated by attenuation inside the optic and by roughness of the interfaces.

Similar to crystal optics, multilayers can be used to monochromatize the x-ray beam. The monochromaticity and the angular acceptance depend on the number of periods that contribute to the reflection. This number is either limited by the total number of periods N in the stack or by the extinction length inside the multilayer. A detailed description of the reflectivity of multilayer systems can be found in [22.35].

To use these optics to focus or collimate the x-ray beam in the geometries shown in Fig. 22.10, the spacing d of the multilayer needs to be adapted to the reflection angle that varies along the optic. Such laterally graded multilayers were first introduced by *Schuster* and *Göbel* to capture a large solid angle from an x-ray tube and collimate it for diffraction experiments [22.36, 37]. A variety of optics exist today that either focus or collimate the beam from an x-ray tube. Since the reflection angles are larger than in the total-reflection case (Sect. 22.2.2) there are sagittally curved elliptical and parabolic mirrors in addition to double-bounce systems of Kirkpatrick–Baez (KB) type.

For scanning microscopy, curved multilayer systems in the KB geometry are used with great success, generating very intensive nanobeams down to well below 100 nm [22.38, 39]. These optics have the ad-

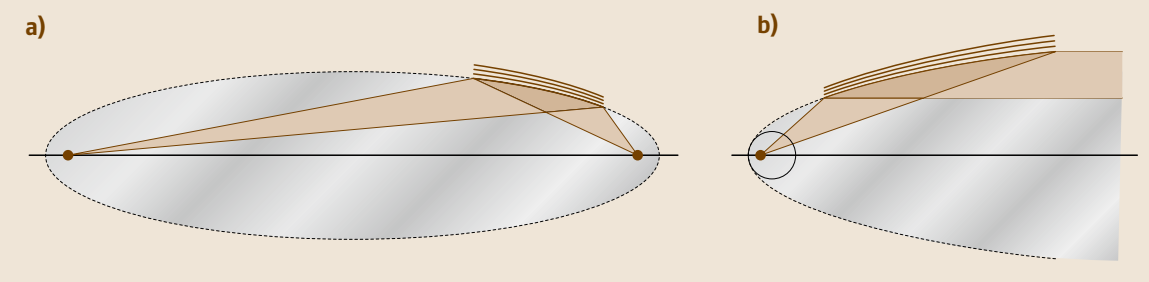

Fig. 22.10 (a) Elliptical graded multilayer for focusing. (b) Parabolic graded multilayer for focusing and collimation. The period d changes as a function of position on the optic, locally adjusting the Bragg angle to the angle of reflection

vantage that they moderately monochromatize the beam at the same time. In this way, an additional crystal monochromator can be avoided. This can be advantageous for experiments that do not require a high degree of monochromatization, since the larger energy band pass leads to a higher flux. Due to the relatively large reflection angles, the numerical aperture of these optics can be relatively large. Recently, one-dimensional focusing of hard x-rays down to 7 nm was demonstrated with these optics [22.40].

The flexibility in the choice of the lattice parameters and its variation over the mirror open possibilities that cannot be realized with crystal optics. Besides lateral grading of the multilayers, depth grading can also be useful, e.g., to tailor the angular acceptance and energy bandwidth of the device. As there are some applications of these optics in conjunction with laboratory x-ray tubes, there is a larger market for these optics, and they are available from a number of laboratories and commercial companies. Multilayers are also of great importance in the extreme ultraviolet (EUV) range, where they are used in lithographic steppers.

Crystal Optics

The main field of application of crystal optics is monochromatization of x-rays using Bragg reflection (Sect. 22.1). Depending on the crystal, crystal cut, reflection, and the arrangement of different crystals, relative energy bandwidths $\Delta E/E$ from about 10^{-3} to 10^{-7} can be reached, finding wide application at nearly every beam line at synchrotron radiation sources. High energy resolutions are needed in particular in inelastic x-ray scattering and nuclear resonance scattering.

Besides pure monochromatization, crystal optics can also be used to focus x-rays from point to point. As one cannot adjust the d-spacing for varying reflection angles as for multilayer optics (Fig. 22.10) a geometry in which the reflection angle is constant and equal to the Bragg angle θ_B for every point on the optic has to be used. Figure 22.11 shows a bent crystal in Johann geometry. In Johann geometry, the Bragg planes are parallel to the crystal's surface. The meridional bending radius R_h is twice the radius of the so-called Rowland circle (Fig. 22.11). To focus also out of plane, the crystal has to be sagittally bent as well. In that direction the bending radius is $R_v = R_h \sin^2\theta_B$ (Fig. 22.11). Both the source and the focus lie on the *Rowland circle*, forming an isosceles triangle with the crystal.

For larger and larger crystals, the surface deviates increasingly from the Rowland circle. To fulfill the Bragg condition strictly in that case, the crystal needs to be cut to follow the Rowland circle when bent. This is called the Johansson geometry, which is very difficult to realize and is therefore not used very often.

The bending of the crystal optic has to be very accurate in order to stay within the width of the Bragg reflection over the whole surface. In addition, the crys-

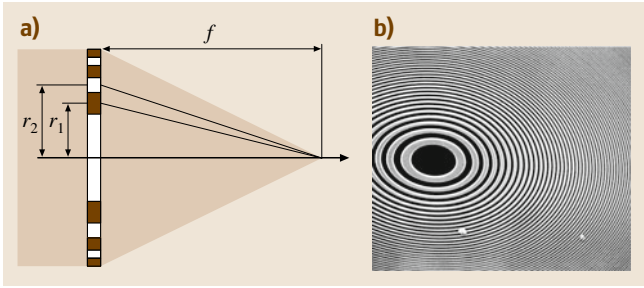

Fig. 22.12 Fresnel zone plate. **(a)** Schematic diagram, **(b)** *Scanning electron microscope* (SEM) image

tal must not be damaged. As this bending procedure is difficult, these optics are not very widespread.

Fresnel Zone Plates

The most important diffractive optical components are Fresnel zone plates. They have found very widespread applications, particularly at energies below a few keV, like for example in the water window. As a genuine imaging optic, they can be used as objective lens in full-field microscopy and to generate a small focus for scanning microscopy.

Fresnel zone plates consist in their simplest form of a set of alternating transparent and opaque rings (Fig. 22.12), so-called zones, with an optical path length difference of $\lambda/2$ between neighboring zones for x-rays propagating from infinity through the zone plate to the focus at distance f behind it. The amplitudes of all transparent zones superpose constructively when the radii of all zones are given by

$$r_n = \sqrt{n\lambda f + \frac{n^2\lambda^2}{4}}, \quad n = 0, 1, 2, \ldots , \tag{22.8}$$

where the even zones are transparent and odd zones are opaque or vice versa. Here, f is the focal length of the optic for a given wavelength λ. In first diffraction order, the zone plate is most efficient, and about 10% of the radiation falling onto its aperture can be focused into this diffraction order. The spatial resolution depends on the numerical aperture $\mathrm{NA} = r_n/f$ and is in this case given by

$$d_\mathrm{t} = 1.22\frac{\lambda}{2\mathrm{NA}} = 1.22\Delta r_n , \tag{22.9}$$

which is approximately equal to the width of the outermost zone Δr_n. The factor 1.22 comes from the Rayleigh criterion for the spatial resolution of a circular optic [22.41]. This means that the spatial resolution corresponds to that of the smallest features in the zone plate. For increasing x-ray energy, it becomes increasingly difficult to make a zone plate with opaque zones. Therefore, this type of optic is mostly used in the soft-x-ray regime, in particular in the so-called water window between the absorption edges of carbon and oxygen. As the opaque zones become more transparent, the zone plate loses its efficiency.

For harder x-rays one therefore pursues another scheme. Rather than blanking out the amplitudes of every other zone, one can shift them by π, adding to the constructive interference in the focus. Such phase zone plates are much more efficient than zone plates with opaque zones and have an optimal efficiency of about 40% in the first diffraction order. Despite this new scheme, the zones still need to have a thickness in the micrometer range for hard x-rays around 10 keV. To reach high spatial resolution efficiently the fabrication of very thin but high zone plate structures is required. While there have been tremendous improvements over the last view years, it is still a challenge to make these structures. However, there are several institutions and commercial sources for these optics. Another phase-shifting optic is a Bragg–Fresnel optic, in which the Fresnel zones are etched into a single crystal surface [22.42]. Tuned to Bragg condition, the x-rays are diffracted from different heights inside the zone plate structure. Refraction introduces the desired phase shift between the even and odd zones.

In the soft-x-ray range, zone plates with spatial resolution down to 15 nm have been made [22.43]. Even higher spatial resolutions have been demonstrated with zone plates made with a special thin film technique [22.44]. In the hard x-ray range, the high aspect ratio of the outermost zones currently limits the spatial resolution to about 50 nm [22.45]. For such a high-resolution zone plate, the aperture is typically in the range of a couple of hundred microns and is made of several hundred zones.

As the aspect ratio increases with decreasing outermost zone width, the thin object approximation for the Fresnel zone plates becomes less appropriate. Propagation effects inside the zone plate structure need to be taken into account. It was shown theoretically that the zones of a zone plate need to be tilted to fulfill a local Bragg condition in order not to lose their focusing efficiency for smaller outermost zone widths [22.46]. While these structures are even more difficult to fabricate, they are predicted to be able to generate focal sizes down to 1 nm and below [22.47, 48]. These structures are currently approximated by so-called multilayer Laue lenses [22.49–51]. Focusing down to below 20 nm has been demonstrated with these devices.

22.3 Characterizing X-ray Nanobeams

As smaller and smaller *nanobeams* are produced, the more difficult becomes their characterization. While beams of several micrometers in size can be directly imaged using high resolution *x-ray cameras*, beams in the submicrometer range are typically characterized by scanning a sharp edge through the beam and recording the transmission, x-ray fluorescence or scattering signal from it. This technique yields the beam profile in scanning direction, integrating over the perpendicular direction. For highest spatial resolutions, phase shifting edges [22.53] and analyzers based on thin film technology [22.54] are scanned through the beam.

Recently, scanning coherent diffraction microscopy also known as ptychography was introduced in the field of x-ray microscopy [22.55, 56]. In this technique, an object is scanned through a confined coherent x-ray beam (Fig. 22.13). At each position of the scan, a *far-field diffraction* pattern is recorded. From these data, the complex transmission function and the complex wave field at the position of the object can be consistently reconstructed [22.57–59], provided there is a sufficient overlap between the illuminated areas of neighboring scan points. The spatial resolution of this technique goes beyond that of classical scanning microscopy, where the beam size limits the spatial resolution. As an example, the reconstructed image of a resolution test pattern is shown in Fig. 22.14a (a detailed description of the experiment is given in [22.52]). It was recorded with a scanning microscope based on *nanofocusing refractive x-ray lenses* at an x-ray energy of 15.25 keV. For comparison, the scanning fluorescence image (tantalum L radiation) is shown in Fig. 22.14b, demonstrating the improvement in spatial resolution obtained by this technique. In ptychography, the spatial resolution is limited by the largest momentum at which diffracted photons are recorded by the detector in the far field. Thus increasing the dose on the sample increases the spatial resolution.

Besides the object *transmission function*, the complex wave field at the sample position can be reconstructed. In this way, a detailed image of the x-ray beam is obtained. Figure 22.15a and b shows the reconstructed nanobeam obtained in the example given above [22.52]. In Fig. 22.15b the beam shows weak side maxima that can be accurately reconstructed. They are responsible for the fact that the object can be reconstructed outside of the scanning region delineated by the white line in Fig. 22.14a. As the complex wave field in the plane of the object is available, the full caustic of the beam can be reconstructed by propagation (Fig. 22.15c). Therefore, the sample does not need to be perfectly in focus. Indeed, the exact focal position

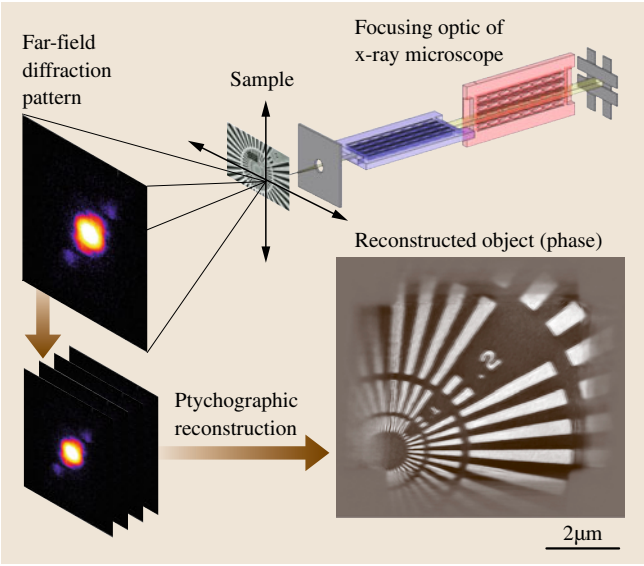

Fig. 22.13 Scanning coherent diffraction microscopy also known as ptychography: the sample is scanned through a focused coherent beam. At each position of the scan, a far-field diffraction pattern is recorded. From these data, the object's complex transmission function can be reconstructed

Amplitude and phase of the wave field are encoded by brightness and hue, respectively (compare color wheel) (after [22.52]) ◀

can be determined by propagation. The intensity distribution is given by the absolute square of the amplitudes. In the given example, a lateral beam size of $78 \times 86\,\mathrm{nm}^2$ was determined [22.52]. The method does not rely on a special test object, but works best for strongly scattering objects with high structural diversity on the scale of the lateral beam size.

This technique is a quick and reliable method to fully characterize diffraction limited nanobeams, and has been applied to diffraction-limited beams from different optics [22.52, 60–62]. In the meantime it is routinely used to characterize the focus in hard x-ray microscopes at the European Synchrotron Radiation Facility in Grenoble, France, and at the synchrotron radiation source PETRA III at DESY in Hamburg, Germany.

23. Radiation and Optics in the Atmosphere

This chapter describes the fundamentals of radiation transport in general and in the Earth's atmosphere. The role of atmospheric aerosol and clouds are discussed and the connections between radiation and climate are described. Finally, natural optical phenomena of the atmosphere are discussed.

There are a multitude of processes in which electromagnetic radiation interacts with the atmospheric constituents:

- Absorption, i. e. radiation is removed from the radiation field and converted into some other form of energy, e.g. heat. Absorption can be due to molecules in the atmosphere (such as ozone, oxygen, or water vapor) or aerosols (such as soot), absorption of solar energy in the atmosphere is an important process in the climate system of the Earth.
- Elastic scattering, which – seen from an individual photon – changes its direction of propagation and polarization, but not its energy (and hence wavelength or *color*). Scattering can be due to molecules (Rayleigh scattering) or aerosol particles (Mie scattering) present in the air.
- Inelastic scattering where, as for elastic scattering, the direction of a photon is changed but

where its energy is also changed. Inelastic scattering by molecules is called Raman scattering, where the energy of the scattered photon can be reduced at the expense of energy transferred to the scattering molecule (Stokes scattering). Likewise, energy can be transferred from the (thermally excited) molecules to the photon (anti-Stokes scattering).

- Thermal emission from air molecules and aerosol particles. The emission at any given wavelength cannot exceed the Planck function (or emission from a black body) for the temperature of the atmosphere, thus noticeable thermal emission only takes place at infrared wavelengths longer than several micrometers. Due to Kirchhoff's law only absorbing gases (such as CO_2, H_2O, O_3, but not the main components of air N_2, O_2, Ar), can emit radiation.
- Aerosol fluorescence. Excitation of molecules within aerosol particles by radiation can result in (broad band) fluorescence; this process will not be further discussed here.

23.1 Radiation Transport in the Earth's Atmosphere

In the following we introduce the basic quantities pertinent to the propagation of radiation in the atmosphere and discuss the fundamental laws governing radiation transport in absorbing and scattering media, i. e. the atmosphere.

23.1.1 Basic Quantities Related to Radiation Transport

A light source will emit a certain amount W of energy in the form of radiation.

1. The radiant flux Φ is defined as the radiation energy W per unit time (regardless of the direction in which it is emitted)

$$\Phi = \frac{\text{radiated energy}}{\text{time interval}} = \frac{\mathrm{d}W}{\mathrm{d}t} \quad \left[\frac{\mathrm{W\,s}}{\mathrm{s}} = \mathrm{W}\right] . \tag{23.1}$$

2. The irradiance B is defined as the radiant flux Φ received by an (*illuminated*) area A_e

$$B = \frac{\Phi}{A_\mathrm{e}} \quad \left[\frac{W}{\mathrm{m}^2}\right] . \tag{23.2}$$

3. The radiation intensity is (Ω = solid angle)

$$I = \frac{\Phi}{\Omega} \quad \left[\frac{\mathrm{W}}{\mathrm{sr}}\right] . \tag{23.3}$$

4. The radiance is (A_s = radiating area)

$$F = \frac{\Phi}{\Omega A_\mathrm{s}} \quad \left[\frac{\mathrm{W}}{\mathrm{m}^2\mathrm{sr}}\right] . \tag{23.4}$$

(All areas are assumed to be oriented perpendicular to the direction of propagation of the radiation.)

23.1.2 Absorption Processes

Radiation is absorbed by molecules in the atmosphere (such as ozone, oxygen, or water vapor), aerosols (such as soot or sea salt) or liquid and solid water particles (cloud droplets (ice crystals)). Absorption of solar ultraviolet (UV) radiation at wavelengths below about 300 nm by atmospheric O_2 and O_3 is important for life on Earth.

23.1.3 Rayleigh Scattering

Elastic scattering (i. e. scattering without change of the photon energy) by air molecules or very small particles is called Rayleigh scattering. The transition between Rayleigh scattering and Raman scattering is described in Fig. 23.1b which shows that the scattering coefficient $Q = \sigma/2\pi r^2$ i. e. the scattering cross section σ devided by the physical cross section $2\pi r$ of a particle (with radius r) as a function of the size parameter $\alpha = 2\pi r/\lambda$. For a given wavelength the scattering cross section increases by 6 orders of magnitude with increasing particle size until it reaches roughly unity at $\lambda \approx r$. While scattering is not an absorption process, light scattered out of the probing light beam will normally not reach the detector, thus for narrow beams it is justified to treat Rayleigh scattering as an absorption process (Sect. 23.2.4). The Rayleigh scattering cross section $\sigma_\mathrm{R}(\lambda)$ (in cm^2) is given by [23.1]

$$\sigma_\mathrm{R}(\lambda) = \frac{24\pi^3}{\lambda^4 N_\mathrm{air}^2} \frac{\left[n_0(\lambda)^2 - 1\right]^2}{\left[n_0(\lambda)^2 + 2\right]^2} F_\mathrm{K}(\lambda)$$

$$\approx \frac{8\pi^3}{3\lambda^4 N_\mathrm{air}^2} \left[n_0(\lambda)^2 - 1\right]^2 F_\mathrm{K}(\lambda) , \tag{23.5}$$

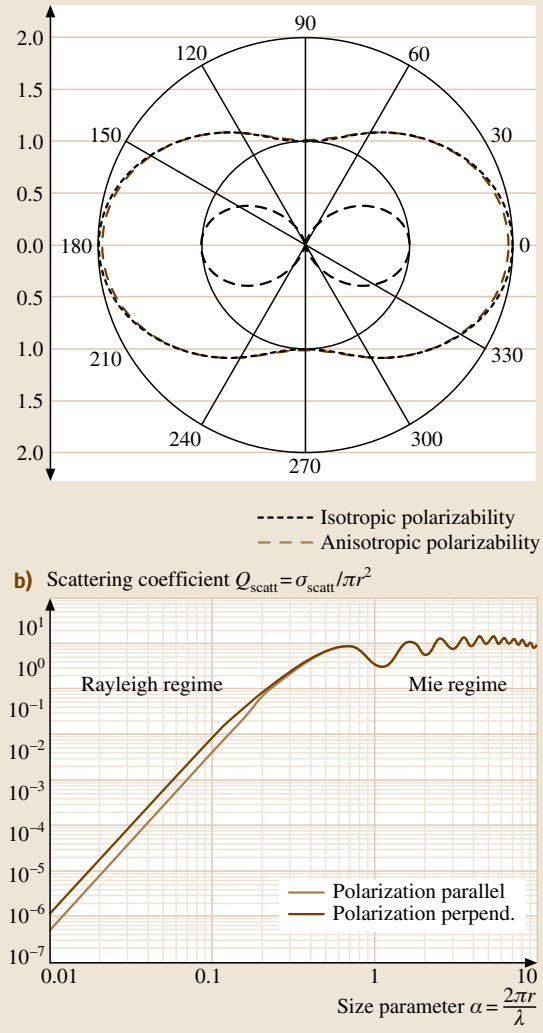

Fig. 23.1 **(a)** Polar diagram of the Rayleigh scattering phase function $\Phi(\vartheta)$ for unpolarized incident light (*dashed line*, normalized to 2). The contribution of light polarized parallel to the scattering plane shows the $\sin^2\vartheta'$ dependence of a Hertz dipole (*dotted line*, normalized to 1), with $\vartheta' = \pi/2 - \vartheta$ being the angle between dipole axis and the Poynting vector of the incident radiation, while the contribution of light polarized perpendicular to the scattering plane (*drawn line*, normalized to 1) is independent of ϑ. (plot by F. Filsinger). **(b)** Dependence of the scattering coefficient ($Q = \sigma/2\pi r^2$) on the size parameter ($\alpha = 2\pi r/\lambda$). For particles small compared to the wavelength the scattering coefficient becomes very small and falls off with $1/\lambda^4$)

where λ denotes the wavelength, $n_0(\lambda)$ is the real part of the wavelength-dependent index of refraction of air, N_{air} is the number density of air (e.g. 2.4×10^{19} molecule/cm^3 at 20 °C, 1 atm), $F_K(\lambda) \approx 1.061$ is a correction for anisotropy (polarisability of air molecules).

Note that $n_0(\lambda)^2 - 1 \approx 2[n_0(\lambda) - 1] \propto N_{air}$, since $n_0 \approx 1$ [in fact n_0 (550 nm) = 1.000293], and $n_0 - 1 \propto N_{air}$, thus $\sigma_R(\lambda)$ is essentially independent of N_{air}. On that basis a simplified expression for the Rayleigh scattering cross section (in cm^2 and λ in μm) is given by *Nicolet* [23.2]

$$\sigma_R(\lambda) \approx \frac{4.02\times10^{-28}}{\lambda^{4+x}} \qquad (23.6)$$

with

$$x = 0.04 \quad \text{for} \quad \lambda > 0.55\,\mu\text{m}\,,$$
$$x = 0.389\lambda + 0.09426/\lambda - 0.3328 \quad \text{for} \quad 0.2\,\mu\text{m} < \lambda < 0.55\,\mu\text{m}\,.$$

For simple estimates the Rayleigh scattering cross section can be written as

$$\sigma_R(\lambda) \approx \sigma_{R0}\lambda^{-4}$$
$$\left(\sigma_{R0} \approx 4.4\times10^{-28}\ \text{cm}^2\,\mu\text{m}^4 \text{ for air}\right). \qquad (23.7)$$

The extinction coefficient due to Rayleigh scattering $\varepsilon_R(\lambda)$ is then given by

$$\varepsilon_R(\lambda) = \sigma_R(\lambda) N_{air}\,. \qquad (23.8)$$

The Rayleigh scattering phase function (Fig. 23.1) is given by

$$\Phi(\cos\vartheta) = \tfrac{3}{4}(1 + \cos^2\vartheta)\,. \qquad (23.9)$$

Taking the anisotropy of the polarisability into account the above equations becomes [23.3]

$$\Phi(\cos\vartheta) = 0.7629(0.9324 + \cos^2\vartheta)\,. \qquad (23.10)$$

23.1.4 Raman Scattering

While Raman (and Mie) scattering can be regarded as elastic scattering processes, where no energy is transferred between the scattering particle and the photon, inelastic scattering occurs, if the scattering particle (i. e. molecule) changes its state of excitation during the scattering process. A part of the photons energy is then passed from the photon to the molecule

(Stokes lines, $\Delta J = +2$, S-branch) or vice versa (anti-Stokes, $\Delta J = 2$, O-branch). The term rotational Raman scattering (RRS) is used if only the rotational excitation is affected ($\Delta v = 0$). If the vibrational state also changes, the term (rotational-) vibrational Raman scattering (VRS) is used ($\Delta v = \pm 1$). Only discrete amounts of energy given by the difference between the discrete excitation states can be absorbed/emitted. For air (O_2 and N_2) RRS frequency shifts of up to $\pm 200\,\mathrm{cm}^{-1}$ occur, for VRS a vibrational shift of $\pm 2331\,\mathrm{cm}^{-1}$ for nitrogen and $\pm 1555\,\mathrm{cm}^{-1}$ for oxygen has to be added. The VRS is one order of magnitude weaker than the RRS, and RRS is roughly one magnitude weaker than Rayleigh scattering.

In the following we give a quantitative description of rotational- and vibrational-Raman scattering by O_2 and N_2 [23.4–7]. The scattered power density $I_{v,J\to v',J'}$ in $[\mathrm{W/m}^2]$ scattered into the full solid angle 4π involving a transition (v, $J \to v'$, J') is given by [23.8]

$$I_{v,J\to v',J'} = I_0 \sigma_{v,J\to v',J'} L N_{\mathrm{air}} g_J (2J+1) \frac{1}{Z} \mathrm{e}^{-E(v,J)/kT} , \tag{23.11}$$

where I_0 is the incident power density, N_{air} is the number of molecules in the scattering volume, L is the length of the volume and g_J is the statistical weight factor of the initial rotational state due to the nuclear spin; J and v are the rotational and vibrational quantum numbers, respectively. The factor $(2J+1)$ accounts for the degeneracy due to the magnetic quantum numbers while $\exp[-E(v, J)/kT]$ accounts for the population of the initial state of the molecule at temperature T. The state sum Z is given by the product of the rotational state sum Z_{rot} and the vibrational state sum Z_{vib}. The absolute cross section in (23.11) is given by $\sigma_{v,J\to v',J'}$, which can be obtained by integration of the differential cross section $\mathrm{d}\sigma_{v,J\to v',J'}/\mathrm{d}\Omega$ over the entire solid angle Ω. Note that the term differential refers to the solid angle. The energy of the molecule is characterized by the vibrational (v) and rotational (J) quantum numbers and given by

$$\begin{aligned} E(v, J) &= E_{\mathrm{vib}}(v) + E_{\mathrm{rot}}(J) \\ &= hc\tilde{\nu}\left(v + \tfrac{1}{2}\right) + hcBJ(J+1) , \end{aligned} \tag{23.12}$$

assuming no coupling between rotation and vibration, B is the rotational constant and $\tilde{\nu}$ is the wave number in cm^{-1} of the ground state vibration. Allowed transitions are, in that approximation, $\Delta J = 0, \pm 2$ resulting in the Q-, O- and S-branches and $\Delta v = 0, \pm 1$ for vibrational transitions. Due to the temperatures in the Earth's atmosphere only the ground vibrational state is occupied significantly, thus leading only to Stokes transitions of the vibrational states.

Table 23.1 Comparison of the total cross section for the different scattering types for 770 nm, 273 K

Scattering type	Cross section (cm^2)	Ratio (%)
Rayleigh	1.156×10^{-27}	100
O_2 RRS	7.10×10^{-29}	6.1
N_2 RRS	2.94×10^{-29}	2.5
Air RRS	3.82×10^{-29}	3.3
VRS	–	0.1

Polarization Properties of Vibrational Raman Scattered Light and Line Filling in

The polarization properties of isotropic and anisotropic component of Raman scattered light are described by (23.13), respectively

$$\begin{aligned} \frac{I_{\mathrm{parallel}}}{I_{\mathrm{perp}}}(\mathrm{anisotropic}) &= \frac{6+\cos^2\Theta}{7} , \\ \frac{I_{\mathrm{parallel}}}{I_{\mathrm{perp}}}(\mathrm{isotropic}) &= \cos^2\Theta , \end{aligned} \tag{23.13}$$

where the terms parallel and perpendicular refer to the plane defined by the sun, the scattering point and the observer. Thus only the isotropic part leads to enhanced polarization of scattered light, especially at large scattering angles (≈ solar zenith angle (SZA)). Since the Q-branch of the vibrational band of the Raman-scattered light consists of an isotropic fraction, this will lead to an enhanced degree of polarization in the center of a Fraunhofer line. But due to the small cross section of vibrational Raman scattering, this enhancement is very small (e.g. ≅ 0.3% for the Ca–I line at 422.7 nm and a resolution of 0.01 nm) and occurs only at large scattering angles. Thus the observed high degrees of polarization at small solar zenith angles cannot be attributed to vibrational Raman scattering [23.9].

Due to the relatively small cross section of vibrational–rotational Raman scattering the additional filling-in of Fraunhofer or terrestrial absorption lines is around 10% of the filling-in due to rotational Raman scattering (Table 23.1).

23.1.5 Mie Scattering

Mie scattering is (after [23.10]) defined as the interaction of light with (particulate) matter of dimensions

comparable to the wavelength of the incident radiation. It can be regarded as the radiation resulting from a large number of coherently excited elementary emitters (i. e. molecules) in a particle. Since the linear dimension of the particle is comparable to the wavelength of the radiation, interference effects occur.

The most noticeable difference compared to Rayleigh scattering is the usually much weaker wavelength dependence (see below) and a strong dominance of the forward direction in the scattered light. The calculation of the Mie scattering cross section can be very complicated (involving summing over slowly converging series), even for spherical particles, but even more so for particles of arbitrary shape. However, the Mie theory (for spherical particles) is well-developed and a number of numerical models exist to calculate scattering phase functions and extinction coefficients for given aerosol types and particle size distributions

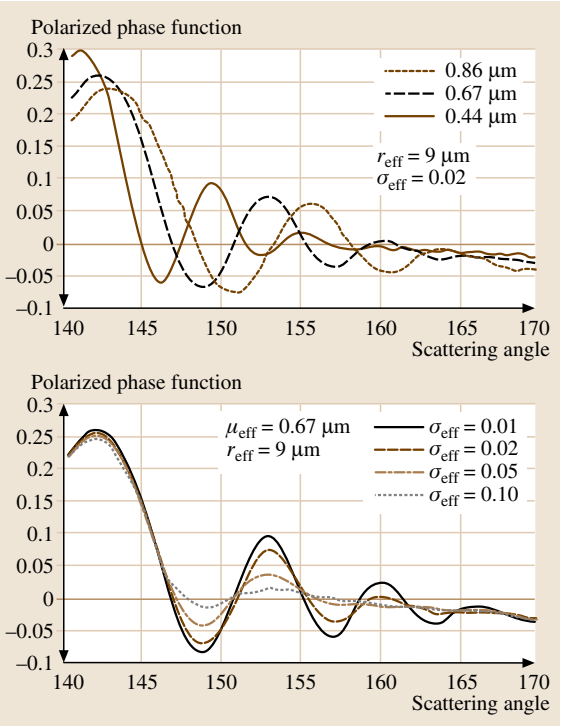

Fig. 23.2 Polarized Mie scattering phase function as a function of scattering angle for cloud droplets having a lognormal particle size distribution with an effective radius $r_{eff} = 9\,\mu m$. *Upper panel*: phase function as a function of wavelength with fixed $\sigma_{eff} = 0.02$ effective size variance; *lower panel*: as a function of effective size variance σ_{eff} (courtesy of *Bréon* and *Goloub*, 2003)

see Figs. 23.2, 23.15 [23.11, 12]. The computational effort is substantially reduced by the introduction of an analytical expression for the scattering phase function, which only depends on a few observable parameters. Most common is the Henyey–Greenstein parameterization

$$\Phi(\cos\vartheta) = \frac{1-g^2}{4\pi(1+g^2-2g\cos\theta)^{3/2}}\,, \qquad (23.14)$$

which only depends on the asymmetry factor g (average cosine of the scattering function)

$$g = \langle\cos\theta\rangle = \frac{1}{2}\int_{-1}^{1} P(\cos\theta)\cos\theta\,\mathrm{d}\cos\theta \qquad (23.15)$$

see e.g. [23.11]. For isotropic scattering [$\Phi(\cos\theta) =$ const] the asymmetry factor $g = 0$ while for a tropospheric aerosol a typical value might be as large as $g \approx 10$.

Tropospheric aerosol is either emitted from the surface (e.g. sea salt, mineral dust, biomass burning) or forms in the gas phase by condensation of chemically formed hygroscopic species (primarily sulphates, nitrates, or oxidized organic material). The aerosol load of the atmosphere, i. e. particle number density and size distribution, depends on the aerosol origin and history. Parameters for typical aerosol scenarios (urban, rural, maritime, background) can be found in the database for the radiative transfer model LOWTRAN [23.13], which includes the extinction coefficients and the asymmetry factors as well as their spectral dependence. Another important aspect is Mie scattering by cloud particles. A radiative transfer model including all cloud effects known to date was, e.g., developed by *Funk* [23.14].

Mie scattering is only partly an absorption process, but by similar arguments as in the case of Rayleigh scattering, for narrow beams it can be treated as an absorption process with an extinction coefficient of

$$\varepsilon_M(\lambda) = \varepsilon_{M_0}\lambda^{-\alpha} \qquad (23.16)$$

with the Angström exponent α being inversely related to the mean aerosol particle radius. Typically α is found to be in the range 0.5–2.5 with an average value of $\alpha = 1.3$ [23.15, 16]. For the ideal case of an exponential aerosol size distribution

$$\frac{\Delta N}{\Delta r} = r^{-(\nu+1)}\,.$$

The Angström exponent is related to the Junge index ν by $\nu = \alpha + 2$ [23.17]. Thus an Angström exponent of 1.3 would correspond to a Junge index of 3.3.

In summary a more comprehensive description of atmospheric extinction (in the presence of a single trace gas species and neglecting Raman scattering) can be expressed as

$$I(\lambda) = I_0(\lambda) \exp\left\{ - L[\sigma(\lambda)c + \varepsilon_R(\lambda) + \varepsilon_M(\lambda)]\right\} . \tag{23.17}$$

Typical extinction coefficients due to Rayleigh and Mie scattering at 300 nm are $1.3 \times 10^{-6}\,\mathrm{cm}^{-1}$ and $1-10 \times 10^{-6}\,\mathrm{cm}^{-1}$, respectively.

23.2 The Radiation Transport Equation

In this section we present the basic equations describing the radiation transport (RT) in absorbing and scattering media as described by the above elementary processes. In physical notation the RT equation is a continuity equation with corresponding source and sink terms (Fig. 23.3); these source and sink terms are assumed to be linear in the radiant flux Φ, intensity I, or radiance F (23.1, 23.3, 23.4).

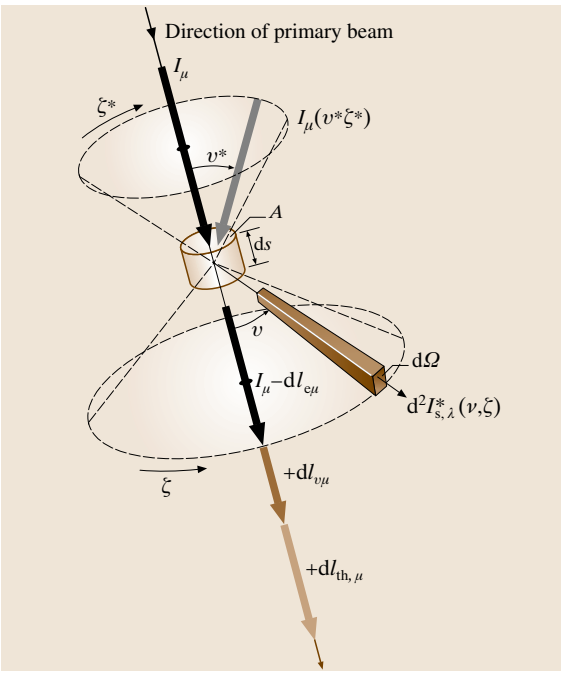

Fig. 23.3 Schematic drawing of the continuity equation for radiative transfer. The continuity assumes linearity of processes in the intensity I_λ. When passing through a distance ds the incoming radiation I_λ is attenuated by extinction (absorption and scattering), $I_{e,\lambda}$. The source term for the outgoing light is the scattered light $\mathrm{d}I^*_{s,\lambda}$ from the space angles θ^* and φ^* and thermal radiation $\mathrm{d}I^*_{th,\lambda}$ (courtesy of Rödel, 1999)

23.2.1 Sink Terms (Extinction)

First we consider the radiant flux Φ per unit space angle Ω and wavelength λ i. e., the incoming intensity I_λ (23.3) which is attenuated within the distance ds by absorption and scattering. As before we refer to the absorption (a) and scattering (s) coefficients with $\varepsilon_a = N\sigma_a(\lambda)$ and $\varepsilon_s = N\sigma_s(\lambda)$, respectively, with N being the number of absorber or scatterers per volume and $\sigma_i(\lambda)$ being absorption or scattering cross sections. Both processes are commonly referred to as extinction. Accordingly, we obtain the following continuity equation for the incoming intensity traversing the distance ds

$$\begin{aligned} \mathrm{d}I_\lambda &= -[\varepsilon_a(\lambda) + \varepsilon_s(\lambda)] I_\lambda \,\mathrm{d}s \\ &= -[\sigma_a(\lambda) + \sigma_s(\lambda)] n I_\lambda \,\mathrm{d}s \,, \end{aligned} \tag{23.18}$$

where ε_a is the absorption coefficient, ε_s is the scattering coefficient, $\sigma_a(\lambda)$ is the absorption cross section of the absorber (molecule), $\sigma_s(\lambda)$ is the scattering cross section of the absorber (molecule), and n is the number of absorbers per unit volume.

23.2.2 Source Terms (Scattering and Thermal Emission)

In the gas phase there are two sources of radiation: thermal emission and scattering, i. e. the radiation removed from the primary beam due to scattering (23.18) reappears as a radiation source.

Scattering

Evidently, the outgoing light receives some intensity $\mathrm{d}I^*_{s,\lambda}$, by scattering from all space angles θ^* and φ^*. We introduce a dimensionless scattering function $S(\theta^*, \varphi^*)$

$$S_\lambda(\theta, \varphi) = \frac{4\pi}{\sigma_s} \frac{\mathrm{d}\sigma_s(\lambda)}{\mathrm{d}\Omega} \tag{23.19}$$

which we integrate over all angles weighted with the incoming intensity $I_s^*, \lambda(\theta^*, \varphi^*)$

$$\mathrm{d}I_s^*(\lambda) = \varepsilon_s(\lambda)\,\mathrm{d}s \int_0^{\pi}\int_0^{2\pi} I^*(\lambda,\theta^*,\varphi^*) \times \frac{S(\theta^*,\varphi^*)}{4\pi}\,\mathrm{d}\varphi^*\sin\theta^*\,\mathrm{d}\theta^* \qquad (23.20)$$

to obtain the intensity added to the outgoing intensity $\mathrm{d}I_s^*$.

Thermal Emission

Finally the intensity due to thermal emission $\mathrm{d}I_{th}(\lambda, T)$ by the volume element ($\mathrm{d}V = A\,\mathrm{d}s$) is added to the outgoing intensity

$$\mathrm{d}I_{th}(\lambda, T) = \varepsilon_a(\lambda) I_p(\lambda, T)\,\mathrm{d}s = \varepsilon_a(\lambda) F_p(\lambda, T) A\,\mathrm{d}s \qquad (23.21)$$

where, as before, K_a denotes the absorption coefficient and $F_P(\lambda, T)$ denotes the Planck function

$$\mathrm{d}F_P(\lambda, T) = \frac{2hc^2}{\lambda^5}\frac{\mathrm{d}\lambda}{\mathrm{e}^{hc/\lambda kT} - 1}\,. \qquad (23.22)$$

Combining the above source and sink terms we obtain the radiation transport equation (23.23)

$$\frac{\mathrm{d}I(\lambda)}{\mathrm{d}s} = -[\varepsilon_a(\lambda) + \varepsilon_s(\lambda)]I(\lambda) + \varepsilon_a(\lambda) I_P(\lambda, T) + \varepsilon_s(\lambda) \times \int_0^{\pi}\int_0^{2\pi} I^*(\lambda,\theta^*,\varphi^*)\frac{S(\theta^*,\varphi^*)}{4\pi}\,\mathrm{d}\varphi^*\sin\theta^*\,\mathrm{d}\theta^* \qquad (23.23)$$

23.2.3 Simplification of the Radiation Transport Equation

Frequently simplifications of the radiation transport equation are possible, if only partial systems are of interest.

For instance at short wavelengths (UV, visible) the Planck term can usually be neglected

$$\frac{\mathrm{d}I(\lambda)}{\mathrm{d}s} = -[\varepsilon_a(\lambda) + \varepsilon_s(\lambda)]I(\lambda) + \varepsilon_s(\lambda) \times \int_0^{\pi}\int_0^{2\pi} F(\lambda,\theta,\varphi)\frac{S(\theta,\varphi)}{4\pi}\,\mathrm{d}\varphi\sin\theta\,\mathrm{d}\theta\,. \qquad (23.24)$$

If thermal radiation (from the atmosphere) is of interest due to its long wavelength, Rayleigh and Mie scattering (by aerosol particles and cloud droplets) can frequently be neglected

$$\frac{\mathrm{d}I(\lambda)}{\mathrm{d}s} = \varepsilon_a(\lambda)[A F_P(\lambda, T) - I(\lambda)]\,. \qquad (23.25)$$

With the definition of the optical density $\mathrm{d}\tau = \varepsilon_a(\lambda)\,\mathrm{d}s$ and after division by A the above equation becomes

$$\frac{\mathrm{d}F(\lambda)}{\mathrm{d}\tau} = F_P(\lambda, T) - F(\lambda)\,. \qquad (23.26)$$

This latter equation is also known as the Schwarzschild equation.

23.2.4 Light Attenuation in the Atmosphere

When considering the question of the attenuation of radiation in the atmosphere, two (extreme) cases can be distinguished, as illustrated in Fig. 23.4: wide beams (WB, as e.g. the illumination of the Earth's atmosphere by the sun) and narrow beams (NB, as e.g. the light

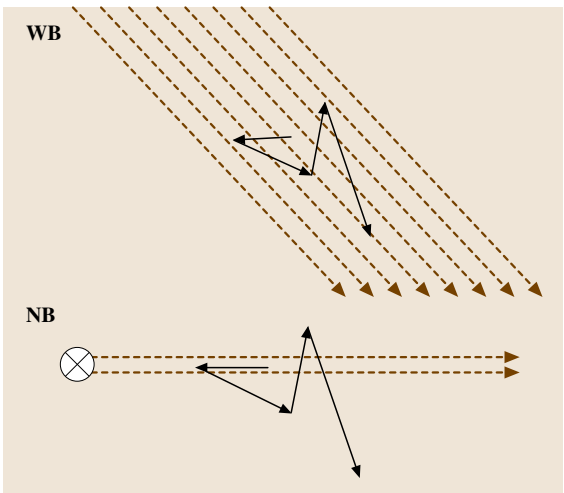

Fig. 23.4 Difference between Wide Beams (WB, *top*) as, e.g., the illumination of the Earth's atmosphere by the sun, and Narrow Beams (NB, *bottom*) as, e.g., the light beam emitted by a searchlight-type light source. In the NB case the probability of a photon being scattered back into the beam after being scattered out of the beam is generally negligible, therefore extinction can be treated like absorption. In the case of a WB the lateral (i. e. perpendicular to the propagation of the incident radiation flux) radiation flux can be neglected. Therefore the scattering has only the effect of reflecting some of the incoming light, as can be calculated by, e.g., a two-stream model (see above)

beam emitted by a searchlight-type differential optical absorption spectroscopy (DOAS) light source).

Wide Beams (WB) in the Atmosphere: The Two-Stream Model

In the following we consider the transport of solar radiation in the atmosphere. Compared to the general form of the radiation transport equation (23.23) the problem is simplified by assuming a flat, horizontally homogeneous and infinite atmosphere. Therefore only the vertical (z) component of the radiance has to be considered.

When radiation enters the atmosphere from above, its vertical component is counted as *downwelling radiation* $F_{\downarrow}(\lambda, z)$; upon interaction with atmospheric constituents (gases or aerosol) this radiation is either absorbed or scattered (Fig. 23.5). These extinction processes reduce the amount of downwelling radiation (according to (23.17), where the extension of the light path for nonvertical rays has to be taken into account). While the absorbed radiation causes no further problems, the scattered radiation appears as a source term, which is split into two parts (taking the phase function into account): A downwelling part, which adds to $F_{\downarrow}(\lambda, z)$ and an upwelling part, which is added to a second, upwelling radiation flux $F_{\uparrow}(\lambda, z)$. Thermal emission adds to both, $F_{\downarrow}(\lambda, z)$ and $F_{\uparrow}(\lambda, z)$. For practical calculation the atmosphere is divided into layers of thickness $\mathrm{d}z$, which change the radiance F traversing it by $\mathrm{d}F$. The net radiance is composed of both components (up- and downwelling radiances)

$$F_n(\lambda, z) = F_{\uparrow}(\lambda, z) - F_{\downarrow}(\lambda, z) \,. \tag{23.27}$$

Narrow Beams (NB) in the Atmosphere

In the case of a WB the lateral (i. e. perpendicular to the propagation of the incident radiation flux) radiation flux can be neglected. Therefore the scattering has only the effect of reflecting some of the incoming light, as can be calculated by e.g. a two-stream model (see above).

In contrast, in the case of narrow beams the probability of a photon being scattered back into the beam after being scattered out of the beam is generally negligible (Fig. 23.4), therefore extinction can be treated as absorption.

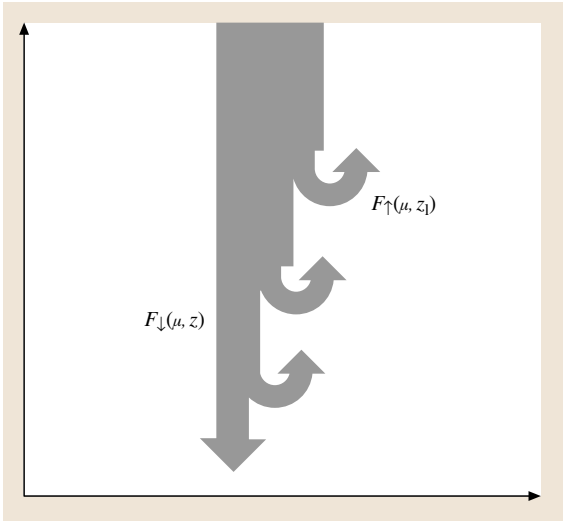

Fig. 23.5 The two-stream model. In a horizontally homogeneous atmosphere radiation transport can be represented by just two 'streams of radiation', the downwelling flux and the upwelling flux

The attenuation of a light beam by extinction due to atmospheric constituents is in principle described by (23.17). For practical purposes of measurements in the atmosphere, however, (23.17) is oversimplified in that it neglects the presence of other causes of light extinction, including absorption by other molecules present in the atmosphere.

In the natural atmosphere many different molecular species will absorb light. Equation (23.17) must therefore be further extended to

$$I(\lambda) = I_0(\lambda) \exp\left(-L\{\Sigma[\sigma_i(\lambda)c_i] + \varepsilon_{\mathrm{R}}(\lambda) + \varepsilon_{\mathrm{M}}(\lambda)\}\right) , \tag{23.28}$$

where $\sigma_i(\lambda)$ and c_i denote the absorption cross section and the concentration of the i-th species, respectively.

23.3 Aerosols and Clouds

Aerosols are a natural constituent of the Earth's atmosphere and their origin is mostly natural, although lately the anthropogenic contribution is increasing. An aerosol is defined as a stable suspension of particles, liquid or solid, in a carrier gas like atmospheric air. Therefore dust, haze, smoke, smog, fog, mist, and

clouds can be considered to be specific aerosol types. The total mass of natural aerosols was found be four times larger than due to human activity in 1968, and by the year 2000 the anthropogenic contribution is estimated to have doubled. According to *Junge* and *Manson* [23.18], aerosols can be classified by sizes: particles with diameters below 0.1 mm are named Aitken particles, while those with sizes between 0.1–1 mm are *large* particles, and those larger than 1 mm are called *giant* particles. The aerosols may also be classified according to their origin into marine, continental, rural, remote, background, and urban aerosol, where each category has different characteristics like chemical composition, size distribution, shapes and so on. Aitken nuclei, i. e. the smallest atmospheric aerosol particles, are naturally produced from supersaturated vapors by a process called gas-to-particle conversion (GPC), often in connection with photochemical reactions between gas-phase constituents (Fig. 23.6). Anthropogenic activities such as combustion and industrial processes increasingly lead to the release of aerosol particles, or precursor gases from which aerosol particles are formed, into the atmosphere. Large aerosol particles can be produced by combustion processes and other anthropogenic or natural processes (e.g. the coagulation of smaller Aitken nuclei). Natural sources for giant particles are bulk-to-particle conversion (BPC) processes like sea-salt aerosol production, or desert dust mobilization, while human activity contributes, for example through emission from industries, mining, biomass and wood burning, and agricultural dust generation.

In the atmosphere, typical particle number concentration decreases with increasing particle size since Aitken particles are newly produced; they subsequently coagulate and form fewer larger particles. Accordingly Aitken particles usually dominate the total number of particles in an air sample, but their contribution to the total aerosol volume is small, whilst an increasing contribution is due to the large and giant particles. Conversely, Aitken particles often dominate the surface available for heterogeneous reactions. For particles with sizes ranging from a few nanometers up to tens of micrometers typical number concentrations can be coarsely specified. For example, typical aerosol numbers are: 1) $\approx 1.4\times10^4\,\mathrm{cm}^{-3}$ at the (continental) ground level total concentrations, 2) $\approx 6\times10^2\,\mathrm{cm}^{-3}$ in remote continental regions, 3) $10^5\,\mathrm{cm}^{-3}$ in large cities, 4) $\approx 3\times10^4\,\mathrm{cm}^{-3}$ in small towns, 5) $\approx 5\times10^2\,\mathrm{cm}^{-3}$ over remote oceans, 6) $\approx 50\,\mathrm{cm}^{-3}$ in the clean Arctic, and 7) even lower in the remote Antarctica. The vertical aerosol profiles (in number of particles per cubic centimeter of air) frequently show an exponential decay for the lowest 6 km of the atmosphere. Above this level, background tropospheric aerosol concentrations (in the Aitken mode) are around 200–300 particles per cm^3. Above the tropopause up to around 30 km, the total number concentration decreases again to a minimum below $1–10\,\mathrm{cm}^{-3}$ particles in volcanically quiet periods and $1000\,\mathrm{cm}^{-3}$ after major volcanic eruptions.

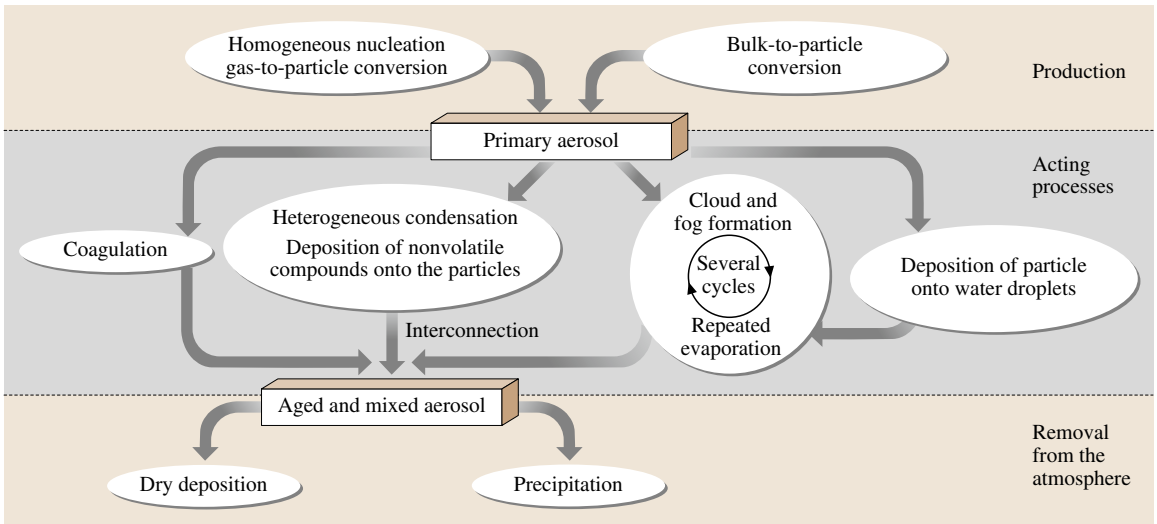

Fig. 23.6 Aerosol-related processes in the atmosphere involving particle formation, processes altering particle characteristics, and removal from the atmosphere

At any time, about 50% of the globe is cloud covered. Atmospheric clouds are volumes of water-supersaturated air containing hydrometeors, which are microscopic objects (e.g. aerosol particles, cloud droplets, ice and snow crystals) as well as macroscopic objects (snowflakes, graupel grains, raindrops, and hailstones). The individual cloud particles have sizes with radii ranging from 0.001 mm to several hundreds of micrometers, or even centimeters, as in the case of hailstones.

Atmospheric clouds can be classified into four major categories: 1) low-level cloud in the lower troposphere (< 2.5 km), 2) middle-level clouds in the middle troposphere (2.5–8 km), 3) higher clouds in the upper troposphere (8–15 km), and 4) middle (stratospheric) and upper (mesospheric) atmospheric clouds, which themselves form 11 major subgroups (1.1 cumulus, 1.2 stratocumulus, 1.3 stratus, 2.1 altocumulus, 2.2 altostratus, 2.3 nimbostratus, 3.1 cirrus and cirrostratus, 3.2 cirrocumulus, 3.3 cumulonimbus, 4.1 polar stratospheric clouds, and 4.2 noctilucent clouds) of some 100 different cloud types in total.

Both aerosols and clouds have a considerable impact on atmospheric photochemistry and radiation. Their effects in atmospheric photochemistry are most noticeably in: 1) the heterogeneous processing of longer-lived and ozone-friendly halogen species ($ClONO_2$, HCl, $BrONO_2$, ...) into ozone-harmful halogen oxides (ClO, BrO) on polar stratospheric cloud particles, which is a major reason for the formation of the Antarctic ozone hole, 2) uptake of acids (e.g., H_2SO_4, HNO_3, HCl, HBr, ...) and of N_2O_5 on the stratospheric or tropospheric aerosols and cloud particles, 3) in the heterogeneous conversion of SO_2 into H_2SO_4, or NO_3 and N_2O_5 into HNO_3 and 4) the uptake of species such as NH_3HNO_3, or NH_4HSO_4 into atmospheric aerosols and cloud particles. Eventually when these particles grow large enough (> some μm), the respective gases attached or solved inside are efficiently washed out from the atmosphere.

Aerosols and clouds also have a large effect on the radiative budget of the atmosphere, primarily by increasing the scattering of the incoming solar and outgoing thermal radiation. Clouds affect radiation both through their three-dimensional geometry and the amount, size and nature of the hydrometeors which they contain. In climate models these properties translate into cloud cover at different levels, cloud water content (for liquid water and ice) and cloud droplet (or crystal) equivalent radius. The interaction of clouds and radiation also involves other parameters (asymmetry factor of the Mie diffusion) which depend on cloud composition, and most notably on their phase.

In effect, the occurrence of aerosols and clouds increases the planetary albedo A of the solar short-wave (SW) radiation, and thus lead to a net cooling of the Earth. Conversely clouds, and to a much lesser degree aerosols, increase the infrared albedo B of the atmosphere and thus increase the downwelling atmospheric long-wave (LW) radiation which increases the surface temperature. The subtle balance between cloud impact on the SW and terrestrial long-wave radiation altered by a change in any of the aforementioned parameters, the dependence of the radiation budget on altitude at which clouds occur and the solar inclination (latitude and season) make clouds the most sensitive factors to affect the global climate in both directions (cooling/warming).

23.4 Radiation and Climate

The atmospheric radiation budget largely determines the Earth's climate. Evidently the incoming solar or short-wave (SW) radiation shining on the globe has to be balanced by the outgoing long-wave (LW) radiation. This thermal equilibrium between incoming SW and outgoing LW radiation and can be simply expressed by

$$S_0(1-A)/4 = \varepsilon(1-B)\sigma T_s^4 \qquad (23.29)$$

where S_0 is the solar constant (1370 W/m^2), A is the terrestrial SW albedo (0.298), the factor 4 coming from geometric considerations, ε is the LW emissivity (0.96), B is the atmospheric LW albedo (0.34), σ is Boltzmann's constant (5.67×10^{-8} $W/(m^2\,K)$), and T_s is the average temperature ($T_s = 286$ K) of the Earth's surface. It thus becomes clear that the globe's surface temperature T_s is given by a delicate balance of the parameters S_0, A, and B. In geological and historic times, the solar constant is known to have varied on different timescales, mostly given by changes in the Earth's orbital parameters, as suggested by *Milankovitch* in 1941 [23.19] and solar activity (Table 23.2), causing well recognized and significant effects on the Earth's climate. In this context, most notable is that the size

Table 23.2 Compendium of change in recognized periods in climate change and changes in the solar constant S_0

Time scale/period	Cause	Change in solar constant S_0	Observation/problem
4.5 Ga	Secular trend in solar output	Secular 25–30% increase	'Faint Sun problem', i. e. liquid H_2O should not have been there, but was present since 4 Ga before present
450 ka	Change in orbital eccentricity $\Delta\varepsilon = 0.06$	$< 0.7\,W/m^2$ [23.19]	Change in ice volume, $\Delta^{18}O/^{16}O$ in H_2O and $CaCO_3$ in foraminifera
100 ka	Change in orbital eccentricity $\Delta\varepsilon = 0.06$	$< 0.7\,W/m^2$ [23.19]	Change in ice volume, $\Delta^{18}O/^{16}O$ in H_2O and $CaCO_3$ in foraminifera
41 ka	Change in obliquity (axial tilt) due to Earth and Jupiter's orbital plane tilt	June insulation changed by 25% at 80° N, no net change on annual S_0 [23.19]	Change in ice volume, $\Delta^{18}O/^{16}O$ in H_2O and $CaCO_3$ in foraminifera
23 ka		June insulation changed by $100\,W/m^2$ at 60° N, no net change on annual S_0 [23.19]	Change in ice volume, $\Delta^{18}O/^{16}O$ in H_2O and $CaCO_3$ in foraminifera
1.5 ka	Unclear whether cause is solar, 'eigenmode' of the climate system?		^{14}C and ^{10}Be variation in oceanic sediments, ^{14}C variation in tree rings
210a (Suess) 148a, and 88a (Gleisberg) cycles	Unclear whether cause is solar, 'eigenmode' of the climate system?		^{14}C variation in tree rings, ^{14}C and ^{10}Be variation ice cores
22a	Sun spot 'overtone', eigenmode in solar magnetic field oscillation	$\Delta S_0 \approx 1.5\,W/m^2$, UV radiation changes by 0.37–0.6%	Change in atmospheric circulation?
11a (Schwabe 1843)	Sun spot 'overtone', eigenmode in solar magnetic field oscillation		Change in atmospheric circulation?
4w (27d)	Sun rotation period	Small	?

ΔS_0 of any of the known processes listed in Table 23.2 has not been sufficiently large to be held solely responsible for documented ΔT_s changes, which were inferred to be as large as some 10 °C. Therefore, it is well accepted that the global climate system amplifies external disturbances (forcing) through interacting complicated positive and negative feedback cycles (Table 23.2).

Another factor important for T_s is of course the magnitude and variability of the SW albedo A (23.35). This is largely influenced by the amount of cloud and the abundance of atmospheric aerosol; the latter is either due to increasing directly back reflection of SW radiation to space, or by altering the cloud particle formation processes, a process called the indirect aerosol effect [23.20, 21]. In the recent past changes in the global albedo due to increasing atmospheric aerosol abundances, mostly particles containing sulphuric acid has been well recognized and held partly responsi-

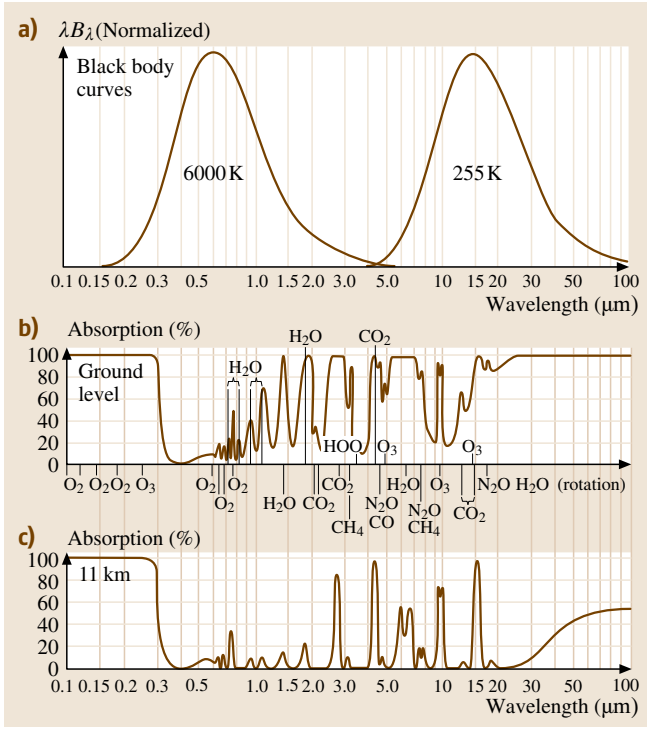

Fig. 23.7a–c Schematic overview of the SW (*left part*) and LW (*right part*) radiative transfer in the atmosphere; *upper panel*: **(a)** incoming solar SW and outgoing LW terrestrial spectrum, **(b)** atmospheric absorption from individual gases at ground level (total atmosphere) and **(c)** at 11 km ▶

ble for lower global T_s between the late 1940s to late 1970s [23.20]. Changing global cloud cover is also likely to have occurred in the past. In the tropics, which are a particularly sensitive region for the global energy budget, the cloud cover appears to be highly variable on timescales ranging from days to decades. Accordingly, satellite-based cloud cover records that began in the late 1970s are still insufficiently long to establish unambiguously an observation-based relation between a changing A and T_s [23.22].

The atmospheric LW albedo B is responsible for the greenhouse effect of the atmosphere. If B were zero, then according to (23.35), T_s would be 255 K, clearly cooler than the habitable Earth is able to provide ($T_s = 287$ K). The value of B is due to the combined action of the most important atmospheric greenhouse gases H_2O, CO_2, CH_4, O_3, N_2O, and many others, mostly man-made, trace molecules [23.20]. It appears that, even though each greenhouse gas has its own specific spectrum, they combine in a way that only a small fraction of the outgoing LW radiation is not absorbed in the atmosphere, i. e., radiation in the atmospheric window (8–14 μm) (Fig. 23.7).

In 1896, the atmospheric greenhouse effect of CO_2 was already recognized by Arrhenius. Accordingly it is undisputed in the scientific community that rising atmospheric CO_2 concentrations affect the atmospheric LW budget and thus T_s. Radiative transfer calculations show that the CO_2 increase from preindustrial 280 ppm to presently 390 ppm alone gives rise to a present day radiative forcing of 1.66 W/m^2 and for all greenhouse gases of 2.67 W/m^2 ([23.20], Fig. 23.8). Naively adding the respective radiative forcing in (23.18) leads to a $\Delta T_s = +0.7$ K, precisely the value that is reported for the global average temperature rise in the past 150 y [23.20]. However, due to the complicated interactions in the climate system, it is under discussion how the global climate system is and will react in detail to future man-induced LW radiative forcing.

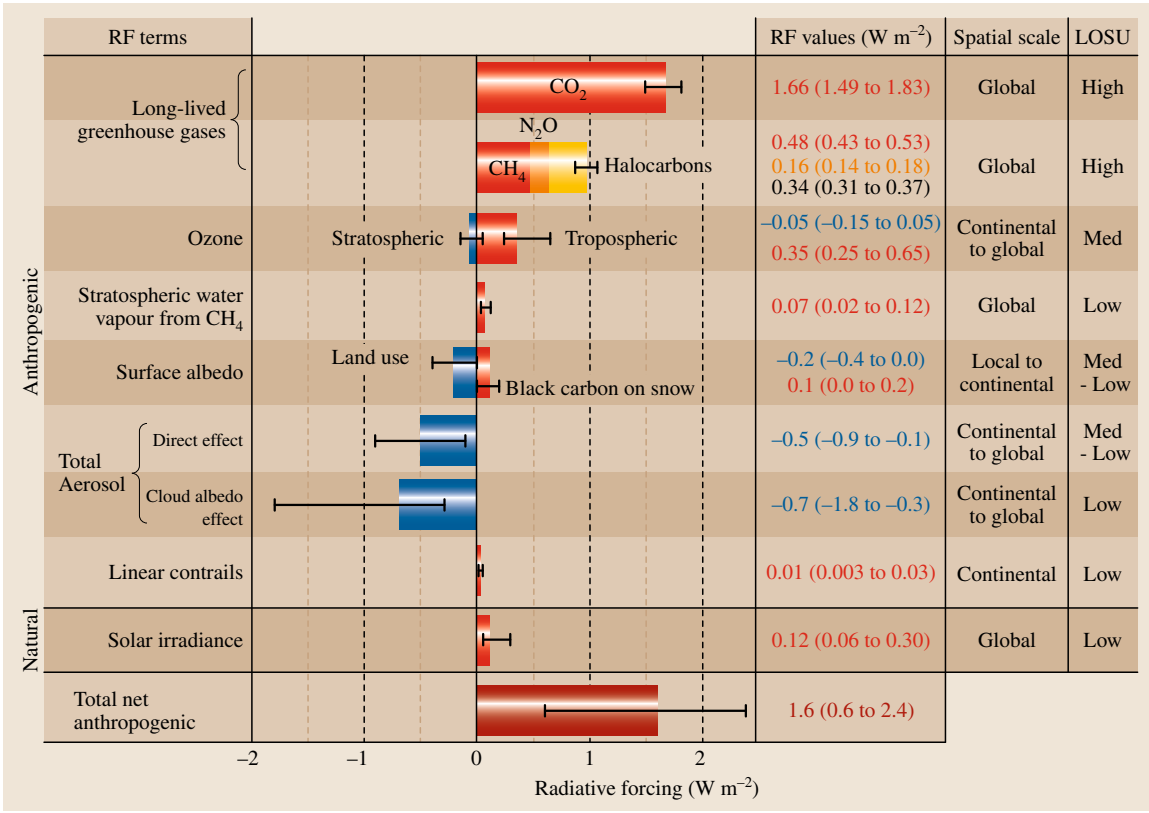

Fig. 23.8 Estimates for external factors (gases and aerosol) which force climate change (after [23.20])

23.5 Applied Radiation Transport: Remote Sensing of Atmospheric Properties

23.5.1 Trace Gases

Measurements of trace gas concentrations (and other quantities such as aerosol distribution or the intensity of the radiation field in the atmosphere) are the experimental prerequisites for the understanding of the physico-chemical processes in the Earth's atmosphere. At the same time the determination of trace gas concentrations in the atmosphere constitutes a challenge for the analytical techniques employed in several respects: It is well known (e.g. *Perner* et al. [23.23]) that species (such as OH radicals) present at mixing rations ranging from as low as 0.1 ppt (one ppt corresponds to a mixing ratio of 10^{-12}, equivalent to about 2.4×10^7 molecules/cm^3) to several ppb (1 ppb corresponds to a mixing ratio of 10^{-9}) can have a significant influence on the chemical processes in the atmosphere. Thus, detection limits from below 0.1 ppt to the ppb range are required, depending on the application. On the other hand, measurement techniques must be specific, i. e. the result of the measurement of a particular species should neither be positively nor negatively influenced by any other trace species simultaneously present in the probed volume of air. Given the large number of different molecules present at the ppt and ppb level, even in clean air, meeting this requirement is also not trivial.

Presently many highly sophisticated techniques for the measurement of atmospheric trace species are in use. Among these, spectroscopic techniques [23.24, 25] offer a series of unique advantages including high (i. e. ppt-level in many cases) sensitivity, very specific detection of a given molecule, inherent calibration, and wall-free operation. These properties, in combination, are difficult to obtain in techniques based on other principles. Here we describe a particular technique, differential optical absorption spectroscopy (DOAS), which has been successfully used in atmospheric measurements for several decades now, while new applications continue to be introduced.

23.5.2 The Fundamentals of DOAS

The DOAS technique [23.26, 27] makes use of the structured absorption of trace gases. Typically spectra are recorded which encompass several hundred spectral channels. Evaluation is done by fitting the spectral structure of the trace gases, thus making use of all the spectral information. DOAS has proven to be particularly useful for the determination of the concentration of unstable species such as free radicals or nitrous acid. In addition, the abundance of aromatic species can be determined at high sensitivity (see below). DOAS, like all spectroscopic techniques, relies on the absorption of electromagnetic radiation by matter. Quantitatively the absorption of radiation is expressed by the Lambert–Beers law

$$I(\lambda) = I_0(\lambda)\exp[-L\sigma(\lambda)c]\,, \tag{23.30}$$

where $I(\lambda)$ is the intensity after passing through a layer of thickness L, while $I_0(\lambda)$ denotes the initial intensity emitted by the light source. The species to be measured is present at the concentration (number density) N_c. The quantity $\sigma(\lambda)$ denotes the absorption cross section at the wavelength λ; it is a characteristic property of any species. The absorption cross section $\sigma(\lambda)$ can be measured in the laboratory, while the determination of the light path length L is trivial in the case of the arrangement of an artificial light source and detector (Fig. 23.9, arrangement a). Once those quantities are known, the trace gas concentration c can be calculated from the measured ratio $I_0(\lambda)/I(\lambda)$. In contrast to laboratory spectroscopy, the true intensity $I_0(\lambda)$, as would be received from the light source in the absence of any absorption, is usually difficult to determine when measurements are made in the open atmosphere or in smog chambers. The solution lies in measuring the so-called differential absorption. This quantity can be defined as the part of the total absorption of any molecule rapidly varying with wavelength and is readily observable, as will be shown below. Accordingly, the absorption cross section of a given molecule (numbered i) can be split into two portions

$$\sigma_i(\lambda) = \sigma_{i_0}(\lambda) + \sigma_i'(\lambda)\,, \tag{23.31}$$

where $\sigma_{i_0}(\lambda)$ varies only slowly with the wavelength λ, for instance describing a general slope, while $\sigma_i(\lambda)$ shows rapid variations with λ, for instance due to an absorption line. The meaning of rapid and slow (or rather smooth and structured) variation of the absorption cross

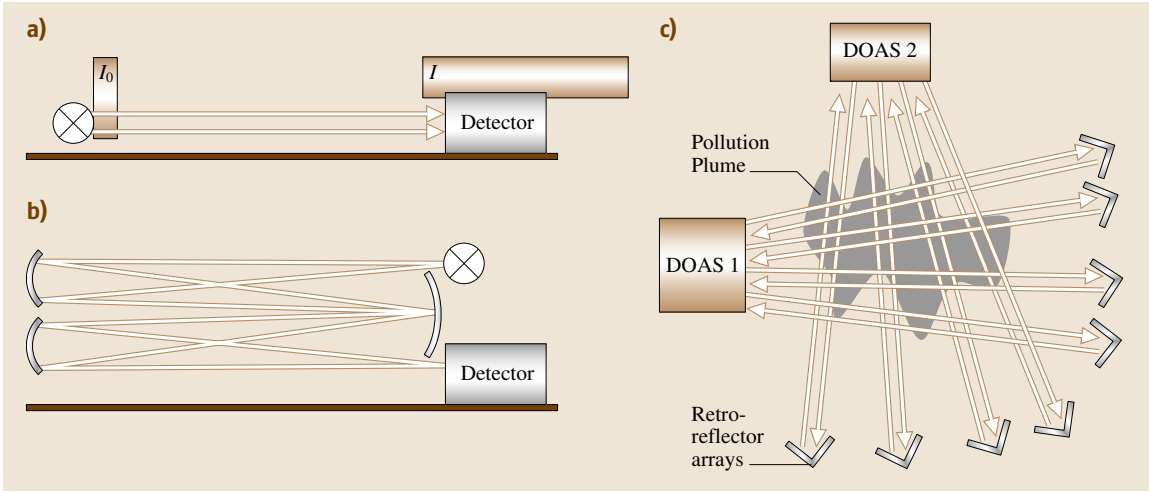

Fig. 23.9a–c The active DOAS principle can be applied in several light-path arrangements and observation modes using artificial light sources such as arc lamps or incandescent lamps in a searchlight-type arrangement, or lasers. The light-path-averaged trace gas concentration is determined in the 'traditional' setup **(a)**. In situ concentrations are measured with multiple reflection cells **(b)**. The new 'tomographic' arrangement **(c)** employing many DOAS light paths allows mapping of (two- or three-dimensional) trace gas distributions

section as a function of wavelength is, of course, a question of the observed wavelength interval and the width of the absorption bands to be detected. Note that extinction due to Rayleigh and Mie scattering can be assumed to be slowly varying with λ. Thus (23.30) becomes

$$I(\lambda) = I_0(\lambda)\exp\left\{-L\Sigma\left[\sigma_i'(\lambda)N_{c_i}\right]\right\} \times\exp\left(-L\{\Sigma[\sigma_{i_0}(\lambda)c_i]+\varepsilon_R(\lambda)+\varepsilon_M(\lambda)\}\right) \times A(\lambda)\,, \quad (23.32)$$

where the first exponential function describes the effect of the structured, differential absorption of trace species, while the second exponential constitutes the slowly varying absorption of atmospheric trace gases as well as the influence of Mie and Rayleigh scattering described by the extinction coefficients $\varepsilon_R(\lambda)$ and $\varepsilon_M(\lambda)$, respectively. The attenuation factor $A(\lambda)$ describes the (slow) wavelength-dependent transmission of the optical system used. Thus we can define a quantity I_0' as the intensity in the absence of differential absorption

$$I_0'(\lambda) = I_0(\lambda)\times A(\lambda) \times\exp\left(-L\{\Sigma[\sigma_{i_0}(\lambda)N_{ci}]+\varepsilon_R(\lambda)+\varepsilon_M(\lambda)\}\right). \quad (23.33)$$

Fortunately the effect of slowly varying absorbers, i. e. the exponential in (23.33), can be removed by high-pass filtering the spectral data, thus only the first exponential function in (23.32) remains, which is essentially Lambert–Beers law ((23.30) for more than one absorber). It should be noted that the length of the light path is more difficult to determine – or might actually not have a precise meaning – in applications where direct or scattered sunlight is used (arrangements d, e, and f and Fig. 23.9), in this case the column density S of the trace gas

$$S = \int_0^\infty N_c(l)\,\mathrm{d}l \quad (23.34)$$

can still be determined. In the case of a constant trace gas concentration $N_{c_0}(l) = c_0$ along a path length L the column density simply becomes $S = N_{c_0}L$.

In order to obtain sufficient sensitivity, light-path lengths L of the order of several 100 m to several 1000 m are usually required. For measurements in the free atmosphere, assuming the arrangement a in Fig. 23.9, the trace gas concentration is averaged over the whole length of the light path, which makes the measurement less susceptible to local emissions. On the other hand measurements must frequently be made in a small volume (e.g. in photo-reactors); in these cases

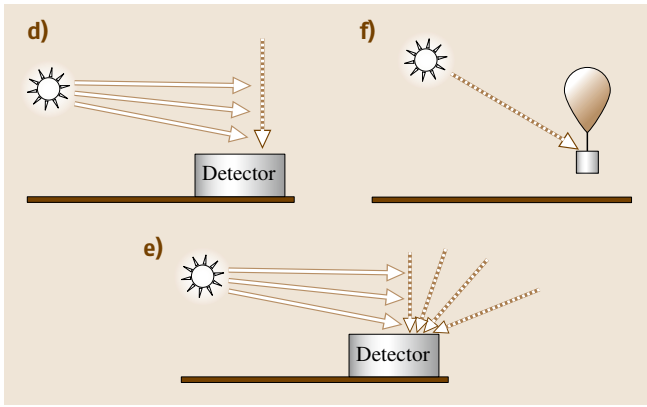

Fig. 23.9d–f The passive DOAS technique can be applied in several light path arrangements and observation modes using natural light sources such as sunlight or moonlight. The zenith scattered light (ZSL-DOAS) set-up **(d)** is most suited for the determination of stratospheric species, while the Multi-AXis (MAX-DOAS) arrangement **(e)** provides highly sensitive trace gas measurements in the atmospheric boundary layer. Direct sunlight and the limb scattered skylight observation of trace gases from aircraft and balloon platforms **(f)** allows the determination of trace gas profiles in the lower and middle atmosphere ▶

multireflection systems can be used to fold the light path into a small volume [23.28]. An example of detection limits attainable with multireflection systems is given in Table 23.3.

23.5.3 Variations of DOAS

The DOAS technique can be adapted to a large variety of measurement tasks; as a consequence there are many variants of the DOAS technique in use. These can be grouped into active techniques, which employ their own light sources (e.g. Xe-arc lamps or incandescent lamps), and passive techniques, which rely natural light sources (e.g. sunlight, moonshine or starlight).

The most common active DOAS light-path arrangements include (Fig. 23.9):

1. The traditional active long-path systems (usually folded once)
2. Active systems using multireflection cells (e.g. white cells)
3. Recently the first tomographic systems allowed the determination of 3-D trace gas distributions by multiple-beam active DOAS.

The most common passive DOAS light path arrangements include (Fig. 23.9):

1. Zenith scattered light (ZSL)-DOAS is well-suited to study stratospheric trace gases. For instance a global network of ZSL-DOAS instruments continuously watches the distribution of stratospheric species (e.g. O_3, NO_2, BrO, OClO).
2. Multi-AXis (MAX)-DOAS allows determination of trace gases and their vertical distribution in e.g. the atmospheric boundary layer or the detection of plumes from cities, stacks, or volcanoes. In addition Airborne Multi-AXis (AMAX)-DOAS is a new technique for application from aircraft.
3. Direct sunlight observation of trace gases from balloon platforms allows the determination of trace gas profiles.
4. Scanning limb observations are used to monitor the temporal or spatial variation of atmospheric con-

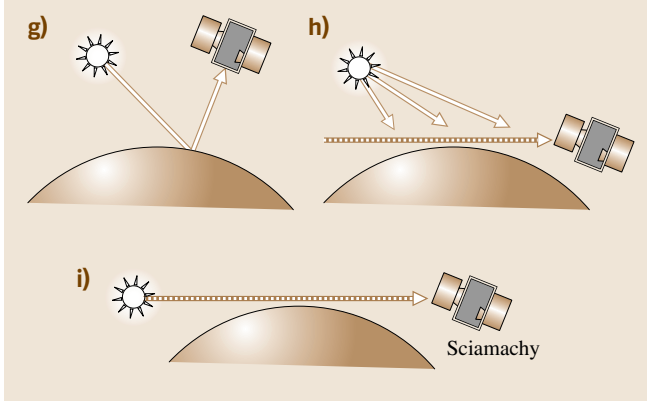

Fig. 23.9g–i Satellite-based DOAS has become an important technique for probing the atmospheric composition on a global scale. The most basic observation geometry is the nadir view **(g)**, here sunlight backscattered from the Earth and its atmosphere is analyzed by DOAS to yield trace gas slant-column densities. Ideally all light recorded by the satellite spectrometer traversed the atmosphere twice. Satellites also allow the observation of scattered sunlight in a limb-viewing geometry **(h)**. This allows the determination of trace gas profiles (although generally only for the stratosphere). Occultation (sunset, sunrise or starlight) measurements **(i)** from satellite are another attractive possibility to determine trace gas vertical profiles ▶

Table 23.3 Selection of species of atmospheric relevance measurable by DOAS and detection limits. Differential absorption cross-sections and corresponding detection limits (assuming 32 passes in a multi-reflection cell with a 8 m base path) for a series of species to be investigated by DOAS in the Valencia smog chamber. A dielectric mirror coating or DOAS measurements in the open atmosphere would allow longer light paths, resulting in correspondingly improved detection limits

Species	Wavelength of prominent band (nm)	Differential abs. cross section (σ_i') (10^{-20} cm^2/molecule)	Detection limit $L = (40-8)\times 8\,\mathrm{m} = 256\,\mathrm{m}$ (ppt)
ClO	280	350	200

stituents in the lower and middle atmosphere from aircrafts, balloons and satellites.

An extremely important, new application is satellite-borne DOAS, pioneered by the GOME and SCIAMACHY instruments [23.29, 30] that allow observation of global stratospheric and tropospheric trace gas distributions (Fig. 23.9):

1. The most basic observation geometry is the nadir view. Here, sunlight backscattered from the Earth and its atmosphere is analyzed by DOAS to yield trace gas slant column densities. Ideally all light recorded by the satellite spectrometer traversed the atmosphere twice.
2. Satellites also allow the observation of scattered sunlight in a limb-viewing geometry. This allows the determination of trace gas profiles (although generally only for the stratosphere).
3. Occultation (sunset, sunrise or starlight) measurements from satellites are an attractive possibility.

In addition it is now possible to determine the photon path-length distribution in clouds by ground-based observation of O_2 and O_4 bands. Here effectively DOAS is reversed: instead of the usual configuration where an unknown concentration is measured while the length of the light path is (at least approximately) known, the photon path-lengths are determined by observing the absorption due to an absorber with known concentration, such as oxygen (O_2) or oxygen dimers (O_4).

23.5.4 Atmospheric Aerosols

The atmospheric aerosol concentration is frequently monitored by light detection and ranging (LIDAR) instruments operated from the ground, aircrafts, or satellites [23.32]. In their most basic configuration they measure the ratio of total extinction due to Mie and Rayleigh scattering versus the calculated expectation of pure Rayleigh scattering for a set of absorbing and nonabsorbing wavelengths.

The ozone lidar experiment (OLEX) LIDAR is used as an aerosol and ozone LIDAR (Fig. 23.10). The system consists of two laser transmitters: 1) a Nd:YAG laser operating at a repetition rate of 10 Hz in the fundamental, second harmonic, and third harmonic with output energies of 200 mJ at 1064 nm, 120 mJ at 532 nm, and 180 mJ at 355 nm, and 2) a XeCl laser operating at 10 Hz, emitting 200 mJ at 308 nm. The receiver system is based on a 35 cm Cassegrain

telescope with a field of view (FOV) of 1 mrad and a focal length of 500 cm. The system uses five detection channels: one channel for 1064 nm, two channels for 532 nm in two polarization planes, one channel for 355 nm, and one for 308 nm. The 308 and 355 nm channels are specifically dedicated to ozone profiling in the stratosphere, while the other wavelengths are used for aerosol and cloud monitoring. The acquisition electronics can acquire each single signature, with the lasers firing at a 50 Hz repetition rate, and the aerosol distributions measured by the system are available in real time. The total weight of the system is about 270 kg and the total power consumption above 1.6 kW.

In the present example, the OLEX LIDAR was assembled on board the DLR-Falcon aircraft in a down-looking mode that enabled aerosol backscattering measurements below the aircraft cruise altitude. On 24 September 1999, a flight was undertaken leading from Oberpfaffenhofen near Munich to the Adriatic Sea. The main scientific objective was to investigate the spatial distribution of made-made aerosols emitted from traffic, industry and house burning into the lower troposphere.

The major detected features were inhomogeneously aerosol-loaded air masses located in the alpine mountain valleys and the fairly uniform planetary boundary layer (PBL) stretching over the whole alpine ridge (Fig. 23.11). Both aerosol layers nicely mark the vertical layering of a vertically layered lower troposphere typical for a high-pressure system at mid-latitudes in fall. Another interesting feature was the

structure of the planetary boundary layer (PBL) located over the Adriatic Sea (≈ 2000 m above sea level), which overlaid a very thin marine boundary layer (250–300 m above sea level). This feature resulted from an advection of polluted PBL air masses originating from the North Italian Apennines and the Po Basin by synoptic westerly winds [23.33].

23.5.5 Determination of the Distribution of Solar Photon Path Lengths

A novel application of differential optical absorption spectroscopy (DOAS) is the measurements of path-length distributions of solar photons (photon PDF) transmitted to the ground [23.34–38]. The knowledge of a photon PDFs is of primary interest in the cloudy atmospheric radiative transfer, atmospheric absorption of solar radiation energy and thus for climate. The method relies on the analysis of highly resolved oxygen A-band (762–775 nm) spectra (Fig. 23.12) observed with a telescope with a small field of view (1°) in zenith-scattered sky light. It uses the fact that solar photons are randomly scattered by molecules, aerosols and cloud droplet during their atmospheric transport. Since a fraction of the solar photons become absorbed in the atmosphere, largely depending on the atmospheric opacity for a given wavelength, for each wavelength solar photons travel on different average, long distances in the atmosphere. Spectral intervals with a largely changing atmospheric opacity but known absorber concentration and spectroscopic constants, such as that given by the oxygen A-band, thus contain information on the photon PDFs. Recent studies have been showing that the atmospheric photon PDFs are highly correlating with the total amount of liquid water in the atmosphere, the spatial arrangement of clouds, cloud inhomogeneity and solar illumination [23.34–38]. For example, for thunderstorm Cb (cumulus nimbus) clouds, average photon path lengths of up to 100 km have been observed, while for Sc (stratus clouds) typically photon paths are 50–100% larger than for the direct and slant path of the sun's rays. Moreover, it appears that even though the spatial distribution of cloud droplets is inhomogeneous with the moments of the density behaving like multifractals, photon PDFs tend to be mono-fractals, mostly due to the so-called radiative smoothing of optically thick clouds [23.39].

23.6 Overview of Optical Phenomena in the Atmosphere

Phenomena based on atmospheric optics can be observed nearly every day and everywhere. Examples are rainbows, halos, mirages, coronas, glories, the colors of the sky, sunsets and twilight phenomena, green flashes, noctilucent clouds, polar lights, and many more. All these different phenomena are due to interaction of light with matter present in the atmosphere (Fig. 23.13).

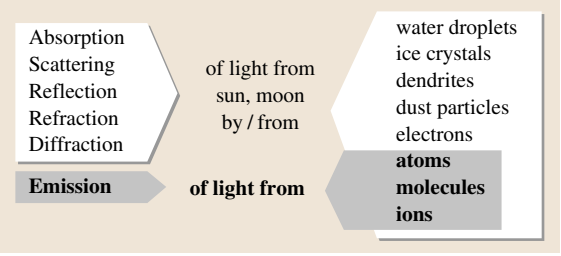

Fig. 23.13 Possible interaction processes of light with constituents of air

In the following, a brief survey of light scattering by molecules and particles with regard to optical phenomena in the atmosphere will be given. More details on light scattering by particles can be found in a number of monographs [23.40–43]. Several books have focussed on one or more optical phenomena [23.44–54]. Some older original publications are available as a collection of articles [23.55] and the proceedings of the regular conferences on atmospheric optics have been published in special issues of the journals of the Optical Society of America [23.56–64], most of them recently put together on a CD-ROM [23.65]. Several videos and movies deal with selected phenomena [23.66–70], some articles focus on connections to the fine arts [23.71–74], a number of books focus on simple experiments as well as observations [23.75, 76] and a number of internet sites with a lot of material are also available (Table 23.4).

23.7 Characteristics of Light Scattering by Molecules and Particles for Atmospheric Optics

Nearly all optical phenomena in the atmosphere are due to light scattering – mostly sunlight and sometimes moonlight – with the constituents of air. The general physics of light scattering was already treated in Sect. 23.1, here a brief general survey of light scattering processes in the atmosphere will be given with regard

Table 23.5 Classification of optical phenomena of the atmosphere. Depending on the homogeneity of the air, different light interaction processes correspond to various phenomena, which are indicated by examples

1. Pure homogeneous air

- refraction ⇒ mirages, shape changes of sun/moon at horizon (Sect. 23.8.1)
- scattering ⇒ blue sky (Sect. 23.8.2)

2. Inhomogenous atmosphere: Air plus water droplets

- refraction and reflection ⇒ rainbows (Sect. 23.9.1)
- forward scattering/diffraction ⇒ coronas (Sect. 23.9.2)
- backward scattering/diffraction ⇒ glories (Sect. 23.9.2)

3. Inhomogenous atmosphere: Air plus ice crystals

- refraction and reflection ⇒ halos (Sect. 23.10)
- forward scattering/diffraction ⇒ coronas (Sect. 23.9.2)

4. Inhomogenous atmosphere: Air plus aerosols

- absorption, scattering ⇒ sky colors (Sect. 23.11)
- absorption, scattering ⇒ visibility (Sects. 23.12.1, 23.12.2)
- forward scattering/diffraction ⇒ coronas (Sect. 23.9.2)

5. Ionized air

- ionization/excitation by solar wind, emission ⇒ auroras (Sect. 23.12.3)
- ionization/excitation by discharges, emission ⇒ lightning (Sect. 23.12.3)

to atmospheric optics and emphasis on wavelength, angular dependence and polarization. Consequences for various optical phenomena of the atmosphere will be systematically discussed in the respective sections according to the constituents of the air that are responsible (Table 23.5).

Molecular Scattering

For pure air, scatterers are mostly N_2 and O_2 molecules, the greenhouse gases CO_2 and H_2O as well as some traces of other gases such as Ar [23.77]. These scatterers are all much smaller than the wavelength of visible light and one speaks of a molecular atmosphere [23.78]. The vertical distribution of the gaseous components of air follows the barometric formula with a scaling height of about 8 km. The scattering of sunlight from the bound electrons of atoms/molecules is usually called Rayleigh scattering [23.1, 79, 80]. (For historical notes on the problem of the blue sky [23.81].)

Scattering from Particles

Normal air usually also contains a variety of different particles, the most predominant being water droplets, ice crystals and snow flakes (dendrites). The size of the water droplets ranges from several micrometers (cloud droplets) to well above 1 mm (raindrops); ice crystals are very often of hexagonal symmetry with sizes on the order of 10–100 μm.

In addition, the atmosphere also contains other liquid and solid particles called aerosols [23.20, 77, 82, 83]. These include many types of particles from dust, oil droplets from forest fires, volcanic ashes as well as anthropogenic droplets/particles with an enormous variety in composition. Typical aerosol particles have size distributions in the range 0.1–10 μm with an average around 1 μm [23.84]. The vertical distribution of the particle components of air may also be described by some kind of exponential formula [23.78], however, the scaling height of 1–2 km is much smaller than that for molecules.

The scattering of light from particles in these size ranges differs dramatically from molecular scattering, since the particle size is comparable to or larger than the wavelength of the light. Since atoms/molecules within particles are very close to each other, they are excited coherently, i. e. the total scattering from all molecules within a particle is quite different from the sum of the scattering of all individual molecules within the particle. In 1908, *Mie* gave the solution of classical electrodynamics for the simplest case, referring to spherical

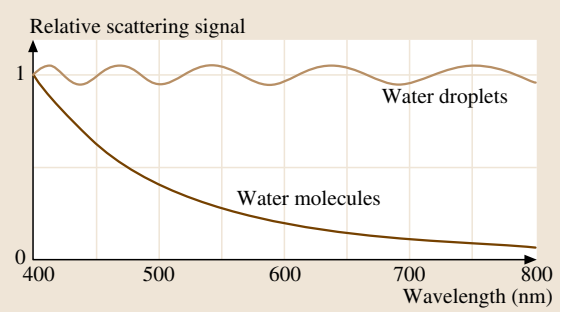

Fig. 23.14 Schematic wavelength dependence for light scattering from water molecules and water droplets of, e.g., 10 μm size

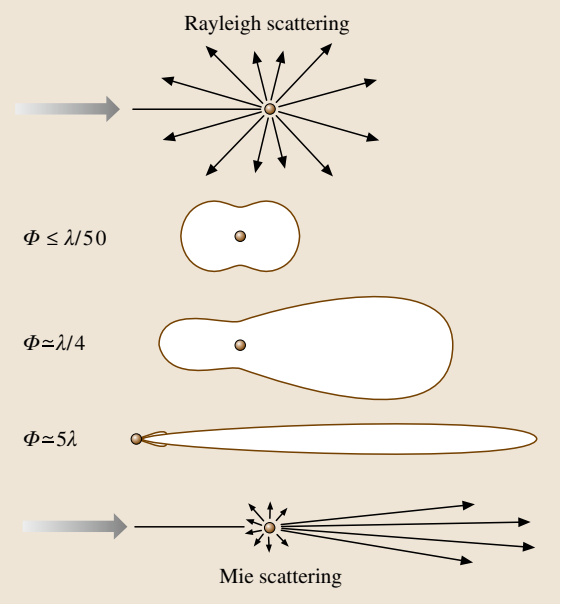

Fig. 23.15 Schematic overview of the angular dependence of light scattering from molecules and very small particles (Rayleigh scattering) to larger particles (Mie scattering)

shapes of the particles [23.10]. Henceforth, this type of light scattering from particles is mostly known as Mie scattering. This name is sometimes also used for extensions to nonspherical particle shapes. For nonabsorbing particles, which are small compared to the wavelength, the Mie scattering gives the same results as Rayleigh scattering. In the general case, however, it shows pronounced differences regarding wavelength dependence, angular dependence, degree of polarization of the scattered radiation as well as scattering cross section per molecule [23.40–42, 78].

Comparison of Rayleigh and Mie Scattering

Wavelength Dependence. Figure 23.14 gives a schematic example of the scattering of light by water molecules as well as water droplets of, say, 10 μm. Whereas molecules or very small particles scatter light mostly according to the inverse fourth power of wavelength, scattering from water droplets is essentially independent of wavelength.

Angular Dependence. Figure 23.15 gives a schematic overview of how the angular dependence of scattering changes with particle size. Molecules scatter unpolarized light nearly isotropically (see also Fig. 23.1) whereas large particles scatter rather asymmetrically in the forward direction. For a given particle size, the scattering also depends on wavelength.

Degree of Polarization. For Rayleigh scattering, and assuming perfectly spherical air molecules, light scatered at an angle of 90° would be perfectly polarized [23.85]. However, air molecules already show an anisotropy, reducing the polarization to only about 94% [23.78, 80]. For larger particles, the degree of polarization varies considerably as a function of scattering angle for fixed size. These patterns, however, strongly depend on size [23.40, 41, 78]. In addition, the degree of polarization at a fixed angle varies as a function of wavelength.

Scattering Cross Section per Molecule. The enormous differences between incoherent and coherent scattering become apparent when comparing light scattering from isolated molecules to those of the same molecules within a particle, e.g. water molecules within a water droplet or a raindrop [23.78]. For example, the scattering per molecule that belongs to a cloud droplet of 1 μm is about 10^9 times larger than scattering by an isolated water molecule and still a factor of about 100 larger than a molecules in a 1 mm raindrop.

Single and Multiple Scattering, Optical Mean Free Path and Air Mass

Light from the sun (or moon) has to traverse the atmosphere before reaching the eye of an earthbound observer. It is attenuated by scattering and absorption, depending on the number of scatterers present in the line of sight. If absorption can be neglected, one may use the scattering coefficient

$$\beta_S = N\sigma \,, \qquad (23.35)$$

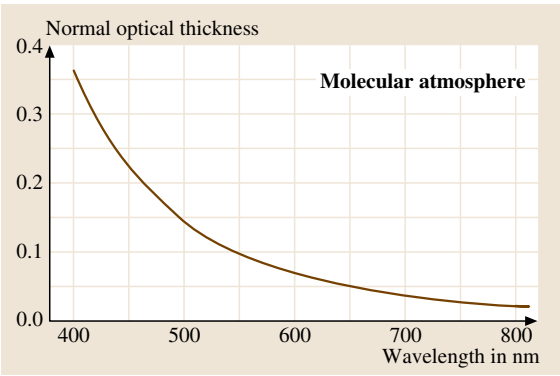

Fig. 23.16 Normal optical thickness of a purely molecular atmosphere (data from [23.3])

where N is the number of scatterers per unit volume and σ is the extinction cross section, $1/\beta_S$ defines the scattering mean free path, i. e. the average distance a photon has to travel before being scattered. (If absorption is included, an additional absorption coefficient β_A is introduced and β_S will be replaced by $\beta = \beta_S + \beta_A$.) Using β_S, one may define the optical thickness τ between two points A and B of the atmosphere as

$$\tau = \int_A^B \beta_S(x)\mathrm{d}x \,. \tag{23.36}$$

The optical thickness is a measure of the physical thickness in units of the scattering mean free path. For light along a radial path, i. e. coming from the zenith, the amount of air to be traversed is least and one refers to the normal optical thickness, which is also called the optical depth. For a pure molecular atmosphere, this is depicted in Fig. 23.16. In the visible spectral range, its values are small compared with unity, hence, a photon is unlikely to be scattered more than once, i. e. single scattering predominates.

The amount of air to be traversed by light, the so called air mass, depends on the sun's elevation. Air mass (AM) is defined to be unity for the light source in the zenith. It increases for smaller sun elevation angles. As a matter of fact, it is the optical thickness, relative to its zenith value. The exact value depends on the surface pressure. At 5° elevation (85° zenith angle) its value is about 10 and it ultimately reaches a value of about 40 at grazing incidence [23.51, 78, 86, 87], i. e. for the case of sunrise or sunset. In this case, the light must pass about 40 times the amount of air compared to the case of the zenith.

Combining the air mass with the normal optical thickness gives the optical thickness for arbitrary sun elevation. Since AM reaches large values, optical thicknesses may become large compared with unity, i. e. multiple scattering events become likely for low sun elevations.

23.8 Pure Air and Clear Sky Phenomena

23.8.1 Mirages

Mirages are due to the propagation of light waves in air that has gradients in the index of refraction [23.44–48, 51]. In general, light which is propagating in clear air (no particles) is partly scattered according to Rayleigh scattering, while the rest propagates undisturbed in the forward direction. The scattered light consists of sideways scattering and forward scattering, the latter being in phase with the incident light. As a consequence, light in clear air is slightly weakened by sideways scattering, the forward-propagating light being the superposition of the incident light and the forward-scattered light. The weakening due to sideways scattering will be discussed below (blue sky). Here, the phenomena associated with the forward-propagating light will be discussed. Scattering effects by particles are neglected here.

In homogeneous media, the forward propagation of light is expressed in terms of the refractive index n (for tables of n [23.3]). n depends on temperature T (in K), pressure p (in mbar) and humidity. Equation (23.37) [23.88] gives an approximation for n of dry air

$$n = 1 + \frac{77.6p}{T} \times 10^{-6} \,. \tag{23.37}$$

For example, $T = 300\,\mathrm{K}$ and $p = 1030\,\mathrm{mbar}$ yields $n \approx 1.000266$. Increasing the air temperature by 40 K (e.g., air directly above the ground which is heated by the sun) gives $n \approx 1.000235$ (for humid air, the numbers only change slightly). These small changes of $\Delta n \approx 3 \times 10^{-5}$ are responsible for all kinds of mirages.

The most simple mirage effect is known from astronomy: if an observer looks at an object in the sky at a certain altitude, the actual position of the object is lower in the sky. This is due to the refraction of light upon propagation in the atmosphere with a gradient in n giving rise to curved light paths.

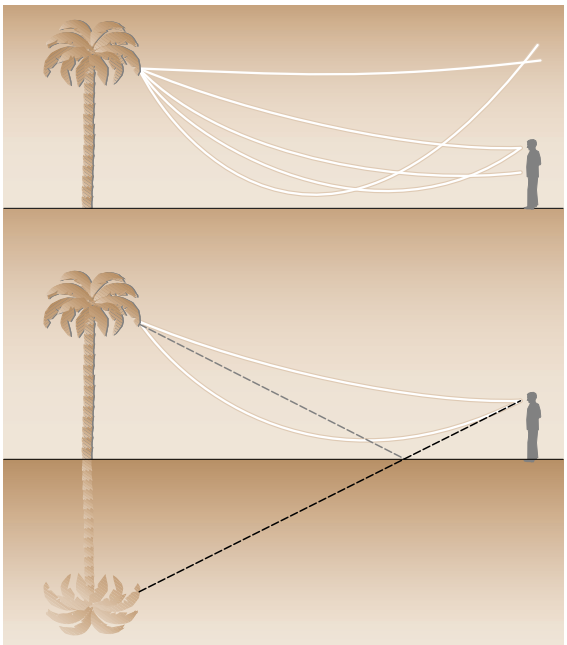

Fig. 23.17 Inferior mirage: A palm tree scatters sunlight in all directions. The atmosphere is heated close to the ground. Therefore the index of refraction is smaller there, giving rise to curved light paths. Direct and refracted light can enter the eye of an observer which is interpreted as an object on top of an inverted image (after [23.48])

At the zenith, the deviation is zero, at 45° zenith distance it amounts to 1′ (1 min of an arc) increasing to more than 38′ at an angle of 90°. This has to be compared with the angular size of the sun or moon, which is about 30′, i. e. half a degree. Since the refraction is only about 28′ at a zenith distance of 89.5°, the sun or the moon in an otherwise undisturbed atmosphere (no inversion layers) will thus be flattened [23.47, 89–94].

Mirages are images of objects which may be seen in addition to the real objects. They can be seen whenever there are temperature differences in the atmosphere, which give rise to unusual gradients in the index of refraction. Similarly to astronomical refraction, gradients in n give rise to curved light paths. If warm air is above the ground, n is smaller close to the ground than above it. This leads to inferior mirages like the well-known wet streets on hot summer days. The formation of inferior mirages is illustrated in Fig. 23.17. A prominent feature of a mirage is the so-called vanishing line of the object [23.48]. Light below certain object points has no chance whatsoever to reach the eye of the observer, i. e. parts of the object cannot be seen, irrespective of the direction into which the light is scattered.

In the case of an inversion layer in the atmosphere, the air at a given height is warmer than below, which may give rise to superior mirages. Similarly to inferior mirages, the propagation of light with curved paths in this case can give rise to multiple images on top of the object. In nature, combinations of inferior and superior mirages may occur. Also, heated vertical walls may result in lateral mirages.

The angular size of mirages is usually about 0.5–1.0°. For observations, binoculars and cameras with telephoto lenses are used. The mirages are often distorted and flicker due to local density fluctuations in the air.

Theoretical progress in understanding mirages came with the computer. The propagation of light rays in a given atmosphere, defined by the vertically varying index of refraction $n(z)$, is computed theoretically using ray-tracing methods. The various methods [23.95–98] differ by their choice of geometry and $n(z)$. Such simulations prove very helpful in understanding the general characteristics of mirages, like e.g. so-called mock mirages [23.99, 100].

Recent research has explained many unusual mirage phenomena quantitatively, including long-range mirages like the Novaya–Zemlya effect from atmospheric ducting [23.101–104] and small-scale movements seen within superior mirages when atmospheric gravity (buoyancy) waves are present [23.105, 106].

Superior mirages seen over large distances (70–100 km) can result from fairly complex atmospheric temperature profiles [23.97]. Also, the origin of double inferior mirages as well as unusual horizontal stripes in inferior mirages has been analyzed theoretically [23.98]. Very recently, focus had been on very precise measurements and comparison to modeled astronomical refraction of the setting sun [23.107, 108] and the occurrence of very bright superior mirages [23.109].

In addition to analysis of observations and theoretical models, inferior mirages and superior mirages with multiple images may also be studied quantitatively or as demonstration experiments in the laboratory [23.66, 110–115].

23.8.2 Clear Sky: Blue Color and Polarization

Light scattering in pure gases is due to the electrons in atoms and molecules. As a result, the scattered light ra-

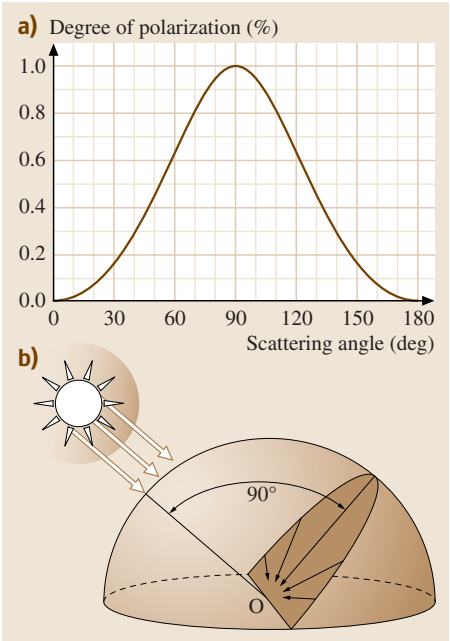

Fig. 23.18 Degree of polarization of skylight due to Rayleigh scattering **(a)**. As a consequence, an observer O should detect strongly polarized light at an scattering angle of 90° **(b)**

diance varies approximately as $1/\lambda^4$ (Fig. 23.14), i. e., red light is scattered much less than blue light [23.1, 79, 80]. When looking at the daylight sky illuminated by the sun one mostly sees scattered light and, hence, a blue sky (the quite common qualitative term intensity of scattering is often not properly defined [23.116], it usually means either radiance, given in $W/(m^2\,sr)$, or spectrally resolved radiance in $W/(m^2\,sr\,nm)$).

The scattered light is strongly polarized at a scattering angle of 90° [23.85] (Fig. 23.18). Quantitatively this is described by the degree of polarization, being defined as

$$P(\varphi) = \frac{I_{max} - I_{min}}{I_{max} + I_{min}} = \frac{1 - \cos^2\varphi}{1 + \cos^2\varphi}\,, \qquad (23.38)$$

where I_{max} and I_{min} are the maximum and minimum radiance signals of the light for scattering angle φ when passing through a polarizer while it is rotated. Concerning the whole sky, the polarization varies and also has neutral points, named after Arago and Babinet [23.44, 46, 51]. In reality, even if very clean air is used, the maximum degree of polarization is about 94% (Sect. 23.7). The atmosphere usually also contains an appreciable number of particles, which show Mie scattering with different angular polarization dependencies. In addition, there may be contributions of multiply scattered light as well as backscattering from the surface of the Earth. Overall, the degree of polarization typically reaches values around 80%. Obviously, this depends on the concentration of particles and is thus related to the transmission of the atmosphere [23.117]. More details on scattering effects and recent research will be given in Sect. 23.11.

23.9 Phenomena Due to Hydrometeors

23.9.1 Rainbows

Rainbows are due to scattering of sunlight from raindrops in the atmosphere [23.43–48, 51]. The drops are in the size range between 10 μm (white fogbow/cloud bow) and several millimeters. One usually assumes spherical droplets, however, drop shapes may vary depending on size [23.118, 119] or they may even oscillate [23.120]. Drop formation and size distributions have been extensively studied [23.121]. The effect of nonsphericity on rainbow phenomena is discussed, e.g., in [23.122, 123].

The observed bows are mostly due to single scattering events. Hence, the complex problem of light scattering from millions of raindrops in a rain shower can be reduced to the scattering of sunlight from a single raindrop. Since raindrops are large compared to the wavelength of light, geometrical optics already gives a rough description. Figure 23.19 depicts a single raindrop and parallel light rays from the sun.

The rays are characterized by their impact parameter b. Each ray is reflected and refracted upon hitting an interface between air and water. For clarity, only the light paths that give rise to the primary rainbow are sketched. They are defined by refraction into the droplet, internal reflection and refraction back into the air. Similarly higher-order rainbows may be constructed by allowing for multiple internal reflections. The central ray (1) is not deflected by the refractions and exits at a scattering angle of 180° with respect to the incident ray. Ray number (2) suffers a scattering angle of about 170° and so on. For increasing impact parame-

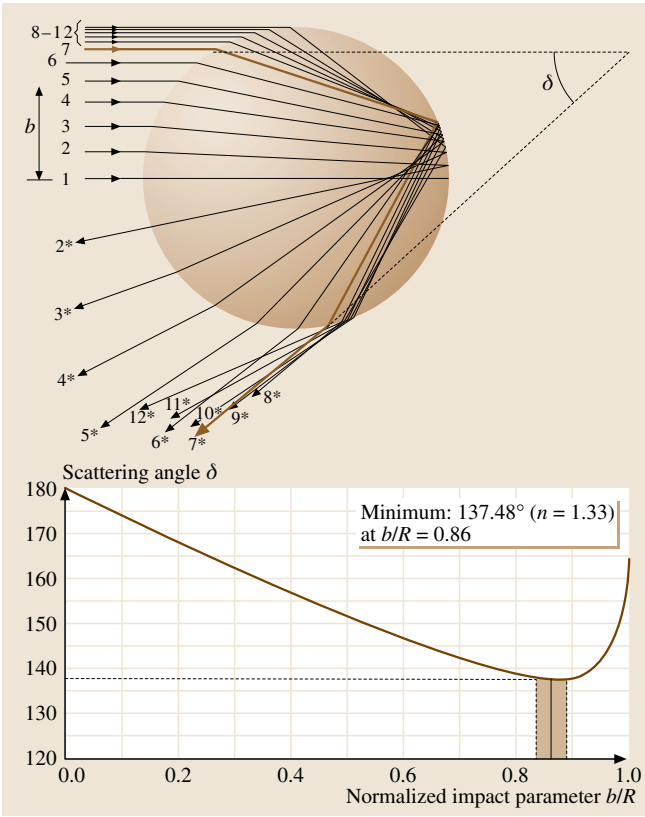

Fig. 23.19 Simple explanation of a rainbow from a single raindrop in terms of geometrical optics. Parallel light rays, characterized by the impact parameter b, are scattered due to refraction, internal reflection and refraction (for clarity other light paths are omitted). The scattering angle δ as a function of b exhibits a shallow minimum, i. e. many incoming light rays with different values of b will be scattered in the same direction ▶

ter the scattering angle δ decreases until a minimum is reached at an impact parameter of about $0.86R$ (ray 7). The flatness of this shallow minimum (Fig. 23.19) at an angle of about 138° is responsible for the fact that much more light is scattered into this direction – geometrically along the surface of a cone – than in others, since many incoming light rays of slightly differing impact parameters will emerge in the same output direction. As a consequence, an observer who is looking at a cloud of raindrops that is illuminated from the back by sunlight, will observe a bow of angular size 42° (Fig. 23.20).

The rainbow angle, i. e. the minimum of δ in the plot of Fig. 23.19, can be easily calculated [23.47, 124, 125] with geometrical optics by finding the minimum of the scattering angle $\delta(\alpha_{\text{inc}})$ with respect to the angle of incidence α_{inc} of the light rays onto the droplet. Assuming $n_{\text{air}} \approx 1$ one finds for the primary bow

$$\delta(\alpha_{\text{inc}}) = 2\alpha_{\text{inc}} - 4\alpha_{\text{refr}} + \pi \,, \quad \text{with}$$

$$\cos\alpha_{\text{inc}} = \sqrt{\frac{n^2-1}{3}} \,. \tag{23.39}$$

Here α_{refr} denotes the angle of the refracted ray within the raindrop and n is the index of refraction of water. For $n = 1.33$, Snell's law gives a scattering angle of $\delta(\alpha_{\text{inc}}) = 137.5°$. Due to dispersion ($n_{650\,\text{nm}} = 1.331$, $n_{400\,\text{nm}} = 1.343$) the rainbow angles depend on wavelength. Taking into account the finite size of the sun of about 0.5° one finds an angular width of about 2.2° for the primary bow. The analysis is easily extended to higher-order rainbows [23.47], most of which may, however, only be observed in the laboratory [23.112, 126–129].

Several rainbow features can only be explained by wave optics. Light from the rainbow is appreciably polarized perpendicular to the plane of incidence, since the angle of incidence for the internal reflection is close to the Brewster angle [23.130]. Also, careful measurements showed that the scattered light signal shows an interference pattern, named after Airy [23.50, 131, 132], which differs markedly from the prediction of geometrical optics (Fig. 23.21).

Until the beginning of the 20th century, wave optics features were computed using Airy's theory, which gives reasonable results for droplet sizes down to 10 μm; for smaller sizes, it fails. Improvements came with Mie theory [23.10, 40, 41], however, its numerical solutions in terms of scattering efficiencies as a function of angle for size distributions of the droplets and finite angular size of the solar disc had to wait for the development of computers. Similarly, Debye developed a tool of how to decompose the partial wave amplitudes for scattering of a plane wave into individual contributions of certain types. This later led to the complex angular-momentum theory [23.133]. Application of the mathematics of catastrophe theory to light scattering showed that the rainbow is a manifestation of the so-called fold caustic [23.134].

Here, results of the full electrodynamic treatment, i. e. Mie theory, are presented [23.40, 41, 135–137]. Figure 23.22 depicts results for monochromatic blue light of $\lambda = 450\,\text{nm}$, scattered by a lognormal distribution of water droplets with mean radii ranging from 2 μm to 200 μm. The full width at half max-

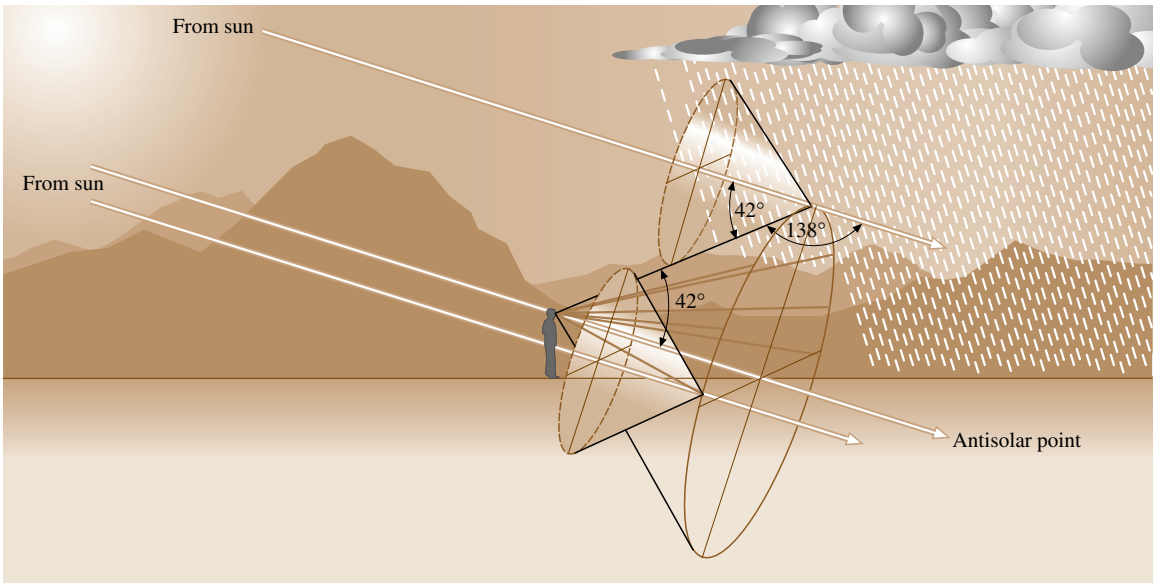

Fig. 23.20 Observation of a rainbow. Each raindrop scatters light preferably in a cone of the rainbow angle. Hence, an observer will see more light when looking in the direction of the surface of a cone that is centered in a droplet. The whole rainbow is due to millions of drops, the effect of which is an observable bright feature, geometrically on the surface of another cone centered in the eye of the observer and making an angle of 42° with regard to the antisolar point (after [23.48]). Its surface touches the surfaces of the scattered light cones of each individual droplet

imum of the size distribution is 10% of the mean radius.

Obviously, large droplets show Airy rings at the rainbow angles. For other wavelengths, these curves would be slightly shifted due to dispersion. The overlapping of the interference rings for all wavelengths leads to so-called supernumerary arcs [23.138,139]. Decreasing the droplet size leads to a broadening of the rainbows due to diffraction. In this case, the overlapping of all wavelengths leads to a white rainbow, also called a fog bow. If the size becomes too small, no rainbows are observable. The other features in Fig. 23.22 will be discussed in Sect. 23.9.2.

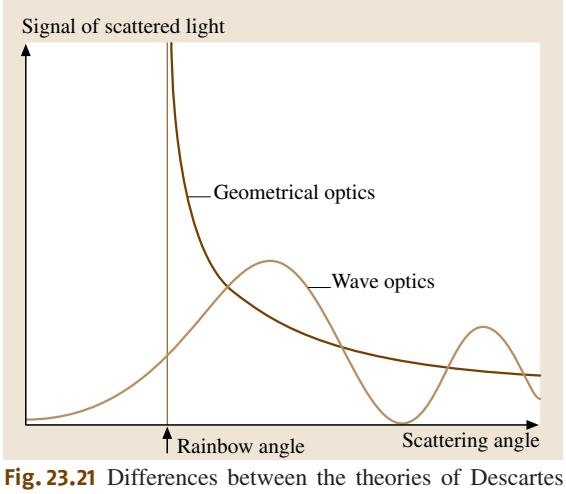

Fig. 23.21 Differences between the theories of Descartes and Airy for the scattered light signal of raindrops

There are many other interesting features of rainbows. For example the first-order rainbow often visually appears brighter at the base of the bow than at the top of the bow. This is due to the fact that, in a rain shower, raindrops are distorted in shape to oblate spheroids. Light reaching an observer from the base of a rainbow traverses a water droplet in the horizontal plane where the droplet cross section is circular. In contrast, light from the top of the rainbow traverses the water droplet in the vertical plane where the droplet cross section is elliptical. Since the scattered light radiance due to the internal reflection is less in the elliptical cross section than that in the circular cross section the base of the rainbow is brighter than the top of the bow (the longer optical path from the top may also lead to increased extinction).

Similar explanations [23.140] are possible for other features such as, e.g., that the supernumeraries of the

first-order rainbow often appear most vividly at the top of the bow or that supernumeraries of the second-order rainbow are almost never seen. Also, the effects of the electric fields [23.141] and acoustic forces accompanying thunderstorms can have observable consequences on rainbows [23.120]. Visibility and general brightness of rainbows depend on multiply scattered and absorbed light [23.142–144]. Even infrared rainbows have been detected [23.145].

In addition to analysis of observations and theoretical models, rainbow phenomena may also be studied in the laboratory either for quantitative comparison to theory or just as demonstration experiments using either single droplets or cylinders of water or other materials [23.111, 112, 126–128, 140, 146, 147].

Present investigations of rainbow phenomena deal, e.g., with experiments on higher-order rainbows from acoustically levitated water drops [23.148], cylinders [23.149, 150], or fountains [23.151] and total internal reflection rainbows [23.152], caustics [23.153, 154] as well as new simulations of rainbows and fogbows [23.155–157].

23.9.2 Coronas, Iridescence and Glories

The forward and backward scattering of small water droplets can also give rise to very distinct features [23.43, 44, 47, 48, 51]. First, colored concentric rings, called coronas, around the sun or the moon with angular distances up to, e.g., 15° may be observed, when looking through thin clouds. The middle whitish part around the light source is often called an aureole. If, second, colorful clouds are observed at larger distances from the sun (up to 45°), one usually speaks of cloud iridescence. Third, backscattering that leads to colorful concentric rings at angles close to 180° with respect to the light source are called glories. Figure 23.23 gives an overview of the light-scattering geometries of rainbows, coronas and glories due to water droplets.

Coronas

In its most spectacular form, coronas can be observed as a concentric series of three or four brilliantly colored rings around the sun or moon. In its simplest form, the corona is just represented by the aureole, which is a white disc near the sun or moon bordered by a bluish ring and terminated by a reddish-brown band.

Coronas are easily explained using Mie theory [23.158, 159]. Coronas occur as strong forward-scattering phenomena (Fig. 23.22) for very small nearly monodisperse sizes of typically about 10 μm. More simply, coronas are treated as diffraction phenomena by water droplets. The first minimum for light of wavelength λ diffracted by a circular aperture of diameter $2R = D$ is given by

$$D \sin \varphi = 1.22\lambda \, . \qquad (23.40)$$

For droplets of nearly uniform size, the diffraction angles φ obviously depend on wavelength, giving rise to rather pure perceived colors of the coronas. In this case, the average droplet size may be estimated from the angular size of the rings from (23.40). To obtain the approximate angle for the red band of the solar corona,

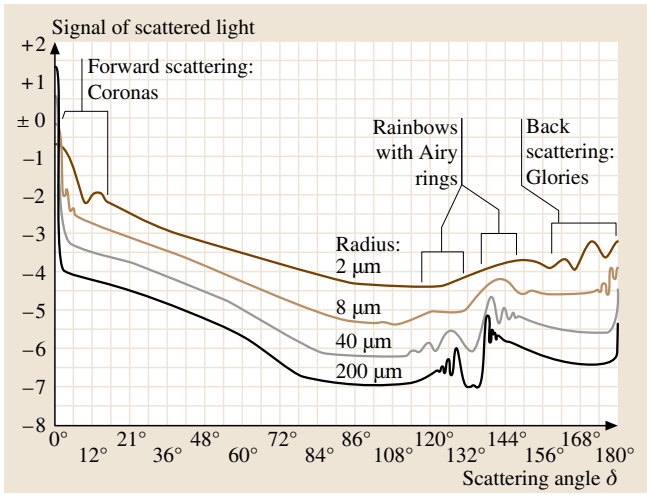

Fig. 23.22 Angular distribution of blue light scattered by water droplets with mean radii ranging from 2 μm and 8 μm (fog and cloud droplets) to 200 μm (small raindrops). Plots are vertically shifted for clarity (computation by E. Tränkle)

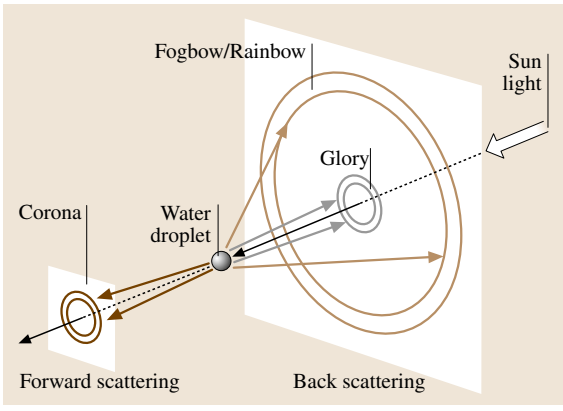

Fig. 23.23 Overview of geometries of light-scattering phenomena from a water droplet

it is customary to use $\lambda = 570\,\text{nm}$ in (23.40) since the positions of the red bands are believed to correspond to the minima for green light [23.160]. (Alternatively to 570 nm, 490 nm has been proposed [23.161].) For example, $2R = 10\,\mu\text{m}$ gives $\varphi \approx 4°$. (Note that there will be deviations between the correct Mie theory and diffraction theory for droplets with sizes of 10 μm and below.) A much better way to judge droplet sizes is to fit the colored rings of computer simulations to those of photos of natural observations [23.159].

An aureole may be produced by relatively large particles that tightly compress the rings, or by the presence of a broad particle size distribution that causes the colored rings to overlap.

Simple diffraction theory has problems for drops with sizes only slightly greater than the incident wavelength. In this case, Mie theory must be applied, since the amplitudes of the diffracted and transmitted light are comparable in the forward-scattering direction, leading to interference between the two components that can significantly alter the scattering pattern.

The nature of the cloud particles that cause coronas has been the subject of controversy [23.161, 162]. Observations of some coronas due to very high clouds suggested that not only supercooled spherical cloud droplets, but also ice crystals may be responsible for coronas. However, ice crystals can assume a variety of shapes and orientations that should not give very pure coronal colors. The issue was settled by experiments which simultaneously used polarization LIDAR data as well as photographic evidence of coronas to demonstrate that cirrus clouds composed of hexagonal ice crystals with particle sizes ranging from 12 to 30 μm (which is unusually small for most cirrus clouds) can generate multiple-ringed colored coronas [23.161]. Later the study also included aircraft probes of the particles [23.162]. In one case a weak corona and a halo display (see below) of the hexagonal crystals were observed simultaneously within the same cloud. This is possible, since laboratory experiments indicate a lower limit of about 20 μm for the sizes of ice crystals that can produce halo effects.

Some while ago, it was also noted that coronas need not be spherical. Elliptical coronas have been reported at special times in early summer. They were explained as diffraction phenomena from nonspherical birch and pine pollen grains [23.163–165]. Also, split coronas due to local variations of droplet size or changes between water and ice have been observed [23.166]. Recently, new simulations have been reported [23.167]. Special coronas, called Bishop's rings, can be produced by volcanic ashes, as has been reported after the explosion of Krakatau in 1883.

Iridescence

Cloud iridescence is a brilliant display, which occurs quite often when appropriate thin clouds are close to the sun or moon or if edges of thick clouds happen to have rather monodisperse droplets. Iridescence is also observed, though more rarely, at much larger angular separation from the sun of up to 45° and it may be easily observed and analyzed within contrails [23.160]. If interpreted using diffraction, like coronas, the drop sizes $2R$ are in the range 2–4 μm. These sizes are indeed quite rare, though possible near the edges of growing or evaporating clouds.

Whereas, coronas are generally observed at smaller angles for mostly monodisperse droplet populations with sizes of about 10 μm, iridescence usually occurs at larger angles and requires cloud droplet sizes on the order of a few microns in diameter with broad size distributions. These conditions are often found in the vicinity of the visible cloud margin where there is also a sharp gradient of the drop sizes. Thus, coronas and iridescence appear to require quite different cloud microphysical conditions to be present, and should also be most frequently observed in different angular regions [23.160]. Recent studies deal with coronas and iridescence in mountain wave clouds [23.166] as well as rare iridescence cases in cirrus clouds [23.168, 169].

Glories

The colored rings of glories, sometimes also called spectre of the Brocken are observed in a backscattering geometry, if sunlight illuminates fog or clouds with very small water droplets. Nowadays, observations can be performed easily when flying in airplanes and observing the shadow of the plane on nearby clouds.

Early interpretations could not use Mie theory (since computers were not available), but tried to understand the phenomenon in simpler terms. The assumption of diffraction of reflected light by the droplets (diffraction from circular apertures) did not work, since intensities and angular distances of the pattern are different. However, diffraction from circular rings could explain the phenomenon [23.40, 170]. For this to happen, glories must be due to light entering the raindrops at grazing incidence (this interpretation was later supported by Mie theory [23.171]). Then, the scattered light is more or less exiting at the opposite side of a droplet, i. e. at scattering angles of 180°. In terms of geometrical optics, this is not possible, however, wave theory allows

for surface waves at the boundary. In the backward direction, all contributions interfere constructively to produce the glory. These model assumptions were supported by experiments with microscopic water droplets supported by submicroscopic spider webs [23.172]. Later on, this model was further developed very successfully [23.133]. Nowadays, glories are explained by using Mie theory. Glories are present in Fig. 23.22 as oscillatory structures in the angular range from about 160 to 180° for droplets of 4 and 16 μm size. The more uniform the droplet size, the more rings may be observed.

Knowing from coronas that colorful rings may also be produced by fairly monodisperse assemblies of ice crystals and even tree pollen, one may ask whether the glories that are often observed from airplane windows may also be due to ice crystals in high-altitude cirrus clouds.

From the above interpretation of Mie theory, the glory is due to circumferential, i. e., surface-wave ray paths which are unique to spheres. Glories are, hence, produced by spherical scatterers. Based on photographic evidence, it was therefore investigated [23.173] whether glories may be also due to spherical or near-spherical ice crystals? In conclusion it was found that ice grows in amorphous and presumably spherical shapes only at unlikely frigid temperatures. Recent studies have, however, suggested that small near-spherical ice particles (diameters ranging from 9 to 15 μm) can sometimes, though very rarely, occur near the tops or along the margins of some ice clouds, and these may give rise to observable glories. Variation of droplet size in contributing clouds of distant glories can also lead to deviations from the circular shape [23.174]. Very recently, new simulations for glories were reported [23.155, 175–178].

23.10 Phenomena Due to Ice Crystals: Halos

Halos are caused by the refraction and/or reflection of sunlight by ice crystals in the atmosphere [23.43–48, 51, 52, 67, 179]. They can already be understood in terms of geometrical optics. Ice crystals that cause good halo displays are usually hexagonal plate or column crystals with sizes in the range of 20–100 μm [23.180]. Such crystals form very often, depending on the temperature and the amount of water vapor in the air [23.181]. Good documentation with micrographs can be found in the literature [23.52, 182, 183].

A great number of different halos may be observed in nature and in the laboratory since there is an enormous variety of possible types of ray paths through the crystals and crystals may have different orientations in the air (Fig. 23.24).

The most simple halos are parhelia, also called sun dogs, which are often observed in cirrus clouds (and sometimes in contrails [23.184]). They are due to oriented plate crystals, i. e. crystals falling with their principal axes vertical. This orientation mode is often possible and is, e.g., similar to movements of leaves (or sky divers), which maximize their air resistance as they fall [23.121]. If light rays from the sun enter a prism face of a crystal and exit an alternate prism face, the situation corresponds to refraction from a 60° prism. The scattering angle as a function of angle of incidence shows a flat minimum (Fig. 23.25) that is at a scattering angle of 22° for ice crystals with $n = 1.31$. Similarly to the explanation of the rainbow, more light is deflected in this direction. Therefore an observer looking at the sun or the moon through a thin cirrus cloud will see more light at an angular distance of 22° from the light source. For randomly oriented crystals, the resulting display will be a circular halo, centered at the light source, for oriented crystals, light will be deflected to both sides of the light source, giving rise to parhelia. The color of the parhelia, reddish towards the sun and bluish tails at the outside, is due to dispersion, i. e. different minimum deviation angles for the various wavelengths.

Similarly, other halos, often referred to as arcs, are due to other ray paths. A very brief survey of some common halos (today, more than 40 different types are known) is shown in Fig. 23.26. The circumzenith arc (No. 7 in Fig. 23.26) is due to rays which enter the top

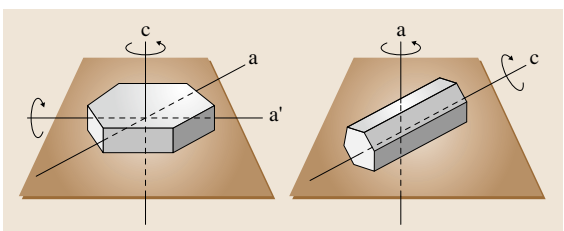

Fig. 23.24 Some possible orientations and rotations of hexagonal plate and column crystals in the atmosphere

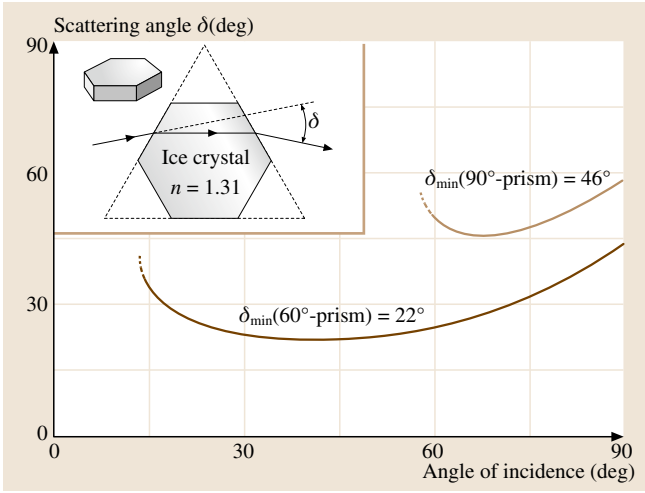

Fig. 23.25 Ray paths within hexagonal ice crystals ($n = 1.31$) show an angle of minimum deviation of 22°. For clarity, other light paths are omitted

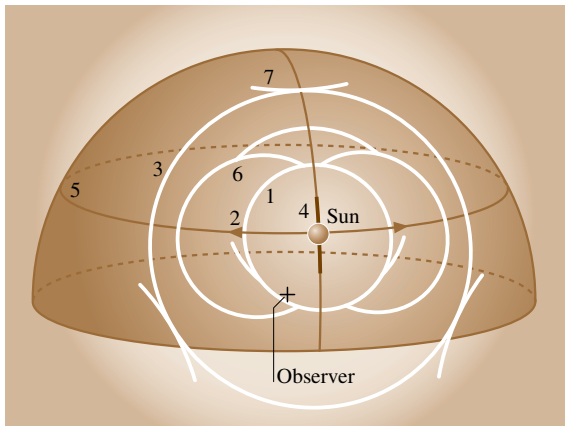

Fig. 23.26 A schematic survey of some halos which may be observed (1: 22° halo, 2: parhelia, 3: 46° halo, 4: sun pillar, 5: parhelic circle, 6: circumscribed halo, 7: circumzenithal arc). These displays all depend on sun elevation

basal face and exit a prism face of crystals with vertical symmetry axis. For random orientation, ray paths which refer to such a 90° prism lead to circular halos of 46° (No. 3 in Fig. 23.26). Pure reflection halos – not colored, since refraction does not contribute – are e.g. sun pillars (No. 4 in Fig. 23.26). They arise when sunlight is reflected at grazing incidence from the horizontal faces of plate crystals oriented with their axes vertical. Similarly oriented crystals also give rise to the parhelic circle (No. 5 in Fig. 23.26), which is due to reflected sunlight from crystal faces lying in the vertical plane.

Singly oriented column crystals – column crystals with axes horizontal but otherwise unconstrained – give rise to the upper and lower tangent arcs. Much more rarely, column crystals orient with two prism faces horizontal. Crystals having these Parry orientations give rise to Parry arcs. Still other crystal orientation modes are possible. Furthermore, crystals occasionally have pyramidal faces that produce halos at other angular distances, referred to as odd-radius halos.

The modern theory of halos started in the 17th century [23.44, 185]. In recent decades, enormous progress has been made. This is due to computer techniques, the application of more traditional, conceptual mathematics [23.186], experiments which collected atmospheric ice crystals during observation of halo displays in cold climates, and to dedicated observers who have documented many new halos.

Probably the biggest step was made by the introduction of computer simulations which allow the computation of complex halos from many different types of crystal shapes, sizes and orientation. They gave a lot of new information, especially regarding signal variations within a given halo [23.48, 187–189] and visibility [23.144]. Various arcs could be directly related to the crystals and the ray paths that were producing them. The theoretical displays could be easily compared with photographs or drawings of real halo displays.

Many excellent displays were documented by Finnish or German observer networks ([23.190], see also Table 23.4) and scientists in Antarctica [23.52] and some rare halos have been reported [23.191, 192]. Computer simulations were also used to explain old documented displays dating back to the 18th century [23.193]. Analysis of halos also include polarization effects, started by systematic studies in the seventies [23.53, 194]. Halo polarimetric studies should allow the detection and identification of birefringent crystals in extraterrestrial atmospheres [23.195–197]. Very recently, the focus had been on comparison of observations with the simulation of halo polarization profiles, the size and shape of the crystals in the model being based on sampled ice crystals [23.198].

Halo phenomena have also been studied in the laboratory for quantitative comparison to theory and as demonstration experiments using prisms or hexagons made of glass, lucite or other materials [23.43, 67, 111, 112, 114].

23.11 Sun and Sky

23.11.1 The Color of the Sun

Light scattering in the atmosphere is responsible for the color of the sun or moon, as perceived by earthbound observers. Outside the atmosphere, solar irradiation has a very broad spectrum, ranging from UV to the deep infrared [23.199]. Neglecting processes in the sun's atmosphere, it more or less resembles the emission of a black body of about 5900 K. This radiation is interpreted as white by human eyes (the exact color may be computed from spectra according to color metric formulae [23.77]). In the Earth's atmosphere, the radiation is absorbed and scattered. Compared to the outside spectrum, the irradiation curve is lowered and shows characteristic absorption features, mostly from H_2O, CO_2 and oxygen (Fig. 23.7).

Color changes occur depending on air mass, i. e. sun elevation. Starting with a purely nonabsorbing molecular atmosphere, atmospheric transmission has been computed for air mass AM = 1 [23.3]. Therefrom the transmission at arbitrary zenith angles φ and starting at height h of an observer may be computed according to [23.87, 117]

$$T(\varphi, h) = T(0, h)^{\mathrm{AM}(\varphi,h)} . \qquad (23.41)$$

Results for the transmission of red ($\lambda = 630$ nm), green ($\lambda = 530$ nm) and blue ($\lambda = 430$ nm) light for a molecular atmosphere and AM = 1, ($\varphi = 0°$, zenith), AM = 10 ($\varphi \approx 85°$) and AM = 38 ($\varphi = 90°$, horizon) are given in Table 23.6.

Whereas the zenith sun is still regarded as white, the sun's spectrum near the horizon is drastically changed in favor of red and green light (Fig. 23.27). Close but still above the horizon ($\varphi_Z = 80-85°$) yellow colors may be observed and close to the horizon ($\varphi_Z = 90°$) red dominates in the spectrum. Since, simultaneously, the radiance of the sun decreases drastically, the brightness also decreases with φ. Naked-eye observations are, however, still not possible in very clear air even if $h = 0$ (sea level). In general, however, haze due to water vapor and aerosols leads to additional weakening.

Aerosols are very important for optical variations within the atmosphere [23.15, 16]. The difference of observations and theoretical spectra, including selective absorption of molecules within the air, is attributed to aerosols [23.117].

Extraordinary color changes of the sun can sometimes occur, if clouds of nearly uniformly sized particles are present in the line of sight. For example, the forest fires in Canada in 1950 ejected large numbers of oil droplets in the air. These were transported over long distances and led to blue sun observations even in Edinburgh [23.75, 200]. Similar events may be due to volcanic eruptions.

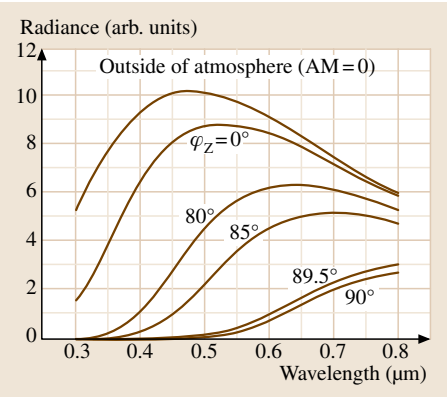

Fig. 23.27 Radiance spectra of a black body source ($T = 6000$ K) representing the sun as a function of wavelength (after [23.43]). The *top curve* represents the spectrum outside of the earth atmosphere. The *lower curves* depict the respective spectra at sea level attenuated due to Rayleigh scattering when observed at zenith angles from $\varphi_Z = 0$ (sun at zenith) to $\varphi_Z = 90°$ (sun at horizon)

Table 23.6 Transmission of a molecular atmosphere ($h = 0$) for sun in zenith (AM = 1: $\varphi = 0°$) or close to the horizon (AM = 10: $\varphi = 85°$, AM = 38: $\varphi = 90°$), $T(\varphi = 0°)$ after [23.3]

λ(nm)	T(AM = 1)	T(AM = 10)	T(AM = 38)
630	0.945	0.625	0.117
530	0.892	0.320	0.013
430	0.764	0.068	0.000036

23.11.2 Sky Colors

Obviously, sky colors are due to many factors [23.43–49, 51]. A simple qualitative explanation of typical sky colors at sunset can be given according to Fig. 23.28. The sun has just set, i. e. it is below the horizon. Sunlight still illuminates portions of the atmosphere. The color that an observer perceives in a given direction is due to contributions of scattered and attenuated light along a line of sight in the respective direction. In simple terms, the amount of radiation entering the observers eye depends on, first, the light path through the at-

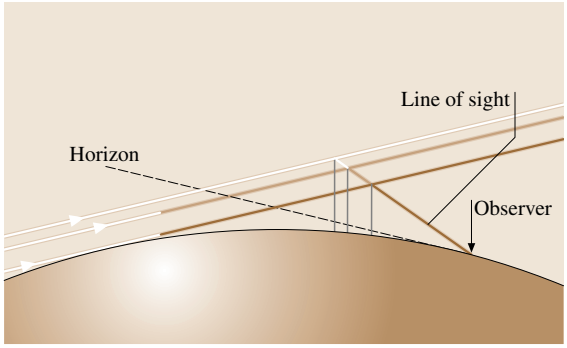

Fig. 23.28 Geometry for qualitative explanation of sky colors after sunset (see text for details)

mosphere before scattering (determining the available spectrum for scattering), second, the height of the scattering event (which determines the density of scatterers, i. e. atoms, molecules and/or aerosols), third, the scattering angle (depending on type and size of scatterer), and fourth, the optical thickness along the line of sight, i. e. the attenuation due to scattering and/or absorption between scattering process and observer. The subtle interplay of these four parameters determines the spectrum of light reaching the eye of an observer and hence the perceived color.

Different locations along the line of sight will contribute to the scattered light with varying amount as well as spectral composition. The light beam most distant from the Earth will reach the line of sight, nearly unattenuated, and a broad spectrum is available for scattering. Due to the large height, only a small amount of radiation is scattered towards the observer, with blue dominating. This light is further attenuated before reaching the observer. The final spectral composition of the light depends on the optical thickness that must be traversed. However, blue is most strongly attenuated, i. e. overall this light will not contribute much and will not dominate the color. The closer the light passes to the ground, the more its spectrum is shifted towards the red. Although less light will intersect the line of sight compared to the large height rays, it will contribute more, since it interacts at lower heights, i. e. with a much larger density of scatterers. Taking into account the further shift of the scattered light spectrum towards the red due to scattering along the line of sight shows that the sky color will be dominated by yellowish and red colors.

The brightness and color of the clear sky has also been investigated for various zenith angles φ [23.201]. For high sun elevations, the zenith sky of a pure Rayleigh atmosphere is blue (as observed for clear air), however, it would turn yellowish after sunset. This is in contrast to the observed blue color. The solution of this puzzle are the Chappuis absorption bands of ozone in the wavelength range between 500 and 700 nm. For high sun elevations, the ozone absorption contribution to sky light is small compared to Rayleigh scattering whereas it dominates for very low sun elevations.

Aerosols within the atmosphere are usually not distributed homogeneously, but in the form of accumulations, carried by the wind, thus undergoing constant qualitative changes, including condensation processes [23.117]. As a consequence, the extinction coefficient for various atmospheric compositions, e.g., for different types of clouds, and low- or high-altitude haze varies considerably [23.77]. For simplicity, let us now assume just a single aerosol layer. Its influence on sky colors is simply to intensify the red and yellow colors in the forward direction. This is due to the fact that the scattering angles are rather small and that aerosol particles show very strong forward scattering, compared to Rayleigh scattering (Fig. 23.15).

Similar qualitative arguments may also be applied to the phenomenon of the so-called blue mountains. During the day, the sky is illuminated by the sun. If the line of sight to a distant mountain is close to the horizon, the radiation entering the eye of an observer is due to two contributions. First, it consists of the light originally scattered by the mountain towards the observer. This light is attenuated due to scattering along the line of sight. Second, the observer will see sunlight that is scattered by the air along the line of sight. This air light will be blue in a Rayleigh atmosphere. Observing a scenery with mountains at various distances will change the amount of the two contributions: the more distant, the smaller the first will be and the more important the second contribution (see the discussion on visual range in Sect. 23.12). As a consequence, distant objects will appear to have a faint blue color [23.45,51]. This scheme can be used to get a measure for the thickness of the atmosphere [23.202] (see also studies of visibility [23.144]).

Very often, one observes that sky light close to the horizon is whitish. This can be understood in a similar way. Since no objects except the sky are observed, the first contribution from the above argument vanishes and only air light has to be considered. Sunlight which is scattered in a length interval close to the observer contributes a large amount of blue light due to Rayleigh scattering at low heights above the ground. Light which is scattered at larger distances from the observer is scattered at larger heights, i. e. contributes

smaller amounts of predominantly blue light. In addition this light is attenuated and spectrally modified by additional scattering along the line of sight. As a result, light which originates far from the observer contributes small amounts of multiply scattered mostly red light. All contributions along the line of sight add up to give an overall white color. Since light from distant portions will cease to contribute if scattered out of the line of sight, the overall brightness has a limit [23.45, 51, 78].

Observations from Mauna Loa of the polarization and color ratio during twilight often show deviations from the clear-sky average. These were attributed to cloud or haze shadow effects and the importance of stratospheric dust layers was emphasized [23.203]. Stratospheric dust clouds from volcanic eruptions do strongly affect the degree of polarization of sky light and also shift the positions of neutral points by more than 15° [23.204]. Such investigations strongly profit from the development of LIDAR systems and the respective theories of backscattering from small particles [23.205–208].

Modern experiments simultaneously measure the sky light radiance distribution at three wavelengths, the degree of polarization, and the plane of polarization [23.209]. Recently, the color coordinates of sky light have been investigated, showing that sky light colors have a wide range of chromaticity curves, depending strongly on location. Sometimes difficulties arise in separating luminance changes from chromaticity changes [23.210]. Astonishingly, clear daytime skies show a local maximum of radiance near the astronomical horizon. Its angular width and elevation vary with the solar elevation, azimuth relative to the sun, and aerosol optical depth. This is understood in terms of second-order scattering processes [23.211].

When the sun is seen through thin clouds, it usually has a sharp edge, but occasionally is fuzzy. This is due to certain clouds with ranges of cloud optical thicknesses depending on the cloud particle sizes [23.212].

Present investigations of sky light deal, e.g., with digital imaging of clear-sky polarization [23.213], twilight modeling [23.214] as well as color and luminance asymmetries in clear [23.215, 216] and overcast [23.217–219] skies. Sky light measurements have also been reported for Mars, based on data from the Viking and Pathfinder missions. The Martian atmosphere has a high dust-particle content resulting in very high sky brightness and the sky colors vary strongly with the angular position of the sun [23.220]. Standard demonstration experiments with milk droplets in water have also been recently reinvestigated [23.221].

Theoretical modeling of atmospheric extinction greatly profited from computer technology. Nowadays, the transmission of the atmosphere is modeled by extensive databases. The most prominent of these are the HITRAN and LOWTRAN databases [23.77, 222]. In particular, the LOWTRAN program calculates the transmission spectrum for molecular absorption, Rayleigh scattering and aerosol extinction at a moderate resolution of 20 cm^{-1}.

23.11.3 Eclipses

Interesting colorful phenomena may be observed during eclipses. For example, the colors and brightness of lunar eclipses are directly related to the scattering of sunlight within the Earth's atmosphere [23.223, 224]. During lunar eclipses, the moon enters the umbra of the earth. However, since the sun light is also refracted within the earth atmosphere, even the center of the umbra is still illuminated by sunlight which in addition of being refracted is at the same time attenuated due to scattering from molecules and aerosols. In order to estimate the irradiance within the umbra, refracted and scattered sunlight is integrated across the terminator, i. e. the portion of the contributing illuminated earth atmosphere. Since scattering depends on the spatial distribution of the scatterers, models must take into account not only the temperature distribution within the atmosphere, but cloud cover, topography and aerosol distributions along the terminator as well. The importance of the aerosols is illustrated by Fig. 23.29a. Without any aerosols, i. e. if attenuation would only be due to Rayleigh scattering from the air molecules, the moon would still look rather bright even at the middle of totality: irradiance would only drop by a factor of about 2000 compared to being outside the umbra. Taking a typical distribution of aerosols into account can lead to an additional factor of 100 at the center of the umbra [23.225]. Such irradiance distributions within the umbra have been successfully used to model the observed brightness of lunar eclipses [23.226]. The moon diameter ranges around 0.5° (30 arcmin) which means that it can completely enter the umbra for durations of more than an hour. The color of the moon as observed from earth depends on the irradiance spectra within the umbra as well as on the additional attenuation of the light scattered by the lunar surface towards the earth on its pass through the earth atmosphere. Figure 23.29b shows model spectra of the refracted and attenuated sunlight within the umbra at the position of the moon orbit [23.227]. Blue and green light

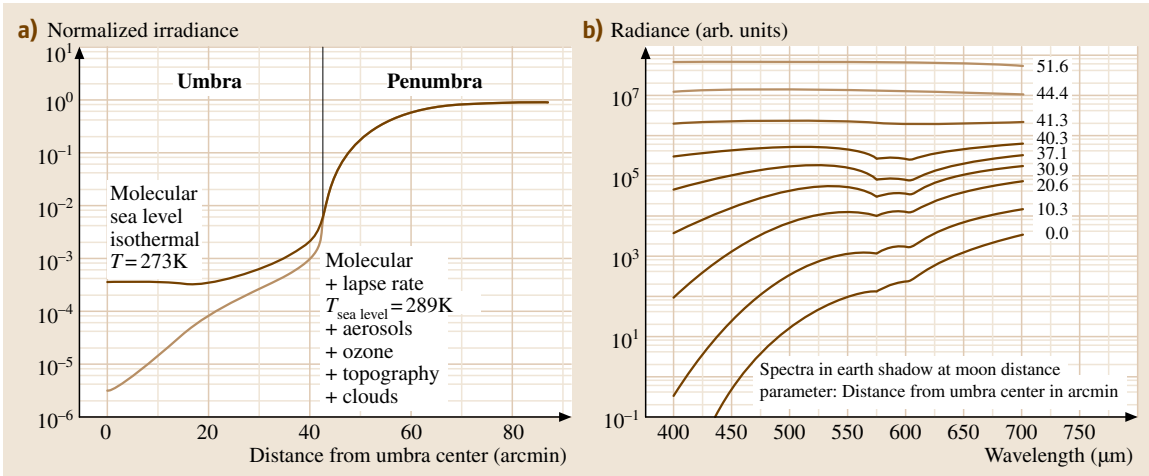

Fig. 23.29 **(a)** Spatial distribution of normalized irradiance in the umbra for a molecular isothermal atmosphere and for one including temperature variation, aerosols, ozone, and topography along terminator. **(b)** Irradiance spectra of eclipsed moonlight for points located at given distances form the center of the umbra as observed from earth for typical eclipse conditions

were more effectively scattered than yellow and red, therefore the moon usually has a characteristic brown-reddish color during total lunar eclipses. Obviously, the larger the amount of aerosols, e.g. larger concentrations may be present after volcanic eruptions, the more attenuation results, this means that the brightness of an eclipse is also a measure of the aerosol content in the atmosphere.

The model spectra in Fig. 23.29b show features around 580 to 600 nm. These are due to the Chappuis absorption bands of ozone and result in a slightly increased attenuation at yellow and red wavelengths. This effect is of no concern at the center of the umbra, however, at its edge, it may be strong enough such that there is more blue light available than at other wavelengths. In this case, it is indeed possible to observe blue moons [23.228].

Other phenomena associated with eclipses examples include polarization of sky light [23.229, 230], twilight phenomena [23.231], illuminance measurements [23.232], and visibility of stars, halos and rainbows [23.233] during solar eclipses.

23.12 Clouds, Visibility, and Miscellaneous

23.12.1 Clouds

Clouds are visible aggregates of water droplets or ice crystals, suspended in the air and grown around condensation nuclei [23.121]. Fog or clouds have droplet sizes around or above 10 μm, with densities ranging from 10 to 1000 droplets/cm^3. On average we will assume 300 droplets/cm^3 [23.234]. Droplets of 5–10 μm radius will then correspond to volume fractions f of about 10^{-7}–10^{-6}.

Clouds exhibit several optical phenomena, the most obvious being their white color, but certain types of clouds show particular phenomena. Cirrus and cirrus-stratus clouds may give rise to coronas, iridescence and halos, contrails of aircraft engines are cirrus-like trails of condensed vapor with characteristics similar to cirrus clouds, and cumulonimbus clouds relate to thunderstorms, i. e. lightning. Also polar stratospheric clouds show optical effects [23.235]. Here, the color of clouds, their absorption and extinction will be briefly discussed. The effect of photon path length distributions within clouds is discussed in Sect. 23.5.5.

If illuminated by white light, most clouds appear white (lower brightness is often interpreted as grey or dark) with the exception of some smoke clouds, e.g. from brush fires [23.236]. Since water droplets are mostly nonabsorbing in the visible, the color must be due to scattering. Scattering of light from monodisperse

water droplets of about 10 μm shows ripple structures (Fig. 23.14) [23.40, 41], for size distributions this is washed out and scattering is mostly independent of wavelength in the visible spectral range. Although this is a sufficient condition for clouds to be white, it is not necessary [23.237]. As a matter of fact, a suspension of Rayleigh scatterers (such as fat droplets in milk), i. e. selective scatterers, also give a white color due to multiple scattering.

The criterion for multiple scattering to take place is that the optical thickness τ is large compared to unity. A molecular atmosphere had $\tau < 1$, therefore the explanation of the blue sky needs only single scattering events. For clouds, τ for a distance x can be estimated by the following argument: within clouds, the extinction coefficient is more or less constant, hence $\tau = \beta x$. The extinction coefficient β can be estimated from Mie theory calculations. Droplets of about 10 μm in diameter have extinction cross sections of about twice the geometrical cross section (this is the extinction paradox [23.41]), i. e. of the order of $10^{-6}\,\mathrm{cm}^2$. For concentrations of $300\,/\mathrm{cm}^3$, this leads to extinction coefficients β of the order of $0.05\,\mathrm{m}^{-1}$. A very simple estimate [23.78] can also be made by starting from $\beta = N\sigma$ and substituting the number density N by the volume fraction $f \approx N\emptyset^3$ and the cross section by approximately the geometrical cross section $\sigma \approx \emptyset^2$ to find

$$\beta \approx f/\emptyset \qquad (23.42)$$

for $f = 10^{-6}$ and 10 μm particles, this also gives the order of 0.1 /m.

Hence, a cloud of several meters thickness corresponds to the optical thickness of the whole normal atmosphere. The transmission is given by $T = \mathrm{e}^{-\beta x}$ and for $\beta = 0.05\,\mathrm{m}^{-1}$ a distance of 20 m leads to $\tau = 1$ ($T = 1/\mathrm{e}$), $x = 100\,\mathrm{m}$ to $\tau = 5$ ($T \approx 7\times10^{-3}$), and $x = 200\,\mathrm{m}$ to $\tau = 10$ ($T \approx 5\times10^{-5}$), which is sufficient to obscure the disc of the sun [23.78]. Low transmission automatically leads to high reflection, i. e. thick clouds have a high albedo which explains the bright white color observed from airplanes above clouds. In conclusion, multiple scattering dominates for any cloud that is optically thick and composed of nearly nonabsorbing particles; upon illumination by white light it will look white. The color of clouds may change during sunrise and sunset if spectrally filtered light illuminates the clouds, giving rise to spectacular sceneries.

The very small transmission of sunlight through thick clouds also accounts for the fact that the bases of such clouds are usually very dark. If droplets near the base grow to form raindrops, the extinction coefficient changes. The volume fraction stays about the same, but raindrops have a size of, say, 1 mm, hence β in a rain shower is about a factor 100 smaller than within the clouds. This explains, why it is easily possible to look through very heavy rainfalls.

23.12.2 Visibility and Visual Range

Visibility is a measure of how far one can see through the air. As quantitative measure it is often called visual range. Even in the clearest air – assuming that no aerosol particles are present and that one is not restricted by the Earth's curvature – the horizontal visibility is limited to a few hundred kilometers. This is due to the scattering and absorption of the components of the air (vertically, the atmosphere is optically much thinner, hence we may see the stars at night). In meteorology, visibility refers to the observation of distant dark objects against a bright background, usually the sky. The basis for a theoretical derivation [23.78, 238–242] is the contrast ratio C, giving the normalized difference between the background signal of the object and the signal of the air light from the line of sight. One finds for the resulting maximum distance D

$$D = -\frac{\ln(C)}{\beta}\,, \qquad (23.43)$$

where β is the scattering coefficient. The sensitivity of the human eye has a maximum at $\lambda = 555\,\mathrm{nm}$, therefore one usually evaluates (23.43) for green light. D then just depends on the threshold contrast C, i. e. the lowest visual brightness contrast, a person can see. It is common to assume $C = 0.02$ although it varies from individual to individual. This gives $D = 3.912/\beta$. Values of D for various β are shown in Table 23.7. Obviously, there is an enormous range of distances from several meters in dense fog to several hundred kilometers in very clear air. Hence, the visibility is an indicator of the aerosol and/or water droplet content.

23.12.3 Miscellaneous

There is a great number of other optical phenomena associated with the atmosphere. In the following, these will be very briefly described and references will be given.

Green flashes or green suns are phenomena when either the last rays at sunset or the first rays at sunrise look green or when, at low sun elevations, the upper rim of the sun looks green. In the first case, just a very small

Table 23.7 Typical values for visibility in molecular atmosphere and examples if aerosols (natural/anthropogenic) and water droplets are present

	β	D	
Molecular atmosphere	$0.013\,km^{-1}$	300 km	Extremely excellent visibility
Some particles	$0.050\,km^{-1}$	80 km	Excellent visibility
Many particles	$0.500\,km^{-1}$	8 km	Poor visibility
Thick fog	$0.050\,m^{-1}$	80 m	Extremely poor visibility

portion of the sun is above the horizon, in the second case, the sun's disc is usually highly distorted due to mirage effects. The explanations of these phenomena require refraction and the scattering of the sunlight as well as mirage effects [23.105, 243, 244].

Noctilucent clouds are blue, white or silvery looking clouds within the stratosphere at heights of about 80 km which can still be illuminated by sunlight 1–2 h after sunset [23.245–247]. They often show wavelike features with wavelengths in the range from 1–100 km.

Shadows are regions in space that are shielded from light. They give rise to very prominent daily-life phenomena in atmospheric optics such as the crepuscular rays, sometimes called sun beams or shadow beams [23.45,48,51,248] or the fact that mountain shadows are always triangular, irrespective of the contour of the mountain [23.249, 250].

A very personal experience, based on our visual system, is the so-called moon illusion, i. e. the fact that the sun or the moon looks much bigger near the horizon than when it is higher in the sky [23.251, 252]. This phenomenon is not reproduced on photos.

In addition to phenomena with external light sources such as the sun, moon or stars, a number of optical phenomena in the atmosphere produce light. The most well known are auroras, multicolored, diffuse and slowly moving lights, usually seen only in high altitudes against the clear dark night sky. They are due to air molecules and atoms, which are excited by collisions with electrons from the solar wind [23.51, 253, 254]. At times of increased solar activity, they may also be observed at low latitudes. These events are accurately predictable, since the solar wind needs time to reach the Earth (see the websites on space weather in Table 23.4).

Lightning, one of the most common and spectacular natural phenomena, is due to electric charging effects in thunderstorm clouds. The exact microphysical processes that are responsible for the charging are still under dispute [23.255–257]. Recent research has revealed a whole new class of phenomena: lightning-related transient luminous events (TLE), including sprites, blue jets, elves, trolls etc. [23.258]. These TLE extend from the top of thunderclouds at heights of up to 100 km and raise serious questions about possible hazards for aerospace operations. In addition, promising efforts are under way concerning lightning protection by initiation of the discharge using intense femtosecond lasers [23.259].

Meteors are sometimes faint, sometimes brilliant streaks of light with luminous trails in the night sky. Meteor incorporates all phenomena when a cosmic particle enters the atmosphere. Outside the atmosphere, they are called meteoroids and, if they reach ground, meteorites. The visual effects are due to heating of particles in the atmosphere due to frictional forces. Small particles heat up until they evaporate. Thereby, they collide with air molecules and ionize a channel of air. Light is then emitted upon recombination [23.260, 261].

24. Holography and Optical Storage

The term holography is composed of the Greek words *holos* (= whole) and *graphein* (= to record, to write), and thus summarizes the key aspects of its underlying principle: recording the complete wavefront of an object, i. e., its intensity as well as its phase. Interference and diffraction phenomena are employed to record and retrieve the full information, a technique pioneered by Dennis Gabor in 1948. He was honored with the Nobel prize in Physics in 1971, reflecting the general impact of holography on modern physics.

Holography plays an essential role in today's science and industry. Relevant applications making use of its principle have been developed, including three-dimensional (3-D) displays and holographic cameras, interferometers for nondestructive material analysis, archival data storage systems, diffractive optical systems, and embossed display holograms for security features. The success of holography was made possible in particular by the availability of coherent laser-light sources. In the meantime holography has even been performed using microwaves, neutrons, electrons, x-rays, and acoustic waves.

The first part of this chapter is dedicated to holography itself. It provides an introduction to the historical development and reviews the principle of wavefront reconstruction. This section also includes an overview of hologram classification, recording/read-out geometries, holographic techniques and recording materials. Special emphasis is given to explaining the principles of some of the most important holographic applications, finishing with a brief insight into a few of the latest discoveries making use of Gabor's principle, such as holographic scattering and neutron diffractive optics.

The second part of this chapter addresses trends in optical storage, focussing on holographic data storage. It highlights different approaches to achieving increased optical storage density. This section also discusses the historical development of optical storage, the need for increased storage densities (and hence storage capacities) and the role of optical storage systems in today's life.

Various approaches to increasing the areal density of optical storage systems are introduced. Next, the advantages of and approaches to volume optical recording that are currently under consideration for future generations of optical storage systems are presented. The state of the art as well as physical and technical attempts to realize holographic data storage are discussed in detail.

24.1 Introduction and History

In May 1948 *Dennis Gabor* (Fig. 24.1) introduced the principle of wavefront reconstruction in the scientific journal Nature [24.2]. In the frame of his one-page contribution *A new microscopic principle* he discussed the high-resolution visualization of microscopic objects and emphasized the impact of his idea for the improvement of electron microscopes. The word *holography*, as his principle was designated shortly thereafter, is a compound of the Greek words? ὅλος (*holos* = whole) and γράφειν (*graphein* = to record, to write) and summarizes the key aspects of Gabor's principle: the recording of the complete/overall wavefront from an object, i. e., recording of the object within all three dimensions. Holography is therefore a serious extension of photography, which is limited to the recording of the projected image of three-dimensional objects. In standard photography, the intensities/amplitudes of the wavefront of the object are recorded without the appertaining phase information. Photography does not include the depth information, i. e., a look around the object is not possible. In holography, viewing the reconstructed image is identical to the observation of the real wavefront of the object. Within geometrical limits the object can be observed from various perspectives and it is possible to look behind the object.

Fig. 24.1 *Dennis Gabor* (1900–1979, born in Budapest, Hungary), Nobel Prize Laureate 1971 (from [24.1])

Holography uses the interference phenomenon for recording both the amplitude and the phase information. The first holograms were realized by Gabor with the light of a mercury-arc lamp, that hence contained distortions and an extraneous twin image. The further history of holography is punctuated by the development of coherent laser-light sources in the 1960s, the real success of holography being initiated in 1962: *Emmett Leith* and *Juris Upatnieks* read Gabor's paper and *simply out of curiosity* they adapted Gabor's principle to an off-axis geometry that they borrowed from their work on side-reading radar. The result was the first laser transmission hologram of three-dimensional objects (a toy train and bird) [24.3–5]. At the same time *Yuri N. Denisyuk* combined holography with the findings of *Gabriel Lippmann* on natural color photography [24.6] and produced a white-light reflection hologram [24.7]. For the first time, a hologram could be reconstructed using the light from an ordinary incandescent light bulb. In 1965 the patent for the off-axis recording geometry for reflection holograms was issued to *N. Hartmann* [24.8] – a technique that emerged as a standard in holographic recording. The invention was due to at least three teams of coworkers: E. Leith, J. Upatnieks, A. Kozma, J. Marks, and N. Massey (University of Michigan); G. Stroke, A. Labeyrie (University of Michigan) with K. Pennington and L. Lin (Bell Labs); C. Schwartz and N. Hartmann (Batelle Memorial Institute). Table 24.1

gives an overview of the impressive milestones within the first decades of the history of holography. A recent review of the history of holography is given in [24.9]. Nowadays, holography touches many fields of our everyday life including arts, archeology, health and medicine, biotechnology, advertising and communication. Gabor's principle continues to be a topic of research and potentially will open up novel perspectives, e.g., in optical data storage (Sect. 24.5). The impact of this invention was honored with the Nobel prize in 1971 [24.1]. *Dennis Gabor* died on February 8, 1979.

24.2 Principles of Holography

24.2.1 Recording of Holograms and Wavefront Reconstruction

The holographic principle makes use of the interference phenomenon, as interference allows the transfer of the phase information of a wavefront into an intensity pattern. Recording both the amplitude and phase of the wavefront of an object, i. e. recording a hologram, is performed by interference of a reference wave with complex amplitude R and a coherent signal wave S using a holographic plate (Fig. 24.2). For the sake of simplicity we do not consider vectorial properties of the waves at the moment. The wavefront of the object is reconstructed by light diffraction if the hologram is exposed only to the reference wave.

The simplest hologram is formed by the interference of two plane waves with noncollinear propagation directions. In this case a pattern with sinusoidally modulated amplitude is recorded on the holographic plate, i. e., an *elementary holographic grating*. Exposure of this grating to the reference wave leads to diffraction along the former direction of the signal wave. Thus the wavefront of the plane signal wave is reconstructed.

More complex wavefronts are reconstructed in an analogous way. Let us consider the reference and signal waves with complex amplitudes R and S. Then the intensity I of the interference pattern can be expressed by

$$I \propto |R+S|^2 = |R|^2 + |S|^2 + R^*S + RS^* , \qquad (24.1)$$

where * denotes the complex conjugate. Exposing a photochromic film (such as a holographic plate) to the interference pattern, the absorption coefficient and hence the transmission T will become spatially modulated. In the case of a linear response of the film to intensity, i. e., $T = T_0 - \Delta TI$, the illumination of the holographic plate with the reference wave results in the

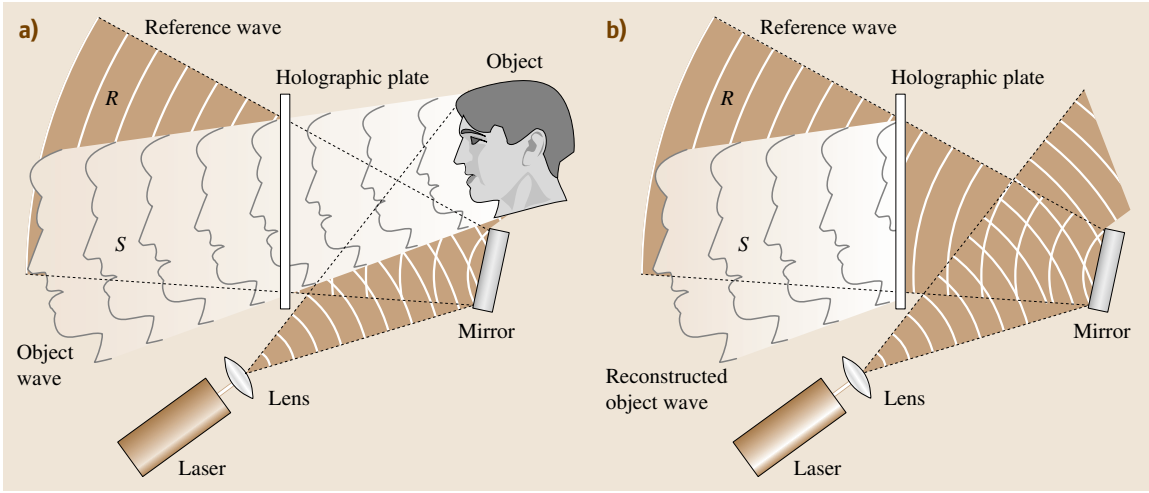

Fig. 24.2 **(a)** Recording a hologram and **(b)** wavefront reconstruction. The intensity pattern from the interfering reference R and signal S waves is recorded by the holographic plate thus representing a hologram. A complete reconstruction of the signal wave S appears by light diffraction if the hologram is exposed to the reference wave only

reconstructed wave

$$RT = R\left[T_0 - \Delta T(|R|^2 + |S|^2 + R^*S + RS^*)\right] . \tag{24.2}$$

Here, T_0 is the transmission prior to illumination and ΔT is a parameter that characterizes the photosensitivity of the film. The important term in (24.2) is $\Delta TRR^*S = \Delta T|R|^2S$. The factor $\Delta T|R|^2$ is constant and phase independent, but the signal wave S is completely revealed with *amplitude and phase*. The other terms in (24.2) describe the transmitted reference wave and further diffracted waves. Separation of these particular waves from each other can be established by choosing a proper recording geometry (spatial separation via off-axis geometry (Sect. 24.2.3)).

The *amplitude* and *phase* information of the recorded object is stored in each singular point of the holographic plate, representing the particular viewpoint onto the object. Thus the lateral dimension of the holographic plate is the limit for the visual angle onto the recorded object. Reconstruction is even possible by exposure of only a small part of the hologram with the reference wave.

In summary, the holographic principle only requires a source of coherent waves, an object, and a photosensitive medium with sufficient spatial resolution. It is worth noting that there is no restriction on the nature of the radiation or its wavelength and thus any (partially) coherent wave can be applied, such as electrons, neutrons, x-rays, microwaves, photons and acoustic waves. All of these have been utilized for holographic recording within the last decades. As for the variety of waves, the spectrum of photosensitive media for hologram recording is rather broad and ranges from photochromic films, ^{3}He detectors (neutrons) to germanium detectors or avalanche photodiodes (x-rays).

24.2.2 Classification Scheme

The fundamental principle of recording and reconstructing an object wave can be realized in a great deal of variants, predetermined by the available recording materials, the optical setups (geometries) or techniques for recording and read out, etc. Therefore one could classify holograms, e.g., with respect to the recording scheme, the read-out configuration or the hologram properties [24.16]. The classification scheme suggested in this section primarily considers the reconstruction properties of the particular holograms. We note that such properties are closely associated with the geometrical schemes for recording (Sect. 24.2.3) and/or the type of holographic recording medium (Sect. 24.2.5), introduced later in this chapter.

The first step in hologram classification is to distinguish between *phase* or *amplitude*, *thin* or *thick*, *transmission* or *reflection* and *static* or *dynamic holograms* (Fig. 24.3). Note, that the combination of these particular types yields a precise designation as well as sufficient information about the hologram. Our previ-

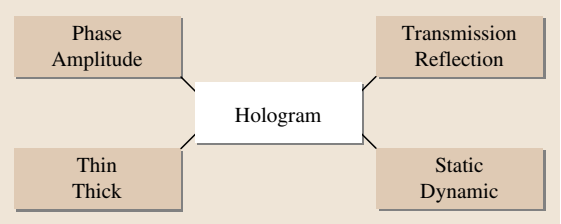

Fig. 24.3 Holograms are primarily classified as phase or amplitude, thin or thick, transmission or reflection and static or dynamic holograms

ous example from Sect. 24.2.1 is a static thick amplitude transmission hologram.

Furthermore, the particular recording and reconstruction properties are considered, which expands the variety of hologram types. Among these are *rainbow holograms*, *polarization holograms*, *holographic stereograms*, *composite holograms*, *multiplexed holograms* (Sect. 24.2.4), *Fresnel holograms*, *Fraunhofer holograms*, *Fourier holograms*, *image-plane holograms*, and *embossed holograms*.

Phase and Amplitude Holograms

In Sect. 24.2.1 we assumed that the recording process results in a spatial modulation of the transmission of the holographic plate. The diffracted reference wave is then affected in its amplitude. Thus the hologram commonly is called an *amplitude* or *absorption hologram*. Figure 24.4 shows the microscopic structure of an *amplitude hologram* that has been determined by means of optical microscopy. In other photosensitive media the refractive index or the thickness is changed upon illumination with light. In this case the phase of the reference wave is affected during diffraction, i. e., reconstruction of the object wave. Therefore this type of hologram is called a *phase hologram*. Usually the latter is more favorable, because the intensity of the reconstructing reference wave is not damped by material absorption, so that holograms with considerable thickness can be recorded.

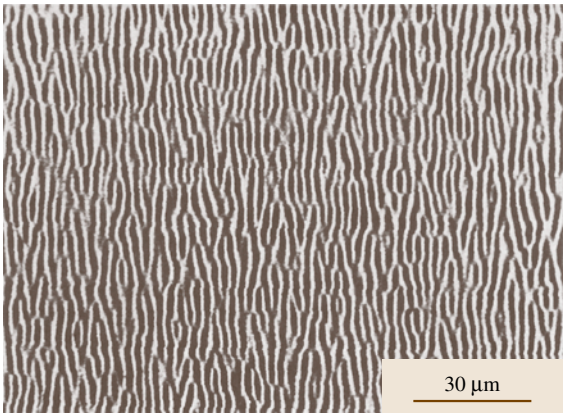

Fig. 24.4 Hologram microstructure of a diffuse object (after [24.17])

Thin and Thick Holograms

Taking into account the effective hologram thickness and the amplitude of the absorption or phase modulation, holograms can be classified as *thin* or *thick*. Note, that effective thickness d_{eff} of the hologram might be less than the thickness of the medium d in which the hologram is recorded ($d_{\text{eff}} \leq d$). The case $d_{\text{eff}} = d$ is valid for nonabsorbing media and diameters of reference and signal waves much larger than d. A rough rule of thumb defines holograms with $d\lambda/\Lambda^2 < 1$ as thin holograms. However, a sharp boundary does not exist and only the extremal cases are unambiguously defined [24.18]. For thick or volume holograms it is mandatory to fulfill the Bragg condition for reconstruction

$$s\boldsymbol{K} = \boldsymbol{k}_{\text{S}} - \boldsymbol{k}_{\text{R}} \quad \text{or} \tag{24.3}$$

$$s\lambda = 2\Lambda \sin\theta_{\text{B}} \,. \tag{24.4}$$

The Bragg condition is a result of energy and momentum conservation. Here, $\boldsymbol{K}$ is the grating vector of the elementary grating, $\boldsymbol{k}_{\text{S,R}}$ are the wave vectors of the signal and reference wave, respectively, and s is the diffraction order. Equation (24.4) is a scalar version of (24.3) for the particular case that the grating vector is perpendicular to the surface normal vector $\hat{\boldsymbol{N}}$. Equation (24.4) imposes a strict relation on the wavelength λ, the angle of incidence (Bragg angle θ_{B}) and the grating spacing $\Lambda = 2\pi/|\boldsymbol{K}|$ to reconstruct the hologram efficiently. At the same time, higher diffraction orders ($s > 1$) are depleted; they are a characteristic property only for thin holograms. The Bragg condition is illustrated by a wave-vector diagram in Fig. 24.5a. The sharpness of the Bragg condition is inversely proportional to the dimensions of the grating. Assuming a symmetric geometry, i. e., $\boldsymbol{K} \perp \hat{\boldsymbol{N}}$, and a grating with thickness d yields an uncertainty of the Bragg condition of $2\pi/d$. This region is indicated by the shaded area in Fig. 24.5. As long as the Bragg mismatch vector $\delta\boldsymbol{k}$ resides within this area, Bragg diffraction can be observed (Fig. 24.5b). The modulus of the mismatch is proportional to the angular and wavelength mismatch ($\Delta\theta$ and $\Delta\lambda$). By this means, an angular accuracy to reconstruct a thick hologram can be in the region of

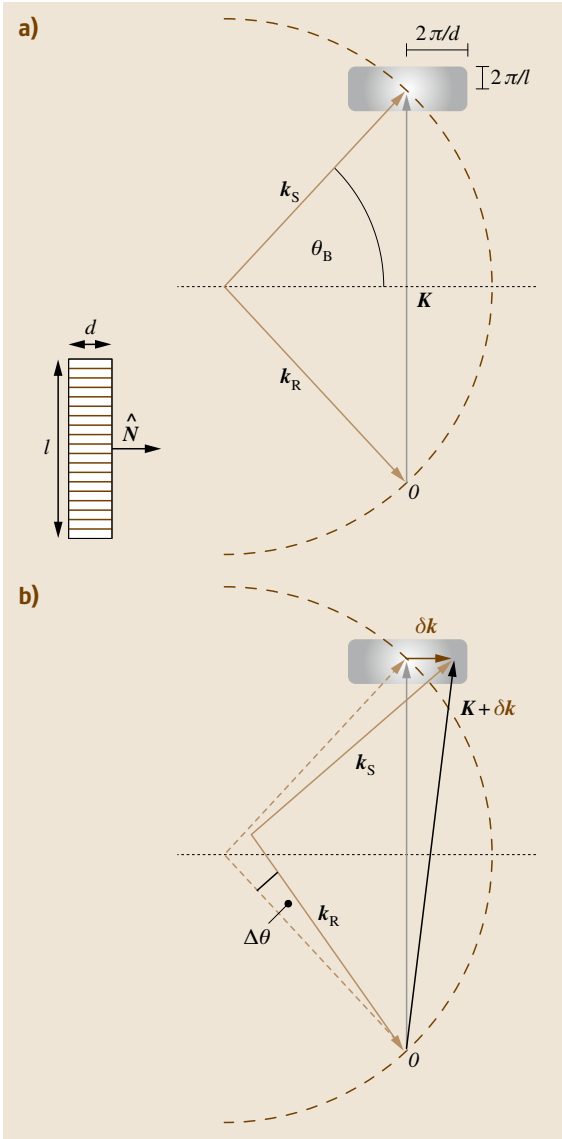

Fig. 24.5a,b Wave vector diagram: energy and momentum conservation in reciprocal space. **(a)** Exact Bragg matching. **(b)** Slight angular mismatch, $|\delta \boldsymbol{k}| < 2\pi/d$. Reconstruction with lower efficiency is still possible as long as the Bragg mismatch vector $\delta \boldsymbol{k}$ ends within the grey area

less than 0.001°, a fact that is utilized for angular and wavelength multiplexing (Sect. 24.2.4).

Transmission and Reflection Holograms

The classification into *transmission* and *reflection holograms* takes the direction of the wave vectors of the reference and reconstructed signal wave with respect to the holographic medium into account. This is schematically illustrated in Fig. 24.6 for two extremal cases. A transmission hologram is characterized by the fact that both reference and signal wave are transmitted through the hologram, i. e., the signal wave is reconstructed by forward diffraction processes. For reflection holograms only the reference wave is transmitted. Thus, the latter is realized if the sign of the dot product between the surface normal vector $\hat{\boldsymbol{N}}$ and the wave vectors $\boldsymbol{k}_R$ and $\boldsymbol{k}_S$, respectively, differ. Reflection holograms require recording media with thicknesses much larger than the grating spacing. Hence they usually represent *thick reflection holograms*. A benefit of a thick reflection hologram or *white-light reflection hologram* is its high wavelength selectivity, which acts as a narrowband wavelength filter for the reference light and allows reconstruction with white-light sources.

Static and Dynamic Holograms

Holograms that do not affect the reference and signal waves during recording, e.g., in holographic media that require further (chemical) processing, are called *static holograms*. In contrast an interaction between the recorded hologram and the recording beams leads to *dynamic holograms*: the recording beams themselves coherently diffract from the hologram and thus influence their own light modulation. Obviously, this feedback subsequently leads to changes of the hologram. This nonlinear dynamic interaction can result in an amplification of weak signal beams. As a consequence the contrast ratio of the interference pattern and thus of the hologram is a function of the material thickness. The ratio might be enhanced, e.g., as a function of the propagation coordinate in transmission holograms. Further coupling between the recorded hologram and the incoming interference pattern is shown to result in light amplification [24.19], which has been successfully applied for image [24.20] or signal amplification [24.21].

Rainbow Holograms

The invention of *rainbow holograms* is due to *Benton* [24.14, 22], allowing the reconstruction of bright, sharp monochromatic images from transmission holograms with white light. For this purpose the hologram information is reduced by losing the vertical parallax, which is an unimportant feature of holography, as three-dimensional viewing depends essentially on the horizontal parallax. Rainbow holograms are produced by copying a transmission hologram (Sect. 24.2.4) in

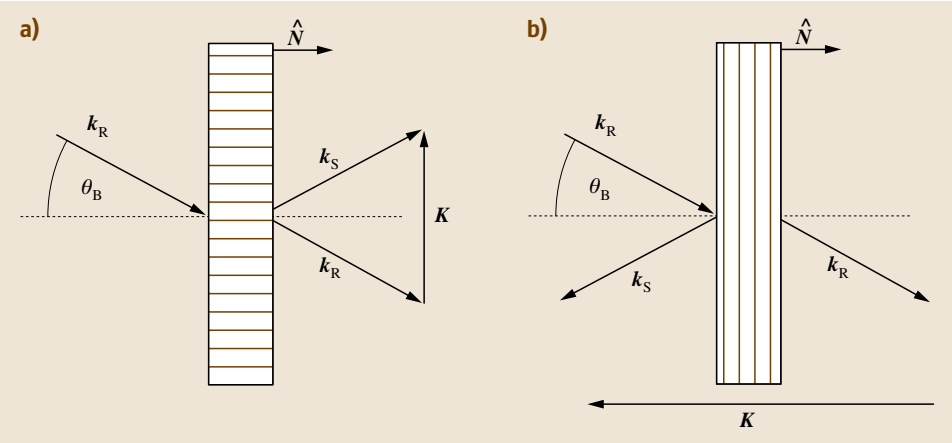

Fig. 24.6a,b Directions of the wave vectors of the reference and signal waves with respect to the holographic recording medium for **(a)** a transmission hologram, and **(b)** a reflection hologram

which the area illuminated by the reference wave is strongly reduced with a horizontal slit. As a result, reconstruction of a rainbow hologram with white light splits the image in the vertical plane to form a continuous (rainbow) spectrum. Thus the reconstructed image can be observed at any part of the spectrum in the corresponding color.

Polarization Holograms

The holographic principle demands reconstruction of the complete object wavefront, usually of its amplitude and phase distribution. However, the object may additionally influence the polarization field of the wavefront, e.g., the electric field vector is influenced by reflection processes on specular surfaces. *Polarization holograms* allow the reconstruction of the polarization field of the signal wave as well and endow the holographic medium with specific recording and reconstruction properties. According to Table 24.2 we distinguish between the materials by their property to record and/or to reconstruct the polarization field. The type I and III media are obviously not suited for recording polarization holograms, although type I is applied to record and reconstruct standard holograms, i. e., phase and amplitude of wavefronts. Type III holograms are of interest, since the reconstructed polarization field is a fingerprint of the material properties and can thus be used to analyze the recording medium.

Table 24.2 Type I media allow only recording of the light polarization. Type II media allow both recording and reconstructing the polarization field. Type III media superimpose a material-specific polarization field to the reconstructed wavefront

	Record	Reconstruct
Type I	✓	×
Type II	✓	✓
Type III	×	✓

A sensitivity to light polarization is known in various media, e.g., media with photoinduced dichroism or photoinduced birefringence (type I, type III) [24.23,24]. Recording and reconstruction of polarization holograms was further shown in photorefractive electrooptic crystals such as iron-doped $LiNbO_3$ [24.25], where the photovoltaic tensor provides the reconstruction of the polarization field (type I, type II and type III). In recent decades further photosensitive materials have been discovered that allow efficient type II recording of the polarization field, among them crystals with a center of inversion [24.26]. A comprehensive recent review is given in [24.27].

Holographic Stereograms and Composite Holograms

Holographic stereograms are recorded by photographing the object from various perspectives in the first step and subsequent holographic recording of the particular photographs at corresponding positions of the stereogram in the second step [24.28, 29]. The advantage of holographic stereograms is that coherent laser light is not required for the primary recording process, and thus it is even possible to record large objects or living subjects. Each hologram reconstructs a two-dimensional photographic image of the object with a particular perspective defined by the spatial position on the stereogram. Obviously, the resolution of the vertical and horizontal parallax depends on the dimension and shape

of the particular hologram (slides or frames [24.30]). Modified recording techniques even allow reconstruction with white light [24.31].

Composite holograms are made up from a multitude of single holograms, which – in contrast to holographic stereograms – reconstruct a three-dimensional image of the object from different perspectives [24.32]. This allows one to reconstruct a 360° view of the object at the expense of losing vertical parallax and strong object distortions when the image is viewed with both eyes.

Fresnel Holograms, Fraunhofer Holograms

If the object is placed a short distance from the hologram, the wavefront is described by Fresnel's approximation to the Fresnel–Kirchhoff diffraction integral [24.33]. This type of near-field holograms is called a *Fresnel hologram*. Each particular point of the image is associated with an emerging spherical wave and the hologram resembles the complex wave interference pattern. Thus each particular point of the hologram can be addressed by a reference wave to reconstruct the complete image but is limited to the corresponding perspective. *Fraunhofer holograms* are generated if the Fraunhofer diffraction pattern is recorded, which appears with small objects that are placed in the far-field. In this case the recorded wavefront is proportional to the Fourier transform of the spatial amplitude distribution of the object. Fraunhofer holograms can be applied to inline holography (Sect. 24.2.3), circumventing the usual problem associated with the presence of the conjugate image. As early as 1963 Fraunhofer holography was applied to visualize distributions of aerosol particles [24.34].

Fourier Holograms, Image-Plane Holograms

Recording the Fourier transform of the complex amplitude of the object and reference waves [24.35] yields *Fourier holograms*. Recording can be performed, for example, by using a lens in the optical path. Fourier holograms offer the useful property that the reconstructed image does not move when the hologram is translated in its own plane, owing to a general property of Fourier transforms [24.36]. In *image-plane holograms* the real image of the object instead of the object itself is recorded [24.37–39]. This can be done, for example, by imaging the object onto the holographic medium with a lens. Thus each point of the object directly relates to a single point of the hologram, i. e., the object information is not distributed over the entire hologram. Image-plane holograms are highly sensitive to mechanical defects.

Embossed Holograms

Holograms can be embossed onto various substrate materials by a stamp that carries the inverse hologram as a surface relief. Embossed holograms are usually generated in four steps:

- A hologram is copied to a photoresist (Sect. 24.2.5), so that the fringe pattern appears as a spatial relief structure.
- A metallic stamping master with the inverted relief structure, commonly called the shim, is made by electrolytic processing of the photoresist.
- This metal stamp is embossed onto a substrate, e.g., a thermoplast material, under heat and pressure.
- The embossed hologram results by coating the substrate relief with a thin silver layer and subsequent hardening by electron beams.

The required minimum spatial resolution of 200 lines/mm ensures sufficient quality in reconstructing the signal wave. Nearly any condensed material can be applied as a substrate for the production of embossed holograms, which are profitable in high volumes. Embossed holograms are therefore of interest in commercial industries and as security features (Sect. 24.3.6).

24.2.3 Recording Geometries

Transmission, 90° and Reflection Geometry

Recording geometries are classified according to the directions of the reference and signal beam, and thus of the grating vector, with respect to the surface normal of the medium. Three principal geometries are distinguished: transmission geometry, reflection geometry and 90° geometry, as schematically shown in Fig. 24.7. In the transmission geometry (Fig. 24.7a) the reference and signal waves enter the holographic recording material through the same entrance face. The resulting interference pattern is characterized by the grating vector $\boldsymbol{K}$, which is perpendicular to this surface normal in the symmetric case ($\boldsymbol{K} \perp \hat{\boldsymbol{N}}$). In order to obtain high diffraction efficiency combined with sharp angular selectivity it is favorable to utilize thick storage media and large Bragg angles.

In reflection geometry (Fig. 24.7b) the beams enter the holographic material from opposite faces of the medium, so that in the symmetric case the grating vector is parallel to the surface normal ($\boldsymbol{K} \parallel \hat{\boldsymbol{N}}$). Note, that the Bragg condition in the form of (24.4) is only valid for the particular case of transmission geometry in the symmetric case ($\boldsymbol{K} \perp \hat{\boldsymbol{N}}$) [24.40]. The

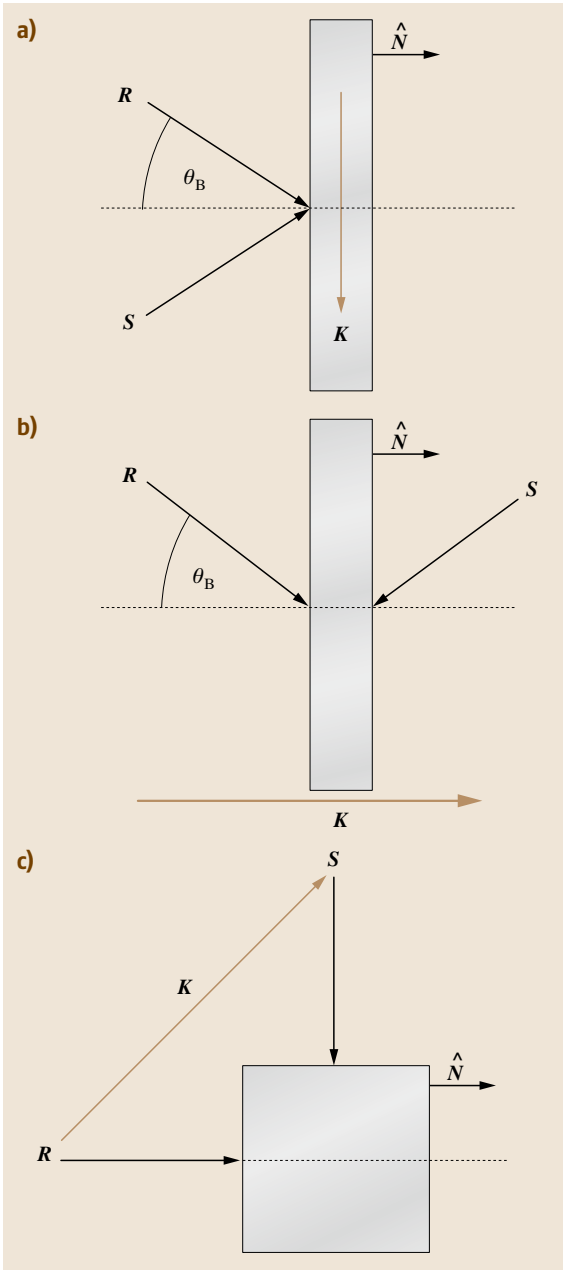

Fig. 24.7a–c Principal geometries for hologram recording. **(a)** Transmission geometry: reference and signal beams penetrate the holographic recording medium through the same entrance face. In the symmetric case, the grating vector is perpendicular to the surface normal $\hat{N}$ of the medium. **(b)** Reflection geometry: reference and signal beams enter the holographic recording medium through opposite entrance faces. In the symmetric case, the grating vector is parallel to the surface normal. **(c)** 90° geometry: reference and signal beams enter the holographic recording medium through two mutually orthogonal entrance faces, usually with a crossing angle of 90° and $\theta_B = 0$. The grating vector encloses an angle of 45° with the surfaces of the medium◀

reflection geometry provides optimal Bragg selectivity for wavelength multiplexing (Sect. 24.2.4), especially for $\theta_B = 0°$. The thickness of the holographic recording medium enhances the selectivity. The angular range that can be used in the different geometries is reduced by the refractive indices of the storage medium. This reduction can be important for materials with high refractive indices.

In the 90° geometry (Fig. 24.7c) the two beams enter the holographic recording medium via two mutually orthogonal faces. Usually $\theta_B = 0$ is chosen, so that the angle between the grating vector and the surface normal is 45°. In this geometry the storage medium has a cubic shape. The highest angular selectivity is realized, and in addition the medium is thick enough to obtain efficient gratings with a high selectivity due to the beam diameters.

Inline Off-Axis Geometries

A recording geometry is designated as *inline* if the wave vectors of the reference and signal wave are collinear (Fig. 24.8). The inline transmission geometry (or *Gabor geometry*) was introduced by Gabor when recording his first holograms [24.2]. The requirements on the coherence length of the recording waves and the spatial resolution of the holographic medium are low. These obvious advantages are accompanied by the disadvantage that the image and reference waves are reconstructed in the same propagation direction, leading to an overlap of various images. The inline geometry is still popular for recording of white-light reflection holograms (*Lippmann–Bragg geometry* or *Denisyuk geometry*), because only a few optical components – at least a laser and a lens for beam expansion – are required in addition to a transparent thick holographic medium.

The *off-axis geometry* introduced by Leith and Upatnieks was enabled after coherent laser systems became available. It spatially separates reference and signal beam, both in recording and reconstruction. An off-axis transmission geometry is sketched in Fig. 24.2 and can be applied to the recording of reflection holograms as well.

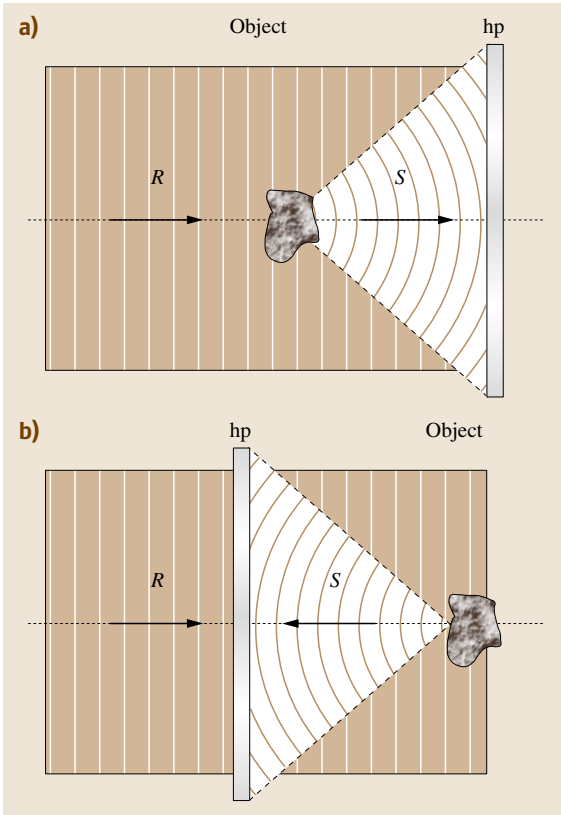

Fig. 24.8 **(a)** Inline transmission geometry (or Gabor geometry), **(b)** Inline reflection geometry (or Lippmann–Bragg geometry or Denisyuk geometry). hp: holographic plate

360° Geometry, Edge-Lit Geometry

The recording of a hologram in a 360° geometry was first demonstrated in 1965 [24.41] and allows one to reconstruct the complete object information from any perspective [24.42] (also called *full-view holograms*). For recording and reconstruction, a cylindrical holographic film that surrounds the object is used. The expanded reference wave propagates along the symmetry axis, thus illuminating both the film and the object. *Edge-lit holograms* [24.43] are recorded with an expanded reference wave entering at one edge of the holographic medium, thus illuminating the entire photosensitive area. An advantage of this geometry is the opportunity to reconstruct the image using a point source, e.g., a laser diode, integrated at the hologram edge. Thus a space-consuming expansion of the reconstruction wave is superfluous and edge-lit holograms are well-suited for compact, portable holographic displays.

24.2.4 Holography Techniques

Hologram Multiplexing

The Bragg condition is of utmost importance in holography as it allows the superimposition of a multitude of holograms in the same volume element of the holographic medium. The number (#) of holograms superimposed in the same volume element of the holographic recording material is limited by the decrease of the efficiency of the particular hologram, $\eta \sim 1/\#^2$ [24.44]. Figure 24.9a shows schematically the concept of *hologram multiplexing* using the example of *angular multiplexing* [24.45, 46]. Each recorded grating vector occupies a certain volume in the reciprocal space that is inversely proportional to the corresponding grating dimensions (Sect. 24.2.2). This is equivalent to saying that Bragg diffraction will occur as long as the mismatch is confined within this volume. As an example, three elementary holographic gratings characterized by their grating vectors $\boldsymbol{K}_{1,2,3}$ are recorded (multiplexed) within the same volume element. The recording waves embrace the same angle, i. e., the grating spacing is constant, but vary in their Bragg angle $\theta_{1,2,3}$. The definition of Bragg angle is adopted from [24.40]. The holograms are reconstructed, completely unaffected from each other, if the angular mismatch $\Delta\theta_B$ for reconstruction of the particular hologram exceeds a certain value $|\delta\boldsymbol{k}|$, which is represented by the shaded area.

In an analogous way the Bragg condition allows *wavelength multiplexing* [24.46–48]. Here holograms are recorded with different writing wavelengths (Fig. 24.9b). Other techniques tune the phases of the reference wave separately for each hologram (*phase-coded multiplexing* [24.49]) or shift the spatial position of the interfering beams slightly with respect to the previously recorded hologram (*shift multiplexing* [24.50]), i. e., phase and spatial shift are further Bragg selective measures. As early as 1962 *Denisyuk* [24.7, 51] and *van Heerden* [24.52] discussed the possibility of using the high selectivity of the Bragg condition for volume data storage in order to obtain extremely high data storage densities. The high Bragg selectivity further provides a high diffraction efficiency [24.40, 53], the suppression of the conjugated image [24.54], the reconstruction of holograms with white light [24.38, 55] and the recording of multicolor holograms (*color holography*) [24.56, 57].

A second class of multiplexing methods takes the recording geometry and the properties of the recording material into account and is not based on the Bragg se-

lectivity. Such *fractal methods* [24.58] can therefore be applied to thin holograms as well. As an example holograms can be recorded within different volume elements

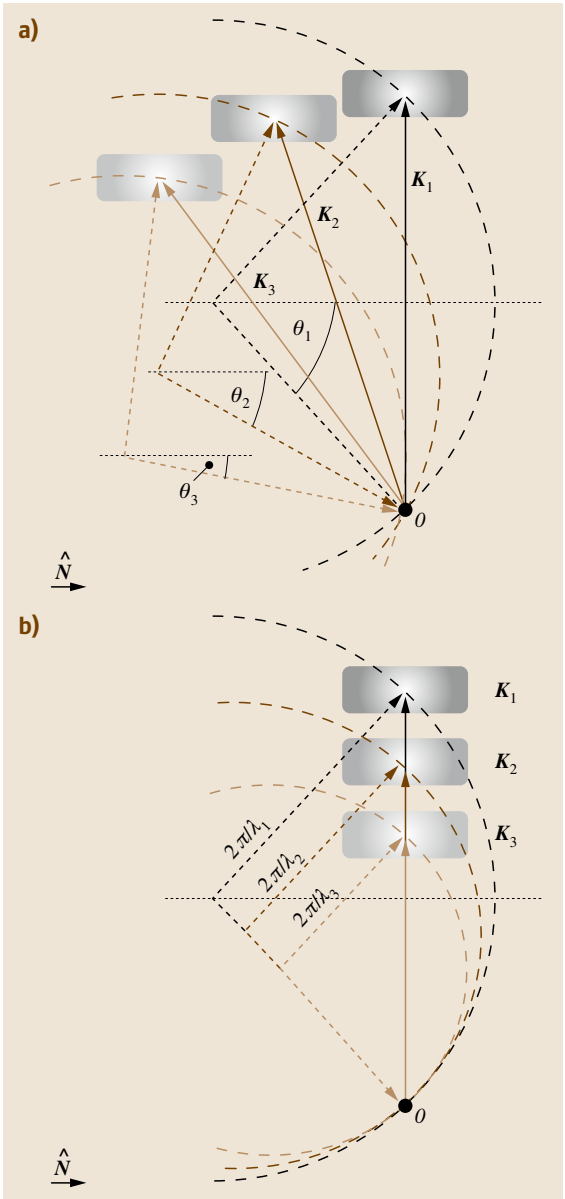

Fig. 24.9a,b The *shaded area*, proportional to $(dl)^{-1}$ (Sect. 24.2.2), represents the region in reciprocal space, that is occupied by a particular recorded grating. Thus, grating vectors with overlapping areas would produce cross-talk. **(a)** Angular multiplexing. **(b)** Wavelength multiplexing

of the holographic medium without affecting each other (*spatial multiplexing* [24.59, 60]). Other methods include *out-of-plane angular multiplexing* [24.61–63], *peristrophic multiplexing* [24.64] and *out-of-plane shift multiplexing* [24.65]. In addition, the combination of different multiplexing techniques greatly enhances the number of superimposed holograms and has successfully been shown to have a high impact on holographic data storage [24.63, 66–72].

Copying Holograms

White-light reflection holograms are usually produced by a direct copy from a transmission hologram, called the transmission *master hologram*. In the copying process the real image is generated from the master and can thus be used as a signal wave to record a copy in reflection geometry. As a result the initial virtual image of the master is reconstructed from the copy. This process offers some unique advantages such as:

1. A multitude of identical white-light reflection holograms can be fabricated without the presence of the original object.
2. The reconstructed object of the master hologram can be placed before, in, and behind the plane of the hologram copy.
3. The copying process does not require the high mechanical stability of the optical setup in a *contact copy*, i. e. the master and hologram copy are next to each other.
4. The contrast ratio between the signal and reference wave can be adjusted and thus optimized.

However, interference due to reflected waves between the master and copy, mechanical deformations of the master or copy and the presence of higher diffraction orders by reconstructing the master may result in unwanted image distortions, such as *Talbot* fringes.

Digital Holography

An interference pattern of wavefronts can be recorded digitally by using computer-addressable photosensitive detectors with sufficient spatial resolution, such as charge-coupled devices (CCDs). This opens up the field of *digital holography*, sometimes also called *television (TV) holography* or *electroholography* [24.73]. The recording geometry for digital holography is limited by the low spatial resolution of the photosensitive digital array. Recording in the off-axis geometry with a standard array resolution of about 100 lines/mm limits the maximum angle between the reference and signal

waves to a few degrees. Thus, only small objects at large distances can be recorded [24.74] encouraging the development of concepts to overcome this limitations, such as *phase-shifting digital holography* [24.75].

Digital holography further allows the reconstruction of digitally recorded fringe patterns by optoelectronic devices, i. e., by sending the information of the fringe pattern to a computer-addressable array such as a spatial light modulator (SLM). The SLM pixels manipulate the phase or amplitude of transmitted (or reflected) waves and hence it is possible to reconstruct the spatial distribution of the phase or amplitude of the signal wave. Such digital holograms offer several advantages, as the fringe pattern sent to the SLM can be manipulated digitally and actively. This allows, e.g., the suppression of the annoying twin and conjugate images by digital filtering or switching between different fringe patterns. The latter is useful for active optics or real-time holographic displays. Digital holograms are finally limited by the spatial resolution and the particular modulation depth of the phase or amplitude of the computer-addressable array. The field of applications for digital holograms is of increasing importance for *computer-generated* or *synthetic fringe patterns* and will be presented in more detail in Sect. 24.3.5.

24.2.5 Holographic Recording Materials

Holographic recording with high contrast of the reconstructed waves requires a photosensitive recording material with an optical resolution down to a light wavelength of $\approx 0.2\,\mu m$ ($= 5000$ lines/mm), i. e., more than a factor of 5–10 better than photographic films. Besides the optical resolution a linear photosensitive response (linear transfer characteristic), low noise from background scattering, the possibilities to reuse the holographic recording material as well as to record phase and/or amplitude holograms are key characteristics of a recording material. The properties of holographic recording materials have been of interest from the beginning of holography and a first review appeared as early as 1977 [24.76, 77]. At present the variety of holographic recording materials basically can be classified into reversible and irreversible media (Table 24.3).

In recent years the variety of holographic recording media has been extended to new classes of materials. The search for alternatives was in particular triggered by the development of applications such as holographic data storage (Sect. 24.5). At present there is pronounced scientific interest in reversible high-efficient materials with fast response or long-term properties. In the course of this research a new class of materials became apparent, characterized by their unique photosensitive behavior, despite the fact that the physical origin for their photosensitivity is completely different [24.78–81]. These are centrosymmetric crystals, so that the linear electrooptic effect is forbidden by symmetry. Photorefraction and photochromism were discovered, e.g., in centrosymmetric molecular crystals [24.82] where the photosensitivity originates from structural alterations within the molecular building blocks. In particular, the rotation of the NO-bond with respect to the central metal atom by 90 and 180° was uncovered [24.83]. It was shown that this physical mechanism appears in a large variety of nitrosyl compounds [24.84] and other molecules that feature photoinduced linkage isomerism [24.85]. Here, the unique properties are:

Table 24.3 Some of the common reversible and irreversible holographic recording materials. Still, photographic emulsions and hardened dichromated gelatin [24.11] are the most convenient and widely used materials for display holograms, whereas photoresists are ideal for the production of nickel masters for embossed holograms (Sect. 24.2.2). Photochromic materials keep their importance for holographic interferometry (Sect. 24.3.3) and high storage densities in holographic data storage is based on thick volume phase holograms recorded in photorefractive crystals (Sect. 5.10)

highly efficient recording of polarization holograms, a photoreversible recording process, and the possibility to tune the spectral range of photosensitivity and the storage time over a wide range simply by material design. The photorefractive response is local, i. e. intensity pattern and index changes are in phase, in contrast to organic photoswitchable molecular materials, where a huge gain was found, only recently [24.86]. Further promising candidates from this new group of holographic recording materials are photorefractive garnets, e.g. $Gd_3Ga_5O_{12}$ [24.87] (Fig. 24.10). Another novel, fascinating type of holographic materials is a composite of liquid crystals and polymers, so-called polymer-dispersed liquid crystals. The initial stage is a homogeneous solution, that is a mixture of mesogenic molecules and photosensitive monomers. Upon holographic exposure, a photopolymerization reaction takes place more rapidly in the bright regions of the optical interference pattern and consequently the monomers diffuse to these regions while the liquid-crystalline molecules congregate in the dark regions [24.88]. The advantages over other holographic media are the large amplitudes of the light-induced change of the refractive index, and the ability to tune this amplitude using external electric fields [24.89, 90]. A similar type of photosensitive materials are nanoparticle polymer composites. In these systems, monomers exhibit diffusion under holographic illumination whereas (inorganic) nanoparticles with a typical size of around 10 nm counterdiffusion. This finally results in a spatial distribution of nanoparticles which accurately reflects the optical interference pattern [24.91,92]. Such holographic gratings show a number of practical advantages over pure photopolymer systems, in particular low optical losses [24.93, 94], an improved thermal and mechanical stability [24.91, 95] and a considerable flexibility with respect to nanoparticle species (Au, SiO_2, ZrO_2, TiO_2) [24.96–98], their size (from 2–50 nm) and volume fraction [24.99]. Specific properties of the nanoparticles such as superparamagnetism might thus be transferred to the composite material [24.100].

24.3 Applications of Holography

From the beginning, Gabor's principle of wavefront reconstruction primarily was applied in the field of wave optics. Gabor himself emphasized the possibility to enhance the optical resolution in electron microscopy by holography, which was finally demonstrated, but not until 1990 [24.101]. It is therefore not surprising that the first dominant applications of holography were in the field of *high-resolution three-dimensional displays*. This initiated the entry of holography into the fields of arts and commerce, accompanied by great interest from the film industry and the military. The first museum for holography opened its doors already in 1976 in New York City.

Holographic interferometry developed as a further key application for holography, as was already recognized in 1965 [24.10]. The technique allows the

visualization of object deformations and movements with a resolution down to the order of the light wavelength – even in real time. Holographic interferometry has had a great impact in *object recognition*, which has only recently attracted interest since it was adapted to work with digital holography [24.102].

Wavefront reconstruction with computer-generated holograms has driven the important field of *diffractive optics* in applied holography. Today it is possible to generate any phase and intensity wavefront distribution using synthetic holograms. In this way, beams can be deflected, focused or shaped with high precision and velocity, which is a basic property for a lot of other common optical applications, such as optical switches and filters in optical telecommunication. A new frontier in this field is the development of aperiodic volume optical elements that outperform the features of photonic crystals and diffractive optics [24.103].

Besides, dynamic wavefront reconstruction with computer-controlled large-area displays is of growing interest taking popular 3-D-videos into account. Using optically addressable photorefractive polymers, an updatable holographic 3-D-displays [24.104, 105] even on large areas [24.106] has been successfully demonstrated.

During recent decades holography has been applied with microwaves, neutrons, electrons [24.107–110], x-rays [24.111–113], and acoustic waves. The latter, e.g., finds its applications in nondestructive material testing, in medicine for diagnostic purposes and nanoparticle imaging in cells (combined with scanning probe techniques) [24.114, 115], in ultrasound microscopy, in seismology or in underwater positioning. In contrast, microwave holography has had its impact in understanding the important microwave techniques such as radar, doppler radar, antennae with synthetic apertures, etc. [24.116].

Electron holography and tomography have become an important tool for materials analysis in the field of nanoscience [24.117]. For instance, nanoscale holographic interferometry has been applied for the study of strain in nanoscale electronic devices [24.118]. A more detailed insight into the complex physics of colossal magnetoresistance has been revealed from the observation of nucleation and growth of magnetic domain walls [24.119].

A tremendeous breakthrough for x-ray holography was the development of the free electron laser that features subnanometre wavelength, femtosecond pulse duration and high brilliance [24.120]. X-ray imaging with high spatial and temporal resolution is applied in a time-delay scheme to monitor ultra-fast dynamics of materials on an interatomic length scale [24.121] including noncrystallized macromolecules [24.122, 123]. A number of classes of lensless x-ray imaging have been developed, so far [24.124]. Furthermore, sequential x-ray imaging for recording of a molecular movie [24.125] and further technical developments to increase the efficiency of x-ray Fourier-transform holography [24.126] have been demonstrated.

At present the overall field of applications is still growing and new discoveries in the field of holography are currently being recognized, such as second-harmonic holography [24.127–130], holographic creation of photonic crystals [24.89, 131–133], three-dimensional harmonic holographic microscopy for cell imaging [24.134], reconstruction of wave dynamics in nonlinear optical media [24.135], self-adaptive intracavity holography in lasers [24.136, 137] or quantum holographic encoding [24.138]. All these applications indicate that holography remains an exciting field in optics. In the following we present some selected impressive applications – beyond the field of science – to give an insight into this broad spectrum of applied holography: holographic data storage, holography in archaeology, holographic interferometry, holography in medicine and biology, applications of computer-generated holograms, holograms as security features, holographic scattering for material analysis, atomic-resolution holography and neutron optics.

24.3.1 Holographic Data Storage

The application of holography for optical data storage was introduced by *van Heerden* in 1963 [24.52]. He discussed the recording of multiple holograms within the same volume element, which was successfully demonstrated by *Leith* using a photographic plate as the storage medium three years later [24.46]. High-density recording using the angular multiplexing technique was not applied to holographic data storage until 1973 [24.139].

Today, after 40 years, a holographic data storage system is still not commercially available. Most of the technological components that are necessary for such a system, such as, e.g., the laser, camera, and two-dimensional liquid-crystal display (LCD), were available in the past, with breakthroughs in specification and cost being achieved in recent years. For instance, a liquid-crystal laser has been realized only recently, that is outstanding in respect to the tuning range, the large coherence emitting area and the out-

put power related to its cavity dimension [24.140]. However, the search for a holographic storage material fulfilling all the application requirements is still in progress, since holographic storage demands unique specifications such as high light sensitivity and nearly no light absorption. Today we find a multitude of development platforms that have been built in the last four decades. They prove the principles and demonstrate the different ways to store a large amount of data at a sufficient high rate [24.141–144]. An insight into holographic data storage is given in [24.145, 146] and Sect. 24.5.

24.3.2 Holography in Archaeology

Holography is ideal for archival recording not only of digital data but also of any valuable or fragile, analogue three-dimensional objects, such as museum artifacts. The technique is of increasing significance in the field of archaeology, as it allows the production of true replicas of the original for distribution throughout the world [24.147, 148]. In particular color holography is applied to achieve optimum results, as shown in Fig. 24.11 [24.149, 150]. Besides presentation or display purposes, objects can seldom be studied in places remote from the museum and this makes it possible to compare and even to assembly pieces excavated from different places in the world.

Fig. 24.11 Hologram of a plate of clay with cuneiform writings exhibited in a museum in Nicosia (Cyprus). As the hologram reconstructs the three-dimensional object information it is possible to decipher the cuneiform writings, which contain important information in their relief structure. (Photo courtesy of G. von Bally, Laboratory of Biophysics, University of Münster, Germany)

24.3.3 Holographic Interferometry

The principle of *holographic interferometry* with its broad variety of applications is already a key topic of several books [24.151–154]. The technique was first discovered in 1965 [24.10, 155–159] and is also referred to as *hologram interferometry* or *holometry*. In the following we introduce three of the basic inventions of *holographic interferometry*: double-exposure, real-time, and time-average interferometry.

Double-Exposure Interferometry

The technique of *double-exposure interferometry* is applied to visualize and/or to determine object deformations or dilatations down to the scale of the light wavelength [24.160–163]. The object is holographically recorded twice, before and after the object deformation or dilatation. Thus the hologram reconstructs two signal waves at the same time and a fringe pattern results by signal wave interference. The fringe pattern is correlated to the phase differences of the object wavefronts between the two exposures. Holographic interferometry is advantageous when compared with nonholographic techniques, since it allows the visualization of changes in the object's wavefront arising at two different times. The *heterodyne technique* was the first automated analysis in holographic interferometry with sufficiently high precision [24.164–166]. Two reference waves of slightly different frequencies are used for hologram recording. In this way, each pixel of the reconstructed image is time-dependent and can be monitored by photodiodes. As a result the resolution in the object's wavefront distortion is less than 1 nm. However, the analysis of the fringe pattern is ambiguous when the scale of object deformation exceeds the light wavelength because of the phase-shift periodicity of modulo 2π in the fringe pattern. This problem is solved in part by the *phase-shift technique*. Here, two reference waves of the same wavelength but at different recording angles are used for recording and reconstruction [24.167–169]. Thus the intensity of the fringe pattern is a function of both the object's wavefront distortion and the phase difference between the two reference waves. Impressing an external phase shift on one of the reference beams during reconstruction, the intensity of any object point oscillates modulo 2π

as a function of the external phase shift. The phase distortion of the object wavefront is then equal to the phase difference between the reference and reconstruction waves, both of which are automatically determined with high precision.

Real-Time Interferometry

The optical principle of *real-time interferometry* [24.171] is equivalent to double-exposure interferometry, but allows the determination of the kinetics of phase distortion of the object's wavefront. The hologram is recorded only once in a holographic recording material and is reconstructed within the same optical setup. Thus, the reconstructed signal wave interferes with the object wave itself and any distortion of the object's wavefront is immediately visualized by a corresponding fringe pattern in the reconstructed image. In this way, deformations or dilatations of the object can be investigated with respect to the holographically recorded object wave in real time, i. e., the reconstructed signal wave of the hologram acts as the initial measure.

Time-Average Interferometry

Linear or harmonic oscillations are visualized with *time-average interferometry* [24.172,173], as shown for a violin at various frequencies in Fig. 24.12. The key idea is that the contrast of the hologram is reduced by moving objects, i. e., the recorded amplitude of the phase or amplitude modulation decreases due to movement of the interference pattern during the recording process. This feature is a disadvantage in holography as it requires extremely high mechanical stability of the optical setup (less than $\lambda/10$) during holographic recording. However, in the case of linear or harmonic oscillations, the intensity of the reconstructed image is shown to follow a Bessel function, so that it is a function of the phase amplitude of the periodic object deformation. Thus it is possible to visualize amplitudes of oscillating membranes with high precision. In order to overcome the problem of the mechanical stability of the optical setup due to mechanical coupling with the oscillating objects, *real-time time-average interferometry* is commonly applied, including a phase-shift technique for the reference beam [24.174,175]. A hologram of the unexcited object is recorded and the method of real-time interferometry is used to visualize the oscillation amplitudes. Stroboscopic reconstruction [24.176–178] with the same frequency as the object oscillation can also be applied to visualize object deformations restricted to single frequencies.

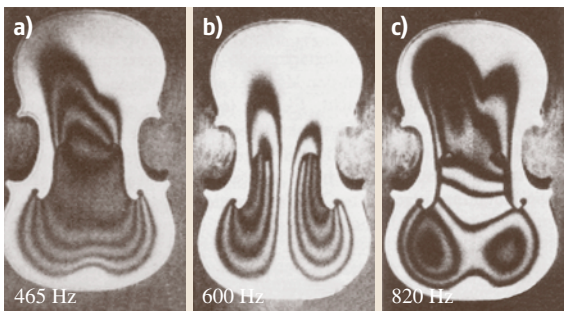

Fig. 24.12a–c Reconstructed double-exposed hologram of resonant eigenmodes of a violin at **(a)** 465 Hz, **(b)** 600 Hz, and **(c)** 820 Hz. The *brightest areas* indicate oscillation nodes (after [24.170])

24.3.4 Holography in Medicine and Biology

The fields of medicine and biology have impressively demonstrated how different holographic inventions, such as holographic interferometry and digital holography, can be applied together to give powerful results. Life sciences already make extensive use of holography being one of the fastest developing areas for this optical technology [24.179].

Endoscopic holography was the first important medical application of holography. This method combines the advantages of endoscopic intra-cavity observation with holography, and thus offers the physician new in situ diagnostic capabilities. Recording of a hologram with the use of a single fiber for both the signal and the reference beam was demonstrated as early as 1976 [24.180]. Further improvements used fiber bundles [24.181] and gradient-index optical imaging systems [24.182] or even combined with an articulated arm [24.183]. The problem of the cumbersome equipment of conventional holography was overcome by migrating from analog to digital recording [24.184] using numerical reconstruction, enabling morphology studies of cavities and tissues even at the cellular level.

Holography is applied as a nondestructive optical technique to image the properties of biological objects and tissues and to detect abnormalities such as tumors. In medicine, holographic interferometry in its different variants is the method of choice to perform in situ and even in vivo detection of tissue. Phase-shifting holographic interferometry was demonstrated to work for breast-cancer detection [24.185] by using mild pressure stressing of the breast and pulsed laser light. Pulsed digital holography has also been employed as a noninvasive

technique to measure the elasticity of biological tissues, e.g., a human hand, pig tissue or human tumors in gel, by exciting them by short-shock mechanical pulses prior to recording phase-difference maps [24.186, 187].

Imaging an object located below the flesh of a human being, i. e., recording a hologram through a living person, has been performed by using a low-intensity continuous-wave laser [24.188] and the principle of first-arriving light [24.189]. Digital holography has been applied as a gating method, which allows a rapid succession of holograms to be made, thus increasing the signal-to-noise ratio.

True three-dimensional representation (*holographic display*) is another facet of the use of holography in cardiology, where the third dimension might be an electric potential, time or any other variable of interest [24.190]. Standard medical imaging techniques such as magnetic resonance imaging or computerized tomography provide two-dimensional transect images of the organ or object to be examined. Employing digital holography a three-dimensional hologram can be obtained, which considerably facilitates the interpretation of the data [24.191, 192]. Utilizing a photorefractive film in conjunction with digital Fourier holography, it has been demonstrated that abnormalities detected in mammography, which usually vary in size, can be picked out according to their size and then visualized with high resolution down to about 10 μm [24.193].

Digital holographic microscopy is a useful noninvasive method for the visualization of transparent objects, e.g., living cells or tumors with high accuracy. In contrast to phase-contrast microscopy it provides a full-field, high-resolution amplitude measurement and even detects the quantitative distribution of the optical path length created by the specimen. Therefore information on the morphology and the refractive-index pattern can be gained, which allows subwavelength axial accuracy [24.194, 195]. Scan-free motionless 3-D fluorescence holographic microscopy was demonstrated as a fast imaging method from fluorescent specimen, e.g., immunofluorescent nerve fibres [24.196]. Using a SLM holographic light activation of caged neurotransmitters in brain tissues can be obtained, thus allowing truly simultaneous activation of multiple synapses [24.197].

24.3.5 Diffractive Optics with Computer-Generated Holograms

Since the early days of holography the generation of holograms by means of simply computing the interference pattern has attracted attention [24.198–201] and is still one of the fastest developing topics in holography. The main advantage is that the object only has to be known in mathematical terms and does not need to exist physically. Starting with one-bit holograms drawn by plotters, which were photographically reduced and recorded on a film, computer-generated holograms (CGHs) have developed greatly with increasing computing power and the availability of high-resolution eight-bit spatial light modulators (SLM) with refresh rates of up to 1 kHz [24.202, 203].

Various applications making use of CGHs have been realized, in particular as device for beam steering and manipulation, i. e., as computer-generated holographic optical elements. CGHs are employed as so-called *laser tweezers*, i. e., tools for micromanipulation of particles in both physics [24.204, 205] and life sciences [24.206], using the principle of optical trapping [24.207]. Another fascinating application is the realization of nondiffracting beams by means of CGH [24.208]. Contrary to standard Gaussian beams, a fundamental Bessel beam does not undergo diffraction, i. e., the transverse optical intensity distribution does not change during propagation [24.209]. Optical phase singularities can be created with CGHs, calculated by the interference between a plane wave and superposition of the TEM_{10} and TEM_{01} Gauss–Hermite optical-resonator modes (hybrid doughnut mode) [24.210]. Moreover, CGHs are utilized for quality control of optical systems, e.g., for the characterization of aberrations. In particular, the assembly and adjustment of multicomponent optical systems can be monitored [24.211].

24.3.6 Holography for Security Issues

A valuable, practical and widespread application of holography is its use for authentication or security devices. Holograms on credit cards, banknotes and identity documents are state of the art today, see e.g. [24.212, 213]. However, the impact of holography as a security feature becomes much more impressive, e.g., in optical data transmission. Data must not only be transferred in a fast but also a secure way, which is realized using *holographic encryption*. Benefits of this technique over others are that optical processing provides the maximum number of degrees of freedom and that optical encryption is ideal for information stored in holographic media. One promising approach is to process data using a double-random phase encryption technique [24.214] and record them as a digital hologram [24.215]. Sophisticated geome-

tries and elaborate techniques such as phase-shifting interferometry [24.216] allow fast and secure encryption/decryption using electronic, optoelectronic or even all-optical approaches. The latter is inexpensive in time, whereas pure electronic decryption requires a huge computer load. Further possibilities are orthogonal phase-coded multiplexing with a random phase mask in the reference-beam path [24.217], fabrication of CGHs using incoherent multiplexing (synthetic double-exposure) by electron-beam lithography [24.218], or encrypted optical storage in a photorefractive crystal using angular multiplexing [24.219]. Besides its other advantages over standard methods holography provides the unique possibility of watermarking three-dimensional objects [24.220], again employing phase-shifting interferometry and digital holography.

24.3.7 Holographic Scattering for Material Analysis

Light scattering in holographic recording materials is a disadvantage for wavefront reconstruction as it generates a serious scattering background in the reconstructed image and thus strongly affects the signal-to-noise ratio. Scattering in holographic recording materials with nonlinear response to intensity shows up as a bright intensity distribution with a characteristic shape. The scattering appears over a wide apex angle and is a function of the exposure. At present such scattering phenomena have gained considerable interest in the scientific field of optical nonlinearities [24.224]: besides investigations of their physical origin [24.225–229], *holographic scattering* phenomena are useful for material analysis [24.222, 230]. It has been demonstrated that holographic scattering can be applied as a nondestructive contact-free optical method, e.g., to investigate phase transitions [24.231, 232], ferroelectric properties [24.233, 234] and complex light-induced transport mechanisms [24.235]. Figure 24.13 shows the example of a far-field steady-state scattering pattern observed in three different holographic recording materials. The diameter of the ring in Fig. 24.13a allows the determination of the birefringence [24.236]. Photoinduced light scattering in $Sr_{0.61}Ba_{0.39}Nb_2O_6$:Ce (SBN:Ce, Fig. 24.13b) and $LiTaO_3$ (Fig. 24.13c) can be used to determine the direction of the polar *c*-axis. In SBN:Ce, the scattering lobe is oriented in a direction antiparallel to the polar axis.

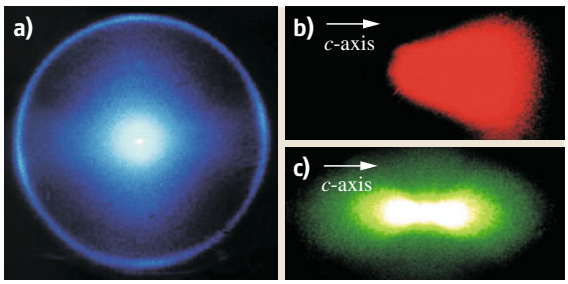

Fig. 24.13a–c Far-field nonlinear holographic light scattering as observed in various recording materials in the steady state. **(a)** Holographic scattering ring in $Na_2[Fe(CN)_5NO]\cdot 2H_2O$: the scattered light is orthogonally polarized to the incident pump beam polarization. The diameter of the ring depends on the birefringence [24.221], **(b)** photoinduced light scattering in $Sr_{0.61}Ba_{0.39}Nb_2O_6$:Ce: the scattering lobe is directed antiparallel to the orientation of the polar *c*-axis [24.222], **(c)** beam fanning in $LiTaO_3$:Fe: the two scattering lobes are directed parallel to the polar *c*-axis [24.223]. One lobe shows higher intensity which indicates the orientation of the spontaneous polarization

24.3.8 Atomic-Resolution Holography

The key technique for the determination of atomic and molecular structures, in particular for investigations of crystallographic structures, has been diffraction for a long time. However, this method is not a true physical solution, as it only yields information about the intensities and not about the amplitudes of the diffracted waves. Holography, on the other hand, is known to overcome this obstacle by recording the interference pattern of the reference and object waves. However, its spatial resolution is limited by the wavelength of radiation and also by the resolution of the recording medium. The first limitation is lifted simply by using electrons, high-energy electromagnetic waves (x-rays, γ-rays) or neutrons with wavelengths in the range of Å for holographic recording. To overcome the second limitation *Szöke* proposed a scheme to study the atomic order of solids by employing atomic-resolution holography [24.237], an idea that was first experimentally demonstrated by using electrons [24.238]. In this experiment a 3-D reconstruction of the relative positions of atoms was performed by evaluating the angular distributions of the scattering intensities. The intensity patterns are formed by interference between electrons that are emitted from a source atom and reach the detector either directly (reference wave) or after scattering from neighboring atoms (object wave). This is called the inside-source

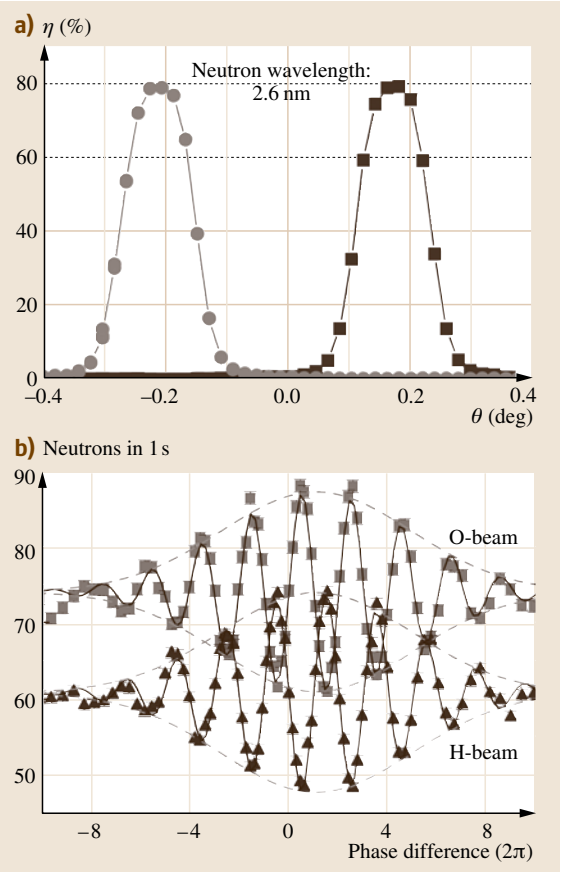

Fig. 24.14 **(a)** Diffraction efficiency for neutrons with 2.6 nm wavelength. **(b)** Interference fringes obtained by introducing a phase difference between two partially coherent neutron beams. *Squares* and *triangles* show the measured intensity of the output beams as a function of the phase shift. Wavelength 2 nm

concept, where a point-like source is produced inside the investigated material. The inverse scheme exchanges the role of the source and detector (inside detector), i. e., the interference pattern of the incident and scattered waves is investigated using a point-like detector in the material [24.239, 240] [24.241, Fig. 1].

Several experimental approaches for atomic-resolution holography have been demonstrated, employing electrons, positrons [24.242, 243], x-rays, γ-rays, and neutrons, each of them characterized by its specific interaction with matter. Therefore, electrons and positrons are mostly used for investigating the structure of surfaces because of their low penetration depth. X-rays are sensitive to the electronic properties, whereas with neutrons the nuclear structure is probed.

Various mechanisms of electron emission from a localized atomic source have been utilized, e.g., Kikuchi scattering [24.238], the photoelectric effect [24.244–246], low-energy electron diffraction [24.242, 247, 248] or Auger-electron diffraction [24.249]. Atomic-resolution x-ray holography was first performed by using fluorescent x-radiation [24.250], later by employing a multienergy inverse mode [24.241] or a combination of these [24.251, 252]; γ-ray holography was experimentally demonstrated using the example of an ^{57}Fe film in the inverse scheme [24.253]. Only recently an advanced γ-ray holography technique has been developed that allows the distinction between atoms of the same kind that occupy inequivalent crystallographic sites, a task where x-rays and neutrons failed. Here, coherent effects in the Mößbauer nuclear absorption are utilized, which provide local spectroscopic information [24.254]. The latest development is atomic-resolution neutron holography, suggested by *Cser* et al. [24.240] and subsequently realized in both experimental schemes, the *inside source* [24.255, 256] and *inside detector* arrangement enabling an accuracy of interatomic distances, i. e., less than a picometer [24.257, 258].

Still there is a steady improvement of the evaluation techniques, e.g., complex γ- or x-ray holography to remove the disturbing twin image without making measurements too time consuming [24.259, 260].

24.3.9 Neutron Diffractive Optics

In 1990 it was demonstrated that a holographically recorded refractive-index pattern could be reconstructed not only with light but also with cold neutrons [24.261]. Obviously, the illumination induced refractive-index changes for both light and neutrons. In analogy to light optics this phenomenon was called the *photo-neutron-refractive effect* [24.262]. The efficient diffraction of cold neutrons from light-induced gratings was a huge step in the development of neutron diffractive optics by means of optical holography, as such methods were not previously possible. For thermal neutrons (with wavelengths in the subnanometer range) single crystals are usually used as diffractive optics, for very cold neutrons (with wavelengths of about 3 nm and more) mechanically ruled gratings are used. The method of preparing gratings by means of light optical holography closed the gap between these two approaches. Nowadays, mirrors and beam splitters can be pro-

duced [24.263, 264], which were even arranged to form an interferometer for cold neutrons [24.265, 266]. In Fig. 24.14a the angular dependence of the diffraction efficiency for a holographically prepared volume grating that acts almost like a mirror is shown. Figure 24.14b depicts the results of an interferometric measurement utilizing three holographically prepared thick diffraction gratings as beam splitters and a mirror. The interferometer may be regarded as one of the most useful neutron optical devices as it provides information about the wave function, i. e., *amplitude and phase*, in contrast to standard scattering or diffraction techniques where only the intensity is measured. The principal future application of such an instrument could be the investigation of mesoscopic structures and their kinetics in the fields of condensed-matter physics and engineering, chemistry, and biology. A recent review on neutron optics with gratings employing the photo-neutron-refractive effect and light optical holography is given in [24.267].

24.4 Summary and Outlook

There is no doubt that holography is an important field in optics and one of the key inventions of the 20th century. It is stressed that the idea of Dennis Gabor could not have its full impact until the development of light sources with sufficient coherence – nearly 20 years after discovery. Obviously, Gabor was quite ahead of his time when inventing holography.

Holography offers a multitude of applications in various fields of our life. Now, new developments are making use of the wavefront reconstruction principle. As it will probably have an increasing influence on our life, the history of holography will continue to be an exciting journey.

24.5 Optical Data Storage

After the correction of vision with glasses, contact lenses or reshaping of the cornea, and after the recording of still and moving images on film or electronic cameras, the most pervasive application of optics in our daily life is optical data storage: the storage and retrieval of data using optics close to the diffraction limit and a miniature solid-state laser, all realized at very affordable prices.

The distribution of audio information on a removable disc – sound stored as modulations in a flat surface – had a long and successful track record. At first, analog signals were imprinted on shellac and then later vinyl platters. Then, for a number of years, sound was almost exclusively distributed as and replayed from digitally encoded data, molded into the surface of compact polymer discs. This migration was driven by consumer demand for higher fidelity, i. e., higher bandwidth in recording, replication and playback, which in turn required dramatic increases in the amount of stored information. At first the diameter of the disc was increased, but this soon reached its practical limit. With a mechanical stylus, higher areal storage density increased the susceptibility to wear and tear, which forced a transition from mechanical detection to a noncontact optical scheme.

In the form of the read-only compact disc (CD), optical data storage became the dominant distribution vehicle for music (CD) and later for computer software with the CD read-only memory (CD-ROM) [24.268, 269]. With the ferocious appetite of consumers for ever more information at ever higher data rates, the CD and the CD-ROM underwent a metamorphosis into the digital versatile disc (DVD) [24.270]. The DVD standard offered higher areal density per layer, with as many as four layers of prerecorded information, and could provide sufficient read-out bandwidth and capacity for the distribution of several hours worth of high-quality compressed video. But with the advent of high-definition television (HDTV), even higher data rates and capacities were needed, requiring yet another increase in areal density. After a prolonged battle between two different formats, the Blu-ray Disc (BD) outlasted the HD DVD standard, and as of 2011, major movie studios tend to release content on both DVD and Blu-ray Disc.

In addition to this distribution of prerecorded content on removable and interchangeable media, the desire of consumers to record information by and for them-

Table 24.4 Comparison between CD, DVD, and the BD format (after [24.271–277])

	CD	DVD	Blu-ray Disc (BD)
Capacity (single layer)	0.65 GB	4.7 GB	25 GB (single layer)
Laser wavelength	780 nm	650 nm	405 nm
Numerical aperture	0.45	0.6	0.85
Track density	16 000 /in	34 000 /in	79 000 /in
Minimum length pit ($\approx 2-3$ bit)	0.833–0.972 µm	0.4–0.44 µm	0.138–0.16 µm
Areal density (user)	0.39 Gbit/in^2	2.77 Gbit/in^2	14.7 Gbit/in^2
Reference velocity	1.2 m/s	3.49–3.84 m/s	4.55–5.28 m/s
Base data rate (1×)	1.47 Mbit/s	11.08 Mbit/s	36 Mbit/s
Maximum (practical) rotation factor	52×	20×	12×

selves has been an important economic and technical driver. The wax-coated drum of Edison, with analog information engraved with a vibrating needle, has given way to the CD, DVD, and BD *burner*, with carefully modulated and interleaved digital data imprinted with a flashing laser beam. Recordable optical discs rely on using high laser power to write marks that low laser power can still read. The high laser power must modify the local optical properties of the recording medium to provide a significant change of signal; conversely, the low read-out power must *not* affect the properties of the media so as to protect any recorded data. Processes such as ablation of a dye layer are irreversible and thus are well suited for *write-once, read-many times* (WORM) applications. The first implementation of this technique was the CD-R: WORM media with a form factor and functionality nearly identical to a CD or CD-ROM once it has been recorded. Other recording processes – foremost the change between amorphous and crystalline structure in a thin metal, semiconductor or alloy film – can be reversible and allow erasable or rewritable (R/W) media. For these types of media, the thermal characteristics are as important as the optical parameters. One has to ensure that, after short transient heating with the tightly focussed laser, each very small spot will cool fast enough to quench the film rapidly into an amorphous phase. On the other hand, the same R/W medium must cool slowly after a large area is uniformly illuminated, allowing recrystallization of the film and erasure of previously recorded data. Simultaneous optimization of the optical, thermal and device engineering for WORM and R/W recording can be extremely complex [24.269].

In addition to the pervasive 120 mm-diameter CD/DVD disc, many other disk diameters have been used. One early niche application was the laser disc, used for the distribution of high-quality prerecorded movies before DVD-level areal densities and data compression were available. For high-end data storage applications, diameters of 5.25″, 12″ and up to 14″ have even been used. Smaller discs for small-form-factor, portable consumer electronics devices are still popular, although MP3 players, digital still and digital video cameras that used optical disc media with diameters as small as 1″ have mostly switched over to other storage formats.

Table 24.4 compares the pertinent characteristics of the CD, DVD and the Blu-ray Disc formats, highlighting the significant technical progress that has been made over the past 30 years of optical storage. For each standard, there are numerous variants offering either smaller diameter (typically 8 cm rather than 12 cm), higher readout speeds (up to 12× is possible for Blu-ray Disc [24.278]), more layers, and a set of read-only memory (ROM), recordable, and rewriteable formats. For BD, these are termed BD-ROM, BD-R, and BD-RE, respectively [24.276]. A two-layer, 50 GB Blu-ray Disc can store over 9 h of high-definition (1920×1080) video or 23 h of standard-definition (720×480) video [24.276, 278]. While the BD standard can support an arbitrary number of layers, practical issues become significant when moving beyond 8 layers for prerecorded content [24.278] and 4 layers for writeable discs [24.279]. The issues for recordable discs are formidable, related to balances between signal-to-noise-ratio (SNR) and absorption [24.279]; the issues for prerecorded content could potentially be overcome if fabrication tolerances, aberration correction, and sufficient laser power were available [24.278, 280, 281].

Around the turn of the millenium, optical readout of cheaply replicated, injection-molded CDs, CD-ROMs, and DVD discs clearly dominated multimedia content and software distribution. On the other hand, even at that time, general-purpose read–write information storage was still the exclusive domain of magnetic recording. Magnetic recording in the form of hard disc drives (HDDs) has consistently delivered higher

areal densities, higher data rates and faster access times than optical storage, while supporting millions of write/erase cycles and many years of retention time at very competitive cost. To obtain these high performance characteristics, the removability offered by the once ubiquitous floppy disc was readily sacrificed. Thus the key advantages of optical recording have always been the removability and interchangeability of the media, as well as the parallel replication of prerecorded discs in seconds via injection molding.

Over the ensuing decade, the pervasive use of computers and storage in consumer electronics devices has required more storage in smaller form factors. Internet connection speeds have increased and compression formats have improved. Optical storage has been greatly affected by the rise of network-based, online content distribution, and by the availability of large amounts of flash-based solid-state memory. The vast majority of audio content is now downloaded, either directly to cellphones, smartphones, or tablets (which typically use NAND flash), or to hard disc drives of PCs. Later, such HDD-based content may be played locally or transferred to the solid-state memory of a portable device (such as a cellphone or MP3 player). While CD-R and DVD-R may play a role in transferring or archiving, it is definitely a secondary role. Prerecorded audio CDs and the *record stores* that used to sell them are now mostly a thing of the past. It is expected that the purchase of prerecorded DVDs will follow, since online streaming of standard-definition video has become widespread [24.282], and can be expected to eventually replace the purchase or rental of DVDs by mail [24.283].

Thus the current success of BD can be entirely traced to the discrepancy between the SD-level video quality that can presently be delivered over the average consumer's Internet connection [24.282], and the (HDTV or higher [24.284]) peak video quality offered by that person's high-resolution television and computer displays. The pivotal question that will dictate the future of optical data storage is how these interlocking trends will evolve. On the one hand, it can be expected that broadband network speeds will continue to increase, although probably at a modest pace given the slow nature of infrastructure changes. On the other hand, the expected rise of 3-D TV will require even higher capacity (and thus higher density) physical distribution formats. The critical issue is how much higher capacity would be required, and the pace at which the installed base of 3-D capable displays grows. These considerations would drive the demand for suitable content and for distribution methods, online or physical, for that content.

It is entirely possible that evolutionary extensions of the Blu-ray format (more layers, slight reworking of the standard, higher-power lasers) will satisfy most near-term requirements for higher-capacity optical storage. However, it is likely that another standardized physical-distribution storage format will eventually be needed, which will drive optical data storage to try to deliver even higher storage densities [24.271–273] to compete for this opportunity.

The remainder of this chapter highlights different approaches towards achieving the goal of increased optical storage density. This can be achieved either by increasing the density at the surface of an optical recording material, or by utilizing the unique capability of optics to access the volume of suitable media. Given that the BD standard can be expected to eventually deliver 100 GB on a 12 cm platter, only techniques that could potentially exceed this significantly can be considered as promising. In addition, the features that drove the success of the CD, DVD and BD standards – removability, interchangeability, inexpensive replication of prerecorded content, inexpensive readers (when manufactured in volume), and a family of formats that offers read-only, write-once, and re-writeability – these features will be critical to the success of any future optical storage format.

24.6 Approaches to Increased Areal Density

For many years, the demands for better data storage have been met by evolutionary advances: increases in the areal density and other performance specifications of magnetic and optical recording devices. The areal density of magnetic hard discs has been growing continuously through more than seven orders of magnitude over the last 60 years, accelerating at one point to a compounded annual growth rate of more than 100%. Optical storage, with a much shorter track record, increased in storage density by a factor of 5 from the original CD standard to the DVD format, and another factor of 5 to the Blu-ray format (Table 24.4).

The reason for this dramatic difference in the increase of aerial densities for magnetic and optical

recording is that optical data storage has specialized on applications that require removability of the optical recording media. Since high-performance magnetic recording does not support removability, hard drives need not work with the media of previous generations. Thus the only standards to satisfy are those on data input/output and form factor, which has encouraged strong technical competition and resulted in tremendous progress. Optical storage, however, is dominated by removable, interchangeable media with backward compatibility. This compatibility facilitates the introduction of each new generation of technology in the market, due to the large existing base of recorded material, but forces a time-consuming standards process for each higher-density generation.

Still, optical storage has substantial potential as a storage technology. While the limits of magnetic recording are perpetually debated and then later exceeded [24.285], the limits of conventional optical recording are well understood [24.271–273]. Optical storage technology is already working close to the optical diffraction limit. However, some future increases in density could be delivered by further taking advantage of the wavelength and/or numerical-aperture dependence of the diffraction limit, or by going beyond it with near-field techniques. In addition, if the SNR is sufficient then gray-scale techniques allow the storage of more than one bit per location [24.286].

The diameter of the diffraction-limited spot is directly proportional to the laser wavelength λ and inversely proportional to the numerical aperture (NA) of the imaging lens (Fig. 24.15). The area A of the spot is then proportional to the square of these parameters [24.287]

$$A \sim \left(\frac{\lambda}{\mathrm{NA}}\right)^2 , \tag{24.5}$$

and the resulting maximum areal density $\mathcal{D}$ is simply the inverse of this area times b, the number of bits per spot,

$$\mathcal{D} \sim b\left(\frac{\mathrm{NA}}{\lambda}\right)^2 . \tag{24.6}$$

As described in Table 24.4, the differences in capacity and data rate between the CD, DVD, and Blu-ray formats are a clear consequence of reducing the diffraction-limited spot size of the focus at the medium. Other factors were also involved in the density improvement found in the newer standards – such as stronger modulation coding, signal processing, error correction, and more aggressive tolerancing – but it is unclear how much more improvement may be extracted from these areas in future optical disc standards.

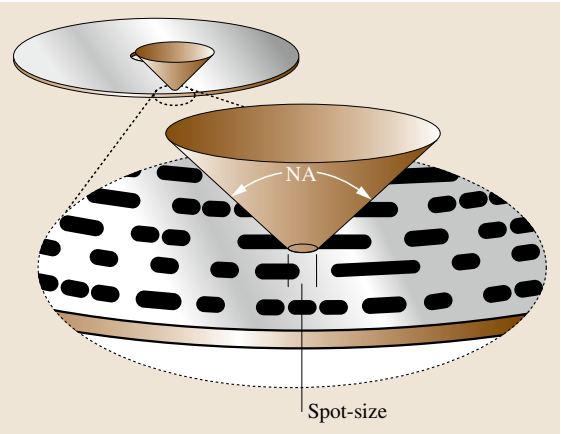

Fig. 24.15 Conventional optical storage uses a tightly focussed laser beam to access individual bits in a single layer

24.6.1 Short-Wavelength Lasers

Early optical storage products used infrared wavelengths between 830 and 780 nm, simply because these were the only diode lasers available with the reliability, optical power, quantities and cost that the industry required for a consumer product. As the development from CD to DVD to Blu-ray highlights, the obvious path to further increases in storage density has been the development of suitable lasers with shorter wavelengths. A critical component to the success of the BD standard was the success of the GaN 405 nm blue (technically *violet*) laser. In particular, one of the motivations of the competing HD-DVD standard was to achieve higher density without having to rely on the success of this light source, which at the time was not guaranteed. A combination of material improvements introduced by Japanese and Polish researchers led to the production of high-quality GaN crystals, which were capable of delivering both high power and long device lifetimes at low cost [24.288]. Since then a number of fabrication methods have been introduced [24.289], and both higher power (100 mW) [24.281] and lower wavelengths [24.290] are being pursued. In particular, higher power is important for increasing the number of layers for BD-ROM [24.276, 281].

24.6.2 Increased Numerical Aperture

Instead of reducing the laser wavelength, a corresponding increase in numerical aperture can achieve the same

increase in areal density. The increases in density when making the transitions from CD to DVD and then to BD were partially due to an increase in NA. There are, however, practical limits to the increase in NA, such as manufacturing tolerances for diffraction-limited optics. The key issue here is depth of focus δ, which is directly proportional to the wavelength, but inversely proportional to the square of the numerical aperture [24.287]

$$\delta \sim \frac{\lambda}{\mathrm{NA}^2} \,. \tag{24.7}$$

To maximize density, the data layer of the media should be as close as possible to the focus of a diffraction-limited read-out beam. Inevitably, manufacturing tolerances on the drive and media make a fast focusing servo essential. For ultimate performance, even dual-stage servos with multiple lenses have been considered. Obviously, these issues become more difficult as the optical depth of focus decreases. Smaller depth of focus requires that the thickness of the cover layer over the recorded data (which takes up some of the working distance of the optics and forces correction for spherical aberration) decreases. The Blu-ray format includes a cover layer that is only 100 μm thick [24.275, 276]. As such, Blu-ray discs are much more susceptible to scratches than DVDs, since the same size scratch on the surface subtends much more of the optical beam. One of the critical components in the success of the BD format was the development of hard coatings that protect the disc from scratches and relieve the requirement for a costly protective cartridge.

Although the maximum NA in air is 1.0, microscopists have long improved their resolution beyond this by using oil-immersion objective lenses. Rather than coating optical discs with oil, however, numerical apertures greater than 1.0 can similarly be attained by bringing a solid-immersion lens into close proximity of the disc media [24.291], as shown in Fig. 24.16. If the gap between the bottom of the lens and the media is smaller than the light wavelength, then evanescent coupling of light across this gap illuminates a subwavelength-diameter spot on the media. Similar to the read–write head in magnetic recording, it is possible to fly a solid immersion lens on an air bearing over the media [24.291]. This approach to high storage density, although it has been pursued aggressively for several years, has yet to deliver a successful commercial storage product. In addition, because of the susceptibility of this tiny air gap to external contaminants on the disc, such near-field approaches would seemingly have to sacrifice media removability: one of the very advantages that optical storage has historically had to offer.

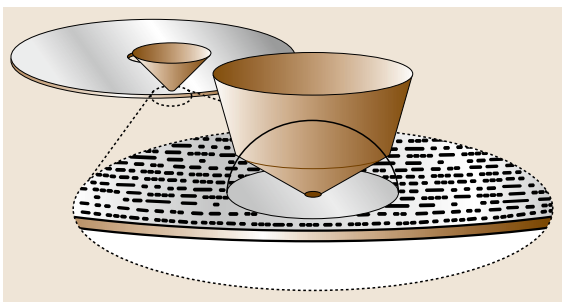

Fig. 24.16 A solid-immersion lens (SIL) can increase the effective NA beyond 1.0, further increasing density but requiring evanescent coupling between the SIL and disc

24.6.3 Magnetic and Optical Superresolution

In magnetooptic recording, another interesting effect can be utilized to increase the resolution. In this technology, bits are stored by heating a magnetic film locally with a laser in the presence of an externally applied magnetic field (Fig. 24.17). In the portions of the film that exceed the Curie temperature, the local magnetization will orient with the applied field. This magnetization change is then sensed optically by detecting the slight rotation of the polarization due to the Faraday effect [24.287]. Here, thermal diffusion processes rather than optics can dominate the resolution. A short exposure with a laser beam of nonuniform spatial profile, such as a simple Gaussian beam, can produce a temperature distribution that exceeds the Curie temperature only for a brief time, and only in the very

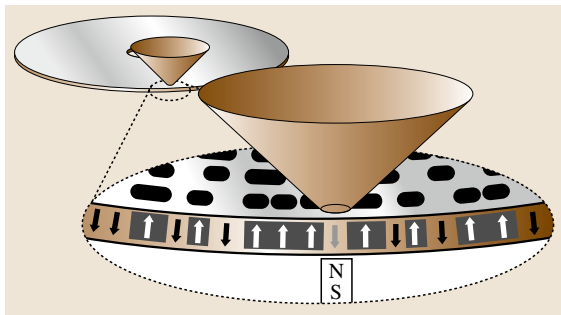

Fig. 24.17 Magnetooptical storage uses a tightly focussed laser beam to record bits, using local heating of a magnetic film above its Curie temperature in the presence of an external magnetic field

center of the beam. Subsequent heat diffusion away from the spot quickly brings the temperature below the Curie point, resulting in magnetic reversal in an area of suboptical-wavelength dimensions, including marks as small as 100 nm [24.292].

However, such marks must still be optically detected. With dozens of such marks within the diameter of each focussed spot, deconvolving each mark individually from the aggregate optical signal would be quite challenging. An elegant technique called magnetic superresolution (MSR) can overcome this read-out problem using the highly nonlinear behavior of thermal diffusion [24.292]. The MSR technique adds a magnetooptic read-out layer above the magnetic storage layer. For read out of a particular subwavelength spot, this top layer is briefly heated with a laser just as in the recording process described above: the power density in the center of the beam barely exceeds the Curie temperature. As above, the magnetization of the hot spot orients with the applied field, which in this case is the field due to the recorded bit in the lower layer. The surrounding area of the upper layer does not reach the Curie point and is not affected. After the magnetization at that location has been *revealed*, the read-out layer contains only the subresolution spot with reversed magnetization surrounded by a magnetically homogeneous background (Fig. 24.18). This subresolution spot can then be optically detected with sufficient SNR, despite the much larger diameter of the focussed laser beam. Magnetic superresolution is, therefore, a near-field technique, where the aperture is created in close proximity to the recording layer by illuminating a cover layer with a suitable laser.

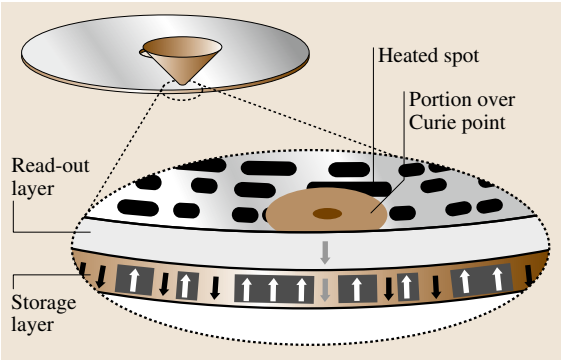

Fig. 24.18 Magnetic superresolution uses two layers, with the heat from the laser spot transferring just the bits of interest from the bottom storage layer into the top read-out layer

Similar nonmagnetic superresolution techniques, termed super-RENS, have been developed by using thin metal layers above a recordable layer, such as a phase-change material [24.293–295]. These work by having a large change in transmissivity that is gated by the exposure or induced heating from the focussed beam. The effective nonlinearity, sometimes assisted by plasmonic nanostructures [24.294], leads to an effectively superfocussed exposure in the underlying recording layer. It is not clear how easily such techniques may be implemented over multiple tightly-spaced layers, though.

24.7 Volumetric Optical Recording

In both magnetic and conventional optical data storage technologies, individual bits are stored as distinct magnetic or optical changes on or near the surface of a recording medium. For several years, these techniques have been forced to finesse, and push back by clever engineering, the physical limits beyond which individual bits become too small or too difficult to store and retrieve. Storing information throughout the volume of a medium – not just on its surface – offers an intriguing high-capacity alternative.

Three-dimensional optical storage literally opens up another dimension to increase the capacity of storage media. In principle, a volume element with the dimensions of the wavelength should suffice to store one bit. The volumetric density that can be achieved in the diffraction limit would then scale with $1/\lambda^3$. Trade-offs between density and data rate make it possible, at least in principle, to forgo some of this density to obtain blistering data rates. Some of the techniques that have been proposed do not require mechanical motion, enabling access times in the range of tens of microseconds, albeit to a small storage volume with moderate capacity.

24.7.1 Volumetric Addressing Techniques

Several approaches for volumetric optical data storage have been explored. These can be distinguished by the method used to address the stored data. Some of the techniques simply extend the multilayer nature of conventional optical storage that began with the two-layer

DVD standard, while others take advantage of the 3-D character of optics. The techniques described here are:

- Adjusting focus to access data on a particular layer
- Addressing a particular point, line, or plane in a medium by intersecting two laser beams
- Using material with extremely narrow spectral sensitivities to address data
- Addressing data by the spacing and direction of interference fringes, known as ***k***-vector or holographic addressing.

24.7.2 Addressing by Depth of Focus

Depth of focus, a phenomenon familiar to anyone that has used a microscope, is already an integral part of the DVD and BD standards. To increase the capacity per disc over the single-layer DVD capacity of 4.7 GB per disc [24.297], the standard doubled that capacity with two data layers, or quadrupled it with a two-sided, two-layer-per-side option (the disc had to be flipped to access data with a single objective, or a second optical pick-up was required to address both sides of such a data carrier simultaneously). The BD standard supports a large number of layers, although the approaches that could be retrofitted to existing players (with simple firmware updates) offer from four to sixteen layers [24.276].

Using depth of focus has the clear advantage of being similar to existing optical disc technology, and of being highly compatible with the large installed base of optical storage devices. As shown in Fig. 24.19, the key disadvantage is that the individual layers must be widely separated to avoid crosstalk errors on readout, or tracking problems with the focus servo. The required diffraction-limited performance is difficult to accomplish over a sizable depth range, limiting the maximum number of layers. In addition, recordable multilayer discs need to have a significant absorption to allow writing, which introduces an additional constraint on stacking of layers [24.279, 298].

One way to improve this is to use fluorescence for readout: since the light from a mark is now incoherent, the effects of interference and scattered light can be reduced and a higher SNR obtained. These reduced noise effects trade off with the omnidirectional output of the fluorescence from the illuminated voxel (volumetric pixel).

24.7.3 Two-Photon Absorption for Addressing of a Bit Cell

Another means of limiting the interaction volume of the addressing beam in the medium is by using two-photon absorption, which scales with the square of the beam intensity. This effectively shortens and narrows the focus volume where the intensity is sufficient for writing. These approaches often require femtosecond lasers with high peak intensities, but could enable media with hundreds of layers allowing capacities approaching 1 TB per disc. Here the media is initially homogeneous (not layered), with two-photon effects used to either initiate or quench fluorescence at each voxel [24.299, 300]. Confocal microscopy has been used to detect extremely small marks in initial studies, but it is unclear whether such an approach would work on a rapidly spinning disc.

Further gains in depth resolution can be realized by crossing two laser beams of the same or different wavelength, using two-photon absorption to initiate a change

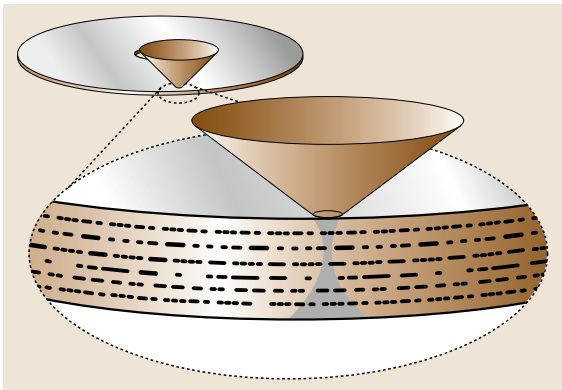

Fig. 24.19 The effective optical areal density can be increased by using depth of focus to access multiple bit layers within a disc

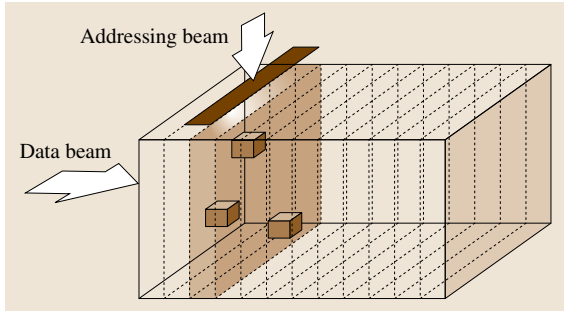

Fig. 24.20 Orthogonal beams can write and read data in parallel into a three-dimensional volume, using two-photon fluorescence at the intersection of the beams (after [24.296])

of the media's optical properties only in the commonly illuminated volume [24.296, 301], as shown in Fig. 24.20. Here just one volume element within a larger block of recording media can be selected for recording or readout without affecting adjacent volume elements, thus avoiding inter-track and inter-layer interference. Extensions of this technique use columns or sheets of light to address a large number of volume elements in parallel, although these extensions make diffraction-limited performance for submicron-sized marks more difficult to obtain.

Even so, effective areal densities greater than 100 Gbit/in^2 would appear achievable by using many layers with relatively large marks (i. e., greater than 1 μm). Once written, the marks (or columns or pages) may be nondestructively read by the two-photon fluorescence. Demonstrated capabilities include the recording and reading of media with more than 100 data layers, recording tracks of $2\times2\,\mu m^2$ data marks, and the construction of several proof-of-principle portable read-out systems [24.296, 301, 302].

This two-photon 3-D optical storage technology seeks to provide disc drive systems with high capacity (100–500 GB/disc) and high data rates (1–10 Gbit/s) using inexpensive, easily manufactured, and long-lived plastic media. The drive technologies are potentially backward compatible with conventional DVD media. The media could be removable and offers the possibility of wide wavelength and mechanical tolerances in drives for near-line/online servers.

Efficient two-photon absorption recording requires moderate average laser power (50 mW) but high peak intensity at the focused spot (on the order of GW/cm^2), necessitating the use of a pulsed laser source for recording. Suitable diode-pumped solid-state pulsed lasers are available, albeit at a significant price and size disadvantage as compared to semiconductor laser diodes. These laser requirements remain the largest risk to this approach.

24.7.4 Persistent Spectral Hole Burning (PSHB)

Spectral hole burning uses media that can support dopants with extremely selective spectral response (Fig. 24.21). Accessing this narrow spectral response requires a tunable narrow-band laser, which tends to be a complex and expensive light source. Thus high storage densities and storage volumes are essential to amortize the cost of this light source over a large storage capacity. Unfortunately, these very high densities are currently only possible at cryogenic temperatures, adding additional complexity and cost. However, the latency and the data transfer rates that could theoretically be achieved by this technique are superior, allowing spectral hole burning to play in the memory as well as in the storage arena.

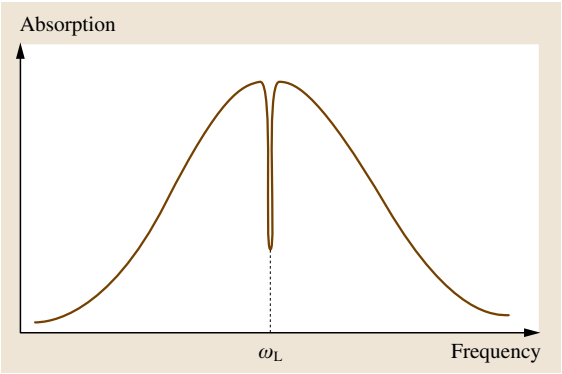

Fig. 24.21 After illumination with a narrow-band laser at ω_L, a persistent and very narrow spectral hole has been *burned* into the absorption spectrum

Several groups have pursued variations of spectral hole burning for data storage and memory applications [24.303, 304]. PSHB materials can alternatively be addressed using time-domain interference techniques, in which holograms laid down in the frequency spectrum allow time sequences to be replayed as *photon echoes* [24.305, 306]. Both time- and spectral-access alternatives support spatial multiplexing across numerous locations, and would support the prospect of combining this technique with the spatial holographic techniques to be described below. Crosstalk and distortions between spectral channels, and photon flux are typically the important limiting factors. Time-domain access relieves the requirement for laser tunability, although the laser source does still need to be narrow band and extremely stable. It can also enable content addressability (accessing data by its correlation or similarity with search data). However, efficient time-domain addressing schemes are yet to be developed and random access to data is difficult to provide.

24.7.5 Spectroscopic Storage

A similar approach for using ultra-short pulses to retrieve data spectroscopically (through the modification of the optical spectrum) features plasmonic nanostructures [24.307, 308]. Here a wide-spectrum light source, passing through extremely small features recorded on

the surface of a disc, would read out multiple bits of data at each focussed spot position. This allows wavelength to be added, here as a 3rd dimension to the x, y positioning on the surface of the disc.

This approach was taken two *dimensions* further by *Gu* and coworkers, who used spectroscopic and polarization-dependent recording and readout of plasmonic gold nanorods suspended within a 3-D solid to implement 5-D storage [24.320]. Here, the resonance frequency at which the nanorods absorb strongly depends on both the polarization and wavelength of the incoming light. Thus a high-power polarized beam of a particular wavelength, focussed at an x, y, z position within the storage material, will preferentially damage only those nanorods with the right size and orientation to strongly absorb that incoming light [24.320]. Subsequent readout light will then detect the induced change in absorption for that particular polarization and wavelength combination. Of course, only two orthogonal polarizations are available, and a large number of effectively-independent wavelengths can be achieved only if each individual nanorod has a narrow frequency response. This is similar to the selective spectral response in the PSHB materials, except at room temperature.

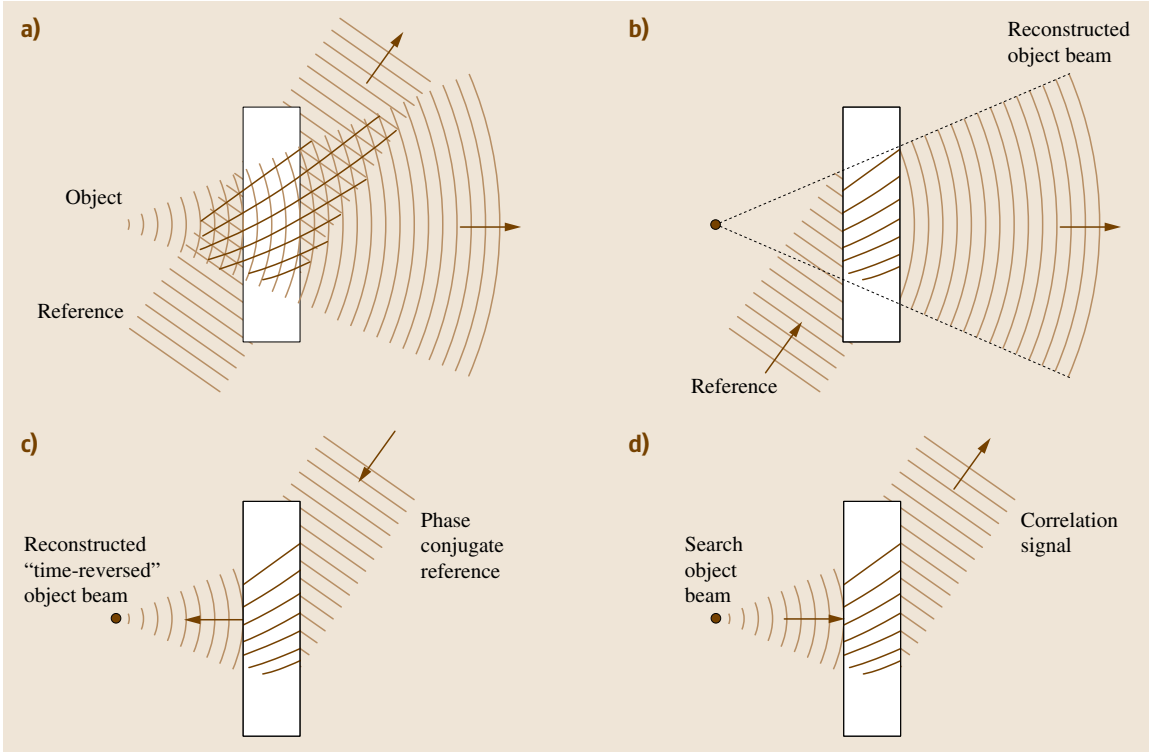

Fig. 24.22a–d How to record and read data using holograms. **(a)** Holographic storage of a single data bit. The spherical wave from a single pixel interferes with a coherent plane wave in the reference beam. The resulting interference pattern changes the refractive properties of the photosensitive medium. **(b)** The hologram is read out using the original reference beam, which is diffracted by the stored interference pattern to reconstruct the original spherical wavefront. An image of this beam can be formed on a single detector pixel, resulting in the retrieval of a single bit. **(c)** The hologram can also be read out by illuminating it with a counter-propagating (or *phase-conjugate*) reference beam, which reconstructs a phase-conjugate copy of the original object beam. This beam returns to its original point of origin, where the bit value can be read without requiring a high-quality imaging system [24.309–313]. **(d)** A third way to retrieve data involves illuminating it with a diverging object beam, which reconstructs the original plane-wave reference beam. This beam can be focused onto a detector and provides an optical measurement of the correlation between the stored data and the illuminating object beam [24.314, 315]. This technique can allow one to search the stored data according to its content, rather than according to its address [24.316–318] (after [24.319])

24.7.6 Holographic Storage

Holographic data storage is a volumetric approach which, although conceived decades ago, made great progress toward practicality between 1994 and 2009, with the appearance of lower-cost enabling technologies, significant results from long-standing research efforts, and progress in holographic recording materials [24.321–323].

A hologram preserves both the phase and amplitude of an optical wavefront of interest – called the object beam – by recording the optical interference pattern between it and a second coherent optical beam (the reference beam). Figure 24.22a shows this process. The reference beam is designed to be simple to reproduce at a later stage, such as a simple collimated plane wave. These interference fringes are recorded if the two beams have been overlapped within a suitable photosensitive media. The bright and dark variations of the interference pattern create chemical and/or physical changes in the media, preserving a replica of the interference pattern as a change in absorption, refractive index or thickness. When the recording is illuminated by a read-out beam that is similar to the original reference beam, some of the light is diffracted to reconstruct a weak copy of the object beam (Fig. 24.22b). If the object beam originally came from a 3-D object, then the reconstructed hologram makes a virtual image of the 3-D object reappear [24.314]. Interestingly, a backward-propagating or phase-conjugate reference wave, illuminating the stored grating from the back side, reconstructs an object wave that also propagates backward toward its original source (Fig. 24.22c), creating a real but pseudoscopic image.

Although holography was conceived in the late 1940s, it was not considered a potential storage technology until the development of the laser in the 1960s. The resulting rapid development of holography for displaying 3-D images led researchers to realize that holograms could also store data at a volumetric density of as much as $1/\lambda^3$ [24.324]. In contrast to conventional data storage, where each bit of data is assigned to a particular location within the storage volume or upon the storage surface, holographic storage distributes data throughout a volume in a delocalized way. Data are transferred to and from the storage material as 2-D images composed of thousands of pixels, with each pixel representing a single bit of information. No one location in the crystal is responsible for storing that one bit; each is distributed throughout the associated recorded interference fringes. The direction and spacing of those particular fringes ensures that light arrives at a particular photodetector (within the large detector array) only when a particular read-out beam is incident.

The $1/\lambda^3$ theoretical density limit can thus be intuitively understood as a crosstalk limit forced by diffraction. Given that each reconstructed object beam must pass through an aperture A to reach a detector array, then two sets of fringes that differ in direction by less than $\lambda/\sqrt{A}$ will be indistinguishable due to diffraction. Given that the contributions of the fringe spacings will be integrated over a thickness of L, two sets of fringes that differ in spacing by less than λ/L cannot be individually reconstructed. So roughly L/λ data pages of A/λ^2 pixels each can be holographically stored within a volume $V = AL$. While this simple argument ignores the role of the bulk index of refraction (as well as real-world media and noise issues), $1/\lambda^3$ would be impressive density performance, corresponding (for green light) to the storage of 1 TB of data in a cubic centimeter.

Since each data page is retrieved by an array of photodetectors in parallel (Fig. 24.23), rather than bit-by-bit, the holographic scheme promises fast read-out rates as well as high density [24.319, 322, 325–328], because laser beams can potentially be moved rapidly without inertia, unlike the actuators in disc drives. With the inherent parallelism of its page-wise storage and retrieval, a very large compound data rate could be reached by having a large number of relatively slow (and therefore cheap) parallel channels. If a thousand

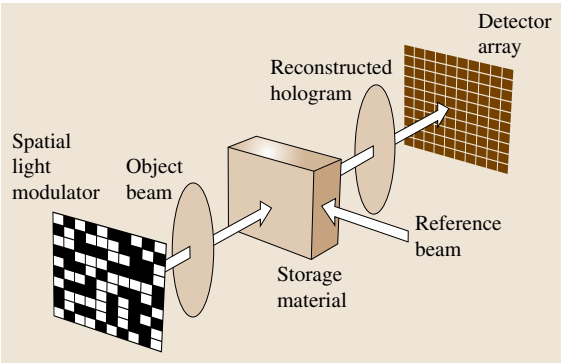

Fig. 24.23 Data are imprinted onto the object beam by shining the light through a pixelated input device called a spatial light modulator. A pair of lenses image the data through the storage material onto a pixelated detector array, such as a charge-coupled device (CCD). A reference beam intersects the object beam in the storage material, allowing the holograms to be stored and retrieved later (after [24.319])

holograms, each containing a million pixels, could be retrieved every second, for instance, then the output data rate would reach 1 Gbit/s.

A rather unique feature of holographic data storage is associative retrieval, or content-addressable data storage [24.317]. If a partial or search data pattern is imprinted on the object beam, illuminating the stored holograms reconstructs all of the reference beams, each weighted by the similarity between the search pattern and the content of their particular data page. By determining, for example, which reference beam has the highest intensity, the closest match to the search pattern can be found without initially knowing its address.

Despite this attractive potential and fairly impressive early progress [24.329, 330], holographic storage has been – for nearly four decades – an intriguing but elusive alternative to conventional data storage techniques. With the recent availability of relatively low-cost components, such as liquid-crystal displays as input devices and camera chips from electronic cameras and camcorders for detector arrays, interest in commercializing holographic storage efforts was rekindled. Around the turn of the millennium, as part of an effort that was sponsored by the United States Defense Advanced Research Projects Agency (DARPA), members of the holographic data storage systems (HDSS) consortium were able to demonstrate impressive performance with experimental platforms: at the IBM Almaden Research Center a data density of 250 Gbit/in^2 was achieved [24.331]; at Stanford University a data rate of 10 Gbit/s was reached for the read out of holographic data [24.332], and a team at the Rockwell Science Center demonstrated access times on the order of 10 μs [24.333]. Each of these demonstrations were the product of extensive studies of recording physics, systems trade-offs, signal processing, and coding techniques. These experiments showed that it would be difficult, but not impossible, to obtain a combination of all three desirable performance characteristics in one hardware platform.

In the next decade, teams of researchers formed three small companies (Aprilis, InPhase Technologies, and Optware) that along with several Japanese manufacturers (including Sony, Samsung, and Hitachi) aggressively pursued the commercialization of disc-based holographic storage. Although many materials developments, systems improvements and even new multiplexing concepts were developed, at the time of this writing, no holographic storage product has achieved commercially-viable success. Despite this unfortunate track record, holographic storage remains one of the more attractive combinations of theoretically-achievable potential and practically-achievable performance among the future optical storage techniques. For instance, shortly before the company was re-organized in Spring 2010 [24.334], InPhase Technologies together with Hitachi demonstrated areal densities of ≈ 700 Gbit/in^2 [24.323, 335] and were headed into final qualification of their first product drives [24.336]. One could make the case that InPhase would have been in a strong competitive position relative to magnetic tape, particular for archival applications such as high-performance video editing, if it had been able to deliver this product a few years earlier at lower cost, rather than in late 2009 for ≈ $ 18 000 per drive [24.336, 337].

24.7.7 Holographic Multiplexing

If a hologram is recorded in a thin material – as on many credit cards – the read-out beam can differ in angle or wavelength from the reference beam used for recording the image; the scene will still appear. However, if the hologram is recorded in a thick material, the reconstructed object beam will only appear when the read-out beam is nearly identical to the original reference beam.

For any read-out beam, some of the incident optical power is diffracted by the recorded hologram to create a diffracted wavefront. In a thick hologram, this diffracted wavefront accumulates energy from throughout the thickness of the storage material. The Bragg condition applies when the diffracted wavefront is momentum matched to the read-out beam and grating. For holographic media that record an exact copy of the interference fringes, this occurs when the read-out beam is identical in wavelength and incidence angle to the original recording beam. Away from this condition, the discrepancy between the wavefront that would be momentum matched (to the read-out light and the grating) and the wavefront that can actually propagate (the closest solution of the wave equation) represents a phase error. Thus the wavefront diffracted by the front portion of the hologram, after propagating through most of the thick material, finds itself out-of-phase with the wavefront diffracted by the rear portions of the hologram. The integration of this phase error over the thickness of the volume hologram creates Bragg selectivity: the hologram disappears as the angle or wavelength is tuned away from the Bragg condition.

As the material becomes thicker, accessing a stored volume hologram requires tight tolerances on the stability and repeatability of the wavelength and the angle

provided by the laser and read-out optics. However, Bragg selectivity also opens up a tremendous opportunity: a small storage volume can now store multiple superimposed holograms, each distributed throughout the entire volume yet selectively accessible with its original reference beam. Any particular data page can then be read out independently by illuminating the stored gratings with the reference wave that was used to store that particular page. The theoretical limits for the storage density of this technique are around tens of terabits per cubic centimeter [24.321, 322].

Several different techniques [24.338] have been developed to define a set of suitable reference beams. It has already been implied that tuning the incidence angle [24.339, 340] or wavelength [24.341] will multiplex holograms. The former has been used much more than the latter, simply because rotating a mirror through large angles has been easier to implement than rapidly – and widely – tunable lasers.

Instead of recording one hologram per incidence angle, it is possible to use all the incidence angles for each hologram, imposing a unique phase on each of these beamlets individually. The number of holograms that can be superimposed depends on the number of orthogonal phase codes. Such phase-code multiplexing [24.342, 343] has been widely investigated because spatial light modulators could be used to apply these phases rapidly without mechanical motion. One issue is the need for low phase error (both random and deterministic [24.344, 345]) in these devices; another is the impact of grating degeneracy on any phase codes arranged in a 2-D pattern, a consideration that is unfortunately often overlooked.

Another improvement upon angle multiplexing actually exploits this grating degeneracy. Although holographic data pages do not disappear when changing the incidence angle out of plane, they are displaced on the detector array as the diffracted beam moves to remain in the plane formed by the incident beam and the grating vector. Once the data page *slides* completely off the detector array, the same Bragg angle can be used to store a second hologram. This is referred to as fractal multiplexing, because one backs off from $(A/\lambda)^2$ pixels per page to some fractal dimension (say, $(A/\lambda)^{2-x}$), allowing an increase in the number of stored pages to $(L/\lambda)\times(A/\lambda)^x$ [24.346]. Using a combination of angle and fractal multiplexing, as many as 10 000 holograms have been stored in a 1 cm^3 volume [24.347,348]. Techniques analogous to angle and fractal multiplexing, called shift and peristrophic multiplexing, have been developed for multiplexing holograms in thin discs and are described later, as is a newer multiplexing technique, called polytopic multiplexing.

24.7.8 Media

Media for holographic storage has long been one of the primary focus points for researchers in this field. There are two major classes of holographic storage media: write-once media, typically to be used as thin (0.2–2 mm) discs and accessed through disk rotation or translation; and read–write media, typically kept stationary and accessed by beam steering.

24.7.9 Write-Once Read-Many

A material that permanently stores volume holograms must generally support some irreversible photochemical reaction or photophysical process, triggered by the bright regions of the optical interference pattern, that then leads to changes in index of refraction or absorption. For example, a photopolymer material (as its name would suggest) polymerizes in response to optical illumination: material diffuses from darker to brighter regions so that short monomer chains can bind together to form long molecular chains [24.349–353]. Because this diffusion process can be phototriggered, sensitivities can be made high enough to support holographic recording with single short pulses [24.354]. While high sensitivity is desirable in a commercial application, so that holograms can be rapidly recorded with a cheap, low-power laser, high sensitivity can also cause problems. For instance, some of the media volume may be inadvertently affected by partial exposure as nearby spots are recorded, forcing either a reduction in sensitivity or in areal density (e.g. guard bands). In contrast to photopolymers, the illuminated molecules in a so-called direct-write or photochromic material undergo a local change in their absorption or index of refraction, driven by photochemistry or photoinduced molecular reconfiguration. Examples include photoaddressable polymers [24.355], and binding of absorbers to polymer hosts (such as phenanthraquinone (PQ) to polymethylmethacrylate (PMMA) [24.356]).

Both types of materials are inexpensive to make in bulk, but both can have problems reproducing the object beam faithfully. Photopolymers tend to shrink during recording, distorting the reconstructed pixelated images [24.357]. Direct-write media respond both to the rapid variations of the interference pattern encoded with data and to long-range brightness variations across the illuminated spot. Such effects also distort the recon-

structed data pages. These problems can be minimized by careful system design, such as signal-processing techniques that can compensate for shifted and distorted data pages [24.358,359], and optical illumination systems that deliver beams with extremely uniform brightness [24.360].

Although problems with shrinkage, scattering and dynamic range remain, by 2003 developments in these write-once materials had overcome previous difficulties with poor optical quality and excessive absorption and led to fairly thick samples (0.5–1 mm) [24.323]. Together with multiplexing techniques that used peristrophic beam rotation [24.361], spherical [24.362] or randomly speckled [24.363] reference beams to increase the number of holograms that could be superimposed in thin media, these important developments seeded a number of long-running commercialization efforts of write-once read-many holographic storage systems.

24.7.10 Read–Write

In contrast to the organic WORM media, most erasable holographic materials tend to be inorganic photorefractive crystals doped with transition metals or rare-earth ions [24.364–367]. These crystals are often available in centimeter-thick samples and include lithium niobate, strontium barium niobate, and barium titanate, doped with iron, cerium, manganese or other dopants.

For details on these materials please see Sect. 24.5 on photorefractive crystals by Buse and Krätzig. Before discussing the important issue of volatility in photorefractive crystals, we describe some alternative read–write holographic storage media. These include photorefractive polymers [24.368–371], bacteriorhodopsin [24.372–374], and the DX center in semiconductor materials [24.375]. These materials are difficult to obtain in the thicknesses that would be required for competitive capacities, and also have their own idiosyncrasies. While photorefractive polymers can achieve large index changes very rapidly and provide many avenues for tuning through constituent substitutions, they require large voltages to create the orientational analogue of the electrooptic effect and tend to have fairly short dark lifetimes (seconds to minutes) [24.368–371]. Bacteriorhodopsin can be tuned by genetic and chemical modifications [24.372, 374] and does not require an external electric field. However, volatility and dynamic range are serious issues [24.373, 374], and the required operating wavelengths tend to be tightly tied to the protein's innate photocycle [24.372–374]. Essentially, bacteriorhodopsin acts much like a write-once direct-write saturable material, where readout fills in the holograms. By completing the photocycle with a second wavelength, holograms are erased and new ones can be written in the photosensitive molecules reset to their initial state. Finally, at low temperatures (< 150 K), the persistent photoconductivity exhibited by the DX center in semiconductors offers an opportunity for writing strong phase holograms [24.375]. Photoexcited electrons persist in the conduction band without decaying, leading to large index changes. This DX-center material also acts as a saturable material. Here, raising the temperature erases the holograms, since the photoelectrons now have enough thermal energy to make it back to the original ground state [24.375].

24.7.11 Nonvolatile Read–Write Storage

Index modulation in photorefractives is produced by space charge that is built up by the optical excitation and migration of mobile charge carriers. While this physics is what enables recording of holograms, it also means that photorefractive materials erase upon any charge re-excitation, such as that induced by any subsequent optical exposure. This means that stored holograms erase while other holograms are being recorded, and worse still, while any of the holograms superimposed within that same volume are being read out. In addition, there is gradual erasure in the dark through thermal excitation [24.376, 377].

These erasure effects can be counteracted during recording by carefully scheduling the sequence of exposures, to ensure that the final diffraction efficiencies will be equal [24.315, 378]. The first holograms are recorded to somewhat higher diffraction efficiencies with longer exposures, so that as subsequent holograms are recorded and these first ones decay, all final diffraction efficiencies are equal [24.378]. As a result of the recording schedule, the effects of erasure are mitigated at some small cost in effective recording rate. (Recording schedules are also used in write-once media, to compensate for changes in sensitivity as a function of recording exposure [24.323, 379, 380]. This can include any preexposure required before the material begins to change its index of refraction.)

The more crucial issue is erasure of the stored holograms during readout. With some photorefractive crystals, stored holograms can be fixed – made semipermanent and resistant to erasure during read out – by separate thermal [24.381–385] or electronic [24.386,

387] processes. Unfortunately, these fixing processes affect all the stored holograms within a volume simultaneously, only preserve a fraction of the original grating strength, and tend to be slow and cumbersome. For instance, it is not clear how to thermally fix holograms in one subvolume while not affecting holograms in any of the immediately neighboring subvolumes.

Another proposed solution to the volatility problem is periodic copying and refreshing of the pixelated data pages [24.388]. Here the data pages are read out periodically and rewritten into the memory. Most of the experimentally demonstrated schemes have involved methods to reinforce the original hologram, but copying the data page into a separate storage location should also work. The problems with all of these is their complexity, the possibility of loss of data fidelity in all the copying and re-copying, and the reduced performance from having the system inaccessible to user-generated read and write commands during the refresh operations.

A third approach to nonvolatile holographic storage is to read the hologram with a wavelength different from that used for recording [24.389, 390]. The idea is that if the absorption at this new read-out wavelength is much lower, the erasure will take place much more slowly. The systems problem with this is that not all of the spatial frequencies in the hologram will be Bragg-matched simultaneously, and there will be a trade-off between how much of the page will be visible, whether the pixels in the page will land where they are supposed to, and how hard one can push towards the theoretical density limit of $1/\lambda^3$ [24.389, 390]. These systems issues grow worse as the ratio between the two wavelengths grows larger; but given the broad absorption spectra in these crystals, significant changes in absorption require large ($\approx 50\%$) changes in wavelength.

A fourth method for achieving nonvolatile storage in photorefractive materials is by recording at a wavelength of light which is only absorbed by the crystal in the presence of an additional gating beam of different wavelength [24.391–395]. This additional beam is present only during recording and is switched off while the information is read out, allowing the data to be retrieved without erasure. The recorded interference fringes thus remain Bragg-matched to the read-out wavelength, and both read-out and diffracted wavefronts experience low absorption losses.

Conventional photorefractive materials can be optimized for this gated, two-color recording process by changing the way in which they are fabricated or by adding multiple dopants. For instance, the two-color response of lithium niobate can be enhanced by changing the ratio of lithium to niobium in the compound [24.392], or by doping it with both manganese and iron atoms [24.393]. Gated, two-color photorefractive materials received enormous attention around 2000, leading to improvements in both the sensitivity and dynamic range of the materials (increasing both the speed with which data can be written and the capacity) [24.392, 393, 395]. However, the pace of improvement towards performance levels sufficient to enable read-write system prototypes has since slowed considerably.

24.7.12 Phase-Conjugate Read Out for Read–Write Systems

Experimental demonstrations of holographic data storage have concentrated on demonstrating high density and fast read out. High areal density can be achieved in holographic data storage by carefully balancing inter-pixel crosstalk (introduced by the small aperture through which each data page is focused) against the loss of signal associated with recording multiple holograms. For instance, in 2000 an equivalent areal density of 250 Gbit/in^2 (394 bit/μm^2, 80× larger than single-layer DVD) was demonstrated [24.331]. (The equivalent volumetric density was 1.1% of $1/\lambda^3$). Conversely, fast read-out rates can be attained by reading out large data pages in rapid succession. An optical read-out rate of 10 Gbit/s at moderate density (≈ 10 bit/μm^2) was demonstrated, and a full system read-out rate of 1 Gbit shown (including the camera and decoding hardware) [24.396]. Both of the demonstrations reached these specifications by combining large *megapixel* data pages of 1024×1024 pixels with the short focal length optics needed for high density. More recently, areal densities as high as ≈ 700 Gbit/in^2 (≈ 1085 bit/μm^2) were demonstrated using a monocular architecture and polytopic multiplexing [24.323, 335].

However, extending read–write holographic storage to high capacity without sacrificing fast access means that this same high density must be achieved at many storage locations without moving the storage media. The demands this would impose upon optical imaging performance are quite severe – thus the further improvements in capacity that could be achieved by simply designing better lenses would be limited to commercially uninteresting values. However, several researchers have long proposed bypassing these imaging constraints with phase-conjugate read out [24.309–

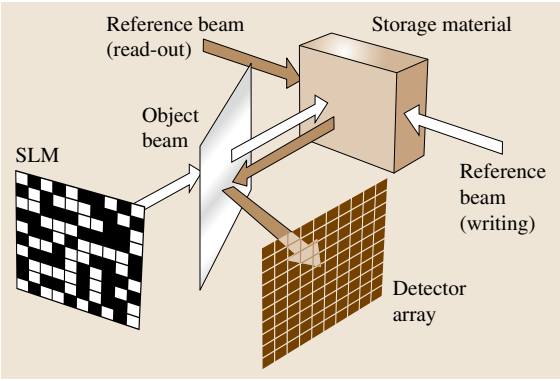

Fig. 24.24 By adding a counter-propagating readout beam, a phase-conjugate object beam can be reconstructed which retraces the original path of the object beam in reverse. Proper placement of a polarizing beam splitter and detector array can allow high-fidelity data retrieval without expensive imaging optics

312], as shown in Fig. 24.24. Once a hologram is recorded, the wavefront reconstructed by a phase-conjugate read-out beam will retrace the path of the incoming object beam in reverse, canceling out any accumulated phase errors from lens aberrations or material imperfections. This allows data pages to be retrieved with high fidelity using image confinement in fiber-type media [24.309, 310], an inexpensive lens, or even without imaging lenses for an extremely compact system [24.311, 312]. However, many pairs of phase-conjugate reference beams are needed to read the many different holograms recorded within the same volume – and maintaining these beams over long periods of time would be impossible from a practical point of view.

One solution to this problem is to separate the phase-conjugation and hologram storage processes into two successive steps with a *buffer* hologram [24.313]. Holograms can then easily be multiplexed at a large number of separate storage locations using only one SLM and one detector array. With gated, two-color media, the long-term storage material does not absorb the information-bearing beam until the gating light is present [24.313]. With the phase-conjugate read-out, total internal reflection could be used to confine the image-bearing beam within a small cross section without sacrificing the ability to retrieve this image at the detector array [24.309, 310, 313]. Such a system only requires a single pair of phase-conjugate beams, generated either by carefully alignment or with a self-pumped phase-conjugate mirror [24.313].

A second proposed solution to phase-conjugate read out is to attain high capacity from multiple compact modules, each created by attaching an SLM, a detector array, and the storage media directly to a pair of beam splitters [24.311]. The phase-conjugate readout allows the whole system to remain extremely compact, and density can be further augmented by increasing the page size. It has been shown that phase-conjugate read out can retrieve pages with pixel pitches as small as 1 μm [24.397]. This approach has the advantage that the object beam need not be confined with total internal reflection because it is never allowed to propagate far from the SLM. But it does require that the components be very inexpensive, since the capacity per set of components is relatively low. Both the compact and buffer-enable phase-conjugate systems still require a low-power and convenient method for supplying thousands of unique reference beams to hundreds or thousands of spatial locations, using either micromechanical mirrors, liquid-crystal beam steerers, individually addressable lasers, or wavelength-tunable lasers.

The successful use of phase-conjugation in holographic storage should enable compact and affordable high-capacity systems, with only a moderate increase in the overall system complexity. Obviously, such systems still await a recording material that supports both read–write access and nonvolatile storage [24.393, 394, 398]. Even so, there remain other serious issues that must be addressed before commercialization. Thermal stability must be good lest the interference patterns change spacing and orientation as the media expands or contracts with temperature. Good mechanical and laser stability are also required (the media and interference fringes must not move during exposures, and motion afterwards can cause the reconstructed optical signals to veer away from their assigned detector pixels). Fortunately, the stability during recording will become easier to attain as exposure times decrease through improvements in material sensitivity and increases in available laser power.

Despite all of the techniques for removing and suppressing volatility, it is unlikely that any read–write holographic storage material will be truly nonvolatile: most likely the data will slowly fade over several months or years due to thermal effects (slow excitation from electron traps, diffusion of compensating ions) or through residual absorption. So while blocks of read–write media may be removable from the read–write head (which enables something like a petabyte jukebox), the media will probably need to remain within the jukebox so that data can be periodically refreshed.

24.7.13 Write-Once Systems Using Spinning Disks

In contrast to read–write holographic systems, progress in write-once materials research (especially photopolymers [24.352, 353, 399]) was so significant that write-once systems moved well beyond prototypes into the development of holographic storage products.

Beyond the problems of perfecting the media (in characteristics such as dynamic range, scatter, sensitivity, shelf-life before and after recording, and thermal expansion properties) are the systems engineering issues of building robust holographic data storage devices around a spinning disc format. What makes this even more challenging is that the obvious application areas (low-cost data archiving, possible next-generation distribution format for data and multimedia) call for inexpensive and robust disc readers (as well as cheap media). The first systems problem is the interplay between high rotation speed (needed for low latency) and the need for a high-power, compact pulsed laser to read and write with single pulses. And then there are the difficulties of getting the pulse to the right spot (tracking, focusing, synchronizing pulses to disc rotation), and getting the reconstructed data page to the detector array (compensating for tracking, tilt, disc jitter). *Zhou* et al. have demonstrated tracking for low-density holographic discs [24.400]. They showed both tracking and tilt compensation: the former by measuring the data page rotation to synchronize the beam shutter (on a continuous wave (CW) laser), and the latter by tuning the reference beam angle so that data pages landed squarely on the pixelated detector array [24.400]. Similarly, InPhase technologies introduced several techniques to compensate for temperature shifts, and to servo the reference beam angle by writing holograms in a *wobble* pattern (with intentional offsets of alternating sign) [24.323, 336].

To reach high density, the reference beam must cover a wide spread of incidence angles, so good antireflection coatings are essential to keep power from being lost in Fresnel reflections (and this increases media cost). To get the best density while suppressing aberrations in the imaging system, the object beam should enter the holographic disc media at or near normal incidence. As this must be done with a short-working-distance optical system, the delivery of writing and reading beams around these imaging optics (without increasing the scatter into them) is further complicated. Although a read-only transmission-geometry head can avoid passing the reference beam past input optics, transmission geometry has conventionally implied that the read head is split into two parts on either side of the rotating disc (and both sides must be carefully aligned).

24.7.14 Collinear Holography

However, there are two alternative approaches for implementing transmission geometry, which offers superior angle multiplexing performance and lower sensitivity to wavelength and temperature changes [24.322, 323]. One is to use coaxial holography, in which the reference and signal beams reach the disc through a single lens [24.396, 401]. This reduces the number of components that must be held near the spinning disc, at the cost of splitting the space-bandwidth product of the lens among the reference and object beams. This means that the object beam typically contains fewer pixels and fewer reference beam angles are available. But if the motivation is to keep the system simple, it is essential to avoid having to precisely align the x, y, and z positions of two large objects on opposite sides of the disc. One can do so by using the same single lens for readout, provided that there is some way to reflect one of the two beams. One way is to use a simple reference beam that can be provided on the far side of the disc with a somewhat simpler read head [24.335,336], thus still requiring a two-sided readout system; another is to add a reflective layer into the disc substrate [24.323, 401–403], thus increasing the complexity and cost of the media. The latter technique has also been used in a read-only holographic memory, in which discs are copied quickly from master and submaster disks [24.323, 380]. In both types of systems, a critical noise source in a collinear holographic system is the strong reference beam, which must be prevented from reaching the detector array when it is trying to read the much weaker reconstructed object beam [24.403].

24.7.15 Write-Once Multiplexing

Several novel multiplexing methods have been developed to allow holograms to be superimposed very densely, even in thin discs. High density can be reached with peristrophic multiplexing, at the cost of a fairly complicated read head that rotates the reference beam around the normal to the disc surface [24.361]. In contrast, by using either a spherical [24.362] or a randomly speckled [24.363] reference beam, the motion of the spinning disc can allow the reference beam to recon-

struct stored holograms selectively with an extremely simple read heads. If this shift multiplexing is done with a spherical reference beam, then holograms can be packed densely along one line (i. e., along the track), but only sparsely along the orthogonal direction (tracks must be widely spaced) [24.362].

Speckle-shift, or correlation, multiplexing using a random phase plate or diffuser [24.363] can allow dense packing in both radial and along-track dimensions, but this advantage does not come for free. Essentially, the size of the random speckles determines the disc motion needed to make each hologram disappear through destructive interference [24.363]. This should be small to maximize density, but not as small as the innate disc wobble and jitter of an inexpensive disk and spindle. On the other hand, the destructive interference depends on the number of random speckles that are spatially integrated as the reconstructed hologram transits the thickness of the disc. So while smaller speckle lead to better inter-page crosstalk SNR, they also make the read-out conditions so selective that holograms might not be reliably found with inexpensive components. Another consideration is any noise from gratings and index changes recorded into the highly sensitive WORM recording media by the speckle pattern itself.

Although these multiplexing techniques seem attractive for thin discs, the main InPhase Technologies platform relied on tried-and-true angle-and-spatial multiplexing, combined with phase-conjugate readout in a form termed *polytopic multiplexing* [24.323, 404]. Essentially, the lateral spacing between different multiplexed stacks of holograms is reduced to the minimum allowable based on the 0th order Nyquist sampling area of the Fourier transform of the object beam [24.405]. When compared to the much larger spacing required to avoid any overlap between any portion of obliquely incident reference and signal beams, this would seem to provide a significant density improvement; however, researchers had long been closely spacing hologram stacks [24.331, 347, 406], so the actual improvement was quite modest. The real advantage of this technique comes from the phase-conjugate readout, which allows a single *polytopic aperture* sitting at the Fourier transform plane to play two roles. Upon recording, this aperture filters the incoming object beam, avoiding unwanted exposure at other portions of the holographic disc; upon readout, it passes the desired reconstructed object beam but filters out (most of) the reference beam and any holograms reconstructed from other nearby portions of the disc [24.323].

24.7.16 Micro-Holograms

An alternate approach to wavelength multiplexing is to use micro-holograms [24.298, 407–409]. Here each micro-hologram occupies a few square microns of surface area, and can either extend throughout the thickness of the disc or exist in one of several thick layers. One or more bits of data are written at each micro-hologram by means of reflection gratings, which can be read out by active wavelength multiplexing (laser light scanned across the appropriate spectral band) [24.407], wavelength multiplexing (white light in, colored light out containing data) [24.408] or by angle multiplexing [24.407]. The beams are confined either by the focussed beam itself within a thin film [24.407], or by a micro-fiber within the material [24.408]. Although the recording process requires beams entering from both sides (or again, a reflective layer at the bottom of the disc), this can be implemented in a way in which alignment tolerances are modest, so that conventional servos used in conventional optical storage systems would be sufficient [24.298].

24.7.17 Content-Addressable Storage

With a conventional memory or data storage device, a user must supply an address at which the desired data is located. In volume holographic data storage, this implies that the data – which were once imprinted on an object beam and stored within the volume – can be read out later by illuminating the volume with the correct addressing reference beam (Fig. 24.22a,b). However, this hologram can also be illuminated by the object beam (Fig. 24.22d), reconstructing all of the angle-multiplexed reference beams that were used to record data pages into the volume (Fig. 24.25). The amount of power diffracted into each output beam is proportional to the similarity between the input data page being displayed on the spatial light modulator and the stored data page. The set of output beams can be focused onto a detector array, so that each beam forms its own correlation peak. The stored pages that match the input page can be identified by setting a threshold on the detected optical signal. If the patterns that make up these pages correspond to the various data fields of a database, and if each stored page represents a data record, then this optical correlation process can be used to compare an entire digital database against the search argument simultaneously.

This search parallelism gives content-addressable holographic data storage an inherent speed advantage

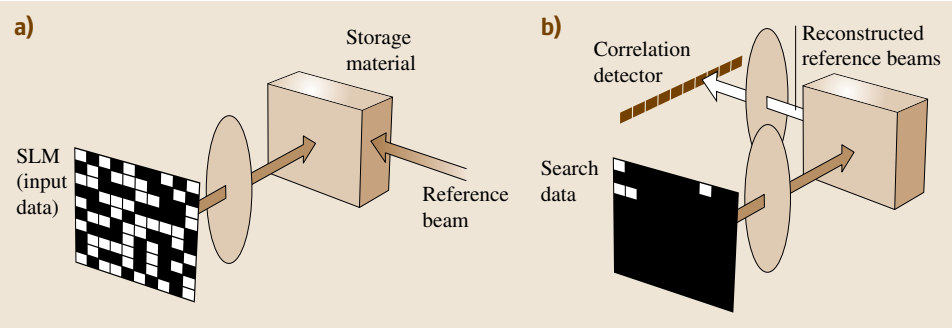

Fig. 24.25 **(a)** After multiple holograms are stored, each with a structured data page modulated onto the object beam and the reference beam introduced at a unique angle, then **(b)** illuminating the stored holograms with a new data-bearing object beam (the search data page) will reconstruct all of those reference beams in parallel. The optical power in each is proportional to the 2-D cross-correlation between the search page and the associated stored page, making it possible to search an entire database with a single optical exposure (after [24.317, 410])

over a conventional serial search. This is particularly true for searches on complex queries through large databases, where an index for every possible search query becomes untenable. For example, it would take a conventional software-based search $\approx 40\,\mathrm{s}$ to go through one million records, each containing 1 kB of data, if this gigabyte of data has to be pulled off a hard drive for each search. Connecting a gigabyte of dynamic random-access memory (DRAM) to a 1 GHz microprocessor could reduce this search time to $\approx 1\,\mathrm{s}$. In comparison, an appropriately designed holographic system could search the same records in about 1 ms. The potential performance speed of such a holographic content-addressable memory depends on having sufficient hologram output power (diffraction efficiency times read-out power) as well as a spatial light modulator capable of 10 kHz frame rates (e.g., one search every 100 µs). The key to the massive parallelism is to arrange multiple storage volumes, which can each store around 1000 holograms, along the path of the data-bearing object beam [24.410]. As the optically encoded search beam passes through each subvolume, a small amount of power diffracts from the holograms that are significantly similar to the search information [24.317, 410]. By using one photodetector per hologram, millions of analog similarity metrics could be measured simultaneously. Exact matches to a query [24.316–318], or records that are just similar to a query [24.317, 410, 411] could be identified.

However, since the detected analog result of each correlation is subject to random noise, it is possible that database records which sufficiently match the search argument may be overlooked in favor of records that *almost* sufficiently match it. Fortunately, a hybrid system can combine the speed advantage of the holographic content-addressable memory with the digital precision of serial electronics [24.317, 410]. By passing both matching and near-matching records from the holographic front-end to a subsequent electronic processor, the probability of overlooking even one matching record can be made arbitrarily low ($< 10^{-12}$) while retaining much of the speed advantage [24.317]. Given sufficient signal-to-noise ratio and a spatial light modulator of merely 1 kHz frame rate, a database of 1 million one-kilobyte records could be searched in less than 0.5% of the time required by a 1 GHz microprocessor connected to 10 GB of DRAM.

If the ability to search thousands or millions of holograms in parallel can be demonstrated and a suitable nonvolatile holographic recording media developed, volume holographic content-addressable data storage could be an attractive method for rapidly searching large databases with complex queries.

24.8 Conclusion

Evolutionary optical storage approaches that are based on current technologies and have the potential to be forward compatible – such as the use of depth of focus – have the lowest risks in terms of media, storage

device and cost. However, the benefits for potential density gains are also limited, especially if the key features of optical data storage – removability and interchangeability – are to be retained. And, given the success and extendability of the Blu-ray Disc format, the window of opportunity for a new evolutionary optical storage format may well be closed.

On the other hand, the *revolutionary* approaches promise much higher densities at substantially higher risk. Some of this risk arises because laboratory development tends to demonstrate features individually, avoiding effects which only show up when performance is pushed across-the-board. For instance, as density and data rates increase, maintaining an acceptable signal-to-noise ratio and accessing each desired record without crosstalk become severe concerns that cannot be considered independently. Fortunately, some of the more exotic techniques have additional attributes that may make them advantageous for niche applications.

Some of these revolutionary approaches, particularly holographic storage, have gotten to the point of product prototypes and failed. The primary issues here have been the relatively high complexity, and thus high cost, of the drive. Yet it is very possible that one or more of these (or similar) techniques that have been discussed will succeed at some point in the future, most likely by targeting one or more applications that take advantage of some unique capability. In order to achieve commercial viability now, though, any revolutionary optical storage technology will need to either ride some new source of immense demand for a much-higher-density physical distribution format, or alternatively take advantage of continuing technological developments (in components, coding, electronics, and light sources) from other similar applications in order to implement a customized storage system that is simple and low-cost enough to succeed even in low-volume-manufacturing. Then the market size can be increased as the technology matures.

While the demand for more data capacity and higher densities are there, there are also many competing forces (streaming video, magnetic hard-drives, solid-state memory) that can offer attractive alternatives to optical storage. Thus the jury is still out on the best approach to meet the ferocious appetites of the information age.

25. Laser Safety

After a short introduction on current applications of lasers at the beginning of this chapter, Sect. 25.1 gives some historical remarks on laser safety.

In Sect. 25.2, biological interactions and the effects of laser radiation on human tissue are described. Absorption, penetration, and transmission of optical radiation are dealt with in detail. The wavelength-dependent transmission through the eye from the cornea to the retina and the role of the pigment epithelium as a selectively absorbing layer are illustrated quantitatively. The optical gain as a result of the focusing capability of the eye is demonstrated, together with the increase of irradiance on the retina relative to the power density of the laser beam in front of the eye. State-of-the-art descriptions of photochemical, photothermal, and photoionizing effects on biological tissue in general are given, and the effects of laser radiation, especially on the various parts of the eye, are described. Retinal and nonretinal injuries of the eye are analyzed and illustrated. In addition, injuries to the skin are shown.

The topic of Sect. 25.3 is maximum permissible exposure. Its relevance to the prevention of short- and long-term effects is described, and some remarks on safety or reduction factors are made. The relationship between radiant exposure and irradiance is derived, and its general connection to maximum power values and exposure duration is demonstrated. For the eye, the influence of physiological factors such as eye movements is discussed in more detail for the case of continuous-wave exposure from a point source. In addition, the concept of an angular subtense to describe the irradiation from an extended optical source is analyzed. Furthermore, recent results are described which show that the strong belief in aversion responses and especially in the blink reflex as a reliable physiological reaction is no longer valid, since no more than about 20% of people perform a blink reflex and even less avert the head. In addition, indirect effects such as disturbance of visual functions as a result of temporary blinding due to intrabeam viewing are described for the first time.

International standards and regulations on laser safety worldwide are summarized in Sect. 25.4.

Laser classes are described in Sect. 25.5 according to the classification scheme of the international standard IEC 60825-1. The meanings of acceptable exposure limits and time base are explained. A comprehensive description of the various laser classes is given, and valuable hints about dealing with each laser class are also described. It is shown how the nominal ocular hazard distance might be calculated from given data.

In Sect. 25.6, protective measures are described. As is usually the case, technical and engineering measures rank more highly than administrative and personal protective measures. The protective measures are assigned to the respective laser classes. In addition, the role of a laser safety officer is described.

In Sect. 25.7, special recommendations for the most hazardous situations are given and common unsafe procedures are listed. Finally a special topic deals with laser pointers and gives a résumé on the most recent findings on temporary blinding as a consequence of direct laser beam viewing.

25.1 **Historical Remarks** 1570
25.2 **Biological Interactions and Effects** 1571
25.2.1 Fundamental Interactions 1571
25.2.2 Effects of Laser Radiation on the Eye and Skin 1575
25.3 **Maximum Permissible Exposure** 1578
25.3.1 Threshold Values and ED-50 1578

25.6.5 Beyond Optical Hazards 1595
25.6.6 Recently Released and Future Regulations 1596
25.7 **Special Recommendations** 1597

References 1598

Lasers are used in various applications in industry, science, and medicine, for materials processing, distance measurement, alignment, industrial and medical heat treatment, etc. In addition, there is increasing public use in the entertainment field and for simple laser pointers.

The laser is often hidden in a protective enclosure, and the laser beam is not visible like in an optical-fiber communication system, compact disc (CD) player, or laser printer, to name but a few. In other applications, such as diagnostic devices, laser endoscopes, or devices for cutting, welding, and soldering, the laser beam irradiates a target either to measure levels of some substance or to treat a material. The objective is to deliver enough energy to heat or even vaporize the respective material, while the construction of the laser product and the mode of operation ensure that no harmful laser radiation can escape from the laser device or laser product. In some cases so much optical radiation, i. e., laser radiation and/or secondary and collateral optical radiation, can be scattered or produced during material processing procedures that adverse health effects cannot be completely excluded.

Normally, lasers used in industrial applications are not a source of special health concern under normal operating conditions, but the situation may be completely different during maintenance or service, where the laser beam is freely accessible and a potentially hazardous situation might arise if the necessary safety measures are not in place.

Special care has to be taken in research and development laboratories, where the open beam is accessible and intrabeam viewing (direct viewing into the beam) may involuntarily happen.

Since there are a large number of devices where lasers are incorporated and since the wavelengths cover the whole optical spectrum, and the power ranges from a few micro- or milliwatts to petawatts, various hazardous situations have to be considered in laser safety. In addition, not only continuous-wave (CW) lasers but also pulsed ones are in use, even in the femtosecond range; i. e., a few $\mathrm{mW/cm^2}$ as well as power densities such as $10^{21}\ \mathrm{W/cm^2}$ are achieved in special cases.

25.1 Historical Remarks

Due to the fact that the first laser, which had originally been named an optical maser by *Maiman* in 1960, emitted a red beam at 694.3 nm in a pulsed mode [25.1] and the first He-Ne lasers emitted in the near infrared [25.2] or at 632.8 nm, experience was limited to a few special laser types and their corresponding wavelengths in the beginning of the laser era.

Initially, only common-sense safety guidelines could be developed based on a qualitative understanding of the interactions. There was no quantitative understanding at that time.

A dramatic change was observed when ion lasers, such as the argon-ion laser, became commercially available in 1966 and output powers of a few watts became available in science, medicine, and entertainment in the subsequent years.

The recommended corneal exposure levels, mainly given for the ruby laser wavelength, varied at that time between 6.8×10^{-4} and $1\ \mathrm{mW/cm^2}$, i. e., by a factor of about 1500 [25.3]. Less-conservative laser safety factors were used as more biological data became available; this tendency toward an increase in the recommended safe exposure levels was quite different from that for other physical or chemical agents.

The increasing number of laser users, the spread of laser applications into new fields, and the lack of adequate measures for protection resulted in an increasing number of accidents in these early years. Damage to the eyes was noted relatively often, whereas injuries to the skin, such as burning or even charring, occurred very seldom, since powerful infrared lasers such as the

Nd:YAG or CO_2 laser at 1.064 and 10.6 µm, respectively, were not as widespread at that time.

The increasing number of laser accidents prompted the establishment of a conference dealing with the topic of laser accidents and how to prevent them; laser safety has been regarded as an integral part of laser application development since then.

The fact that there has never been a single organization with the competence or legislative power to establish an applicable system of safety procedures, rules, and protective measures worldwide, to be respected by all laser users irrespective of their geographic location or national affiliation, resulted in many different systems of regulations and recommendations.

One of the first supranational recommendations was published in 1982 by the World Health Organization (WHO) as the Environmental Health Criteria [25.4].

Since optical radiation is normally defined in the wavelength range from 100 nm to 1 mm, the same is true for laser radiation; i. e., a very large range of laser wavelengths has to be taken into account. In addition, lasers might be used as a continuous-wave emitter or in a pulsed mode with pulse durations from milliseconds to a few femtoseconds. Simultaneously there exists a huge range of power and energy densities that can be achieved with the various laser types. This fact clearly shows that it is not possible to simply allocate a laser to either a safe or to an unsafe group of products.

Therefore, more than two so-called laser classes have been used from the very beginning in international, regional, and national standards. Today, laser products are categorized into as many as seven different laser classes in order to take account of the various parameters of emitted radiation and the associated hazard level.

In order to protect against adverse health effects of exposure to laser radiation, so-called exposure limits (ELs) or maximum permissible exposure (MPE) values have been introduced, based on the best available scientific and experimental knowledge and have been adapted whenever new experience justified a change of the former values.

25.2 Biological Interactions and Effects

25.2.1 Fundamental Interactions

Laser radiation might hit every site on the surface of a human being. Due to their anatomical and optical characteristics, the eyes are most vulnerable to laser radiation from about 400 to about 1400 nm, i. e., covering the visible and the near-infrared regions of the optical spectrum, where optical radiation is transmitted from the cornea to the retina (Fig. 25.1).

The eye is divided into two parts: the front or anterior chamber, which is bounded by the cornea, the iris, and the lens; and the back or posterior eye ball, which is bounded by the retina and contains the gel-like vitreous humor (vitreous body). If we look in the direction of the laser beam shown in Fig. 25.1 into the eye with an ophthalmoscope we will see an image of the ocular fundus. It looks reddish, but the prominent retinal vessels can be clearly seen. Other distinctive features are the whitish optic disc (blind spot), and the fovea. The fovea is a small depression in the retinal surface that may be more highly pigmented than the surrounding retina and is the area of most acute vision. The fovea is the center of the macula. The macula is responsible for detailed and color vision.

The retina consists of several layers of nerve cells (horizontal, bipolar, amacrine, and ganglion cells) that cover the photosensitive rods and cones; i. e., light falling on the retinal surface has to pass through the different layers of cells before it reaches the photoreceptors. Underneath the layer of rods and cones is a layer called the retinal pigment epithelium (RPE), which contains a brownish black pigment called retinal melanin, and beneath this is a layer of fine blood

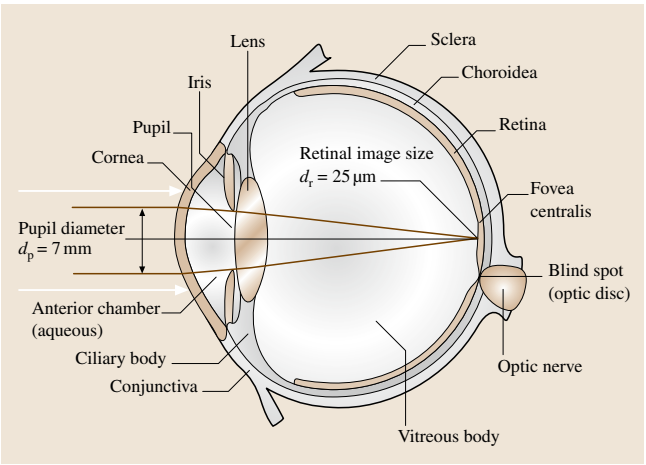

Fig. 25.1 Schematic drawing of the human eye with the standardized pupil diameter

vessels, the choriocapillaris. The final absorbing layer is the choroid, which contains both pigmented cells and blood vessels. The outside of the eye ball is called the sclera (Fig. 25.1).

The eyes and the skin are the organs that are most susceptible to potential damage from laser radiation. The degree of interaction between laser radiation and biological tissue is determined mainly by its optical characteristics. Only laser radiation that is transmitted through the respective surface and not reflected can interact with the tissue structures. Since the tissue consists of various substructures and components such as vessels, cells, membranes, and proteins, the inhomogeneous materials mainly demonstrate Mie scattering, since the components and areas are larger than the respective laser wavelength.

Some of the photons are scattered hundreds or even thousands of times per centimeter, but the most important fundamental interaction is absorption. Only in this case is the energy carried by the photons transformed into other kinds of energy, namely the excitation of atoms and the vibration of molecules. This increases the heat content of the respective tissue volume.

Normally, the interaction of laser radiation with biological tissue can be described as a function of the irradiance, given in units of W/m^2, or radiant exposure in J/m^2.

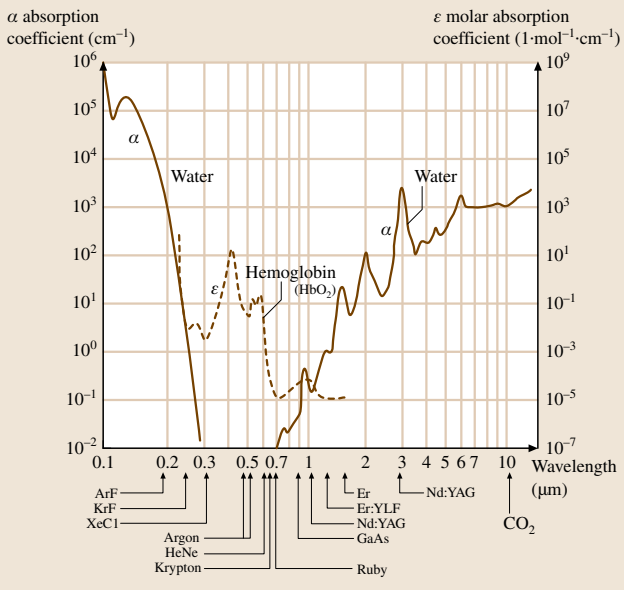

Fig. 25.2 Absorption of water and hemoglobin as a function of wavelength

Irradiance and radiant exposure correspond to the power and energy density and describe the power of a laser beam at a given position in space at a given time; the exposure duration is one of the most relevant quantities describing the extent of a biological effect.

Comparing the interaction of laser radiation with organic versus inorganic material, the main difference is given by the fact that specific processes may happen in living tissue as a result of the time course of the interaction where destructive and repair processes have to be taken into account; i. e., the result of laser irradiation is not only dependent on the physical parameters of the laser beam but on biological capabilities and characteristics as well.

The reflection from a light-colored surface is normally much larger than from a dark-pigmented one, especially in the visible part of the optical spectrum. Between 400 and 1400 nm a lot of photons are backscattered from biological tissue, i. e., generalized reflection coefficients as large as about 50% are possible. In the case that only absorption takes place, the power density or irradiance $E(z)$ decreases exponentially according to the Lambert–Beer law

$$E(z) = E_0 \exp(-\alpha z)\,, \tag{25.1}$$

where α is the absorption coefficient of the respective medium given in cm^{-1}, E_0 is the irradiance just below the tissue surface (incident irradiance), and z denotes the optical axis (direction of the laser beam).

From (25.1) the depth of penetration z_0 can be derived as

$$z_0 = \frac{1}{\alpha}\,; \tag{25.2}$$

i. e., the laser beam penetrates a less-absorptive tissue more than a translucent or opaque material. In human tissue the absorption is determined by the components of the corresponding structures.

Absorption and Penetration Depth of Water

Since many parts of the human body contain a lot of water, the wavelength dependence of absorption in water, which is shown in Fig. 25.2, determines the absorption characteristics of tissue with high water content.

In this graph the increase of absorption in the ultraviolet due to the excitation of the constituent atoms can be clearly seen. In addition the infrared spectrum is a fingerprint of the fundamental valence vibrations at about 6 and 3 μm, and of the respective overtones (second harmonics and above) at shorter wavelengths. The decreased strength of absorption of the harmon-

ics, which normally decreases by a factor of about 10 between orders of harmonics, can be seen in Fig. 25.2.

In addition to the absorption coefficient of water, that of hemoglobin is shown in Fig. 25.2. The absorption of the red chromophore of blood fills the gap in the water absorption to a certain extent; i. e., in human tissue both components normally have to be considered in calculations.

With respect to (25.2) the penetration depth in water, where the irradiance decreases to $1/e$ of the amount at the surface, might be calculated from Fig. 25.2 and is shown in Fig. 25.3.

Transmission and Absorption of the Human Eye

Since the human eye has a thickness of about 25 mm between the surface of the cornea and the retina, and since the ocular media, especially the anterior chamber and the vitreous body (cf. Fig. 25.1) might be considered from optical data to be like water, it can be seen from Fig. 25.3 that optical radiation between ultraviolet A (UV-A) and about 1500 nm reaches the retina. Due to the fact that the cornea and the lens show some absorption in the ultraviolet, the range of ocular transmission is given, as shown in Fig. 25.4, as 400–1400 nm.

In addition to the ocular transmission, Fig. 25.4 shows the wavelength-dependent absorption of the retinal pigment epithelium, which is anatomically located between the retina and the choroid. To estimate the most hazardous wavelength region, the curves for T and A in Fig. 25.4 have to be multiplied to give the actual percentage of optical radiation that is absorbed in the most sensitive layer of the human eye [25.6]. The product TA may be thought of as the action spectrum for retinal injury.

Since the eyes are the doors to the brain, function as the gateway to the optical environment, and possess the capability to focus optical radiation onto a relatively small spot on the retina, which in correct vision is located in the fovea (Fig. 25.1), the irradiance is increased by a factor of about 500 000. This optical gain is equivalent to the quotient of the area of the beam at the front of the eye to the small spot on the retina. Since the pupil limits the extension of the beam (Fig. 25.1) the ratio is given by

$$\left(\frac{\text{largest diameter of the pupil}}{\text{smallest spot on the retina}}\right)^2 \approx \left(\frac{7\,\text{mm}}{10\,\mu\text{m}}\right)^2 \approx 500\,000\,. \qquad (25.3)$$

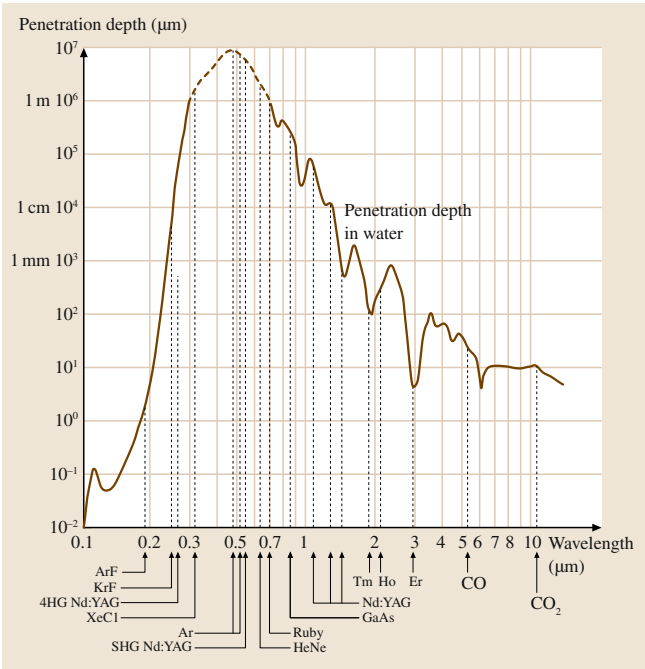

Fig. 25.3 Depth of penetration in water as a function of wavelength (cf. some often used laser lines)

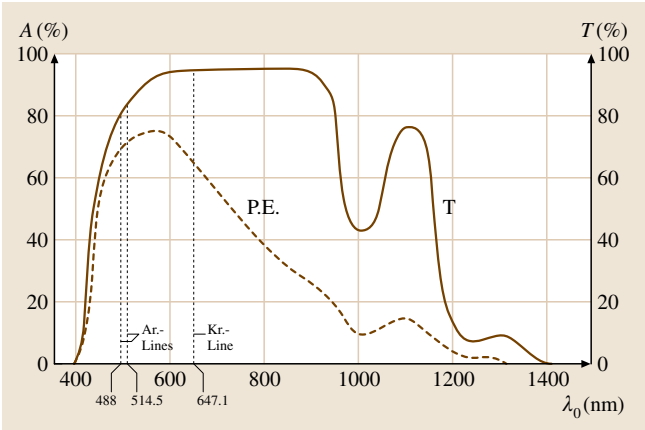

Fig. 25.4 Transmission T of the eye from the cornea to the retina and absorption A of the retinal pigment epithelium (PE) as a function of wavelength λ_0 (after [25.5])

Due to the special characteristics of a laser beam, namely that it is

- Monochromatic
- Coherent (capable of interference)

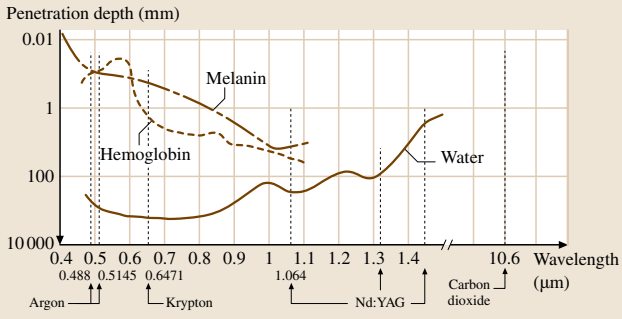

Fig. 25.5 Penetration depth of water, hemoglobin, and melanin as a function of wavelength ◀

- Directional (laser generally radiate in a narrow beam),

a 60 W laser with a 4 mm-diameter beam produces about 480 000 mW/cm^2 on a surface 1.0 m away, whereas a conventional 60 W light bulb (with theoretical efficiency of 100%) produces only about 0.5 mW/cm^2 at the same distance. For comparison the irradiance of the sun is about 100 mW/cm^2.

Laser radiation is distinguished from most other known kinds of radiation by its beam collimation. Considering the capability of the human eye to focus the beam onto the retina, a laser beam with a power density of about 1 mW/cm^2 in the plane of the pupil or at the cornea might be transformed into an irradiance of up to 500 W/cm^2 due to the optical gain in irradiance from the cornea to the retina. This characteristic has to be taken into account in the wavelength region of 400–1400 nm.

Due to the fact that the transmission is nonzero in this wavelength region, it is often called the *retinal hazard region*, but wavelengths outside this band should not be described as *eye-safe*, since other parts of the eye are vulnerable to shorter or longer wavelengths and adverse health effects may happen there.

The most likely effect of intercepting a laser beam with the eye is a thermal burn that destroys the retinal tissue. Since retinal tissue does not regenerate, the damage is permanent.

In addition to the absorption of water, other chromophores have important characteristics for eye and skin. Figure 25.5 compares the penetration depth of water, hemoglobin, and melanin.

Photochemical, Photothermal, and Photoionizing Effects

In general the irradiance or radiant exposure can result in a large spectrum of biological effects, which can be divided into photochemical, photothermal, and photoionizing effects.

The irradiance or power density is the radiant power incident per unit area upon a surface expressed in watts per square meter (W/m^2), and the radiant exposure or energy density is the time integral of the irradiance, expressed in joules per square meter (J/m^2). In some cases the radiance is used to describe the respective bioeffect. The radiance is the radiant flux or power output per unit solid angle per unit area, expressed in watts per square meter per steradian (W m^{-2} sr^{-1}).

The irradiance E is given as

$$E = \frac{\mathrm{d}P}{\mathrm{d}A} \quad \text{in W m}^{-2}\,, \tag{25.4}$$

and the radiant exposure H as

$$H = \int_0^t E(t)\,\mathrm{d}t \quad \text{in J m}^{-2}\,, \tag{25.5}$$

where $\mathrm{d}P$ is the power expressed in watts (W), $\mathrm{d}A$ is the surface in square meters (m^2), and t is the time or duration of the exposure, expressed in seconds (s).

Values of $E(t)$, E, and/or H come from measurements, or may be calculated from data provided by the manufacturer of the laser product.

Irradiances up to 1 W/cm^2 normally result in reversible processes such as photo/biostimulation or photochemical reactions in the skin, especially for exposure durations longer than 1 s. However, there exist photochemical reactions at higher irradiances that may also result in permanent damage. Photochemical reactions generally follow the law of Bunsen and Roscoe, and for exposure durations of the order of 1–3 h or less (where repair mechanisms come into play), the threshold expressed as a radiant exposure is constant over a wide range of exposure durations.

At higher irradiances between about 10 and 10^5 W/cm^2 in the millisecond regime up to a few seconds, biological tissue becomes heated and denaturation, i. e., coagulation of proteins, results in cell necrosis (cell death). If a temperature level of 100 °C is achieved, vaporization of cell substances such as water happens.

At even higher irradiances up to about 10^{10} W/cm^2 and exposure durations as short as microseconds and somewhat shorter, as in the case of Q-switched pulses, so-called nonthermal effects are initiated. These result in the ablation of superficial layers of the tissue caused

by mechanical disruption, where only a minimal temperature rise can be measured in the circumference of the irradiated area and the respective necrotic zones extend only some micrometers, i. e., comparable to the cell dimensions.

In the case of very short exposure durations at power densities/irradiances up to $10^{12}\,W/cm^2$, so-called optical breakdown happens. The electrical field amplitudes might have values of 1–100 MV/cm, which is comparable to the atomic or intramolecular Coulomb field, and therefore a microplasma is created, resulting in an ionizing effect. The rapid expansion of this plasma results in a shockwave and has the capability to destroy even the hardest substances in the human body.

If a photoacoustic effect occurs in the eye, a shockwave in the retinal tissue is induced that causes tissue rupture. This damage is permanent, as with a retinal burn. Acoustic damage is actually more destructive than a thermal burn. Acoustic damage usually affects a greater area of the retina, and the threshold energy for this effect is substantially lower. Table 25.1 summarizes these various effects.

All these effects are used in various medical treatments for the benefit of patients. In this case the application of laser radiation is under medical supervision and control, whereas involuntary exposure can result in a hazardous situation and/or damage of the respective tissue. This can be very dramatic if the eyes are involved, and therefore maximum permissible exposure limits have been established, based on the best available knowledge of these effects as a function of irradiance, radiant exposure, exposure duration, wavelength, size of the irradiated area, etc.

25.2.2 Effects of Laser Radiation on the Eye and Skin

Since laser radiation might be generated at nearly every wavelength in the range between 100 nm and 1 mm, various effects have to be considered as a result of acute or chronic exposure. Table 25.2 gives an overview of the various processes and effects that might predominantly happen in these wavelength regions in the eyes or skin, since these organs are the most susceptible to damage by laser radiation.

Table 25.1 Effects of laser radiation on biological tissue

Effect		
Photochemical	**Photothermal**	**Photoionizing**
Biostimulation	Hyperthermia	Ablation
	Coagulation	Disruption
	Carbonization	Fragmentation
	Vaporization	
$t = 10–1000\,s$	$t = 1\,ms–1\,s$	$t = 10\,ps–10\,\mu m$
$\leq 100\,mW$	$1–100\,W$	
$\leq 50\,mW/cm^2$	$1–100\,W/cm^2$	

The anatomical and physiological characteristics of the eye result in the most dangerous wavelength region being 400–1400 nm, where transmission of laser radiation from the cornea to the retina occurs, as can be seen in Fig. 25.4.

In this case most of the optical energy is absorbed by the photopigments (chromophores) of the retinal pigment epithelium, which has a layer thickness of about 10 µm, whereas not more than about 15% of the incident laser radiation is absorbed in the chromophores located in the cones and/or rods. As a result thermal damage is initiated in the RPE, but extends to the receptor cells in the retina and may, in addition, destroy the neuroretina, which contains horizontal, bipolar, and amacrine cells and finally projects onto the ganglion cells. Hazardous irradiation in the human eye can extend as far as the choroid.

Retinal Injuries

Photothermal damage might appear as a minimal lesion, where only a few receptor cells are destroyed, but at higher optical energy values much larger, permanent destruction may happen. A mild burn on the retina appears yellow or grey, and a white patch is produced at greater power. A lesion which is only visible as a slight discoloration is a threshold lesion. If a victim is looking directly into the beam (intrabeam viewing), he might receive a foveal burn; i. e., his center of vision is destroyed. If this region is damaged, the effect may appear initially as a blurred white spot obscuring the central area of vision; however, within two or more weeks, it may change to a black spot. Ultimately, the victim may cease to be aware of this blind spot (scotoma) during normal vision. However, it can be revealed immediately on looking at an empty visual scene such as a blank sheet of white paper. Figure 25.6 shows two examples of retinal injuries from a visible laser beam.

A burn in the peripheral retina may only cause a small scotoma, which may not be detected subjectively or even during a systematic eye examination.

Photoacoustic retinal damage may be associated with an audible pop at the time of exposure. Visual impairment due to retinal damage may not be apparent to the victim until considerable thermal damage has occurred. Hole burning and bleeding might also happen

Table 25.2 Effects of laser radiation as a function of wavelength region on the eye and skin

Wavelength region	Eye	Skin
UV-C: 100–280 nm	Photokeratitis (corneal inflammation, cornea surface absorbs all) Photoconjunctivitis	Erythema (reddening of the skin) Pre-carcinoma
UV-B: 280–315 nm	Photokeratitis Photoconjunctivitis Cataractogenesis (cataract formation)	Increased pigmentation Enhanced skin photoaging (accelerated skin aging) Erythema Edema Pre-carcinoma Carcinoma (skin cancer)
UV-A: 315–400 nm	Cataract formation (lens is principal absorber)	Acute pigmentation Enhanced skin photoaging Skin burns Carcinoma (skin cancer)
Vis: 400–700 nm	Photochemical and photothermal damage to the retina	Photosensitive reactions (photosensitization) Skin burns (reddening of skin, blisters, charring)
IR-A: 700–1400 nm	Cataract formation from heating proteins in the lens Photothermal retinal damage	Skin burns (reddening of skin, blisters, charring, damage to underlying organs)
IR-B: 1400–3000 nm	Cataract formation (corneal or lenticular opacities) Photothermal damage (burns) to the cornea	Edema of the skin Skin burns
IR-C: 3000–1 mm	Photothermal damage of the cornea	Skin burns

with sufficiently high power levels; i. e., in addition to field defects, hemorrhage and debris projected into the vitreous humor can permanently impair vision.

This kind of injury will be clearly noticed by the victim, whereas smaller retinal lesions might not even be recognized and can barely be found in a routine ophthalmoscopic inspection.

Exposure to a visible laser beam can be detected by the bright color flash of the emitted wavelength and an afterimage of its complementary color; e.g., a green 532 nm laser light would normally produce a green flash followed by a dominantly red afterimage.

Since laser radiation at wavelengths above about 700 nm is invisible to the human eye, near-infrared ra-

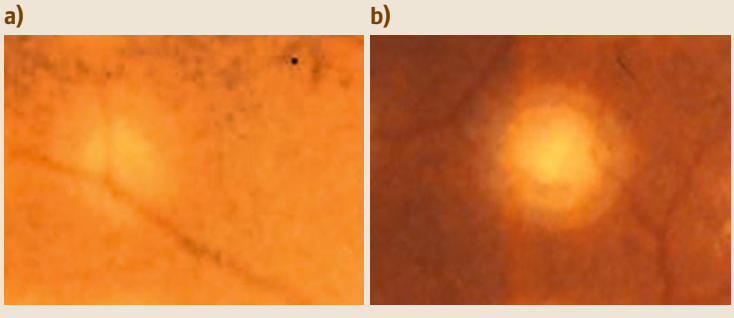

Fig. 25.6a,b Photothermal retinal lesions from a visible laser beam: **(a)** small lesion of about 150 μm; **(b)** lesion diameter about 500 μm

diation has to be regarded as particularly hazardous and might result in serious injuries. Exposure to the Q-switched Nd:YAG laser beam (1064 nm) is especially hazardous and may initially go undetected because the beam is invisible and the retina lacks pain sensory nerves. At these longer wavelengths photothermal effects still dominate for exposure durations in excess of 10 s, which is important when using near-infrared lasers in the CW mode.

The real extension of a retinal injury is very often not apparent directly after the laser irradiation, but several hours later. This is related to time-dependent processes that are incurred with thermal damage such that inflammation and repair processes have to be taken into account.

At lower irradiance values chronic injuries may result from laser radiation in the wavelength region of 400–600 nm, when the respective exposure duration is long enough, i. e., several seconds or more [25.7], and the so-called *blue-light hazard* exists. The explanation of such effects is given by a photochemically initiated process, which is not connected to a measurable temperature increase of the tissue. However, a small temperature rise in the retina appears to be synergistic with the photochemical effect. Photoretinitis is one of these special radiation-induced effects, which may even result in blindness; i. e., due to the photochemical processes, the respective photoreceptors are no longer able to fulfill their normal functions.

Damaging effects can also be the direct result of specific molecular absorption of a given light. Rather than releasing the energy, however, the species undergoes a chemical reaction that is unique to its excited state. This is what is known as the photochemical effect.

Nonretinal Injuries

In addition to retinal injuries, hazards are also possible in the ultraviolet and the mid- and far-infrared spectrum to the anterior parts of the eye, i. e., the cornea, conjunctiva, and lens.

Similar to the photochemically induced, so-called athermal, retinal injuries, photokeratitis and photoconjunctivitis, which are inflammations of the cornea and the conjunctiva, respectively, are both wavelength dependent and can be described by their respective action spectra. This is a characteristic of all photochemical effects, which show a relatively strong wavelength dependence and a maximum sensitivity.

In the UV-A part of the spectrum, the intensities or exposure durations required to produce photokeratitis or erythema are much greater than for so-called actinic UV radiation (UV-B and UV-C). The cornea and the skin are nearly as sensitive in the actinic UV region, but corneal damage is more painful.

In addition to these photochemical effects, lenticular cataracts may be formed by ultraviolet [25.8] and infrared radiation.

Exposure to the invisible carbon-dioxide laser beam (10 600 nm) can be detected by a burning pain at the site of exposure on the cornea or sclera. A corneal burn may be manifested as a surface irregularity or a white opacity (Fig. 25.7). In Fig. 25.7 the damaging capability of a short exposure of a 60 W CO_2 laser of the cornea is illustrated, where even the mode pattern of the laser beam can be seen. If the lesion is minor, i. e., restricted to the outer cellular layer, then it will heal and disappear within about 48 h. Deeper burns may cause permanent damage.

Figure 25.8 shows an example of a 1-s exposure with a 100 W Nd:YAG laser (1.064 µm) in a laboratory trial with an animal eye from a slaughterhouse, where it can be seen that even the anterior parts of the eye are destroyed by coagulation. Retinal damage was not the goal of this special investigation, but has certainly happened due to the high transmission at this wavelength and the focusing capabilities of the eye.

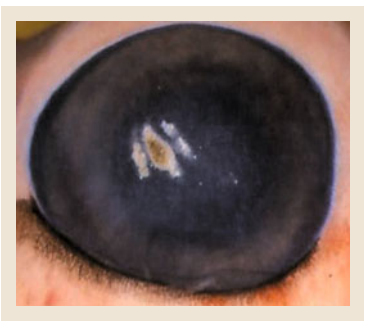

Fig. 25.7 Damage of the eye with a CO_2 laser with the mode pattern visible on the cornea (animal eye from a slaughterhouse)

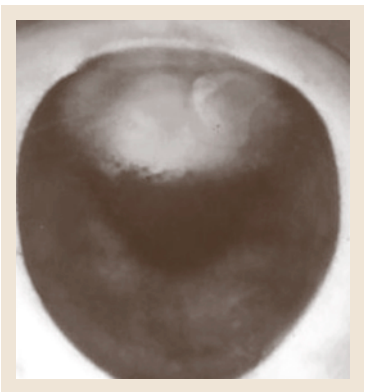

Fig. 25.8 Damage of the eye with a Nd:YAG laser (deep coagulation of the anterior parts; illumination with and scattering of an aimed He-Ne laser beam)

Injuries to the Skin

In contrast to eye injuries, any damage to the skin is of minor importance as far as skin burns are concerned, although even third-degree burns might not be completely excluded at higher laser power levels. Injury to the skin normally results from temperatures exceeding 45–60 °C, but this value is also time dependent.

Special care has to be taken if ultraviolet radiation is present, since erythema (skin reddening resulting from vasodilatation), edema (swelling), and even carcinoma might result from acute (short-term) or chronic (long-term) exposure.

Ultraviolet radiation may not only arise from UV lasers, such as excimer lasers, but also from so-called secondary optical radiation, which comes from various material-processing applications such as cutting and welding with high-power Nd:YAG or CO_2 lasers. Concerning its biological effect, it is not important whether it is coherent or incoherent radiation which interacts with biological tissue, but this characteristic clearly determines the smallest spot on the retina.

Exposure of the skin to high-power laser beams (1 W or more) can cause burns. At the sub-5 W level, the heat from the laser beam will cause a flinch reaction before any serious damage occurs. The sensation is similar to touching any hot object: you tend to pull your hand away or drop the object before any major damage occurs. With higher-power lasers, a burn can occur even though the flinch reaction may rapidly pull the affected skin out of the beam. These burns can be quite painful as the affected skin can be cooked and forms a hard lesion that takes considerable time to heal.

Figure 25.9 shows examples of tissue reactions and penetration depth achieved with an argon-ion laser, a CO_2, and a Nd:YAG laser. As can clearly be seen, the penetration depth is largest for near-infrared wavelengths, as might be explained from Figs. 25.4 and 25.5, whereas due to the high absorption in water or hemoglobin, the penetration depth is low with the CO_2 (10.6 μm) and argon-ion (450–515 nm) lasers.

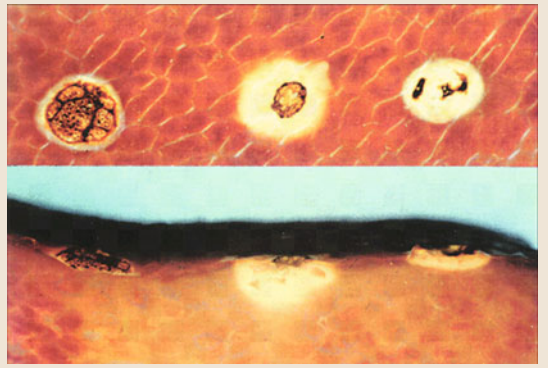

Fig. 25.9 Surface reactions (*top*) and penetration depth (*below*) of various laser beams (*left* to *right*: CO_2, Nd:YAG, and argon-ion laser), beam diameter: about 4 mm, tissue: liver

In addition to incoherent optical radiation, other secondary effects have to be taken into account when lasers are applied. To name but a few, the respective hazards might arise from electrical currents and high voltages, electromagnetic high-frequency fields, optical pump radiation, x-rays, explosive atmospheres, inflammable materials, and toxic and infectious or even carcinogenic liquids or solid materials.

The various so-called secondary physical and chemical agents associated with laser products and applications must be considered in the risk assessment and shall be restricted to a given level of exposure or dose.

25.3 Maximum Permissible Exposure

25.3.1 Threshold Values and ED-50

In order to protect human beings from any hazardous laser radiation, maximum permissible exposure (MPE) values have been established. The MPEs represent that level of laser radiation to which, under normal circumstances, persons may be exposed without suffering adverse effects. The MPE levels represent the maximum level to which the eye or skin can be exposed without consequential injury immediately or after a long time and are related to the wavelength of the radiation, the pulse duration or exposure duration, the tissue at risk, and for visible and near-infrared radiation at 400–1400 nm, the size of the retinal image.

Whereas these MPEs were very conservative at the beginning, many values were increased in later years due to improved investigation methods and more sophisticated models taking into account the various effects as a function of wavelength and exposure duration.

Since in many cases there is no distinct threshold value for humans, MPEs have been derived from experimental results on different animal species. Therefore, a certain degree of uncertainty exists as far as extrapolations from animal experiments to effects in humans have to be made. However, all currently available scientific knowledge indicates that the respective exposure limits (ELs) provide a safe level of protection against known biological laser radiation effects.

By agreement, the MPEs have mainly been established at 1/10 of the so-called effective dose 50% (ED-50) value, which is the value of irradiance or radiant exposure where an ophthalmoscopically visible lesion exists in 50% of irradiated cases. The ED-50 is also often referred to as the *threshold*. Since the slope of the probit curve is relatively steep, it might be expected that at 10% of the ED-50 no harmful effects can be found, and therefore the MPE values include this safety or reduction factor.

Not only individual susceptibility but also biological and biophysical variables affect the data, and therefore it is not possible to define a single safety or reduction factor between the threshold of an injury (observed effect) and the exposure limit.

As has been shown in different laboratory studies, microscopically visible injuries usually appear at between 25% and 50% of ED-50, but never at values less than 10% [25.9]. A safety or reduction factor of about 2 in the UV and 5–10 in the visible part of the spectrum is used for most corneal and retinal effects [25.9].

MPE values should be used as guides in the control of exposures, and should not be regarded as precisely defined dividing lines between safe and dangerous levels. In any case, exposure to laser radiation should be as low as possible.

The extent of injury varies considerably with wavelength, and therefore it is necessary to adjust the exposure limits and the MPEs for different wavelengths, but in a simple manner, i. e., by correction factors given as straight lines (potential functions or constants) in a logarithmic illustration; for example, this factor increases from 1 to 5 as the wavelength increases from 700 to 1050 nm. As a consequence of the increased absorption of laser radiation in the ocular media (Fig. 25.4), another factor has been introduced in the MPEs, which increases from 1 to 8 in the wavelength region between 1150 and 1200 nm.

At exposure durations exceeding about 10 s the difference between the ocular exposure limits for shorter wavelengths, i. e., below about 500 nm, and longer ones increases with greater exposure durations, since short-wavelength visible laser radiation causes predominantly photochemical retinal injuries; i. e., the MPEs are much lower for longer exposure durations at shorter wavelengths.

Since exposure limits are based on experimental results and on understanding of the possible photochemical, photothermal, photomechanical, and photoionizing interactions with biological tissues that should not cause adverse effects, it can easily be understood that there was and still is a lack of accurate data for some wavelengths, exposure durations, beam parameters, etc. Therefore worst-case exposure conditions have been assumed.

In addition, new and improved data have shown that some of the earlier exposure limits had overconservative safety factors, and revised exposure limits have been recommended.

One could certainly follow the contours of the experimentally achieved bioeffect threshold curves, as far as they exist, resulting in more gradual exposure limit curves, but up to now step functions and relatively simple mathematical functions have been used for the MPE values.

MPE values were derived to preclude not only acute effects but delayed adverse effects too. Since to date only limited data are available for chronic, long-term exposures, delayed effects might not be completely excluded. Until now no MPE values have been given for extremely long exposures, i. e., more than 8 h. On the other hand, intrabeam exposure situations seldom last more than 100 s. However, situations where long-term scattered or diffusely reflected laser radiation is present should be included in a risk analysis, especially in the case of occupational exposure.

25.3.2 MPE Values for the Eye

MPE values are given for the cornea and for the skin. The values for the cornea have been derived for worst-case situations, i. e., a pupil diameter of 7 mm and a stable image of the respective laser beam on the retina. Since these conditions might happen very rarely, e.g., with an anesthetized eye, the MPE values for the eye implicitly include an additional safety factor.

The pupillary aperture averages the radiant exposure and the irradiance. For many years a 7 mm aperture, corresponding to the dark-adapted, maximal, dilated pupil, has been standard. This is equivalent to a worst-case situation. The risk does not decrease proportionally with decreasing pupillary area when a point source is viewed [25.10]. In the visible and near-infrared region,

since laser radiation is focused on the retina, it does not matter whether the laser beam is 1 or 2 mm in diameter when it enters the pupil. Ultimately all the optical power/energy is concentrated into approximately the same spot on the retina.

Based on diffraction theory a retinal image diameter of about 3–6 μm would be expected, but the human eye is not such a good optical device and therefore a minimal image size of about 25 μm has been chosen for safety considerations, although somewhat smaller spots have been reported.

Point Sources and Eye Movements

In the case of CW exposure, physiological factors have to be taken into account whenever exposure situations are analyzed. Pupillary activity (pupillary reflex), eye movements (saccades, microsaccades, drift, tremor), breathing, heart beat, blood flow, and other bodily movements are the physiological factors that influence the exposure duration, being greatest for point sources and least for large, extended sources. On the other hand the person's visual task is also governed by visual fixations; i. e., there are periods when the retina fixes an object only on the fovea. The fixation time is normally about 200–400 ms, but depending on the level of processing or cognition, longer times might not be excluded. The eye movement studies of *Ness* et al. [25.10] clearly showed that the retinal image can remain remarkably still for a few seconds. It turned out in investigations that correction factors for eye movements were only important for viewing conditions longer than 10 s [25.9].

It has been shown that the expected image diameter of about 25 μm, which is equivalent to an angular subtense (visual angle) α of 1.5 mrad for an object of 150 μm at a distance of 100 mm, which is taken as a very conservative minimal distance of accommodation, and is given by the focal length of 17 mm, is blurred due to eye movements. The respective diameter increases to about 50 μm within an exposure duration of 250 ms for unrestrained head viewing, to 75 μm for 10 s, and it is rare to achieve an illuminated zone as small as 135 μm for 100 s [25.10].

As stated in a revision of the laser guidelines given by the International Commission on Non-ionizing Radiation Protection (ICNIRP) [25.11], the earlier recommendations for exposure limits have not been changed as far as exposure durations between 1 ns and 10 s are concerned, but due to the fact that the image is blurred by physiological reactions such as various eye and body movements, the safety factor is further increased. On the other hand the MPEs for longer exposure duration, i. e., longer than 10 s, have been increased, especially from 2001.

The accumulated radiant exposure in the retinal image area directly predicts the extent and position of photochemical retinal injury such as photoretinitis; i. e., fixation and eye movement studies have permitted the determination of the so-called *blue-light hazard* exposure limits. It is important to note that thermal retinal injury thresholds decrease for increasing retinal image or spot size due to radial heat flow during and after exposure.

Due to the influence of eye movements, the photothermal exposure limit is given as a constant irradiance of $1\,\mathrm{mW/cm^2}$ for point sources (i. e., $\alpha \leq 1.5$ mrad) in the visible part of the spectrum for exposure durations longer than 10 s. For longer exposure durations the photochemical exposure limit becomes the important part, especially below 500 nm.

It has been shown by modeling the exposure situation for longer exposure durations, taking into account experimental data relating to eye movements, that thermal damage of the retina is not possible with a laser beam power of 0.4 mW at the 632.8 nm wavelength of a He-Ne laser, which is equivalent to an irradiance of $1\,\mathrm{mW/cm^2}$ through a 7 mm pupil [25.12].

With the same model and a higher absorption in the green–blue part of the spectrum (cf. Fig. 25.4) it can be shown that a beam power of 5 mW can be sufficient to increase the retinal temperature by about 18 K, and can therefore result in protein denaturation, i. e., coagulation of the area on the retina. It should be taken into account that most of the thermal denaturation of proteins (coagulation) occurs after the pulse, which means that the geometry of the retinal exposure influences the lesion size. Radial heat flow is responsible for a relatively strong dependence of retinal injury on retinal image or spot size [25.13].

In addition, long-term irradiation with wavelengths shorter than about 500 nm can result in predominant photochemical damage of the retina. This is the main reason that exposure limits are lower for shorter wavelengths for longer exposures.

Extended Sources

In order to take into account that there is a difference concerning the image size and the dynamics of the thermal processes, an additional factor has been included in the MPE values. This is important for extended optical sources. Such cases might happen when diffuse surface reflections, transmission through a dif-

fusing translucent material or, e.g., laser-diode arrays have to be treated in safety considerations. Due to the optical imaging relationships for extended sources in the 400–1400 nm wavelength region, the correction factor increases from 1 for point sources and collimated beams up to 100/1.5 for a maximum angular subtense of 100 mrad, equivalent to a retinal image diameter of 1.7 mm. If the extension of the respective source is larger than 10 mm, no further increase of the MPE values occurs.

For collimated beams (focused at infinity) and point sources the angular subtense, i. e., the visual angle subtended by a circular source at a distance of, e.g., 100 mm at the eye, is denoted by α. If the value of α is greater than $\alpha_{\min} = 1.5$ mrad, so-called extended-source conditions apply. The angle α should not be confused with the beam divergence, which is a characteristic of the laser. The beam divergence is the far-field plane angle of the cone defined by the beam diameter, and the beam diameter at a point in space is the diameter of the smallest circle that contains a certain amount of the total laser power (or energy). For the purpose of standards dealing with laser safety, the percentage is taken to be 63%. In the case of a Gaussian beam, 63% corresponds to a diameter where the irradiance (radiant exposure) falls to $1/\mathrm{e}$ of its central peak value. It should be borne in mind that the beam diameter is very often taken in textbooks at the point where the intensity, i. e., the power density, falls to $1/\mathrm{e}^2$. In this case the amount of power/energy passing through an aperture with such a diameter would be about 86%. The relationship between both diameters is simply a factor of $\sqrt{2}$ in the case of a Gaussian beam (TEM_{00} or fundamental mode); i. e., the diameter corresponding to a decrease to $1/\mathrm{e}^2$ of the maximum value is larger by this factor compared with the diameter used in safety standards.

The consideration of image size in the exposure limits is done by applying another correction factor, which is related to the angular subtense. This simplifies the MPE values, since the point-source exposure limits simply have to be multiplied by this factor to yield the linearly increased extended-source exposure limits; i. e., limits applicable to extended sources are based on the intrabeam viewing exposure limits modified by a correction factor $\alpha/\alpha_{\min}$.

For biological effects, the irradiance or radiant exposure on the retina is important. These two quantities are directly proportional to the radiance or integrated radiance of the optical source, which are inherent characteristics of the source. This means that the energy entering the eye increases as the square of the diameter of the retinal image when an extended source is viewed [25.5]. Because of heat dissipation by the choroidal blood flow, this image-size dependence fails above about 100 mrad, which is equivalent to an image size of 1.7 mm.

For visual angles subtending the source that exceed 100 mrad the exposure limits increase as the square of the angle or can be expressed as a constant radiance.

Based on many years of experience in laser safety it is important to recognize that almost all hazardous ocular exposure conditions occur for intrabeam point-source or collimated-beam conditions. Extended sources very seldom pose a realistic hazard, but nevertheless should be treated with care, in order not to exceed the respective MPEs.

25.3.3 MPEs Given as Radiant Exposure and Irradiance

As an example, the MPE values for the radiant exposure H_{MPE} and the irradiance E_{MPE} are given for the wavelength region 400–700 nm as [25.11]

$$H_{\mathrm{MPE}} = 18 t^{0.75} C_{\mathrm{E}} \quad \text{in J/m}^2 \tag{25.6}$$

and

$$E_{\mathrm{MPE}} = \frac{H_{\mathrm{MPE}}}{t} = 18 t^{-0.25} C_{\mathrm{E}} \quad \text{in W/m}^2\,, \tag{25.7}$$

where $C_{\mathrm{E}} = \alpha/\alpha_{\min}$ for $\alpha_{\min} = 1.5\,\mathrm{mrad} \le \alpha \le \alpha_{\max} = 100$ mrad, and t is the exposure duration.

Because the thermal injury threshold, expressed as the radiant power entering the eye, decreases as the exposure duration raised to the -0.25 power, moderate increases in the exposed retinal area will compensate for the increased risk for longer viewing duration. A reduction of, e.g., only 44% results in a tenfold increase in the exposure duration. On the other hand, doubling the optical power and therefore the irradiance requires that the exposure duration be decreased by a factor of 16, i. e., only 6.25% of the former value is allowed, in order to stay below the MPE value.

From (25.6) and (25.7) the maximum optical power P_{MPE} can be calculated as

$$\begin{aligned} P_{\mathrm{MPE}} &= E_{\mathrm{MPE}} A \\ &= E_{\mathrm{MPE}} \frac{\pi}{4} d_{\mathrm{p}}^2 \approx 0.7 t^{-0.25} \quad \text{in mW}\,, \end{aligned} \tag{25.8}$$

where the diameter d_{p} of the pupil has to be taken as 7 mm according to IEC 60825-1 [25.14], and t is meas-

ured in seconds for ocular exposures in the wavelength range 400–1400 nm. The MPE values are not to be adjusted to take into account smaller pupil diameters as, for example, in situations where the pupil of the eye is smaller than 7 mm due to adaptation.

Table 25.3 presents some examples of maximum power and the corresponding maximum exposure duration $t \approx 0.23/P^4$ derived from (25.8).

A pupil size of 7 mm is certainly unrealistically large for longer exposure durations, since the pupillary reflex, which decreases the pupil diameter with a velocity of some millimeters per second and starts after a latency period of about 0.2–1 s, limits the incident optical power in the case of beams with a somewhat larger diameter. In addition, it is conservatively assumed that the retinal thermal injury threshold varies inversely with the retinal spot size.

For photochemically induced retinal injury such a relationship does not exist, but the threshold values are wavelength and dose (i. e., radiant exposure) dependent; i. e., the photochemical thresholds expressed as irradiances decrease inversely with lengthening exposure duration.

Outside the retinal hazard region, i. e., below 400 and above 1400 nm, the source size is not important and therefore the exposure limits are given without a correction factor based on the angular subtense.

In addition to alterations in the exposure limits for exposure duration above 10 s, exposure limits for pulse durations between 1 ns and 100 fs are recommended in the revised exposure limit guidelines [25.9]. The main reasons for this are that the corresponding data have not appeared to be consistent until recently and that the underlying damage mechanisms for subnanosecond laser-induced injury have not been well understood.

The development of exposure limits for very short laser pulses has been very difficult because of the different mechanisms involved. It was found that the damage produced by nonlinear effects does not follow the same relationship with wavelength, pulse duration, and retinal image size as thresholds from thermochemical (photothermal) and thermoacoustic injury or damage mechanisms [25.15, 16]. In addition, self-focusing of the ocular media further concentrates incident laser energy and increases the retinal radiant exposure.

For many years the ICNIRP has published guidelines on limits of exposure to laser radiation [25.9, 11], which have become part of various laser safety standards and especially Annex II of the so-called Artificial Optical Radiation Directive (AORD), which was published in 2006 [25.17]. The Member States of the European Union had to bring into force the laws, regulations, and administrative provisions necessary to comply with this directive by 27 April 2010. In the ICNIRP guidelines, recommendations are given that have been accepted in various standards, concerning the treatment of single-pulse laser exposure and exposure of the eye to any continuous-wave laser [25.11].

Aversion Responses Including the Blink Reflex; Active Protective Reactions

For exposure of the eye to a CW laser, an aversion response time of 0.25 s is recommended as an adequate hazard criterion, if purposeful staring into a visible laser beam is neither intended nor anticipated. A maximum exposure duration of 10 s is recommended for hazard analysis for either unintended or purposeful viewing conditions for ocular exposures of the eyes in the near infrared. These two recommendations are based on expected natural behavior.

There was a strong belief in aversion responses and especially in the blink reflex as a reliable physiological reaction if a bright light, such as laser radiation/light, is viewed. A laser source certainly represents a very bright light; for example, a 1 mW laser has a luminance (brightness) that exceeds even the luminance of the sun at noon. However, as has been shown in recent investigations, a class 2 laser is not sufficient to stimulate more than about 20% of people to perform a blink reflex [25.18, 19]. Aversion responses such as head and body movements are even less frequent, and therefore active protective measures such as those given in the adapted recommendations for class 2 and 2M (Table 25.4) are strongly recommended to prevent any hazard that might result from omission of the expected natural physiological behavior and prolonged exposure. This recommendation has now gone into the 2nd edition of the standard IEC 60825-1 in the informative description of the respective laser classes amongst other things [25.20].

Table 25.3 Maximum power P_{MPE} and exposure duration t (examples given for point sources and collimated beams, i.e., $C_E = 1$)

P_{MPE}/mW	0.39	0.5	0.6	0.7	1.0	2.0	4.0	5.0
t/ms	10 000	3700	1800	1000	250	15	1	0.37

Table 25.4 Laser classes according to IEC 60825-1 [25.14, 20] and additional advice for safety as a result of recent research studies

Class 1
The accessible laser radiation is nonhazardous under all reasonable foreseeable conditions. These conditions hold during the intended use and are valid including long-term direct intrabeam viewing, even when exposure occurs while using optical viewing instruments (eye loupes or binoculars). Class 1 lasers do not emit harmful levels of radiation. Although neither photochemical nor photothermal damage is possible, it might not be excluded that glare, dazzling, and reduction in color vision due to afterimages might happen, especially when the emitted power is close to the upper limit of class 1 laser products which emit visible radiant energy and intrabeam viewing occurs particularly in low ambient light.
Class 1M
The accessible laser radiation is restricted to the wavelength region between 302.5 and 4000 nm, since this is the preferred range where optical instruments are used. The accessible laser radiation does not pose any hazard for the eyes as long as the beam diameter is not decreased by optical instruments such as eye loupes, lenses, or telescopes. As long as no optical instrument that decreases the beam diameter is used, the hazard is similar to that of class 1. However, use of optically collecting instruments might result in hazards comparable to those for classes 3R or 3B. The optical power is limited to class 3B. This fact is the hidden hazard, which might become reality if either a diverging beam or a collimated beam with diameter larger than the measurement diameter according to the laser safety standard IEC 608251-1 is reduced with optical instruments so that the MPE can be exceeded and eye injury may occur. In addition, intrabeam viewing of class 1M laser products which emit visible radiant energy may still produce dazzling visual effects, particularly in low ambient light.
Class 2
The accessible laser radiation is restricted to the visible part of the optical spectrum, i. e., 400–700 nm. Additional radiation outside the visible spectrum has to fulfill the conditions of class 1. The laser radiation is nonhazardous for short-term or momentary exposure (i.e., up to 0.25 s), even for the eyes, but can be hazardous with deliberate staring into the beam. The classification time base of 0.25 s is inherent in the definition of this class, and it is presumed that there is very low risk of injury for momentary exposures that are somewhat longer. However, on the other hand it is believed that it is possible to stare long enough into a beam from a class 2 laser to cause damage to the eye. At least, there are a few reports where minor eye injuries happened. However there is some uncertainty in these cases as far as the actual laser output power is concerned. Since the eyes are not in danger as far as accidental and short-term exposure is concerned, laser products of class 2 may be applied without any additional protective measures if it is ensured that neither deliberate intrabeam viewing of more than 0.25 s nor repeated intrabeam viewing into a specular reflected laser beam could happen. However, it should be taken into account that neither the blink reflex nor aversion responses limit the exposure duration to 0.25 s, as was convincingly stated since the first edition of IEC 60825-1 in 1984 (at that time IEC 825 [25.21]) and was supposed until the second edition was released in 2007 [25.20]. It has been shown in a larger study that the frequency of the blink reflex is less than about 20% and aversion responses occur even less frequently [25.22–25]. These results are in agreement with investigations on human pupil and eyelid response found in another study as far as the frequentness of the blink reflex is concerned [25.26].

Table 25.4 (continued)

These findings do not state that class 2 lasers are no longer safe, but that users of such lasers should be instructed to perform active protective reactions, i.e., close the eyes actively and avert the head in the case of intrabeam viewing. These measures can increase the safety of laser class 2 sufficiently, as has been shown in an investigation [25.27], and prevent violation of the MPE values. The research results have been adopted now in the 2nd edition of the international standard IEC 60825-1 [25.20], and it is stated there now that "Users are instructed by labelling not to stare into the beam, i.e., to perform active protective reactions by moving the head or closing the eyes and to avoid continued intentional intrabeam viewing."

In addition to deterministic hazards, indirect effects such as temporary blinding are included in the description of laser class 2 now. The respective phrase in IEC 60825-1 provides the following information: "However, dazzle, flash blindness and afterimages may be caused by a beam from a Class 2 laser product, particularly under low ambient light conditions. This may have indirect general safety implications resulting from temporary disturbance of vision or from startle reactions. Such visual disturbances could be of particular concern connected with performing safety-critical operations such as working with machines or at height, with high voltages or driving." This consideration and view improves the safety for laser class 2 applications and takes into account more recent research results [25.28–30].

In the case of continuous-wave (CW) operation, i.e., for emission durations longer than 0.25 s, the optical power is limited to 1 mW, as far as collimated beams or point sources are considered. For extended sources the power might be increased by a correction factor depending on the angular subtense up to a maximum of about 66.7 mW.

Class 2M

The accessible laser radiation is restricted to the visible optical spectrum (400–700 nm). Additional radiation outside the visible spectrum has to fulfill the conditions of class 1M. Laser radiation from class 2M lasers does not pose any hazard to the eyes as long as the beam diameter is not decreased by optical instruments such as eye loupes, lenses, or telescopes.

In principle the same safety considerations as in the case of a class 2 laser are valid for class 2M lasers too. In addition, it should be taken into account that eye injury may occur following exposure with one of the two categories of optical viewing instruments (eye loupes or binoculars) under the following conditions:

– For diverging beams if the user places optical components within 100 mm from the source to concentrate (collimate) the beam

– For a collimated beam with a diameter larger than the measurement diameter specified for the respective classification rule.

Therefore, as long as no optical instruments that decrease the beam diameter are used, the hazard is similar to that in class 2 and the same recommendations are valid for class 2M. In addition, the use of optical collecting instruments might result in hazards comparable to those for classes 3R or 3B.

Especially since the optical power is limited to class 3B for class 2M, this fact might be regarded as a hidden hazard as in the case of class 1M, with the difference that the wavelength is restricted to 400–700 nm, i.e., the visible region. Nevertheless, care should be taken when handling such lasers.

Due to the fact that class 2M lasers have the capability to disturb vision in the case of intrabeam viewing, indirect effects arising from dazzle, flash blindness, and afterimages should be included in the risk assessment.

Class 3R

The accessible laser radiation is between 302.5 and 10^6 nm (1 mm or 300 GHz) and might be hazardous for the eyes.

Laser products belonging to this class are potentially dangerous, but the risk of eye damage is less than for class 3B due to the fact that the AELs are restricted to a much lower level.

Class 3R laser products emit radiation that can exceed the MPE under direct intrabeam viewing, but the risk of injury in most cases is relatively low, since the optical power or energy is a maximum of five times the AEL of class 2 between 400 and 700 nm and five times the AEL of class 1 for all other wavelengths.

Table 25.4 (continued)

In the case of CW operation the optical power is limited to 5 mW for collimated beams and point sources between 400 and 700 nm.
The risk of injury increases with exposure duration, and exposure is hazardous for deliberate ocular exposure.
Due to the fact that the maximum power is not large compared with class 3B, minor protective measures and safety requirements have to be fulfilled. However, any laser belonging to this class should be treated with care, since a fivefold excess of the MPE could result in minimal but nevertheless persistent defects on the retina.
This is especially important to consider since aversion responses including the blink reflex might not limit the exposure duration as required in the visible part of the optical spectrum.
As far as class 3R laser products in the visible wavelength range are concerned, at least the same safety instructions with respect to indirect effects arising from various effects of glare such as dazzle, flash blindness, and afterimages should be included in the respective risk assessment, if direct viewing might happen.
Concluding, the 2nd edition of IEC 60825-1 states in the description of this laser class that "class 3R lasers should only be used where direct intrabeam viewing is unlikely."

Class 3A

In the former edition of the international standard IEC 60825-1 up to 2001 this class was used for laser products that did not pose a hazard either for short-term exposure up to 0.25 s in the visible part of the spectrum or for long-term exposure at all other wavelengths, as long as no optical instruments capable of reducing the beam diameter sufficiently, i.e., to a diameter less than 7 mm, were used.
This laser class is not hazardous when viewed momentarily with the naked eye, but poses severe eye hazards when viewed through optical instruments (e.g., microscopes and binoculars).
This special class has a double limit: first, a power ceiling of 5 mW in the visible part of the optical spectrum, and simultaneously, a 25 W/m^2 limit, to restrict the power entering a 7 mm pupil to 1 mW, like in the case of a class 2 laser. This particular class has resulted in quite a lot of trouble, mainly due to the fact that some standards never incorporated these double limits. In addition, instead of class 3A, these laser products are labeled as class IIIA, IIIa or 3a, which resulted in many mistakes. Moreover, due to national regulations, many imported laser products have been classified incorrectly, e.g., a class IIIA laser product according to the ANSI standard has to be classified as a class 3B product wherever the EN 60825-1 standard is applied, and the manufacturer requirements according to this standard have to be fulfilled. In addition the user has to be familiar with the different demands concerning class 3B instead of class IIIA, which should not be confused with class 3A. In some cases there was a difference in labeling for class IIIA; i.e., if the power density did not exceed 25 mW/cm^2 a *caution* label was used, and if $E > 2.5\,mW/cm^2$ a *danger* label was used.
The misunderstanding arising from this situation has been overcome with the introduction of the new class 3R, where reduced requirements have to be fulfilled, but a certain risk, although not very high, does exist, especially for worst-case conditions, such as adjustment and alignment of the beam in intrabeam viewing and accommodation of the eyes.
Voluntarily staring into the beam would increase the risk of retinal eye damage; therefore, care has to be taken when the MPE values are exceeded.

Class 3B

The accessible laser radiation is normally hazardous for the eyes and often even for the skin. Intrabeam ocular exposure is especially dangerous when it occurs, i.e., within the nominal ocular hazard distance (NOHD), including accidental short-time exposure.
The classification of laser products into this class is based on the conditions that a reflection of a beam from a perfect diffuse reflector might be safely viewed from a distance of 13 cm for a 10 s period. However, diffuse reflection seldom exists and instead partially direct reflections should be considered in a risk assessment, especially when the maximum power of 500 mW in this laser class is used.
Even active aversion responses including active closure of the eyes are not sufficient to protect against laser radiation from such a laser.

Table 25.4 (continued)

In addition to the fact that the MPE values of the eye are exceeded, the same is true in general for the skin too. Class 3B lasers which approach the AEL for class 3B may produce minor skin injuries or even pose a risk of igniting flammable materials. However, this is only likely if the beam has a small diameter or is focused.
Class 4
The accessible laser radiation is very dangerous for the eyes and dangerous for the skin. Even diffuse scattered laser radiation might be hazardous. In addition, this laser radiation can result in fire and explosion. Lasers belonging to this class are regarded as high-power lasers, where the power or energy exceeds the AELs of class 3B. The laser radiation of class 4 laser products is so intense that damage can be expected for all kinds of exposure of the eyes or the skin. Special care has to be taken concerning fire and explosion hazards.
Note on laser class nomenclature The "M" in class 1M and class 2M is derived from magnifying optical viewing instruments. The "R" in class 3R is derived from reduced, or relaxed, requirements: reduced requirements both for the manufacturer (e.g., no key switch, beam stop or attenuator, and interlock connector required) and the user. The "B" in class 3B has historical origins, as in the pre-Amendment A2: 2001 version of the standard IEC 60825-1, a class 3A existed, which had a similar meaning to what is now class 1M and class 2M.

Temporary Blinding as an Indirect Effect Due to Viewing into a Low-Power Laser Beam

Safety considerations in the field of laser radiation have traditionally been restricted to maximum permissible exposure levels as a function of wavelength and exposure duration mainly; i. e., besides photochemical, photothermal, and photoacoustic effects, no other interactions have been incorporated in the specification of the various limit values. However, more recently a certain paradigm change is noticeable; i. e., indirect effects such as temporary blinding have been included in risk assessments and treatments of situations where intrabeam viewing of low-power laser emissions in the visible spectrum is likely. However, other than with the well-established limit values, there are no threshold values or durations as far as adverse effects or impairment of visual functions are concerned.

For the first time ever, there are instructions for the safe use of a laser as far as temporary blinding is regarded in a laser safety standard, namely in the 2nd edition of IEC 60825-1 [25.20]. The respective information is given for laser classes 2, 2M, and 3R (with visible wavelengths), and in a weaker manner for class 1 and 1M, likewise restricted to the visible spectrum. According to the laser safety standard, "dazzle, flash blindness and afterimages may be caused by a beam from a class 2, 2M or 3R laser product, particularly under low ambient light conditions". Simultaneously "temporary disturbance of vision or from startle reactions" are itemized as the main complications or effects which might be expected, especially associated with safety-critical operations (Table 25.4).

The fact that temporary blinding has to be included in the risk assessment demands further knowledge as far as the various parameters and their influence on the impact is concerned.

In an extensive study, indirect effects arising from bright laser beams as a result of temporary blinding have been investigated and the impairment of visual functions such as visual acuity, contrast sensitivity, and color discrimination was determined with the goal of improving current knowledge, especially as far as the recovery duration of visual functions is concerned. To date, a few relations for two wavelengths, namely 632.8 and 532 nm, can be quantitatively given for exposure durations between 0.25 and 10 s and laser output powers between 10 and 30 μW. To cite an example, the expected afterimage duration in seconds might be calculated from the relation $50.6 \ln(P\Delta t) - 13.4$, where P is the power of a red laser beam and Δt the exposure duration, with $(P\Delta t)$ in μJ, when the laser beam hits the fovea [25.29].

Glare might be defined as the dazzling sensation created by a very bright light, such as a laser beam. The

visual effects last only as long as the laser light is actually present affecting the individual's field of vision. This effect is similar to looking into the bright flash of a camera, and vision usually returns to baseline within a while, which is why it is called temporary blinding. Nevertheless, during this refractory time, an exposed individual is visually handicapped, especially due to the accompanying occurrence of an afterimage.

As has been found even at such a short exposure duration as 250 ms, which is taken as the so-called aversion response time or often equivalent to the blink reflex time and which is used as the classification time base for class 2, 2M and 3R lasers between 400 and 700 nm, a power of 0.39 mW (or about 0.1 mJ) results in a disruption between about 2.5 up to 10 or even 15 s. Such an exposure situation can easily be achieved with a class 1 laser in the blink of an eye. To give another example, the inability to read due to the disturbance produced by afterimages lasts for about 20 s even if the exposure duration is not more than 0.25 s from a laser with about 0.8 mW optical output power.

The wavelength-dependent relation for the two values investigated, i. e., 532 and 632.8 nm, might be approximated by a factor of about 1.5, whereas a factor of about 3.6 would be expected from a comparison of the respective Commission International de l'Éclairage (CIE) $V(\lambda)$ values for the luminous efficiency function which describes the average visual sensitivity of the human eye to light of different wavelengths. About 50% less optical energy is necessary for the shorter wavelength, which is closer to the maximum of the visibility function, to result in the same impairment of visual functions [25.30].

Up to now, there has been only one standard, namely ANSI Z136.6 [25.31], in which the following values are introduced for distraction of airline pilots: 100 nW cm^{-2}, dazzle: 10 μW cm^{-2}, and afterimages: 100 μW cm^{-2}, equivalent to 38.5 nW, 3.8 μW, and 38.5 μW, respectively, for a 7-mm aperture. Due to interindividual human differences it is not possible and even not reasonable to specify an exact threshold value as far as glare and its temporary effects are concerned, but the experimentally determined impact starts at even lower values than given in the ANSI standard.

Nonvisible Laser Radiation and Repetitively Pulsed Lasers

A duration of 10 s is regarded as sufficient for near-infrared exposure situations, since in this case eye movements will provide a natural physiological exposure limitation and thus eliminate the need to consider exposure durations greater than 10 s. Unusual situations, where even longer exposure durations have to be taken into account, should be treated in a special hazard analysis.

In the case of repetitive laser exposures, UV and non-UV lasers are treated differently. For UV lasers, the exposure dose is additive regardless of the repetition rate, whereas for visible and infrared laser the exposure limit per pulse for repetitively pulsed intrabeam viewing must be reduced by a correction factor of $N^{-0.25}$, where N is the number of pulses, i. e., the product of the pulse repetition frequency (PRF) and the total exposure duration (e.g., 0.25 or 10 s).

The thermal repetitive-pulse exposure obeys what is referred to as the additivity rule where the net effect is modified by the described correction factor [25.11]. This reduces the exposure limit for a single pulse in a train of pulses. However, if multiple pulses exist within a shorter duration than a wavelength-dependent minimal time, e.g., 18 μs for 400–1050 nm, the pulses are treated like a single pulse.

Although there is some lack of knowledge in special exposure situations, current knowledge of bioeffects from the last 40 years seems to be sufficient to establish guidelines for exposure limits. There is no special need for separate MPEs for the general population compared with occupational exposure as is the case for electromagnetic fields with frequencies below 300 GHz. Exposure limit values or maximum exposure limits are limits on exposure to laser radiation that are based directly on established health effects and biological considerations. Compliance with these limits will ensure that people exposed to artificial sources of laser radiation are protected against all known adverse health effects.

Exposure levels below the MPE should not result in adverse health effects, since the exposure limits incorporate the knowledge of scientific research and practical experience, based upon the best available information.

25.4 International Standards and Regulations

In the USA, the manufacturer of a laser product has to fulfill the legal requirements given in the Food and Drug Administration/Center for Devices and Radiological Health (FDA/CDRH) regulation 21CFR1040.10 [25.32], i. e., by the federal government, while the establishment of standards for laser users is left to the individual states.

The federal government of the USA has established requirements covering the manufacture in or import into the USA of any product containing lasers. These regulations provide for product classification and require certain product features and labels in accordance with the product class. The categories utilized are classes I, IIa, II, IIIa, IIIb, and IV, corresponding to increasing levels of hazard.

Standards exist on an international, regional, and national basis. As far as laser safety is concerned, the International Electrotechnical Commission (IEC) published a first standard in 1984. This standard IEC 825 [25.21] has been updated or amended several times and has been valid until 2001, when instead of five different laser classes, seven were introduced in IEC 60825-1 [25.14]. In 2007, a 2nd edition was released [25.20], where the previously included part of a *user's guide* was removed from the content and only *equipment classification and requirements* form the main content. The user's guide is shifted to a separate part, namely part 14 [25.33], which is a so-called technical report. Simultaneously, the MPE values are no longer in the mandatory body of the main standard IEC 60825-1, but have been shifted to an informative annex since 2007. This is especially important as far as European standards are considered, because it is no longer possible to give exposure limits in a standard since the European directive on physical agents (artificial optical radiation) came into force in 2006.

This is especially important since the standardization process has been governed since 1996 by the so-called Dresden Agreement between the standardization bodies CENELEC and IEC, which creates the framework necessary for an intensive consensus-finding process between European and international standard development activities. According to this agreement, all new standards worked out by IEC will always be conducted in parallel at CENELEC, and international standards are therefore automatically European standardization projects too. In addition, there is a so-called parallel voting procedure.

Since many national standard organizations are members of the IEC, the standard IEC 60825-1 is accepted as a horizontal product safety standard by many countries around the world. Due to the preceding agreement, this international standard is transferred into regional ones, such as the European standard EN 60825-1, which is published by the Commission Européenne Normalisation Electrotechnique (CENELEC) for its member states. All national standards based on regional ones such as the European Normalization (EN) standards must only be translated into the language of the respective country; i. e., alterations or modifications are not allowed in this process. This results in national editions of the fundamental laser safety standard such as DIN EN 60825-1 in Germany, BS EN 60825-1 in the UK, ÖVE/ÖNORM EN 60825-1 in Austria, AF EN 60825-1 in France, etc.

One important disparity between the CDRH requirements and the IEC standard reflects the fact that the IEC is not an enforcement body but only publishes standards written by expert committees. Implementation and enforcement depend on the laws and regulations of the individual nations.

The European standard EN 60825-1, which is equivalent today to IEC 60825-1, applies throughout the European Union (EU) and the European Free Trade Association (EFTA) countries and became increasingly important as it is referred to as a harmonized standard in the official journal of the EU under the *Low Voltage Directive (LVD) 2006/95/EC*.

However, in addition to the international standard IEC 60825, other standardizing organizations have developed their own standards dealing with laser products and laser safety. For a long time the standard ANSI Z136.1 [25.34, 35], which is edited by the American National Standards Institute (ANSI), has been a competitor in the standardization marketplace. The ANSI standard provides guidance for safe use of lasers and laser systems for four laser classes, i. e., 1, 2, 3, and 4, where the medium-power lasers are divided into two subclasses, 3a and 3b. For the purpose of the ANSI standard, laser products which have been classified earlier than 2000 as class IIa under the federal laser product performance standard should be treated the same as class 1. Due to a *laser notice* [25.36] published by the CDRH/FDA, there is now relatively wide-reaching agreement between IEC 60825-1 and ANSI Z136.1 since 2001. This so-called laser notice supersedes the

notice released in 2001 for the first time. In addition, ANSI Z136.1 includes an appendix where harmonization with the IEC 60825-1 is described in more detail and some differences are stressed.

Since standards are being developed as a market-regulating or supporting element in many cases, national and/or regional divergence is sometimes economically explainable, but for laser safety in general, a consistent and widely agreed level should exist. This is currently the case.

In addition to the general product safety standard IEC 60825-1, other safety requirements are specified in other relevant standards, e.g. for medical lasers [25.37], information technology or machinery [25.38].

For the safety of optical-fiber communication systems the standard IEC 60825-2 [25.39] provides guidance concerning products that enable laser radiation including light-emitting diode (LED) radiation for communications applications. Another part of IEC 60825 describes laser guards [25.40]. IEC 60825-12 is one of the younger standards of the IEC 60825 series and describes the safety of free-space optical communication systems [25.41]. In total, 13 parts of IEC 60825 (-1, -2, -3, -4, -5, -8, -9, -10, -12, -13, -14, -16, and -17) are currently published or exist as drafts.

25.5 Laser Hazard Categories and Laser Classes

Three aspects of the use of lasers need to be taken into account in the evaluation of the possible hazards and in the application of control measures:

- The capability of the laser or laser system to injure people. This includes any consideration of human access to the main exit port or any subsidiary port.
- The environment in which the laser is used.
- The level of training of the personnel who operate the laser or who may be exposed to its radiation.

The practical means for evaluation and control of laser radiation hazards is to classify laser products according to their relative hazard potential, and then to specify appropriate controls for each class. The use of the classification system will, in most cases, preclude any requirement for radiometric measurements by the user. In many cases it is therefore unnecessary to make use of the MPEs directly. The experience from laser use in industrial, scientific, and medical applications has permitted the development of a system of laser hazard categories.

Laser products are assigned, therefore, to different laser classes. This should aid the user in hazard evaluation of the laser and provide the necessary information concerning protective and control measures. Thus, the classification of laser products is based on the increasing degree of hazard or risk posed by the laser product. Currently, there exist seven classes, namely 1, 1M, 2, 2M, 3R, 3B, and 4 in IEC 60825-1. In addition, the laser class 3A exists, but new laser products have no longer been classified into this special category since 2001.

One of the main objects of the international standard IEC 60825-1 is to protect persons from laser radiation in the wavelength range 180 nm to 1 mm by indicating safe working levels of laser radiation and by introducing a system of classification of lasers and laser products according to their degree of hazard. In addition, requirements for both user and manufacturer to establish procedures and supply information are laid down so that proper precautions can be adopted. To ensure adequate warning to individuals of hazards associated with accessible radiation from laser products, signs, labels, and instructions have to be used.

The increasing classification number applies not only to an increasing hazard, i. e., the capability to cause an injury, but also to more protective measures as well, which form the requirements to be specified by the manufacturer and used by the user. The manufacturer is required to perform the classification and to label the laser product accordingly.

25.5.1 Accessible Emission Limits

The classification of laser products is based on so-called accessible emission limits (AEL), i. e., maximal power or energy values. The respective values are given in tables for the different laser classes in the product standard IEC 60825-1.

The determination and derivation of the AELs, although generally based upon the MPEs, necessitated a risk analysis and determination of reasonably foreseeable exposure conditions.

A main characteristic of the AELs is that the respective MPEs, which are valid for the time base of 30 000 or 100 s, are not exceeded for laser class 1. The AELs of class 1 are simply derived by multiplication of

the respective MPEs by the area of the averaging aperture as specified, e.g., 7 mm in the case of visible laser radiation. The time base of 30 000 s is used when intentional or deliberate and long-term exposure is intended, whereas 100 s is used when unintentional exposure is expected. However, in the case of ultraviolet radiation, 30 000 s always has to be used, since this shorter optical radiation shows dose-related effects.

The classification of a laser product has to be done by the manufacturer for normal use and maintenance under reasonable, foreseeable, so-called single-fault conditions.

Maintenance implies tasks which are necessary to ensure routine performance of the laser, i. e., maintenance might be done by the laser user. This includes tasks such as cleaning, and replenishing of expendables. Beam access is usually not required. This should not be confused with service, which is performed less frequently and usually requires beam access, e.g., to replace resonator mirrors or to repair components of the laser product.

The AEL for class 2 is derived by assuming an exposure duration of 0.25 s, i. e., the time base for class 2, and multiplying the MPE for 0.25 s for visible laser radiation by the area of a 7 mm aperture.

25.5.2 Description of the Laser Classes

The classes can be described as in Table 25.4. Besides the definitions in IEC 60825-1, some additional advice is given in order to improve the safety of working with lasers considering the latest findings, particularly for low-power lasers.

The maximum power of a laser product belonging to class 1M or 2M is limited to the AEL of class 3B. When exposure with optical instruments is unlikely, the use of class 1M and 2M lasers does represent a small risk, but if it is reasonably foreseeable that optical instruments might be used, controls and restrictions are required.

One of the main reasons to alter the former classification system, which was valid until 2001, has been that LED products have been included in the scope of the international standard IEC 60825-1 whenever the word "laser" is used. The newly defined measurement conditions for classes 1M and 2M had the effect that fewer LED products were classified at unrealistically high levels, e.g., 3B. In the meantime it was decided to remove LEDs from the scope of IEC 60825-1. This is the case now in the 2nd edition of the standard. LEDs are treated as lamps according to the Commission International de l'Éclairage (CIE) standard S 009 [25.42], except when used in combination with optical-fiber communication systems (OFCS) when IEC 60825-2 is applicable.

The standard S 009 has been published as the so-called dual-logo standard IEC 62471/CIE S 009 in its edition (2006–2007) on photobiological safety of lamps and lamp systems [25.43]. In this new standard, lamps including LEDs are categorized into so-called risk groups (exempt, low risk, moderate risk, and high risk, or RG 0, RG 1, RG 2, and RG 3).

In the meantime, a second part of this standard has been released [25.44]. IEC/TR 62471-2:2009 provides the basis for optical radiation safety requirements of nonlaser products, serving as a guide for development of safety requirements in vertical product standards and assisting lamp system manufacturers in the interpretation of safety information provided by lamp manufacturers. This technical report provides guidance on:

- Requirements for optical radiation safety assessment
- Allocation of safety measures
- Labeling of products.

Risk Analysis

In order to perform a risk analysis and to classify a laser product, the characteristics of the laser itself and its applications must be known. This means that the following data in particular should be available:

- Wavelength
- Mode of operation [continuous wave (CW), single pulsed, Q-switched, repetitively pulsed (scanning), mode locked, very short pulses (femtosecond laser)]
- Optical power (W) or optical energy (J or J/pulse)
- Pulse duration
- Pulse repetition frequency (PRF)
- Beam diameter
- Beam divergence
- Mode profile.

It is worth mentioning that for safety calculations the beam diameter and the beam divergence are taken at the $1/e$ decrease of the irradiance and not at $1/e^2$, which means that the corresponding values according to the standard are a factor of $\sqrt{2}$ less.

Beam Divergence and Nominal Ocular Hazard Distance

The beam produced by a laser does spread according to its divergence, which is the rate at which the beam spreads. The laser radiation covers a continually

larger area as it travels away from the laser product. This angle is measured in radians or milliradians and is usually very small compared with beams from other light sources. A typical divergence value for a laser is 1 milliradian (1 mrad). This means that the beam spreads such that its spot increases in diameter at a rate of 1 mm for every 1 m (1000 mm) from the laser.

Because the beam spreads at a fixed and measurable angle, the diameter of the beam can be determined at any desired distance from the laser. To approximate the beam size (diameter D) for long distances z one can use a linear equation

$$D = \text{divergence angle} \cdot \text{range} + a = \Theta z + a \,, \quad (25.9)$$

where z is the distance (range), Θ is the divergence angle, and a is the diameter of the beam at the aperture of the laser product.

When estimating the situation near the laser aperture, i. e., in the so-called near field, the following equation has to be used

$$D = \left[(\Theta z)^2 + (a)^2\right]^{1/2} \,. \quad (25.10)$$

From (25.9) the nominal ocular hazard distance (NOHD) can be calculated as

$$z = \text{NOHD} \geq \frac{1}{\Theta}\left[\sqrt{D^2} - a\right] \,, \quad (25.11)$$

and together with (25.8),

$$\text{NOHD} \geq \frac{1}{\Theta}\left[\sqrt{\frac{4P}{\pi E_{\text{MPE}}}} - a\right] \quad (25.12)$$

is obtained. This equation might be used to estimate the safe distance from a given laser source with a given optical power and beam divergence for the respective MPE value.

25.6 Protective Measures

The majority of injuries involve the eye and, to a lesser extent, the skin. The injuries occur mainly during alignment procedures, or because protective eyewear is either inappropriate or not used.

In order to reduce the possibility of injury by minimizing unnecessary accessible radiation and to give improved control of the laser radiation hazards through protective features and provide safe usage of laser products by specifying user control measures, IEC 60825-1 has been published.

Laser products require certain built-in safety features, depending on the class to which they have been assigned by the manufacturer.

Usually technical and engineering protective measures shall be applied to protect against hazardous laser radiation. The trivial and most effective solution is total enclosure of the laser (encapsulation) and of all accessible beam paths. If this is not possible, partial beam enclosure or restricted access to beam paths, and administrative controls have to be applied whenever possible instead of using personnel protective equipment (PPE) such as laser eye protectors (laser safety goggles).

The safest laser products rely upon engineered safety features. Technical measures might be divided into those measures that are part of the laser product itself or that have to be installed as a consequence of the degree of hazard of the respective laser product; for example, safety interlocks can isolate the laser if anyone enters an area of high risk.

25.6.1 Manufacturer's Requirements

According to the international standard IEC 60825-1 the manufacturer has to fulfill the appointed requirements in the standard. Table 25.5 summarizes these requirements. Details are given in the respective subclauses in the standard.

It is a pity that in the table which summarizes the manufacturer's requirements in IEC 60825-1 a class 2 laser is described as "low power; eye protection normally afforded by aversion responses" as far as the description of hazard class is concerned, since this is certainly not in full agreement with the more detailed description in annex C of the standard, where "active protective reactions by moving the head or closing the eyes" are clearly recommended, and besides that scientific research results have shown that physiological aversion responses might no longer be regarded as sufficient. Therefore, the given description is only helpful if aversion responses are used as synonymous for active protective reactions.

Table 25.5 Manufacturer's requirements (according to IEC 60825-1 [25.20])

Requirement	1	1M	2	2M	3R	3B	4
Protective housings		Required for each laser product; limits access necessary for performance of functions of the products					
Safety interlock in protective housing	Designed to prevent removal of the panel until accessible emission values are below that for class 3R				Designed to prevent removal of the panel until accessible emission values are below that for class 3B or 3R for some products		
Remote interlock	Not required					Permits easy addition of external interlock in laser installation	
Manual reset	Not required						Requires manual reset if power interrupted or remote interlock is actuated
Key control	Not required					Laser inoperative when key is removed	
Emission warning device	Not required				Gives audible or visible warning when laser is switched on or if capacitor bank of pulsed laser is being charged. For class 3R, only applies if invisible radiation is emitted		
Attenuator	Not required					Gives means to temporarily block beam	
Location controls	Not required				Controls so located that there is no danger of exposure to AEL above classes 1 or 2 when adjustments are made		
Viewing optics	Not required		Emission from all viewing systems must be below class 1M AEL				
Scanning	Scan failure shall not cause product to exceed its classification						
Class label	Required wording		Wording according to the respective figures in the standard				
Aperture label	Not required				Specified wording required		
Service access label	Not required	Required as appropriate to the class of accessible radiation					
Override interlock label	Required under certain conditions as appropriate to the class of laser used						
Wavelength range label	Required for certain wavelength ranges						
User information	Operation manuals must contain instructions for safe use. Additional requirements apply for class 1M and class 2M						
Purchasing and service information	Promotion brochures must specify product classification; service manuals must contain safety information						
Medical products	Not required					For the safety of medical laser products, IEC 60601-2-22 applies	

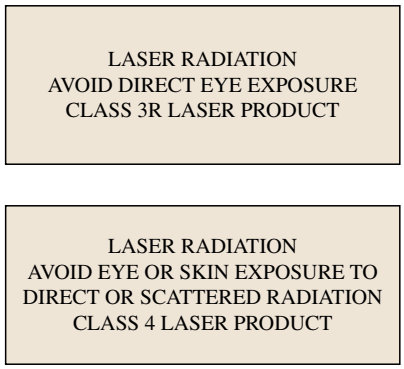
25.6.2 Technical and Engineering Measures

Table 25.6 gives an overview of technical and engineering measures as a function of the laser class and degree of hazard, whereas Table 25.7 gives some information concerning administrative measures. Protective housings with interlocks, service access panel with interlocks, master switch, key control, viewing portals/display screens, safe collecting optics, and enclosed or encapsulated open beam paths are all types of engineering controls. In addition a remote interlock connector, beam-stop attenuator, activation warning systems, and a controlled area where the nominal hazard zone (NHZ) has to be determined are required; equipment labels and area posting are required or recommended for class 3B and class 4 lasers.

For more specific and detailed information on manufacturing requirements the standard is obligatory. The warning labels for class 2, 3R (in the wavelength range 400–1400 nm) or 4 read as follows according to IEC 60825-1:

LASER RADIATION
DO NOT STARE INTO BEAM
CLASS 2 LASER PRODUCT

Table 25.6 Technical and engineering measures



Measure	1	1M	2	2M	3R	3B	4
Walls					Matt, light, diffuse reflecting		
Shielding					High absorption for the laser wavelength and effective against secondary radiation		
Nominal ocular hazard distance (NOHD)					Labeling of the boundaries/limits		
Beam warning; emission warning					Optical or acoustical at the entrance; on top of the laser product; only for nonvisible radiation	Optical or acoustical at the entrance; on top of the laser product	
Emergency switch	Dependent on the product-specific risk analysis						
Protective housing	Class 1 should be the goal						
Safety interlock					Designed to prevent removal of the panel; reliable implementation		
Remote control	Necessary if class 3B or 4 are embedded					At the door contact or connection of an emergency stop	
Key-switch; key control						Limited subgroup of people; remove key when laser is not used	
Viewing optics			Install laser filter; AEL of class 1/1M must not be exceeded				
Scanning	Scan failure shall not cause laser product to exceed its classification						
Class label	Required wording		Warning label/hazard symbol and required wording on explanatory label				
Aperture label					Specified wording required		
User information	Operation manuals must specify product classification and contain instructions for safe use						

Table 25.7 Administrative measures for the different laser classes. These are examples according to accident insurance at the workplace in Germany only; different regulations may be valid in other countries, institutions, etc.

Measure	1	1M	2	2M	3R	3B	4
Advice	Required when a laser class 3R, 3B or 4 is embedded				Registration of the laser product		
Laser safety officer (LSO)	In general not required				Required; written appointment		
NOHD Nominal hazard zone (NHZ)	In general not required, labeling necessary if the beam belongs to class 2 or 2M and passes the working place				Determination of the boundaries/limits; eventually for a limited duration; movable shielding during maintenance; the area must be posted with appropriate warning signs		
Laser protective filters	Not required as long as intrabeam viewing is not mandatory				Required* if engineering and administrative procedures are not practicable; ambient luminance should eventually be increased		
Special training	Not required	Required; written confirmation; at least annually					
Beam paths		Block the beam at the end of its path; avoid specular reflections					

According to the first edition of IEC 60825-1 an LSO was not required for class 3R laser products for visible emission
* According to the first edition of IEC 60825-1 eye protection was not required for class 3R; ANSI Z136.1 requires an LSO for embedded class 3a too if service is performed

Note: The requirements concerning the LSO and eye protection are no longer contained in the 2nd edition of IEC 60825-1 [25.20] but have been stated in the former edition [25.14]. Administrative measures are mandatorily stated in the special regulations of the responsible institutions or in national legislation.

The laser hazard symbol, the safety alert symbol, and information carried by the sign are different in IEC 60825-1 and ANSI Z136.1.

25.6.3 Administrative Measures

Administrative measures are an important backup for technical measures and controls. Administrative controls might be given by written standard operating procedures (SOP), maintenance and service procedures, output emission limitations, education and training, authorized personnel, controlled access, and a limit on the number of spectators, to name but a few. Lights and notices should warn people when they approach a laser hazard zone.

Laser Safety Officer

According to the former IEC 60825-1 [25.14] the presence of a laser safety officer (LSO) is not required when working with lasers classified less than class 3B. However, since class 3R was part of the former class 3B up to 2001, the requirement is still valid according to the regulations applicable, e.g., in Germany as far as occupational laser safety is concerned [25.45]. This is especially justified since the MPEs might be exceeded when working with class 3R lasers and the LSO is a person who is aware of the safe working practices with these laser products. The special responsibility of the LSO may be regulated according to national regulations. In some countries the LSO is an adviser or consultant only; in others he/she is a certified person, i. e., one who is knowledgeable in the evaluation and control of laser hazards and has responsibility for oversight of the control of laser hazards [25.46].

The complexity of the hazards associated with many laser systems has created the need for organizations to clearly identify those individuals with the proficiency necessary to manage advanced laser safety issues. The Board of Laser Safety (BLS) has developed a certified laser safety officer (CLSO) program, by which individuals who have demonstrated comprehensive knowledge in the area of laser safety may designate themselves a CLSO [25.46].

As an obligation of the European directive on artificial optical radiation [25.17], the 27 Member States of the European Union had to transpose this directive into national legislation.

In Germany the accident insurance regulations [25.45] took precedence over recommendations in a technical standard up to now, and the duties of an LSO have been mandatorily fixed for many years.

In principle the appointment of an LSO and his/her respective duties and responsibilities are a matter for national regulations and might therefore differ from country to country, being either more or less demanding. The Artificial Optical Radiation Directive 2006/25/EC will alter the current situation in the near future. However, this depends on the decision of the different countries on how they transpose the respective clauses laid down in the directive on minimum health and safety requirements regarding the exposure of workers. Since the LSO is not even mentioned in the directive, the laser community has been worried that the approved functions of an LSO might be lost [25.47].

In Germany the respective order was brought into force in July 2010 [25.48]. In this legal ordinance the designation of a LSO is required in clause 5, and this qualified person has to pass a course successfully. The respective contents of such a course will be laid down in a technical rule in the near future.

The main duties of the LSO according to the German order are:

- Support of the employer by the implementation of the necessary protective measures according to the risk assessment according to the state of the art.
- Supervision of safe operation of laser classes 3R, 3B, and 4 [25.47, 48].

The German order simultaneously will change the legal situation in this country, since the accident insurance regulation will be withdrawn and instead the new order has to be complied with from now on.

Although it is not clear what will be the requirements on the special course a person has to attend in order to obtain the essential information and instructions, the following main topics for a LSO training course are recommended [25.47]:

- Fundamentals of laser physics and radiation terms
- Hazard to eyes and skin from laser radiation
- Laser applications
- Laser classification
- Regulations for the safe use of laser products
- Protective measures including secondary hazards
- Personal protective equipment
- Duties of an LSO
- Miscellaneous.

Training and Education

Training and education is certainly one of the most important things which have to be done in advance of using certain lasers. Operation of class 1M and class 2M laser products where there is a need to use optical instruments, as well as class 3R, class 3B, and class 4 laser products, can represent a hazard not only to the user but also to other people over a considerable distance. Because of this hazard potential, only persons who have received training to an appropriate level should be placed in control of such systems. The training, which may be given by the manufacturer or supplier of the laser product, the laser safety officer, or by an approved external organization, should include, but is not limited to:

- Familiarization with system operating procedures
- Proper use of hazard control procedures, warning signs, etc.
- The need for personal protection
- Accident reporting procedures
- Bioeffects of the laser beam upon the eye and the skin.

25.6.4 Personnel Protective Equipment

Last but not least, protective equipment may be used to prevent hazardous situations or even damage to the eyes. This PPE should be in compliance with the respective standards. In Europe, PPE have to meet the essential safety requirements stated in a directive of the European Economic Community (EEC)/EU [25.49] and must be labeled with a Conformité Européenne (CE) mark.

Concerning adequate PPE, i. e., laser safety goggles, one has to determine wavelength and maximum viewing duration. The maximum irradiance or radiant exposure is calculated, and from these data an adequate level of protection is chosen.

In general, the following should be considered when specifying suitable protective eyewear:

- Wavelength of operation
- Radiant exposure or irradiance
- MPE value(s)
- Level of protection/optical density of eyewear at laser output wavelength
- Visible-light transmission requirements
- Resistance or radiant exposure or irradiance, at which damage to eyewear occurs
- Need for prescription glasses
- Comfort and ventilation
- Degradation or modification of absorbing media, even if temporary or transient
- Strength of materials (resistance to shock)
- Peripheral vision requirement
- Any relevant national regulations.

Protective eyewear should be comfortable to wear, provide as wide a field of view as possible, maintain a close fit while still providing adequate ventilation to avoid problems of misting up, and provide adequate visual transmittance. Care should be taken to avoid, as far as possible, the use of flat reflecting surfaces which might cause hazardous specular reflections. It is important that the frame and any side-pieces should give equivalent protection to that afforded by the lens(es)/filters. In addition, all laser eye protectors shall be clearly labeled with information adequate to ensure the proper choice of eyewear for use with particular lasers.

In Europe two standards exist which include the essential requirements for personal protective eyewear [25.50, 51]. These standards contain the necessary detailed information on the respective requirements. According to the standard EN 207, laser safety glasses should not only absorb laser light of a given wavelength, but they should also be able to withstand a direct hit from a continuous-wave laser during a duration of 5 s or 50 pulses in the case of a pulse laser without breaking or melting. In this respect, the European standard is stricter than the American standard (ANSI Z 136), which only regulates the required optical density but does not say anything about the capability to withstand a laser beam.

25.6.5 Beyond Optical Hazards

In some laser applications, mainly with class 4 laser products, in addition to optical hazards, control measures may be necessary for electrical and fire hazards, x-rays, noise, and airborne contaminants.

Most lasers utilize high voltages that can be lethal. Some lasers require hazardous or toxic substances to operate (i. e., chemical dye, excimer lasers). The sol-

vents used in dye lasers are flammable. High-voltage pulses or flash lamps may cause ignition. Flammable materials may be ignited by direct beams or specular reflections from high-power continuous-wave (CW) infrared lasers.

25.6.6 Recently Released and Future Regulations

Administrative regulations and controls are included in the current edition of the technical report IEC/TR 60825-14. This guide was part 3 of the main standard IEC 60825-1 [25.14], but was removed from the main body of the 2nd edition in 2007 [25.20]. However, guidelines for users in standards are only informative and not normative, since it is the right of the various countries to set local regulations according to the given laws, decrees, regulations, etc.

In the European Union, a *Directive of the European Parliament and of the Council on the minimum health and safety requirements regarding the exposure of workers to the risks arising from physical agents (optical radiation)* has been published as the 19th directive within the remit of article 16(1) of Directive 89/391/EEC [25.52]. Member States of the European Union had to bring into force the laws, regulations, and administrative provisions necessary to comply with Directive 2006/25/EC [25.17] by April 2010. In the meantime many countries have their special regulations now (see remarks in the Sect. 25.6.3 on laser safety officer).

It is one of the main goals of the treaty of the council of the EU, by means of directives, to adopt minimum requirements for encouraging improvements, especially in the working environment, to guarantee a better level of protection of the health and safety of workers. This will be done by the introduction of minimum health and safety requirements regarding the exposure of workers to the risks caused by physical agents, in this case by artificial optical radiation, which includes laser radiation.

The directive lays down minimum requirements, thus giving Member States of the EU the option of maintaining or adopting more stringent provisions for the protection of workers, in particular the fixing of lower exposure limit values. Adherence to the exposure limit values should provide a high level of protection as regards the health effects that may result from exposure to optical radiation.

Since the exposure limits in the European directive are in agreement with the values given in the ICNIRP guidelines, it might be expected that there is no strong influence as far as current regional laser safety regulations in Europe are concerned.

In the German order [25.48] there is a so-called gliding reference on the respective annex in Directive 2006/25/EC as far as the exposure limits are regarded. Austria, e.g., has added a table for the evaluation and assessment of the laser classes to the respective annex of the directive in its national order [25.53]. Unfortunately this order affirms that class 2 and 2M laser are *eye-safe* due to aversion response and the blink reflex and that exposure limits might be exceeded only if these physiological reactions are constricted or inhibited.

In order to facilitate implementation of Directive 2006/25/EC, the Commission shall draw up a practical guide to the articles dealing with the determination of exposure and assessment of risks as well as provisions aimed at avoiding or reducing risks. Such a guide was prepared by the UK's Health Protection Agency (HPA) under contract to the EU in the meantime and has been published [25.54]. The nonbinding guide provides a useful background into different types of optical radiation and describes what can be regarded as a simplified approach to assessing optical radiation exposure. In detail the following topics are dealt with in the guide:

- So what's in the nonbinding guide?
- What is optical radiation?
- Biological effects and exposure limits.
- The Artificial Optical Radiation Directive.
- Risk assessment.
- Practical assessments.
- Sources in the workplace.
- Practical control measures.
- What can go wrong?
- Sources of further information.

Laser safety is treated in several textbooks, handbooks, and publications from various institutions. In addition to the international, regional, and national standards, more detailed information on laser safety in general can be found in a recent publication [25.55], but nevertheless even more historical texts should be regarded as a source of information, especially if background knowledge is needed [25.56, 57]. Laser safety is dealt with on many Internet websites, although many of these need a thorough update.

25.7 Special Recommendations

Up to now the number of accidents has been low relative to the number of applications of lasers worldwide. However, nevertheless there is a risk, especially during situations such as beam alignment and working with high-power lasers, where even reflected beams might be hazardous.

The most dangerous situations and causes of ocular beam accidents besides exposure during alignment are misaligned optics, lack of training, improper restoration, intentional intrabeam viewing, use of multiple wavelengths, and last but not least when PPE are not utilized.

The beams of laser types such as ruby, argon ion, krypton ion, dye, He:Cd, SHG-Nd:YAG (second-harmonic generated, so-called green-lasers at 532 nm), He:Ne, and many diode lasers (semiconductor lasers) can all be focused on the retina, due to the fact that the ocular media are transparent. The same is true for Nd:YAG too, but in this case the beam is nonvisible, which enhances the risk. This is especially true for Q-switched Nd:YAG lasers, which have caused a lot of ocular incidents. In nearly all cases eye protection normally available was not worn in ocular incidents.

However, even with laser safety goggles, one cannot be sure of being adequately protected, since there exist a lot of eye protectors that do not guarantee resistance against a laser beam as stated in the European standard EN 207 [25.50]; rather, they are rated according to optical density only. This is an important characteristic of safety goggles, but might not be sufficient for high-power laser radiation. The European standard ensures not only a specified safety level for the laser eye protector but also resistance against damaging laser radiation of 5 s.

In addition to laser eye protectors, laser adjustment eye protectors are used, especially during adjustments. Laser adjustment eye protectors according to the relevant European standard [25.51] reduce the incident laser radiation to a value according to class 2 conditions, i. e., the safety is based on short-term exposure, and the blink reflex was chosen as an argument in the former edition of EN 208. In the 2009 issue it is pointed out in the annex on requirements for the application of laser adjustment eye protectors that a duration of 0.25 s will be to short to perform an aversion response, even for active reactions, as shown in recent research studies. Therefore a prolongation to 2 s, called the reaction time instead of the time base, is recommended in this standard, and reduced values for power and energy are given in the respective tables which incorporate the longer duration.

Due to the new findings, laser adjustment eye protectors should be used with care in order not to trust in this expected physiological reaction, but to perform active protective reactions (e.g., close the eyes and turn the head away) in case of intrabeam viewing with this kind of goggles. As recommended in the current issue of EN 2008 the choice of an adjustment eye protector according to the reaction time of 2 s certainly improves the safety of working with visible laser radiation and the respective laser classes emitting such beams.

Laser Pointers

It is not possible to close this chapter without the following remarks on the special topic of laser pointers.

On the subject of laser pointers, ICNIRP states that [25.58]:

> *based upon current medical knowledge a* 5 mW *laser is incapable of producing a permanent retinal thermal injury for a momentary (*0.25 s*) exposure under ideal optical conditions of exposure.*

In addition it is said [25.58, 59]:

> *Although an unintentional momentary intrabeam viewing will not produce a permanent retinal injury, it is theoretically possible to produce retinal photocoagulation in an eye with perfectly clear ocular media by staring at a collimated* 5 mW *laser beam for more than* 10 s.

According to the ICNIRP, one is assured that "in adults, the pupillary, blink, and aversion responses terminate accidental laser pointer exposures in less than 0.25 s". This clearly says that there is no realistic risk for permanent eye damage from a laser pointer, but at least on that score the statement is wrong, as has been shown in laboratory and field trials with more than 1500 volunteers [25.19], since the frequency of aversion responses including the blink reflex is less than 20%. It cannot be denied that physiological eye movements exist, as have been described above, but nonetheless one should avoid shining a laser pointer into anyone's eye, and it should be common sense not to stare into the beam of a laser pointer. Any person engaging in a trial to find out whether there is a risk or not could end up with a small but permanent eye injury. This is especially worthy of note since laser pointers are mass-produced devices where quality control is not a particular fea-

ture, which is supported by the fact that specimens with power of more than 10 mW have been found and such specimens would certainly be sufficient to produce permanent damage to the retina within a quarter of a second. Currently it is not very difficult to order a laser pointer with an output power of 250 mW or even 1000 up to 2000 mW – even for the general public. This is mainly the reason why the messages on attacks against airplanes and helicopters have achieved a serious dimension worldwide. It is therefore wise that some countries have restricted the sale or use of laser pointers above class 2 in order to increase safety against retinal injury. In addition, even green class 1 laser pointers could do the job, since their photopic brightness is much higher compared with red laser-diode pointers. Temporary blinding from laser pointers or similar laser devices should receive particular attention in the application of lasers emitting in the visible part of the spectrum.

Hazardous Situations

The following list contains some reasons for hazardous situations and common unsafe practices that are causes of preventable laser accidents:

- High retinal irradiance results when the beam is focused by the lens of the eye to create an extremely high retinal hazard risk for visible and near-infrared lasers.
- Low beam divergence resulting in a large intrabeam hazard distance.
- Not wearing protective eyewear during alignment procedures.
- Not wearing protective eyewear in the laser control area.
- Available eye protection not used.
- Wearing the wrong eyewear.
- Misaligned optics and upwardly directed beams.
- Equipment malfunction.
- Improper methods of handling high voltage.
- Intentional exposure of unprotected personnel.
- Bypassing of interlocks, door, and laser housing.
- Insertion of reflective materials into beam paths.
- Lack of preplanning.
- Turning on power supply accidentally.
- Operating unfamiliar equipment.
- Lack of protection from nonbeam hazards.
- High irradiance at the focal point of an external lens creating greater skin hazard risk.

In order to prevent laser accidents it is highly recommended to use the lowest possible or practical power, especially during alignments. It is recommended that the plane of the laser beam be above or below the level of a seated or standing person.

Perhaps the most important recommendation is never to aim a laser beam at a person, especially not at a person's eye. As quickly as it takes to blink – spontaneously or voluntarily – a laser beam can severely damage the eye. Though these injuries are relatively rare, they are permanent and can be avoided.

Acknowledgements

A.1 The Properties of Light

by Richard F. Haglund

The author thanks Prof. Emil Wolf for helpful discussions, and gratefully acknowledges the financial support of a Senior Scientist Award from the Alexander von Humboldt Foundation and of the Medical Free-Electron Laser program of the Department of Defense (Contract F49620-01-1-0429) during the preparation of this chapter.

A.4 Nonlinear Optics

by Aleksei Zheltikov, Anne L'Huillier, Ferenc Krausz

We acknowledge the support of the European Community's Human Potential Programme under contract HPRN-CT-2000-00133 (ATTO) and the Swedish Science Council.

A.5 Optical Materials and Their Properties

by Klaus Bonrad

The author of Sect. 5.10.2 is grateful to Dr. Thomas Däubler, Dr. Dirk Hertel, and Dr. Frank Voges for fruitful and stimulating discussions.

C.11 Lasers and Coherent Light Sources

by Gerd Marowsky, Peter Simon, Klaus Mann, Charles K. Rhodes

As well as the acknowledgements mentioned in the footnotes within the text, all authors would like to acknowledge very helpful discussions with A. Borisov, A. Görtler, J. Ihlemann, R. Pätzel and C. Peth, and other coworkers of Dr. Rhodes from the University of Chicago, Illinois. The patient assistance of T. Eggers and J. Jethwa is greatly appreciated as their support has been central to the final version of the text – both for the first as well as the second edition of this handbook. The part 13.5 nm *Technology* is based on a contribution from former coworkers of XTREME Technologies, Göttingen and Jena, Germany, in particular U. Stamm and G. Schriever.

by Helen Wächter, Markus W. Sigrist

The authors thank a number of coworkers for their valuable input, notably Dr. R. Bartlome, Dr. C. Fischer, Dr. D. Marinov, Dr. J. Rey, M. Stahel, and Dr. D. Vogler. The financial support by the Swiss National Science Foundation and ETH Zurich is gratefully acknowledged.

by Jürgen Helmcke, Fritz Riehle

In writing the chapter on frequency-stabilized lasers, the author has greatly benefited from fruitful cooperation and helpful discussions with his colleagues at PTB, in particular with Drs. Harald Schnatz, Uwe Sterr, and Harald Telle. Special thanks belong to Dr. Fritz Riehle for his careful and critical reading of the manuscript. Part of the work discussed in this chapter was supported by the Deutsche Forschungsgemeinschaft (DFG) under SFB 407.

C.12 Short and Ultrashort Laser Pulses

by Matthias Wollenhaupt, Andreas Assion, Thomas Baumert

Finally the authors would like to acknowledge Marc Winter for help in preparing various figures and like to thank Andrea Klumpp as well as Marc Winter for carefully proofreading the manuscript.

D.13 Optical and Spectroscopic Techniques

by Sune Svanberg, Wolfgang Demtröder

The author gratefully acknowledges a most stimulating collaboration with a large number of colleagues and graduate students in the field of laser-based remote sensing. This work was supported by the Swedish Space Board, the Swedish Natural Sciences Research Council, the FORMAS Research Council, the Knut and Alice Wallenberg Foundation and the European Community within the EUREKA-LASFLEUR (EU380), and the Access to Large Scale Facility/Research Infrastructure programmes.

D.20 Optics Far Beyond the Diffraction Limit

by Christoph Cremer

In the development of some of the nanoscopy approaches outlined above, at the Kirchhoff Institute for Physics numerous graduates, postgraduates, re-

search staff, and other partners have contributed, which are warmly thanked here (http://www.kip.uni-heidelberg.de/). The text presented here contains numerous quotations from joint original publications and previous reviews including in particular Brunner et al. (2011) and Cremer et al. (2011). The research was supported by grants of the University Heidelberg (Frontier Projects); the Land Baden-Württemberg/Landesstiftung Baden-Württemberg; the Deutsche Forschungsgemeinschaft (DFG); and the European Union.

D.24 Holography and Optical Storage

by Mirco Imlau, Martin Fally, Geoffrey W. Burr, Glenn T. Sincerbox

The authors acknowledge financial support by the Austrian Science Fund and the Deutsche Forschungsgemeinschaft. Mirco Imlau is indebted for a visiting professorship with the University of Vienna that considerably facilitated this work. We thank Romano Rupp for valuable comments and remarks.

About the Authors

Kiyoshi Asakawa

University of Tsukuba
Graduate School of Pure and Applied Science
Tsukuba, Japan
asakawa.kiyoshi.ga@u-tsukuba.ac.jp

Chapter B.8, Sect. 8.10

Kiyoshi Asakawa holds a Doctor of Engineering from the University of Tokyo (1992). He graduated from the University of Tokyo in Applied Physics in 1968 and joined the Central Research Laboratories of NEC Corporation in 1968, where built his career to Senior Research Scientist at the Optoelectronic Research Laboratory. Subsequently, he served as a Guest Researcher at the University of California, Santa Barbara (1987-1988) and as a Senior Group Leader at the Femtosecond Technology Research Association (FESTA) (1996–2004). From 2004–2008 he was Professor at University of Tsukuba, 2008–2010 Auditor /Visiting Researcher at the National Institute for Materials and Science. From 2010 to 2011 he was a Visiting Professor at University of Tsukuba where he worked on nanophotonics including nanofabrication technologies and photonic integrated device applications.

Andreas Assion

Femtolasers Produktions GmbH
Vienna, Austria
andreas.assion@femtolasers.com

Chapter C.12

Andreas Assion joined Femtolasers in January of 2005. Prior to joining Femtolasers, he worked with ultrafast lasers on the observation and control of quantum optical phenomena in atoms and molecules. He earned his Diploma and Doctorate studying molecular dynamical effects, including coherent control of complex molecules. After a post-doctoral position with the German Space Agency, he completed his Habilitation 2004.

Thomas E. Bauer

Optics Balzers Jena GmbH
Product Management
Jena, Germany
thomas.bauer@opticsbalzers.com

Chapter A.5, Sect. 5.7

Thomas Bauer is a physicist working at Optics Balzers Jena GmbH (former MSO Jena) as product manager. His main areas of interest are optical filter coatings.

Thomas Baumert

Universität Kassel
Institut für Physik
Kassel, Germany
baumert@physik.uni-kassel.de

Chapter C.12

Professor Baumert received is PhD with Prof. Gerber, University of Freiburg, Germany, in 1992. Further positions in his career were: 1992–1993, postdoc with Prof. Zewail, Caltech, Pasadena; 1993–1997, "Habilitation", University of Würzburg, Germany; 1998–1999, Head of LIDAR group, DLR Oberpfaffenhofen, Germany; 1999 Full Professor of Experimental Physics at University of Kassel, Germany. His research area: Femtosecond spectroscopy and ultrafast laser control of matter. Awards: Gödecke Thesis Award (1992), Heisenberg-Scholarship of DFG (1997–1998), Philip-Morris-Award (2000).

Dietrich Bertram

Philips Lighting
Aachen, Germany
dietrich.bertram@philips.com

Chapter C.10

Prior to joining the CTO office at Philips Lighting as technical officer solid-state lighting, Dietrich Bertram headed a project on LED light sources at Philips Research. His background education is physics, where he obtained a MS at Marburg University in epitaxy of III-V materials and a PhD from the Max-Planck Institute of Solid State Research, Stuttgart, Germany.

Klaus Bonrad

Merck KGaA
Performance Materials Division PM ATG
Darmstadt, Germany
klaus.bonrad@merckgroup.com

Chapter A.5, Sect. 5.10.2

Klaus Bonrad studied chemistry in Darmstadt and received his PhD from the~Max-Planck-Institute of Polymer Research in Mainz for synthesis and characterization of electrooptical macrocycles. After a post-doc position at Virginia Polytechnic Institute and State University in Blacksburg/USA, he worked for IBM and Schott Spezialglas AG in the field of organic light emitting diodes developing large area displays in Mainz. Since 2005 Klaus Bonrad works for Merck KGaA (Darmstadt). He spent one year in Japan for developing stacked OLEDs from solution and after his return he initiated and headed diverse projects within the OLED group. 2011 he became responsible for Merck's activities in the field of inorganic printed electronics.

Matthias Born

Philips Technologie GmbH
Innovative Technologies
Zentrum für Biomedizintechnik (ZBMT)
Aachen, Germany
matthias.born@philips.com

Chapter C.10

Matthias Born is a physicist and joined Philips Research Aachen, Germany, in 1992. He is leading several projects about plasma physics and diagnostics of gas discharges with a major topic on mercury-free lamps for general and automotive lighting applications. He is also working as a Professor of Physics at the Heinrich-Heine-University of Düsseldorf, Germany.

Annette Borsutzky

Kardinal-von-Galen-Gymnasium Hiltrup
Münster, Germany
bor@kvg-gymnasium.de

Chapter C.11, Sect. 11.9

Annette Borsutzky studied Physics in Bielefeld and Hannover, Germany, where she received in 1992 her Dr. rer. nat. working on nonlinear frequency mixing in crystals and gases. Joining the University of Kaiserslautern studies of optical parametric oscillators, diode-pumped solid state lasers as well as the characterization of new nonlinear and laser-active materials were at the center of her work.

Hans Brand

University of Erlangen-Nürnberg LHFT
Department of Electrical, Electronic and Communication Engineering
Erlangen, Germany
hans@lhft.eei.uni-erlangen.de

Chapter C.11, Sect. 11.4

Hans Brand received the degrees Dipl.-Ing. in 1956, Dr.-Ing in 1962 and Dr.-Ing. habil. in 1962 from the RWTH Aachen, Germany. In 1969 he became professor at the Chair for Microwave Engineering at the FAU Erlangen, Germany. His main fields of research are microwaves, millimeter wave and terahertz components and systems as well as gas laser and infrared laser technology. In 1996 he became Fellow of the IEEE. He is Emeritus since 1998.

Robert P. Breault

Breault Research Organization, Inc.
Tucson, AZ, USA
bbreault@breault.com

Chapter B.7

Robert P. Breault is the Chairman and Founder of the Breault Research Organization. He works on stray light analysis and suppression. He is the author of the APART stray light analysis program, used to analyze the Hubble telescope and many others. He received the BS in mathematics from Yale University, and his MS and PhD in optical sciences from the University of Arizona. He is a Fellow of SPIE and Founder and member of the Board of Directors of the Arizona Optics Industry Association.

Matthias Brinkmann

University of Applied Sciences
Mathematics and Natural Sciences
Darmstadt, Germany
matthias.brinkmann@h-da.de

Chapters A.5, B.8, Sects. 5.1.9, 5.11, 8.3

Dr. Brinkmann is a Professor of Optical Engineering at the University of Applied Sciences Darmstadt, Germany. He obtained his PhD degree in Physics from the Ruhr-Universität Bochum, Germany in 1997 for his work on high-temperature superconductors. Prior to joining the University of Applied Sciences Darmstadt, he worked as a staff scientist and research manager at Schott Glas Corporate Research in Mainz, Germany. His main scientific focus covered thermal material properties of glass and microstructured optical glass for photonic applications. His current research activities include diffractive microoptics for various photonic applications and modern lighting technologies.

Robert Brunner

SciTec University of Applied Sciences
Jena, Germany
robert.brunner@fh-jena.de

Chapter B.8, Sects. 8.1, 8.2, 8.4

Robert Brunner graduated from the University of Ulm in 1994 and received his PhD degree in the field of near-field optical microscopy. Between 1998 and 20009 he worked for the Research Center of Carl Zeiss where he was the responsible Lab Manager for Microstructured Optics. Since 2010 he holds the chair for applied optics at the University of Applied Sciences in Jena. His current research interests are hybrid diffractive/refractive optics, sub-wavelength structures, refractive microoptics, interference lithography and high-resolution optics.

Geoffrey W. Burr

IBM Almaden Research Center
San Jose, CA, USA
burr@almaden.ibm.com

Chapter D.24, Sects. 24.5–24.8

Geoffrey W. Burr received his BS in Electrical Engineering (EE) and BA in Greek Classics from the State University of New York at Buffalo in 1991. That year Eta Kappa Nu selected him as the Alton B. Zerby Outstanding EE Senior in the US. He received his MS and PhD in EE from the California Institute of Technology in 1993 and 1996, respectively. Since that time, Dr. Burr has worked at the IBM Almaden Research Center in San Jose, CA, where he is currently a Research Staff Member. He has worked extensively in holographic data storage. Dr. Burr's current research interests include phase-change and resistive nonvolatile memory, electrical device testing, and the physics of crystal nucleation and growth. He is a member of SPIE, OSA, IEEE, MRS, Eta Kappa Nu, and Tau Beta Pi.

Karsten Buse

Fraunhofer Institute of Physical
Measurement Techniques IPM
Freiburg, Germany
karsten.buse@ipm.fraunhofer.de

Chapter A.5, Sect. 5.10.3

Karsten Buse received his PhD from the University of Osnabrück, Germany. From 2000 to 2010 he was holding the Heinrich Hertz Professorship for Physics at the University of Bonn. Since 2011 he is the Director of the Fraunhofer Institute of Physical Measurement Techniques IPM in Freiburg and Kaiserslautern. In parallel he is building up a chair for Optical Systems at the Institute of Microsystems Engineering at the University of Freiburg. His research focus is on nonlinear-optical and photosensitive dielectric materials. He authored and co-authored more than 200 publications and holds more than 25 patents in this field.

Carol Click

Schott North America
Regional Research and Development
Duryea, PA, USA
carol.click@us.schott.com

Chapter A.5, Sect. 5.1.2, 5.1.3

Dr. Click received her PhD from the University of Missouri – Rolla in ceramic engineering focused in contamination in phosphate laser glasses. She is now involved in the research and development necessary to commercialize Schott's inorganic low-temperature reactive bonding technology for producing light-weighted Zerodur optics and precision optical components.

Christoph Cremer

Lightoptical Nanoscopy Institute of
Molecular Biology (IMB)
Mainz, Germany

University Heidelberg
Kirchhoff-Institute of Physics
Heidelberg, Germany
cremer@kip.uni-heidelberg.de

Chapter D.20

Christoph Cremer studied Physics at the Universities of Freiburg and Munich, Germany. Since October 1983 he is Professor for Applied Optics and Information Processing at the Kirchhoff-Institute of Physics, University Heidelberg, Germany, and since August 2011 Head of a Lightoptical Nanoscopy Group at the Institute of Molecular Biology (IMB) in Mainz, Germany. His research includes contributions to the development of laser-UV-microirradiation, confocal laser scanning fluorescence microscopy, 4Pi microscopy, structured illumination excitation, and spectrally assigned localization microscopy, as well as biomedical and biophysical applications of these techniques.

Mark J. Davis

Schott North America
Regional Research and Development
Duryea, PA, USA
mark.davis@us.schott.com

Chapter A.5, Sect. 5.1.5, 5.5

Mark Davis earned his PhD in Geology from Yale University in 1996, focusing on the kinetics of nucleation in glass-forming melts and related topics. Since then, his research has centered on the development of new glass-ceramic materials for a range of applications, in addition to continued efforts towards a more fundamental understanding of crystallization processes.

Giuseppe Della Valle

Politecnico di Milano
Department of Physics
Milan, Italy
giuseppe.dellavalle@polimi.it

Chapter C.11, Sect. 11.1

Giuseppe Della Valle received his PhD in Physics from the Politecnico di Milano in 2005. In 2007 he was awarded with the QEOD Thesis Prize of the European Physical Society. He is currently Assistant Professor of Physics at the Politecnico di Milano. Giuseppe Della Valle has authored more than 50 papers in peer-reviewed international journals in the fields of laser physics, photonics and nanooptics.

Wolfgang Demtröder

TU Kaiserslautern
Department of Physics
Kaiserslautern, Germany
demtroed@physik.uni-kl.de

Chapter D.13, Sects. 13.1, 13.2

Wolfgang Demtröder studied Physics, Mathematics and Science of Music at the Universities of Münster, Tübingen and Bonn. He received his PhD in 1961 with Prof. Paul in Bonn. He was research assistant in Freiburg, visiting fellow at JILA in Boulder, Colorado and since 1970 he is Professor of Physics at the University of Kaiserslautern, and visiting Professor at the Universities at Stanford (USA), Kobe (Japan), New South Wales in Sydney (Australia) and at the Technical University in Lausanne (Switzerland). His fields of research are high-resolution laser spectroscopy of molecules and metal clusters, time-resolved spectroscopy, spectroscopy of collision processes. He received the Max Born Prize in 1994 and the Heisenberg Medal in 2001. Since 2000 he is retired but still active in science as author of textbooks and as chairman of the selection committee of Laser Lab Europe. He has followed invitations as visiting professor at the MPQ for Quantum Optics in Garching and the University of Konstanz.

Frank J. Duarte

Interferometric Optics
Rochester, NY, USA

University of New Mexico
Electrical & Computer Engineering
Albuquerque, USA
drfjduarte@gmail.com

Chapter C.11, Sect. 11.8

Frank J. Duarte has made key contributions to the development of tunable lasers and introduced the multiple-prism grating dispersion theory applicable to narrow-linewidth oscillator design and pulse compression. He is also working on very large N-slit laser interferometers and the application of Dirac's notation to classical and semi-classical optics. He is cited in some 140 scholarly books including several classics.

Henrik Ehlers

Laser Zentrum Hannover e.V.
Department of Thin Film Technology
Hannover, Germany
h.ehlers@lzh.de

Chapter A.6

Henrik Ehlers is working as a physicist in the field of optical thin films. He received his PhD from the University of Hannover and is currently Head of the Process Development Group in the Department of Thin Film Technology at the Laser Zentrum Hannover. The focus of the group is on R&D in modern deposition processes, in situ process monitoring, and advanced process automation.

Rainer Engelbrecht

University Erlangen-Nürnberg
Department of
Electrical-Electronic-Communication
Engineering
Erlangen, Germany
rainer@lhft.eei.uni-erlangen.de

Chapter C.11, Sect. 11.4

Rainer Engelbrecht graduated in electrical engineering at the Friedrich-Alexander-University Erlangen-Nürnberg (FAU) and received his PhD in 2001 for gas analysis in CO_2 lasers by diode laser spectroscopy. Presently he is an Academic Director and the team leader of the photonics laboratory at the Chair of Microwave Engineering and High Frequency Technology at the FAU. His current fields of research include nonlinear fiber optics, Raman fiber lasers, fiber-optic sensors, and medical applications of lasers and photonics.

Martin Fally

University of Vienna
Faculty of Physics
Vienna, Austria
martin.fally@univie.ac.at

Chapter D.24, Sects. 24.1–24.4

Martin Fally earned both his PhD in Physics (1996) and his Habilitation in Solid-State Physics (2003) from the Vienna University, Austria. Since then he is Associate Professor at the Faculty of Physics. In 2003–2004 he held a Mercator Visiting- Professorship at the University of Osnabrück, Germany. He authored or co-authored more than 80 publications mostly in the fields of holography, photorefractive materials and neutron optics (experimental and theoretical). In 2001 he was awarded the Prize of the City of Vienna for research in natural sciences.

Yun-Hsing Fan

Finisar Shanghai, Inc.
Shanghai, Pudong Destrict, China
claire.fan@finisar.com

Chapter A.5, Sects. 5.10, 5.11

Dr. Yun-Hsing Fan is currently a senior NPI manager at Finisar (Shanghai, China). She received her PhD in optics from College of Optics and Photonics, University of Central Florida in 2005. Her current acitivities focus on using liquid crystal (LC) photonic devices for optical communications.

Enrico Geißler

Carl Zeiss AG
Central Research and Technology
Jena, Germany
e.geissler@zeiss.de

Chapter B.8, Sect. 8.5

Enrico Geißler completed his studies of electrical engineering at the University of Applied Sciences Jena, Germany, in 1998. Since graduation he has been at the Research Center of Carl Zeiss, where he is currently Senior Scientist for Digital Visualization Systems. His current research interests are spatial light modulators and MEMS.

Ajoy Ghatak

Indian Institute of Technology Delhi
Physics Department
New Delhi, India
ajoykghatak@yahoo.com

Chapter D.14

Ajoy Ghatak has published more than 170 research papers in international journals and has authored several books related to fiber optics, quantum mechanics and special theory of relativity. He is a Fellow of the Optical Society of America (OSA) and also of SPIE. He is the recipient of the 2008 SPIE Educator Award, the 2003 OSA Esther Hoffman Beller Award, the 1998 International Commission for Optics Galileo Galilei Award and the 1979 CSIR S.S. Bhatnagar Award. His areas of interests are fiber optics and quantum mechanics.

Michele Gianella

ETH Zurich
Institute for Quantum Electronics
Department of Physics
Zurich, Switzerland
michele.gianella@phys.ethz.ch

Chapter C.11, Sect. 11.10

Michele Gianella received his PhD in physics from ETH Zurich, Switzerland, in 2011, where he studied the chemical composition of surgical smoke with near- and mid-infrared laser spectroscopy. Since 2011 he is a postdoc at the Institute for Quantum Electronics at ETH Zurich, where his research focuses on the sensing of cocaine in saliva with laser spectroscopic techniques.

Alexander Goushcha

Aliso Viejo, CA, USA
goushcha@cox.net

Chapter B.9

Dr. Alexander Goushcha (aka Gushcha) is a VP Technology and CTO at Array Optronix, Inc. He obtained his PhD in Physics from the Institute for Physics, Ukrainian Academy of Sciences in Kyiv (Ukraine). He has been working in the fields of semiconductor physics and technology, biophysics and molecular electronics, and nonlinear optics at the Institute for Physics, Kyiv, Ukraine, MPI Strahlenchemie, Mülheim a.d. Ruhr, Germany, and UC Riverside, CA. Dr. Goushcha is the author of about 100 technical papers in referred journals and holds over 25 patents and patent applications.

Daniel R. Grischkowsky

Oklahoma State University
Electrical and Computer Engineering
Stillwater, OK, USA
daniel.grischkowsky@okstate.edu

Chapter D.21

Daniel R. Grischkowsky is a Regents Professor and the Bellmon Professor of Optoelectronics at Oklahoma State University. He received his BS from Oregon State University in 1962 and his PhD degree in Physics from Columbia University in 1968. In 1969 he joined the IBM Watson Research Center, Yorktown Heights, New York, where he developed and experimentally verified the adiabatic following model in 1972. In 1982 his research group developed the optical-fiber pulse compressor, and later in 1989 developed the technique of THz time-domain spectroscopy (THz-TDS). In 1993 he relocated to Oklahoma State University to pursue THz-TDS, and THz Photonics applications. He is a fellow of The American Physical Society (APS), The Institute of Electrical and Electronics Engineers (IEEE) and The Optical Society of America (OSA). He was awarded the Boris Pregel Award (1985) by the New York Academy of Sciences, the R.W. Wood Prize (1989) from OSA, the William F. Meggers Award (2003) from, and the 2011 Kenneth J. Button Prize from the International Society of IR, mm and THz Waves.

Malte Hagemann

University of Applied Sciences
Mathematics and Science Faculty
Darmstadt, Germany
malte.hagemann@h-da.de

Chapter B.8, Sect. 8.3

Malte Hagemann studied optical engineering and image processing at the University of Applied Sciences Darmstadt and received his diploma for results on high-intensity laser-beam diagnostics at the GSI Helmholtzzentrum für Schwerionenforschung, Darmstadt. In his doctoral thesis he discusses the electrooptical optimization of organic light-emitting diodes. His current research focuses on the optimization of beam-shaping optics for LED lighting technologies.

Richard F. Haglund

Vanderbilt University
Department of Physics and Astronomy
Nashville, TN, USA
richard.haglund@vanderbilt.edu

Chapter A.1

Professor Haglund earned his PhD in Experimental Nuclear Physics from the University of North Carolina, Chapel Hill. He was staff member, Los Alamos National Laboratory from 1975 to 1984. Since 1984 he is Professor of Physics at Vanderbilt University. He was Alexander von Humboldt awardee in 2003 and is a Fellow of the American Physical Society. His current research activities are in plasmonics, metamaterials and excton-plasmon coupling; size and dimensional effects in metal-insulator transitions; and mid-infrared laser processing of polymers and organic materials.

Theodor W. Hänsch

Max Planck Institute of Quantum Optics
Garching, Germany
t.w.haensch@mpq.mpg.de

Chapter D.17

Theodor W. Hänsch received his doctoral degree from the University of Heidelberg in 1969. He is currently a Director at the Max Planck Institute of Quantum Optics and a Professor at the Ludwig Maximilian University in Munich, Germany. For his research in the field of laser spectroscopy and ultracold quantum gases, he has been awarded numerous prizes, including the 2005 Nobel Prize in Physics.

Joseph Hayden

Schott North America
Regional Research and Development
Duryea, PA, USA
joe.hayden@us.schott.com

Chapter A.5, Sects. 5.4, 5.11

Dr. Joseph Hayden has a BS in Physics from Saint Joseph's University and a PhD in Chemical Physics from Brown University. He joined the Schott Group in 1985, where he has worked in glass composition and process development with emphasis on laser, nonlinear and technical glasses. He is presently a Research Fellow at Schott's North American Research and Technology Development site in Duryea, Pennsylvania.

Joachim Hein

Friedrich-Schiller-University
Institute for Optics and Quantum Electronics
Jena, Germany
jhein@ioq.uni-jena.de

Chapter C.11, Sect. 11.13

Dr. Joachim Hein is a scientist at the faculty of physics of the University of Jena since many years. He is working on femtosecond lasers, new laser materials for broadband amplification and applications of ultra-high peak power light sources. He is an expert for diode-pumped high-energy laser systems as well as solid-state laser design and modeling.

Jürgen Helmcke

Physikalisch-Technische Bundesanstalt (PTB)
Braunschweig, Germany
juergen.helmcke@ptb.de

Chapter C.11, Sect. 11.14

Until his retirement at the end of 2003, Dr. Jürgen Helmcke headed the~Department Quantum Optics and Length Unit' at the Physikalisch-Technische Bundesanstalt in Braunschweig, Germany. His main interests are in the fields of precision laser spectroscopy, laser cooling, optical and atom interferometry, and optical frequency measurements. From 1977 to 1978 he spent a year as NATO scholar with Dr. John L. Hall at the Joint Institute of Astrophysics in Boulder, CO. In 1999, together with F. Riehle, H. Schnatz, and T. Trebst, J. Helmcke received the Helmholtz Price of Metrology for the paper "Atom interferometer in the time domain for precision measurements".

Hartmut Hillmer

University of Kassel
Institute of Nanostructure Technologies and Analytics (INA)
Kassel, Germany
hillmer@ina.uni-kassel.de

Chapter C.11, Sect. 11.3

Professor Hillmer received his doctor and habilitation degrees from Stuttgart and Darmstadt University, respectively. He worked 10 years in telecommunication industry (German Telekom and NTT Japan) on design, implementation and characterization of fast and tunable semiconductor lasers. As a full Professor at Kassel University since 1999, he deals with optical MEMS and nanotechnology and is a coordinator in the Hess Nano Network (nnh10-9). He published more than 200 papers, holds 15 patents and received the European Grand Prix of Innovation Awards 2006.

Günter Huber

Universität Hamburg
Institut für Laser-Physik
Department Physik
Hamburg, Germany
huber@physnet.uni-hamburg.de

Chapter C.11, Sect. 11.2

Guenter Huber is Professor of Physics at the Institute of Laser-Physics, University of Hamburg, Germany. His research on solid-state lasers includes the growth, development and optical spectroscopy of laser materials, new diode-pumped lasers in the near infrared and visible spectral region, as well as up-conversion and waveguide lasers. He is Fellow of the Optical Society of America, the European Physical Society and received the Quantum Electronics and Optics Prize of the European Physical Society in 2003.

Mirco Imlau

University of Osnabrück
Department of Physics
Osnabrück, Germany
mimlau@uos.de

Chapter D.24, Sects. 24.1–24.4

Dr. Imlau studied physics at the University of Cologne, where he received his PhD for work on optical nonlinearities in centrosymmetric molecular crystals. Since 2002 he is Professor at the University of Osnabrück and Head of the Optics/Photonics Research Group. His research is focused on ultrafast phenomena in advanced dielectrics. Main topics include the study of optical nonlinearities related to the optical formation of small polarons and to photoinduced linkage-isomerism in small transition-metal compounds. Having his expertise in holography, he authored more than 80 publications in refereed journals, 5 book chapters, and 10 international patents. He received a visiting professorship for holographic materials at the university in Vienna in 2005.

Kuon Inoue (deceased)

Chapter B.8, Sect. 8.10

Thomas Jüstel

University of Applied Sciences Münster
Steinfurt, Germany
tj@fh-muenster.de

Chapter C.10

Thomas Jüstel studied Chemistry at the University of Bochum from 1987 to 1992. He received his PhD in Coordination Chemistry in 1995 in the Before joining Philips Research, he worked as a postdoctoral fellow at the MPI Mühlheim for Radiation Chemistry. From 1995 to 2003 he was with Philips Research Laboratories Aachen as a Research Scientist, where he started to work on luminescent materials. In 2004, he became a Professor for Inorganic Chemistry and Material Sciences at the University of Applied Sciences in Münster. His current research at Philips and at the University deals with nanoscale materials and novel luminescent materials for LEDs, UV radiation sources and x-ray detectors. His work has been published in 60 papers and lead to more than 150 patents on luminescent compositions and their application in fluorescent lamps, plasma displays, and LEDs.

Jeffrey Kaiser

Spectra-Physics
Division of Newport Corporation
Mountain View, CA, USA
jeff.kaiser@spectra-physics.com

Chapter C.11, Sect. 11.5

Jeffrey Kaiser is a Product Manager in the Spectra-Physics Division of Newport Corp. He has held a variety of positions in marketing, product development, engineering, and manufacturing for gas lasers. He holds several patents in gas-laser technology. He received his MS in Applied Physics from Stanford University and BS in Physics from Purdue University

Eckhard Krätzig

University of Osnabrück
Physics Department
Osnabrück, Germany
eckhard.kraetzig@uos.de

Chapter A.5, Sect. 5.10.3

Eckhard Krätzig received his PhD in Physics from the Johann Wolfgang Goethe University of Frankfurt/Main, Germany in 1968. Then he joined the Philips Research Laboratories Hamburg, where he headed the Solid State Physics Group. Since 1980 he has been a Professor of Applied Physics at the University of Osnabrück. During the last years his research interests were focused on photorefractive effects and light-induced charge-transport phenomena

Ferenc Krausz

Max-Planck-Institut für Quantenoptik
Garching, Germany
ferenc.krausz@mpq.mpg.de

Chapter A.4, Sect. 4.5

Ferenc Krausz earned his MS in Electrical Engineering at Budapest University of Technology in 1985, his PhD in Quantum Electronics at Vienna University of Technology in 1991, and his "Habilitation" degree in the same field at the same university in 1993. He joined the Department of Electrical Engineering as Associate Professor in 1998 and became Full Professor in the same department in 1999. In 2003 he was appointed as Director of Max Planck Institute of Quantum Optics (MPQ) in Garching, Germany, and since October 2004 he has also been Professor of Physics and Chair of Experimental Physics at LMU of Munich. His research has included nonlinear light-matter interactions, ultrashort light pulse generation from the IR to the x-ray spectral range, and studies of ultrafast processes. By using chirped multilayer mirrors, his group made intense light pulses with a few wave cycles available for applications and utilized them for pushing the frontiers of ultrafast science into the attosecond regime. His most recent research focuses on attosecond physics. Since 2006 he is Director of the Munich Centre for Advanced Photonics. He co-founded Femtolasers GmbH, a Vienna-based company specializing in femtosecond laser sources and initiated the foundation of Ultrafast Innovations GmbH, a Munich-based company of the LMU and the MPQ making attosecond technologies and devices available for research groups throughout the world.

Stefan Kück

Physikalisch-Technische Bundesanstalt
Optics Division
Braunschweig, Germany
stefan.kueck@ptb.de

Chapter C.11, Sect. 11.2

Dr. Kück is department leader in the Optics Division at the Physikalisch-Technische Bundesanstalt, the German National Metrology Institute. He obtained his PhD in 1994 and his Habilitation in 2001 in the field of solid-state lasers. His main research topics are development of new methods, procedures and standards for high-precision measurements of laser power and laser pulse energy as well as metrology for single photon sources and detectors.

Thomas Kusserow

University of Kassel
Institute of Nanostructure Technologies and Analytics (INA)
Kassel, Germany
kusserow@ina.uni-kassel.de

Chapter C.11, Sect. 11.3

Thomas Kusserow has a Diploma in Optical Image Engineering and a MSc in Optical Engineering and Photonics. In 2010 earned his Doctor degree from Kassel University, where he is currently Head of the nanophotonics group at the Institute of Nanostructure Technologies and Analytics. His main research interests are in the field of periodic optical structures, cavity devices and micro-/nanotechnology.

Anne L'Huillier

University of Lund
Department of Physics
Lund, Sweden
anne.lhuillier@fysik.lth.se

Chapter A.4, Sect. 4.4

Anne L'Huillier defended her PhD thesis in Paris in 1986. She worked at the Commissariat à l'Energie Atomique, in Saclay, France until 1995 and then moved to Lund University, Sweden, where she became Professor in 1997. Her current research is on the generation of high-order harmonics of laser light in gases and its application to attosecond science. In 2003, she got the Julius Springer Prize for Applied Physics together with Ferenc Krausz. She became Member of the Royal Swedish Academy of Sciences in 2004.

Johannes A. L'huillier

Photonik-Zentrum Kaiserslautern e.V.
Kaiserslautern, Germany
johannes.lhuillier@pzkl.de

Chapter C.11, Sect. 11.9

Johannes L'huillier studied Physics at the University of Kaiserslautern (Germany), where he received his PhD for work on the characterization of new laser active materials in 2003. Today his research is focused on the characterization of new nonlinear and laser active materials, optical parametric processes, ultrashort pulse lasers as well as on laser micromachining. Since 2009 he is the CEO of the Photonik-Zentrum Kaiserslautern e.V.

Bruno Lengeler

Aachen University (RWTH)
II. Physikalisches Institut
Aachen, Germany
lengeler@physik.rwth-aachen.de

Chapter D.22

Bruno Lengeler is Professor Emeritus of Physics and former head of a physics institute at Aachen University. He is a solid-state physicist who has worked for many years on spectroscopy and imaging with synchrotron radiation, in particular on the development of parabolic refractive x-ray lenses. He was Director of Research at the European Synchrotron Radiation Facility.

Martin Letz

Schott Glas
Materials Science, Central Research
Mainz, Germany
martin.letz@schott.com

Chapter A.5, Sects. 5.1.1, 5.1.4, 5.1.6, 5.1.7, 5.11

Dr. Martin Letz studied Physics at the Universities of Braunschweig, Stuttgart (Germany) and Tartu (Estonia) and finished his PhD in 1995 at Stuttgart University in the field of theoretical solid state physics with a work on magnetic polarons. In the following he worked as a postdoctoral fellow at Queen's University, Kingston (Canada) and at the~University of Mainz (Germany). During this time he performed investigations on statistical physics of strongly correlated quantum-mechanical systems of strongly correlated classical systems, light scattering and on the dynamics of the glass transition in molecular fluids. In 2001 Martin Letz joined the central research of Schott Glas.

Gerd Leuchs

University of Erlangen-Nürnberg
Institute of Optics, Information and Photonics
Erlangen, Germany
Gerd.leuchs@physik.uni-erlangen.de

Chapters A.2, A.3

Gerd Leuchs studied physics and mathematics at Cologne University and received his PhD from Munich University in 1978. After research years in USA, he headed the German Gravitational Wave Detection Group, then became Technical Director at Nanomach AG, Switzerland. Since 1994 he has been Professor of Physics at the University of Erlangen, since 2009 also Director of the newly founded Max Planck Institute for the Science of Light (MPL) in Erlangen, Germany.

Norbert Lindlein

University of Erlangen-Nürnberg
Institute of Optics, Information and Photonics
Erlangen, Germany
norbert.lindlein@physik.uni-erlangen.de

Chapters A.2, A.3

Norbert Lindlein received in 1996 his PhD from the Friedrich-Alexander-University Erlangen-Nürnberg (Germany). In 2002 he finished his Habilitation in Physics and is a member of the Physics Faculty of the University of Erlangen-Nürnberg since. In 2009 he was appointed as so called "außerplanmäßiger" Professor at the University of Erlangen-Nürnberg. His research interests include the simulation and design of optical systems, diffractive optics, microoptics and optical measurement techniques using interferometry or Shack-Hartmann wavefront sensors

Stefano Longhi

University of Politecnico di Milano
Department of Physics
Milano, Italy
longhi@fisi.polimi.it

Chapter C.11, Sect. 11.1

Stefano Longhi is Associate Professor of Physics of Matter at the Polytechnic Institute of Milan. He has authored more than 200 papers in the fields of laser physics, photonics, nonlinear and quantum optics. Professor Longhi is Fellow of the Institute of Physics. In 2003 he was awarded with the Fresnel Prize of the European Physical Society for his outstanding contributions in the fields of optics and photonics.

Ralf Malz

LASOS Lasertechnik GmbH
Research and Development
Jena, Germany
ralf.malz@lasos.com

Chapter C.11, Sect. 11.6

Ralf Malz studied Physics at the Friedrich-Schiller-Universität Jena 1984-1989 and received his PhD in1993 at the same university. Then he joined Carl-Zeiss-Jena and later LASOS in the field of CO_2 waveguide and slab lasers. His current work is on argon-ion and HeNe lasers, diode-laser modules, and fiber coupling.

Klaus Mann

Laser-Laboratorium Göttingen e.V.
Department Optics/Short Wavelengths
Göttingen, Germany
kmann@llg-ev.de

Chapter C.11, Sect. 11.7

Klaus Mann received his MS degree in Physics in 1981 and the PhD in 1984 from University of Göttingen. After post-doctoral appointments at IBM Yorktown Heights (USA) and Alcan Deutschland he joined Laser-Laboratorium Göttingen in 1988, where he currently leads the 'Optics / Short Wavelengths' Department. His research activities cover optics characterization, laser beam propagation and generation of EUV/XUV radiation. He is author of more than 100 scientific publications.

Wolfgang Mannstadt

Schott AG
Research and Technology Development
Mainz, Germany
wolfgang.mannstadt@schott.com

Chapter A.5, Sect. 5.1.4, 5.8, 5.11

Dr. Wolfgang Mannstadt studied physics and received his PhD from the Philipps University in Marburg. His main research field is the materials simulation with ab initio DFT methods. He received a Feodor-Lynen fellowship from the Humboldt Foundation and worked as a research assistant in the group of Prof. A.J. Freeman at the Northwestern University in Evanston, IL. His current work in the R&D department at Schott is focused on the simulation of materials properties with DFT and nanostructured optical materials.

Gerd Marowsky

Laser-Laboratorium Göttingen e.V.
Göttingen
gmarows@gwdg.de

Chapter C.11, Sect. 11.7

Dr. Marowsky graduated in 1969 from the University of Göttingen, Germany in fields of experimental and theoretical physics and mineralogy, and currently is Director of Laser-Laboratorium Göttingen. He has made numerous scientific contributions to the general field of lasers and high-field interactions. Current research interests include quantum electronics in general, lasers, laser applications in environmental research, nonlinear optics, nonlinear inorganic and organic materials, and applications of short-duration ultraviolet laser pulses. Gerd Marowsky is also Professor of the University of Göttingen, and holds Adjunct Professor positions in Electrical and Computer Engineering at both Rice University, Houston and the University of Toronto.

Dietrich Martin

Carl Zeiss Meditec, Inc.
Dublin, CA, USA
d.martin@meditec.zeiss.com

Chapter B.8, Sect. 8.8

Dietrich Martin received his BSc from the University of Technology, Dresden in 1992, his MSc from theUniversity of Oldenburg in 1997. He earned his PhD from the University of Kassel in 2002 working on optical properties of alkali metal clusters. After joining the Corporate R&D Department of Carl Zeiss and doing research on microstructured as well as variable optical components he transferred to the medical business sector of the Carl Zeiss Group and is currently developing OCT based instruments for ophthalmological applications.

Reinhard März

Intel Mobile Communications GmbH
Principal Design for Lithography
Neubiberg, Germany
reinhard.maerz@intel.com

Chapter D.15

Reinhard März received his Diploma and PhD in Theoretical Physics from the University of Frankfurt, in 1980 and 1983, respectively. In 1984, he joined the Research Laboratories of Siemens AG in Munich, Infineon Technologies in April 1999, and Intel Mobile Communications in February 2011. He is co-founder of JCMwave, a company developing electromagnetic finite-element solvers. Dr. März has scientifically contributed to integrated optics, photonic crystals with special attention to the optical communications especially in wavelength division multiplexing. In recent times, he moved to lithography simulation and design for manufacturing for advanced technology nodes of silicon mainstream technologies. Dr. März has authored numerous scientific papers, a textbook and several book chapters.

Yvonne Menke

Schott AG
Corporate Research and Technology Development
Mainz, Germany
yvonne.menke@schott.com

Chapter A.5, Sect. 5.9

Dr. Yvonne Menke studied Metallurgy and Materials Engineering at the RWTH Aachen. After finishing her Diplôme d'Études Approfondies at the Ecole Nationale Supérieure de Céramique Industrielle (ENSCI, Limoges, France) in 1997, she continued to receive her PhD in 2000 in Materials Science and Technology from the University of Limerick (Ireland). During her post-doc time at the Politecnico di Torino (Italy) her scientific focus was on the preparation and characterization of photosensitive multicomponent silicate glasses as well as glasses containing noble metal nanoclusters for biosensing, optical and optoelectronic applications. Since 2006 she works within the Research and Development Department at Schott AG, Mainz (Germany). Her work involves the development and investigation of transparent ceramics with special optical properties.

Bernhard Messerschmidt

Grintech GmbH
Research and Development, Management
Jena, Germany
messerschmidt@grintech.de

Chapter B.8, Sects. 8.6, 8.7

Bernhard Messerschmidt studied physics at the Jena University, Germany and graduated with a PhD in 1998 from the Fraunhofer Institute of Applied Optics in Jena on modeling and optimization of ion exchange processes in glass for the generation of GRIN lenses. From 1994 to 1995, he was a Research Fellow at the Institute of Optics, University of Rochester, New York. In 1999, he established the company Grintech as a co-founder and is currently one of the principal managers of Grintech and responsible for research and development.

Katsumi Midorikawa

RIKEN
Laser Technology Laboratory
Wako, Japan
kmidori@riken.jp

Chapter C.11, Sect. 11.12

Dr. Katsumi Midorikawa is a director and chief scientist of Laser Technology Laboratory at RIKEN. He received his PhD degree from Keio University in Electrical Engineering. His research interests currently focus on ultrashort high-intensity laser – matter interaction and its application, including the generation of~coherent x-ray by high-order harmonics and atttosecond science

Gerard Milburn

The University of Queensland
School of Physical Sciences Center for Engineered Quantum Systems
St. Lucia, QLD, Australia
milburn@physics.uq.edu.au

Chapter D.18

Milburn's research is largely in the fields of quantum optics, quantum measurement and control, and quantum computing and has published more than 200 papers and three books. He is a Fellow of the Australian Academy of Science and The American Physical Society. He is currently an Australian Research Council Federation Fellow at The University of Queensland.

Kazuo Ohtaka

Chiba City Museum of Science
Chiba City, Japan
Kazuo.Ohtaka@kagakukanQ.com

Chapter B.8, Sect. 8.10

In 1965, Dr. Kazuo Ohtaka graduated from Department of Applied Physics, University of Tokyo, where he was Assistant Professor since 1967. Since 1998 he was Professor of Department of Applied Physics of Chiba University and since 2000 he is Professor of the Center for Frontier Science, Chiba University. In 2000 he obtained the Best Papers Award of the Physical Society of Japan. He is currently working in the field of photonic crystals, their fundamentals and application.

Motoichi Ohtsu

University of Tokyo
Department of Electrical Engineering
and Information Systems
Research Center
Tokyo, Japan
ohtsu@ee.t.u-tokyo.ac.jp

Chapter D.19

Dr. Ohtsu is a Professor of the University of Tokyo. He is also a Director of Nanophotonics Research Center, the University of Tokyo. As a founder of nanophotonics, he is a director of several national projects for nanophotonic devices, storage, fabrication, energy conversion, and system applications. He has authored more than 470 technical papers and 62 books and he holds 83 patents. He is a Fellow of the Optical Society of America and has been awarded more than ten prizes from academic institutions including the I. Koga Gold Medal from URSI. He was also awarded the Medal with Purple Ribbon from the Japanese Government and the Julius Springer Prize for Applied Physics.

Roger A. Paquin

Advanced Materials Consultant
Oro Valley, AZ, USA
materials.man@att.net

Chapter A.5, Sect. 5.10

Roger Paquin is an independent materials consultant specializing in materials and processes for dimensionally stable components for optical and precision instrument systems, with emphasis on Be, SiC and composites for mirrors and structures. He has published over 50 papers and book chapters and teaches short courses on the subject. Mr. Paquin is a Fellow of SPIE.

Klaus Pfeilsticker

Universität Heidelberg
Institut für Umweltphysik
Heidelberg, Germany
klaus.pfeilsticker@iup.uni-heidelberg.de

Chapter D.23, Sects. 23.1–23.6

Dr. Klaus Pfeilsticker is a Professor of Physics at the University of Heidelberg since 2004. Before he worked at the Max-Planck-Institut für Kernphysik, Heidelberg, the Alfred Wegner Institut, Bremerhaven, the Research Center Jülich, Germany, and at the National Oceanic and Atmospheric Administration (NOAA), Boulder, Colorado, USA. His main research interests are the photochemistry and the radiative transfer of the atmosphere. His recent research focuses on the photochemistry, budget and trend of reactive halogen species in the upper troposphere and stratosphere, the spectral solar irradiance and its variability, and photon pathlength distribution of solar photons in clear and cloudy skies.

Nathalie Picqué

Max Planck Institute of Quantum Optics
Garching, Germany
nathalie.picque@mpq.mpg.de

Chapter D.17

Nathalie Picqué received her doctoral degree from the University de Paris-Sud Orsay, France, in 1998. She is currently a permanent Senior Research Scientist with the Centre National de la Recherche Scientifique seconded to the Max Planck Institute of Quantum Optics and the Ludwig Maximilian University in Munich, Germany. Her research interests include laser frequency combs and the development of new techniques of molecular spectroscopy.

Ulrich Platt

Universität Heidelberg
Institut für Umweltphysik
Heidelberg, Germany
ulrich.platt@iup.uni-heidelberg.de

Chapter D.23, Sects. 23.1–23.6

Dr. Ulrich Platt is a Professor of Physics at the University of Heidelberg since 1989. Before he worked at the research Center Jülich and at the University of California, Riverside. His main interests are atmospheric chemistry of free radicals and spectroscopic measurements of atmospheric constituents. He is the co-inventor of the DOAS technique. His current research centers on reactive halogen species in the troposphere and their role in the tropospheric chemistry as well as on remote sensing of trace gas distributions in the atmosphere.

Markus Pollnau

University of Twente
MESA+ Institute for Nanotechnology
Enschede, The Netherlands
m.pollnau@ewi.utwente.nl

Chapter C.11, Sect. 11.2.2

Markus Pollnau obtained his Diploma and PhD in Physics from the Universities of Hamburg, Germany, and Bern, Switzerland, respectively. Following research at the University of Southampton, UK, and the Swiss Federal Institute of Technlogy, Lausanne, Switzerland, he was appointed full Professor at the University of Twente, The Netherlands, in 2004. Currently, he works on light generation in integrated dielectric structures. He has co-authored over 200 international publications

Steffen Reichel

Schott AG
Product Manager Optical Filters
Mainz, Germany
steffen.reichel@schott.com

Chapters A.5, B.8, Sect. 5.1.1, 5.1.6, 5.1.7, 5.1.8, 5.11, 8.3

Dr. Reichel is an electrical engineer with extensive experience in optics and electromagnetics. He got his PhD in Er-doped fiber amplifiers and worked on several topics in wave and laser optics, optical fibers/waveguides, and geometrical optics. He is Senior Member of the IEEE, worked for Lucent Technologies and then joined Schott where he was manager of the Physical Science at the Central Research of Schott. He moved to the business unit Advanced Optics of Schott where he is now Product Manager for optical filters.

Hans-Dieter Reidenbach

Cologne University of Applied Sciences
Institute of Applied Optics and Electronics
Cologne, Germany
hans.reidenbach@fh-koeln.de

Chapter D.25

Dr. Reidenbach is a retired Professor at the Cologne University of Applied Sciences, but still Head of the research laboratory Medical Technology and non-ionizing radiation. He obtained the Dr.-Ing. degree from the University of Erlangen. His scientific work resulted in new applications of laser beams, incoherent optical radiation and high-frequency currents in operative endoscopy, transanal surgery and interstitial thermotherapy. He is the author of more than 200 scientific publications. His research is on optical irradiation and psychophysical behavior, especially aversion responses including the blink reflex and pupillary constriction. Currently he is engaged in a research project on temporary blinding and the respective protection measures, especially for pilots against misuse from hand-held laser pointers.

Hongwen Ren

Chonbuk National University
Deptartment of Polymer-Nano Science and Technology
Chonju, Chonbuk, Korea
hongwen@jbnu.ac.kr

Chapter A.5, Sect. 5.10

Dr. Hongwen Ren received his Ph.D. degree from Changchun Institute of Optics, Fine Mechanics and Physics, Chinese Academy of Sciences in 1998. After that, he was faculty member of the North Liquid Crystal R&D Center, Chinese Academy of Sciences as an assistant professor. In August 2001, he joined the College of Optics & Photonics, University of Central Florida as a research scientist. Currently, he is an associate professor at Chonbuk National University, Korea. His research interests include liquid crystal/polymer dispersions, nano-liquid crystal devices, and adaptive lenses

Charles K. Rhodes

University of Illinois at Chicago
Physics Department
Chicago, IL, USA
rhodes@uic.edu

Chapter C.11, Sect. 11.7

Dr. Rhodes is the Albert A. Michelson Professor of Physics, a distinquished appointment in the University of Illinois system, and the Director of the Laboratory for X-Ray Microimaging and Bioinformatics in the Department of Physics at the University of Illinois at Chicago.

Fritz Riehle

Physikalisch-Technische Bundesanstalt
Division of Optics
Braunschweig, Germany
fritz.riehle@ptb.de

Chapter C.11, Sect. 11.14

Dr. Fritz Riehle is Head of the Division Optics at the Physikalisch-Technische Bundesanstalt in Braunschweig, Germany. His research interests are the realization of optical clocks and frequency standards, high-resolution spectroscopy, laser cooling, and atom interferometry. He is also engaged in the Centre for Quantum Engineering and Spacetime Research, Leibniz Universität Hannover, Germany.

Detlev Ristau

Laser Zentrum Hannover e.V.
Department of Thin Film Technology
Hannover, Germany
d.ristau@lzh.de

Chapter A.6

Detlev Ristau is a physicist with an extensive research background in optical thin film technology. He received his PhD degree from the University of Hannover in 1988 and is presently Director of the Department of Thin Film Technology at the Laser Zentrum Hannover, Germany. In 2010. he was appointed as a Professor for Applied Physics at the Leibniz University in Hannover and also assumed responsibility for a research group on Ultrahigh Quality Optical Layers. He is author or co-author of more than 250 technical papers and has published several book chapters. Current research activities include the development and precise control of ion processes as well as the measurement of the power handling capability and losses of optical components.

Simone Ritter

Schott AG
Division Research and Technology
Development
Mainz, Germany
simone.ritter@schott.com

Chapter A.5, Sect. 5.3

Dr. Simone Ritter studied Chemistry in Leipzig and Tübingen and received her PhD in 1994 for syntheses and characterization the structures and reactivity of complexes with rhenium-nitrogen multibonds. For the last years, she worked as scientific referent for colored and optical glasses at Schott. Her research involves development and characterization of glasses with new optical properties.

Frank Rohlfing (deceased)

Chapter C.11, Sect. 11.4

Evgeny Saldin

Deutsches Elektronen Synchrotron (DESY)
Hamburg, Germany
evgueni.saldin@desy.de

Chapter C.11, Sect. 11.11

Dr. Evgeny Saldin is an expert in the field of physics of charged particle beams, accelerators, and free-electron lasers. He has authored a book on free-electron lasers and more than a hundred papers in peer-reviewed journals.

Roland Sauerbrey

Helmholtz-Zentrum
Dresden-Rossendorf e.V.
Dresden, Germany
r.sauerbrey@hzdr.de

Chapter C.11, Sect. 11.13

Roland Sauerbrey is the Scientific Director of the Forschungszentrum Dresden-Rossendorf and a Professor at the Technical University of Dresden. After receiving his PhD in Physics from the University of Würzburg in 1981 he worked as a Professor at Rice University in Houston, Texas. In 1994, he moved to the Friedrich-Schiller-University in Jena where he stayed until 2006 as a Professor of Physics. During the last 20 years, he has been actively involved in the emerging field of relativistic light – matter interaction and the development of ultrashort pulse, ultrahigh-intensity lasers. He is a Fellow of the Optical Society of America and the Institute of Physics.

Evgeny Schneidmiller

Deutsches Elektronen Synchrotron (DESY)
Hamburg, Germany
evgeny.schneidmiller@desy.de

Chapter C.11, Sect. 11.11

Evgeny Schneidmiller is an expert in the field of physics of charged particle beams, accelerators, and free-electron lasers. He has authored a book on free-electron lasers and more than a hundred papers in peer-reviewed journals.

Bianca Schreder

Schott AG
BU Advanced Optics
Mainz, Germany
bianca.schreder@schott.com

Chapter A.5, Sects. 5.1.5, 5.6

Dr. Bianca Schreder studied Chemistry in Würzburg and received her PhD from the~Department of Physical Chemistry for her work on laser spectroscopy on II–VI-semiconductor nanostructures. She is now working as Head of Product Development within the Business Unit Advanced Optics at Schott AG, Mainz. Her work involves development, optimization and transfer to production of new products for optical applications, such as lenses, filters, etc.

Christian G. Schroer

Dresden University of Technology
Institute of Structural Physics
Dresden, Germany
schroer@physik.tu-dresden.de

Chapter D.22

Christian G. Schroer made his doctoral studies in mathematical physics at the Research Centre Jülich (doctoral degree University of Cologne in~1995). After a visit as postdoctoral fellow to the University of Maryland, he worked as a research and teaching associate at Aachen University in the field of x-ray optics and microscopy. After his Habilitation in 2004, he was a Staff Scientist at DESY in Hamburg until he became full Professor at the Institute of Structural Physics at Technische Universität Dresden in early 2006.

Markus W. Sigrist

ETH Zürich
Department of Physics Institute for
Quantum Electronics
Zürich, Switzerland
sigrist@iqe.phys.ethz.ch

Chapter C.11, Sect. 11.10

Markus W. Sigrist is Professor of Physics at ETH Zurich (Switzerland) and Adjunct Professor at Rice University in Houston (USA). His current research involves development and implementation of tunable mid-infrared laser sources and sensitive detection schemes for spectroscopic trace analyses in environmental, industrial and medical applications. He published 2 books, several book chapters and over 150 papers. He is Fellow of the OSA, Associate Editor of the "Encyclopedia of Analytical Chemistry" and on the Editorial Board of several journals.

Peter Simon

Laser-Laboratorium Göttingen e.V.
Ultrashort Pulse Photonics
Göttingen
peter.simon@llg-ev.de

Chapter C.11, Sect. 11.7

Dr. Simon received his Dipl. and PhD degrees in Physics from the University of Szeged in 1982 and 1986, respectively. In 1988 he joined the Laser-Laboratorium Göttingen to continue his research. In 1992, Dr Simon was appointed Group Leader of the High Intensity Laser Technology Group. Since 2005, he is Head of the Department Ultrashort Pulse Photonics. The subjects of his research include the generation and amplification of UV ultrashort pulses, the generation of coherent radiation in the VUV spectral range, the development of high brightness femtosecond laser systems, and the submicron-scale surface texturing of technical materials.

Glenn T. Sincerbox

University of Arizona
Optical Sciences
Tucson, AZ, USA
sinbox@cox.net

Chapter D.24, Sects. 24.5–24.8

Glenn Sincerbox is currently a Professor Emeritus of the College of Optical Sciences of the University of Arizona where he was a Professor of Optical Sciences and the Director of the Optical Data Storage Center; a Center that performed leading-edge research on advanced optical storage materials, systems and techniques. Prior to that, Mr. Sincerbox was with IBM Research for 34 years holding numerous technical and management positions.He has published over 50 technical papers and presented over 60 papers. He holds 40 US Patents and has 70 patent publications. His research was primarily in the field of optical storage with emphasis on holographic storage. He is a fellow of the OSA and has been active for over 15 years in the International Commission for Optics holding positions as vice president and treasurer.

Elisabeth Soergel

University of Bonn
Institute of Physics
Bonn, Germany
soergel@uni-bonn.de

Chapter B.8, Sect. 8.9

Elisabeth Soergel studied Physics at the Ludwig-Maximilian-University in Munich. She received her Diploma and PhD from the Max-Planck Institute for Quantum Optics in Garching in the field of scanning probe microscopy. After a postdoc stay at the IBM research laboratory in Rüschlikon, Switzerland, she joined the University of Bonn in 2000 with the main research field on visualization of ferroelectric domains by scanning probe techniques.

Steffen Steinberg

LASOS Lasertechnik GmbH
Jena, Germany
steffen.steinberg@lasos.com

Chapter C.11, Sect. 11.6

Steffen Steinberg studied Physics and received his doctoral degree at Friedrich-Schiller-University, Jena, Germany with a work on manipulation of laser light with integrated optical devices. Later, his work concentrated on different applications of gas and solid-state lasers especially laser display technology and fiber optical devices. Currently he is working as Sales Manager at Lasos in Jena, Germany.

Sune Svanberg

Lund University
Division of Atomic Physics
Lund, Sweden
sune.svanberg@fysik.lth.se

Chapter D.13, Sect. 13.3

Sune Svanberg made his PhD in Physics at Göteborg University in 1972. He was Professor and Head of the Atomic Physics Division, Lund University, from 1980 to 2008, and Director of the Lund Laser Centre, a European Large Scale Infrastructure, from 1996 to 2009. Since then he is a Senior Professor at Lund University and now also a distinguished Professor at South China Normal University, Guangzhou. He is fellow of the American Physical Society, the Optical Society, and the European Optical Society, member of 5 Academies and multiple honorary doctor/professor. His reseach interests include basic atomic laser spectroscopy, high-power laser-matter interaction and applications of laser spectroscopy to energy, environmental and medical research.

Orazio Svelto

Politecnico di Milano
Department of Physics
Milan, Italy
orazio.svelto@fisi.polimi.it

Chapter C.11, Sect. 11.1

Orazio Svelto is Emeritus Professor at the Politecnico di Milano. His research activities include ultrashort-pulse generation and applications, physics of laser resonators and techniques of mode selection, laser applications in biology and biomedicine, and physics of solid-state lasers, also including the generation of femtosecond laser pulses, down to the record value of 3.8 fs recently established by the group, and to the applications of these ultrashort pulses. He is the author of "Principles of Lasers". Professor Svelto is a Fellow of the Optical Society of America and the Institute of Electrical and Electronics Engineers, and a member of several Italian Academies including the Accademia dei Lincei. He was the recipient of the Italgas Prize for research and technology innovation, the Quantum Electronics Prize of the European Physical Society, the Charles H. Townes Award of the Optical Society of America and the Jiulius Springer Prize for Applied Physics 2011.

Bernd Tabbert

Advanced Photonix, Inc.
Engineering Department
Camarillo, CA, USA
btabbert@advancedphotonix.com

Chapter B.9

Bernd Tabbert received his PhD from the University of Heidelberg, Germany in 1994. For several more years his research focused on optical studies of impurity atoms and bubbles in cryogenic liquids including a project at the University of California, Los Angeles. He is now working as an engineering manager for a semiconductor manufacturer developing sensors for medical, industrial and aerospace applications.

K. Thyagarajan

Indian Institute of Technology Delhi
Physics Department
New Delhi, India
ktrajan@physics.iitd.ac.in

Chapter D.14

K. Thyagarajan is currently a Professor at the Physics Department, IIT Delhi, India. He has published more than 140 research papers in international journals, has filed five patent applications and is the co-author (with Professor A. K. Ghatak) of seven books, the latest being Lasers: Fundamentals and Applications (2010). In 1998 he was the co-recipient (with Prof B P Pal) of the "Fiber Optic Person of the Year 1997" award by Lucent Technologies- Finolex and Voice and Data, India. In 2003 he was decorated with the title of "Officier dans l'ordre des Palmes Académiques" by the French Government, in 2005 he was elected a Fellow of the Optical Society of America and in 2008 Fellow of the Indian National Academy of Engineers. He has been a consultant to Tejas Networks India Pvt. Ltd., Bangalore looking into advanced issues related to high capacity communication through optical fibers. His current research interests are in the fields of guided-wave quantum optics, optical fiber amplifiers and nonlinear optical effects in photonic bandgap structures.

Michael Totzeck

Carl Zeiss AG
Corporate Research & Technology
Oberkochen, Germany
m.totzeck@zeiss.de

Chapter D.16

Michael Totzeck received his PhD in Physics from the Technical University of Berlin in 1989 and his Habilitation in 1995 for his work on microwave and diffraction optics. He worked on high-resolution optical imaging, interferometry and numerical simulation in Berlin and Stuttgart before joining Carl Zeiss in 2002. He is currently Senior Principal at Corporate Research & Technology of the Carl Zeiss AG. His current research interests are optical lithography, metrology, and polarization optics.

Mary Turner

Engineering Synthesis Design, Inc.
Tucson, AZ, USA
mturner@breault.com

Chapter B.7

Dr. Turner has been involved with the development of optical software and conducted training on optical design and optical software for the previous 12 years. She wrote a chapter on "Optical Aberrations" in "The Optics Encyclopedia" and on "Reflecting and Catadioptric Objectives" in the "Optical Engineer's Desk Reference". She is a Fellow of SPIE and a member of SID and OSA.

Michael Vollmer

University of Applied Sciences
Brandenburg
Microsystem and Optical Technologies
Brandenburg, Germany
vollmer@fh-brandenburg.de

Chapter D.23, Sects. 23.6–23.11

Michael Vollmer studied Physics in Heidelberg where he received his PhD and Habilitation, working on optical spectroscopy of metal clusters. Presently, he is Professor of Experimental Physics working in the fields of infrared thermal imaging, spectroscopy, atmospheric optics, and didactics of physics. He is author of three books and member of the editorial boards of several journals.

Christoph Wächter

Fraunhofer Institute for Applied Optics
and Precision Engineering
Microoptical Systems Department
Jena, Germany
christoph.waechter@iof.fraunhofer.de

Chapter D.15

Christoph Wächter received the Diploma and the Dr.rer.nat degrees in Physics from the Friedrich-Schiller-University, Jena, Germany. He started his research activities in the area of multilayer and waveguide optics in 1983. In 1992, he joined the microoptics division of the Fraunhofer Institute for Applied Optics and Precision Engineering, Jena, where he is concerned with the design of integrated optical and microoptical devices.

Helen Wächter

Queen's University
Department of Chemistry
Kingston, Ontario, Canada
helen.wachter@chem.queensu.ca

Chapter C.11, Sect. 11.10

Helen Wächter made her PhD in Physics at ETH Zurich, Switzerland, in 2007 working in the field of IR laser spectroscopy and trace gas monitoring. This included the development of new coherent light sources by difference-frequency generation (DFG) and new, sensitive detection schemes with emphasis on isotope-selective trace-gas analysis. Since 2008 she is a postdoc at Queens University in Kingston, Canada where her current research focuses on fiber-loop ringdown spectroscopy for absorption detection in dilute liquid samples of nanoliter volumes.

Silke Wolff

Schott AG
Department Research and Technology Development
Material Development Optical Glasses
Mainz, Germany
silke.wolff@schott.com

Chapter A.5, Sect. 5.2

Dr. Silke Wolff, laureate of R&D award, is an expert in glass development with an origin in analytical chemistry. Her main areas of research are innovative optical glasses, including market and customer-related material development, application, optimization of~production processes and patent protection. Actual topics are exceptional optical properties, superstrate properties in flat glass, prevention of radiation-induced damage, suitability for reheat hot forming and/or precision moulding and environmental compatibility.

Matthias Wollenhaupt

Universität Kassel
Institut für Physik
Kassel, Germany
wollenha@physik.uni-kassel.de

Chapter C.12

Professor Matthias Wollenhaupt did research in high-resolution laser spectroscopy at the DLR in Göttingen with applications to the aero-thermodynamics of reentry vehicles. At Max Planck Institute for Chemistry in Mainz he studied radical reactions in atmospheric chemistry. His current research in femtosecond laser spectroscopy at the University of Kassel is focused on pulse-shaping techniques for the design of tailored femtosecond laser pulses as a tool to control ultrafast light-induced processes. His scientific interests range from basic research, such as coherent control of molecular dynamics in strong laser fields, to applications of non-linear optics in microscopy and materials processing.

Shin-Tson Wu

University of Central Florida
College of Optics and Photonics
Orlando, FL, USA
swu@mail.ucf.edu

Chapter A.5, Sect. 5.10

Dr. Wu is is a Pegasus professor at College of Optics and Photonics, University of Central Florida (UCF). Prior to joining UCF in 2001, he was with Hughes Research Laboratories (Malibu, California) for 18 years. He has co-authored 7 books, about 400 journal publications, and 70 U.S. patents. He is a Fellow of the IEEE, OSA, SID, and SPIE, and the recipient of 2011 SID Slottow-Owaki Prize, 2010 OSA Joseph Fraunhofer award/Robert M. Burley prize, 2008 SPIE G.G. Stokes award, and 2008 SID Jan Rajchman Prize. He was the founding Editor-In-Chief of the IEEE/OSA Journal of Display Technology.

Mikhail Yurkov

Deutsches Elektronen Synchrotron (DESY)
Hamburg, Germany
mikhail.yurkov@desy.de

Chapter C.11, Sect. 11.11

Dr. Mikhail Yurkov is an expert in the field of physics of charged particle beams, accelerators, and free-electron lasers. He has authored a book on free-electron lasers and more than 150 papers in peer-reviewed journals.

Aleksei Zheltikov

M.V. Lomonosov Moscow State
University
Physics Department
Moscow, Russia
zheltikov@phys.msu.ru

Chapter A.4, Sects. 4.1–4.3

Aleksei Zheltikov's current research is related to nonlinear optical processes in photonic-crystal fibers and nanostructures

Detailed Contents

List of Abbreviations XXV

Part A Basic Principles and Materials

1 **The Properties of Light**
Richard F. Haglund 3
1.1 Introduction and Historical Sketch 4
1.1.1 From the Greeks and Romans to Johannes Kepler 4
1.1.2 From Descartes to Newton 4
1.1.3 Newton and Huygens 5
1.1.4 The 19th Century: The Triumph of the Wave Picture 5
1.2 Parameterization of Light 6

12.1.1 Descriptive Introduction 1048
12.1.2 Mathematical Description 1049
12.1.3 Changing the Temporal Shape via the Frequency Domain . 1057

12.2 Generation of Femtosecond Laser Pulses via Mode Locking 1069

12.3 Measurement Techniques for Femtosecond Laser Pulses 1072
12.3.1 Streak Camera 1073
12.3.2 Intensity Autocorrelation and Cross-Correlation 1074
12.3.3 Interferometric Autocorrelations 1076
12.3.4 Time–Frequency Methods 1079
12.3.5 Spectral Interferometry 1087
References 1089

Part D Selected Applications and Special Fields

13 Optical and Spectroscopic Techniques

Sune Svanberg, Wolfgang Demtröder 1097

13.1 Stationary Methods
Wolfgang Demtröder 1097
13.1.1 Absorption- and Emission-Spectroscopy and Laser-Induced Fluorescence 1109
13.1.2 Laser Spectroscopy in Molecular Beams 1110
13.1.3 Nonlinear Laser Spectroscopy 1114
13.1.4 Polarimetry and Ellipsometry 1120
13.1.5 Optical Pumping and Double-Resonance 1122
13.1.6 Spectroscopy with Optical Frequency Combs 1123

13.2 Time-Resolved Methods
Wolfgang Demtröder 1125
13.2.1 Basic Principles 1125
13.2.2 Wavelength-Tunable Short Pulses 1126
13.2.3 Time-Resolved Spectroscopy 1132
13.2.4 Coherent Time-Resolved Spectroscopy 1137
13.2.5 Applications of Short Laser Pulses 1140

13.3 Lidar
Sune Svanberg 1146
13.3.1 Lidar Basics 1146
13.3.2 Instrumentation 1148
13.3.3 Atmospheric Lidar Applications 1149
13.3.4 Lidar Monitoring of Condensed Targets 1154
13.3.5 Unconventional Lidar Applications 1159
13.3.6 Discussion and Outlook 1160

epitaxial layer 1243
epitaxially grown material
– GaAs 863
EQE (external quantum efficiency) 607
equifrequency surface (EFS) 518
equivalent current 576
Er laser 711
Er^{3+} laser 688
Er^{3+}-doped Yb^{3+} 717
Er-based upconversion laser 690
erbium iron garnet 1410
Er-doped fiber (EDF) 1196
Er-doped fiber amplifier (EDFA) 672, 1186, 1191, 1195
Er-doped fiber laser 511, 718
erf (error function) 22
error
– positioning 1376
– uniformity 463
error budget 436
error function (erf) 22
error signal for frequency control 938
ESA (excited-state absorption) 676–678, 690, 737, 740, 745, 748, 753, 754, 756

ESI (electron spectroscopic imaging) 1390
ESRF (European Synchrotron Radiation Facility) 1466
etalon 856, 1269
etching velocity 451
ethanol 1446
European Synchrotron Radiation Facility (ESRF) 1466
EUV (extreme ultraviolet) 57, 833, 850, 1469
– lithography 915
evanescent mode 1213
evanescent wave 103, 127
EWOD (electrowetting on dielectrics) 498
excess
– loss 1194
– noise factor 575
excimer laser 224, 834
– beam 838
– beam parameter 838
– electronics industry 840
– femtosecond pulse 842
– processing of materials 842
– radiation property 833
– spatial coherence 839
– technical design principles 835
excimer laser annealing (ELA) 842
excimer laser pulse
– femtosecond 832, 843
excimer transition 834
exciplex molecule 834
excitation
– circuit 837
– spectroscopy 1106, 1112
– transfer 835
excited dimer 832
excited vibrating molecule 1145
excited-state absorption (ESA) 676–678, 690, 737, 740, 745, 748, 753, 754, 756
exciton
– effect 272
– energy level 1339
– trap 354
exciton–exciton annihilation 220
exit pupil 62, 443
explosive solids
– absorption features 1452
extended source 1580
external cavity semiconductor 856
external quantum efficiency (EQE) 607
external-cavity diode laser (ECDL) 893, 943
extinction coefficient 262
extraordinary
– axis 267
– polarization 361
– wave 666
extreme ultraviolet (EUV) 57, 833, 850, 1469
– lithography 915
extreme ultraviolet (XUV) 1129, 1288, 1289
– probe spectroscopy 238
– pulse 234
– pulse measurement 231
– pump/XUV-probe experiment 237
– radiation 223
– soft x-ray 912
extrinsic
– defect 357
– photoconductor 550
eye 80
– damage 1577
– movement 1580
– sensitivity curve 635

F

F number 78
F_2-laser 832
$f-2f$ interferometer 1287
fabrication 368
– error 437
– tolerance 428
Fabry–Pérot (FP)
– interferometer 1063, 1431
– laser 766, 771
– resonator 656, 938
Fabry-Pérot cavity (FPC) 174, 1296
face-centered cubic (fcc) 513
fan plot 434
Faraday isolator 856
Faraday rotator (FR) 937, 1119
far-distant objects 81
far-field (FF) 838
– beam 838
– diffraction 1471
– fluorescence light microscopy 1375
– fluorescence microscopy 1359
– light microscopy 1359, 1369
– light nanoscopy 1390
– spatial profile 228
far-infrared gas laser 814
fast Fourier transformation (FFT) 130, 137
fast response photodiode 564
fast saturable-absorber 671
fast switch 1403
fast-axis collimation 493, 495
FBG (fiber Bragg grating) 1187, 1189, 1197, 1206, 1235
FC coupling 1242
fcc (face-centered cubic) 513
FD (finite differences) 1212, 1224
FDA (Food and Drug Administration) 1588
FDPM (frequency-domain phase measurement) 1085, 1086
FDTD (finite-difference time-domain) 182, 520, 1223
– method 1223
– technique 188
FE (finite elements) 1212
Fe^{2+} laser 755
feedback
– control 1065
– resonator 870
FEL (free-electron laser) 902
– applications 904
– radiative instability 903
– resonance wavelength 903
– user facility 904
FEM (finite-element method) 1224
femtosecond
– amplifier 1076
– CARS spectroscopy 215
– excimer laser pulse 832, 843
– OPA 217
– oscillator 1064, 1126
– spectroscopy 1144
– terawatt pulse 1128
femtosecond laser 955
– pulse 1069, 1072
femtosecond pulse 213
– shaping 1065
– shaping technique 1088
Fermat's principle 486, 1231
ferrimagnetic resonance 1411
ferroelectric domain
– engineering 508
– structure, visualization 510
ferrofluid
– rheological characteristics 504
FET (field effect transistor) 573
FETD (finite-element time-domain) 1223
few-cycle
– driven surface HHG 1129
– laser pulse 232, 239
– light pulse 187
– streaking light field 236
Feynman diagram 1336

FF (far-field) 838
– beam 838
– diffraction 1471
– fluorescence light microscopy 1375
– fluorescence microscopy 1359
– light microscopy 1359, 1369
– light nanoscopy 1390
– spatial profile 228
FFT (fast Fourier transformation) 130, 137
FHD (flame hydrolysis deposition) 1243
fiber
– glass 722, 1171
– hollow 229
– hollow-core 843
– laser 783
– low-loss optical 1172
– microstructure 208, 1206
– multimode 1178
– nonlinear 1200, 1288
– parabolic index 1180, 1181
– practical 1175
– probe tip 1344
– refractive index 1200
– single-mode optical 1412
– waveguide laser 299
fiber Bragg grating (FBG) 1187, 1189, 1197, 1206, 1235
fiber optic 1212
– coupler 1193
– sensor 494
fiber optic communication 1195
– system 1174, 1204
fiber–chip coupling 1226, 1242
fiber-optical
– attenuator 493
– device 493
– sensor 494
field
– absorption 1412
– angle 63
– distortion 467
– distribution 1211
– stop 63, 443
– stop for telescope 84
field effect transistor (FET) 573
field of view (FOV) 431, 442
field-effect-based phototransistor 581
figure of merit (FOM) 299, 315, 548, 865, 888, 889, 1219
filling factor 767, 1406
film
– amorphous 353
filter
– band stop 1235
– channel 524
– characteristic 1235
filter curve
– $\Delta\kappa$-coupler 1227
– asymmetrical directional coupler 1227
finite differences (FD) 1212, 1224
finite distant objects 82
finite elements (FE) 1212
finite nanosystem 1337
finite-difference time-domain (FDTD) 182, 520, 1223
– method 1223
– technique 188
finite-element method (FEM) 1224
finite-element solver 1223
finite-element time-domain (FETD) 1223
first Brillouin zone 518
first-harmonic detection 954
first-order
– correlation function 26
– optical design 429
Fizeau interference 1264, 1268, 1269
flame hydrolysis 1243
flame hydrolysis deposition (FHD) 1243
flames 1438
FLASH (free-electron laser in Hamburg) 907
flashlamp-pumped dye laser 852
flatness of setting sun 1497
flatness test 1262
flat-top beam profile 839
flint glass 262
flint-like material 322
flip-chip attachment 1246
floating-diffusion amplifier 589
fluidic adaptive lens 501
fluidic lens
– activation mechanism 503
– effective focal length 501
fluorescence 1107
– coating 626
– excitation 1362
– intermittent 1378
– lamp 626
– lidar technique 1156

MZ-type interference configuration 528

N

N_2 laser 834
NA (numerical aperture) 63, 140, 338, 492, 840, 1360, 1470, 1541
nabla operator 90
NAND flash 1540
nanobeam 1468, 1471
– characterization 1462
nanocrystalline detector 609
nanofocusing 1471
nanofocusing lens (NFL) 1466
nanoimaging 1392
– life cell 1384
nanomastering technology 1354
nanometric
– material 1338
– particle 1338
– particle size 1338
– space 1355
– Zn particle 1344, 1345
nanometric subsystem 1337
– electrons and photons 1355
nanometrically rough material surface 1347
– self-organized smoothing 1347
nanooptics 1335
nanoparticle 222, 1531
– polymer composite 1531
nanophotonic
– fabrication 1344
– NOT gate 1346
nanophotonic device
– features 1343
– heat generation 1343
– input and output terminals 1342
– optical switch 1339
– single photon operation 1343
– tamper resistance 1343
nanophotonics 1335, 1336, 1355
– basic devices 1338
– industrial applications 1354
– inherent hierarchy 1353
nanoplasmonic field 1145
nanoprobe 1466
nanorod 1341, 1546
nanoscale
– holographic interferometry 1532
– imaging 1384
– localization 526
– superresolution microscopy 1392

nanoscopy 1359
– structured 1391
nanosecond OPO 877
nanostructure 225, 1381
– analysis 1376
– biological 1376, 1381, 1392
– periodic 843
nanowire single photon detector 612
– superconducting 612
narrow-linewidth 853, 855, 858
– dye laser oscillator 854
– oscillation 852, 857
NAS copolymer 324
National Ignition Facility (NIF) 920
natural
– broadening 651
– vignetting 467
nature of light 89
NCPM (noncritical phase matching) 507, 867, 892
Nd laser 696
Nd:glass laser 224
Nd:$Y_3Al_5O_{12}$ (Nd-doped yttrium aluminum garnet) 672
Nd:YAG
– (2ω) laser 511
– microsphere laser 341
– pumped OPO 1148
Nd:YAG ceramics
– laser oscillation 340
Nd:YAG laser 224, 511, 912
– transmittance 334
Nd:YAG microchip pumped distributed feedback (DFB) 858
Nd:YLF-laser 192
near-degenerate PPLT OPO 874
near-field (NF) 838
– spot size 1212
– storage media 1354
– technique 1541
near-field scanning optical microscopy (NSOM) 1359
near-infrared (NIR) 567
nearly index-matched (NIM) 458
negative
– refraction 515
– refractive index 518
neodymium dopant level 298
NEP (noise equivalent power) 549, 559, 576
neutral density 229
neutron
– diffractive optics 1537
– interferometer 1538
Newton equation 52
next-generation information processing 1343
next-generation lithography (NGL) 850
NF (near-field) 838
– spot size 1212
– storage media 1354
– technique 1541
NFL (nanofocusing lens) 1466
NGL (next-generation lithography) 850
Ni^{2+} laser 753
NIF (National Ignition Facility) 920
Ni-like Mo 910
NIM (nearly index-matched) 458
niobium 1409
NIR (near-infrared) 567
nitrogen 798
– laser 834
NLO (nonlinear optical) 515, 1212
– crystal 886, 1126, 1127
– device 884
– effect 1212
– interaction 167
– material 269
– photonic-crystal fiber (PCF) 213
– polymer 1246
– susceptibility 200
NLO effect 1212
NLSE (nonlinear Schrödinger equation) 170, 193, 1203
NLSG (nonlinear signal generator) 1074
NLTL (nonlinear transmission lines) 1404
noctilucent cloud 1510
nodal point 47, 49, 50
NOHD (nominal ocular hazard distance) 1591
noise 932
– charge transfer 588
– dark current shot 588
– excess factor 575
– figure 1198
– frequency 933
– generation–recombination 547, 551
– power spectrum 1323
– process 934
– random frequency 700, 933
– source 546, 1291
– spike 1070
– technical 663
– total 1099
noise equivalent power (NEP) 549, 559, 576
Nomarski
– interferometer 1273
– prism 1271
nominal ocular hazard distance (NOHD) 1591
non return to zero (NRZ) 1183
nonclassical light 27
noncollinear optical parametric amplifier (NOPA) 1127, 1136
noncollinear phase matching 882
noncommon-path interferometer 1275
noncritical phase matching (NCPM) 507, 867, 892
nondegenerate level 644
nondestructive
– readout 360
– testing 1255
nonequilibrium carrier 550
noninvasive attack 1343
nonlinear
– absorption 220, 1115
– chirping 1203
– coefficient 886
– coupling 846
– detector 1077
– dielectric 864
– holographic light scattering 1536
– interaction 363
– laser spectroscopy 1114
– lens 172
– mechanism 271
– medium 170, 1086
– optics 98, 161
– patterned excitation 1374
– phase shift 170
– polarization 1204
– process 168, 270
– Raman spectroscopy 198
– refractive index 194
– spectroscopy 198
nonlinear crystal 231, 508, 865, 870, 887, 1404, 1445
– material 509
– poling 509
nonlinear fiber 1200, 1288
– ytterbium-doped 1288
nonlinear optical (NLO) 515, 1212
– crystal 886, 1126, 1127
– device 884
– effect 1212
– interaction 167
– material 269
– photonic-crystal fiber (PCF) 213
– polymer 1246
– susceptibility 200

nonlinear photonic crystal (NPC) 515
nonlinear Schrödinger equation (NLSE) 170, 193, 1203
nonlinear signal generator (NLSG) 1074
nonlinear susceptibility 167, 366, 508
– even-order 168
nonlinear transmission lines (NLTL) 1404
nonmagnetic material 99
nonparaxial aberration 466
nonradiative decay 643, 644, 652, 737, 745, 748, 755, 756
nonretinal injury 1577
nonsequential ray tracing 69
non-steady-state photocurrent 365
nonuniform mesh 1223
nonvisible laser radiation 1587
nonzero dispersion shifted fiber (NZ-DSF) 1185, 1202, 1205
NOPA (noncollinear optical parametric amplifier) 1127, 1136
NOT gate operation 1341
not phase-matched interaction (NPM) 865
NPC (nonlinear photonic crystal) 515
NPM (not phase-matched interaction) 865
NRZ (non return to zero) 1183
NSOM (near-field scanning optical microscopy) 1359
n-th harmonics 1129
n-type 1443
– semiconductor 553
nuclear topography 1390
number
– *M* 1108
– operator 14
– squeezed 28
– states 28
numerical
– efficiency 1223
– implementation of diffraction effect 137, 141
– method 1224
numerical aperture (NA) 63, 140, 338, 492, 840, 1360, 1470, 1541
n-wave mixing 270
Nyquist sampling area 1554
NZ-DSF (nonzero dispersion shifted fiber) 1185, 1202, 1205

O

OADM (optical add/drop multiplexer) 1230
object and image space 50
object beam 1547, 1552
object recognition 1532
OC (output coupler) 643, 647, 1069
occultation 1490
OCT (optical coherence tomography) 491, 494, 1206
octave spanning comb 956
OD (output diode) 586
odd harmonic component 227
OEIC (optoelectronic integrated circuits) 1210
OFC (oxygen free copper) 372
off-axis geometry 1527
Öffner telescope 1062
off-the-shelf solution 429
OFHC (oxygen-free high-conductivity) 801
OFI (optical-field ionization) 910
oil spill clear spectral signature 1157
OLED (organic light-emitting diode) 351, 636, 637, 842
– kinds of failure 355
– reduction of brightness 355
on vision 4
on-chip diode sampler 1405
one-center model 357
one-photon transition 1119
OP (oriented-patterned) 508
OPA (optical parametric amplifier) 213, 217
OPCPA (optical parametric chirped pulse amplification) 882, 922
OPD (optical path difference) 93, 137, 433
open
– circuit voltage 555
– optical resonator 648
OPG (optical parametric generation) 510, 863, 890
ophthalmological instrument 453
OPL (optical path length) 36, 67, 488, 489, 1059, 1224
OPO (optical parametric oscillator) 213, 507, 863, 883, 956
– components 870
– design and performance 870
optic design 325
optical
– 3-D resolution 1383
– amplification 1201
– amplifier 645, 1195, 1234
– anisotropy 266, 1120
– areal density 1544
– axis 42, 486
– bandwidth 1198
– bistability 174
– buffering 1342
– ceramics 333
– characterization 518
– chopper 1435
– clock 952, 954, 1293, 1294
– communication 1172, 1206
– communication system 349, 492, 525, 947, 1172, 1183
– confinement 758
– damage 356, 366
– damage threshold 508
– delay line 525
– design 64, 488
– diffraction limit 1541
– diode 1119
– double resonance 1123
– element 321
– energy 526
– field eigenmode 1221
– filter 786
– gain 765
– glass 292, 378
– holography 126
– imaging 42
– instrument 74, 454
– isolation 1375
– Kerr effect 272
– lattice 954
– lithography 147
– loss 208
– mammography 1159
– memory 526
– modulator 1234
– nanofountain 1342, 1354
– network 1237
– nonlinear quantum dot (QD) 527
– octave 1287
– performance 501
– phase conjugation 173
– phased array 1232, 1233
– pick-up 1544
– poling 269
– power 1239
– pulse compression 1127
– pulse generator 1342
– pumping 646, 1122
– ray 37
– rectification 1433
– resolution 1362, 1368
– resonator 526, 656

– sensing 494
– shape 321
– signal energy 1342
– superresolution 1542
– surfaces 57
– switch 505, 1234
– system 46, 427
– technology 1343
– thickness 785, 1496
– tomography 1143
– volumetric recording 1543
optical add/drop multiplexer (OADM) 1230
optical coherence tomography (OCT) 491, 494, 1206
optical component 321
optical data
– storage 147, 218, 673, 763, 1519, 1532, 1540, 1547
– transmission 1535
optical design 430, 431, 438
– optimization process 431
optical design program 430
– information needs 430
optical detector
– dye-sensitized 608
– hybrid organic/inorganic 608
– polymer-based 605
optical fiber
– field distribution 1177
– graded-index 1178
– losses 1173
– pulse dispersion 1180
optical frequency
– doubling 1109
– measurement 954, 955, 1123, 1287
– metrology 1300
– standard 951, 1294
optical frequency comb 1123, 1124, 1285
– generator 1287
– principle 1285
– technique 1285
optical interference
– control 1335
optical near-field 1336
– interaction 1335, 1340, 1353
– memory retrieval 1354
– response 1354
optical parametric 270
– amplification 1126
– device 1127
– generation 510, 1288
optical parametric amplifier (OPA) 213, 217
optical parametric chirped pulse amplification (OPCPA) 882, 922
optical parametric generation (OPG) 510, 863, 890
optical parametric oscillator (OPO) 213, 507, 863, 883, 956
– components 870
– design and performance 870
optical path difference (OPD) 93, 137, 433
optical path length (OPL) 36, 67, 488, 489, 1059, 1224
optical signal to noise ratio (OSNR) 1198
optical signal transmission system
– performance 1354
optical storage
– diffraction-limited optics 1542
– format 1540
– performance 1542
– product 1541
– technology 1541
– three-dimensional 1543
– volumetric 1543
optical transfer function (OTF) 1372
optical/electrical energy conversion 1350
optical/electrical energy up-conversion 1351
optical/magnetic hybrid disc storage density 1354
optical/optical energy conversion 1350
optical-field ionization (OFI) 910
optical-field-driven attosecond streaking 1131
optically active compound 852
optically pumped semiconductor laser 683
optical-microwave double resonance 1122
optics 4
– atmospheric 1493
– high-damage-threshold 302
– integrated 1209
optimization algorithm 431
optimization process 431
optimized confocal focussing 872
optimized narrow-linewidth 857
optimized nonlinear material 863
– BBO 863
– $KTiOPO_4$ (KTP) 863
– LiB_3O_5 (LBO) 863
optoacoustic spectroscopy 1102
optoceramics 335
optoelectronic antenna 1400, 1416
optoelectronic device 791
optoelectronic integrated circuits (OEIC) 1210
optoelectronic THz beam 1412
– system 1400, 1416
optoelectronics 1399
optofluidic technology 506
optogalvanic spectroscopy 1104, 1105
optomechanical system 1322
optothermal
– expansion coefficient 460
– load 367
– spectroscopy 1102, 1112
ordinary
– axis 267
– polarization 361
– waves 666
organic
– photoconductor 636
– photovoltaic film 611
– semiconductor 862
organic light-emitting diode (OLED) 351, 636, 637, 842
– kinds of failure 355
– reduction of brightness 355
organic molecule 1380
– photophysics 1380
organic solids
– THz property 1449
organically modified silicates (ORMOSIL) 857
organic-inorganic gain media 858
organic-inorganic matrix 858
organic-inorganic nanomaterial 858
oriented-patterned (OP) 508
ORMOSIL (organically modified silicates) 857
orthogonality condition 37, 93
orthogonality relation 104
orthogonally polarized wave 1257
oscillating bandwidth 669
oscillator-amplifier 854
OSNR (optical signal to noise ratio) 1198
OTF (optical transfer function) 1372
out-of-plane angular multiplexing 1529
out-of-plane radiation 1217
out-of-plane shift multiplexing 1529
output coupler (OC) 643, 647, 1069
output coupling efficiency 661
output diode (OD) 586

output power 669, 787
outside vapor deposition (OVD) 1173
OVD (outside vapor deposition) 1173
overall doubling 364
overall rectification 364
overtone absorption line 1101
oxide stripe laser 769
oxidic bulk glass 296
oxygen 800
oxygen A-band 1492
oxygen free copper (OFC) 372
oxygen-free high-conductivity (OFHC) 801

P

p/n junction photodiode 554
PA (photon avalanche) 687, 693
PALM (photoactivated localization microscopy) 1378
PALMIRA (with running acquisition) 1378
parabolic
– index fiber 1180, 1181
– mirror 1467
– secant-hyperbolic index profile 486
– slab waveguide 1225
parallel detection geometry 236
parallel plate waveguide (PPWG) 1449
parametric
– amplification 167, 865, 1126
– down-conversion 1331
– four-wave process 361
– gain 865
– mixing process 363
– oscillator 875
para-phenyleneethylene (pol) (PPE) 353
parasitical loss 872
paraxial 429
– approximation 43, 155, 171
– geometrical optics 42, 157
– Helmholtz equation 149, 150
– law of refraction 44
– matrix 156
– transfer matrix 44
– wave equation 654
paraxial matrix theory 44, 58
– 3×3 matrix 59
– local coordinate system 61
– plane parallel plate 45
– refraction at plane surface 45
– sign conventions 45
– thin prism 60
– transfer matrix 44
– transformation between global and local coordinates 61
paraxial ray 42, 44
– definition 44
– diffraction grating 59
– tracing 42, 44, 59
parhelia 1503
Parry arc 1504
partial
– dispersion 292
– reflector 647
partially reflecting mirror 1265
particle accelerator 1145
passive infrared detectors (PIR) 595
passive loss 677
passive mode locking 671, 855
path difference fan plot 435
patterned excitation microscopy (PEM) 1359, 1360
patterned/structured illumination excitation microscopy (PEM/SIM) 1371
patterning 1347
Paul trap 951, 952
Paul trap (RF ion trap) 952
PB (photonic band) 513
PBG (photonic bandgap) 512, 1206
– fiber 1206
– incomplete 513
PBS (photonic band structure) 512, 513, 790
PBS (polarizing beam splitter) 937, 1272
PC (photonic crystal) 511, 790, 1211, 1212, 1335, 1532
– 2-D 1216
– band structure 1217
– fiber 171, 177, 193, 512, 517, 1200, 1206
– lattice 791
– light state 512
– optical characterization 518
– phase fronts 1216
– planar 1217
– slab 512
– waveguide 517, 1216
PC (Pockels cell) 666, 1127
PC (polycarbonate) 324, 326, 460
– based device 523
– laser 528
– nanocavity 526
– waveguide 524
– waveguide design 524
PCA (polycrystalline alumina) 333, 335
PCB (printed circuit board) 842
PCF (heated hollow photonic-crystal fiber) 212
PCF (hollow-core photonic-crystal fiber) 209
PCF (photonic-crystal fiber) 177
– light source 197
PCVD (photochemical vapor deposition) 1344
PD (photodetector) 937
PDE (photon detection efficiency) 579, 614
PDH frequency stabilization technique 937
PDLC (polymer dispersed liquid crystal) 347
PDLC (polymer-dispersed liquid crystal) 347, 1531
PDMS (polydimethylsiloxane) 500
– membrane 503
peak-to-valley (PTV) 431
PECVD (plasma-enhanced chemical vapor deposition) 413, 1243
PEM (patterned excitation microscopy) 1359, 1360
PEM/SIM (patterned/structured illumination excitation microscopy) 1371
penetration depth 1572, 1574
Penning trap 1120
Penrose tilting 515
perfectly matched layer (PML) 1223, 1384
– tranparent boundary condition 1223
performance 1294
periodic
– Bragg grating 1235
– domain inversion 366
– nanostructure 843
– PC lattice 516
– waveguide structure 1212
periodically poled crystal 893
periodically poled KTP (PPKTP) 874
periodically poled $LiNbO_3$ (PPLN) 510, 873, 891, 893, 897
periodically poled lithium tantalate (PPLT) 874
periodically poled material 888
periodically poled nonlinear grating 515
periodically poled potassium titanyl phosphate (PPKTP) 510

periodically poled structure
– fabrication 508
periodically structured ferroelectric 863
peristrophic multiplexing 1529, 1553
perovskite structure
– electrooptic property 336
perovskite-type crystal 357, 367
perpendicular detection geometry 236
persistent spectral hole burning (PSHB) 1545
personnel protective equipment 1595
perturbation theory
– coupled mode theory 1220
– local normal modes 1220
perturbations 939
PESRO (pump-enhanced SRO) 871
PET (positron emission tomography) 342
PF (polyfluorene) 353
PG (polarization-gate) frequency-resolved optical gating (FROG) 1082
PHASAR 1232
phase 1522
– matching 1085
– modulation function 1057
– retrieval 1088
– shifting interferometry 123
– velocity 18, 93, 258
phase change velocity 1281
phase error 915, 1552
phase factor 654
phase function 1049, 1477
phase hologram 1522, 1523
phase locking 233
phase matching 200, 225, 229, 230, 865, 913
– non-collinear 868
phase measurement 1273
phase mismatch 178, 181, 507, 864, 895
phase modulation 364, 935, 1058, 1100
phase modulator 1276
phase shift (PS) 1134
phase shifter 1274
phase squeezed 28
phase transition 1536
phase transition field 464
phase unwrapping 1050
phase velocity 1057, 1182, 1406
phase-change material 1543
phase-coded multiplexing 1528, 1549
phase-conjugate geometry 174
phase-conjugate read out 1551
phase-conjugate reference beam 1546
phased array 1230
– blaze point 1233
– light path function 1233
– Rowland mounting 1233
phased array, optical 1232
phase-imaging 1262
Phase-level profile 471
phase-locking condition 231
phase-matching 1432
phase-matching angle 867
phase-matching condition 891, 1126, 1128, 1131
– generalized 180
phase-matching effect 1289
phase-modulation technique 936
phase-offset 1256
phase-sensitive detector (PSD) 946
phase-shift CRFS 1134
phase-shifted interferogram 1275
phase-shifting digital holography 1530
phase-shifting interferometry (PSI) 123, 1273
phase-unwrapping algorithm 124
phenanthraquinone (PQ) 1549
phonon-assisted desorption 1348
phonon-assisted PCVD 1345
– deposition rate 1344
phonon-assisted photochemical etching 1348
phonon-assisted photolithography 1346
– diffraction grating 1346
– Fresnel zone plate 1346
– patterning ability 1345

two-mode stabilization 944
two-photon
– 3-D optical storage 1545
– absorption 316, 1544
– absorption for addressing 1544
– diode 1075
– excitation 359, 949, 1364
– holographic recording 360
– interference 1331
– ionization 233, 1112
– pumped fluorescence 862
– resonant ionization 239
– spectroscopy 1125
– transition 947
two-photon absorption (TPA) 1245
two-photon-absorption (TPA) 316
two-stage microscope 85
two-step excitation 1345
– by DP-CP 1350
two-stream model 1482
two-time correlation function 1323
Twyman–Green interferometer 122, 1268
type
– glass 381
Type I laser 783
Type II laser 783

U

UFC (ultrafast ceramics) 342
UHP lamp 630
ultimate sensitivity 1097
ultrafast 1399
– electrical pulse 1402, 1403
– laser technology 856
– optoelectronics 1401
– process in biology 1143
– switching 527
ultrafast ceramics (UFC) 342
ultrashort
– laser 1143
– optical pulse 525, 1129
ultrashort light pulse 185
– linear property 1048
ultrashort wavelength x-ray generation 832
ultraviolet (UV) 1085
– laser system 843
– lithography 850
– optical material 339
– pulse 1089
– transparency 289
umbra irradiance spectra 1507
umklapp
– scattering 529
– shift 518
unconventional application
– lidar technique 1159
uncoupled mode 513
undulator 17, 902, 903
uniaxial 267
unidirectional ring resonator 656
uniform beam profile 452
uniformity error 463
unipolar laser 782
unit plane 47
unity-gain frequency 942
unsaturated gain 1108
unstable resonator 656, 810
up-chirped pulse 1048
upconversion 687, 1288
– frequency 1351
– pumped Pr^{3+} lasers 687
upconverted absorption 861
uranium 849
Urbach absorption tail 339
UV (ultraviolet) 1085
– laser system 843
– lithography 850
– optical material 339
– pulse 1089
– transparency 289

V

V parameter 1215
V^{2+} laser 752

vacuum permittivity 254
valence band (VB) 757
– structure 761, 763
vanishing line 1497
vapor phase epitaxy (VPE) 771
varactor diode 1404
variable
– lens 496
– optical component 506
variable aperture
– schematic drawing 506
VB (valence band) 757
– structure 761, 763
VBG (volume holographic grating) 877
VC (vertical cavity) 765
VCSEL (vertical-cavity surface-emitting laser) 766, 771, 774, 785
vector coupling 1214
vectorial Helmholtz equation 1217
vegetation monitoring 1157
Vernier technique 1297
vertical cavity (VC) 765
vertical guidance 1218
vertical-cavity surface-emitting laser (VCSEL) 766, 771, 774, 785
very large scale integration (VLSI) 1400
very large telescope (VLT) 311
V-groove 891
V-groove waveguide 1219
vibrational
– energy level 794
– spectrum 22
– temperature 799
vidicon 599, 600
VIM (virtual microscopy) 1370
virtual cloud of photons 1336
virtual focus 54
virtual microscopy (VIM) 1370
virtual photon 1355
– Feynman diagram 1336
virtual plane plate 1267
visibility 1509
visible
– Er^{3+} laser 691
– Pr^{3+} laser 684
– Pr^{3+} fiber laser 695
visual range 1509
Vleck–Weisskopf theory 1445
VLSI (very large scale integration) 1400
VLT (very large telescope) 311
Voigt line shape 22
Voigt-profile 1112
voltage-sensitive detector 593
volume hologram 1548
volume holographic grating (VBG) 877
volume optical element 1532
volume scattering 275
– coherent scattering 277
– Mie scattering 277
– multiple scattering 277
– single scattering 277
volumetric
– optical data storage 1543
– pixel 1544
VPE (vapor phase epitaxy) 771

W
