One can speculate that drugs interfering with specific platelet–leukocyte interaction mechanism(s), would block both platelet and leukocyte contribution to thrombus formation and might prove to be clinically more effective than drugs only affecting either cell type[9]. Although platelet GpIIbIIIa might be indirectly involved in platelet–leukocyte interaction mediated by fibrinogen, compounds directly inhibiting the function of P-selectin, β2-integrin or their respective counter-receptors should be identified and developed for experimental and clinical testing.

Following the already mentioned observation[91] that platelet P-selectin-dependent leukocyte accumulation in an experimental thrombosis model in the baboon promotes fibrin deposition, it has been shown that P-selectin blockade by specific monoclonal antibodies[219] or with a soluble recombinant form of PSGL-1[220] accelerates the pharmacological lysis of arterial thrombi and prevents reocclusion in animal models. P-selectin blockade also reduces PMN adhesion to platelets at the site of a deep injury in the carotid artery of pigs[221] and reduces cyclic occlusion in a canine model of recurrent arterial thrombosis[222]. P-selectin antagonism with recombinant soluble PSGL-1 inhibits early platelet–leukocyte adhesion on pig injured arteries and reduces restenosis after angioplasty through a positive impact on vascular remodelling[223].

Compounds interfering with the intracellular signalling mechanisms, including the control of tyrosine kinases, might also be of some pharmacological and therapeutic relevance. In this context, it is of interest to mention that genistein, piceatannol and other relatively specific inhibitors of leukocyte tyrosine kinases have been found in naturally derived nutrients and/or in wine[224]. And wine is presently considered as a dietary means to prevent ischemic heart disease[225,226]. *Trans*-resveratrol, a polyphenolic compound also contained in red wine, prevents platelet–PMN adhesion and Mac-1 expression by PMN in vitro[227].

In conclusion, inflammation plays a major role in atherogenesis and thrombosis[228]. While the role of platelets in these phenomena was recognized by many investigators over the last century, the involvement of leukocytes, major players in inflammation, was only appreciated in the last two decades[229].

Slowing, tethering and subsequent attachment of circulating leukocytes to the vascular endothelium is presently considered among the earliest inflammatory steps leading

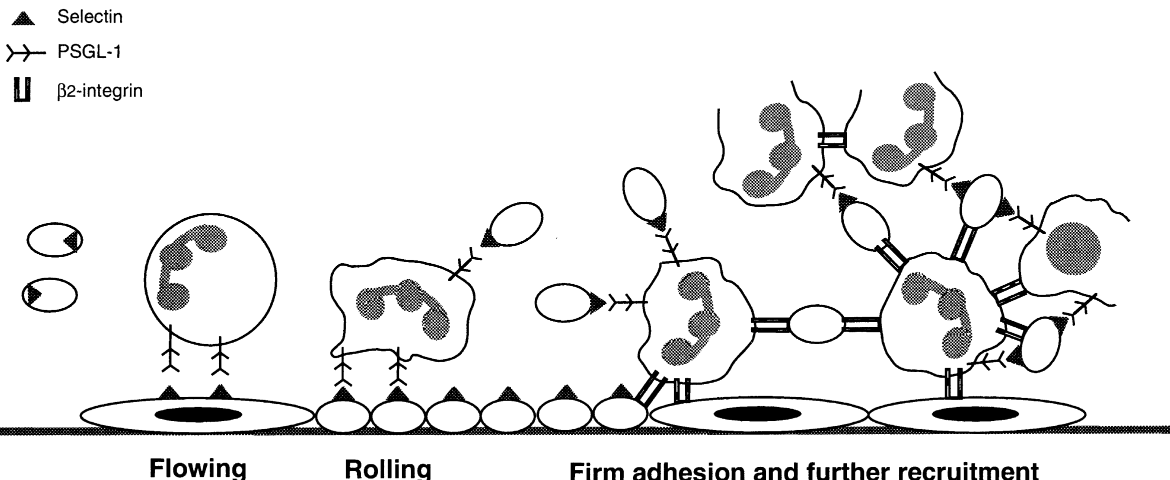

Fig. 28.7. Hypothetical sequence of the interactions between PMN leukocytes and activated platelets or injured endothelial cells. Binding of P-selectin (or E-selectin) to PSGL-1 promotes tethering and rolling of PMN leukocytes on vascular surface. PSGL-1-induced activation of PMN β2-integrin(s) allows stable multicellular interactions. Cathepsin G released by activated PMN leukocytes may facilitate further platelet and PMN recruitment at the vascular injury site. (This figure is reprinted[8], with permission.)

to vascular occlusion[228]. In this process the possible contribution of platelet–leukocyte interactions has been progressively characterized[7,8], as well as the importance of the selectin and integrin families of cell adhesion molecules[230–232] (Fig. 28.7). Basic work in vitro and in experimental models suggests that platelet–leukocyte cross-talk plays an important role in the initiation and progression of athero-thrombosis.

Clinical and epidemiological data, although relatively limited, already provide confirmation of the cardiovascular risk associated with cell–cell interaction and related molecular adhesive mechanisms[191].

Finally, it is likely that new pharmacological avenues will be scoured to develop new preventive and therapeutic approaches based on the cellular and molecular pathways described in this chapter.

Acknowledgements

Marina Molino, Paola Piccardoni, Serenella Rotondo, Rita Sideri, Licia Totani, Antonio Celardo, Giuseppe Dell'Elba, Angelomaria Di Santo, Stefano Manarini, Nicola Martelli, Emanuela Napoleone, Antonio Piccoli contributed to the authors' experimental work mentioned in this chapter.

Mrs Filomena Cinalli and Maria Grazia Mencuccini helped prepare the manuscript.

Introduction

The vascular endothelium is a dynamic cellular interface between the blood and subendothelial tissue and is critical for the maintenance of blood flow and hemostasis. The endothelium releases substances (Fig. 29.1) that play an important role in the modulation of vascular tone and permeability, as well as blood fluidity. These substances affect vascular tone by causing both vasodilation [prostaglandin I_2 (PGI_2), nitric oxide (NO), and endothelium-derived hyperpolarizing factor (EDHF)] and vasoconstriction [thromboxane A_2 (TXA_2) and endothelin (Et-1)], with the interaction between these two processes ultimately determining the tone of the vessel. In addition to modulating vascular tone, substances released from the endothelium affect platelet adhesion and aggregation. Nitric oxide inhibits platelets adhesion and aggregation, and PGI_2 inhibits platelet aggregation.

Abnormal endothelial responses (endothelial dysfunction) or frank damage to or denudation of the endothelium promotes a prothrombotic state by reducing antiplatelet factors and by inducing adhesion molecule expression. Furthermore, endothelial dysfunction may be involved in the pathogenesis of several cardiovascular disorders, including atherosclerosis, diabetes mellitus, essential hypertension, hypercholesterolemia, and hyperhomocysteinemia.

In this chapter we will review the control of normal endothelial function, with specific emphasis on antiplatelet effects of substances released from the endothelial cell. We will also review the consequences of endothelial dysfunction, giving specific examples in several disease states.

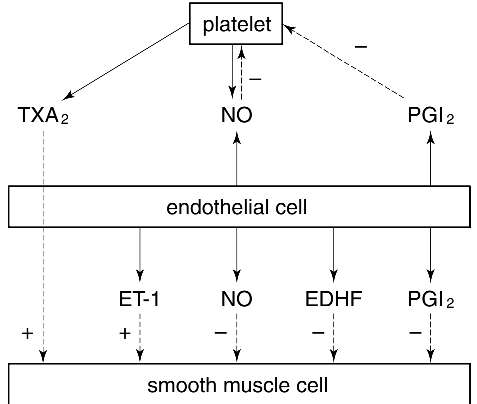

Fig. 29.1. Effect of substances released (solid line) from the endothelial cell. Nitric oxide, PGI_2, and EDHF released from the endothelial cell act on the smooth muscle cell to produce vasodilation (−) of the vessel. In addition, NO and PGI_2 also inhibit platelet activation and aggregation (−). Endothelin-1 released by the endothelial cell and TXA_2 released by platelets produce vasoconstriction (+) of the vessel.

Molecular determinants of endothelial function

Vasoactive substances

Prostaglandin I_2

Prostaglandin I_2, or prostacyclin, is a major product of arachidonic acid metabolism. When hydrolyzed from membrane phospholipids, arachidonic acid is metabolized by cyclooxygenase to the endoperoxide, prostaglandin H_2 (PGH_2). Prostaglandin H_2 is a substrate for a series of enzymes that form PGI_2, PGE_2, and $PGF_{2\alpha}$ as the major prostanoid products in vascular endothelial and smooth muscle cells; however, PGI_2 is produced principally by the endothelial cell[1]. The endothelial production of PGI_2 and

PGE_2 is increased by agonists, such as adenosine 5-diphosphate (ADP)/ adenosine 5-triphosphate (ATP), platelet activating factor (PAF), histamine, leukotrienes C_4 and D_4, thrombin, and bradykinin[2–8].

Prostaglandin I_2 is a potent endothelium-derived vasodilator[9,10] the release of which can be enhanced by hemodynamic forces, such as shear stress and pulsatile pressure, as well as by biochemical mediators, including thrombin, bradykinin, angiotensin II, histamine, platelet-derived growth factor (PDGF), interleukin-1 (IL-1), TXA_2, and adenine nucleotides[11–16]. Prostaglandin I_2 acts by binding to a G protein-coupled receptor on the vascular smooth muscle cell linked to adenylyl cyclase, causing an increase in the intracellular levels of cyclic 3′,5′-adenosine monophosphate (cAMP)[17]. In turn, cyclic AMP activates protein kinase A, which influences calcium regulatory mechanisms, resulting in decreased intracellular calcium concentration, decreased calcium-dependent actomyosin ATPase activity, relaxation of vascular smooth muscle cells, and vasodilation[18].

In addition to its effect on the vascular smooth muscle cell, endothelium-derived PGI_2 also inhibits the activation and aggregation of platelets and promotes their disaggregation[19–21]. This action on platelets is mediated, as well, by increases in intracellular cyclic AMP levels[1,22]. However, unlike NO, which inhibits both adhesion and aggregation of activated platelets partly via a cyclic 3,5-guanosine monophosphate (cyclic GMP)-dependent mechanism, PGI_2 only inhibits platelet activation and aggregation and has no effect on adhesion[23].

The other prostaglandins produced by the metabolism of arachidonic acid may achieve high enough concentrations locally (adjacent to the endothelium) to contribute to vascular homeostasis. Prostaglandin H_2 is a potent vasoconstrictor, indicating that vasodilation by arachidonic acid products, such as PGI_2, depends largely on the conversion of PGH_2 to PGI_2[24]. In a variety of vascular diseases, the conversion of PGH_2 to PGI_2 may be impaired, leading to endothelium-dependent contraction by the precursor prostaglandin endoperoxides[25]. Thus, the conversion of PGH_2 to PGI_2 in endothelial cells may be a key event on which rests the balance between endothelium-dependent vasodilation and constriction, particularly that associated with vascular diseases[24,26].

Nitric oxide

The importance of endothelial NO was first observed in 1980 by Furchgott and Zawadzki, who demonstrated that exposure of an isolated rabbit aorta to acetylcholine induces release of a vasodilator substance[27]. This substance was subsequently termed endothelium-derived relaxing factor (EDRF). Endothelium-derived relaxing factor has since been identified as NO or a closely related redox form of NO[28–32]. Nitric oxide is derived from L-arginine (Fig. 29.2) via NO synthase (NOS) by oxidation of its terminal guanidino nitrogen[33,34]. Molecular oxygen and NADPH are cosubstrates in this reaction[35,36]. There are several isoforms of NOS, one is a constitutive enzyme class that is present in the vascular endothelium (eNOS or NosIII), neuronal cells (nNOS or NosI), and other cell types, while the other is an inducible form of the enzyme (iNOS or Nos II), which has been found in many cell types, including macrophages, neutrophils, and vascular smooth muscle cells[37]. Nitric oxide synthases contain both flavin adenine dinucleotide and mononucleotide[38] and require the presence of several redox-active cofactors, including tetrahydrobiopterin, reduced glutathione, and a heme complex[39–42], for optimal activity.

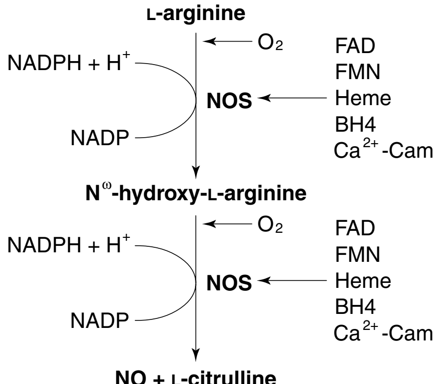

Fig. 29.2. The formation of NO from L-arginine by nitric oxide synthase (NOS). Nitric oxide synthase requires FAD, FMN, Heme, BH_4, and Ca^{2+}-CaM as essential cofactors. *Abbreviations:* BH_4, tetrahydrobiopterin; Ca^{2+}-CaM, calcium-calmodulin; FAD, flavin adenine dinucleotide; FMN, flavin mononucleotide; NADP, nicotinamide adenine dinucleotide phosphate.

In the vascular endothelium, agonists such as acetylcholine and bradykinin stimulate inositol 1,4,5-trisphosphate (IP_3) production by activating the phosphoinositide second messenger system[43]. Inositol 1,4,5-trisphosphate binds to receptors on the endoplasmic reticulum and causes calcium release from intracellular stores; this calcium binds to calmodulin, and, once formed, the calcium/calmodulin complex activates cNOS[44,45]. The rapid and transient production of NO by nNOS allows NO to function in neuronal tissue as a neurotransmitter. Similarly, in the vascular endothelium, eNOS is well suited for its role in maintaining basal vascular tone[46] owing to its capacity to generate low-level NO constitutively.

After production, NO readily diffuses across cell

Cambridge Books Online © Cambridge University Press, 2009

membranes to interact with specific molecular targets[33]. Nitric oxide regulates protein activity by binding reversibly to available acceptor functionalities, including heme iron and thiols[47]. After entering the target cell, NO binds to the heme moiety of soluble guanylyl cyclase and activates the enzyme, which then catalyses the production of cyclic GMP from guanosine 5′-triphosphate (GTP)[48,49]. Cyclic GMP, in turn, serves as a second messenger, activating cyclic GMP-dependent protein kinase, which decreases cytosolic calcium concentration and modulates ion channel functions, leading to relaxation of vascular smooth muscle cells[50]. Nitric oxide can also directly activate calcium-dependent potassium channels in vascular smooth muscle cells, producing hyperpolarization and relaxation[51]. In addition, nitric oxide inhibits platelet aggregation by a guanylyl cyclase mechanism[52,53].

Nitric oxide is continuously produced by the vascular endothelium, and this basal release of NO regulates vascular tone[54,55]. For example, in isolated arteries, the specific NOS inhibitor N^G-monomethyl-L-arginine (L-NMMA) produces endothelium-dependent contraction[56], while infusion of L-NMMA in the human forearm induces an increase in peripheral vascular resistance[6,57]. Furthermore, systemic doses of L-NMMA evoke long-lasting increases in blood pressure[58]. Normal NO release opposes the vasoconstrictor responses to clinically relevant stimuli, such as catecholamines[59] and serotonin[60]. Thus, NO synthase inhibition is associated with increased systemic blood pressure, decreased blood flow responses to exercise and local ischemia[61,62], and shortened bleeding time[63]. Inhibition of NO production is also associated with increased adhesion of leukocytes[64] or platelets[65] to cultured endothelial cells. Nitric oxide production by endothelial cells is stimulated by several factors present in the vascular milieu, including acetylcholine, bradykinin, calcium ionophore, adenine nucleotides, thrombin, substance P, neurokinins, vasopressin, oxytocin, uridine triphosphate (UTP), histamine, and $PFG_{2\alpha}$[65–67], although the responsiveness to these agonists exhibits some heterogeneity among vascular cells derived from different species and different vascular beds[66].

Endothelium-derived hyperpolarizing factor

Prostaglandin I_2 and NO are potent endothelial vasodilators; however, not all endothelium-dependent relaxation can be fully explained by their presence alone. For example, endothelium-dependent relaxation and hyperpolarization can be partially or totally resistant to inhibitors of cyclooxygenase and NOS[68–72]. Thus, there is at least one additional endothelial substance, as yet unidentified, that contributes to endothelial hyperpolarization; this has been termed endothelium-derived hyperpolarizing factor (EDHF)[69,73,74].

Although the precise nature of EDHF is not known, in some blood vessels epoxyeicosatrienoic acids, metabolites of P_{450} monooxygenase pathways of arachidonic acid metabolism, have been proposed as possible candidates for EDHF[75–77]. The vasodilator effect of EDHF is mediated by the activation of potassium channels in the vascular smooth muscle cell, with the amplitude of hyperpolarization inversely related to the extracellular concentration of potassium ions[78]. In addition, endothelial relaxation can be blocked by non-selective potassium channel inhibitors[71,79,80]. Some of the actions of EDHF have also been attributed to calcium-dependent potassium channels and potassium ATP channels[81]; however, these responses differ among species[82].

Endothelium-derived hyperpolarizing factor-mediated vasodilation is observed in both humans and animals[83,84]. The contribution of EDHF to endothelium-dependent relaxations increases as vessel size decreases, both in humans and in animals[84,85].

Elevated NO induces an impairment of the EDHF pathway[86,87] through a cyclic GMP-dependent mechanism[86]. This effect of NO appears to involve a reduction in the mobilization of arachidonic acid by agonists[87]. Impairment of EDHF by NO occurs only under conditions of excessive production of NO, such as those obtained in pro-inflammatory states, suggesting a role for the high-flux production of NO by iNOS. In arteries isolated from rats treated chronically with NOS inhibitors, EDHF-mediated relaxation is of the same magnitude as that obtained when NOS is inhibited acutely in vitro[88].

Endothelin

In addition to releasing vasodilatory substances, the endothelium also has the capacity to release/synthesize the vasoconstrictor endothelin (ET). Endothelin acts locally to oppose the vasodilation produced by PGI_2, NO, and EDHF. It is the interactions among these opposing substances that ultimately determine the vasomotor response of the vessel.

Endothelins are divided into three distinct peptide groups, ET-1, ET-2, and ET-3, which are derived from a separate gene product, prepro-endothelin, via 'big' endothelin through a series of subsequent peptide cleavages. Endothelin-1 is an extremely potent vasoconstrictor synthesized by the endothelium that produces long-lasting contractions of vascular smooth muscle. However, vasoconstriction can be prevented by proteases and inhibitors of protein synthesis[89]. Endothelin is synthesized in a two-step process. A pre-propeptide is cleaved by protease to

Cambridge Books Online © Cambridge University Press, 2009

form big ET-1 (39 amino acids), which is further cleaved by the endothelin converting enzyme (ECE) to form the 21-amino acid active peptide[90]. Big ET-1 can be identified intracellularly in endothelial cells, suggesting that ET-1 is synthesized constitutively and not stored. Endothelin-1 is found primarily in the endothelium, whereas ET-2 and ET-3 are present in nonvascular tissue[91]. A variety of stimuli can evoke ET-1 production by the endothelial cell, including IL-1, thrombin, TGF-β, phorbol esters, calcium ionophore, arginine vasopressin, hypoxia, shear stress, and vasoactive substances released by platelets[92–97], although the detection of stimulated levels requires 3 to 6 hours, consistent with alterations in gene expression. Importantly, ET-1 synthesis can also be inhibited by NO[92,98–100].

The endothelin receptor comprises two subtypes: ETa receptors (which have a higher affinity for ET-1 than ET-3) found mainly on the vascular smooth muscle cell and cardiomyocyte[98], and ETb receptors (which are non-selective for ET subtypes) located primarily on the endothelial cell and vascular smooth muscle cell[99]. Thus, ETa and ETb receptors mediate vasoconstriction in a variety of blood vessels and vascular beds, with a large degree of heterogeneity demonstrated among different species[100].

Vasomotion is affected by ETa and ETb receptors located on endothelial and vascular smooth muscle cells[101]. Endothelin-1 acts on ETa and ETb receptors located on vascular smooth muscle cells to elicit long-lasting vasoconstriction. This effect is mediated by the opening of ion (sodium and calcium) channels, which produces an increase in intracellular calcium[102]. In addition, ET-1 can activate ETbi receptors on the endothelium that leads to release of factors, such as NO and PGI_2, which, in turn, lead to an initial vascular smooth muscle relaxation mediated by increased cyclic AMP and cyclic GMP levels, respectively, with subsequent inhibition of L-type calcium channels[103]. Thus, under normal conditions, endothelial ET-1 synthesis contributes to the maintenance of basal vascular tone and blood pressure principally through activation of ETa receptors on vascular smooth muscle cells.

Thromboxane A_2

The endothelial cell metabolizes arachidonic acid via cyclooxygenase, which leads to the secretion of vasoconstrictor substances, such as PGH_2. In addition, thromboxane A_2 is secreted from platelets by the metabolism of arachidonic acid via thromboxane synthase. Prostaglandin H_2 and TXA_2 subsequently act on endoperoxide/thromboxane receptors in vascular smooth muscle cells to induce vasoconstriction and on platelets to induce activation and aggregation[104]. Prostaglandin H_2 has been shown to attenuate endothelium-dependent vasodilation induced by acetylcholine in isolated aortic rings from spontaneously hypertensive rats[105]. However, PGH_2 can also be converted to PGI_2 by the endothelial cell, which then opposes vasoconstriction.

Antiplatelet substances

Prostaglandin I_2

Endothelial cells and platelets can both generate eicosanoids from arachidonic acid via cyclooxygenase. However, the products formed in each cell type have opposing effects. Endothelial cells contain prostacyclin synthetase, which can produce PGI_2 from endoperoxides (PGH_2)[106], while platelets contain thromboxane synthetase, which produces TXA_2[18]. Thromboxane A_2 formation in the platelet induces platelet aggregation, which is accompanied by the platelet release reaction whereby serotonin and other granule components are expelled from platelet stores. Thromboxane A_2 also induces a rise in the concentration of ionized calcium in the platelet cytosol and a decrease in platelet cyclic AMP formation by inhibiting adenylyl cyclase. In addition, TXA_2 acts on vascular smooth muscle cells to produce vasoconstriction. As platelets are unable to resynthesize cyclooxygenase, in the presence of the irreversible cyclooxygenase inhibitor aspirin, TXA_2 production is completely blocked. In contrast, endothelial cells are able to resynthesize cyclooxygenase; thus, aspirin only leads to a transient decrease in PGI_2 production.

Endoperoxides (PGG_2, PGH_2) released from the platelet by the conversion of arachidonic acid can also be used by the endothelium to produce PGI_2[106]. In addition to its potent vasodilatory effects, PGI_2 also inhibits platelet function. Prostaglandin I_2 binds to a specific receptor on the surface of the platelet and stimulates adenylyl cyclase[22]. The resulting increase in platelet cyclic AMP leads to calcium reuptake by the dense tubular system and, thereby, inhibits platelet activation, platelet granule secretion, platelet aggregation, and the development of platelet procoagulant activities[107].

Nitric oxide

Nitric oxide is a potent endothelial product that is principally involved in the regulation of vascular tone and in maintaining the antithrombotic properties of the endothelium. Nitric oxide achieves these ends by decreasing vascular smooth muscle tone and by inhibiting platelet responses, such as platelet adhesion, platelet granule secretion, platelet aggregation, and arachidonic acid liberation[108–110], respectively.

Cambridge Books Online © Cambridge University Press, 2009

Nitric oxide released by the endothelium diffuses readily across the platelet membrane and binds to the heme moiety of soluble guanylyl cyclase. Heme binding leads to guanylyl cyclase activation and an increase in cyclic GMP production, which, in turn, activates a cyclic GMP-dependent protein kinase that phosphorylates myosin light chain kinase and regulates actomyosin ATPase activity[111,112]. Activation of cyclic GMP-dependent protein kinase also leads to phosphorylation of calcium transporters, which decrease intracellular calcium concentration[113]. Nitric oxide also inhibits the normal activation-dependent increase in platelet surface glycoprotein expression, such as P-selectin and the active conformation of glycoprotein (GP) IIb–IIIa[114]. Endothelial NO production is stimulated by shear stress and by substances released during platelet activation (such as ADP and 5-HT), as well as by determinants of the coagulation cascade, such as thrombin[115].

In addition to the effect of endothelial NO, platelets themselves possess both constitutive and, possibly, inducible NOS (cNOS and iNOS), whereby NO is produced during platelet aggregation[116–118]. Platelet aggregation can be enhanced by incubation with inhibitors of NOS and decreased by the NOS substrate L-arginine[119], and this platelet-derived NO pool also limits platelet recruitment to the growing platelet thrombus[116], potentially limiting the self-amplification of platelet thrombus formation in vivo. Thus, NO appears to be involved in the regulation of platelet function and platelet aggregate formation.

The anti-thrombotic properties of the endothelial surface may be a consequence of the combined actions of NO and PGI_2. Prostaglandin I_2 is as potent local vasodilator and a potent inhibitor of platelet aggregation as is NO[120]. By contrast with NO, the physiological antiplatelet effects of PGI_2 are mediated by an increase in cyclic AMP[19]. Nitric oxide also causes vasodilation and inhibits platelet aggregation, but unlike PGI_2, NO also inhibits platelet adhesion to the vascular endothelium[121]. Nitric oxide and PGI_2 have been shown to have synergistic antiaggregatory effects on platelets[108,120], and may act in concert to oppose local vasospasm or thrombus formation at sites where platelets aggregate and the coagulation cascade is activated[115]. It has been proposed that the antiplatelet effects of endothelial NO may prevent thromboembolic events during administration of potent PGI_2 inhibitors, such as aspirin[46].

Phosphoinositide 3-kinase

Phosphoinositide 3-kinase (PI3-kinase) is involved in many cellular functions, including the regulation of glucose transport, mitogenesis, and cytoskeletal rearrangements[122]. Phosphoinositide 3-kinase catalyses the phosphorylation of the inositol ring at the 3′ position of a variety of phosphoinositides[123,124]. In addition, some isoforms can catalyse the phosphorylation of protein serine residues[125,126].

Platelets contain a p85/PI3-kinase[127], which is a heterodimer composed of a p85 regulatory subunit (with two SH2 domains and one SH3 domain) and a catalytic p110 subunit. The p85/PI3-kinase can be activated by G-protein linked receptors, including the thrombin receptor in platelets[128,129]. Recent work in our laboratory has shown that S-nitrosoglutathione, an NO donor, inhibits PI3-kinase activation induced by thrombin receptor-activating peptide (TRAP) in human platelets[122]. In addition, the PI3-kinase inhibitor, wortmannin, when used in conjunction with S-nitrosoglutathione was shown to have additive inhibitory effects on TRAP-induced platelet aggregation. Although wortmannin has previously been shown to mimic the effects of NO on the platelet, such as inhibition of TRAP-induced platelet aggregation[130], the study by Pigazzi and colleagues is the first to demonstrate an inhibitory effect of NO on PI3-kinase in platelets[122].

Phosphoinositide 3-kinase has also been shown to induce NO synthesis when endothelial cells are stimulated by either insulin or vascular endothelial growth factor (VEGF)[131]. For example, endothelial cells pre-treated with wortmannin inhibit the production of NO by insulin[132]. The relative importance of the opposing effects of NO on PI3-kinase activation in platelets and in endothelial cells is yet to be determined.

AKT

The serine/threonine protein kinase AKT (protein kinase B) is a downstream target of PI3-kinase[133,134] and has previously been shown to be a general antiapoptotic effector induced by proangiogenic stimuli[135]. For example, VEGF stimulates AKT, which promotes endothelial cells survival[136,137], and inhibitors of endothelial cell apoptosis, shear stress, and insulin, also activate AKT[138,139]. More recently, AKT has been shown to phosphorylate eNOS directly leading to calcium-independent activation of the enzyme[140,141]. In addition, inhibition of the AKT/PI3-kinase pathway by wortmannin prevents activation of eNOS[141], while activated AKT (delivered via adenovirus-mediated gene transfer) increases basal NO release from endothelial cells[140]. Thus, AKT-dependent phosphorylation of eNOS represents an additional mechanism by which endothelial NO production is modulated. The role of AKT in platelet aggregation and effects of NO on this process are, as yet, unknown.

Cambridge Books Online © Cambridge University Press, 2009

Cyclic GMP-independent mechanisms
Nitric oxide also interacts with target cells by cyclic GMP-independent mechanisms. Nitric oxide can activate cytosolic adenosine 5′-diphosphate (ADP)-ribosyltransferase in human platelets, an enzyme that catalyses the transfer of ADP ribose to glyceraldehyde 3-phosphate dehydrogenase[142]. The addition of ADP ribose to GAPDH inactivates the enzyme and, thereby, slows glycolysis and decreases ATP production[43]. Nitric oxide-mediated injury in processes such as myocardial stunning or neurotoxicity may be secondary to NO stimulation of GAPDH ADP-ribosylation, with the resultant inhibition of glycolysis[43]. There are additional cyclic GMP-independent effects of NO on endothelial cells of possible importance to vascular function. Endothelium-dependent relaxation can occur without a rise in cyclic GMP[51]; this response is attributed to direct activation by NO of calcium-dependent potassium channels[81], which produce relaxation by hyperpolarization of the vascular smooth muscle cell. Furthermore, sodium–potassium ATPase can be activated by NO independent of cyclic GMP[143], which, again, leads to hyperpolarization. Nitric oxide-mediated inhibition of cytosolic calcium influx in platelets[144] activated by strong agonists is a consequence of inhibition of capacitative calcium influx resulting from increased sarcoplasmic/endoplasmic reticulum calcium-ATPase-dependent refilling of intracellular calcium stores[145].

EctoADPase
In addition to inhibiting platelet aggregation via endothelium-derived PGI_2 and NO, the endothelial cell reduces the extent of platelet aggregation by decreasing the local concentration of the platelet agonist ADP via surface ecto-nucleotidase activity. Adenosine 5′-diphosphate released from activated platelets induces platelet recruitment and aggregation by binding to platelet purinergic type-2 receptors (P2Y or P2X)[146]. Adenosine 5′-triphosphate diphosphohydrolase (ADPase, ATPDase, ecto-apyrase, or CD39), located on the luminal surface of the endothelial cell, metabolizes extracellular ATP and ADP to AMP. Within the endothelial cell, AMP is then rapidly metabolized by 5′-nucleotidase to adenosine, which inhibits platelet aggregation[147]. Ecto-ADPase is a glycoprotein that belongs to the E-type ATPase family[148] and hydrolyzes all physiologically occurring nucleoside 5′-triphosphates and 5′-diphosphates equally well[147]. The activity of ecto-ADPDase is dependent on calcium and magnesium, and can be inhibited by divalent cation-chelating agents[149,150].

Ecto-ADPase is insensitive to the effects of aspirin[149] and inhibits platelet recruitment and aggregation in the absence of PGI_2 or NO. For example, in vitro PGI_2 and NO production from endothelial cells can by inhibited by aspirin and hemoglobin, respectively; however, under these conditions, inhibition of platelet responsiveness by endothelial cells persists[149]. Furthermore, CD39-deficient mice have an increased spontaneous thrombotic tendency compared to wild-type mice[151]. Thus, endothelial ecto-ADPase plays an important role in the regulation of hemostasis and platelet-mediated thrombosis independent of PGI_2 or NO.

Consequences of endothelial dysfunction

Exposure to the subendothelium

Under normal conditions, unstimulated platelets do not adhere to intact endothelial cells; however, when normal endothelial function is impaired (endothelial dysfunction) or the endothelium is absent and the subendothelial matrix exposed (as in deep vessel injury), platelets come into contact with substances that promote adhesion and aggregation. In this context, endothelial dysfunction may play an important role in the pathogenesis of certain disease states, including atherosclerosis, hypercholesterolemia, hypertension, diabetes mellitus, and hyperhomocysteinemia. Some of the effects of endothelial dysfunction and subendothelial matrix exposure specifically leading to increased platelet adhesion and aggregation are discussed next.

von Willebrand factor
von Willebrand factor (vWF) is a polymeric glycoprotein that promotes platelet adhesion and thrombus formation at sites of endothelial dysfunction or vascular injury[152,153], especially under conditions of high shear rates. von Willebrand factor is produced by endothelial cells[154], platelets[155], and megakaryocytes[156]. Endothelial cells synthesize vWF, the majority of which is secreted constitutively, either abluminally into the subendothelial matrix or luminally into the circulation. Constitutively secreted vWF is synthesized at a steady-state rate that is not altered by stimulation[157] and contains both pro-vWF and mature subunits. In contrast, endothelial cells stimulated with the calcium ionophore A23187 or thrombin secrete vWF that consists of only large multimers of mature subunits, released from storage in the Weibel–Palade bodies[158,159]. These large multimers of vWF preferentially bind to the extracellular matrix and fibrin. Similarly, platelets and megakaryocytes also contain large multimers of vWF, which are stored in their α-granules[160,161].

Cambridge Books Online © Cambridge University Press, 2009

Released vWF interacts with both the GP Ib–X–V and GP IIb–IIIa receptors on platelets. By binding to subendothelial collagen and glycosaminoglycans, vWF then tethers platelets to the vascular matrix. This interaction initiates platelet adhesion and activation of the GP IIb–IIIa complex[162–165]. The GP IIb-IIIa complex promotes irreversible platelet adhesion as well as platelet spreading at the site of injury, thus allowing additional platelets to be recruited to the growing thrombus.

The importance of vWF in thrombosis is evident in patients with various types of von Willebrand disease (vWD). These patients have decreased platelet adhesion to the subendothelium, which can subsequently be reversed by administration of exogenous vWF[166,167]. In addition, the involvement of vWF in endothelial dysfunction has been established. For example, Fuster and colleages showed that pigs with vWD on a high fat and cholesterol diet are less likely to develop atherosclerosis of the abdominal aorta than normal pigs[168]. In addition, vWF-deficient mice have prolonged bleeding times and increased bleeding events when compared to wild-type mice[169]. Furthermore, in disease states associated with endothelial dysfunction, such as diabetes mellitus and hypertension, plasma vWF levels are markedly elevated[170,171].

Plasminogen activator inhibitor

The endothelium regulates fibrinolysis through the release of several factors, including tissue-type plasminogen activator (t-PA) and plasminogen activator inhibitor-1 (PAI-1). Tissue-type plasminogen activator is synthesized and secreted by endothelial cells[172,173] and converts inactive plasminogen to plasmin, which degrades fibrin[174]. Release of t-PA from endothelial cells is augmented by several physiological stimuli, including shear stress[175], and receptor-dependent agonists, such as histamine and thrombin[176–178]. Endothelial cells also express t-PA receptors, which localize plasminogen activation to the endothelial surface. The action of t-PA is principally opposed by PAI-1, which is synthesized by endothelial cells[179] and other cells, such as platelets[180]. Synthesis of PAI-1 is affected by various factors, including inflammatory cytokines[181,182], lipoproteins[183], thrombin[178], and angiotensin II[184]. Under normal conditions, the balance between t-PA and PAI-1 determines the response to thrombus formation in the vessel, which generally favours fibrinolysis. However, when the endothelium is absent (deep vessel injury) or its function is impaired (endothelial dysfunction), the relative preponderance of PAI-1 over t-PA reduces fibrinolysis and promotes thrombosis.

Endothelial dysfunction is associated with several cardiovascular disease states, including atherosclerosis and hypercholesterolemia[33,77], and endothelial control of fibrinolysis is correspondingly altered in these conditions. For example, increased PAI-1 activity was found in young survivors of myocardial infarction and in venous thrombotic states; a reciprocal decrease in t-PA activity was also observed in these conditions in some studies[185]. In addition, increased t-PA antigen levels with decreased t-PA activity and increased PAI-1 activity have been reported in patients with coronary artery disease[186,187] and diabetes mellitus[188]. Increased PAI-1 activity has also been shown to correlate with elevated triglyceride levels[189,190]. Overexpression of PAI-1 in rat carotid arteries increases mural thrombus accumulation[191], while PAI-1-deficient mice have decreased thrombus formation in response to photochemically-induced thrombosis when compared to wild type mice[192]. Furthermore, substances that cause endothelial dysfunction, such as oxidized-LDL and lysophosphatidylcholine, stimulate PAI-1 and inhibit t-PA release from endothelial cells[193].

Thrombin

Antithrombin III present in plasma rapidly inactivates thrombin by forming the thrombin/antithrombin complex, which is subsequently cleared by the liver[194]. The inactivation of thrombin by antithrombin III alone proceeds slowly, but is dramatically increased by heparin, free heparan sulfate, or endothelial cell-bound heparan sulfate[195,196]. Antithrombin III also binds to heparan sulfate in the subendothelium, which catalyses thrombin inactivation[197]. Endothelial cells support the inactivation by antithrombin III of factors IXa, Xa, and XIIa. During aggregation, platelets release platelet factor 4, which binds to glycoaminoglycans and blocks the ability of heparan to accelerate the inactivation of thrombin by antithrombin III[198].

Most normal endothelial surfaces express thrombomodulin, which serves as a binding site for thrombin to activate protein C. Protein C subsequently cleaves and inactivates factors Va and VIIIa[199,200]. Protein S is a cofactor for activated protein C and is required for the expression of protein C's anticoagulant effects[201]. Once thrombin binds to thrombomodulin, the complex is internalized by endocytosis, the attached thrombin is degraded, and the thrombomodulin recycled to the endothelial surface[202]. When the endothelium is minimally damaged, there is evidence to suggest that owing to the high-affinity interaction between thrombin and the endothelial surface, thrombomodulin effectively removes thrombin from plasma and concentrates it on the surface of the endothelial cells downstream of the site of vascular injury. However, with greater extents of injury or endothelial dysfunction, the

Cambridge Books Online © Cambridge University Press, 2009

regulation of thrombin inactivation by antithrombin III and thrombomodulin is decreased, resulting in increased plasma thrombin concentrations. Thrombin is a potent stimulus of platelet aggregation. At low concentrations (less than 1 nM), thrombin stimulates platelets to secrete ADP, serotonin, and fibrinogen, which all enhance platelet aggregation and clot formation. At higher concentrations, thrombin is able to stimulate platelet aggregation by ADP-independent mechanisms[203]. In addition to platelet aggregation, thrombin activates procoagulant factors V and VIII, as well as factor XIII, which catalyses the formation of a covalently crosslinked stable fibrin clot[204,205]. Thrombin can also induce vasoconstriction of the vessel[206]. The mechanism of activation of thrombin and its pathophysiological importance in thrombosis is demonstrated in patients with inherited antithrombin III deficiencies, who have an increased incidence of thrombosis[207,208]. In addition, individuals with autosomal deficiency of protein S, which results in up to an 85% reduction in protein S activity, also have an increased incidence of thrombosis[209], while inherited activated protein C resistance is a major risk factor for venous thrombosis[210]. Furthermore, elevated levels of homocysteine, which are associated with endothelial dysfunction, atherosclerosis, and increased thrombotic events, inhibit thrombomodulin surface expression and protein C activation by endothelial cells[211].

Tissue factor

The main physiological function of tissue factor (TF) is to initiate the coagulation process. Tissue factor binds factor VII in plasma in the presence of calcium and increases the activity of factor X by factor VII. Factor Xa then activates factor VII to VIIa, a process accelerated by endothelial cells and factors VIII and IX[212,213]. Factor Xa generates thrombin that produces local activation of platelets and factors V and VIII[204].

Under normal homeostatic conditions, endothelial cells are devoid of TF. In contrast, the subendothelial matrix possesses TF. Endothelial damage (vessel injury) leads to exposure of plasma and platelets to TF. Expression of TF by vascular smooth muscle cells is rapidly increased by growth factors and thrombin in vitro and by vascular injury in vivo[214]. Furthermore, TF has been identified in atherosclerotic plaques[215], suggesting a role for this proteolipid in the progression of thrombotic complications of cardiovascular disease. In addition to exposure of the subendothelial matrix, endothelial dysfunction can also produce TF expression. Endothelial cells exposed to thrombin or endotoxin markedly increase their TF expression, and the expression of TF initiates fibrin formation[216,217]. Nitric oxide has recently been shown to suppress TF expression by endothelial cells[218], demonstrating yet another antithrombotic action of this vascular effector.

Increased platelet activation

Prostaglandin I_2

Endothelium-derived PGI_2 is a potent vasodilator and inhibitor of platelet aggregation. Physiologically, its actions are counterbalanced by other eicosanoids, such as PGH_2 and TXA_2, with the interaction among these substances determining the response of the vessel. However, when normal endothelial activity is impaired, there is a reduction in the release of bioactive endothelial relaxing factors, such as PGI_2 and NO, and a subsequent increase in the release of endothelial constricting factors (PGH_2 and TXA_2). This shift in prostanoid mediators of vessel tone would be expected to be associated with a shift from an antithrombotic to a prothrombotic state.

Prostaglandin I_2 production is reduced in disease states associated with endothelial dysfunction. For example, in human coronary arteries taken from heart transplant patients, the contribution of PGI_2 towards basal release of relaxing and hyperpolarizing factors was 32% in normal arteries but only 12% in atherosclerotic arteries[219].

Increased production of vasoconstrictor prostaglandins have been shown in diabetes mellitus and hypertension[25,220,221]. Endothelial-dependent vasodilation to acetylcholine in the forearm of patients with essential hypertension is improved by the infusion of the cyclooxygenase inhibitor, indomethacin[222]. In addition, acetylcholine-induced vasodilation of isolated rabbit aorta is improved by treatment with indomethacin[220].

Nitric oxide

Under physiological conditions, endothelium-derived NO plays an important role in the regulation of vascular tone, platelet adhesion, platelet aggregation, myocardial contractility, smooth muscle proliferation, and leukocyte adhesion. However, in disease states associated with endothelial dysfunction, the role of NO is altered. There is evidence that diminished endothelial NO production, and, therefore, decreased bioavailable NO, contributes to atherogenesis by allowing unopposed platelet–endothelial interactions and through the loss of NO-mediated inhibition of vascular smooth muscle proliferation[43]. In contrast, excess NO production has been demonstrated in the pathogenesis of sepsis-induced hypotension and myocardial depression[33]. For the purpose of this review, only impairment in endothelial NO production leading to decreased bioavailable NO will be discussed.

Cambridge Books Online © Cambridge University Press, 2009

The normal endothelium-dependent vasodilator response to intracoronary acetylcholine infusion (via NO release) is converted to a vasoconstrictor response in patients with early or advanced coronary atherosclerosis[223]. However, the vasodilator response to nitroglycerin, a non-endothelium-dependent nitrovasodilator, is unaltered[223]. In addition, endothelium-dependent coronary dilation is lost in hypercholesterolemia before the development of atherosclerosis[224], while impaired flow-mediated dilation has been demonstrated in the brachial arteries of children with familial hypercholesterolemia[225]. Furthermore, the vasodilator responses to stimuli for NO release, such as serotonin[60], substance P[226], and shear stress[227], are impaired in coronary artery disease[228]. Thus, these findings suggest impaired action of NO.

Impaired endothelium-derived NO is also associated with increased platelet adhesion and platelet aggregation. For example, platelets from diabetic subjects demonstrate increased adhesiveness and aggregation[229]. In addition, patients with coronary artery disease exhibit an increased extent of aggregation when compared to age-matched control subjects[230]. Furthermore, patients with acute coronary syndromes also have impaired platelet production of NO[231], which may act in concert with decreased endothelium-derived NO to contribute to the development of coronary atherothrombosis.

Impaired nitric oxide bioavailability

The most important mechanism of impaired endothelium-derived NO bioactivity is increased oxidative stress. Increased production of reactive oxygen species and oxidative modification of lipoproteins account for the majority of oxidative stress in the vessel.

The superoxide anion is produced by a number of enzymatic sources in vascular cells under physiological conditions as a consequence of normal oxidative metabolism[65]. Increased superoxide anion production has been documented in a number of disease states, including hypercholesterolemia[232], diabetes mellitus[233], and hypertension[234]. Enhancing superoxide dismutase activity or inhibiting superoxide anion production is associated with improved endothelium-dependent vasodilator function in atherosclerosis[232]. In addition, patients with coronary atherosclerosis administered ascorbic acid, a potent scavenger of superoxide anion, demonstrate improved flow-mediated brachial dilation[235].

Superoxide anion has also been shown to stimulate platelet aggregation. For example, pyrogallol (a generator of superoxide anion) induces platelet aggregation in vitro, which is completely abolished by superoxide scavengers[236]. In addition, coronary artery disease patients receiving ascorbic acid have shown a reduction in both platelet adhesiveness and platelet aggregation when compared to placebo controls[237].

Superoxide anion interferes with NO, thus limiting its biological activity[238,239]. Nitric oxide and superoxide anion may interact in a diffusion-limited process to form peroxynitrite ($ONOO^-$). Peroxynitrite not only decreases endothelium-derived NO bioavailability, but also initiates lipid peroxidation and oxidization of critical thiols or tyrosine residues[240]. The superoxide anion also undergoes dismutation to hydrogen peroxide, which is subsequently reduced to the hydroxyl radical[241]. Hydrogen peroxide has been shown to mediate endothelial cell injury[242] and impair endothelial production of NO from cultured cells[243].

Lipid peroxidation

The formation of oxidized low-density lipoproteins (ox-LDL) impairs the action of endothelium-derived NO and other endothelial functions by several mechanisms. Oxidized-LDL promotes the recruitment of inflammatory cells to the vessel wall, which may increase local production of reactive oxygen species[244–246]. Oxidized-LDL is also cytotoxic to the endothelial cell and may either directly inactivate NO[247] or decrease eNOS protein levels in endothelial cells[248]. Products of lipid peroxidation, including lysophosphatylcholine, may interfere with signal transduction and receptor-dependent stimulation of NOS activity[249,250], as well as activation of guanylyl cyclase[251].

Increased oxidative stress as a mechanism for endothelial dysfunction is supported by drug therapies directed against LDL oxidation, such as α-tocopherol. For example, α-tocopherol therapy has been shown to preserve endothelium-derived NO function via inhibition of superoxide anion production and cell-mediated LDL oxidation[65].

Other mechanisms for impaired nitric oxide bioavailability

Several other mechanisms exist by which endothelium-derived NO bioavailability can be decreased. These include alterations in NOS expression or NO signalling, reduced availability of the NOS substrate L-arginine, and decreased availability of NOS cofactors, such as tetrahydrobiopterin[252]. However, a detailed discussion of these mechanisms is beyond the scope of this overview[252a].

Ecto-ADPase

Ecto-ADPase is responsible for the enzymatic degradation of ATP and ADP to AMP, which is subsequently converted into the anti-aggregatory substance, adenosine. Ecto-

Cambridge Books Online © Cambridge University Press, 2009

ADPase inhibits platelet recruitment and aggregation in the absence of PGI_2 and NO, and, thus, plays an important role in the regulation of hemostasis and thrombosis. As with PGI_2 and NO, the activity of ecto-ADPase is reduced by endothelial dysfunction.

When endothelial cells are activated by inflammatory cytokines, the activity of ecto-ADPase (CD39) decreases compared with unstimulated cells[253]. This decreased activity has been attributed to inactivation of the enzyme by oxidative stress, and can partially be reversed by antioxidants[151]. In addition, CD39-deficient mice demonstrate substantial fibrin deposition in various tissues. As the activity of ecto-ADPase in these animals is markedly decreased, this pathology suggests impairment in vascular thromboregulation. CD39-deficient mice also demonstrate increased bleeding times, which is contrary to this hypothesis of impairment in thromboregulation. This effect appears to be due to desensitization of the platelet purinergic receptor, since these mice lack both in vivo and in vitro platelet responsiveness to ADP[151]. This lack of platelet responsiveness can be reversed by administration of soluble nucleoside diphosphatase (apyrase).

Pathological conditions associated with endothelial dysfunction

Atherosclerosis

Endothelium-mediated vasodilation is attenuated in atherosclerotic human coronary arteries[254]. Human epicardial arteries dilate in vivo in response to endothelium-dependent agents, such as acetylcholine[223,255], substance P[256], serotonin[60], and histamine[77,257,258], and dilation is impaired in atherosclerotic coronary arteries[77,258]. This impairment in endothelium-dependent vasodilation may be a consequence of decreased production or impaired bioavailability of NO[254]. Furthermore, diminished NO production at atherosclerotic sites may promote atherogenesis by allowing unopposed platelet activation and adhesion of platelets and leukocytes[33,259].

Progressive impairment of endothelial function within the coronary circulation has been observed in patients. For example, impaired endothelium-dependent vasodilation is observed not only in advanced atherosclerotic lesions but also in arteries with minor irregularities[223,260]. This observation also suggests that endothelial dysfunction occurs early in the course of atherosclerosis. The loss of flow-mediated vasodilation in atherosclerotic segments may favor vasoconstriction at sites where vasodilation could ordinarily occur with an increase in flow[223]. Such an impaired response to increased flow may, in part, explain the abnormal vasomotor responses, and, thus, the associated clinical symptoms, accompanying physiological stimuli, such as exercise, mental stress, or exposure to cold environments[261].

Hypercholesterolemia is a well-known risk factor for atherosclerosis and coronary artery disease. Endothelial dysfunction secondary to hypercholesterolemia may be involved in the early pathogenesis of the disease process[224]. Endothelium-dependent vasodilation to serotonin and catecholamines is impaired by hypercholesterolemia in a porcine model[262]. In addition, hypercholesterolemia impairs endothelium-dependent vasodilator responses to aggregating platelets[77]. In humans, hypercholesterolemia impairs vasodilation in resistance vessels[263], which can be acutely improved by infusion of L-arginine.

Hypertension

In animal models of hypertension, endothelium-dependent vasodilation is reduced[264]. However, this endothelial dysfunction varies depending upon the model of hypertension studied. For example, in aortas from spontaneously hypertensive rats the release of endothelium-derived contracting factors in response to serotonin, ADP, and arachidonic acid is increased and explains the inability of the endothelium to attenuate contractions induced by aggregating platelets[259,264]. There is also an increased endothelium-dependent release of prostaglandin H_2 in this model when aortas are exposed to acetylcholine[265]. This response is associated with an enhanced expression of cyclooxygenase-1. In addition, the diminished endothelium-dependent vasodilation to acetylcholine in the forearm of patients with essential hypertension is partially restored by indomethacin[222]. In contrast, in Dahl salt-sensitive hypertensive rats the impairment of endothelium-derived vasodilation is not due to the release of endothelium-derived contracting factors, but decreased responsiveness to NO, as direct vasorelaxant effects of nitrovasodilators are reduced[266]. Furthermore, patients with hypertension have reduced endothelium-derived NO release under basal conditions or during activation of the endothelium[267]; this effect was subsequently shown to be a consequence of impaired NO synthesis or release of NO from the endothelium rather than reduced availability of substrate for NO production[268].

Diabetes mellitus

Endothelium-dependent vasodilation is also impaired in models of diabetes mellitus. Exposure of isolated vascular tissue to high glucose concentrations in vitro produces impairment in the endothelium-dependent vasodilation to acetylcholine[220]. In contrast, the vasodilatory response

Cambridge Books Online © Cambridge University Press, 2009

to A23187 and sodium nitroprusside was unaltered. In addition, the endothelium-dependent vasodilator response is decreased in animals rendered diabetic by alloxan and streptozotocin treatment[269,270]. In diabetic rabbits exposed to high glucose concentrations, impaired endothelium-dependent vasodilation was accompanied by an increased production of vasoconstrictor prostaglandins[220], which could be reversed by inhibitors of prostaglandin synthesis and specific antagonists of prostaglandin H_2/TXA_2.

Impaired endothelium-dependent vasodilation has also been demonstrated in patients with type I diabetes in the absence of clinical complications[271–273]; however, not all studies have shown consistent dysfunction in these patients[274,275]. Similar variability exists in the endothelium-dependent vasodilator responses of patients with type II diabetes[276].

Hyperhomocysteinemia

In epidemiological studies, hyperhomocysteinemia has been associated with premature peripheral artery disease, cerebrovascular disease, and coronary artery disease, independent of the effects of factors such as hyperlipidemia, cigarette smoking, and hypertension[277,278]. Addition of homocysteine to isolated endothelial cells induces functional abnormalities in the release of endothelium-derived NO[279] and detachment of cells[280]. In addition, methionine-induced moderate hyperhomocysteinemia in non-human primates leads to abnormal vasomotor activity[281].

In humans, homozygous homocystinuria is associated with markedly accelerated atherosclerosis and thrombosis, and with endothelial dysfunction in children as young as 4 years old[282]. Furthermore, subjects with no known vascular risk factors other than hyperhomocysteinemia demonstrate impaired arterial endothelium-dependent flow-mediated vasodilation[283]. In this group, hyperhomocysteinemia was not associated with renal failure or deficiencies in folate or vitamin B12. Treatment with folate has been shown to restore endothelial dysfunction during a methionine challenge in healthy volunteers without affecting the rise in plasma homocysteine levels[284]. Hyperhomocysteinemia may also be associated with early arterial injury in adults[285].

Several possible mechanisms exist whereby hyperhomocysteinemia may account of impaired endothelium-dependent vasodilation. These include, increased oxidative stress[286] altered expression of eNOS[287], and suppression of cellular glutathione peroxidase[288].

Hyperhomocysteinemia also effects platelet activation. Homocystinuric patients have abnormally high TXA_2 biosynthesis[289], which is associated with increased platelet activation. In addition, homocysteine rapidly auto-oxidizes in plasma and as a consequence reactive oxygen species, such as superoxide anion, the hydroxyl radial, and hydrogen peroxide are formed[290]. The hydroxyl radical subsequently initiates lipid peroxidation. Di Minno and colleagues demonstrated that short-term administration of probucol, which prevents the oxidative modification of low-density lipoproteins, to homocystinuric patients results in a 40 to 60% decrease in TXA_2 biosynthesis, while having no effects on TXA_2 biosynthesis of normal volunteers[291]. The decrease in TXA_2 biosynthesis was not correlated with either plasma homocysteine levels or plasma cholesterol levels.

Animal models of endothelial dysfunction

Several animal models exist for the investigation of endothelial dysfunction and its relationship to thrombosis and atherosclerosis. These models allow for the study of the mechanisms of platelet activation and interaction with the vessel wall. One of the major models utilized is the Folts coronary thrombosis model of cyclic flow variations (CFVs), which was first described in 1974[292]. This model is used to study platelet aggregation and thrombosis in stenosed arteries with endothelial or medial damage. The CFVs produced are due to the repetitive accumulation and dislodgement of platelet aggregates at the site of endothelial damage associated with arterial stenosis[293–295]. The Folts coronary thrombosis model is created by exposing the heart and dissecting free either the left anterior descending or left circumflex artery from the surrounding tissue. A Doppler flow probe is then placed in the proximal portion of the exposed artery. Endothelial damaged is then produced in the artery, usually by pinching the artery several times with cushioned forceps, just distal to the flow probe. A device (plastic sleeve) is then placed around the artery at the site of endothelial damage and a fixed amount of constriction is produced. Although originally performed acutely in open chested dogs and rabbits the model has been adapted for use in chronic, awake, and unsedated animals[293]. Cyclic flow variations can be abolished by agents that inhibit platelet adhesion and aggregation, such as sodium nitroprusside[296], nitroglycerin[297], TXA_2 or serotonin receptor antagonists[293], aspirin[298], and GP IIb-IIIa receptor antagonists[299,300]. In addition to the Folts coronary thrombosis model, CFVs have been demonstrated in patients undergoing coronary angioplasty[301].

Some other models of endothelial damage and thrombosis are the electrical injury model and the copper coil model. Electrical injury produces endothelial damage by establishing a positive electrical potential on the inner surface of an otherwise normal artery. If sufficient electri-

Cambridge Books Online © Cambridge University Press, 2009

cal potential is supplied, thrombosis occurs[302]. The copper coil model involves the placing of a small metal coil into the left coronary artery of an anesthetized animal via a large-bore catheter inserted in either the carotid or femoral artery[303]. After placement, thrombus formation occurs rapidly and complete arterial occlusion usually occurs within 10 to 20 minutes. Thus, this model has been utilized to study thrombolytic agents[304,305]. However, one of the major problems associated with the above models, at least in the context of endothelial dysfunction, is that they all produce severe endothelial damage. Thus, they represent more accurately models of primary thrombus formation. Other models or variations of the existing ones that are capable of evaluating the role of endothelial dysfunction in thrombosis and atherosclerosis are clearly necessary.

This issue has, in part, been addressed by the development of genetic models with targeted gene disruptions that lead to endothelial dysfunction. Apolipoprotein E (apoE) is a 34 kDa glycoprotein that serves as a ligand for the receptor-mediated clearance of several classes of lipoproteins from plasma, including, very low density lipoproteins, high density lipoproteins, cyclomicrons, and lipoprotein remnants[306]. Thus, targeted disruption of the apoE gene leads to accumulation of plasma cholesterol: homozygous deficiency in apoE (apo$E^{-/-}$) is associated with hypercholesterolemia and spontaneous atherosclerosis[307–309]. Endothelial dysfunction has also been described in apo$E^{-/-}$ mice. Yang and colleagues showed that 7.5-month-old apo$E^{-/-}$ mice develop increased arterial pressure and impaired endothelial function in addition to hypercholesterolemia and atherosclerosis[310]. In this study, endothelial dysfunction was evident by decreased cutaneous blood perfusion on the dorsal side of one hind paw after topical application of mustard oil (NO-mediated vasodilation). In contrast, the same study demonstrated that 6-week-old apo$E^{-/-}$ mice, which were hypercholesterolemic but without atherosclerosis, did not exhibit abnormal arterial pressures or endothelial dysfunction. This result implies that hypertension and endothelial dysfunction are primarily attributed to atherosclerosis, and that NO-mediated vasodilation is diminished with age, at least in this model.

Impaired endothelium-derived NO production / bioavailability is one of the main features of endothelial dysfunction, and has been shown to occur in atherosclerosis, hypertension, and diabetes mellitus. Disruption of the gene encoding eNOS in mice produces hypertension and lack of endothelium-dependent vasodilation by acetylcholine. In addition, mice with transgenic overexpression of eNOS are hypotensive[311]. These findings suggests that eNOS mediates basal release of endothelium-derived NO[312]. However, atherosclerosis has not been reported in eN$OS^{-/-}$ animals.

Hypercholesterolemia is also associated with endothelial dysfunction and is a risk factor for atherosclerosis and thrombosis. Mice heterozygous for a deficiency in the cystathione β-synthase ($CBS^{+/-}$) gene have mild hyperhomocysteinemia[313]. In addition, we have recently shown that $CBS^{+/-}$ mice have attenuated aortic relaxation to the endothelium-dependent agonist, acetylcholine, as well as paradoxical vasoconstriction of the mesenteric microcirculation to methacholine, bradykinin, and A23187[314]. These results are consistent with endothelial dysfunction induced by mild hyperhomocysteinemia. Furthermore, the above study demonstrated that $CBS^{+/-}$ mice have increase superoxide anion production, suggesting that mild hyperhomocysteinemia contributes to endothelial dysfunction by increasing oxidant stress and depleting bioavailable NO.

Glutathione peroxidase-1 (GPx1) catalyses the conversion of hydrogen peroxide and lipid peroxides to water and lipid metabolites, respectively[315]; thus it plays an important role in inhibiting mitochondrial reactive oxygen species production, thereby protecting the animal from oxidative stress. Mice lacking mitochondrial GPx ($GPx^{-/-}$) have increased mitochondrial hydrogen peroxide production, reduced mitochondrial respiratory rates, decreased mitochondrial power output indices and increased levels of lipid peroxides[316]. In addition, these animals display a growth deficiency at 8 months of age. Furthermore, work in our laboratory has demonstrated that $GPx^{+/-}$ and $GPx^{-/-}$ mice have increased oxidative stress when compared to wild type mice[317], and that the mesenteric microvasculature of $GP^{-/-}$ mice paradoxically constricts in response to the vasodilator β-methacholine[318]. This response is reversed by treatment with L-2-oxothiazolidine-4-carboxylate (OTC), which increases the intracellular thiol reducing potential. These results suggest that oxidant stress plays a role in this model of endothelial dysfunction.

Modulation of platelet aggregation by platelet products

Antiplatelet

Nitric oxide

In addition to endothelium-derived NO, which effects vasodilation and inhibits platelet aggregation, NO can also be produced directly by platelets. Once activated, platelets stimulate further thrombus formation and recruitment of

Cambridge Books Online © Cambridge University Press, 2009

additional platelets by releasing ADP and serotonin, producing TXA_2, and promoting surface thrombin generation. However, this activation is somewhat opposed by the release of platelet-derived NO. Platelets contain both cNOS and iNOS[231,319], and upon activation, NO is produced within the context of aggregation. This platelet-derived NO appears to be involved in the regulation of platelet function. For example, systemic infusion of the NOS inhibitor L-NMMA causes a reduction in bleeding time without a change in vessel tone[63], and enhances platelet reactivity to various platelet agonists[320]. We have previously demonstrated that platelet-derived NO only modestly inhibits the primary aggregation response; however, NO released from activated platelets markedly inhibits platelet recruitment. Thus, this mechanism may act to limit the size of an arterial thrombus[116].

In parallel with impaired endothelium-derived NO responsiveness in atherosclerosis, platelet-derived NO production is also decreased in this disease state. We have demonstrated that patients with acute myocardial infarction and unstable angina have decreased platelet-derived NO when compared to normal subjects[231]. In addition, low platelet NO production was independently associated with the presence of acute coronary syndromes. Furthermore, this finding was not attributed to concurrent medical therapy of heparin, nitroglycerin, or aspirin, or to other clinical or coronary risk factors.

Pro-aggregatory

Platelets also secrete a number of substances which enhance platelet responsiveness to primary agonists. Adenosine 5′-diphosphate and serotonin are secreted from the dense granules, while TXA_2 is produced from arachidonic acid. Each of these substances independently produces platelet aggregation; however, when released from the platelet upon stimulation, they act in an autocrine fashion to potentiate the aggregation response.

Conclusion

Under normal conditions the vascular endothelium either synthesizes or converts substances that regulate vascular tone. In addition, the endothelium, through PGI_2, NO, and ecto ADPase, inhibits platelet adhesion to the vessel, activation, and aggregation. By balancing these processes, the endothelium plays an important role in the maintenance of perfusion and hemostasis.

However, the response of the endothelium can be altered, either by its removal in deep vessel injury or by dysfunctional changes associated with disease states, such as atherosclerosis, hypertension, diabetes mellitus, and hyperhomocysteinemia. Endothelial dysfunction leads to a decrease in the synthesis of the vasodilator and antiplatelet agent PGI_2, which subsequently is accompanied by an increased platelet production of the vasoconstrictors and platelet agonists PGH_2/TXA_2. In addition, the potent vasodilatory and antiplatelet effects of NO are reduced owing to decreased NO bioavailability by mechanisms such as, increased oxidative stress and lipid peroxidation. Thus, all of these factors contribute to the pro-thrombotic state associated with endothelial dysfunction and demonstrate the pivotal role of platelets in the pathogenesis of vascular disease.

In vitro assays for evaluating platelet function

Perumal Thiagarajan and Kenneth K. Wu

Vascular Biology Research Center and Division of Hematology, University of Texas Medical School, Houston, USA

Role of platelets in hemostasis and thrombosis

Platelets play a primary role in the formation of the hemostatic plug at sites of vessel wall injury and in formation of thrombotic plug at the sites of atherosclerotic lesions[1–3]. Platelets circulate as anucleated cells at the periphery of the bloodstream. When continuity of the endothelial layer is disrupted and the underlying matrix is exposed, platelets rapidly adhere to the exposed matrix through an interaction between the glycoprotein (Gp) Ib–IX–V complex on their surface and von Willebrand factor (vWf) in the subendothelium[2,3]. The high fluid shear stress brought about by vascular constriction also promotes Gp Ib–IX–V–von Willebrand factor interaction[3]. This initial interaction, often called platelet adhesion, sets the stage for other adhesive reactions that allow the platelets to essentially seal the vessel-wall defect.

Following adhesion, platelets are activated by a number of agonists such as adenosine diphosphate (ADP) and collagen present at the sites of vascular injury. These agonists activate platelets by binding to specific receptors on the platelet surface[4]. Occupancy of these receptors leads to a series of downstream events that ultimately increases the intracytoplasmic concentration of calcium ions[5]. Receptors coupled to the G- proteins such as ADP, epinephrine, thromboxane A2 (TXA2) and thrombin receptors activate phospholipase Cβ (PLCb), whereas receptors activating via the non-receptor tyrosine kinase pathways such as collagen receptor GpVI preferentially activate phospholipase Cγ (PLCγ)[6]. Activation of PLCβ or PLCγ results in the production of the two second messengers: diacylglycerol (DAG) and inositol trisphosphate (IP3). DAG activates protein kinase C while the IP3 liberates calcium from intracellular storage granules. In addition, some of the receptors, such as ADP and TXA2 receptors, may also be linked via the G-proteins to ion channels mediating influx of Ca^{2+}. The increased intraplatelet free calcium concentration, in turn, leads to a number of structural and functional changes of the platelet. Morphologically, the platelet changes dramatically from a disc to a spiny sphere (a process called shape change). The granules in the platelet are centralized and their contents (ADP, β-thromboglobulin, platelet factor 4) are discharged into the lumen of the open canalicular system, from which they are then released to the exterior (the release reaction). The increase in intraplatelet calcium stimulates membrane phospholipase A2 activity, which liberates arachidonic acid from membrane phospholipids. Arachidonic acid is converted to an intermediate product prostaglandin H2 (PGH2) by the enzyme cyclooxygenase 1 (COX-1). PGH2 is further metabolized to TXA2 by thromboxane synthase. TXA2 is a very potent activator of platelets. The long membrane projections brought about by a shape-change reaction allow the platelets to interact with one another to form aggregates.

The platelet-platelet interaction (platelet aggregation) is mediated by a membrane protein, GPIIb–IIIa complex[7]. GPIIb–IIIa is an integrin receptor present at high density on platelets (~50 000 copies/platelet). It exists as an inactive form in resting platelets. Platelet activation by almost all agonists induces conformational changes (‘inside-out signalling’) of GPIIb–IIIa which becomes competent to bind soluble plasma fibrinogen. The precise sequence of events leading to inside-out signalling has not been fully elucidated. The roles of receptor clustering, phosphorylation and association with cytoskeletal and other cytoplasmic molecules in inducing GPIIb–IIIa conformational change leading to ligand binding are not totally delineated. Nevertheless, the receptor-bound fibrinogen acts as a bridge between two GPIIb–IIIa on adjacent platelets. This is the final common pathway of platelet aggregation induced by platelet chemical agonists. However, vWF substitutes for fibrinogen as a bridge molecule between

GPIIb–IIIa for platelet aggregation induced by high shear stresses ($>$12 dynes/cm^2) although platelet aggregation under lower shear stresses ($<$12 dynes/cm^2) is mediated by fibrinogen binding to GPIIb–IIIa[7–9].

Activated platelets recruit additional platelets to the growing hemostatic plug by several feedback amplification loops: they release platelet agonists (such as ADP and seratonin stored in the α granules) and they synthesize *de novo* proaggregatory TXA_2. Release of ADP and TXA_2 synthesis consolidate the initial hemostatic plug by promoting the participation of other platelets in the hemostatic plug formed at sites of vascular injury. Finally, platelets also play a dominant role in secondary hemostasis by providing a highly effective catalytic surface for activation of the coagulation cascade. When platelets are activated, negatively charged phospholipids move from the inner leaflet of the membrane bilayer to the outer leaflet. The transbilayer movement of anionic phospholipids is associated with blebbing and release of procoagulant vesicles rich in anionic phospholipids. Both activated platelets and the microvesicles provide binding sites for enzymes and cofactors of the coagulation system, which then efficiently generate thrombin, itself a potent platelet agonist.

Thrombosis results from inappropriate activation of normal hemostatic process in the setting of vessel wall injury. Arterial thrombosis occurs at high flow rates and at sites of atherosclerotic lesions. Clinical, experimental and epidemiological studies have clearly demonstrated a dominant role for platelets in arterial thrombosis. Platelets adhere to the exposed matrix of ruptured atheromatous plaque by a biochemical mechanism similar to that described above for adhesion of platelets to subendothelial matrix of severed normal vessels. Subsequent events such as platelet activation, platelet aggregation and platelet participation in coagulation are also similar to those described above. A notable pathophysiological process in arterial thrombosis is platelet aggregation induced by high shear stress which is mediated by binding of vWF to GPIIb–IIIa[7–9]. This contributes to the initiation and amplification of platelet aggregates not generally noted in normal hemostasis.

Platelet function tests

There have been attempts over the past three decades to detect changes in platelet function and correlate the change with arterial thrombotic events in patients with arterial thrombotic disorders[10]. There have been studies on the association of platelet function and venous thromboembolism, which is described in detail in another chapter in this book. The goal of the platelet function testing is to detect early thrombotic events and even more importantly to predict risk for thrombotic disorders such as myocardial infarction and ischemic stroke. There is circumstantial evidence for individual and interethnic variations of platelet function which forms the basic assumption that interindividual variability of platelet function can impact on arterial thrombus formation. This has been a controversial subject. However, recent genetic analysis of platelet glycoprotein genes suggests that polymorphisms of these genes contribute to variations in the receptor affinity and the magnitude of transmembrane signalling and these detectable interindividual differences may translate to different risk of arterial thrombosis. Environmental factors such as dietary cholesterol, cigarette smoking and exercise influence platelet function[11]. Furthermore, there could be genetic and environmental interactions in influencing platelet function in healthy individuals that collectively may have a larger impact on the risk of arterial thrombosis. Each of these factors contribute to a small variation of platelet function. Therefore, it is highly desirable to have tests that measure small changes in platelet function to assess the risk of thrombosis. Our understanding of mechanisms of platelet-vessel wall interactions has increased rapidly in the last decade. This has led to the introduction of new and potent antiplatelet drugs to treat thrombotic disorders[12]. Many of these drugs are associated with severe hemorrhagic complications. Thus, there is also a need to develop simple reliable platelet function tests that mimic in vivo platelet activity and can guide appropriate dosing of the new and powerful antiplatelet therapy. The platelet function tests, developed over the last four decades to test platelet function, are suited to detect platelet functional defects in bleeding disorders but are limited in capacity to assess platelet hyperactivity in thrombosis. A combined genetic and biochemical analysis of markers may alleviate the limitations. In this chapter we will review platelet function tests with emphasis on recently developed tests.

Tests of global platelet functions

Bleeding time

Bleeding time is the most familiar test of global platelet function. It has been in practice for a century and has been modified several times[13]. In this test, a blood pressure cuff is inflated on the upper arm to a pressure of 40 mm of Hg and a disposable, automated device inflicts a standardized cut of 10 mm length and 1 mm in depth on the volar surface of the forearm. The wound is gently blotted every 30 seconds until bleeding stops. The normal bleeding time is

Cambridge Books Online © Cambridge University Press, 2009

less than 10 minutes. The arrest of bleeding from this superficial wound is almost exclusively due to platelet adhesion and aggregation. As there is progressive prolongation of bleeding time when platelet counts are less than 100 000 per microlitre, the bleeding time test has limited value to detect functional platelet defects in thombocytopenic patients[14]. A prolonged bleeding time in the presence of normal platelet count is very significant indicating a qualitative dysfunction of platelets.

Despite its simplicity, the clinical utility of the bleeding time test has been called into question[15]. It is difficult to perform the test with consistency. It is greatly influenced by the skill and experience of the operator. The depth of the wound, local skin thickness, skin temperature and vascular patterns affect the results. A critical review of bleeding time concluded that bleeding time is not a specific indicator of platelet function and a poor indicator of bleeding risk[15]. A shortened bleeding time was claimed to be associated with arterial thrombosis but the claim has not been validated by rigorous proof.

Several attempts have been made to measure global platelet functions in primary hemostasis by reliable, simple, reproducible tests in vitro under flow conditions. Two new tests have been introduced and evaluated in clinical laboratories for their utility in detecting platelet functional defect in primary hemostasis. They have the potential to replace the conventional bleeding time technique. These two tests, the PFA-100 in vitro platelet function analyser and the Xylum clot signature analyser are described below.

PFA-100 in vitro platelet function analyser

This is a bench-top automated instrument based on an original principle described by Kratzer et al. that assess primary hemostasis under shear stress[16]. It uses a disposable test cartridge which contains a cup and a nitrocellulose membrane at the bottom with a central aperture of 150 μm in diameter. The nitrocellulose membrane is impregnated with type I equine fibrillar collagen plus ADP (Col/ADP membrane) or epinephrine (Col/Epi membrane). The cartridge is inserted into the instrument and kept at 37 °C. A blood sample of 0.8 ml of citrated blood is placed in a cup and aspirated at 200–240 dynes/cm^2 through the aperture. The shear stress and the agonists in the membrane activate platelets leading to platelet aggregation. The end point expressed as closure time is the stopping of blood flow due to occlusion of aperture by platelet aggregates. The platelet aggregate formation depends on (i) vWF binding to collagen-coated nitrocellulose membranes, (ii) platelet adhesion to vWF via platelet glycoprotein Ib–IX–V complex, (iii) platelet activation and (iv) platelet aggregation mediated by interaction of GPIIb–IIIa with vWF and fibrinogen. Normal closure times range from 77–133 seconds for Col/ADP membrane and 98–185 seconds for Col/Epi membrane. This instrument has been tested in bleeding disorders but has not been evaluated in thrombotic disorders. The closure time using the collagen/epinephrine (CEPI) cartridge is abnormal in patients with congenital platelet function defects, von Willebrand disease and aspirin ingestion while the closure time with collagen/ADP (CADP) cartridge is abnormal mainly in patients with von Willebrand disease or thrombocytopathies[17–20]. Aspirin prolongs the closure time 94% of the time with CEPI cartridge and only 27% of the time with CADP cartridge. A dose-dependent prolongation of Col/Epi closure time by aspirin is recently reported[20]. Glanzmann's thrombasthenia, Bernard–Soulier syndrome and most mild von Willebrand disease have a prolonged closure time with both cartridges, while storage pool defect and giant platelet thrombopathy have a prolonged closure time with CEPI cartridge only[18]. The advantages of this instrument include simplicity and reproducibility. It has been reported to have a coefficient of variation of less than 10%. It may have a use in determining the association of global platelet function with arterial thrombosis and in assessing the efficacy and complication of antiplatelet therapy.

Clot signature analyser

The Xylum clot signature analyzer (CSA) is an automated test of primary hemostasis which provides information about platelet adhesion, platelet aggregation and coagulation reactions in a more physiological milieu without adding platelet agonists[21–23]. Fresh blood is perfused, under a microprocessor control, in two separate channels (punch and collagen channel) under constant flow conditions simulating physiological blood flow. The luminal pressure is measured continuously. In the punch channel, vascular injury is simulated by piercing the blood line with a needle causing a sudden decrease in the pressure. The punch hole closes as platelets aggregate and form a hemostatic plug. The time from the punch to recovery of the pressure due to the formation of the hemostaic plug is reported as platelet hemostasis time. The blood flowing in the lumen eventually coagulates which stops the blood flow and causes the pressure to drop to 0. The time interval is reported as the clotting time. In the collagen channel, type I bovine collagen (1.9 cm long) is placed on the lumen aligned to the direction of the blood flow. As blood flows, platelets adhere to collagen leading to thrombus formation and lumen occlusion causing a continuing drop of blood pressure eventually to zero. The time interval from the start of blood flow to 50% drop in luminal pressure is reported

Cambridge Books Online © Cambridge University Press, 2009

as collagen-induced thrombus formation. The CSA mimics physiological conditions better than any other instrument. It is currently undergoing clinical evaluation in a number of conditions. Its utility as predictor of arterial thrombosis remains to be determined.

Platelet aggregation tests

A myriad of methods have been developed for testing platelet aggregation over the last four decades. These tests are classified into the following categories: platelet aggregation tests by aggregometer; shear induced platelet aggregation; and platelet aggregation under flow. These tests are considered separately.

Tests for platelet aggregation with aggregometers

Gus Born originally developed a device to measure platelet aggregation based on changes in light transmission of platelet rich plasma (PRP)[24]. This method has been used in detecting reduced platelet aggregation in hereditary and acquired bleeding disorders, bleeding due to drug complication, evaluating new drugs and determining hyperactive platelets in patients with thrombosis. Born's aggregometer was initially developed for assessing platelet function using PRP. Subsequently, aggregometers were developed for assessing platelet function using whole blood[25].

For measuring PRP platelet aggregation, blood is collected by a clean venipuncture in 1/10 volume of citrate (0.109–0.129 M sodium citrate). The PRP is obtained by centrifugation at 150–200 *g* for 10–15 minutes. The PRP is stirred at 37 °C by a magnetic stirrer in an aggregometer with or without addition of an agonist. Light passing through the PRP suspension is measured by a photometer, over a 5–10 minutes period. Kinetics of aggregation as determined photometrically manifests multiple phases. Following the addition of an agonist, there is a change in the shape of platelets from discoid to spherical. This is reflected as a slight decrease in light transmission. This is followed by an increase in light transmission as aggregates are formed. This initial phase of platelet aggregation (primary wave) is reversible unless it is followed by secretion of contents from α and dense granules, which induce an irreversible aggregation (secondary wave). The magnitude of aggregation is detected by measuring the maximum change in light transmission. Some workers have proposed to measure the rate of aggregation (the slope of the curve, i.e. tangent to the curve as the magnitude of aggregation)[26]. These two measurements correlate well[27]. For optimal platelet aggregation in the PRP, platelets come in close contact with one another by stirring. Platelet aggregation requires divalent cations and fibrinogen. Citrated plasmas contain ~40 μM calcium and plasma fibrinogen, which are adequate for the aggregation test.

Spontaneous platelet aggregation

PRP obtained from some individuals form platelet aggregates by stirring alone without stimulation by an agonist. This phenomenon is called spontaneous platelet aggregation (SPA)[28]. SPA was reported to be more frequent in patients with myocardial infarction and ischemic stroke[29]. A prospective study has shown that individuals with SPA have a higher risk of developing myocardial infarction[30]. SPA may represent extremely hyperactive platelets but the exact mechanism by which this occurs has not been elucidated.

Agonist-induced platelet aggregation

ADP, at low concentrations, 0.2–2 μM, causes a biphasic platelet aggregation. The second phase of aggregation induced by low doses of ADP requires TXA_2 synthesis. Aspirin and other cyclooxygenase inhibitors abolish the secondary wave. However, ADP at high concentrations causes a merger of these two phases of aggregation into a single aggregation curve. Epinephrine induces biphasic platelet aggregation at 0.5–7 μM concentration. It does not cause platelet shape change or marked primary aggregation. Thrombin is a potent aggregating agent. However, PRP is unsuitable for thrombin-induced platelet aggregation because thrombin induces blood clotting which alters light transmission. Collagen fibrils do not induce primary aggregation, but platelet adhesion to collagen particles induces secretion of endogenous proaggregatory substances. Collagen-induced platelet aggregation is thus secretion-dependent and very sensitive to aspirin. Arachidonic acid causes platelet aggregation which depends entirely on its transformation to TXA_2. Arachidonic acid-induced platelet aggregation is absent in the presence of cyclooxygenase inhibitors.

Agonist-induced platelet aggregation has been extensively evaluated in patients with myocardial infarction and ischemic stroke[31,32]. In order to provide a more quantitative evaluation of platelet aggregability in thrombosis, a 'threshold' concentration end point has been used[33]. In this assay system platelet aggregation in response to an agonist is titrated using increasing concentrations of the agonist and the minimal concentration of the agonist that induces maximal aggregation is defined as the threshold concentration. Patients with arterial thrombosis have a lower threshold value of ADP, arachidonic acid and collagen-induced platelet aggregation. Taken together, regardless of the end points of aggregation used (threshold concentration, maximal aggregation with a standard con-

Cambridge Books Online © Cambridge University Press, 2009

centration and rate of aggregation) the reported results are consistent with increased platelet aggregability in patients with arterial thrombosis. However, a causal relationship between platelet hyperaggregability and thrombotic events has not been established. The mechanism by which platelet hyperaggregability occurs is also unknown. As mentioned above, there is circumstantial evidence to support the notion that platelet hyperaggregability exists preceding thrombotic events, which may be due to combined genetic and environmental factors.

Ristocetin-induced platelet agglutination

The interaction between vWF and Gp Ib–IX–V complex in vivo following shear stress induces activation of platelets[2,3]. In vitro, the binding of soluble vWF to the GP Ib–IX–V complex under static conditions is artificially induced by modulators such as ristocetin. Ristocetin, a vancomycin-like antibiotic from *Nocardia lurida*, binds to the proline-rich sequence of vWF, altering vWF conformation to facilitate its binding to Gp Ib–IX–V complex. This interaction which does not require divalent cations is called platelet agglutination rather than aggregation. Ristocetin-induced platelet agglutination is defective in von Willebrand disease and in Bernard–Soulier syndrome[34]. In type IIB and pseudo von Willebrand disease there is heightened response to ristocetin[35]. There is limited information regarding changes in ristocetin-induced platelet agglutination in arterial thrombosis.

Platelet aggregometry has several limitations that preclude its routine use in assessing risk of arterial thrombosis. It requires high technical competency and needs standardization in each laboratory at every step of the test, including blood collection, centrifugation speed for the preparation of PRP, adjusting the platelet count and selection of agonist concentration. Furthermore, blood samples need to be processed and tested immediately after blood collection. Furthermore, the test has considerable day-to-day and diurnal variations. However, under stringent conditions, it is a valuable test for determining genetic influence of platelet hyperactivity.

Whole blood platelet aggregation

The whole blood aggregometer eliminates the variabilities associated with preparation of PRP and can be performed in lipemic blood[25,36]. This test is based on measuring the electrical current passed through whole blood where two electrodes are immersed. When the current is passed, the electrodes are immediately coated with a single layer of platelets. The build-up of platelet aggregates impedes the current flow. If no agonist is added there is only a basal accumulation of platelets on the electrodes and the conductance between the electrodes is constant. Following addition of an aggregating agent, platelet aggregates form on the layer of platelets adhered to the electrodes and impair the conduction. This agonist-induced increase in impedance is displayed as a function of time on the recorder.

Several studies have compared platelet aggregation in whole blood to that in PRP and have reported similar results. The value of whole blood aggregometer in assessing platelet function in arterial thrombosis has not been extensively evaluated[37].

Rapid platelet function assay

A new platelet function testing system also using whole blood, the so-called ‘rapid platelet function assay’ (RPFA), has been developed commercially to measure the degree of platelet GPIIb–IIIa blockade[38]. It is an automated turbidometric bead agglutination assay in whole blood, based on the ability of activated platelets to bind fibrinogen. Fibrinogen coated microparticles are mixed with whole blood and the extent of microparticle agglutination is proportional to the quantity of unblocked GPIIb–IIIa on platelets. As activated platelets bind and agglutinate fibrinogen-coated beads, there is an increase in light transmittance. The RPFA device consists of a cartridge and a microprocessor with a digital readout. Results of this assay system correlate very well with the platelet aggregation test performed in PRP with an aggregometer.

Measurement of shear-induced platelet aggregation

Platelet aggregation in response to high shear stress plays a critical role in initiating platelet aggregation at sites of atherosclerotic narrowing of the arteries. High shear stress induces changes in Gp Ib–IX–V complex allowing it to bind vWF multimers and this association accentuates intracellular signalling and GPIIb–IIIa activation. ADP released from platelets and red blood cells is also necessary for shear-induced platelet aggregation[7–9,39].

Shear-induced aggregation in vitro is tested in a rotational viscometer. The cone-and-plate viscometer is the most commonly used rotational viscometer. It generates a constant and uniform shear rate throughout the liquid in between the cone and plate. The shear rate is proportional to the rotations per minute and inversely proportional to the gap angle between the cone and plate. Shear-induced aggregation is quantified by measuring the disappearance of single platelets by electronic counting or more recently by flow cytometry. Several modifications have been made in the instrument to allow real-time optimal measurement of platelet aggregation or calcium flux. Shear-induced aggregation can be performed in whole blood or PRP anticoagulated with heparin or citrate.

Cambridge Books Online © Cambridge University Press, 2009

Shear-induced aggregation is enhanced in myocardial infarction[40]. Shear-induced platelet aggregation is also enhanced in patients with acute stroke and increased aggregation persists 3 months after an acute episode[41]. These results suggest that platelets are more reactive to shear stress in certain subjects which increases their risk of cerebrovascular thrombosis. Prospective studies are needed to determine whether increased shear-induced aggregation is an independent risk factor of arterial thrombosis.

Evaluation of platelet functions under flow

To assess the effect of rheological parameters on the sequence of events leading to formation of mural thrombus resembling physiological conditions, several approaches have been developed[42]. These approaches are based on a similar principle in which platelets were perfused through an appropriate surface under a defined shear rate in a flow chamber in which laminar flow, mimicking in vivo flow conditions is generated. The flow chamber is an annular or parallel plate. The interaction of platelets with the surface components is determined by morphological techniques. Platelets that adhere to the surface are called contact or spread platelets based on their morphological appearance. The subsequent platelet–platelet interaction with the eventual formation of detectable platelet aggregates is called mural platelet thrombus. Several test surfaces including the subendothelium of vessel fragments, cultured vascular cells, artificial surfaces coated with various adhesive molecules (e.g. collagen) have been studied in systems using native anticoagulated blood, citrated PRP or reconstituted blood. In recent years, investigators have combined parallel flow perfusion chambers with computerized epifluorescence microscopy[43]. These techniques, allowing three-dimensional reconstruction of mural thrombus formation in real time have provided valuable information on the role of individual components of platelet activation. Unfortunately, in assessing thrombus formation, these techniques are still within the realm of research laboratories and not suitable for clinical assessment.

Measurements of soluble platelet activation markers

β-thromboglobulin and platelet factor 4

Platelet activation by myriad physiological and pathological stimuli leads to a rapid cytoskeletal contraction, widening of the open canalicular system with eventual secretion of substances stored in α granules, dense bodies and other intracellular granules to the extracellular milieu. These released molecules, such as ADP, play an important role in platelet aggregation and platelet interaction with leukocytes. The released molecules may also serve as a marker of platelet activation *in vivo* because of sensitive assays available for accurately measuring their levels in blood and other body fluids and, more importantly, because of their platelet specificity. β-thromboglobulin (βTG) and platelet factor 4 (PF4) are two such molecules whose utility as a marker of platelet activation in human thrombotic disorders has been extensively investigated[44]. βTG and PF4 are synthesized in megakaryocytes and stored in α-granules of mature platelets. Since they are platelet specific and are secreted into extracellular milieu only after platelet activation, their plasma levels are considered to reflect the extent of platelet activation in vivo. This concept was initially supported by experimental results from in vivo studies[45]. Subsequently, numerous studies show that their levels are elevated in patients with arterial thrombotic diseases such as acute myocardial infarction and thrombotic stroke[46]. However, comparison of plasma βTG or PF4 levels among these studies reveals a large variability in healthy control subjects as well as in patients[47]. It was recognized that a major source of variability is originated from traumatic venipuncture which causes platelet activation and release of βTG and PF4. This source of artificial βTG and PF4 values has been substantially reduced after the introduction of less traumatic venipuncture systems in conjunction with the use of combination anticoagulants consisting of potent antiplatelet and antithrombin reagents[47]. PF4 binds to glycosaminoglycan on endothelial cell surface and has a short half-life in circulating blood. It is less reliable than βTG as a marker of platelet activation. βTG is excreted by kidneys and measurement of urinary βTG levels is considered a reliable test, which is not subject to in vitro platelet activation during venipuncture and blood processing. Plasma βTG levels are elevated in patients with acute myocardial infarction and thrombotic stroke and it has been reported to be associated with subclinical carotid atherosclerosis[48,49]. The value of βTG levels in predicting coronary heart disease and cerebrovascular disease has not been established by prospective studies.

Urinary TXA_2 metabolites

Platelet activation is accompanied by synthesis of TXA_2, which is released at sites of platelet activation. TXA_2 has a very short half-life and is rapidly converted to its stable inactive metabolite TXB_2. TXB_2 is further metabolized to 2,3-dinor-thromboxane B_2 and 11-dehydrothromboxane B_2 and excreted in the urine[50]. The concentration of 11-dehydrothromboxane B_2 in plasma is too low to measure reliably. However, urine 11-dehydrothromboxane B_2 has been determined by radioimmunoassay or enzyme immunoassay. Measurement of 2,3 dinor thromboxane B_2 is also

Cambridge Books Online © Cambridge University Press, 2009

useful, but requires gas chromatography combined with mass spectrometry, which limits its widespread use. 11-dehydrothromboxane B_2 in urine has been shown to be a useful marker of platelet activation and correlates well with βTG levels[51]. However, it should be noted that TXA_2 is also synthesized by activated monocytes and therefore may not be a monospecific marker of platelet activation[52].

Soluble P-selectin

P-selectin is localized to α-granule of platelets and Weibel-Palade body of endothelial cells[53]. A soluble form of P-selectin (sP-selectin) is detected in plasma of healthy subjects, which is thought to originate from an alternatively spliced form of P-selectin[54]. Platelet activation leads to secretion of P-selectin to platelet outer surface and the membrane P-selectin is cleaved by proteolytic enzyme to form sP-selectin[54]. Detection of membrane P-selectin by flow cytometry is accepted as a sensitive method for detecting platelet activation. This will be described in more detail below. Plasma sP-selectin in plasma is also considered as a marker of platelet activation[55,56]. However, it is not specific for platelets. It can also be shed from activated endothelial cells.

Glycocalicin

Glycocalicin is a carbohydrate-rich amino-terminal proteolytic fragment of GpIb. It is cleaved during platelet activation or during destruction by calpains and circulates in the plasma[57]. Glycocalicin levels in plasma are dependent on platelet count and platelet turnover. Plasma glycocalicin was measured with an enzyme-immunoassay. The level is reported to be elevated in conditions associated with platelet destruction. Low glycocalicin levels are seen in patients with aplastic anemia or amegakaryocytic thrombocytopenia[58].

Flow cytometry-based platelet function tests

The flow cytometer is being increasingly used to detect activated platelets. It has several advantages[59,60]. It can be used to detect platelets because of the smaller size of platelets than red blood cells and white blood cells. It can be performed in very small volumes of blood. Furthermore, availability of a large number of fluorescent antibodies, ligands and probes to assess expression of neoantigens, ligand binding and the calcium fluxes has rendered flow cytometry to be very versatile for detecting different platelet markers. Another advantage is that platelets can be analysed in their native plasma milieu and do not require isolation. The flow cytometry can be used to evaluate platelet function in severe thrombocytopenic patients. Furthermore, platelets can be fixed before or after antibody labelling. Flow cytometry has also the capacity for detecting circulating activated platelets and leukocyte–platelet aggregates, as well as to enumerate platelet-derived microvesicles[60]. As in the measurement of soluble markers, utmost care is necessary to draw blood with a clean venipuncture and samples should be processed immediately to avoid activation in vitro.

Detection of circulating activated platelets

Platelet activation results in the appearance of new markers on the platelet surface. These markers include changes in the conformation of GPIIb–IIIa detectable by monoclonal antibodies (e.g. PAC1 epitope), changes in GPIIb–IIIa induced by ligands (e.g. LIBS1 and LIBS6) or GPIIb–IIIa-induced conformational changes in fibrinogen (e.g. 9F9, F26)[61–65]. In addition, activated platelet surface acquires additional membrane markers from the intra-platelet granules. These markers include P-selectin, thrombospondin, multimerin (from alpha granules), CD 63 and LAMP-1 (from lysosome)[66–70]. Furthermore, the exposure of anionic phospholipid due to transbilayer movement can also be used as a marker for platelet activation[71]. The anionic phospholipid can be detected as annexin V positive platelets. Of these markers, GPIIb–IIIa detected by PAC1 antibodies and CD62 (P-selectin) have been widely used in clinical studies to detect activated platelets in the circulation. These studies have shown the presence of circulating activated platelets in coronary artery disease[72] and following coronary angioplasty[73]. The presence of activated platelets in the circulation may predict subsequent occurrence of ischemic events[74].

Detection of platelet-derived microvesicles

Externalization of anionic phospholipid during platelet activation is accompanied by shedding of phosphatidylserine-rich microvesicles[75]. In the vesiculation process, small areas of the surface membrane are shed in a true budding process. By freeze fracture electron microscopy, these microparticles have been shown to possess bilayer structure. These vesicles are enriched in platelet procoagulant activity and contain platelet membrane GP Ib, IIb, IIIa and IV as well as membrane-bound factor Va[76,77]. These microvesicles possess procoagulant activity as intact platelets and may play a physiological role in providing a catalytic surface for optimal thrombin formation. Shear stress is also a potent stimulus for microvesiculation[78,79]. Platelet-derived microvesicles can be detected by flow cytometry by gating the GPIIb–IIIa positive particles and measuring the annexin V positivity[70]. Increased microvesicles have been detected in circulation in patients with

Cambridge Books Online © Cambridge University Press, 2009

disseminated intravascular coagulation[80], heparin-induced thrombocytopenia[81] and 'antiphospholipid antibody syndrome'[82], transient ischemic attacks[83], and thrombotic thrombocytopenic purpura[84]. These associations suggest that, while they may be necessary for normal hemostasis, elevated microvesicle concentrations could predispose to thrombosis.

Detection of circulating platelet aggregates

Circulating platelet aggregates can be measured by flow cytometry. The existence of circulating platelet aggregate (CPA) was first proposed by Wu and Hoak[85]. They developed a formalin fixing method for measuring CPA in patients with myocardial infarction and stroke[86]. This method was widely used in the 1970s by many laboratories worldwide. However, the method is semiquantitative. Recent measurements of CPA by flow cytometry have confirmed the presence of CPA in patients with arterial thrombosis[87]. Flow cytometry for CPA provides a quantitative measurement of the number of aggregates as well as the size of aggregates. On the flow cytometer, the aggregates appear as a smearing of the platelets in the upper right quadrants[88]. Activated platelets also interact with neutrophils and monocytes to form heterotypic aggregates. Using platelet-specific and leukocyte-specific monoclonal antibodies these aggregates can be detected in the peripheral blood. These aggregates are increased in myocardial infarction[89], unstable angina[90], coronary artery disease[91] and cardiopulmonary by pass[92]. It will be interesting to determine by prospective studies whether CPA, a reflection of SPA, is a risk factor of CHD and stroke.

Measurement of platelet procoagulant activity

As discussed earlier, during secondary hemostasis, activated platelets provide a highly efficient procoagulant surface[93]. Anionic phospholipids translocate from the inner leaflet of the platelet membrane to the outer leaflet and there support the binding and activation of vitamin K-dependent coagulation proteins: factors VII, IX, and X and prothrombin (see Ref. 5 for a general review of the coagulation pathways). In addition, factor V which is present in the α-granules of the platelets, is activated and the resulting factor Va, provides a binding site for factor Xa[94]. The complex of factor Xa–Va assembled on the anionic phospholipid surface of platelets is called the prothrombinase complex. Zwaal et al. have measured this procoagulant activity, i.e. the capacity to catalyze prothrombin or factor X activation in a quantitative manner in kinetic assays[95]. However, this assay is technically demanding and the product of the reaction, thrombin, is a potent platelet activator[96]. As platelets become activated during the assay, the thrombin generation rate increases, and measurement of the initial rate of thrombin generation is often unreliable. Jesty et al. have used acetylated prothrombin in a modified assay[97]. This modified prothrombin is activated by prothrombinase, but is generated as an abnormal thrombin that does not activate platelets but still retains amidolytic activity towards small synthetic substrates. This modification allows quantitative measurement of platelet procoagulant activity without the feedback effect of thrombin. The clinical utility of this assay has not been studied.

Test of platelet gene polymorphism

There is increasing evidence that platelet function is influenced by polymorphisms of platelet membrane glycoproteins notably GPIIb–IIIa, GPIb and GPIaIIa[98]. The data so far reported represent the tip of the iceberg. The rapid progresses in genomic polymorphism determinations provide an unheralded opportunity to investigate the influence of genome-wide polymorphisms of functionally important genes on platelet function and platelet function tests. Since DNA polymorphism techniques are not subjected to in vitro variations encountered with almost all in vitro platelet function tests, genetic testing should provide valuable information regarding interindividual variation in platelet function. The genetic testing will be potentially useful in assessing risk of arterial thrombosis and response to antiplatelet drugs.

A commonly used method for detecting single nucleotide polymorphism (SNP) is amplification of the region of polymorphism by polymerase chain reaction and digest the amplified DNA with an appropriate restriction enzyme. SNP may create a new restriction site or obliterate an existing restriction site in the amplified region. In both cases, restriction enzyme digestion will yield a single DNA vs. two bands on gel eletrophoresis. Under certain circumstances under which polymorphism does not create or obliterate a restriction site, the SNP is detected by single strand conformation polymorphism (SSCP). Platelet glycoproteins are highly polymorphic and several of the polymorphisms have been identified as platelet alloantigens[99]. One of the alloantigens, P1A1 and P1A2 (or HPA-1) is identified as a SNP of GPIIIa (Leu33Pro)[100]. This polymorphism was shown in a non-prospective study to be associated with myocardial infarction especially in younger individuals (<60 years old)[101]. However, prospective studies did not find an association of this polymorphism with coronary heart disease[102,103]. Polymorphisms in other alloantigens, i.e. HPA-2 (GP1b Met 145 Thr), HPA-3 (GPIIIa Ile 843 Ser) and HPA-5 (GPIa, Glu505Lys) were not found to be asso-

Cambridge Books Online © Cambridge University Press, 2009

ciated with an increased risk of stroke[104]. Two linked allelic SNP of GPIa (nucleotide 807 C→T, 873 G→A) were found to influence the expression of GPIa integrin. Individuals with C807G873 allele have lower levels of GPIaIIa[105]. The T807 allele was found to be associated with non-fatal myocardial infarction in younger patients[106]. However, it is unclear that this polymorphism predicts the risk of development of myocardial infarction in healthy subjects. Variable numbers tandem repeat (VNTR) polymorphism of GPIbα gene[107] has been shown to be associated with arterial thrombotic disease[108] but the predictive value remains unknown. Overall, single SNP or VNTR polymorphism of GPIIb–IIIa, GPIb–V–IX and GPIaIIa appears to have limited association, if any, with coronary heart disease or stroke. It has become increasingly recognized that the biological effect of a single polymorphism of a given gene is small. It may be necessary to study the association of multiple polymorphisms with arterial thrombosis. This can be done by determining all known polymorphisms of candidate platelet glycoprotein genes in cases and controls and analysing the allellic association with thrombotic events. Alternatively, all the polymorphism sites of a given gene are identified by oligonucleotide microarray techniques in well-defined cases and controls and the association of alleles with risk of coronary heart disease and stroke analysed. These approaches are now being developed and tested but their value in assessing risk of arterial thrombosis or drug response has not been reported.

Conclusion

Availability of new and more specific methods for measuring platelet aggregability and activated platelets provides an opportunity to investigate the relationship of altered platelet function with human thrombotic and bleeding disorders. Now there are methods available for providing answers to a question that has intrigued investigators for decades: do hyperreactive platelets predispose individuals to arterial and venous thrombosis? Tests such as flow cytometry for detecting activated platelets and circulating platelet aggregates, enzyme immunoassays for measuring plasma βTG, and urinary 11-dehydrothromboxane B_2 and genetic tests for platelet gene polymorphism will provide reliable information when implemented in well-designed case-control and population-based case-cohort studies. These tests will also provide useful information regarding the influence of genetic and environmental factors on risk of thrombosis. Another potential utility of these tests is to monitor the effect (and side effects) of antiplatelet agents.

Monitoring antiplatelet therapy

Dermot Cox and Desmond Fitzgerald

Centre for Cardiovascular Science, Royal College of Surgeons, Dublin, Ireland

Introduction

The introduction of glycoprotein (GP) IIb/IIIa antagonists as new and powerful antiplatelet agents has focused attention on the need for methods to monitor antiplatelet therapy. Administration of GPIIb/IIIa antagonists is complicated as they have a very steep dose–response relationship. Moreover, their therapeutic index is low, with the necessity for strong inhibition to see benefit but bleeding complications arising if inhibition is too severe. The traditional method of monitoring by platelet aggregometry has serious limitations and is being replaced by new, faster, more convenient and more sensitive assays.

Platelet function assays

Platelet assays are divided into two groups: physiological assays, which measure the ability of an antiplatelet agent to inhibit a known function of platelets or a biochemical assay, which measures a change in a surrogate platelet marker.

Physiological assays

A major physiological response of platelets to an agonist is to bind fibrinogen and aggregate. Alternatively, platelets can adhere to a matrix without prior activation. Physiological assays monitor platelet aggregation or adhesion. These assays require fresh platelets, specialist equipment and trained staff. While these assays are potentially useful as they provide information on any alteration in the physiological function of platelets, they may not detect more subtle changes indicative of altered platelet function.

Biochemical assays

Surrogate markers of platelet function may also be useful. These include assays that measure changes in a receptor upon binding a drug, assays that measure enzyme function or assays that measure changes in surface proteins upon activation. These assays are sensitive and can detect changes in platelets in the absence of an alteration in platelet aggregation. However, changes in these platelet assays are not necessarily reflected in changes of platelet function.

Some of the biochemical assays utilize flow cytometry to estimate the quantity of antigen per platelet. One advantage of flow cytometry is that individual platelets can be examined. On the other hand, quantification of the antigen is difficult. However, antigen quantification can now be performed using special calibration kits.

Agonists

The selection of platelet agonist needs to be matched to the drug under study. Agonists generate a response through two signalling systems. One is phospholipase A_2-dependent and utilizes cyclooxygenase and thromboxane synthase to produce the agonist thromboxane A_2 (see Chapter 16). The other is phospholipase C-dependent and leads to the activation of protein kinase C (see Chapter 16). Agonists can act via one or other pathway, and some agonists act via phospholipase A_2 at low concentration and phospholipase C at high concentration. Hence the term weak agonist for those using phospholipase A_2 only and strong agonists for those using phospholipase C with or without phospholipase A_2 activity[1].

Thrombin

Thrombin is a strong platelet agonist (see Chapter 8) and can generate a response when no other agonist can. Thrombin studies in plasma require an anticoagulant as it causes coagulation or the use of washed or gel-filtered platelets. The thrombin response occurs through two different mechanisms. In gel-filtered platelets, aggregation occurs with concentrations of 0.01–0.05 U/ml thrombin and is inhibited by anti-GPIb antibodies[2]. At concentrations above 0.2 U/ml, anti-GPIb antibodies have no effect and the response is dependent on the protease activated receptors 1 and 4[3]. In platelet-rich plasma higher concentrations of thrombin are needed due to neutralization of thrombin by antithrombin III. Here 0.2–0.4 U/ml is the lowest concentration that will induce platelet aggregation.

TRAP

As an alternative to thrombin, a thrombin receptor activating peptide (TRAP) can be used. This is the peptide exposed by thrombin on the amino-terminal of the PAR-1 receptor. TRAP is synthesized as the hexapeptide SFLLRN and is used in the range 5–20 µM. This mimics the action of thrombin on the protease activated receptor-1 without the problems of coagulation[3].

ADP

ADP (see Chapter 9) is normally used at two concentrations. At 3–5 µM ADP-induced aggregation is strongly inhibited by aspirin while at 20 µM it is unaffected. However, platelets lose their responsiveness to ADP after a few hours[4]. Platelet sensitivity can be prolonged by storing PRP at room temperature in a tube with minimum air space.

Collagen

There are two collagen receptors on platelets (see Chapter 11), the integrin $\alpha_2\beta_1$ and GPVI. $\alpha_2\beta_1$ signals via phospholipase A_2 and is inhibited by aspirin, while GPVI signals through phospholipase C and is unaffected by aspirin[5]. There are a number of different collagens with different affinities for the two receptors, thus, the effect of aspirin on collagen-induced aggregation depends on the source of collagen and the concentration used. If it is to be used, collagen from different suppliers should be tested for sensitivity.

Arachidonic acid

The action of phospholipase A_2 is to cleave arachidonic acid from the cell membrane and make it available as a substrate for COX (see Chapters 15 and 25). Thus, arachidonic acid is a useful agonist for studying the integrity of the cyclooxygenase pathway. Arachidonic acid can be obtained in the acid form soluble in organic solvents or as sodium arachidonate, which is water soluble.

U46619

U46619 is a thromboxane receptor agonist[6]. It is useful for selectively activating the thromboxane receptor independently of thromboxane synthesis. It can be used to detect inhibition by thromboxane receptor antagonists[7] and is not affected by aspirin.

Adrenaline

There are large variations in response to adrenaline and some people do not respond at all or need very high doses[8,9]. There can also be a lag in the response to adrenaline of up to several minutes. Failure to obtain a response to adrenaline could be due to the presence of an antiplatelet agent or just insensitivity to adrenaline.

Ristocetin

Ristocetin is an antibiotic that binds to vonWillebrand factor (vWf) allowing it to bind to GPIb (see Chapter 12). When paraformaldehyde-fixed platelets are used the response is agglutination rather than aggregation[10,11], is independent of GPIIb/IIIa and can be used as a measure of GPIb function.

Botrocetin

Botrocetin is a snake venom and another vWf modulator that can be used in agglutination studies[11,12] but its expense means that it is usually only used as a research tool.

Antiplatelet agents

Antiplatelet agents have different modes of action and knowledge of these is necessary to monitor therapy.

Cambridge Books Online © Cambridge University Press, 2009

Inhibitors of platelet agonist receptors

While platelets can be activated by many agonists, ADP receptors appear to be especially important probably due to the role of secreted ADP in amplifying the aggregation response (see Chapter 9). ADP receptor antagonists such as ticlopidine and clopidogrel[13] inhibit ADP-induced aggregation but not thrombin-induced aggregation (see Chapter 64). Thromboxane receptor antagonists on the other hand can inhibit arachidonic acid-induced aggregation but not aggregation due to high concentrations of ADP or thrombin[14].

Platelet signalling inhibitors

Platelet agonist receptors use two principle signalling pathways. Pharmacologically the most relevant is the phospholipase A_2 pathway, which generates thromboxane A_2 via cyclooxygenase from arachidonic acid (see Chapter 15). This pathway is inhibited by aspirin (see Chapter 61). Agonists such as collagen and thrombin use the phospholipase C pathway to signal and are not affected by aspirin[1]. Samples from patients on aspirin will not aggregate to arachidonic acid but will aggregate to high concentrations of thrombin, collagen and ADP.

GPIIb/IIIa receptor antagonists

Fibrinogen binding to its receptor, GPIIb/IIIa, is an essential step in platelet aggregation (see Chapter 13 and Chapter 63). Inhibitors of this receptor inhibit aggregation induced by all agonists[15]. However, they exhibit greater inhibition of a weak agonist like ADP compared with a strong agonist such as TRAP[16].

GPIb receptor antagonists

The interaction of GPIb with immobilized vWf under shear is one of the primary initiating steps in thrombus formation (see Chapter 12). There is on-going research to produce antagonists for this receptor but to date none have been developed clinically.

Agents which elevate cAMP

cAMP acts to inhibit platelet aggregation by all agonists[17]. This can be achieved by the use of prostacyclin analogues or phosphodiesterase inhibitors (see Chapter 20). Another antiplatelet agent that is used is dipyridamole. Its proposed mechanism of action is inhibition of adenosine uptake as well as phosphodiesterase activity[18]. Increased plasma levels of adenosine also results in increased levels of intracellular cAMP[19].

Platelet aggregation

The gold standard for monitoring antiplatelet therapy is aggregometry which is based on a turbidometric technique devised by Born in 1962[20]. Platelet aggregometry utilises the principle that the absorbance of a suspension is dependent on the number of particles rather than on their size. Thus, as aggregation occurs the number of particles decrease and absorbance decreases and is usually expressed as light transmission. Rather than use whole blood, platelet-rich plasma (PRP) is prepared by centrifugation of blood at a low speed (850 x *g* for 3 min or 100 x *g* for 10 min). This PRP is added to a cuvette with a stirrer and stirred (900–1200rpm) while agonist is added.

An issue with aggregation is what to measure. There is the option of measuring percent aggregation or the slope of the aggregation curve. There is also the question of whether to measure the extent of aggregation at a fixed time-point (e.g. 2 min) or maximum aggregation. These can be different as some agonists induce reversible aggregation (see Chapter 23). The advantage of using the slope rather than extent of aggregation is that it is independent of the time of measurement and of reversible aggregation.

Some agonists produce aggregation only after a lag time. This is noticeable with adrenaline and collagen. In the case of bacteria-induced aggregation the lag time can be more pronounced, 5 min with some strains of *Streptococcus sanguis*[21] and 15 min with others[22].

Thrombocytopenia

Aggregation may be influenced by the platelet count. Aggregometry requires platelet counts between 200 000 and 400 000 platelets/µl. Some researchers adjust the platelet count to ensure it is within these levels for the sake of uniformity[23]. There is evidence that platelet count may affect the degree of inhibition by GPIIb/IIIa antagonists[23]. Diluting a sample with a high platelet concentration is relatively simple although it requires a particle counter, which can be difficult to calibrate and maintain. It also assumes that all particles the size of platelets are in fact platelets which is not necessarily the case as particles such as cell fragments may have a similar size. Concentrating a dilute platelet sample is difficult without activating the sample.

Drug-induced thrombocytopenia can occur in response to antiplatelet agents (see section 3 chpt 6) and is a known complication with GPIIb/IIIa antagonists[24]. Patients on

Cambridge Books Online © Cambridge University Press, 2009

GPIIb/IIIa antagonists are often on heparin and either of these agents can cause thrombocytopenia (see section 3 chpt 6). If the platelet count is low it can be difficult to perform aggregation, however, platelet aggregometers will still give a response with counts as low as 50 000 platelets/μl although this response will be attenuated. An alternative is to use the single platelet count method or flow cytometry, which are not affected by platelet count.

Anticoagulant

There are many anticoagulants available today but the standard anticoagulant for platelet aggregometry is 3.8% sodium citrate. There are mixed reports on using antithrombins such as heparin, low molecular weight heparin, hirudin and PPACK as anticoagulants for aggregometry. Some authors suggest that they are suitable for aggregometry[25] while others have shown that some agonists are affected by their use[26]. Although blood for aggregation is often collected in sodium citrate, some GPIIb/IIIa antagonists show different potencies in citrate and heparin anticoagulated blood[27,28]. This appears to be due to chelation of calcium from GPIIb/IIIa and the resulting conformational change increases the affinity for eptifibatide. If physiological calcium levels are required for aggregation requiring the use of an antithrombin as anticoagulant it is important to choose the appropriate agonist, ideally high dose ADP, collagen or TRAP. The alternative is to re-calcify citrated PRP immediately prior to aggregation. This works well as aggregation occurs more rapidly than coagulation[26].

Reliability

There is a large variation in aggregation responses. In one study the standard deviation ranged from 3.6% to 7.7%, day-to-day variation accounted for 42% to 63% and variation between operators accounted for 1% to 33% of the total variation. Repeat measurements of a given sample by a given operator on a single day contributed 22% to 36% of the total variation[29]. These variations can be due to sample preparation, dietary factors including high levels of lipids in the sample, smoking, drinking and ageing of the sample.

Selectivity

A difficulty with platelet aggregation is the problem of identifying the drugs involved. Patients on GPIIb/IIIa antagonists are usually on aspirin. Some may have two different GPIIb/IIIa antagonists in their plasma: abciximab for use during intervention and non-peptide antagonist such as tirofiban for maintenance. Aggregation cannot distinguish between the different agents, only the total effect. However, use of a strong agonist like TRAP can select for actions due to a GPIIb/IIIa antagonist rather than those due to aspirin.

Platelet count

A platelet aggregometer measures the changes in light transmission when a suspension of platelets aggregate. However, its sensitivity is such that only aggregates of around eight platelets are detected. Using a particle counter to determine the platelet count before and after activation, it is possible to measure the loss of single platelets with a very high sensitivity. The inhibition of microaggregate formation has been used to study the effects of GPIIb/IIIa antagonists[28,30,31] and beraprost (prostacyclin analogue) was found to be between two and ten times more potent than in platelet aggregometry[32]. This assay can be used on thrombocytopenic samples unlike any of the functional assays such as light transmittance aggregometry. One advantage of the assay is that it requires no specialist equipment other than a particle counter, which is available in most hematology departments. The principle has also been used for the development of the ICHOR point-of-care assay[33].

Platelet function analyser (PFA-100™)

Recently a number of simpler systems have been devised to replace platelet aggregometry. The first to be introduced is the Platelet Function Analyzer PFA-100™, from Dade International, Miami, Florida, USA. This consists of a membrane that is coated with collagen–adrenaline or collagen–ADP. Whole blood is aspirated through a hole pierced in the membrane. The time to closure, which is due to the formation of a platelet plug, is a measure of platelet function[34].

This device has the advantage of using small volumes of whole blood directly applied to a cartridge. However, only cartridges with the supplied agonists can be used. Clinically it has been used to monitor GPIIb/IIIa antagonists[35] and aspirin[36,37].

Ultegra™ rapid platelet function analyser

This assay is based on TRAP-induced platelet aggregation. It consists of a cartridge containing blue beads coated with fibrinogen, a magnetic stirrer and TRAP. Whole blood is added to the cartridge and the resulting activated platelets bind to the coated beads forming aggregates. Aggregation

Cambridge Books Online © Cambridge University Press, 2009

is detected by monitoring the loss of the blue beads by the turbidometric method using filters to analyze the blue portion of the spectrum[38]. This device is made by Accumetrics Corporation, San Diego, CA, USA, and received FDA approval in 1999.

The advantage of this assay is that it only uses a small volume of whole blood and requires no sample preparation. It is also a bedside device, which makes testing convenient. However, it is only used for measuring inhibition by GPIIb/IIIa antagonists and only uses TRAP as the agonist. It has been successfully used to monitor abciximab[39,40] and orbofiban[41] levels in blood. The Ultegra™ gives results similar to platelet aggregation but the IC_{50} value tends to be lower.

Whole blood aggregometry

As its name implies this technique monitors platelet aggregation in whole blood. The extent of aggregation is determined by measuring changes in impedance across two wires as platelet aggregates form on them. These devices are manufactured by Chrono-Log Corporation, Havertown, PA, USA. This technique has the advantage of being rapid as there is no sample preparation required and is potentially more relevant physiologically as all the components of the blood are present. It has been reported to be more sensitive than aggregometry and it has been used successfully to monitor the effect of GPIIb/IIIa antagonists[42], aspirin[43], dipyridamole[44] and pentoxyfylline[45].

A modification of this technique is whole blood lumi-aggregometry. This allows for monitoring aggregation by the impedance method and ATP-secretion simultaneously[46]. Secretion is measured by a chemiluminescent assay using luciferase.

Flow cytometry

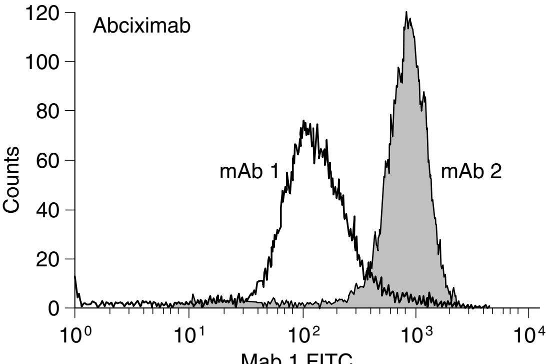
GPIIb/IIIa is capable of undergoing a number of conformational changes. Upon activation of the platelet by an agonist, GPIIb/IIIa changes from a resting to an active conformation. This new conformation can bind soluble fibrinogen. Fibrinogen binding to platelets can also be used to measure inhibition of GPIIb/IIIa. If PRP is activated and fixed the bound fibrinogen can be measured by flow cytometry. This has been used to monitor the effects of the GPIIb/IIIa antagonist YM337[47] and abciximab and orbofiban inhibition were measured using fluorescently labelled fibrinogen[48]. Another option is to utilise the conformational changes that fibrinogen undergoes when it binds to GPIIb/IIIa. These conformational changes expose neo-epitopes known as receptor-induced binding sites (RIBS)[49,50]. The antibody 9F9 recognises this RIBS epitope on fibrinogen and can be used to measure fibrinogen binding in whole blood[51].

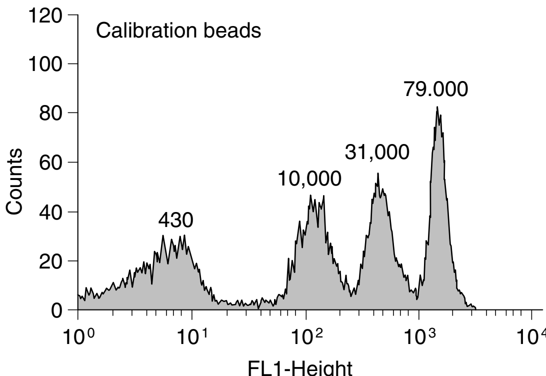
Activated GPIIb/IIIa undergoes a conformational change which can be recognized by the antibody PAC-1[52]. Fluorescently labelled PAC-1 has been used in flow cytometry to monitor inhibition of platelet activation by aspirin and clopidogrel[53] and inhibition of GPIIb/IIIa by the antagonists abciximab and orbofiban[48]. As well as conformational changes induced in the receptor by activation, the binding of antagonists to the receptor also induce conformational changes known as ligand-regulated binding sites (LRBS). One such LRBS occurs when ligands bind to GPIIb/IIIa and induce a conformational change in the receptor that results in the expression of neo-epitopes. These neo-epitopes are referred to as ligand-induced binding sites (LIBS)[54] and can be measured with anti-LIBS antibodies such as D3[55] and AP6[56] by flow cytometry. LIBS formation is not an all or none response and the degree of neo-epitope formation varies with different antagonists. However, LIBS formation, when it occurs at a reasonable level, can be used to estimate the number of occupied receptors on a platelet[57] and, used in combination with an antibody that recognizes all GPIIb/IIIa receptors, data on the free receptors and percent receptor occupancy can be obtained[58,59].

Another class of LRBS are epitopes whose expression is lost on ligand binding, i.e. ligand attenuated binding site (LABS). An antibody to a LABS has been used to develop the GPIIb/IIIa Receptor Occupancy assay from BioCytex, Marseille, France. This assay uses three antibodies: an isotype control and two anti-GPIIb/IIIa antibodies. One of these antibodies mAb2 recognises a drug-dependent LABS. A number of small molecule GPIIb/IIIa antagonists inhibit the binding of mAb2, although it is not inhibited by abciximab. The third antibody in the kit (mAb1) competes with abciximab and is not inhibited by small molecule antagonists. Together, these three antibodies can determine percent receptor occupancy[60].

One problem with flow cytometry is the inability to measure absolute binding of antibody rather than relative fluorescence. This problem has been overcome with the Receptor Occupancy Assay through its use of calibration beads. These are 2 μm beads with a known number of antibody molecules bound (there are four populations of beads). A labelled second antibody is used to stain the samples and beads. As a result it is possible to relate fluorescence to antibody molecules bound. This is known as quantitative fluorescence cytometry. As the antibodies are

Cambridge Books Online © Cambridge University Press, 2009





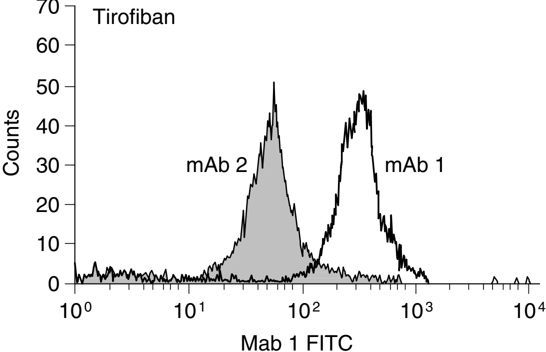


Fig. 31.1. Receptor occupancy assay. Binding of mAb 1 and mAb 2 to platelets from patients treated with abciximab or tirofiban. Also shown are the calibration beads showing four different populations of beads with different numbers of molecules bound.

differentially displaced by GPIIb/IIIa antagonists, mAb1 and mAb2 binding, after subtraction of the isotype binding, gives the number of free receptors and the number of occupied receptors. The ratio of the inhibited antibody to the uninhibited antibody (depending on the drug used) is the percentage inhibition (see Fig. 31.1).

The advantages of this assay are that it requires small amounts of whole blood (50μl) and does not require a baseline sample to estimate percentage inhibition. In addition it gives the number of free receptors as well, which may be more relevant than percent inhibition. If blood is activated with an agonist such as TRAP prior to use in the assay it allows comparison of inhibition in resting and activated samples. The receptor occupancy assay has been used to measure GPIIb/IIIa receptor occupancy by xemilofiban[61], orbofiban[16] and abciximab[62].

Thromboxane B_2

Measurement of thromboxane B_2 is especially useful for monitoring inhibition by aspirin. Thromboxane B_2 production is a measure of cyclooxygenase activity and can easily be measured by RIA/ELISA[63]. Measuring serum thromboxane B_2 by ELISA has been used to study the effects of aspirin[64], coated aspirin[65] and aspirin and nimesilide[66].

As an alternative to measuring serum thromboxane levels, the urinary metabolites of thromboxane can also be measured, in particular 2,3-dinor-TXB_2 and 11-dehydro-TXB_2 can be measured by gas chromatograph/tandem mass spectrometry (GC/MS) or ELISA[63,67]. The advantage of this is that urine is used rather than blood, and that platelet activation is not required (with serum thromboxane assays there is maximum activation of platelets). The assay is also suitable for large studies but does require specialist equipment. GC/MS analysis of urinary TXB_2 metabolites has been used to study the effects of aspirin[68], GPIIb/IIIa antagonists[57], L-arginine[69], nimesulide[66] and selective cyclooxygenase 2 inhibitors[70]. ELISA has been used to detect the actions of aspirin on urinary thromboxane B_2 levels[71].

There have been reports on resistance to the effects of aspirin[72]; however, results from platelet aggregometry can be misleading. True aspirin resistance only occurs when the drug does not completely inhibit thromboxane formation. Failure to inhibit platelet aggregation can be due to the involvement of the phospholipase C pathway in response to the agonist rather than a failure of aspirin to inhibit cyclooxygenase. Thus, measurement of COX activity by measuring thromboxane B_2 production is the most reliable method for detecting aspirin resistance.

cAMP and cGMP levels

Prostacyclin is a very potent inhibitor of platelet function and acts by elevating cAMP levels. Drugs which elevate cAMP such as the prostacyclin analogue beraprost and the phosphodiesterase inhibitor cilostazol can be monitored

Cambridge Books Online © Cambridge University Press, 2009

by measuring cAMP levels in platelets using an ELISA[73]. Equally, drugs which elevate cGMP (NO-donors) also inhibit platelet function and their actions can be monitored by ELISA/RIA for cGMP[74–76].

Platelet adhesion

Aside from platelet aggregation, platelets also adhere to the extracellular matrix. Adhesion to a fibrinogen-coated surface occurs in an activation independent manner and involves GPIIb/IIIa. Inhibition of adhesion can be used to monitor the levels of GPIIb/IIIa antagonist. A number of adhesion systems have been described in the literature. They can be static[77] or under flow conditions[78]. Under static conditions adhesion is predominantly a GPIIb/IIIa mediated event[77] and gives an indication of the levels of drug present. However, the IC_{50} values tend to be much higher than those obtained from platelet aggregometry. In some systems the shear stress can be regulated and increased to represent that found in arteries. This system depends largely on GPIb/IX/V rather than on GPIIb/IIIa[79]. The choice of substrate is also very important. However, there are no commercially available systems and those systems that are used require major investments in time and resources and are primarily research tools.

One system uses a chamber of known rheological properties containing a coverslip coated with ligand. Whole blood is pumped through this at different rates producing a range of different shear levels from those equivalent to venous conditions to those found in stenosed arteries. The coverslip is then removed, fixed, stained and the number of adherent platelets determined by microscopic examination[80]. Another shear system is the cone-and-plate viscometer[81]. The plate can be stained to allow the number of adherent particles and their sizes to be measured. Flow chambers can also be used in conjunction with real-time epifluorescence videomicroscopy[82].

Platelet adhesion has been applied in a number of clinical studies including studies on aprosulate, a novel synthetic glycosaminoglycan[83], the GPIIb/IIIa antagonist abciximab in combination with ticlopidine under shear[84], the GPIIb/IIIa antagonist YM337 under static conditions[47] and the GPIIb/IIIa antagonist eptifibatide under static and shear conditions[85].

Template bleeding time

The template bleeding time is the only in vivo assay of platelet function. Bleeding time is measured using a device that provides a standardized cut to the skin. The two principle methods are the Ivy and Simplate methods[86] and the bleeding time is the time taken for bleeding to stop (normally 8–12 min). It has been used to study the effects of the GPIIb/IIIa antagonist YM337[47]. At least 80% inhibition of platelet aggregation is necessary to cause a prolongation of bleeding time[87]. However, the effects of GPIIb/IIIa on bleeding time are not simply dependent on receptor occupancy but also on the nature of the antagonist. Some drugs have stronger effects on bleeding time than others relative to the levels of inhibition of platelet aggregation[88]. Other antiplatelet agents such as aspirin[36], clopidogrel[89], ticlopidine[90] and heparin[91] can also prolong the bleeding time.

The template bleeding time is not a sensitive assay, as high levels of inhibition are required to see an effect. However, as the principle adverse effect of anti-platelet agents is bleeding events, it is a good indicator of excessively high levels of inhibition. However, it is not popular with patients, as it is painful and can lead to scarring. The template bleeding time is also a poor predictor of bleeding events. In a clinical study with abciximab it was found that prolongation of the bleeding time was a poor predictor of bleeding events[92] and bleeding time was also shown to be a poor predictor of blood loss during surgery[93]. Thus, prolongation of bleeding time can indicate strong inhibition of platelet function but does not predict bleeding events.

Drug plasma level assays

Another approach is to directly measure plasma drug levels using ELISA, HPLC or mass spectrometry. However, with GPIIb/IIIa antagonists that have a fast on-rate and a slow off-rate such as abciximab[94] most of the drug is platelet bound and very little is free in the plasma. A similar situation arises with aspirin, which is an irreversible inhibitor of platelet cyclooxygenase[95], where the effects of the drug remain long after the drug is cleared.

Platelets and coagulation

Activated platelets undergo the membrane flip–flop, which exposes phospholipids, primarily phosphatidylserine, on their surface which are essential for the coagulation cascade. As a result the prothrombinase (FXa: Fva) and tenase (FIXa: FXa) complexes form on the platelet surface[96]. GPIIb/IIIa antagonists inhibit this procoagulant activity[97] which has led to the development of the Hemostatus test, which selectively measures the activity of GPIIb/IIIa antagonists[98].

Cambridge Books Online © Cambridge University Press, 2009

Another coagulation-based assay is the Clot Signature Analyzer™ from Xylum Corporation, New York. This assay uses non-anticoagulated whole blood and measures the time taken for platelets to occlude channels which are either uncoated (platelet hemostasis time, PHT) or coated with collagen (collagen-induced thrombus formation, CITF)[99]. Clinical studies report that the PHT is not affected by aspirin unlike the conventional bleeding time. The CITF however is more sensitive than collagen-induced aggregation but is considered overall to be unreliable[100].

The Sonoclot analyser™ from Sienco Inc., Morrison, Colorado, which measures plasma viscosity shows reasonable correlation with collagen-induced whole blood aggregation[101] although it was found to have a large coefficient of variance[102].

Clot retraction is mediated by a GPIIb/IIIa–fibrin interaction and involves platelet pseudopod contraction and is inhibited by GPIIb/IIIa antagonists[103]. Thromboelastography measures clot strength and is primarily dependent on fibrinogen and platelets. Tissue factor thromboelastography has been used to monitor levels of GPIIb/IIIa antagonists[104]. The Hemodyne™ (Hemodyne, Inc, Midlothian, VA) analyser which measures platelet-induced clot retraction[105] and a modified thrombelastograph (Haemoscope™, Skokie, IL), which measures clot strength, were found to be capable of monitoring activity of the GPIIb/IIIa antagonist abciximab[106].

Platelet function and environmental and genetic factors

The response of platelets to agonist stimulation is highly influenced by environmental factors. These can either inhibit the response to agonist, thereby mimicking the actions of a drug or else they can sensitize the platelets and as a result mask the effects of a drug.

Smoking

Smoking is one of the most common environmental factors influencing platelet function. Many researchers specifically exclude smokers when collecting blood from volunteers for studies. Smoking has been shown to increase the aggregability of platelets[107] and to increase spontaneous platelet aggregation (aggregation without the addition of agonist)[108]. Smokers were found to have increased levels of P-selectin on the platelet surface indicating platelet activation and this was not inhibited by low dose aspirin[109]. However, people who consider themselves to be non-smokers may be exposed to high levels of environmental tobacco smoke. Exposure to environmental tobacco smoke has been shown to increase the risk of cardiovascular disease[110,111]. Smoking increases thromboxane production as a consequence of platelet activation[112] and decreases prostacyclin production[113]. Aspirin was found to have a greater inhibitory effect on platelets from smokers than non-smokers, possibly reflecting altered thromboxane metabolism as in vitro thromboxane synthesis was decreased but urinary thromboxane secretion was increased[114].

Diet

Folic acid deficiency leads to enhanced platelet aggregation and thromboxane production[115]. Vitamin B12 supplementation can decrease platelet responses to platelet agonists. The flip side of this is that low intake of vitamin B12 especially in conjunction with hyperhomocysteinemia, which can occur in vegetarians, may be a risk factor for thrombosis[116]. Oxidant stress has also been shown to increase platelet reactivity suggesting that antioxidants may reduce platelet responses[117]. Vitamins C[118] and E[119] have been shown to inhibit platelet activation probably by acting as antioxidants, while vitamin B6 down regulates GPIIb levels on platelets[120]. Iron deficiency results in suppression of platelet aggregation[121,122] as does alcohol[123,124], garlic[125] and fish consumption[126]. Caffeine intake results in an increase in adenosine receptors with a resulting increase in cAMP levels[127].

Exercise

Exercise is known to increase platelet reactivity. This is probably due to increased catecholamine levels and is not inhibited by aspirin[128,129]. LDL lipid peroxides have also been implicated[130]. However, this increase in aggregability seems to be balanced by an increase in prostacyclin production in patients with a functional endothelium[131]. Exercise also increases sensitivity to antiplatelet agents[132].

Hormonal effects

GPIIb/IIIa on platelets from premenopausal women are more activatable than those of platelets from young men. An effect of menstrual cycle was also noted and changes in serum levels of estrogens and progestins were proposed as the mechanism of this effect[133]. Oral contraceptives are also known to increase the risk of thrombotic events, especially in women who smoke[113] or who are deficient in folic acid[115], although this may be a consequence of enhanced coagulation. However, physiological concentrations of estrogen were found to inhibit platelet aggregation and further inhibition was not seen in aspirin-treated platelets[134,135].

Cambridge Books Online © Cambridge University Press, 2009

Depression

There is a well-established link between depression and increase in platelet function[136] that is corrected by treatment with antidepressants[137].

Genetic

There is mixed evidence to suggest that polymorphisms of platelet receptors alter the response of platelets to agonists[138]. Some studies have shown an increased sensitivity of platelets with the PLA_2 polymorphism in GPIIIa to agonist stimulation compared with the PLA_1 variant[139,140] while others have shown no effect[141]. Platelets with the PLA_2 polymorphism have been shown to be less responsive to inhibition by the GPIIb/IIIa antagonists orbofiban[142] and to inhibition by aspirin[143], although they are more responsive to inhibition by estrogen[135]. A polymorphism in the collagen receptor has been shown to increase responsiveness to collagen by increasing the density of $\alpha_2\beta_1$ collagen receptors on the platelet surface and may be related to resistance to aspirin[144]. The Kozak polymorphism in GPIbα is associated with the levels of GPIb on the surface of platelets and may be implicated in enhanced platelet function[145] although it has been shown to have no effect on the incidence of myocardial infarction[146].

Conclusion

The importance of monitoring anti-thrombotic therapy has been seen with the oral GPIIb/IIIa antagonist trials. Failure to closely monitor drug levels can result in underdosing and therefore lack of efficacy, while overdosing means increased bleeding events for the patient. At present there are many assays available for monitoring antithrombotic therapy. The gold standard is still platelet aggregometry. It is flexible in that all anti-platelet agents can be measured and a range of agonists can be used. However, due to the specialist nature of the equipment, aggregometers are not widely available and it is time consuming due to sample preparation. There is also a lot of variation in the results. Newer rapid assays, some of which are bedside devices, have the advantage of using whole blood. This is more physiological and easier to perform as sample preparation is not necessary. The Ultegra™ is an effective system but at present only useful for monitoring anti-GPIIb/IIIa therapy. The PFA-100™ is also very effective and has a broader range of uses compared to the Ultegra™, although there are only two agonist combinations to use. Whole blood aggregometry offers the benefit of using whole blood but the flexibility of conventional aggregometry. One difficulty with the physiological assays is the choice of agonist and anticoagulant. Knowledge of the mechanism of action of the drug to be monitored is essential in selecting the appropriate agonist. For GPIIb/IIIa antagonists the issue of anticoagulant is also important. The quantitative fluorescence cytometry assay is the only assay not to require an agonist. While many of the assays described have been used to monitor the effects of antiplatelet agents some are difficult or unreliable or are only suitable as research tools.

Below are the three most widely used classes of antiplatelet agent and the most appropriate assays for monitoring them:

GPIIb/IIIa antagonists

Most assays are effective for monitoring GPIIb/IIIa antagonists. Whole blood assays such as the Ultegra™ and PFA-100™ are particularly suitable. If platelet aggregation is used the appropriate agonist is TRAP to selectively detect GPIIb/IIIa antagonist blockade. Drugs should be checked for the effects of calcium on their activity. If necessary, PPACK can be used as anticoagulant with TRAP as agonist. Quantitative fluorescence cytometry is also very effective for GPIIb/IIIa antagonists as it can give an indication of the number of free receptors available. If samples are stimulated with TRAP first it can give the number of free receptors on a maximally activated platelet. Apart from platelet aggregation all these methods use whole blood which makes them very convenient. As many hospitals have at least one flow cytometer the quantitative flow cytometry method is the only method which does not require specialist equipment. Another useful method is the single platelet count method. Not only does this use whole blood, it is the only method that is reliable when used on thrombocytopenic samples. Also cell counters are available in most hospitals and it is more sensitive than the other assays.

Aspirin

Aspirin is the most widely used antiplatelet agent and is often used in conjunction with other anti-platelet agents. The most sensitive and specific method to monitor inhibition by aspirin is to measure serum thromboxane levels by ELISA. This method can be used in the presence of other antiplatelet agents. In the absence of other antiplatelet agents, platelet aggregation can also be effective, especially if arachidonic acid is used as the agonist.

Ticlopidine/clopidogrel

These drugs are best monitored using platelet aggregation with ADP as the agonist. If aspirin is used as well, high dose ADP should be used to select for inhibition by these drugs.

Flow cytometric analysis of platelet function

Alan D. Michelson, Marc R. Barnard, Lori A. Krueger, A.L. Frelinger III and Mark I. Furman

Center for Platelet Function Studies and Division of Cardiovascular Medicine, University of Massachusetts Medical School, Worcester, USA

Introduction

This chapter will review the use of flow cytometry for the detection of circulating activated platelets and the analysis of many other aspects of platelet function[1,2]. Flow cytometry rapidly measures the specific characteristics of a large number of individual cells. Before flow cytometric analysis, cells in suspension are fluorescently labelled, typically with a fluorescently conjugated monoclonal antibody. In the flow cytometer, the suspended cells pass through a flow chamber and, at a rate of 1 000–10 000 cells per minute, through the focused beam of a laser. After fluorescent activation of the fluorophore at the excitation wavelength, a detector processes the emitted fluorescence and light scattering properties of each cell. (Ref.[3] provides a very readable overview of the principles of flow cytometry.)

In the absence of an added exogenous platelet agonist, whole blood flow cytometry can determine the activation state of circulating platelets, as judged by the binding of an activation-dependent monoclonal antibody. In addition to this assessment of platelet function in vivo, inclusion of an exogenous agonist in the assay enables analysis of the reactivity of circulating platelets in vitro. In the latter application, whole blood flow cytometry is a physiological assay of platelet function in that an agonist results in a specific functional response by the platelets: a change in the surface expression of a physiological receptor (or other antigen or bound ligand), as determined by a change in the binding of a monoclonal antibody.

A typical schema of sample preparation for whole blood flow cytometry is shown in Table 32.1. The anticoagulant is usually buffered sodium citrate, although other anticoagulants can be used[4]. The purpose of the initial dilution is to minimize the formation of platelet aggregates (see below). Typically, two monoclonal antibodies are used, each labelled with a different fluorophore. A wide variety of fluorophores are available for antibody conjugation, e.g. phycoerythrin, fluorescein isothiocyanate (FITC), peridinin chlorophyll protein (PerCP), phycoerythrin-Cy5, phycoerythrin-Texas Red, allophycocyanin (APC). The 'test' monoclonal antibody (recognizing the antigen to be measured) should be added in a saturating concentration. The 'platelet identifier' monoclonal antibody, e.g. glycoprotein (GP) Ib-, IIb-, or IIIa-specific should be added at a near saturating concentration. Physiological agonists that can be used in the assay include thrombin, thrombin receptor-activating peptide (TRAP), ADP, collagen, and thromboxane A_2 analogues. Samples are stabilized by fixation, typically with a final concentration of 1% paraformaldehyde. The test monoclonal antibody can be added after fixation, provided fixation does not interfere with antibody binding[5] (see below).

Analysis

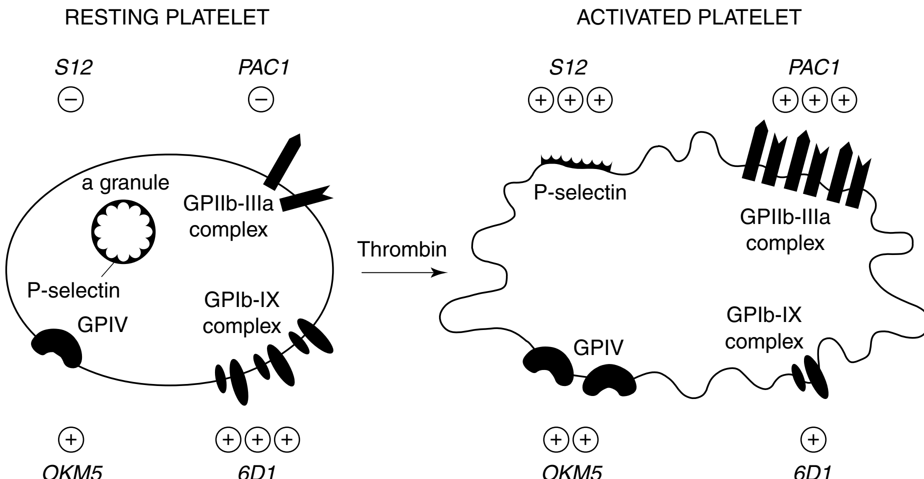

Fig. 32.1. Effect of platelet activation on monoclonal antibody binding. The cartoon depicts the binding of monoclonal antibodies (*in italics*) to resting platelets and the relative change in the binding of these antibodies after thrombin activation. *S12* is directed at the α granule membrane protein P-selectin (CD62P). P-selectin is not detectable on the surface of resting platelets. After thrombin activation, P-selectin is translocated to the platelet plasma membrane. Thus, *S12* only binds to the surface of activated platelets. *PAC1* is directed at the fibrinogen binding site on the GPIIb–IIIa complex. This fibrinogen binding site is not exposed on resting platelets. Thrombin stimulation results in a conformational change in the GPIIb–IIIa complex that exposes the fibrinogen binding site. Thus, *PAC1* only binds to the surface of activated platelets. *OKM5* is directed at the thrombospondin binding site on GPIV. *OKM5* binds to resting platelets but binding is increased following thrombin stimulation. *6D1* is directed at the von Willebrand factor binding site on GPIb. In contrast to the other monoclonal antibodies, the binding of *6D1* is markedly reduced following thrombin stimulation. (Modified[28]).

Samples are then analyzed in a flow cytometer. After identification of platelets both by their characteristic light scatter and by, for example, phycoerythrin positivity, binding of the, for example, FITC-conjugated test monoclonal antibody is determined by analysing 5000–10000 individual platelets for phycoerythrin fluorescence. Background binding obtained from parallel samples with FITC-conjugated, isotypic species-specific immunoglobulin may be subtracted from each test sample.

Monoclonal antibodies

Laboratory markers of platelet activation include activation-dependent changes in the glycoprotein GPIIb–IIIa complex, exposure of granule membrane proteins, binding of secreted platelet proteins, and development of a procoagulant surface (Fig. 32.1, Table 32.2).

The two most widely studied types of activation-dependent monoclonal antibodies are those directed against conformational changes in the GPIIb–IIIa complex and those directed against granule membrane proteins (Fig. 32.1, Table 32.2). The GPIIb–IIIa complex (CD41/CD61, integrin $\alpha_{IIb}\beta_3$) is a receptor for fibrinogen, von Willebrand factor, fibronectin, and vitronectin that is essential for platelet aggregation[6]. Whereas most monoclonal antibodies directed against the GPIIb–IIIa complex bind to resting platelets, monoclonal antibody PAC1 is directed against the fibrinogen binding site exposed by a conformational change in the GPIIb–IIIa complex of activated platelets (Fig. 32.1)[7]. Thus, PAC1 only binds to activated platelets, not to resting platelets. Other GPIIb–IIIa-specific activation-dependent monoclonal antibodies are directed against either ligand-induced conformational changes in the GPIIb–IIIa complex ('ligand-induced binding sites' or 'LIBS')[8] or receptor-induced conformational changes in the bound ligand (fibrinogen) ('receptor-induced binding sites' or 'RIBS')[9] (Table 32.2).

The most widely studied type of activation-dependent monoclonal antibodies directed against granule membrane proteins are those directed against P-selectin (CD62P). P-selectin mediates adhesion of activated platelets to monocytes and neutrophils[10]. P-selectin is a component of the α- granule membrane of resting platelets that is only expressed on the platelet surface membrane after α-granule secretion (Fig. 32.1)[11]. Therefore a P-selectin-specific monoclonal antibody only binds to degranulated platelets, not to resting platelets. The activation-dependent increase in platelet surface P-selectin is not reversible over time in vitro[12]. However, in vivo circulating degranulated

platelets rapidly lose their surface P-selectin, but continue to circulate and function[13,14]. Platelet surface P-selectin is therefore not an ideal marker for the detection of circulating degranulated platelets, unless (i) the blood sample is drawn immediately distal to the site of platelet activation, (ii) the blood sample is drawn within 5 minutes of the activating stimulus, or (iii) there is continuous activation of platelets. The length of time that other activation-dependent surface markers remain expressed on the platelet surface in vivo has not yet been determined.

Methodological issues

Advantages of flow cytometry

Other tests used to study platelet activation and function in clinical settings have limitations. Platelet aggregometry may show whether a particular clinical condition results in changes in platelet reactivity, but cannot determine whether the condition directly activates platelets[15]. In contrast, plasma assays of β-thromboglobulin[16,17], platelet factor 4[16,17], and soluble P-selectin[18], as well as plasma and urinary assays of thromboxane A_2 metabolites[19,20], may indirectly determine that a clinical condition activates platelets, but cannot measure changes in platelet reactivity associated with the condition. None of these assays can measure the extent of activation of individual platelets nor can they detect distinct subpopulations of platelets. Platelet aggregation studies are semiquantitative and subject to standardization problems[15,21]. As a result of the plasma separation procedures required, assays of plasma β-thromboglobulin and platelet factor 4 concentrations are particularly vulnerable to artefactual in vitro platelet activation[16,17]. Furthermore, soluble P-selectin in plasma may be of endothelial cell origin[18].

Whole blood flow cytometric assays of platelet activation have none of these limitations. Platelets are directly analysed in their physiological milieu of whole blood (including red cells and white cells, both of which affect platelet activation[22,23]). The minimal manipulation of the samples prevents artefactual in vitro activation and potential loss of platelet subpopulations[24–27]. Both the activation state of circulating platelets and the reactivity of circulating platelets can be determined. The flow cytometric method permits the detection of a spectrum of specific activation-dependent modifications in the platelet surface membrane. Furthermore, as new monoclonal antibodies directed against novel functional epitopes are developed, they can easily be incorporated into the assay. A subpopulation of as

Cambridge Books Online © Cambridge University Press, 2009

few as 1% partially activated platelets can be detected by whole blood flow cytometry[28]. Only minuscule volumes (~5 μl) of blood are required[24,25] making whole blood flow cytometry particularly advantageous for neonatal studies[29]. The platelets of patients with profound thrombocytopenia can also be accurately analysed.

Platelet activation by thrombin, one of the most physiologically important platelet activators[30–32] can be directly measured in whole blood through the use of the synthetic tetrapeptide glycyl-L-prolyl-L-arginyl-L-proline (GPRP)[25,27,28]. In the absence of GPRP, addition of thrombin to whole blood results in a fibrin clot, thereby precluding the use of thrombin as an agonist in the whole blood assay. Furthermore, thrombin is a potent inducer of platelet-to-platelet aggregation, which precludes analysis by flow cytometry of activation-dependent changes in individual platelets. However, addition to whole blood of GPRP together with thrombin inhibits both fibrin polymerization and platelet-to-platelet aggregation, without affecting thrombin-induced platelet activation[25,27,28]. An alternative to the use of thrombin and GPRP in the whole blood flow cytometric assay is the use of a thrombin receptor agonist peptide (TRAP). TRAP is a peptide fragment of the protease-activated receptor 1 (PAR1) 'tethered ligand' receptor for thrombin[33]. Without the need for GPRP, TRAP directly activates platelets in whole blood without resulting in a fibrin clot[34]. However, TRAP may not reflect all aspects of thrombin-induced platelet activation, because PAR1 is not the only platelet receptor for thrombin[35,36]. Other platelet receptors for thrombin include PAR4 and GPIb[35,36].

Disadvantages of flow cytometry

There are disadvantages to flow cytometry. First, flow cytometers are expensive instruments to purchase and maintain. Secondly, for a clinical assay, sample preparation is quite complicated and requires a dedicated operator, although the future development of automated systems and more user-friendly software should simplify the assay. Thirdly, to avoid ex vivo platelet activation, blood samples should be processed within approximately 45 minutes of drawing[24]. (For some monoclonal antibodies, this problem can be circumvented by immediate fixation – see **'Fixation'** below.) Fourthly, flow cytometry only measures the function of circulating platelets, whereas plasma assays of β-thromboglobulin and platelet factor 4, and plasma and urinary assays of thromboxane A_2 metabolites, also reflect platelet activation at the blood vessel wall and recently cleared platelets. Thus, if the activated platelets are rapidly cleared, adherent to blood vessel walls or to extracorporeal circuits, or have lost surface P-selectin[13], flow cytometry may not detect evidence of platelet activation. For example, during cardiopulmonary bypass, flow cytometry demonstrates only modest evidence of circulating activated platelets[37,38], whereas radioimmunoassays of plasma β-thromboglobulin and platelet factor 4 consistently provide evidence of marked activation of platelets[39,40].

Table 32.3. Methods of sample preparation for whole blood flow cytometry that minimize the formation of platelet aggregates

Prepare reagents in advance and avoid delays in procedure
To collect blood, use a light tourniquet and a needle not narrower than 21 gauge
Smooth, easy flow from blood draw
Discard the first 2 ml of blood
Polypropylene (or siliconized glass) tubes or syringes
Immediate mixture with anticoagulant
No washing, centrifugation, gel filtration, vortexing, or stirring steps
Reduce the platelet count by dilution of the samples
If thrombin is the agonist, inclusion of the peptide GPRP in the assay
Mix gently after addition of agonist, then incubate undisturbed
Fixation

Blood drawing

After discarding the first 2 ml of blood, collection of blood into a 3.2% sodium citrate Vacutainer (Becton Dickinson, Rutherford, NJ) does not result in significant platelet activation[37]. However, each laboratory should determine whether their method of collection, including the drawing of samples through angioplasty and other catheters, results in artefactual in vitro platelet activation, as determined by the binding of activation-dependent monoclonal antibodies.

Minimizing platelet aggregates

Platelet aggregates can be measured by flow cytometry[41]. However, if the platelets are aggregated, the amount of antigen per platelet cannot be determined by flow cytometry. This is because flow cytometry measures the amount of fluorescence per individual particle, irrespective of whether the particle is a single platelet or an aggregate of an unknown number of platelets. Platelet aggregates can be minimized in the preparation of plate-

Cambridge Books Online © Cambridge University Press, 2009

lets for whole blood flow cytometry by a combination of the methods shown in Table 32.3. RGD-containing peptides can also be used to minimize platelet aggregates[42,43], but these peptides may interfere with the binding of detecting antibodies, e.g. PAC1 and result in exposure of LIBS[8,44]. Each sample should be monitored for evidence of platelet aggregation ('smearing' of the platelets into the upper right quadrant of the log side (orthogonal) light scatter vs. log forward light scatter histogram).

Fixation

Fixation is very advantageous in a clinical setting where there may not be immediate access to a flow cytometer. Fixation prevents subsequent artefactual in vitro platelet activation. For most antibodies, the 'antibody labelling before fixation' method described above results in no significant differences in fluorescence intensity between samples analysed immediately and samples analysed within 24 hours of fixation[24]. A 'fixation before antibody labelling' method also results in no significant differences in fluorescence intensity between samples analysed immediately and samples analysed within 24 hours of antibody labelling[37]. However, fixation is an important variable to be controlled for, especially in a 'fixation before antibody labelling' method, because the binding of activation-dependent monoclonal antibodies to fixed platelets is often decreased compared to unfixed platelets[5]. Furthermore, the binding of some antibodies further decreases after fixation in a time-dependent manner. The optimal fixation method for each new monoclonal antibody must therefore be defined by each laboratory.

An argument in favour of immediate fixation is that activation-dependent changes are often time dependent, at least in vitro. For example, the platelet surface expression of the GPIb–IX–V complex decreases within 30 seconds of platelet activation, reaching a nadir at approximately 5 minutes, but over the next approximately 45 minutes the platelet surface expression of the GPIb–IX–V complex returns to normal[12,34]. The activation-dependent increase in the platelet surface expression of the GPIIb–IIIa complex and CD154 (CD40 ligand, CD40L) are also reversible with time[45,46]. In contrast, although circulating degranulated platelets rapidly lose their surface P-selectin in vivo[13], the activation-dependent increase in platelet surface P-selectin is not reversible over time in vitro[12,45].

Choice of monoclonal antibodies

Because the exposure of different antigens may reflect different aspects of platelet activation, it may be preferable to use a panel of monoclonal antibodies (see above). Monoclonal antibodies are preferable to polyclonal antibodies in whole blood flow cytometry, because they (i) can more reliably saturate all specific epitopes and (ii) result in less non-specific binding. Platelet-specific monoclonal antibodies are now available from a wide variety of commercial sources, and can often be purchased already conjugated to FITC, biotin, phycoerythrin, PerCP, APC, or a tandem conjugate, e.g. phycoerythrin-Cy5 or phycoerythrin-Texas Red. Alternatively, unlabelled antibodies can be FITC conjugated by the method of Rinderknecht[47] or (easier and more rapidly) by a kit method (commercially available from, for example, Boehringer Mannheim (Indianapolis, IN), Molecular Probes (Eugene, OR), and Sigma-Aldrich (St Louis, MO)). Antibodies can be biotinylated as described by Shattil et al.[24] or by following the biotin manufacturer's directions. The use of antibodies that are directly conjugated with FITC, phycoerythrin, PerCP, APC, or tandem conjugates eliminates the requirement for the addition of secondary antibodies, thereby avoiding time-consuming additional incubations and washing procedures which, in unfixed samples, may result in artefactual in vitro activation of platelets. Furthermore, the use of secondary antibodies is likely to result in increased background fluorescence and decreased sensitivity of the assay.

F_{ab} fragments of monoclonal antibodies can be used to avoid F_c-mediated binding and the F_c-induced platelet activation that has been reported with some monoclonal antibodies[48]. However, the use of F_{ab} fragments is usually unnecessary, provided: (i) the absence of antibody-induced binding of other activation-dependent monoclonal antibodies is demonstrated in control samples, or the problem is avoided by fixation before test antibody binding; (ii) the F_c-mediated and non-specific binding obtained from parallel samples with isotypic species-specific immunoglobulin is subtracted from the binding of the test antibody, or (iii) immunoglobulins, F_c fragments, or peptides are used as blocking reagents.

The saturating concentration of each antibody for platelet binding must be specifically determined by each laboratory. This concentration is typically between 0.25 and 20 μg/ml. In addition, when two monoclonal antibodies are used in the same assay (as is standard in whole blood flow cytometry), it is necessary to determine that they do not interfere with each other for platelet binding.

Platelets can be detected in whole blood by light scatter only. However, under certain experimental conditions, some of the particles falling within the light scatter gate for platelets may not bind any platelet-specific monoclonal antibody. It is therefore recommended that a minimum

Cambridge Books Online © Cambridge University Press, 2009

two colour/two antibody technique be used for whole blood flow cytometry: one monoclonal antibody (for example, GPIb-, GPIIb-, or GPIIIa-specific, typically phycoerythrin-conjugated) to identify a particle as a platelet; another monoclonal antibody (typically FITC conjugated) to quantify the expression of the glycoprotein of interest.

Expression of antibody binding

Antibody binding can be expressed as mean fluorescence intensity (MFI) or as the percent of platelets staining positive for a particular antibody (based on a positive analysis region placed just to the right of the negative control fluorescence histogram). Depending on the experimental circumstances and the physiologic nature of the antigen being measured, either MFI or percent positive platelets may have more relevance than the other. Unlike the MFI method, the 'per cent positive platelets' method is independent of variations in signal amplification, e.g. as a result of changes in PMT voltage or gain, because the isotypic control signal increases in proportion with the test sample. The 'per cent positive platelets' method may detect subpopulations of platelets arising from a local in vivo insult. However, it is important to realize that 'antibody-positive' platelets may have very little antigen expressed on their surface. For example, in a given clinical setting, the data may be reported as 20% circulating activated platelets, based on P-selectin positivity. However, if each P-selectin-positive platelet expresses only 10% of maximal platelet surface P-selectin, the overall average increase in platelet surface P-selectin is only 2%. If the goal is to determine the total amount of platelet surface antigen, MFI is therefore the preferred method of data presentation. For activation-dependent antibodies, inclusion of a control sample maximally activated by thrombin, TRAP, or phorbol myristate acetate assists in the quantification of the amount of surface antigen per platelet. The activation-dependent decrease in platelet surface GPIb–IX–V[25,34,49,50] should be quantified by MFI rather than by the 'percentage of positive platelets' method, because the decrease in platelet surface GPIb–IX–V on each platelet is usually insufficient to result in a 'negative' platelet. Methods have been described for the calculation of a binding index that takes into account both MFI and percent positive platelets[51].

Although standard flow cytometry does not result in a measure of the absolute number of binding sites, Shattil et al.[24] and Johnston et al.[52] used monoclonal antibodies double-labelled with ^{125}I and biotin to demonstrate a direct linear relationship between the number of antibody binding sites per platelet as determined by ^{125}I-labelled and (after incubation with phycoerythrin-streptavidin) fluorescent-labelled antibody. Once this relationship is known for a given monoclonal antibody, it is possible to use subsequent batches of the biotinylated or FITC-conjugated antibody for binding site quantitation, provided that the molar ratio of fluorescein to antibody is known.

Commercial kits, e.g. Quantum, Flow Cytometry Standards Corp., San Juan, PR, containing a set of calibrated fluorescent standards and software can be used to determine molecules of equivalent soluble fluorochrome (MESF). Use of these standards allows: (i) quantitation of the fluorescence intensity of samples in terms of MESF, (ii) determination of the fluorescence threshold of the instrument, (iii) determination of the linearity and stability of the instrument, and, most importantly, (iv) data comparison over time and between different instruments and laboratories[53]. Furthermore, flow cytometric methods are now available for the absolute quantitation of the number of antibodies bound per cell, e.g. Quantum Simply Cellular Microbeads Kit, Flow Cytometry Standards Corp. The lower limit of detection of antibody binding by flow cytometry is approximately 500 antibody molecules per platelet.

Calibration of the flow cytometer

To ensure day-to-day sample reproducibility, the flow cytometer should be calibrated daily using commercially available fluorescent beads. Daily confirmation of satisfactory instrument electronics, fluidics, and alignment should also be performed. Because of spectral emission overlap, the proper electronic color compensation must be set for each combination of antibodies (fluorophores) per the instructions of the manufacturer of the flow cytometer and confirmed by each laboratory.

Detection of the activation-dependent decrease in the platelet surface expression of the GPIb–IX–V complex

Whole blood flow cytometric assays frequently employ a GPIb-specific monoclonal antibody to identify platelets. Because GPIb is not present on any circulating blood cell except platelets[54,55], the activation-induced decrease in the platelet surface expression of GPIb[25,49,50] generally does not result in fluorescence below the threshold used to distinguish platelets from other cells and debris[24,28]. Thus, no subpopulations of platelets are excluded. A method of avoiding the activation-induced decrease in binding of a GPIb-specific monoclonal antibody is to add a direct conjugate of the GPIb-specific antibody before addition of the agonist[56] (see below).

Cambridge Books Online © Cambridge University Press, 2009

To specifically analyse the activation-induced decrease in the platelet surface expression of the GPIb–IX complex in whole blood, a GPIIb- or GPIIIa-specific monoclonal antibody can be employed as the platelet-identifying reagent[37].

There is an important methodologic point that needs to be emphasized with regard to the flow cytometric detection of the activation-induced decrease in the platelet surface expression of the GPIb–IX complex[56]. If a FITC-conjugated GPIb–IX-specific test monoclonal antibody is added prior to the platelet agonist (as in the typical schema shown in Table 32.1), the activation-induced redistribution of GPIb–IX to the surface-connected canalicular system[57] will not result in a significant decrease in platelet fluorescence, because a flow cytometer can detect FITC fluorescence, irrespective of whether the conjugated antibody is on the surface or the interior of the platelet. Therefore, in flow cytometric assays, GPIb–IX-specific antibodies that are directly conjugated, e.g. with FITC must be added to the assay after the addition of the agonist.

Clinical applications of whole blood flow cytometry

Platelet hyper-reactivity and/or circulating activated platelets in acute coronary syndromes

Whole blood flow cytometric studies have demonstrated circulating activated platelets in patients with unstable angina and acute myocardial infarction[58,59]. Whole blood flow cytometric studies have also demonstrated circulated activated platelets and increased platelet reactivity in patients with stable coronary artery disease[60]. In addition, coronary angioplasty results in platelet activation, as evidenced by whole blood flow cytometric analysis of coronary sinus blood[61,62].

Flow cytometric analysis of platelet activation-dependent markers can be used to determine optimal antiplatelet therapy in clinical settings, e.g. in acute coronary syndromes[63,64] and after coronary stenting[65,66]. Flow cytometric analysis of platelet activation markers before angioplasty may predict an increased risk of acute[67] and subacute[68] ischemic events after angioplasty.

Circulating activated platelets in cerebrovascular ischemia

Increased circulating P-selectin-positive and CD63-positive platelets have been reported in acute cerebrovascular ischemia[69]. Furthermore, increased expression of surface P-selectin on platelets is a risk factor for silent cerebral infarction in patients with atrial fibrillation[70].

Leukocyte–platelet aggregates

By a combination of platelet-specific and leukocyte-specific monoclonal antibodies, heterotypic aggregates, e.g. monocyte–platelet or neutrophil–platelet can be determined by flow cytometry[60,71]. Platelet degranulation with surface P-selectin exposure is necessary for the formation of these monocyte–platelet and neutrophil–platelet aggregates[72,73]. In the clinical settings of stable coronary artery disease, percutaneous coronary interventions, and venous insufficiency, circulating monocyte–platelet aggregates (but not neutrophil–platelet aggregates) are, in fact, a more sensitive marker of in vivo platelet activation than circulating P-selectin-positive platelets[60,74–76].

Circulating leukocyte–platelet aggregates are increased in acute myocardial infarction[77,78], unstable angina[79], stable coronary artery disease[60], and cardiopulmonary bypass[80]. Circulating leukocyte–platelet aggregates also increase after coronary angioplasty, with a greater magnitude in patients experiencing late clinical events[81].

Monitoring of GPIIb–IIIa antagonist therapy

GPIIb–IIIa antagonists are increasingly prescribed in clinical settings. Flow cytometric methods can be used to monitor this therapy by measuring receptor occupancy by these drugs. These methods can be categorized as either direct or indirect. One type of direct method is a competitive binding assay with either (i) biotinylated[82] or FITC-conjugated[83] GPIIb-IIIa antagonist (ii) blocking monoclonal antibodies[84,85] (iii) peptides with very high affinities for GPIIb–IIIa (disintegrins[86] or cyclic RGD peptides[87]); or, (iv) fibrinogen binding after platelet activation (detected by either a polyclonal anti-fibrinogen antibody[88] or by an anti-RIBS antibody [A.D. Michelson and M.R. Barnard, unpublished data]). Another type of direct method measures the binding of an antibody directed against the GPIIb–IIIa antagonist[89]. Indirect methods measure either (i) the GPIIb–IIIa antagonist-induced binding of an anti-LIBS antibody[90] or, (ii) platelet aggregation, as determined by light scatter[82].

Quality control of stored platelet concentrates in the blood bank

As determined by P-selectin, CD63, and the GPIIb–IIIa complex, flow cytometric studies of platelets stored in the blood bank prior to transfusion have provided direct

Cambridge Books Online © Cambridge University Press, 2009

evidence of a time-dependent platelet activation[91–93]. These changes correlated with modifications in platelet morphology (decrease in swirling), leakage of lactate dehydrogenase, and release of b-thromboglobulin[91]. It has been suggested that platelet surface P-selectin may be useful as a quality control measurement, based on correlations between the platelet surface expression of P-selectin in stored blood bank platelets and (i) post-transfusion platelet counts[94], (ii) platelet survival determined by In^{111} [92,95], and (iii) enhanced clearance of P-selectin-positive platelets from the recipient[92].

However, in vivo in a primate model, Michelson et al.[13] demonstrated that circulating degranulated platelets rapidly lose surface P-selectin but continue to circulate and function. This study was confirmed in a knockout mouse model by Berger et al.[14] who demonstrated that P-selectin, despite its binding to leukocytes, does not mediate platelet clearance in any of the following settings: physiological ageing, platelet activation, and platelet storage at 4 °C.

Platelet hyporeactivity

Although there are currently few published studies in this area, whole blood flow cytometry may be useful in the clinical assessment of platelet hyporeactivity. For example, compared to adults, the platelets of very low birthweight preterm neonates are markedly hyporeactive to thrombin, ADP/epinephrine and thromboxane A_2, as determined by flow cytometric detection of (i) the exposure of the fibrinogen binding site on the GPIIb–IIIa complex, (ii) fibrinogen binding, (iii) the increase in platelet surface P-selectin, and (iv) the decrease in platelet surface GPIb[29]. This platelet hyporeactivity may contribute to the propensity of very low birth weight neonates to intraventricular hemorrhage.

Diagnosis of inherited deficiencies of platelet surface glycoproteins

Flow cytometry provides a rapid and simple means for the diagnosis of the homozygous and heterozygous states of platelet membrane glycoprotein deficiencies, such as Bernard–Soulier syndrome (deficiency of GPIb–IX–V) and Glanzmann's thrombasthenia (deficiency of GPIIb–IIIa)[96,97]. Furthermore, in Bernard–Soulier syndrome, whole blood flow cytometry allows analysis of platelets without attempting the technically difficult procedure of physically separating the giant platelets from similarly-sized red and white blood cells. Because light scatter (especially forward light scatter) correlates with platelet size, light scatter gates may need to be adjusted in giant platelet syndromes, including Bernard–Soulier syndrome. This adjustment may result in overlap of the light scatter of giant platelets with red and white blood cells. It is therefore essential to include in the assay a platelet-specific monoclonal antibody as a platelet identifier. For Bernard–Soulier syndrome platelets, this identifier antibody obviously cannot be GPIb, GPIX, or GPV specific.

In addition, a panel of activation-dependent monoclonal antibodies can be used to evaluate patients with defects in platelet aggregation[98], secretion[99], or procoagulant activity[100].

Diagnosis of storage pool disease

Inherited dense granule storage pool deficiency, a relatively common cause of a mild hemorrhagic diathesis, cannot be reliably diagnosed by standard platelet aggregometry. However, using mepacrine-loaded platelets, storage pool deficiency can be accurately diagnosed by a simple, rapid, one-step flow cytometric assay in a clinical laboratory[101,102].

Reticulated platelets

Whole blood flow cytometric methods have been developed for the identification of young platelets, i.e. those containing mRNA by their staining with thiazole orange[103–105]. Because of the analogy to reticulocytes, these thiazole orange-positive platelets have been termed 'reticulated platelets'[104,106]. Thrombocytopenic patients whose bone marrow contained normal or increased numbers of megakaryocytes had significantly elevated proportions of circulating reticulated platelets[103]. In contrast, the proportion of reticulated platelets in thrombocytopenic patients with impaired platelet production (reduced bone marrow megakaryocytes) did not differ from normal controls and the absolute number of reticulated platelets was significantly lowered[103]. Measurement of reticulated platelets has been used as an aid in assessing bone marrow recovery after bone marrow transplantation[107]. Because thiazole orange also binds to ADP and ATP (contained in dense granules), important controls in the flow cytometric measurement of reticulated platelets are the demonstration that thiazole orange staining is (i) abolished by pretreatment of the sample with RNAase, and (ii) not abolished by pretreatment of the sample with thrombin.

Platelet-derived microparticles

As determined by flow cytometry, in vitro activation of platelets by some agonists, e.g. C5b-9, collagen/thrombin,

Cambridge Books Online © Cambridge University Press, 2009

and the calcium ionophore A23187 results in platelet-derived microparticles (defined by low forward angle light scatter and binding of a platelet-specific monoclonal antibody) that are procoagulant (determined by binding of monoclonal antibodies to activated factors V or VIII or by annexin V)[108,109]. These findings suggest that procoagulant platelet-derived microparticles may have an important role in the assembly of the 'tenase' and 'prothrombinase' components of the coagulation system in vivo.

Platelet-derived microparticles are present in blood bank fresh frozen plasma and cryoprecipitate[110]. Platelet-derived microparticles have been reported to be increased in the following clinical settings: immune thrombocytopenic purpura[111,112], transient ischemic attacks[113], acute coronary syndromes[114], and cardiopulmonary bypass[38,115]. Increased platelet microparticles and procoagulant activity occur in symptomatic patients with prosthetic heart valves and provided a potential pathophysiological explanation of cerebrovascular events in this patient group[116]. Procoagulant platelet-derived microparticles are decreased in preterm neonates compared with adults, and this may contribute to the propensity of preterm neonates to intraventricular hemorrhage[117]. GPIIb–IIIa antagonists also decrease procoagulant platelet-derived microparticles, and heparin and enoxaparin augment this reduction[118].

Diagnosis of heparin-induced thrombocytopenia

Unlike normal sera and sera from patients with quinine- or quinidine-induced thrombocytopenia, sera from patients with heparin-induced thrombocytopenia generate procoagulant platelet-derived microparticles from normal platelets[119]. This observation has been used to develop a rapid, specific, and sensitive flow cytometric assay for the diagnosis of heparin-induced thrombocytopenia[120].

Other potential clinical applications of flow cytometry

Other conditions in which whole blood flow cytometric measurement of platelet hyperreactivity and/or circulating activated platelets may prove to have a clinical role include pre-eclampsia[121,122], peripheral vascular disease[123], diabetes mellitus[124], and Alzheimer disease[125].

Because of the minuscule volumes of blood required, whole blood flow cytometry can be used to analyze the shed blood that emerges from a standardized bleeding time wound[25,37,38,126]. The time-dependent increase in the platelet surface expression of P-selectin in this shed blood reflects in vivo activation of platelets[25,37,38,126]. Immediate fixation (prior to antibody incubation) is obligatory, in order to observe these time-dependent changes. The assay can be used to demonstrate deficient platelet reactivity in response to an in vivo wound, for example during cardiopulmonary bypass[37].

Flow cytometry can also be used to: immunophenotype platelet HPA-1a[127]; detect maternal and fetal anti-HPA-1a antibodies[128]; measure platelet-associated IgG in immune thrombocytopenias[129] and alloimmunization[130]; and crossmatch platelets, which may be useful for alloimmunized patients for whom HLA compatible platelets are not readily available[131].

Flow cytometry can be used to measure platelet calcium flux with Indo-1[132,133] or Fluo-3/Fura Red ratios[134], including in whole blood[135,136]. Platelet cytoskeletal rearrangement can be analyzed flow cytometrically by measuring F-actin content with NBD- or bodipy-phallicidin or FITC-phalloidin[136,137].

Flow cytometry can be used to easily and precisely count very low numbers of platelets. A known number of fluorescently labelled microbeads is added to a given volume of diluted anticoagulated whole blood. After fluorescent labelling of the platelets, the platelet count can be calculated. This method is particularly advantageous for severely thrombocytopenic patients for whom standard Coulter counters are less accurate.

Animal models of platelet-dependent thrombosis

Paolo Golino and Francesco Loffredo

Department of Internal Medicine, Division of Cardiology, University of Naples Federico II, Naples, Italy.

Introduction

Acute thrombotic occlusion of an atherosclerotic coronary or cerebral artery, leading to myocardial infarction or stroke, respectively, is still the leading cause of mortality in the Western world. Furthermore, acute thrombotic complications seriously compromise modern interventional approaches to the management of atherosclerotic vascular disease. Therefore, the development of effective antithrombotic therapies for acute arterial thrombotic occlusion still represents an important public health strategy.

Our understanding of the basic molecular processes involved in the formation and dissolution of thrombus has expanded rapidly in recent years, and this basic research has led to the generation of novel, potent, and clinically relevant antithrombotic agents, such as tissue plasminogen activator and its mutant forms, ticlopidine and clopidogrel, and Gp IIb/IIIa inhibitors. These agents are currently part of the clinical armamentarium available to the clinical cardiologist for the treatment of thrombotic disorders. With no doubts, therefore, the evaluation of these – as well as newer and perhaps even more effective – molecules requires relevant quantitative animal models of acute thrombosis; the ultimate application of new antithrombotic pharmacological agents being developed through the use of modern technology depends on the appropriate assessment in vivo to ensure their efficacy and safety[1].

Thus far, however, it has not been possible to reproduce, in an experimental model, the most common clinical cause of arterial thrombosis – an ulcerated or fissurated atherosclerotic plaque. Although during the past few years many animal models have been developed, the ideal model is far from being available, and this limitation should always be kept in mind. On the other hand, however, it should be also clear that these models represent an invaluable tool for the study of the pathophysiological mechanisms involved in the process of thrombus formation, as well as for the preclinical screening of new antithrombotic compounds; without the aid of these animal models it would not have been possible to develop antithrombotic compounds, such as tissue plasminogen activator or abciximab, which represent a cornerstone of the modern antithrombotic therapy. The purpose of this chapter is to describe the most commonly used animal models of intravascular thrombus formation and thrombolysis, pointing out the salient features of each model, including their advantages and drawbacks.

The Folts' recurrent coronary thrombosis model

In 1976 Folts and coworkers[2] described a model of repetitive thrombus formation in stenosed coronary arteries of open chest, anesthetized dogs. Subsequent to that description, other groups of investigators have used the Folts model, not only to test the antithrombotic effects of a variety of drugs, but also to investigate the mechanisms responsible for the interaction between platelets/coagulation factors and the vascular wall, ultimately leading to thrombus formation; the model is now extensively employed by investigators in the field of intravascular thrombosis in a variety of arteries, as well as in different species.

After opening of the chest at the fifth intercostal space under general anesthesia, the heart is suspended in a pericardial cradle. Either the left anterior descending (LAD) or the circumflex (Cx) coronary artery is isolated from the surrounding tissue. Next, endothelial and medial damage is produced by squeezing the artery between a pair of rubber-covered forceps and a plastic constrictor is placed around the injured arterial segment in order to obtain a

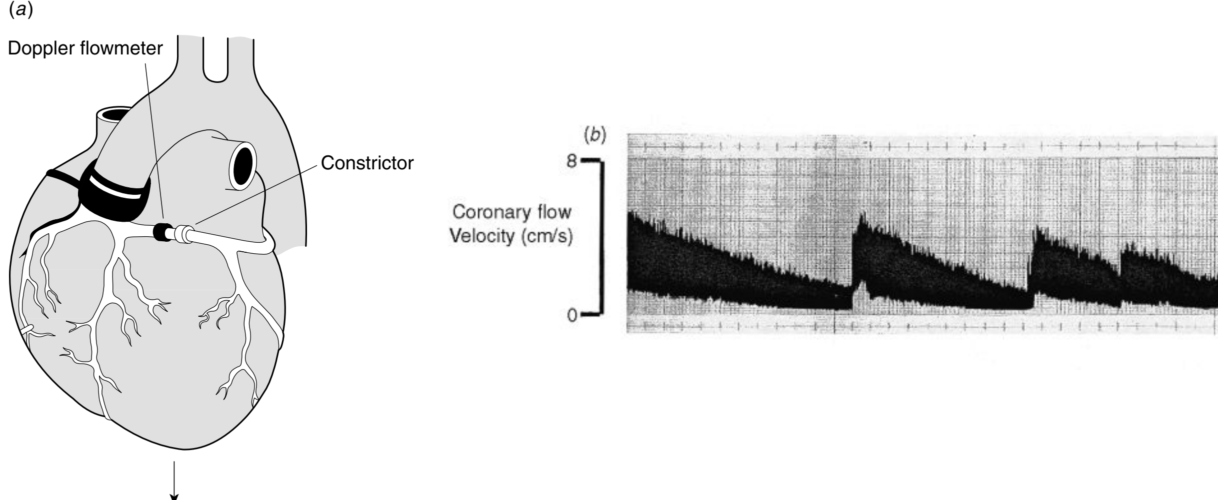

Fig. 33.1. Schematic representation of the experimental preparation of recurrent intravascular thrombosis. This model is thought to mimic the clinical situation of unstable angina. (*a*) Schematic representation of surgical preparation of the dog coronary artery. A short segment of coronary artery is exposed surgically under general anesthesia. Endothelial injury is produced and a plastic constrictor is then placed around the de-endothelialized segment to create a stenosis of about the 75% of the luminal diameter. Coronary blood flow velocity is measured continuously by a Doppler flow probe placed proximal to the constrictor. (*b*) In this model, cyclic flow variations (CFVs), characterized by gradual decrease in blood flow to almost zero values followed by restoration of flow to normal values usually develop within few minutes after placement of the constrictor.

stenosis of about 70% of the luminal diameter. An electromagnetic or ultrasonic Doppler flowmeter probe of appropriate size is placed around the proximal coronary artery for measuring volume flow or flow velocity (Fig 33.1). Within a few minutes after instrumentation, the large majority of the animals develop a typical pattern of flow characterized by gradual decreases in blood flow to almost zero values, followed by sudden restorations of flow to baseline values (Fig. 33.1). This pattern of flow has been defined in terms of cyclic flow reductions (CFRs).

In this model, recurrent intravascular thrombosis originates from the combination of two thrombogenic stimuli: a hemodynamically significant stenosis and focal, intimal and medial injury. With very few exceptions, CFRs will not develop unless both stimuli are provided. An interesting feature of this model is that it closely mimics the pathophysiological conditions encountered in patients with acute coronary syndromes, i.e. unstable angina and acute myocardial infarction, in whom a thrombogenic surface is exposed to flowing blood under conditions of high shear stress, like those found in close proximity of a complicated atherosclerotic plaque[3,4].

After damaging and stenosing the coronary artery sufficiently, coronary blood flow starts declining immediately, reaching zero within a few minutes and remaining there until there is a deliberate, manual restoration of flow. This is usually accomplished by either flicking the constrictor or sliding the constrictor up and down the artery to mechanically dislodge the thrombus (Fig. 33.1). Spontaneous flow restorations may also occur, but usually under non-severe conditions, i.e. minimal stenosis or damage, or after administration of a partially effective antithrombotic agent.

Several groups have examined histologically the coronary arteries harvested from dogs undergoing CFRs: extensive intimal and medial injury, including de-endothelialization with rupture of the internal elastic lamina and various degree of medial tears with adherent platelets and/or microthrombi, are consistently observed (Fig. 33.2). Arteries harvested when coronary flow is at its nadir invariably reveal a platelet-rich thrombus filling the stenotic segment (Fig. 33.2)[2,5–11]. These histologic observations, coupled with the pattern of gradual, progressive declines in coronary flow and abrupt increases thereof (whether spontaneous or induced), provide further evidence that CFRs are indeed caused by progressive accumulation of platelet thrombi. Folts et al.[6] have provided angiographic evidence that CFRs are thrombotic by demonstrating a temporal relationship between cessation of coronary flow and angiographic visualization of vessel obstruction. In that study, restoration of flow was followed in subsequent angiographic frames by the passage of a

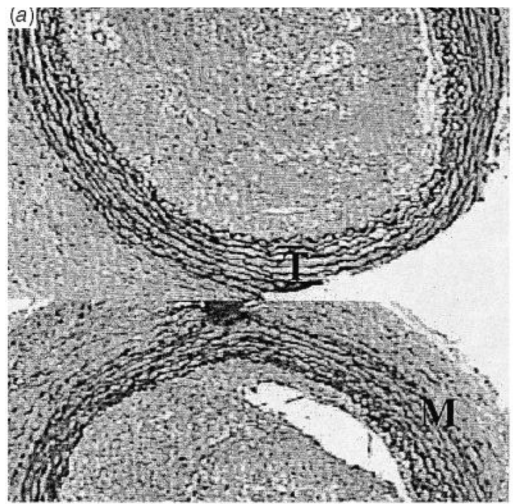

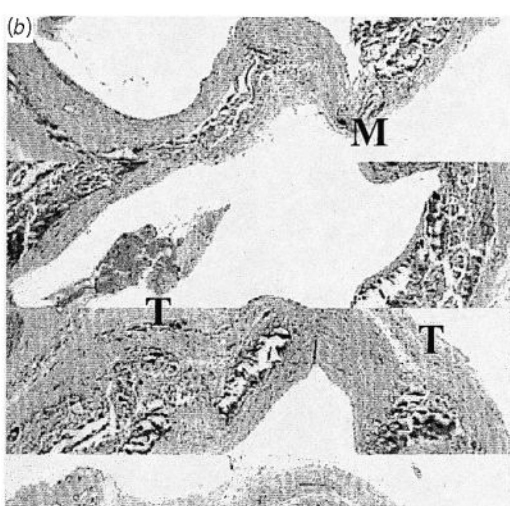

Fig. 33.2. (*a*) Histological examination of coronary arteries obtained from the Folts' model when coronary flow reached its nadir, shows that the lumen of the coronary artery is occluded by a platelet/fibrin rich thrombus (T). M indicates the medial layer. (*b*) Histological examination of coronary arteries obtained when coronary flow was normal shows that the artery lumen is clear, even if traces of the thrombus are still visible (T).

radiopaque material downstream from the stenosis. Additional and perhaps more convincing evidence for platelet-rich thrombi as the main cause of CFRs comes from a study by Golino et al. in which the authors have labelled endogenous platelets with ^{111}In: it could be shown that platelet accumulation at the site of the stenosis was maximal when coronary flow reached its nadir, while little accumulation was evident when the vessel was widely clear[11].

Although it has been demonstrated that the primary cause of CFRs is platelet aggregation at the site of stenosis, it is possible that local vasoconstriction, mediated by release of chemical mediators released by activated platelets, might contribute to the cyclic reductions in blood flow observed in this model, particularly when the endothelium is altered or absent. By means of ultrasonic crystals implanted immediately distal to the stenosis and 1–2 cm below, Golino et al. have demonstrated the occurrence of a marked coronary vasoconstriction at the site of the stenosis, i.e. where the endothelium had been previously damaged and where platelets and platelet-derived substances accumulate maximally in the arterial wall[12]. On the contrary, the vasoconstriction observed at the site more distal to the stenosis, i. e. where special attention was paid to maintain the endothelium intact, was much less severe and not different from that observed during a mechanical external occlusion of the coronary artery[12]. It is of note that the marked vasoconstriction observed at the site of the stenosis could be completely prevented by administration of LY53857, a selective serotonin receptor antagonist, or SQ29548, a selective TxA_2 receptor antagonist[12], but not by nitroglycerin or diltiazem[13], thus indicating a prominent role of serotonin and TxA_2 in causing this platelet-related coronary vasoconstriction.

Pathophysiological and pharmacological observations

Initial studies have demonstrated that TxA_2 represents an important mediator of CFVs: interventions that interfere with the synthesis of this prostaglandin, such as aspirin or dazoxiben, a selective TxA_2 synthase inhibitor, or with the receptor of TxA_2, such as SQ 29548, usually result in elimination of CFVs in about 70% of the treated animals[2,6,8,9]. Furthermore, plasma concentrations of TxB_2 in the blood obtained distally from the stenosis are elevated during CFVs, while they return to control values after abolition of CFVs[8].

The observation that interventions that interfere with the synthesis and/or the receptors of TxA_2 resulted in elimination of CFVs in only 70% of the animals suggested that other chemical mediators are involved in initiating and/or sustaining CFVs. It was later found that serotonin concentrations (another chemical mediator released upon platelet activation) at the site of the stenosis increase significantly during CFVs[14] and that the administration of different serotonin receptor antagonists also results in elimination of CFVs in the majority of the animals[14–16].

Cambridge Books Online © Cambridge University Press, 2009

Administration of serotonin receptor antagonists abolished CFVs virtually in all animals that did not initially respond to TxA_2 inhibitors[16]. Thus, TxA_2 and serotonin play an important role in promoting and sustaining platelet aggregation and thrombus formation at sites of coronary artery stenosis and endothelial injury. Later studies have then demonstrated that TxA_2 and serotonin are not the only mediators of CFRs, as other substances are involved in the formation of intravascular thrombi under conditions of arterial stenosis and endothelial injury, like those found in this experimental model, including ADP[17], PAF[18], and oxygen free radicals[19].

It was initially believed that this model was exclusively platelet dependent; however, the importance of activation of the coagulation cascade in this model has been later emphasized, as thrombin inhibitors resulted in elimination of CFRs in the vast majority of the animals treated[20]. In addition, more recent studies have shown the importance of tissue factor-dependent activation of the coagulation cascade in initiating and/or sustaining CFRs in this model[21–23]. Finally, it should be mentioned that intravascular thrombi formation may be favoured not only by the presence of activating chemical mediators, but also by the relative lack of inhibiting substances, such as EDRF[24] or tissue factor pathway inhibitor[25].

Applicability to different arteries and to other species

In recent years several investigators, including ourselves, have shown that the same combination of severe vessel narrowing and de-endothelialization results in CFRs in arteries other than the coronary. CFRs have been elicited in femoral arteries in anesthetized dogs with similar degrees of vessel narrowing and deliberate denudation of the artery. Folts et al.[6] have demonstrated that CFRs can be produced in awake dogs with chronically implanted coronary constrictors and flow probes. CFRs were prevented in the interim between implantation and acute study by the administration of aspirin. Al-Wathiqui[26] and Gallagher[27] and coworkers have demonstrated that progressive carotid or coronary arterial narrowing with ameroid constrictors will result in CFRs days to weeks after surgical implantation. These dogs apparently did not undergo deliberate vessel denudation at the time of implantation. Perhaps focal inflammation developed in the intervening week (or weeks) between surgery and the development of CFRs in these animals. CFRs have also been elicited in the renal[28] and carotid[29] arteries of cynomologus monkeys and in rabbit carotid arteries[30]; the latter species has been extensively utilized in our laboratory[18,21,31–34].

Recently, Eidt et al.[35] showed that conscious dogs equipped with the same constrictors over segments of the LAD showing endothelial injury undergo repetitive CFRs in response to exercise, but not ventricular pacing. The frequency and severity of CFRs varied more in this model. Some CFRs were non-occlusive. CFRs of most dogs eventually deteriorated to persistent no- or low-flow states. Unlike the open chest preparation, flow restorations observed in this model occurred spontaneously, probably because the severity of the stenosis produced by Eidt et al.[35] was not as great as that produced by most practitioners of the Folts' model, as reflected by the ability of CBF to increase above control levels initially during exercise.

Advantages and disadvantages

The Folts' model has several advantages that make it very attractive for investigators in the field of intravascular thrombosis. Perhaps the most important attractive feature of this model is that it closely mimics the clinical situation of acute coronary syndromes, characterized by plaque rupture and arterial stenosis. In this respect, the Folts' model of coronary thrombosis should be considered 'more physiologic' than other models like those described below. Another advantage of the Folts' model is its amenability to dose–response studies. Unlike other models in which the thrombotic processes are dynamic, occurring over several minutes to hours, CFRs in the Folts' model are repetitive and unchanging. In the many dogs that received either no intervention or vehicle after initiating CFRs, flow patterns usually remain unchanged for at least several hours. Thus, one can evaluate several doses of an investigational drug in a single dog, and this points out another feature of the model: its amenability to quantification of drug response.

The most important disadvantage of the Folts' model is that we are dealing with a healthy artery, as opposed to atherosclerotic arteries (which undergo rupture or ulceration at a site of a pre-existing atherosclerotic plaque) in the clinical scenario. This might, in theory, result in different mechanisms of thrombus formation, as well as in different responses to various drugs. For example, flow restorations in the Folts' model require vigorous shaking, while in unstable angina the thrombus is usually not persistent, and only occasionally can lead to a persistent and total thrombotic coronary occlusion. However, if these (few) limitations are taken into proper consideration, the Folts' model of thrombus formation is a well-established method to study the pathophysiology of platelet-coagulation factors/vessel wall interactions, as well as to determine the pharmacology of antithrombotic agents.

Copper coil model of arterial thrombosis

In the mid-1960s, Blair et al.[36] reported on the ability of spiral wires constructed of aluminum/magnesium alloy inserted into the coronary circulation of dogs to produce slowly developing occlusive thrombi. In this early description of the technique, the spiral was inserted through the coronary vessel wall in open-chest dogs. Several years later, Kordenat et al.[37] described a modification of this model, the salient feature being insertion of the thrombogenic coils via the left carotid artery under fluoroscopic guidance in closed-chest dogs. Later studies by Cercek et al.[38] and Bergmann[39] and coworkers used this basic experimental method for producing arterial thrombi to evaluate thrombolysis and the utility of reperfusion.

As described by Kordenat et al.[37] and Bergmann et al.[39], a thrombogenic coil is advanced via the left carotid artery into a coronary artery with the aid of a guiding catheter and a smaller inner catheter or guidewire in closed-chest dogs. Occlusive thrombosis, heralded by electrocardiographic signs of ischemia and confirmed by the development of a filling defect distal to the coil, occurs almost invariably in the animals in which the coil is implanted. Ventricular fibrillation occurs in approximately one of five dogs undergoing coronary thrombosis, but most of these dogs can be converted to sinus rhythm by DC countershock. A thrombotic occlusion consistently occurs within minutes to hours, depending on the composition (alloy) and size of the coil after insertion, following a flow pattern that suggests gradual thrombus growth, leading in turn to a progressively narrowing stenosis within the coil. Occasionally, spontaneous flow restorations similar to those seen in the Folts' and electrical stimulation models precede total occlusion, but this occurs infrequently.

Thrombi produced in the coil model are considered to be relatively fibrin-rich, on the basis of the model's pharmacologic profile. Clinically relevant doses of t-PA and streptokinase lyse these thrombi[39–41], and heparin prolongs (but does not prevent) original thrombosis[37,38]. However, histologic examination of thrombi removed from copper coils 15 mm after occlusive thrombus formation reveals a platelet-rich thrombus that also contains red blood cells and fibrin[42].

Certain methodologic factors can greatly influence the nature of thrombi in this model and thus may contribute significantly to the differences in the relative composition of the thrombus, and thus to different results between investigators. The speed with which the copper coil is inserted to its destination may have important consequences. Copper coils have been inserted into the LAD and femoral arteries[42]. Despite the longer distance, it takes less time to insert coils into the femoral artery compared with the LAD. Moreover, we have observed more varied and shorter average times to occlusion in the coronary model. Sometimes a filling defect is observed immediately after coil placement, due presumably to snow-ploughing by the coil of clotted blood adherent to the guidewire during its passage to the coronary artery.

Another technical aspect worth noting is the geometry and composition of the coil. Kordenat and Kezdi[37] observed times to occlusion exceeding 2 hours, with shorter coils containing fewer spirals. Aluminium and magnesium alloys appear to be less thrombogenic than copper coils, as signs of infarction did not appear until 24–48 h after placement of coils or spirals constructed of these metals[36,37].

Pathophysiological and pharmacological observations

In contrast to the Folts' model, the copper coil model has been used almost exclusively for the evaluation of either thrombolytic agents or adjunctive drugs[38–42]. The original description of this model for the study of thrombolytic agents and their influence on myocardial injury was by Bergmann et al.[41], who demonstrated that timely reperfusion with intracoronary streptokinase salvaged myocardium and metabolic function. Subsequent studies from that group with this model demonstrated for the first time the ability of t-PA to lyse thrombi in vivo[39].

Bush et al.[42] and van der Werf et al.[43] have demonstrated a dose–response with t-PA and prourokinase, respectively, in this model. In addition, several adjunctive compounds have been evaluated for their ability to improve the thrombolytic effects of t-PA and/or to prevent or delay reocclusion after discontinuation of thrombolytic therapy. For example, heparin[38], Abciximab[44,45], as well as selective serotonin and thromboxane receptor antagonists[40,46,47], all are associated with a potentiation of the thrombolytic properties of t-PA and a simultaneous delay of reocclusion following discontinuation of t-PA infusion.

Applicability to other arteries and to other species

Bush et al. recently described a femoral arterial version of this model in closed-chest, anesthetized dogs[42]. It uses the same thrombogenic coils, but does not entail fluoroscopy. With Doppler flow probes placed directly on the femoral artery just proximal to the site of thrombosis, it allows the exact moment of thrombosis and thrombolysis to be detected, and the extent of blood flow restoration after lysis to be monitored continuously and accurately. An attractive

Cambridge Books Online © Cambridge University Press, 2009

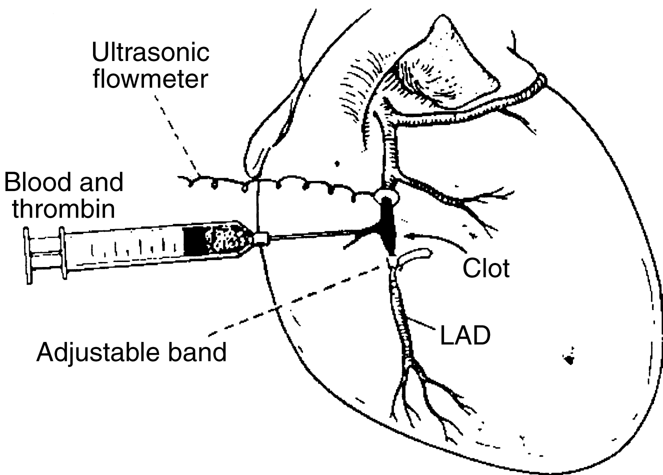

Fig. 33.3. Schematic representation of experimental preparation of a whole blood clot in canine left anterior descending artery (LAD) with a distal high-grade stenosis and a proximal ultrasonic flow probe (see text for details).

feature of this model is the ability to perform the procedure in smaller dogs, which may save expensive thrombolytic agents or investigational adjunctive drugs. Moreover, use of the femoral artery enables the model to be adapted to smaller animals, such as rabbits[47].

Advantages and disadvantages

One important disadvantage of this model is represented by the need for fluoroscopy to correctly position the coil in the coronary artery; this equipment is quite expensive and not all investigators have it at their disposal. Moreover, of all the models discussed in this review, the present one may be the least attractive from the standpoint of the thrombogenic stimulus resembling the human pathophysiology of myocardial infarction. However, it may be no less relevant to the human situation as the other three in its degree of thrombogenicity and response to thrombolytic agents. A particularly attractive feature of the model is the uniform time to original thrombus formation, response to thrombolytics, and reocclusion[38–48].

Thrombin-induced clot formation

A canine model of thrombin-induced clot formation was developed by Gold et al.[49] in which localized coronary thrombosis was produced in the LAD. This is a variation of the technique originally described by Collen et al.[50] who used radioactively labelled fibrinogen to monitor thrombolysis of rabbit jugular vein clots. The vessel was intentionally de-endothelialized by traumatization via external compression with blunt forceps. Snare occluders were then placed proximal and distal to the damaged site, and thrombin (10 U) was injected into the isolated LAD segment in a small volume via a previously isolated side branch. Autologous blood (0.3–0.4 ml) mixed with calcium chloride (0.05 M) also was injected into the isolated LAD segment, producing a stasis-type red clot superimposed on an injured blood vessel. The snares were released 2–5 min later and total occlusion was confirmed by selective coronary angiography (Fig. 33.3).

This model of coronary artery thrombosis relies on the conversion of fibrinogen to fibrin by thrombin. The fibrin-rich thrombus contains platelets, but at no greater concentration than in a similar volume of whole blood. Once the thrombus is formed, it is allowed to age for 1–2 hours, after which a thrombolytic agent can be administered to lyse the thrombus and restore blood flow.

Pathophysiological and pharmacological observations

In the initial study described by Gold et al.[49] in 1984, recombinant t-PA was characterized for its ability to lyse 2-hour-old thrombi. Tissue plasminogen activator was infused at doses of 4.3, 10, and 25/kg/min, i.v., and resulted in reperfusion times of 40, 31, and 13 min, respectively. Thus, in this model of canine coronary thrombosis, t-PA exhibited dose-dependent coronary thrombolysis; it has been also demonstrated that streptokinase also elicited dose-dependent thrombolysis in this model. Furthermore, it is possible to study the effect of different doses of t-PA on parameters of systemic fibrinolytic activation, such as fibrinogen, plasminogen, and α_2-antiplasmin as well as to assess myocardial infarct size.

Subsequently, Gold et al.[44,52] modified the model to study not only reperfusion, but also acute reocclusion. Clinically, reocclusion is a persistent problem after effective coronary thrombolysis, which is reported to occur in 15–45% of patients. Thus, an animal model of coronary reperfusion and reocclusion would be important from the standpoint of evaluating adjunctive therapies to t-PA to hasten and/or increase the response rate to thrombolysis as well as prevent acute reocclusion.

The model of thrombin-induced clot formation in the canine coronary artery was modified such that a controlled high-grade stenosis was produced with an external constrictor. Blood flow was monitored with an electromagnetic flow probe. In this model of clot formation with superimposed stenosis, reperfusion in response to t-PA

Cambridge Books Online © Cambridge University Press, 2009

occurs with subsequent reocclusion[44]. The monoclonal antibody against the human GPIIb/IIIa receptor developed by Coller et al.[29] and tested in combination with t-PA in the canine thrombosis model hastened t-PA-induced thrombolysis and prevented acute reocclusion[44,45]. These actions in vivo were accompanied by abolition of ADP-induced platelet aggregation and markedly prolonged bleeding time.

Applicability to other arteries and to other species

Localized thrombosis can also be produced in rabbit peripheral blood vessels such as the femoral artery by injection of thrombin, calcium chloride, and fresh blood via a side branch[53]. The advantage of using a rabbit femoral artery instead of a dog coronary artery relates to the availability of test compounds under study. On a per kilogram basis, 5–10 times less compound will be required in the rabbit, as opposed to the dog.

Either femoral artery is isolated distal to the inguinal ligament and traumatized distally from the lateral circumflex artery by rubbing the artery with blunt forceps. An electromagnetic flow probe is placed distal to the lateral circumflex artery to monitor femoral artery blood flow. The superficial epigastric artery is cannulated for induction of the thrombus: localized thrombi distal to the lateral circumflex artery with snares approximately 1 cm apart are induced by the sequential injection of thrombin, $CaCl_2$ (1.25 mmol), and a volume of blood sufficient to distend the artery. After 30 mm the snares are released and femoral blood flow is monitored for 30 mm to confirm total obstruction of flow by the thrombus.

After establishing a fully occlusive thrombus, t-PA can be administered alone or in combination with various other agents. At doses of 5.0, 7.5, and 10 μg/kg/min i.v. for 90 mm, t-PA caused reperfusion in 30, 50, and 100% of animals, respectively[45], although the times to restoration of flow did not differ between doses, occurring between 60 and 70 min.

Advantages and disadvantages

These models are not appropriate for evaluating drugs for their ability to inhibit original thrombosis. The model does lend itself well to the evaluation of both thrombolytic agents and adjunctive therapies, e.g. for their ability to hasten and/or enhance lysis or prevent acute reocclusion after discontinuing administration of the thrombolytic drug.

Electrically induced coronary thrombosis

An interesting technique for inducing coronary artery thrombosis was described by Salazar[54] in 1961; in this model anodal current was delivered to the intravascular lumen of a coronary artery in the dog via a stainless steel electrode. The electrode was positioned under fluoroscopic control, which somewhat complicated the procedure. Subsequently, Romson et al.[55] modified the procedure such that the electrode was placed directly into the coronary artery of an open-chest, anesthetized dog. This technique then allows one to produce a thrombus in the anesthetized animal or to close the chest after inserting the electrode and allow the animal to recover, after which thrombosis can be elicited in the conscious state. The advantage of this modification is that it allows induction of thrombus formation without the need for fluoroscopy.

The stimulation electrode may be constructed from a 25–26-gauge stainless steel hypodermic needle tip, which is attached to a 30-gauge teflon-insulated, silver-coated copper wire. Anodal current is delivered to the electrode via either a 9 V nickel-cadmium battery with the anode connected in series to a 250 000 ohm potentiometer or with a Grass stimulator connected to a Grass constant current unit and a stimulus isolation unit. The cathode in both cases is placed into a subcutaneous site completing the circuit. The anodal current can be adjusted to deliver 50–200 μA. Anodal stimulation results in focal endothelial disruption, which in turn induces platelet adhesion and aggregation at the damaged site. This process is then followed by further platelet aggregation and consolidation with the growing thrombus entrapping red blood cells.

A modification of the method of Romson et al. involves placement onto the coronary of an external, adjustable occluder[56] to produce a fixed stenosis on the coronary artery. A flow probe to record coronary blood flow is placed on the proximal portion of the artery followed by the stimulation electrode, with the clamp being placed most distally (Fig. 33.4). The degree of stenosis can then be controlled by adjusting the clamp. The resulting stenosis is produced in an effort to mimic the human pathophysiology of atherosclerotic coronary artery disease, whereby thrombolytic therapy restores CBF through a coronary artery with residual narrowing due to atherosclerotic plaque formation.

Another modification of the electrical stimulation model that merits discussion is described by Benedict et al.[57] They discontinued anodal current when mean distal coronary flow velocity (measured with a Doppler flowmeter) increased by approximately 50%, reflecting disruption of normal axial flow by the growing thrombus. Occlusive

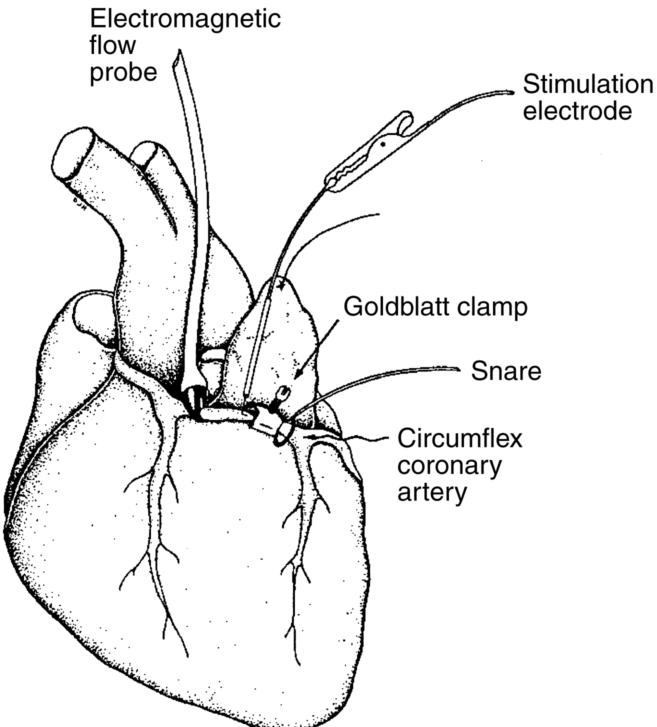

Fig. 33.4. Model of coronary artery thrombosis induced in the dog by electricity. Electrical injury to the intimal surface of the artery leads to occlusive thrombus formation. The thrombus is formed in the presence of a flow-limiting stenosis induced by a Goldblatt clamp (see text for details).

thrombosis occurred within 1 hour after stopping the current (2 hours after starting the current). In these studies coronary sinus plasma levels of serotonin, an index of intravascular platelet aggregation, were increased approximately 20-fold just before occlusive thrombus formation. The results of these studies agree with others in showing that either proximal flow velocity or electromagnetically measured CBF decline trivially over the majority of the time period in which the thrombus is growing. The largest declines in flow occur over a small and terminal fraction of the period between initial vessel perturbation and final occlusion. During that interval, coronary luminal area decreases rapidly and to a critical degree, as platelets accrue at the growing thrombus. The studies by Benedict et al.[57] show that this final phase of thrombosis can occur independently of electrical stimulation. This variation of the model may be attractive to those who wish occlusive thrombosis to occur without continued electrical stimulation.

Pathophysiological and pharmacological observations

Several studies evaluating anticoagulants, antithrombotic, and/or thrombolytic drugs have been performed using this model. In the initial report by Romson et al.[56], the cyclooxygenase inhibitor ibuprofen was evaluated. Comparison of myocardial infarct size, thrombus weight, arrhythmia development, and scanning electron microscopy of drug-treated and control animals indicated that ibuprofen protected against the deleterious effects of coronary artery thrombosis in the conscious dog. Subsequent studies in the same model and laboratory evaluated the antithrombotic potential of various TXA_2 synthetase inhibitors, such as U 63557a, CGS 13080, OKY 1581, and dazoxiben. When the TXA_2 synthetase inhibitors were administered before induction of the current, OKY 1581[58] and CGS 13080[59] reduced the incidence of coronary thrombosis, whereas U 63557A[60] and dazoxiben[61] were ineffective and partially effective, respectively. The differences in efficacy noted among the TXA_2 synthetase inhibitors were ascribed to differences in potency and duration of action.

Other investigators have used this model to study the prevention of original coronary thrombosis in the dog. FitzGerald et al.[62] studied the combination of the TXA_2 synthetase inhibitor, U 63557A, alone or in combination with L-636 499, an endoperoxide/thromboxane receptor antagonist. U 63557A alone did not prevent non-specific coronary thrombosis when administered before current application, whereas the combination of U 63557A and L-636 499 was highly effective. These data suggest that prostaglandin endoperoxides may modulate the effects of TXA_2 synthetase inhibitors and that this response may be blocked by concurrent administration of an endoperoxide/thromboxane receptor antagonist. The murine monoclonal antibody to the platelet GPIIb/IIIa (7E3, Abciximab) was studied in this model for its ability to prevent thrombus formation. At a dose of 0.8 mg/kg i.v., the 7E3 monoclonal antibody completely prevented original thrombus formation[63].

In addition to evaluation of antithrombotic agents, the electrical injury model is useful for studying thrombolytic drugs. Typically, the thrombus is allowed to form without drug intervention and then aged for various periods of time. Schumaker et al.[56] demonstrated that intracoronary streptokinase was an effective thrombolytic drug in this model, the thrombolytic effectiveness being augmented by the concurrent administration of heparin and prostacyclin, or by a TXA_2 synthetase inhibitor[56]. In other studies, Shebuski et al.[64] demonstrated that the TXA_2 receptor antagonist, BM 13.177, hastened t-PA-induced thromboly-

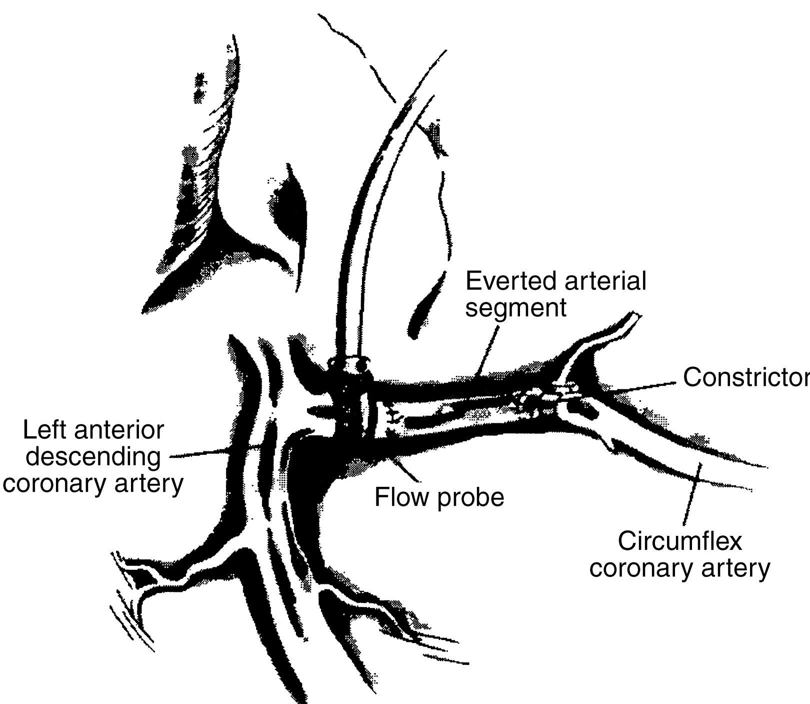

Fig. 33.5. Schematic representation of experimental preparation of a platelet-rich thrombus in canine everted circumflex coronary artery segment graft with a distal high grade stenosis and a proximal ultrasonic flow probe (see text for details).

sis and prevented acute thrombotic reocclusion. Van der Giessen et al.[66] subsequently demonstrated that BM 13.177 prevented original thrombus formation in 75% of pigs undergoing electrical stimulation; aspirin was ineffective in this porcine model[65].

These and other studies underscore the potential for adjunctive therapy to accelerate thrombolysis and/or prevent reocclusion, both contributing to greater salvage of ischemic myocardium.

Advantages and disadvantages

One important advantage of the electrically induced coronary thrombus model is represented by its versatility: original thrombosis responds to antithrombotic agents; furthermore, after establishment of an occlusive thrombus and administration of thrombolytic agents, it develops spontaneous reocclusion, making it amenable to evaluation of potentially adjunctive agents. Finally, as is true for the coil and thrombin injection models, the electrically induced thrombus model may be used to produce and study myocardial infarction. One potential disadvantage is the lack of similarity with the pathophysiology of arterial thrombosis in patients.

Arterial eversion graft model

The model is schematically represented in Fig. 33.5. Mongrel dogs are anesthetized with intravenous sodium pentobarbital, intubated, and artificially ventilated. A left thoracotomy is performed, and the internal mammary artery is cannulated for continuous blood pressure monitoring. An ultrasonic blood flowmeter is placed around the circumflex coronary artery proximal to the site of the eversion graft. A stenosis is then produced with a 2 mm-wide plastic wire tie placed around the coronary artery distal to the eversion graft and constricted to reduce the blood flow to about 40% of baseline, which corresponds to a more than 90% reduction in luminal diameter. The circumflex coronary artery is then dissected out of the epicardium, and a 1 cm segment is excised between two microvascular clamps, stripped of excessive adventitial tissue, everted inside-out, and reinserted by end-to-end anastomosis using 8 to 12 interrupted sutures with 7–0 nylon. The microvascular clamps occluding the proximal and distal ends of the transsected artery are then released. The surgical procedure is carried out without an extracorporeal circulation device. Coronary angiography is performed by manual injection of 1–2 ml Renografin 76 through a

Cambridge Books Online © Cambridge University Press, 2009

modified Judkin's 7F left Amplatz catheter inserted from a carotid artery. After release of the vessel clamps, spontaneous persistent occlusion of the everted graft segment occurs in approximately 80% of the dogs within an average of 5 minutes, as demonstrated with the flow probe and confirmed by angiography.

Intravenous administration of thrombolytic drugs is usually carried out when the thrombus is demonstrated to be persistent, i.e. after a complete and stable occlusion is obtained for 30 minutes. After reperfusion has occurred, blood flow is continuously monitored for evidence of reocclusion, with the final confirmation by angiography using the same criteria as for establishing reperfusion.

Pathophysiological and pharmacological observations

The efficacy of thrombolytic agents, including streptokinase, urokinase, and t-PA, were evaluated in this model and compared with their efficacy in the absence of a superimposed stenosis. In the absence of stenosis reperfusion times were similar to animals with a superimposed stenosis; spontaneous reocclusion did not occur within 2 hours after the end of the infusion in the absence of restenosis[66]. Adjunctive therapies, represented by aspirin, Argatroban, or Abciximab were all associated with a simultaneous decrease in reperfusion times and an increase in reocclusion times[67].

Applicability to other arteries and to other species

The arterial eversion graft model can be applied to rabbit femoral arteries. This model was originally developed by Hergrueter et al.[68] Briefly, New Zealand white rabbits are anesthetized with intramuscular injection of ketamine (35 mg/kg) and xylazine (5 mg/kg). A groin incision is made to expose the femoral artery between the inguinal ligament and the distal bifurcation. The epigastric artery is cannulated with Silastic tubing (0.012″ i.d.) for intraarterial administration of study drug. A 5 mm segment of the right femoral artery is excised between two ligations, stripped of excessive adventitial tissue, everted inside-out, and inserted into the left femoral artery under a surgical microscope by end-to-end anastomosis using 12 uninterrupted sutures with 10–0 nylon. The microvascular clamp that clamps off the proximal and distal ends of the transsected artery is released.

Blood flow in the left femoral artery containing the everted graft is continuously monitored with an ultrasonic flowmeter. Thirty minutes after occlusion, study drugs can be administered via the cannulated femoral vein (intravenous route) or superficial epigastric artery (intra-arterial route) by either bolus injections or continuous infusion.

Advantages and disadvantages

The main disadvantage of the arterial eversion graft model is that it requires significant surgical skills to be performed. Additionally, for the rabbit femoral model, a surgical microscope is required. Furthermore, as with the copper coil and the electrical injury models, the thrombogenic stimulus may be considered rather 'unphysiologic'.

Conclusions

We have described four models of arterial thrombosis and/or thrombolysis that allow evaluation of antithrombotic drugs alone or in combination with thrombolytic agents. The experimental animal preparations described in this review were not designed to mimic the pathophysiology of human arterial thrombosis, but instead are models of intravascular coagulation induced by different stimuli. Each model possesses distinct characteristics with regard to a number of important variables, including relative contribution by platelets and fibrin and the speed with which occlusive thrombosis occurs after initiation of the thrombogenic stimulus (or stimuli). For instance, thrombi forming in the Folts' model of de-endothelialization combined with severe stenosis probably are the most platelet rich, whereas those produced in the Gold thrombin injection model are relatively platelet poor. The other models probably lie within these two extremes, as the thrombus contains both platelets and fibrin.

Considering the uncertainties about the relative roles of coagulation vs. platelets in patients undergoing myocardial infarction, unstable angina, or acute coronary reocclusion after thrombolysis, it would be inappropriate to speculate as to which of these models is the most clinically relevant. The prospect for advancing the clinical relevance of animal models of thrombosis is further complicated by the likely variability in the causes of thrombosis in patients: atherosclerotic human coronary arteries undergoing plaque fissure and/or hemorrhage probably differ substantially from the arterial surfaces provided in these models, despite attempts to produce some degree of de-endothelialization and/or vessel narrowing.

If put in the proper perspective, the data obtained in these (and perhaps other) models of intravascular thrombosis may allow the investigator to identify and compare novel therapies. Animal models provide an important link between test tube assays of platelet aggregation, coagula-

Cambridge Books Online © Cambridge University Press, 2009

tion, or fibrinolysis and clinical evaluation in humans. In this process, important information is generated, not the least of which is an answer to the question, 'does it work?' In addition, dosage, duration of action, and some idea about safety can be gleaned from studies of these animal models.

The ultimate model is humans and the ultimate evaluation is a well-defined population of patients. It should be borne in mind that t-PA was evaluated in fewer than a dozen dogs in one arterial thrombosis model (coronary copper coil) before clinical testing in humans was begun. Thus, one probably does not need to evaluate a new antithrombotic or thrombolytic agent in all four models. We would hope that knowledge and availability of several models will allow informed decisions as to which model (or models) to evaluate novel antithrombotic or thrombolytic agents before initiating expensive clinical trials.

Hereditary thrombocytopenias

Chris Van Geet[1,2], Kathleen Freson[2], Rita De Vos[3], and Jos Vermylen[2]

[1]Department of Paediatrics
[2]Centre for Molecular and Vascular Biology
[3]Morphology and Molecular Pathology, University Hospital, Leuven, Belgium

Although hereditary thrombocytopenia is overall a very rare disorder, many different forms have been well described. Inherited thrombocytopenia is frequently mistaken for an acquired platelet disorder. A careful medical and family history can generally allow differentiating congenital from acquired thrombocytopenia based on the duration of symptoms and the onset early in childhood. A detailed pedigree will often help to identify the inheritance pattern. The recognition of hereditary thrombocytopenia is important for avoiding potentially expensive and harmful treatments, as frequently administered in acquired chronic platelet disorders, and which will furthermore mostly be ineffective.

Some patients with hereditary thrombocytopenia have no clinical symptoms due to the moderate or mild thrombocytopenia and are most often detected by chance, due to the routine automated platelet counting and frequently associated automated mean platelet volume determination, when studying the peripheral blood. For this reason, probably more patients are being detected during recent years. It is only in the last few years that the underlying molecular abnormalities have become obvious. Due to the efforts of many research groups, the responsible gene, the defective gene product and the pathogenesis of many of these disorders have been unravelled. For many of these disorders, the clinical picture was well known and only recently the responsible gene and gene product were discovered. For others, the molecular mechanism was first unravelled in mice, and the human pathology was only discovered and defined by analogy with the animal model. Interestingly, discovering the molecular mechanisms of hereditary thrombocytopenia has led to a better understanding of the normal physiology of hematopoiesis.

Table 34.1 classifies the hereditary thrombocytopenias by their mode of inheritance and by the size of the platelets. The individual thrombocytopenia disorders will be discussed accordingly. Moreover, the possible association with qualitative platelet defects or with other clinical abnormalities will be discussed each time.

X-linked recessive thrombocytopenia

Microthrombocytopenia

The Wiskott–Aldrich syndrome (WAS)[1] is an X-linked recessive immunodeficiency disorder involving both B- and T- lymphocytes, and is characterized by eczema, increased susceptibility to infection and thrombocytopenic purpura with small, defective platelets. Patients are symptomatic at infancy with excessive bruising and often bloody diarrhea. The small dysmorphic platelets are destroyed by the spleen, thereby increasing the bleeding problem. Recurrent infections with encapsulated bacteria usually occur during the first year of life, as well as the atopic dermatitis. Therafter, often autoimmune cytopenia and/or vasculitis occurs. The high mortality is mostly due to infection, bleeding or malignancies, in particular lymphoreticular tumours and leukemias. WAS-patients have been treated by bone marrow or cord blood transplantation from an HLA-identical sibling or an HLA-matched unrelated donor, leading to a complete correction of the platelet and immunological abnormalities[2]. Patients who underwent splenectomy to control beeding, showed an increase in platelet count and had a rather good prognosis when prophylactically given antibiotics and intravenous immunoglobulins.

The mutant gene (*WASP*) responsible for this syndrome has been identified[3] and is mapped to Xp11.22–Xp11.23. *WASP* encodes a 502 amino acid protein (WASP) and is preferentially expressed in lymphocyte and megakaryocyte lineages. The gene product is very complex with well-defined

regions that give the protein several faces[4] such as a pleckstrin homology domain, a GTPase binding domain and several proline-rich domains, typical for transcription factors. However, WASP does not reside in the nucleus, as would be expected for a transcription factor, but instead stays just beneath the cell surface, by binding of the pleckstrin homology domain to the phospholipids of the plasma membrane, thereby probably transducing incoming signals to the actin cytoskeleton. Furthermore, WASP binds with its GTPase binding domain to the active, GTP-bound Cdc42, a member of a superfamily of small GTP-hydrolysing proteins (GTP-ases). Cdc42 in its active form is involved in actin remodelling, such as formation of filopodia and the orientation of T-cells toward antigen-presenting cells. The precise function of WASP remains to be elucidated but is implicated through its different

Cambridge Books Online © Cambridge University Press, 2009

domains in signal transduction and the organisation of the actin cytoskeleton. The small, dysmorphic platelets in WAS-patients are due to a disorganized cytoskeleton.

A large number of mutations in *WASP* have been identified in patients with WAS[5], but also in patients with X-linked microthrombocytopenia (XLT). This disorder is not associated with eczema or increased susceptibility to infections and has a less severe clinical phenotype and prognosis. In these patients, the platelet count is moderately to severely reduced and bone marrow examination shows a normal presence of megakaryocytes. IgA is often increased with decreased isoagglutinins. The mutations in the *WASP* gene[6,7] in XLT are different from those found in classical WAS-patients. Why some mutations impair only the megakaryocytic lineage whereas others affect also the lymphoid cells is not yet clear. It seems however that, for predicting the clinical course, not only mutation analysis at the DNA level is important but also evaluation of the transcript at the mRNA level and at the protein level[8,9]: mutations in *WASP* leading to the absence of protein correlate with a more severe phenotype, whereas the translation of a normal-sized protein is more frequently found in patients with a milder clinical picture. Mutations affecting a splice site can be associated with either a severe or mild phenotype, depending on the proportion of normally spliced transcript generated and on the possible dominant negative effect of the abnormally spliced transcript on the normal protein.

Macrothrombocytopenia

X-linked macrothrombocytopenia has only recently been described and is associated with dyserythropoiesis[10]. In the princeps family the two affected half-brothers (same mother) had marked anemia due to dyserythropoiesis and an important bleeding problem related to severe thrombocytopenia (one was platelet-transfusion dependent and the other underwent bone marrow transplantation). The authors found in this family a missense mutation (V205M) in the N-terminal zinc-finger of GATA1. GATA1 is the founding member of the GATA-binding family of transcription factors and has been shown to be an essential protein for normal erythropoiesis and megakaryocyte differentiation[11,12]. The human gene encoding GATA1 has been mapped to Xp11.23[13]. The V205M mutation leads to a decreased binding of GATA1 to its essential cofactor FOG1 (for Friend Of GATA1). We recently found two families with other mutations in the same N-terminal zinc finger of GATA1. The first family with ten documented affected males has a missense mutation, resulting in the replacement of Asp by Gly at codon 218 (D218G), and a less severe

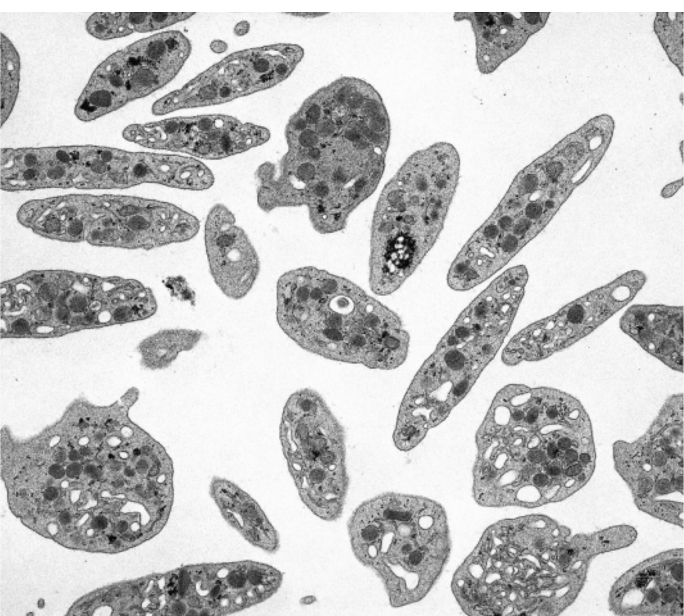

Fig. 34.1. Electron micrograph of normal human platelets. The platelets have a uniform appearance and show the typical discoid shape with normal organelles and platelet specific granules. (Original magnification: ×14 500.)

clinical picture than the previously published family; macrothrombocytopenia and dyserythropoiesis are moderate and with no marked anemia[14]. The second family has another missense mutation in the same codon with replacement of Asp by Tyr (D218Y). In this family the phenotype is very severe and even life threatening with only one affected member still alive; he has severe macrothrombocytopenia and pronounced dyserythropoietic anemia[15]. In each case, the interaction of the mutated GATA1 with FOG1 is disturbed: only mildly with the D218G mutant and markedly with the D218Y mutant, thereby correlating with the clinical phenotype. As compared to normal platelets (Fig. 34.1), the platelets in these GATA1-mutated patients have a characteristic ultrastructure (Fig. 34.2): in electron microscopy, these enlarged platelets are spherical rather than discoid, and contain clusters composed of smooth endoplasmic reticulum and abnormal membrane complexes both in the centre and in the periphery of their cytoplasma. Platelets of the hitherto described female carriers are normal in number and in ultrastructure. Light microscopically, the red blood cells are dysmorphic with anisocytes, poikilocytes, megalocytes and acanthocytes. The bone marrow of the affected patients with the D218G mutation shows normoblasts with punctate basophilia, karyorhexis, budding and pycnosis and also increased dysplastic megakaryocytes with megakaryoblasts,

micromegakaryocytes, vacuolization of the cytoplasma and asynchronous maturation of the nucleus and cytoplasma. The increased number of megakaryocytes in the bone marrow could potentially lead to the misdiagnosis of an acquired chronic ITP in these patients. The function of these platelets has been studied in the patients with the D218G mutation and shows a decreased but not absent ristocetin-induced agglutination due to a disturbed GPIb/V/IX complex. The promoters of many megakaryocyte-expressed genes have a GATA1 recognition site, as is the case for GPIbα, GPIbβ, GPIIb, GPIX, PF4, c-MPL and p45 NF-E2 and mutated GATA1 (D218G) platelets show a decreased GPIbβ and GPIX mRNA expression level.

The role of the GATA1–FOG1 transcription complex had already been demonstrated earlier in mice. Homozygous disruption of either GATA1 or FOG1 causes embryonic lethality due to a severe erythroid defect[12,16] and mice with a mutation in the upstream region of GATA1 (GATA1 knockout mice) show a milder erythroid defect but suffer from severe thrombocytopenia due to absent GATA1 expression in the megakaryocytic lineage[17]. The platelets in this latter mouse model[18] are enlarged and show a similar ultrastructure as in the above-mentioned patients. Therefore, it seems important that in patients with hereditary macrothrombocytopenia or so-called familial chronic idiopathic thrombocytopenic purpura, mutations in *GATA1* (and *FOG1*, once identified in humans) are looked for.

Autosomal dominant thrombocytopenia

Macrothrombocytopenia

May–Hegglin anomaly is an autosomal dominant disorder with high penetrance, first reported by May (1903)[19] and Hegglin (1945)[20] in which thrombocytopenia, giant platelets and basophilic Döhle-like inclusions are found in peripheral leukocytes (Fig. 34.3). These inclusions contain cytoplasmic RNA and are similar to those seen, although transiently, in acute infections[21].

In 1972, the Epstein syndrome was described as a variant of Alport syndrome in patients with renal disease, sensorineural deafness and macrothrombocytopenia and without leukocyte inclusion bodies[22]. Peterson presented a variant of the Epstein syndrome by describing a family with eight affected members in four generations with nephritis, deafness, congenital cataracts, macrothrombocytopenia, and also leukocyte inclusions. This new syndrome was called

Fechtner syndrome, after the surname of this family[23] (Fig. 34.4). The leukocyte inclusions that are present in the neutrophils and eosinophils resemble light microscopically the Döhle bodies or the inclusions seen in May-Hegglin anomaly. However, ultrastructurally, these inclusions might be slightly different[24,25] (Fig 34.5). The renal disease varies from microscopic haematuria to end-stage renal failure. The Sebastian platelet syndrome has the same haematological characteristics (leukocyte inclusions and macrothrombocytopenia) as seen in Fechtner syndrome, but without the clinical expressions of the Alport syndrome[26]. Sebastian platelet syndrome and May– Hegglin anomaly therefore can only be differentiated by subtle ultrastructural leukocyte inclusion features: in both cases an oval cytoplasmic inclusion not bounded by membrane and lacking specific granules is present. In May–Hegglin anomaly (Fig. 34.3) the inclusion bodies contain clusters of ribosomes oriented along parallel filaments 7–10 nm in diameter whereas in Sebastian platelet syndrome (as in Fechtner syndrome, Fig. 34.5) they are composed of highly dispersed filaments and randomly distributed ribosomes[27]. There also was clinical evidence that Sebastian platelet syndrome is only one end of the clinical spectrum of Fechtner syndrome: a four generation family was diagnosed with characteristics of the Sebastian platelet syndrome (macrothrombocytopenia and leukocyte inclusions) and with silent ocular lens opacities as the only Alport-like manifestation[28]. Further evidence that these disorders are linked came from the genetic field. The disease loci for May–Hegglin anomaly and Fechtner syndrome both mapped to overlapping regions on chromosome 22. Also recently it became obvious that Sebastian platelet syndrome, May–Hegglin anomaly and Fechtner syndrome are allelic and have mutations in the same gene *MYH9*, encoding the 224 kD nonmuscle myosin heavy chain IIA (MYHIIA) polypeptide[27,29–31]. This MYHIIA is present in platelets, monocytes, granulocytes, the kidney and the auditory system but also in a lot of other tissues. Why the patients with May–Hegglin anomaly, Fechtner syndrome or Sebastian platelet syndrome do not have symptoms of the other affected tissues remains to be elucidated. The exact disease pathogenesis needs to be unravelled further as well as whether the Epstein syndrome could belong to the same family of disorders on a molecular level.

Grey platelet syndrome is a very rare inherited disorder of the α-granules of the platelets, first described by Raccuglia[32], and characterized by large agranular platelets (Fig. 34.6) and thrombocytopenia[33,34]. The platelets have a grey appearance when studied on Wright-stained blood smears due to the lack or paucity of α-granules, with,

however, a normal content of dense granules. Most cases are sporadic, but the familial pedigree studies suggest an autosomal dominant inheritance. The range of thrombocytopenia is very broad (from 20×10^9/l to normal) and even patients with normal platelet count have a bleeding problem due to the qualitative defect of their platelets (see also chapter on platelet release defect disorder). In this syndrome there is a normal synthesis but a defective packaging of the soluble proteins normally present in these granules: von Willebrand factor (VWF), fibrinogen, thrombospondin, platelet-derived growth factor (PDGF), albumin, fibronectin, thrombospondin, platelet factor 4, β-thromboglobulin, plasminogen activator inhibitor I (PAI1) and factor V. The α-granule membrane proteins, P-selectin, GP IIbIIIa, CD36, and GPIb/V/IX, are expressed normally. The hemostasis in these patients can be improved by platelet transfusion, inhibitors of fibrinolysis or even DDAVP, thereby probably releasing VWF from other cellular stores. The molecular pathogenesis of this syndrome remains unknown.

Von Willebrand Disease (VWD) type 2B is an autosomal dominant bleeding disorder in which large but qualitatively abnormal von Willebrand factor (VWF) multimers are synthesized, that spontaneously bind to the GPIbα on the platelets. As a result of this, patients show a decreased presence of these large multimers in the plasma and a decreased ristocetin cofactor activity. Platelets, moreover, agglutinate at low concentrations of ristocetin that have no effect on normal platelets. Patients with type 2B VWD often demonstrate thrombocytopenia that is variable in time and more pronounced in conditions where the VWF is increased, such as pregnancy or following DDAVP infusion. Nurden et al.[35] demonstrated that the platelets of patients with type 2B VWD have ultrastructural abnormalities. The platelets are large and spherical with zones of membrane complexes and a dilated surface-connecting system containing amorphous material. There are huge amounts of VWF colocalized with GPIb on the surface and within the platelet surface connected canalicular system.

The molecular defects in type 2B VWD are missense mutations located in exon 28 of the gene encoding VWF, leading to amino acid alterations in the disulphide loop between Cys^{509} and Cys^{695}[36]. Therefore, in the differential diagnosis of autosomal dominant macrothrombocytopenia, this type of VWD has to be taken into account.

Platelet-type or pseudo- von Willebrand disease has the same clinical features as the above-mentioned type 2B VWD, but the increased affinity of VWF for the GPIb complex in this condition is due to a mutation in the GPIbα gene instead of in the VWF gene. The platelet number is normal to decreased and the mean platelet volume is mostly increased[37]. The two described mutations in patients with this bleeding disorder, G233V[38] and M239V[39], enrich the valine content of an already valine-rich region within the Cys^{209}–Cys^{248} disulfide loop of GPIbα and thereby are gain-of-function mutations.

Patients with 22q11 microdeletion have mild thrombocytopenia and giant platelets. The clinical picture of this syndrome is very broad (Fig. 34.7): it ranges from the more severe DiGeorge sequence (thymic hypoplasia, conotruncal cardiac defects, and facial dysmorphy) to the milder velocardiofacial syndrome (VCFS) with velopharyngeal insufficiency, conotruncal heart disease and learning disabilities. Levy et al.[40] first reported two female patients with del 22q11 and thrombocytopenia, although the nature of this thrombocytopenia was not clear. Budarf et al.[41] described a boy with del 22q11 and Bernard–Soulier syndrome (BSS). He was a compound heterozygote with the deletion of one allele of the GPIbβ gene, that maps to the deleted 22q11.2 region, and a mutated GATA binding site in the promoter of the remaining allele[42]. Knowing that patients with del 22q11 are obligate carriers of a GPIbβ deletion, these patients can be considered as heterozygous BSS. The platelet count ranges from mildly reduced to normal, and the platelets have an increased size (Fig. 34.8).

Cambridge Books Online © Cambridge University Press, 2009

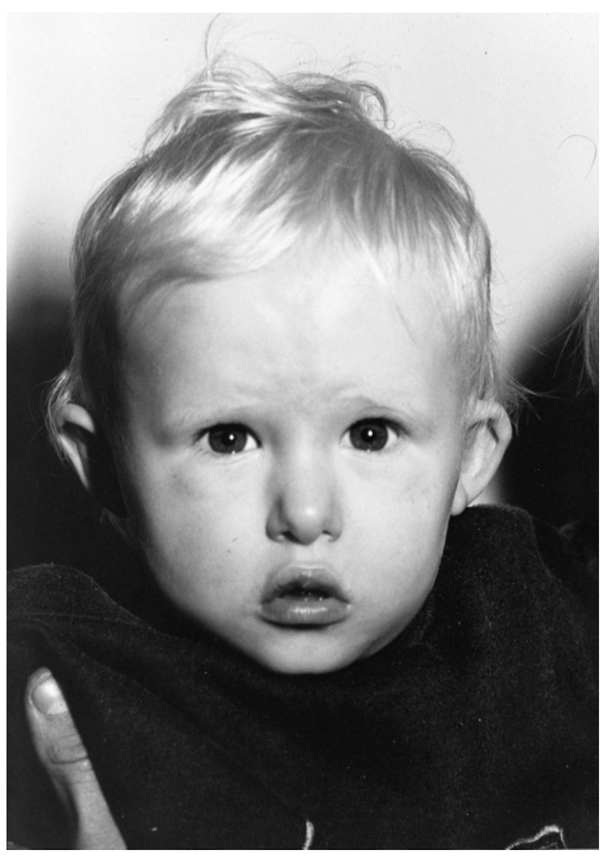

Fig. 34.7. Clinical picture of a patient with 22q11 microdeletion. Note the typical prominant nose with squared nasal root and narrow alar base and auricular abnormalities.

The platelet function however, as tested by platelet aggregation studies and by platelet adhesion studies to collagen in a whole blood perfusion system, is normal[43]. Therefore these patients have only a mild bleeding tendency (if any) that correlates directly with the decrease in platelet count.

Montreal platelet syndrome[34] is an autosomal dominant disorder characterised by giant platelets in the peripheral blood, thrombocytopenia and spontaneous platelet aggregation, probably contributing to the pathophysiology of the thrombocytopenia. The platelet membrane glycoproteins are normal but there seems to be a defect in calpain (calcium-activated neutral proteinase)[44]. The molecular mechanism underlying this disorder is not unravelled yet.

Thrombocytopenia with normal platelet size

Autosomal dominant thrombocytopenia with normal platelet size was first described in 11 members of a four-generation family[45]. Thereafter several other families have

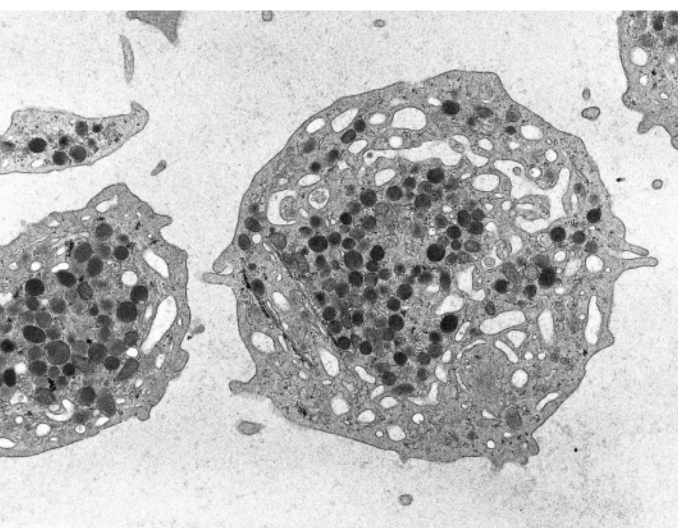

Fig. 34.8. Electron micrograph of a giant round platelet from a patient with 22q11 microdeletion. Numerous alpha granules, rather segregated in the centre, can be seen. (Original magnification: $\times$14 500.)

been reported with mild to moderate thrombocytopenia inherited in a dominant way. Iolascon et al.[46] described a large Italian family with moderate thrombocytopenia in 17 affected members, normal platelet size, normocellular bone marrow and normal platelet function. In the affected patients, the TPO-levels were elevated and the response to TPO was normal, making a defect in the TPO-production or in the TPO-receptor (c-mpl) very unlikely. Moreover, linkage studies to chromosome 3q26.3–q27 and 1p34, regions containing the TPO and c-mpl genes, respectively, could completely rule out this pathogenicity. Other candidate loci on 11q23–24 and 21q11 were excluded. Savoia et al.[47] performed a genomewide search in the same family and demonstrated by microsatellite analysis that the disease locus is linked to chromosome 10p11,1–12 with a candidate region of 6 cM. Recently 13 affected members of another family were studied[48] with a mean platelet count of 42.7×10^9/l (range 18×10^9/l to 106x 10^9/l); males and females were equally affected, compatible with an autosomal dominant mode of inheritance. These patients had no major bleeding diathesis, suggesting normal function of the remaining platelets. Megakaryocytes in the bone marrow are reduced, with delayed nuclear and cytoplasmic maturation. There are no obvious abnormalities in the myeloid or the erythroid cells. Affected members had modestly increased thrombopoietin levels. The medical history of some of these patients revealed no effect of immunosuppression or splenectomy on the platelet count. Genome-wide linkage studies based on 30 members of this

Cambridge Books Online © Cambridge University Press, 2009

family have again identified a 17-cM region on chromosome 10p. Further studies are presently looking for the responsible gene in this region.

Paris-Trousseau thrombocytopenia is a dysmegakaryopoietic disorder due to a cytogenetic abnormality. Wardinsky et al.[49] reported 35 patients with deletion of 11q23 associated with mental retardation, trigonocephaly, depressed nasal bridge, hypertelorism, and cardiac and neurological malformations, of whom 47% suffered from thrombocytopenia. Favier[50] described a mother and son with del 11q23, mental retardation, dysmorphic features such as hypertelorism, long philtrum and low set ears, and chronic thombocytopenia with mild bleeding complications. This condition is characterized by giant α-granules in 15% of platelets in the peripheral blood, resulting from fusion of the α-granules. These giant α-granules do not release their content after stimulation, in contrast to platelets with normal morphology. Platelet lifespan is normal but, in the bone marrow, an increased number of micromegakaryocytes is found with premature megakaryocytic apoptosis evidenced by massive cell lysis at the end of maturation[51]. Probably the Paris–Trousseau thrombocytopenia can be seen as a contiguous gene syndrome as the proto-oncogenes ETS1 and FLI1 map to 11q23.3 and 11q24, respectively, and are absent in terminal 11q23 deletion. They are both essential, along with GATA-1, for the normal expression of megakaryocyte-specific genes[52].

Factor V Quebec was first described by Tracy[53] and is characterized by dominantly inherited mild thrombocytopenia and moderate bleeding problems. The platelet factor V activity is less than 6% of normal and platelet factor V antigen levels are half of normal. This decreased factor V is accompanied by a defect in multimerin[54]. Multimerin is a large, complex, multimeric protein and stabilizes factor V within the platelet α-granule. These patients furthermore have a decreased content in their α-granules not only of factor V but also of fibrinogen, VWF, thrombospondin and osteonectin, possibly by increased degradation of the protein content[55]. The normal content of platelet factor 4 and β-thromboglobulin suggests a normal assembly of the α-granules. The platelets demonstrate a functional defect in their epinephrine-mediated aggregation[56]. The explanation why factor V Quebec leads to thrombocytopenia is currently unknown, neither is the genetic mechanism unravelled.

Familial platelet disorder with predisposition to acute myelogenous leukemia (FPD/AML) is an autosomal dominant disorder characterised by qualitative and quantitative platelet defects and in which the affected members have an increased risk of developing AML[57]. The thrombocytopenia in the first described family, with 22 family members definitively affected, ranged from 30×10^9/l to 150×10^9/l without qualitative or quantitative abnormalities of red or white blood cells. Moreover, a thrombopathy was obvious with decreased platelet aggregation after stimulation with collagen and epinephrine, contributing to the defective haemostasis. Electron microscopy of the platelets revealed normal platelet size and presence of all organelles in adequate quantity and configuration. The platelet survival was normal in these patients. Six of them developed hematologic neoplasms. Ho[58] performed linkage analysis on this originally described family, and found a critical region of 15.2 cM on chromosome 21q22.1–22.2. Finally, by mutational analysis of the candidate genes in the region where FPD/AML maps, a heterozygous mutation of the hematopoietic transcription factor *CBFA2* (formerly *AML1*) was discovered leading to a decrement of megakaryocyte colony formation[59]. It was also suggested that the haploinsufficiency of *CBFA2* may predispose to acquisition of second mutations at other loci that are leukemogenic.

Autosomal recessive thrombocytopenia

Macrothrombocytopenia

Bernard–Soulier syndrome (BSS) is an autosomal recessive bleeding disorder with unusually large platelets and a moderate degree of thrombocytopenia, first described by Bernard and Soulier[60]. These platelets have an important functional defect: they aggregate normally after stimulation by ADP, collagen or arachidonic acid but they do not agglutinate with ristocetin[61] (see also chapter on Platelet adhesive protein defect disorders). This is due to a defective GPIb/V/IX complex, the major receptor for von Willebrand factor[62] with also binding properties for thrombin. As GPIb is the major sialylated glycoprotein on the platelet surface, and as asialylated platelets have a shortened survival[63], absence of this receptor can give rise to thrombocytopenia. BSS has mostly been related to mutations in the gene for GP Ib-α (BSS type A) but also in the gene for GPIb-β (BSS type B) and in the gene for GPIX (BSS type C). Ware et al.[64] disrupted the GPIbα-gene in mice; this resulted in the BSS phenotype. Moreover, he rescued the BSS phenotype by expressing the human GP Ibα subunit on the surface of the circulating platelets. No BSS patient with a mutation in the GPV gene has been found. This is consistent with the finding that GPV knockout mice have normal megakaryocytes with normal GPIb–IX expression on the cell surface[65].

Thrombocytopenia with normal platelet size

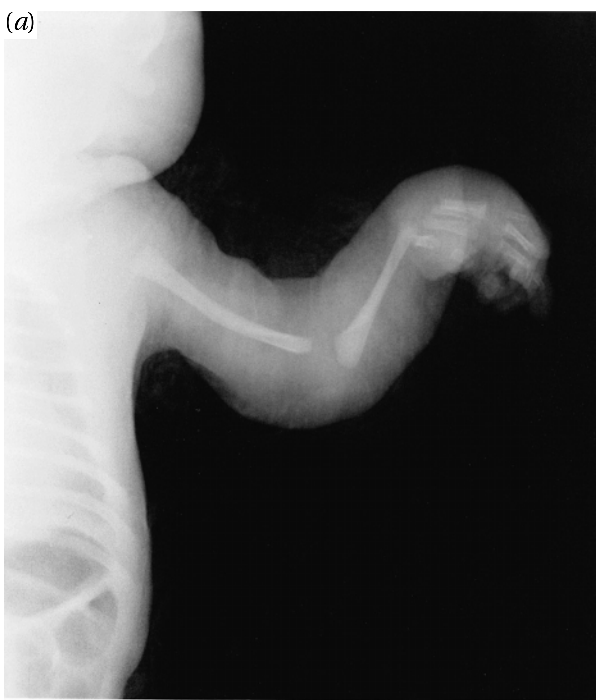
Congenital amegakaryocytic thrombocytopenia (CAMT) without associated physical anomalies is a rare disorder, characterised by isolated thrombocytopenia and megakaryocytopenia in infancy. It is considered a constitutional marrow failure syndrome, because of evolution with time towards bone marrow aplasia and leukemia[66]. The pathogenesis of this disorder remained unsolved until recently, with increasing insight into the mechanisms of megakaryocyte proliferation and differentiation. In 1994, several groups purified the protein thrombopoietin (TPO) or cloned the cDNA for TPO[67]. It became clear that TPO is the principal regulator of megakaryocytic cell proliferation and differentiation. The TPO-receptor gene (c-mpl) belongs to the cytokine receptor superfamily and encodes for five coexpressed mRNA isoforms. It is expressed in the megakaryocytic lineage from late progenitors to platelets[68]. TPO cannot be replaced by other cytokines in many functions: the formation of platelet specific granules, the development of demarcation membranes and platelet fields, the expression of platelet-specific membrane proteins (GP IIb/IIIa and GP Ib/V/IX), megakaryocyte adhesion through activation of GP IIb/IIIa, VLA-4, and VLA-5, endomitosis and its resultant polyploid state and finally the formation of platelets from single megakaryocytes in serum-free cultures[69]. Moreover, TPO and c-mpl also play a role in early hematopoiesis by supporting the survival of early hematopoietic progenitors and by inducing the proliferation of megakaryocytic progenitor cells by synergistic action with interleukin (Il)-3, stem-cell factor, Il-11, and EPO. The mechanism by which TPO exerts this action is probably by decreasing progenitor cell apoptosis[70].

TPO plasma levels are elevated in patients with CAMT[71,72], in line with the finding that TPO levels are high when the thrombocytopenia is due to megakaryocyte deficiency and low when it is due to peripheral destruction[73]. Furthermore, a CAMT patient had an in vitro defective response to TPO in megakaryocyte-colony formation, with decreased numbers of erythroid and myelocytic progenitors in clonal cultures and a lack of c-mpl mRNA in bone-marrow mononuclear cells[71]. Further evidence that c-mpl might be the candidate gene for CAMT without associated physical anomalies came from animal studies. In mice a deficiency of the c-mpl gene results in amegakaryocytic thrombocytopenia, decreased numbers of progenitors and increased concentrations of circulating TPO without any other clinical abnormalities[74–77]. Due to the similarity between human CAMT and murine c-mpl deficiency, this gene was studied in patients with CAMT and a compound heterozygote with two truncating mutations in c-mpl was identified[78] as well as a compound heterozygote for two missense mutations[72]. Van den Ouderijn et al.[79] found mutations in the c-MPL gene in 4 out of 5 CAMT patients, confirming that CAMT is an autosomal recessive disorder that can be due to c-mpl mutations.

Congenital thrombocytopenia with absent radius is referred to by the acronym TAR-syndrome and is characterized by hypomegakaryocytic thrombocytopenia ($<100 \times 10^9$/l) and bilateral absence of the radius with normal thumbs (Fig. 34.9). Initially, this condition was considered to be a form of Fanconi's anemia. However, the natural history of TAR-syndrome is more benign as compared to Fanconi's anemia. The majority of affected families suggested an autosomal recessive inheritance, whereas in some families the TAR-syndrome seemed to be inherited in a autosomal dominant way. Hall reviewed the phenotypic features of this syndrome[80]. 100% of the TAR-patients demonstrate a thrombocytopenia, which is symptomatic in 90% of the patients during the first months of life. Mostly, the platelet count in infancy ranges between 15×10^9/l and 30×10^9/l and thereafter there is a gradual improvement towards almost normal levels by adulthood. Bone marrow shows small, basophilic and vacuolated megakaryocytes. Leukemoid reactions are seen during the first year of life in two-thirds of the patients. True leukemia has never been documented in a patient with TAR-syndrome. The often observed anemia could either be a consequence of the blood loss, due to the thrombocytopenia, or due to a shortened RBC lifespan. The bilateral absence of the radius with the presence of normal thumbs is obligatory for the diagnosis; however, numerous additional skeletal abnormalities have been described, such as abnormal ulna, humerus, or shoulder; one-half of the TAR-patients also have abnormalities of the legs. During embryonic development, disturbances in the heart formation can occur with tetralogy of Fallot and atrial septal defects as most common problems. There is a marked inter- and even intrafamilial variability as to the extent of the skeletal, hematological and cardiac anomalies. The final vital prognosis for an affected child with TAR-syndrome is normal if the child survives the first few years of life.

The molecular defect leading to this syndrome is currently unknown. Elevated serum levels of thrombopoietin (TPO) have been found in patients with TAR-syndrome. The reactivity of TAR-platelets in vitro towards recombinant TPO was decreased, despite normal expression of the TPO-receptor on the surface of the platelets[81]. Strippoli et al.[82] performed mutational screening of the promoter of the TPO-receptor gene (c-mpl) and the coding region of the c-mpl gene in four unrelated TAR-patients and found no mutations thereby excluding c-mpl mutations as a

Cambridge Books Online © Cambridge University Press, 2009



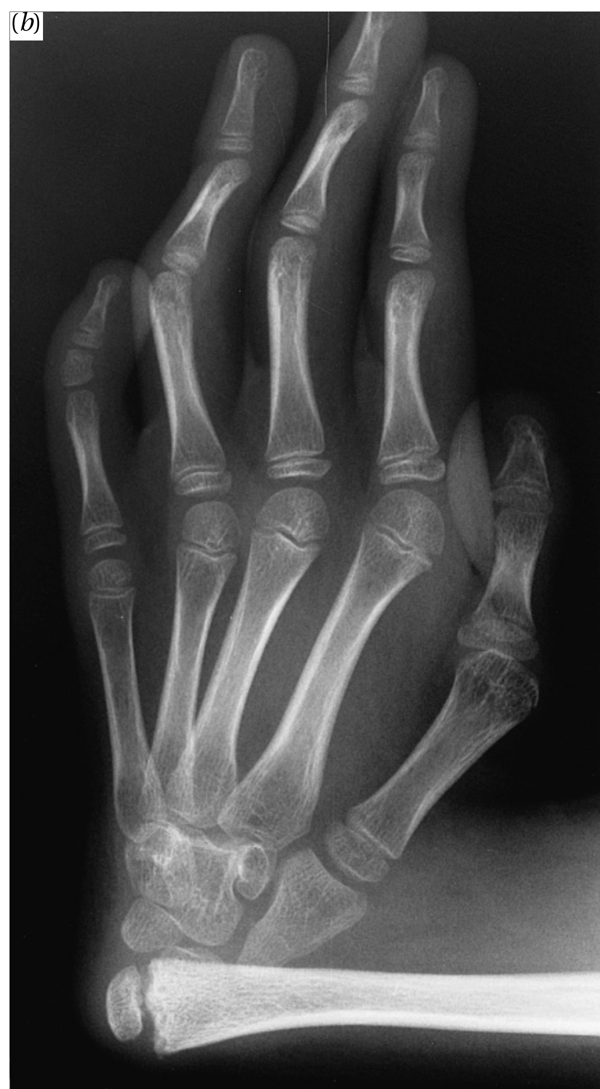


Fig. 34.9. X-ray photographs of the upper limb of a patient with TAR-syndrome. Note the absence of the radius at infancy (*a*) and at the age of 10 years (*b*) with normal hand development.

common cause of thrombocytopenia in TAR-syndrome. Further evaluation of the signal transduction following TPO-c-mpl interaction could possibly clarify the pathogenesis of this syndrome.

Conclusions

Although rare, the hereditary thrombocytopenias allow to identify a number of proteins clearly involved in human thrombopoiesis and will help to clarify further this complex biological phenomenon. What is striking from the overview, is that different mutations in the same gene, or even within the same codon of the gene, can lead to markedly dissimilar phenotypes: Wiskott–Aldrich syndrome or X-linked microthrombocytopenia, the different severities in X-linked macrothrombocytopenia due to GATA-1 mutations, the May–Hegglin anomaly, Sebastian platelet syndrome or the Fechtner syndrome. On the other hand, mutations in two different genes, but with interactions between their gene products, can result in very similar phenotypes: von Willebrand disease type 2B and the platelet-type von Willebrand disease. Careful dissection of the experiments of nature resulting in hereditary disorders continues to be a major source of medical insight.

Thrombocytopenias due to bone marrow disorders

Beng H Chong[1] and Colin Chesterman[2]

[1] *University of New South Wales, Sydney, Australia*
[2] *Centre For Thrombosis and Vascular Research, University of New South Wales, Sydney, NSW, Australia*

Thrombocytopenia is a common manifestation in many bone marrow disorders. As bone marrow is the site of platelet production, it is not surprising that bone marrow diseases would cause thrombocytopenia. It is pertinent to review briefly the regulation of platelet production, and how it could be adversely affected by bone marrow diseases.

Regulation of platelet production

Platelets are produced in the bone marrow by cytoplasmic budding of their precursor cell, the megakaryocyte. The megakaryocyte itself is derived from the hematopoietic stem cell by a series of cell proliferation and differentiation processes. These processes are controlled by a network of growth factors, the most important of which is thrombopoietin, TPO[1–4]. These processes also involve a specific program of gene expression mediated by transcription factors such as GATA-1, FOG-1, Fli-1 and NF-F2[5–7]. Mouse knockout studies revealed that disruption of the TPO gene, and genes of these transcription factors, resulted in marked impairment of megakaryocyte development, severe thrombocytopenia and/or serious bleeding[8–12].

TPO exerts its effect by binding to its receptor, c-mpl on megakaryocytes and their precursor cells. TPO-c-mpl interaction induces activation of intracellular signal transduction pathways (Fig. 35.1) including Jak2 / STAT 3/5, protein kinase C (PKC) and MAPK kinase pathways[13]. The signalling pathway activation ultimately leads to activation of specific transcription factors, e.g. GATA-1. The activated factor then translocates to the nucleus and binds to the regulatory region of a target gene involved in megakaryocyte proliferation and differentiation. Many of these target genes are still unknown. However, some are known such as the megakaryocyte-specific genes, GP Ibα, GP IX and GP II b. These are lineage-restricted proteins that are expressed at various stages of megakaryocyte maturation. We, and others, have found that GATA and Ets transcription factors play a critical role in the regulation of these genes[13,14]. However, these transcription factors do not act alone. For example, GATA-1 and FOG-1 interact with one another and with other still unknown factors to form a large protein complex which regulates transcription of megakaryocyte genes. We found that one member of the transcription factor family may replace another member in the regulatory complex. For instance, FOG-2 may replace FOG-1 in its interaction with GATA-1 in the complex that regulates the transcription of the NF-E2 gene[15]. Furthermore, specific factors are only expressed at certain stages of megakaryocyte differentiation (Holmes & BH Chong, unpublished data), suggesting that each factor may be active at a specific phase of megakaryocyte development.

In health, the platelet concentration in the peripheral blood is kept within a narrow range (140×10^9/l – 400×10^9/l). TPO is the key regulator of platelet production. The plasma TPO level is tightly controlled. It varies inversely with the circulating platelet concentration, or more precisely with the platelet/megakaryocyte mass. Hence, the plasma TPO level is increased in patients with thrombocytopenia and vice versa[16,17].

The liver is an important source of TPO production in the body. Other sites of TPO production include the kidneys and the bone marrow stromal cells. The rate of TPO pro-

duction in the liver and kidneys is constant and not influenced by the circulating platelet concentration. Two mechanisms have been postulated for the regulation of blood TPO levels. The first is a passive mechanism in which the circulating TPO level is regulated by its binding to platelets and megakaryocytes and its subsequent degradation inside the cells. When circulating platelets increase, more TPO molecules are taken up by the cells and degraded. The plasma TPO level falls. The reverse occurs when the platelet level decreases. The increase in TPO level is greater in thrombocytopenic states in which the bone marrow megakaryocytes are markedly decreased, as in aplastic anemia[16,17]. In contrast, the circulating TPO is only slightly increased in idiopathic thrombocytopenic purpura (ITP) in which the megakaryocytes are increased or normal[18]. The TPO levels remain elevated in patients with aplastic anemia in remission when the platelet counts and bone marrow megakaryocyte number are normal[17]. The elevated TPO levels in these patients cannot be explained by the passive mechanism. Similarly, the passive mechanism cannot explain the normal plasma TPO levels in patients with reactive thrombocytosis and essential thrombocythemia[19].

It seems most unlikely that the plasma TPO level, which is critically important for maintaining hemostasis and human survival, would be regulated by a passive mechanism alone. Data from Dr Krushansky's and my laboratory (Sungaran et al.) suggest that there is another more precise mechanism which involves TPO gene regulation[20,21]. This mechanism operates locally at the bone marrow, the site of platelet production. The data from both our laboratories show that TPO production by the stromal cells in the bone marrow is under gene regulation[21]. TPO mRNA expression in bone marrow stromal cells varies inversely with the platelet-megakaryocyte mass. It is increased in thrombocytopenic states such as ITP and aplastic anemia[21]. Subsequent studies from my laboratory showed that there is in fact a feedback regulatory loop via the secretion of platelet/megakaryocyte α-granule proteins which modulate the stromal cell TPO gene expression and TPO secretion by these cells[22]. It must be pointed out, however, that the two mechanisms are not mutually exclusive. Both mechanisms may coexist, one as a broadly based regulatory mechanism and the other a more precise local control mechanism at the site of platelet production.

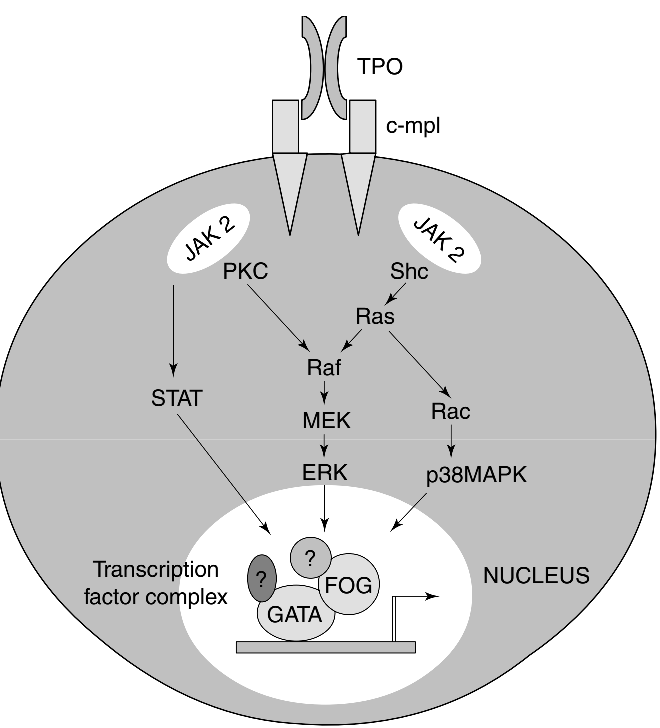

Fig. 35.1. TPO intracellular signalling and gene transcription regulation pathways. This is a diagram showing intracellular cell transduction pathways that become activated when TPO binds to its receptor on a megakaryocytic cell. TPO and c-mpl are in dimeric form. Activation of signal transduction pathway leads to activation and translocation of transcription factors (e.g. GATA-1 and FOG) which bind to the regulatory region of a target gene (e.g. GPIX) and initiate transcription.

Bone marrow disorders that may affect platelet production

Bone marrow disorders could perturb platelet production by several mechanisms. (i) First is depletion of bone marrow hematopoietic stem cells/progenitor cells that give rise to platelets and other mature blood cells by chemotherapeutic drugs, toxic chemicals, ionizing radiation and infective agents. This leads to an aplastic marrow. (ii) Secondly is bone marrow being replaced by cancer or a foreign tissue, resulting not only in thrombocytopenia but also anemia and neutropenia. (iii) Thirdly is replacement of normal hematopoietic stem cells by a malignant/premalignant clone of hematopoietic cells, e.g. in acute leukemias and myelodysplastic syndrome. The abnormal clone has genetic lesions that confer on it a growth or survival advantage, but there is ineffective hematopoiesis resulting in cytopenias (including thrombocytopenia). (iv) Fourthly is a deficiency state, e.g. vitamin B12 or folate deficiency

Cambridge Books Online © Cambridge University Press, 2009

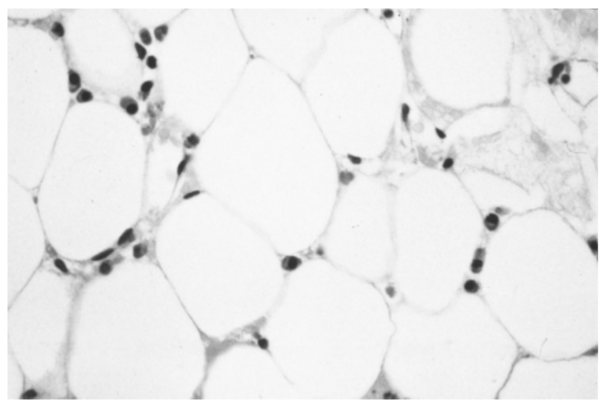

Fig. 35.2 (see also colour plate). A bone marrow trephine biopsy of a patient (male, 25 years of age) with aplastic anemia. It shows predominantly adipose spaces and stromal cells but very few hematopoietic cells.

causing defective cell differentiation and consequently ineffective hematopoiesis/megakaryopoiesis. (v) Fifthly is a defect in regulation of thrombopoiesis.

Thrombocytopenias due to bone marrow disorders will be discussed under the following five headings according to the underlying mechanisms which are responsible for the thrombocytopenia.

Depletion of stem cells: marrow aplasia/ megakaryocytopenia

Aplastic anemia

Aplastic anemia is a heterogenous syndrome characterized by peripheral pancytopenia and bone marrow aplasia. The marrow is devoid of precursors of myeloid, erythroid and megakaryocytic lineages and they are replaced by adipose cells (Fig. 35.2, see colour plate). CD 34+ stem/progenitor cells are markedly reduced in the bone marrow. Bone marrow cells capable of forming granulocyte/monocyte, erythroid and megakaryocyte colonies, CFU-GM, CFU-E and CFU-MK are also decreased[23]. The bone marrow stromal cells are normal. There is no deficiency of hematopoietic growth factors and their levels in plasma, e.g. TPO are compensatorily increased.

Immune mechanism (idiopathic aplastic anemia)

Aplastic anemia can be divided into two types, idiopathic and secondary. Idiopathic aplastic anemia is an uncommon condition which is now widely accepted to be an autoimmune disease[23]. In this condition, there is evidence of suppression of normal hematopoiesis by T lymphocytes mediated by TH-1 type cell activation response, as suggested by increased production of TNF-α, γ- interferon and IL-2. The immune attack causes apoptosis of CD34+ stem/progenitor cells and results in their depletion in the bone marrow[23]. Some secondary aplastic anemias associated with autoimmune disorders such as thymoma and systemic lupus erythematosis (SLE) may share the same T-cell mediated pathophysiology. There may be a genetic predisposition to the development of aplastic anemia. HLA-DR2 occurs twice as frequently in patients with aplastic anemia as in normal individuals[24]. A specific class II haplotype, i.e. DRB 1501 is strongly associated in Japanese patients with cyclosporin-responsive aplastic anemia[25].

Drugs

The commonest cause of bone marrow aplasia is drug. The mechanism may be a direct toxic effect on the stem cells, e.g. alkylating agents, antimetabolites and other cytotoxic drugs or an idiosyncratic (hypersensitivity) reaction. Many drugs have been reported to cause marrow aplasia by an idiosyncratic reaction[26]. The cause-and-effect relationship is only suggestive for some of the reported drugs, but the relationship is more definitive in others such as chloramphenicol, quinacrine, non-steroidal anti-inflammatory drugs (indomethacin, diclofenac, etc.), sulfonamides, hydantoins, pyrazolones, phenothiazines, penicillamine, gold and antithyroid drugs[26]. Incidence of aplastic anemia due to these drugs is largely unknown except for chloramphenicol and quinacrine. The incidence of aplastic anemia caused by these two drugs is estimated to be approximately 1 in 30 000[27,28]. The offending drugs usually cause a generalized marrow aplasia and peripheral pancytopenia. On withdrawal of the offending drug, the marrow usually recovers, but the thrombocytopenia is often the last to do so. Isolated thrombocytopenia due to selective suppression of megakaryocyte may occur with some drugs such as chlorothiazide diuretics[29]. Thrombocytopenia was reported when these drugs were introduced in the 1950s. Thrombocytopenia developed over several weeks, both on initial exposure and on rechallenge. The estimated frequency of thrombocytopenia is one in 15 000 users. There were isolated reports of thrombocytopenia due to diethylstilbestrol caused by a decreased platelet production[30].

Chemicals

Among the chemicals which have been recognized as being toxic to the marrow are benzene, insecticides (pentachlorophenol, lindane and DDT), trinitrotoluene and toluene[31]. These chemicals are used in industry, on the farm and at home. Benzene is used in industry as an organic solvent. It is present in unleaded petrol and tobacco smoke. Benzene and its metabolite *p*-benzoquinone suppress DNA synthesis in hematopoietic pro-

Cambridge Books Online © Cambridge University Press, 2009

genitor cells and inhibit their proliferation[32,33]. These effects may lead to marrow aplasia and subsequent development of myelodysplasia and leukemia. The risk of development of these diseases is higher in individuals who are genetically predisposed. NAD(P)H: quinone oxidoreductase (NQO) plays a critical role in detoxifying benzene metabolites. Chinese workers who were exposed to benzene and had a non-functioning ^{609}C→T polymorphic allele of the NQO1 gene were reported to have an increased incidence of hematologic malignancies[34].

Alcohol

Thrombocytopenia associated with alcohol abuse is usually multifactorial. It may be due to hypersplenism, which is the result of liver cirrhosis, portal hypertension and congestive splenomegaly. Folate deficiency may also contribute to the thrombocytopenia. However, alcohol can cause direct marrow suppression, affecting megakaryocyte maturation resulting in acute thrombocytopenia[35,36]. Ingestion of alcohol for 5–10 days is required for sustained thrombocytopenia. After cessation of alcohol consumption, the thrombocytopenia resolves within 5–21 days. However, since not every alcoholic develops thrombocytopenia, additional factors may need to be present for thrombocytopenia to occur.

Radiation

Acute exposure to radiation may lead to bone marrow suppression, the severity of which is dependent on the radiation dose. A dose of 1–2.5 Gy will result in leukopenia, 4.5 Gy death in 50% of the exposed individuals and >10 Gy universal death[37] unless the patients receive bone marrow transplantation and supportive care. Low doses such as those given during cancer therapy can also cause marrow aplasia. The degree of marrow hypoplasia depends, of course, on the dose, duration and site of radiation exposure and also on whether the patient has had prior chemotherapy. Marrow aplasia may recover but myelodysplasia and leukemia may subsequently occur[38].

Viral infection

There is a close association between viral infection, specifically hepatitis and Epstein–Barr virus (EBV) infection, and the subsequent development of aplastic anemia. Most cases of hepatitis-related aplastic anemia are caused by non-A, non-B and non-C hepatitis, although a few patients have been reported to be due to hepatitis A and B[39]. In many patients, aplastic anemia occurs 1–3 months or occasionally even a year after the onset of infection when the liver disease is resolving or has resolved. At present, it is unclear whether the marrow aplasia is the result of viral

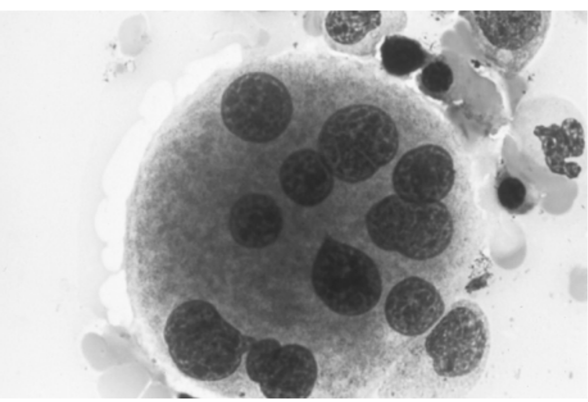

Fig. 35.3 (see also colour plate). This shows an abnormal megakaryocyte with dysplastic changes in a patient with HIV-1 infection and thrombocytopenia. It is a huge cell with nuclear fragmentation.

infection of the hematopoietic stem/progenitor cells or marrow injury by the host immune system. However, there is no association between aplastic anemia and hepatitis C, which can cause thrombocytopenia by hypersplenism and other mechanisms. Pancytopenia is frequently encountered in HIV(human immunodeficiency virus) infection, particularly in the late stages of the disease but the marrow is often hypercellular and the pancytopenia is due to ineffective hematopoiesis as a result of HIV infection of bone marrow stromal cells[40,41]. Occasionally, marrow hypoplasia is seen. This is attributed to marrow suppression by infection and drugs used to control viral replication.

Isolated thrombocytopenia is often noted in viral infection and this is believed to be due to at least two different mechanisms, namely infection of megakaryocytes (Fig. 35.3, see colour plate) and immune peripheral platelet destruction. Thrombocytopenia due to the former mechanism has been reported in measles, HIV (human immunodeficiency virus), varicella, mumps, Epstein-Barr virus, rubella, cytomegalovirus, parvovirus and dengue infection[42]. In these infections, bone marrow biopsy may show nuclear and cytoplasmic vacuolation in megakaryocytes under light microscopy and inclusion bodies on electron microscopy. Interestingly, in HIV infection, the virus enters the megakaryocyte progenitors at a stage when they express CD 4 and other chemokine coreceptors like CXCR4[43]. Infection of megakaryocytes leads to ineffective thrombopoiesis. The thrombocytopenia is, in part, also due to immune platelet destruction, particularly in HIV infection as the thrombocytopenia frequently responds to corticosteroid, high dose IgG infusion and splenectomy[44,45].

Miscellaneous causes

This group of secondary aplastic anemia is likely to have an immune etiology such as aplastic anemia seen in the occasional patients with systemic lupus erythematosus[46]. These patients usually have antibody or suppressive T lymphocytes that inhibit hematopoiesis. Although immune etiology is also likely to be present in rheumatoid arthritis patients with coexisting aplastic anemia, it is difficult to exclude the possibility that drugs used to treat the condition such as gold, methotrexate and D-penicillamine, may also contribute to the marrow aplasia. In eosinophilic fasciitis, the immune etiology of the associated aplastic anemia is even less certain as the pancytopenia is usually unresponsive to immunosuppressive therapy. However, occasional patients have partially or completely recovered with antithymocyte globulin (ATG) and/or cyclosporin[47]. Aplastic anemia is also known to be associated with pregnancy, in which case the disease usually improves with termination of pregnancy or after delivery[48]. It may recur with subsequent pregnancies. However, the condition may also progress even after delivery of the baby.

Treatment of aplastic anemia

If there is an identifiable cause, it should be removed or treated, e.g. cessation of the offending drug, termination of pregnancy or treatment of the underlying infection (e.g. treatment of HIV-1 infection with zidovudine). Supportive treatment is also important and this includes platelet transfusion for bleeding due to thrombocytopenia, packed cell transfusion for anemia and antibiotic treatment for bacterial infection.

Specific treatment is either allogeneic bone marrow transplant (replenishment of hematopoietic stem cells), usually from a histocompatible sibling, or abrogating the immune attack by immunosuppressive therapy[49]. The response to allogeneic transplantation, particularly in children, is very favourable. Long-term survival rates (after 5 years) vary from 75–90%. Acute transplant mortality has decreased substantially and graft-vs.-host disease(GVHD) is now better controlled[50]. GVHD is still a limiting factor in the success of bone transplantation, especially in adult patients as the incidence and severity of GVHD increase with age. Patients without a compatible marrow donor and those who are unsuitable for transplantation, are treated with immunosuppressive therapy using cyclosporin or antithymocyte globulin (ATG)/antilymphocyte globulin (ALG). Patients respond better to cyclosporin plus ATG/ALG than either drug alone. A response rate of 70–80% can be expected in patients receiving the combined therapy with a survival rate at 5 years of 90% among the responders[51].

Acquired amegakaryocytic thrombocytopenic purpura (AATP)

This is a rare disorder characterized by severe thrombocytopenia and absence of megakaryocytes in the bone marrow. Bone marrow aspiration or trephine biopsy shows a marked decrease or absence of megakaryocytes[52] with normal erythropoiesis and granulopoiesis. An antiplatelet antibody is usually not detected. AATP is analogous to pure red cell aplasia in which there is a severe anemia and absence of erythroid precursors in the bone marrow. The pathophysiology of AATP is at present unclear. It may have different underlying mechanisms. Ex vivo culture of the patient's bone marrow cells shows no or very few CFU-MK (colony forming unit-megakaryocyte). Sera or T lymphocytes from patients with AATP have been shown to suppress megakaryocyte colony formation when added to in vitro culture of normal bone marrow[52–55]. These studies suggest a humoral or T suppressor lymphocyte-mediated inhibition of megakaryopoiesis, although an intrinsic CFU-MK defect may also be present.

The pathophysiology of AATP is similar to that observed in aplastic anemia. There have been cases of AATP who progressed rapidly to aplastic anemia[56] and others in whom the disease transformed to acute myeloid leukemia (AML) or myelodysplastic syndrome (MDS)[57]. Like aplastic anemia and pure red cell aplasia, AATP responds well to immunosuppressive therapy including ATG/ALG, cyclosporin and cyclophosphamide[58,59]. There is, as yet, no report of treatment of AATP with bone marrow transplantation.

Paroxysmal nocturnal hemoglobinuria (PNH)

PNH is a disease related to aplastic anemia. The main clinical manifestations of this disease are intravascular hemolysis and increased tendency to thrombosis[60]. Thrombocytopenia may also occur in some patients with PNH. PNH and aplastic anemia are in the same spectrum of diseases as some patients with PNH may transform to aplastic anemia[61] and vice versa. PNH is caused by somatic mutations in the PIG-A (phosphatidyl inositol glycan complementation Group A) gene leading to deficiency of glycosyl phosphatidyl inositol (GPI)-anchored proteins on red cells and other blood cell surfaces[62]. As a result, red cells are very susceptible to lysis by terminal complement components, C5–C9 and this explains the intravascular hemolysis in PNH[62]. The mechanism causes platelet activation and consequently thrombosis in this condition.

The anemia and thrombosis in PNH are usually treated with blood transfusion and anticoagulant therapy. PNH patients with aplastic anemia or severe cytopenia may be treated like non-PNH patients who have aplastic anemia

Cambridge Books Online © Cambridge University Press, 2009

with immunosuppressive therapy or bone marrow transplantation as discussed above.

Fanconi anemia (FA)

Fanconi Anemia (FA) is an autosomal recessive congenital blood disorder, which frequently progresses to aplastic anemia in childhood but occasionally in adulthood[63]. The patients with FA also have a predisposition to development of AML, MDS and other cancers[64]. They frequently have multiple physical abnormalities such as hyperpigmentation, short stature, microophthalmia and microcephaly. Recently, two FA genes have been isolated and specific mutations in these genes have been identified[65,66]. The genetic defects are responsible for the spontaneous chromosomal breakage, which predispose them to the development of aplastic anemia, AML, MDS and other cancers. For laboratory diagnosis of FA, patient lymphocytes are cultured in the presence of DNA cross-linking agents such as mitomycin C and diepoxybutane (DEB)[67,68]. Cells from FA patients often have spontaneous chromosomal breakage which is increased substantially on exposure to these bifunctional alkylating agents.

The anemia and other cytopenias in FA patients are managed with supportive care including transfusion with packed cells and platelets. Androgen and growth factors such as erythropoietin, G–CSF and GM–CSF may also be helpful. For those who develop aplastic anemia, allogeneic bone marrow transplantation should be considered if a compatible donor is available[69]. Patients with FA often have endocrine dysfunction such as growth hormone deficiency and hypothyroidism which may need treatment with the appropriate hormone replacement.

Depletion of stem cells – bone marrow replacement by neoplasm or foreign tissues

Bone marrow infiltration by malignancy

The thrombocytopenia in hematologic malignancy (e.g. multiple myeloma and lymphoma) and metastatic non-hematologic cancer (e.g. prostate, breast, lung and renal cancer) (Fig. 35.4, see colour plate), often occurs together with anaemia and neutropenia (pancytopenia). The pancytopenia is due to suppression of normal hematopoiesis by marrow infiltration by cancer or foreign tissues, e.g. myelofibrosis. Inhibition of the normal hematopoietic clone of cells may be simply due to the overcrowding effect but secretion of an inhibitory factor by the malignant cells has been suggested. Chemotherapy and DIC may also contribute to the thrombocytopenia in this group of patients.

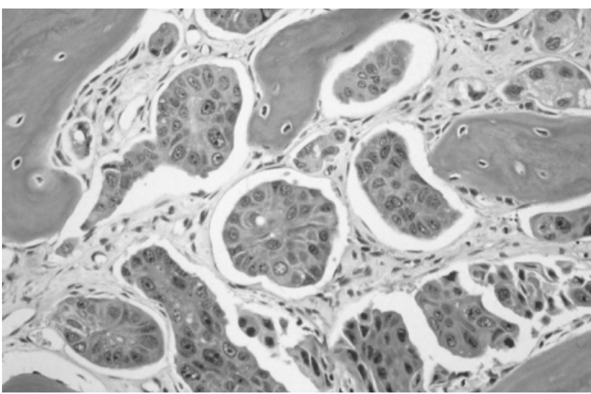

Fig. 35.4 (see also colour plate). A bone marrow trephine biopsy of a patient with metastatic breast cancer showing bone marrow infiltration by malignant cells. The cancer cells are arranged in a gland-like formation (acini).

Ineffective thrombopoiesis: megaloblastic anemia

Folate/vitamin B_{12} deficiency

Megaloblastic anemias are a group of bone marrow disorders showing typical blood and bone marrow abnormalities due to impaired DNA synthesis[70]. The main causes of megaloblastic anemia are vitamin B_{12} and folate deficiency. In these deficiency states, there is a decrease in deoxythymidine triphosphate (dTTP) due to the so-called 'methylfolate trap'[71]. This leads to a slowing of DNA replication and consequently impairment of cell development affecting all hemapoietic lineages. The hypercellular bone marrow shows cells with nuclear maturation lagging behind cytoplasmic. As a result the cells acquire more cytoplasm, and become larger than normal. These changes are most prominent in the erythroid precursors. The abnormally large erythroblasts are termed megaloblasts (Fig. 35.5, see colour plate)[70]. The megaloblastic changes also affect granulocyte precursors and megakaryocytes, which can be abnormally large with a bizarre nucleus containing numerous unconnected lobes[72]. In the peripheral blood, the red cells display marked variation in size but are often large and oval. The neutrophils are hypersegmented and the platelets are small[73]. The ineffective hematopoieis leads to pancytopenia. In severe vitamin B12 deficiency, the platelets are not only reduced in number but can also be functionally abnormal[74].

The commonest cause of folate deficiency is inadequate dietary intake of folate as the hepatic store of folate is small[75]. This occurs frequently in the elderly, the poor, the alcoholic and those with increased folate requirement

such as pregnant women, patients on hemodialysis and those with chronic hemolytic anemia. Besides poor intake, folate malabsorption, e.g. in patients with tropical and non-tropical sprue, celiac disease, regional enteritis and other intestinal disorders, can also cause folate deficiency. Red cell folate concentration is more reliable than serum folate level for the laboratory diagnosis of folate deficiency as it is less variable and correlates better with the tissue folate status[76]. Folate deficiency is treated with 1–5 mg of folate orally per day. Therapeutic effect is usually achieved even in those with folate malabsorption.

The principal cause of vitamin B_{12} is pernicious anemia (PA) which is an autoimmune disease[77]. In this disease, there is a gastric mucosa defect causing achlorhydria and decreased production of intrinsic factor (IF), which is essential for vitamin B_{12} absorption in the ileum. Patients with PA also produce antibodies to IF and IF-B_{12} complex which inhibit the absorption of vitamin B_{12}. There is an association of PA with a number of autoimmune diseases such as thyroid diseases, type I diabetes mellitus, Addison disease, ulcerative colitis and vitiligo[78]. It occurs more commonly in Northern Europeans and in individuals with HLA types A2, A3, B7 and B12 and blood group A[79,80]. Vitamin B_{12} malabsorption is also seen after total or partial gastrectomy, patients with intestinal diseases (see above), blind loop syndrome and fish tape worm infestation (*Diphyllobothrium latum*). A low serum cobalamin level in the appropriate clinical setting indicates the presence of vitamin B_{12} deficiency. The diagnosis of PA requires in addition the detection of IF antibodies and /or a positive Schilling test. Treatment consists of parenteral administration of cyano- or hydroxocobalamin for life, e.g. in patients with PA or until the cobalamin malabsorption is corrected.

Ineffective thrombopoiesis due to an abnormal stem cell clone

Myelodysplastic syndrome (MDS)

MDS is a common bone marrow disorder among the elderly. It is characterized by expansion of a premalignant stem cell clone, ineffective haematopoiesis and peripheral cytopenia. It consists of heterogeneous conditions with different genetic, biological, morphologic (Fig. 35.6, see colour plate) and clinical features and with varying propensity of progression to acute myeloid leukemia (AML)[81]. In USA, the incidence is 3.5 per 100 000 at age of 50 years, and it increases with age to 15 per 100 000 at age of 70 and 35 per 100 000 at age of 90[82]. The French–American–British (FAB) classification divides MDS into five different conditions as shown in Table 35.1[83]. Dissatisfaction with this purely morphologic classification has recently led to a new classification by the WHO[84], attempting to take into consideration the genetic and biological differences among the subtypes.

The pathogenesis of MDS is still unclear. There is now strong evidence that AML and MDS are pathophysiologically linked. Several etiological factors contribute to the development of MDS/AML.

Genetic predisposition

There is an increased incidence of MDS and AML in families with inherited constitutional genetic defects such as Fanconi anemia, neurofibromatosis type1, Schwachman–Diamond syndrome and familial platelet disorder with leukemia (FPD/AML)[85]. The basis for the increased propensity to MDS/AML is defective DNA repair in Fanconi anemia

Table 35.1. FAB classification of myelodysplastic syndrome[83]

Refractory anemia (RA)	Cytopenia of one PB lineage; normo- or hypercellular marrow with dysplasia: <1% PB blasts and <5% BM blasts
Refractory anemia with ringed sideroblasts (RARS)	Cytopenia, dysplasia and the same % blast involvement in BM and PB as RA. Ringed sideroblasts account for >15% of marrow nucleated cells
Refractory anemia with excess blasts (RAEB)	Cytopenia of two or more PB lineages; dysplasia involving all three lineages; <5% PB blasts and 5–20% BM blasts
Refractory anemia with excess blasts in transformation (RAEB-T)	Hematologic features identical to RAEB >5% blasts in PB or 21–30% blasts in BM or the presence of Auer rods in the blasts
Chronic myelomonocytic leukemia (CMML)	Monocytosis in PB ($>1 \times 10^9$/l); <5% blasts in PB and up to 20% BM blasts

Notes:
PB = peripheral blood; BM = bone marrow.

and deregulation of the RAS signal transduction pathway in neurofibromatosis[63,86]. An association of NQ01 gene polymorphism with MDS/AML has also been reported recently[34] (see above).

Environmental carcinogens

Recent epidemiologic studies have revealed an association between MDS and smoking/exposure to toxic agents, e.g. petroleum products, organic solvents, fertilizers, arsenic, thallium, etc.[87].

Cytogenetic abnormalities

Gain or losses of specific chromosomal regions, e.g. 7q-, 5q-, 20q11–12, trisomy 8, 12p- and 3q-, are frequently detected in patients with MDS[88].

Genetic defects

Besides the inherited genetic changes described above, acquired mutations in the RAS, p53 and FLT3 genes have been reported in MDS patients[86,89,90]. Progressive methylation and inactivation of cell cycle regulatory genes e.g. $p15^{INK4b}$ have been found in some patients with MDS[91]. Erythropoietin-induced activation of the STAT 5 signal transduction pathway has been found to be impaired in patients with MDS[92] and this is believed to be responsible for the refractory anemia seen in these patients.

These findings suggest that the disease develops over a period of time by a multistep genetic progression to MDS and then AML. At least in some patients, there is a strong inherited predisposition, e.g. defects in DNA repair genes, mutation in AML1 gene or NQO1 polymorphism with reduced ability to detoxify benzene metabolites[34,63,85]. Subsequently insult by environmental carcinogens[87] and genomic instability lead to stepwise gains/losses of specific chromosomal regions (described above) or chromosome translocations /inversion e.g. t(3; 21), t(8; 21), t(12; 21) and inv[16], that ultimately result in further genetic changes[88] that may involve a tumour suppressor gene (e.g. p53), a gene in a signalling pathway (e.g. RAS) or a cell cycle regulatory gene, e.g. $p15^{INK4b}$ [89–92]. From these genetic changes, a premalignant hematopoietic stem cell clone with growth or survival advantage, emerges and expands. MDS is established. With further genetic changes, it progresses to AML.

Role of aberrant cytokine production and apoptosis in development of MDS

Several studies have reported elevated levels of tumour necrosis factor-α (TNF-α), transforming growth factor-β (TGF-β) and interleukin-1 β (IL-1β). Increased IL-1β is believed to play a role in supporting the expansion of the premalignant clone. Excessive TNF-α may contribute to the accelerated apoptosis and ineffective hematopoiesis in MDS. There could be additional reasons for the excessive apoptosis such as perturbed adhesive interactions between hematopoietic and stromal cells[88].

Immune mechanisms in MDS

It has been postulated that transformation of normal to aberrant stem cells induces an autoimmune T cell response. The MDS stem cell clone is more resistant than the normal clone to the immune attack and expands at the expense of the normal clone[88]. The data in support of an autoimmune process in MDS are:

(i) the presence of skewed T cell receptor V-β repertoire suggesting T cell clonal expansion in MDS[88];
(ii) MDS T cells inhibit CFU-E and CFU-GM in vitro[93,94]; and
(iii) immunosuppressive therapy with ATG and cyclosporin improve cytopenia in MDS[94,95].

Cambridge Books Online © Cambridge University Press, 2009

In summary, MDS arises after a series of genetic changes that confer growth/survival advantage on an aberrant hematopoietic stem cell clone. An autoimmune T cell response which attacks the normal stem cell clone more severely, further allows expansion of the aberrant clone at the expense of the normal stem cell clone. Excessive apoptosis of the progeny of the aberrant stem cells, mediated by increased TNF-α and other mechanisms, leads to intramedullary death of the mature blood cells before their release into the blood stream and pancytopenia.

Treatment

Younger patients with MDS have been treated with curative intent using allogeneic bone marrow transplantation[96]. The results have been variable and are poor for those with unfavourable cytogenetics and other features. Consolidation treatment with autologous bone marrow transplant after intensive chemotherapy may lead to long-term survival in a small proportion of high risk MDS patients[88]. Treatment with low dose 5-azacytidine has delayed progression to AML and death in also a small proportion of high risk patients[97]. The treatment in the majority of patients who are elderly is largely supportive care with blood transfusion for anemia, platelet transfusion for thrombocytopenia and bleeding and antibiotic therapy for infection. Recently, erythropoietin and granulocyte colony-stimulating factor have been shown to act synergistically to increase Hb levels and to lengthen the time interval between transfusions[98]. Immunosuppressive therapy with ATG or cyclosporin may improve the cytopenia in MDS, especially in patients with the subtype refractory anemia[88,94,95].

Acute leukemia (AL)

In AL, normal hematopoietic precursors in the bone marrow are replaced by a malignant clone of cells which fail to differentiate into mature blood cells resulting in pancytopenia (thrombocytopenia included). The block in differentiation occurs at a very early stage of myeloid maturation in AML or lymphocytic differentiation in acute lymphoblastic leukemia. A subtype of AML, acute promyelocytic leukemia (APML) deserves a special mention. In APML, the maturation arrest is at a later stage (the promyelocyte stage). The promyelocytes possess abundant cytoplasmic primary granules, which contain myeloperoxidase, proteases (e.g. cathepsin G) and other procoagulant materials. Death of the leukemic cells and release of the granules lead to disseminated intravascular coagulation (DIC)[99]. Before the advent of all-*trans* retinoic acid (ATRA) for its treatment, many patients with APML died of bleeding because of DIC[99]. Unlike chemotherapeutic agents, which cause massive leukemic cell kill and sudden outpour of granular constituents into the circulation causing DIC, ATRA eradicates the malignant clone by inducing cell differentiation, avoiding the abrupt leukemic cell death and DIC[100]. With ATRA treatment, serious bleeding and other toxicity could be avoided or minimized. However, the remission in patients treated with ATRA alone is usually short lived. The optimal treatment of APML is a combination of ATRA and chemotherapy. Detailed discussion on leukemia and its treatment is beyond the scope of this chapter. Readers are referred to specific reviews on this topic[99–102].

Disorders of platelet regulation

Thrombopoietin levels in thrombocytopenic states

Knockout studies showed that, in mice in which the TPO gene or its receptor, m-pl gene was deleted, the circulating platelet levels were extremely low, only10–20% of the wild-type or control animal[8,103]. This suggests that TPO is responsible for the regulation of 80–90% of platelet production. A decrease in TPO or m-pl caused by a genetic defect, would result in thrombocytopenia. No congenital thrombocytopenic disorders with decreased blood TPO level have yet been identified. On the contrary, elevated TPO levels were found in congenital thrombocytopenic disorders including congenital amegakaryocytic thrombocytopenia, thrombocytopenia with absent radii, Fanconi's anemia and Schwachman–Diamond syndrome[104–106]. Raised plasma TPO levels are also observed in the acquired thrombocytopenic disorders in adults such as aplastic anemia, thrombocytopenia associated with chemotherapy, leukemia and other primary bone marrow disorders, and idiopathic thrombocytopenic purpura (ITP)[16–18]. These findings indicate that the altered TPO levels are the consequence, and not the cause of the thrombocytopenia.

TPO deficiency: liver disease

The liver is the major source of TPO production in the body. Thrombocytopenia is a common manifestation of liver disease. A known cause of thrombocytopenia in liver disease is platelet sequestration in the enlarged spleen (hypersplenism). Is decreased hepatic TPO production another cause? The plasma TPO levels in patients with chronic hepatitis and many patients with cirrhosis are elevated, particularly if they are not thrombocytopenic[107,108]. The reason for the raised TPO levels is unclear. It may pos-

Cambridge Books Online © Cambridge University Press, 2009

sibly be related to the chronic inflammatory process in the liver. However, the TPO level decreases with the severity of the disease and patients with end-stage liver cirrhosis have slightly decreased TPO levels[109,110]. Liver TPO mRNA levels are also decreased in these patients[110]. The blood TPO levels and platelet counts return to normal after liver transplant[111], suggesting that decreased TPO production by the liver does play a role in the thrombocytopenia of liver disease.

Renal disease

Although the kidney is also a prominent source of TPO, the circulating TPO levels remain normal in patients with end-stage renal failure and thrombocytopenia is not a common clinical finding in these patients.

Autoimmune thrombocytopenia

A decreased TPO blood level as a result of anti-TPO antibody, may also be a cause of thrombocytopenia. Human subjects and animals receiving recombinant TPO have been reported to develop anti-TPO antibodies[112–114], decrease in serum TPO levels and severe thrombocytopenia. These data suggest that, in some patients, chronic thrombocytopenia associated with low plasma TPO levels may be due to anti-TPO antibodies.

Decreased sensitivity to TPO: defects in c-mpl or signalling pathways

Congenital amegakaryocytic thrombocytopenia (CAMT)

CAMT is a rare cause of congenital thrombocytopenia in childhood. It is characterized by isolated thrombocytopenia and absence of megakaryocytes in the bone marrow. The serum TPO levels in these patients are increased[106]. Bone marrow CD 34+ progenitor cells from patients with CAMT failed to differentiate into megakaryocytes. Ihara et al.[115] and van den Oudenrijn et al.[106] have found point mutations and/or a deletion in the coding regions of c-mpl in patients with CAMT[115,106]. These mutations lead to premature stop codon or loss of a splice site, which, if translated, will result in a non-functional receptor. The c-mpl mRNA levels in marrow mononuclear cells are usually very low or undetectable, suggesting defective translation or unstable transcripts in this disorder.

Patients with CAMT are compound heterozygote for two mutations or homozygote for one mutation in the c-mpl gene[106,115]. Their parents or siblings who carry one affected allele had normal megakaryocytes, platelets and TPO levels, suggesting that only one normal c-mpl allele is required for normal megakaryocytopoiesis. As TPO also has an effect on the survival of hematopoietic stem cells and early progenitor cells of other lineages, patients with CAMT often progress to develop, in addition, neutropenia, anemia and ultimately bone marrow failure.

Thrombocytopenia with absent radii (TAR)

TAR is a rare congenital thrombocytopenic disorder characterized by absent megakaryocytes in the bone marrow and absence of radii in both arms. The blood TPO level is increased and c-mpl is normal[104,105]. It appears that there is a defect in the signal transduction pathway of c-mpl that is responsible for the abnormal megakaryocyte proliferation and differentiation in TAR syndrome[104,105].

Cyclic thrombocytopenia

Cyclic thrombocytopenia is a rare disorder in which the platelet counts fluctuate from $<20\times10^9$/l to as high as 1000×10^9/l[116]. It is commoner in women than in men. In women, the platelet cycles usually occur in synchrony with menstruation[117]. Different mechanisms have been postulated for the platelet fluctuation. In some patients, there is a cyclical failure of megakaryocytopoiesis with a decrease in CFU-meg, bone marrow megakaryocytes and platelets, in that sequential order[118]. However, the reason for the cyclical failure of thrombopoiesis is still unknown. In some cases, an immune process may cause cyclical destruction of platelets[119]. It has been suggested that, in women in whom the cyclic thrombocytopenia occurs in phase with the menstrual cycle, the high estrogen level in the late luteal phase enhances macrophage Fcγ receptor in the spleen and causes increased platelet clearance[117].

Immune-mediated thrombocytopenia

Kathryn E. Webert and John G. Kelton

Department of Medicine, Faculty of Health Sciences, McMaster University, Hamilton, Ontario, Canada

Immune-mediated thrombocytopenia

Immune-mediated thrombocytopenia is the term used to describe the group of thrombocytopenic disorders in which platelets are destroyed by immune mechanisms. The thrombocytopenia develops when the rate of platelet destruction is greater than the ability of the megakaryocytes in the bone marrow to compensate with increased platelet production. Different investigators have attempted to quantitate this rate of platelet destruction; however, the estimates are relatively imprecise. Many investigators feel that the marrow can compensate at least fivefold without a detectable fall in the platelet count. The platelet destruction in immune-mediated thrombocytopenia can be caused by autoantibodies, alloantibodies, and immune complexes. These are illustrated schematically in Fig. 36.1. Most episodes of immune-mediated platelet destruction are caused by the binding of IgG antibodies to platelet-specific membrane components.

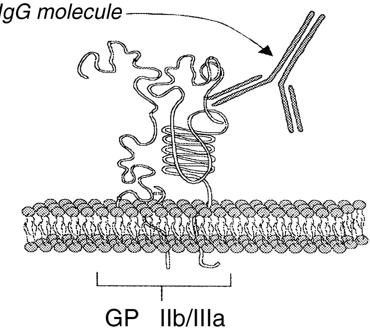
General approach to a patient with suspected immune-mediated thrombocytopenia

When a patient presents with suspected immune-mediated thrombocytopenia, the physician must simultaneously confirm that the patient is thrombocytopenic, begin to determine the general mechanism responsible for the thrombocytopenia, and determine what, if any, treatment is required. Although these various aspects of thrombocytopenia are covered elsewhere in this book, it is appropriate to briefly address each question.

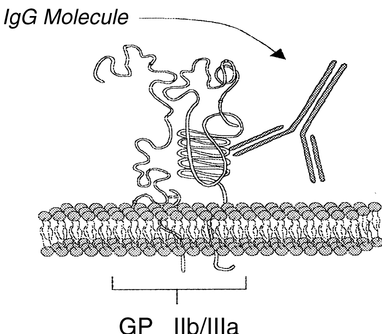
Is the patient thrombocytopenic?

Today, most platelet counts are performed using automated particle counters. With cutbacks in budgets for health care, it has become far less common for every blood film of suspected thrombocytopenic patients to be examined, and even less common for manual (phase-contrast) platelet counts to be performed. Consequently, there is the risk of a patient who has an artefactually low platelet count, also known as pseudothrombocytopenia, to undergo further investigations and even be treated. Pseudothrombocytopenia occurs in 1 in every 500 to 1000 blood samples and occurs when the standard anticoagulant, ethylenediaminetetraacetic acid (EDTA), causes conformational changes in the platelet membrane which cause autoantibodies, typically IgM, to clump the platelets. Automated determination of the platelet count will be inaccurate, as the particle counter will not recognize the larger platelet aggregates as platelets. Pseudothrombocytopenia can have a number of different causes, but is usually due to EDTA-dependent platelet agglutinins. Other causes include cold-dependent platelet clumping, temperature and anticoagulant-independent platelet clumping, and platelet satellitism around leukocytes. All of these artefacts of the platelet count can be detected by examining the stained peripheral blood film. Although an actual platelet count can be difficult to determine, we have found that the most accurate count is obtained by performing a phase-contrast count on a finger prick sample. In summary, the first step when a patient is identified as having thrombocytopenia, particularly if it is asymptomatic thrombocytopenia, is to confirm that the patient is actually thrombocytopenic by examination of the stained blood film.

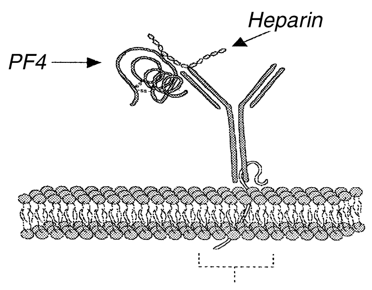
Alloantibodies



Autoantibodies



Drug-dependent antibodies



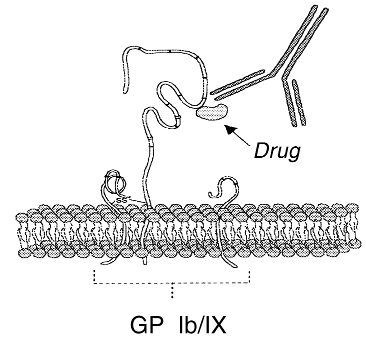


Fig. 36.1. A schematic representation of how different autoantibodies are able to bind to platelets. Most episodes of immune-mediated platelet destruction are caused by the binding of IgG antibodies to platelet-specific membrane components.

Does this patient have immune thrombocytopenia?

This is always the most difficult question of these three questions. Currently, most physicians believe that immune thrombocytopenia is a diagnosis of exclusion. However, recently developed tests to confirm the diagnosis of immune thrombocytopenia (described subsequently) have been shown to have a sufficiently high sensitivity and specificity to prove useful. Thrombocytopenia, like all cytopenias, can be divided into disorders of increased destruction, disorders of underproduction, and disorders of sequestration within an enlarged spleen. Thrombocytopenia caused by increased sequestration in the spleen should be suspected when one documents an enlarged spleen on physical examination, or by videographic confirmation, typically abdominal ultrasound. Hypersplenic thrombocytopenia is confirmed by the performance of autologous platelet survival studies, which document a dramatically reduced platelet recovery (frequently less than 20%), yet a normal or near normal platelet survival. Because these tests are not available to most practising hematologists, the diagnosis of thrombocytopenia caused by splenic sequestration is

Cambridge Books Online © Cambridge University Press, 2009

usually made by confirming mild to moderate thrombocytopenia in association with splenomegaly. Finally, thrombocytopenia caused by reduced production of platelets usually is obvious because of a parallel reduction in the other circulating blood cells, especially the neutrophils, and to a lesser extent the hemoglobin. Examination of the bone marrow helps confirm this diagnosis. Rarely, isolated thrombocytopenia can occur as a consequence of platelet underproduction as seen in amegakaryocytic thrombocytopenia (Chapter 35).

Once the physician has ruled out underproduction and platelet sequestration as a cause of the thrombocytopenia, the mechanism, by default, is an increased rate of platelet destruction. In this category, immune mechanisms predominate. Other causes of increased platelet destruction which can include disseminated intravascular coagulation and generalized infections by viruses, bacteria, or parasites, among other causes, are almost always obvious and usually can be confirmed or excluded by a physical exam in conjunction with appropriate laboratory testing.

In summary, immune thrombocytopenia remains a diagnosis that is made by exclusion; however, there are typical signs and symptoms that can allow a physician to make this diagnosis with considerable confidence. First, unless the patient has a secondary cause for their immune thrombocytopenia, the patient is asymptomatic and has no physical signs with the exception of abnormalities caused by hemostatic impairment. Secondly, many patients with immune thrombocytopenia, especially those with idiopathic thrombocytopenic purpura, have moderate thrombocytopenia with platelet counts ranging from 30 to 100×10^9/l. Most frequently, these patients are entirely asymptomatic and their isolated thrombocytopenia is discovered during routine laboratory testing or after the patient has bled excessively from an otherwise relatively minor hemostatic insult such as surgery or a dental extraction. For many of these patients, a review of previous medical records will confirm that they have had thrombocytopenia for some time that was not detected.

Does the patient with immune thrombocytopenia require treatment?

Recent advances in our understanding of the natural history of immune thrombocytopenia, especially idiopathic thrombocytopenic purpura (ITP), has significantly changed the approach that most physicians use to make management decisions. We now know that many patients with ITP with moderate to severe thrombocytopenia will live healthy, uncomplicated lives and not require any therapy. Many investigators have raised the question of whether the treatment of mild to moderate thrombocytopenia (platelet counts greater than 30×10^9/l) results in greater morbidity than untreated ITP. Our approach is to consider the patient's signs of thrombocytopenia and relate these to the platelet count. For example, patients with mild to moderate thrombocytopenia are almost always asymptomatic and will not have spontaneous bleeding unless they have taken a drug which interferes with platelet function such as aspirin or alcohol. These patients tend to remain asymptomatic. The most frequent question concerning intervention is whether they need treatment to raise the platelet count in anticipation of a surgical procedure such as a tooth extraction or minor surgery. Our general practice is to raise the platelet count if they have moderate thrombocytopenia (platelet count ranging from 30 to 50×10^9/l), with no treatment for those patients whose platelet count is greater than 50×10^9/l. Patients with more severe thrombocytopenia, whose platelet count is less than 20×10^9/l, are more difficult to manage and often require therapy. It is our experience that at a platelet count ranging from 20 to 30×10^9/l, the decision-making should be individualized. Most patients with immune thrombocytopenia whose platelet count is above 30×10^9/l will not require therapy. Conversely, many, but not all, patients whose platelet count is less than 20×10^9/l will require therapy.

There is a hierarchy of symptoms that predict the need for urgent intervention. For example, some patients with platelet counts less than 10×10^9/l are asymptomatic. We tend to treat them, but one may argue that not treating these patients is equally as appropriate. The presence of petechiae and bruising indicates a fairly urgent need for treatment. Furthermore, generalized petechiae suggest that more immediate intervention is required. Blood blisters in the mucous membranes, especially along the bite margins of the buccal mucosa, are an indication of severe hemostatic impairment and the need for urgent intervention. Finally, patients with immune thrombocytopenia can have near fatal hemorrhages, most frequently into the brain or less commonly into the gastrointestinal tract. Almost always, these patients will have had significant bleeding, especially mucous membrane bleeding for some time, which can alert the physician about the need for urgent intervention. The rate of fatal hemorrhages in patients with platelet counts less than 30 X 10^9/l has been estimated to be between 0.012 and 0.130 cases per patient year[1]. For these patients, aggressive therapy including reticuloendothelial (RE) blockade, high-dose corticosteroid therapy and platelet transfusions is indicated.

Table 36.1. Immune thrombocytopenia

Type of antibody	Classification
Autoantibody	Primary
	Idiopathic thrombocytopenic purpura
	Acute
	Chronic
	Secondary
	Systemic lupus erythematosus
	Rheumatoid arthritis
	Sarcoidosis
	Lymphoproliferative disorders
Alloantibody	Alloimmune neonatal thrombocytopenia
	Post-transfusional purpura
	Refractoriness to platelet transfusions
Drug-dependent antibody	Quinine, quinidine
	Heparin-induced thrombocytopenia

Autoimmune thrombocytopenia

In autoimmune thrombocytopenia, the immune destruction is caused by autoantibodies. Most of these autoantibodies bind to individual platelet glycoproteins, especially the glycoprotein IIb–IIIa complex (GP IIb–IIIa). These antibodies, which are almost always IgG, can be associated with a number of clinical disorders. Primary immune thrombocytopenia, which is also known as idiopathic thrombocytopenic purpura (ITP), has no underlying disease associations. Secondary immune thrombocytopenia includes a group of diseases (see Table 36.1) which by definition are associated with a systemic disease.

Primary autoimmune thrombocytopenia, idiopathic thrombocytopenic purpura

ITP is the most common cause of autoimmune thrombocytopenia. ITP occurs in both children and adults, and, simplistically, the childhood form can be considered to be the 'inverse' of the adult form. Eighty per cent of children with ITP will have an acute illness, defined as less than 6 months of disease with spontaneous remission of their illness. Only 20% of children with ITP will have chronic disease requiring ongoing therapy. In contrast, 80% of adults presenting with acute ITP will prove to have chronic ITP. Many will require more definitive treatment such as splenectomy. Although childhood ITP is described elsewhere in this book (Chapter 37), we will briefly summarize its key aspects. Childhood ITP is equally frequent in boys and girls and typically presents in children less than 5 years of age. Often, the children will have had an antecedent infection or, less commonly, a vaccination. The ITP is often dramatic in its presentation as the thrombocytopenia can be quite severe, with platelet counts falling to less than 10×10^9/l. Most children are symptomatic and have evidence of hemostatic impairment with petechiae and purpura. Untreated, the illness usually resolves spontaneously. Although catastrophic hemorrhage such as an intracranial hemorrhage is very rare in these children (less than one percent), many physicians would treat patients who have severe thrombocytopenia and signs of hemostatic impairment with interventions such as high-dose intravenous immunoglobulins (IVIg) or high-dose corticosteroids to speed up their recovery. The extent of the investigation and the necessity for intervention is debated and is described in greater detail in Chapter 37. The likelihood of having chronic disease and requiring ongoing intervention or splenectomy increases with age and rises dramatically to adult levels following puberty. Although there is no sex predominance in the young child with ITP, girls are more frequently affected when ITP presents in adolescence or adulthood.

Adults with ITP may present in one of three ways. About one-third of patients who ultimately are diagnosed as having ITP are asymptomatic, and their thrombocytopenia is discovered at the time of routine blood testing. These patients typically have a platelet count greater than 50×10^9/l and they have mild idiopathic thrombocytopenic purpura. About one-third of patients will give a history of intermittent episodes of bruising that have occurred for months to years. Sometimes, the patient will note that the bruising was associated with alcohol consumption or the use of an antiplatelet agent such as aspirin. This group of patients typically has moderate thrombocytopenia and a platelet count ranging from 20 to 50×10^9/l. Finally, about one-third of ITP patients will present with fairly dramatic and abrupt evidence of hemostatic impairment with petechiae, purpura, and, less commonly, mucous membrane bleeding. These patients often have a platelet count that is less than 20×10^9/l. Treatment is required for these patients.

Physical and laboratory investigations in patients with ITP

The physical examination of ITP patients should parallel the approach described earlier in this chapter. The physician should simultaneously evaluate whether the patient has evidence of secondary immune thrombocytopenia and determine the degree of hemostatic impairment.

Cambridge Books Online © Cambridge University Press, 2009

Patients should be carefully examined for evidence of petechiae. Petechiae are rare at platelet counts greater than 20×10^9/l unless there is a platelet function disorder. Petechiae are tiny (1 to 3 mm) collections of red blood cells that have leaked from capillaries. Petechiae are quite specific for thrombocytopenia and should be differentiated from angioma, which are more commonly found on the upper limbs and abdomen than on the feet and lower limbs. Ecchymoses or bruises are much less specific for thrombocytopenia but also provide useful information since they can help alert the physician about the chronicity of the ITP. The rest of the physical examination should focus on looking for secondary evidence of immune thrombocytopenia such as lymphadenopathy, splenomegaly and hepatomegaly.

The laboratory investigations include an accurate platelet count with examination of the peripheral blood film to exclude pseudothrombocytopenia. Other investigations include evaluation of thyroid function because of the strong association of thyroid hypo- and hyper-function with ITP. Antinuclear antibody serology, antiphospholipid antibodies, and anticardiolipin antibodies are performed if there is suspicion of an associated immune disorder. These tests should also be performed if the female patient has had a history of pregnancy losses suggesting the antiphospholipid antibody syndrome. The performance of other investigations, including viral serology (Epstein–Barr virus and HIV serology, etc.), would depend upon the presentation and associated clinical findings.

We would not perform a bone marrow in a patient with typical ITP. However, one should perform a bone marrow aspiration and examination if the patient has abnormalities seen on examination of the stained blood film or when there are multiple blood cell lineages affected. For example, we have identified elderly patients who appeared to have immune thrombocytopenia, but who proved to have a myelodysplastic syndrome. Often, the thrombocytopenia in these patients is accompanied by macrocytosis. Additionally, the diagnosis of ITP should be questioned if the patient has a poor response to standard therapy. The examination of the bone marrow should include special stains plus cytogenetic analysis, since chromosome abnormalities can found in myelodysplastic syndromes. The finding of normal numbers or increased numbers of megakaryocytes in the bone marrow is consistent with the diagnosis of ITP. Although some investigators have described abnormalities of megakaryocytes including multinuclei, we have not found this to be helpful in the discrimination of ITP from other thrombocytopenic disorders.

Although not currently recommended for the diagnosis and evaluation of ITP[2], various other tests are currently being investigated to diagnose and characterize patients with ITP. These tests include the measurement of reticulated platelets[3–6], serum thrombopoietin levels[6–9] and measurement of platelet glycocalicin[6,7,10].

Platelet antibody testing

A variety of tests have been developed to detect platelet-associated antibodies[11,12]. These assays have been classified into three groups termed phase I, II, and III assays according to the time of introduction and to the general technique involved. Initially, in the 1950s, antiplatelet antibodies were detected by phase I assays. These assays involved the mixing of the patient's serum with control platelets from healthy volunteers. Various platelet-dependent endpoints are measured including platelet aggregation, platelet release, platelet lysis and platelet procoagulant formation. These assays have a low sensitivity and specificity for ITP and, therefore, are no longer used for its diagnosis.

Phase II assays detect platelet-associated IgG (PAIgG) by measuring both specific and non-specifically bound IgG (as well as complement and other immunoglobulins) on the platelet surface. Phase II assays are generally superior to phase I assays because they directly detect IgG or complement on the platelet, rather than infer its presence through an indirect endpoint such as platelet activation. The PAIgG is typically measured by one of three methods: two-stage methods, direct binding assays, and total PAIgG assays[12,13]. In the two-stage method, a known amount of anti-immunoglobulin is incubated with washed platelets. The residual anti-immunoglobulin is then measured and the amount of IgG on the platelets is calculated. Direct binding assays use labelled polyclonal or monoclonal anti-human antibodies to directly quantify the amount of IgG bound to platelets. These assays are performed by incubating the washed test platelets with labelled anti-Ig probe. The amount of labelled probe bound to the platelets is then measured. Finally, total PAIgG assays measure the total PAIgG concentration found on the surface and within the platelet. The patient's platelets are lysed which releases IgG from the membrane, cytosol, and alpha-granules. The immunoglobulin can be measured by a variety of techniques including radioimmunoprecipitation and nephelometry. In patients with ITP, the PAIgG is usually elevated, however, the diagnostic usefulness of this test is limited. These assays produce positive results for most thrombocytopenic patients. However, the finding of elevated PAIgG is not specific for or diagnostic of ITP, as levels are also ele-

Cambridge Books Online © Cambridge University Press, 2009

vated in patients with other non-immune-mediated thrombocytopenic conditions[14,15]. In a study by Kelton et al. the sensitivity of the PAIgG test for clinically diagnosed ITP was found to be 91% and the specificity was 27%. The positive predictive value of an elevated PAIgG as a diagnostic test of ITP in a thrombocytopenic patient was only 49%, while the negative predictive value was 82%[15].

Phase III assays measure the binding of antiplatelet autoantibodies to specific platelet glycoproteins. These assays detect and measure platelet glycoprotein-specific antibodies that recognize GP IIb/IIIa and GP Ib/IX. By measuring antibodies binding to specific glycoproteins, these assays overcome the problem of non-specific binding of IgG that complicates phase II assays. The phase III assays include immunoblotting, radioimmunoprecipitation, and antigen capture or glycoprotein immobilization assays[11]. In immunoblotting or Western blotting, the patient's serum is added to platelet proteins that have been separated by electrophoresis and immobilized on nitrocellulose. The binding of a patient antibody to specific protein bands is detected using a labelled anti-Ig probe. In radioimmunoprecipitation assays, the patient's serum is added to radiolabelled platelet membrane proteins. The protein–antibody complexes are precipitated by the addition of an anti-Ig bound to a solid phase. The precipitated platelet proteins are then separated by sodium dodecylsulfate polyacrilamide gel electrophoresis and detected by autoradiography. Antigen capture assays use monoclonal antibodies to capture specific platelet proteins (for example, GP IIb/IIIa). Labelled anti-Ig is used to detect the patient's IgG bound to captured platelet proteins. Large prospective studies have demonstrated phase III assays to have a high specificity for the diagnosis of ITP but to be relatively insensitive[16,17]. In a prospective study, Warner et al. demonstrated the specificity of these assays to be 92% and the sensitivity to be from 39 to 66%[17].

Treatment of idiopathic thrombocytopenic purpura

The most important decision to make is if the patient requires any treatment. Mild to moderate thrombocytopenia in an asymptomatic patient who will not be undergoing hemostatic challenges such as elective surgery, often does not require any treatment. Again, and as noted previously, we would typically not treat patients whose platelet count was above 30×10^9/l and often will treat a patient whose platelet count was less than 20×10^9/l. For asymptomatic patients with mild to moderate thrombocytopenia (platelet count greater than 30×10^9/l), we organize appropriate serological tests and then monitor the platelets, initially on a weekly, then on an every-other-week basis for 3 to 6 months. The patient maintains a symptom diary and also records his or her own platelet count. Typically, patients with mild to moderate thrombocytopenia will have a consistent platelet count over the initial interval of monitoring. We gradually increase the interval of the platelet monitoring to once a month. We have monitored many of these patients and we have found that they tend to maintain a consistent platelet count that decreases only if the patient has had an immune stimulus, such as an infection. The majority of these patients will never be treated, but they are made aware that it may be necessary to raise the platelet count before a hemostatic challenge such as a tooth extraction. For patients with mild to moderate thrombocytopenia undergoing less extensive surgery, we would often treat them with a fibrinolytic inhibitor such as epsilon aminocaproic acid. Platelet transfusions are almost never required.

Patients with severe thrombocytopenia, and platelet counts less than 10×10^9/l, almost always require treatment, particularly if they have evidence of hemostatic impairment. The first line of treatment is corticosteroids or RE blockade. The corticosteroids are typically given as oral prednisone at a dose of one milligram per kilogram (rounded off to the nearest 5 to 10 milligrams); alternatively, RE blockade using Rho (D) immunoglobulin (anti-D) in an Rh positive individual (75 μg/kg intravenously), or high-dose intravenous immunoglobulins (IVIg) at a dose of 1 to 2 grams per kilogram. Both corticosteroids and RE blockade are equally effective and will raise the platelet count in about two-thirds of patients. Corticosteroids are more likely to produce side effects including Cushing's disease, hypertension, diabetes mellitus, and osteoporosis. RE blockade has fewer side effects, but a higher cost. When corticosteroids are used, they should be given for as short an interval as possible and a taper begun as soon as the platelet count has reached hemostatically safe levels, such as greater than 100×10^9/l. During the tapering phase, we will change the patient to alternate day corticosteroids, since this is more likely to have fewer adverse side effects with the same immunosuppressive effects. RE blockade using anti-D or high-dose IVIg causes the platelet count to rise within days, peak within one to two weeks, and then slowly fall over the next four to eight weeks. About 10 to 20% of adult patients who present with apparent acute ITP (no history of bruising prior to presentation) will have a complete recovery of their platelet count or will achieve a safe platelet count off all therapy. The remaining 80% of patients require more definitive therapy, and recognizing this fact, we proceed to splenectomy early in the treatment.

Cambridge Books Online © Cambridge University Press, 2009

Splenectomy

Splenectomy is the definitive therapy for ITP, and we perform this procedure within six months of the first presentation of ITP in adults if the patient requires ongoing therapy. Prior to splenectomy, the patient should receive pneumococcal, meningococcal, and probably *Hemophilus influenza* vaccines. The vaccine should precede the splenectomy by at least two weeks. Patients are prepared for surgery by raising their platelet count before the procedure. Again, platelet transfusions are rarely required, even in those patients with very severe thrombocytopenia who require surgery. Because of its reduced morbidity and significantly shortened hospital stay, laparoscopic splenectomy is preferred over open splenectomy[18]. Splenectomy will result in a long-term remission or cure in more than 70% of patients[19]. In general, patients who do not have a normal platelet count following splenectomy are easier to manage.

Patients who have a complete remission following splenectomy have less than 20% risk of relapse. Patients who do relapse, particularly after a prolonged interval of normal platelet count, should be investigated for the presence of an accessory spleen. Studies using sensitive imaging techniques have shown that as many as 40% of these patients will have residual splenic tissue[20–22]. It is important to recognize that the presence of postsplenectomy changes in the peripheral blood film do not rule out the possibility of an accessory spleen[20,22]. It has been estimated that about half of patients will have a second remission after removal of an accessory spleen, although our personal experience has been less positive[20–22].

Management of a patient with chronic refractory ITP

About one-third of patients with ITP who require therapy will fail splenectomy and have platelet counts less than 20×10^9/l. The optimal approach to these patients remains uncertain. Issues such as age and anticipated natural lifespan, mobility of the platelet count, and, finally, tolerance to medication all must be considered when discussing future therapy. For these patients, we believe that it is particularly important to have a full discussion of treatment options including the risks and benefits. For example, some patients with severe ITP and platelet counts less than 10×10^9/l will not have significant hemostatic impairment, and these patients can be monitored with consideration of short-term interventions such as high-dose IVIg or corticosteroids at the time of hemostatic challenge such as surgery.

A significant proportion of refractory patients require therapy, and we use a 'staircase' approach with the progressive addition of more medicines.

Some patients can be maintained at a safe platelet count using intermittent corticosteroids delivered every few days to every few weeks or high-dose IVIg given every few weeks to every few months. For this type of patient, we arrange outpatient blood testing and recommend that the patient maintain a diary of symptoms as well as record their own platelet count. Sometimes, patients can be managed with sufficiently low doses of corticosteroids given at sufficiently long intervals that long-term side effects are minimized. If larger doses of corticosteroids are used, steps should be taken to prevent osteoporosis.

The next 'step in the staircase' is the addition of the anabolic steroid danazol, which can be delivered at doses of 200 to 1200 milligrams per day. This drug causes dose-dependent elevation of liver enzymes and can cause hepatotoxicity. Therefore, its use requires careful monitoring and seldom can patients be maintained at high doses for long intervals. Vinca alkaloids, such as vincristine and vinblastine occasionally can cause a short-term rise in the platelet count, but treatment is usually limited by dose-dependent neurotoxicity. These medications are usually administered intravenously at weekly intervals. Some investigators have reported remissions induced by the administration of platelets that have been incubated with either vincristine or vinblastine[23,24]. However, equivalent responses have been obtained by simply infusing these medications[25].

Refractory patients who do not respond to any of these manoeuvres have about a 50% likelihood of responding to any of the following agents, which we typically use in combination: cytotoxic agents, such as cyclophosphamide or azathioprine, and broad immunosuppressant agents such as cyclosporine. For both of these classes of agents, we administer them orally and at moderate doses over long intervals. Typically, an interval of 3 to 6 months is required to know whether a patient will respond to therapy. It is our opinion that some of the most common errors in managing patients with severe and refractory ITP is the ongoing use of potent agents which produce side effects (corticosteroids, vinca alkaloids, cytotoxic agents, etc.), when the patient has had no response. Sometimes, we see patients who have had greater morbidity from the treatment than from nontreated disease.

Emergency treatment of ITP

Patients with ITP who have acute or potentially catastrophic bleeding require aggressive therapy including platelet transfusions, high dose IVIg, and high-dose corticosteroids, in addition to standard resuscitation that can include blood replacement if required.

Cambridge Books Online © Cambridge University Press, 2009

Experimental treatments of ITP

A large number of new therapies for ITP are currently being investigated. Emilia et al., in a small number of patients, have demonstrated that eradication of *Helicobacter pylori* infection led to a complete response in 33% of patients treated and a partial response in 17% of patients[26]. Other agents being investigated for the treatment of refractory ITP include rituximab, an anti-CD20 monoclonal antibody[27,28], rhuIL-11[29], MDX-33, a monoclonal antibody directed against the Fcγ1 receptor[30], taxol[31] and immunoabsorption over a protein-A sepharose column[32,33].

ITP in pregnancy

Because ITP is a common illness that affects young women, physicians often manage pregnant patients with ITP. In this area, there has been a dramatic evolution in our understanding of the natural history, the outcome for both mother and infant, and consequently the requirement for intervention. We remind pregnant patients with ITP that their overall morbidity and the risk to their infant is very small. Nonetheless, they will require frequent physician visits during the pregnancy with careful monitoring of both mother and infant at the time of delivery. In the past, physicians tended to assume that ITP was the usual cause of thrombocytopenia in pregnancy. We now recognize that immune disorders of pregnancy are uncommon and contribute overall to less than five percent of all episodes of thrombocytopenia in pregnancy. Large prospective studies have shown that about 74% of thrombocytopenias in pregnancy are caused by incidental thrombocytopenia of pregnancy; 21% are caused by hypertensive disorders of pregnancy; and 4 percent are caused by immune disorders of pregnancy[34] (Fig. 36.2).

Incidental thrombocytopenia of pregnancy is defined as mild thrombocytopenia (platelet count of 80 to 150×10^9/l) that occurs at the time of delivery in an otherwise well woman. This is not a disorder, nor does it have implications for mother or her infant. By investigating a large cohort of these women, we have found that these women can safely have epidural analgesia at the time of delivery, and their infants are well and not thrombocytopenic.

Approximately 2 in 1000 births are delivered to women with ITP, and overall ITP accounts for three percent of women with thrombocytopenia in pregnancy[35]. A series of prospective and retrospective studies have clarified the risk to the infant if the mother has ITP. About 10% of infants born to mothers with ITP will have a platelet count less than 50×10^9/l, less than 5% will have a platelet count less than 20×10^9/l, and less than 1% of the infants will have severe thrombocytopenia[36]. ITP remains a challenge for

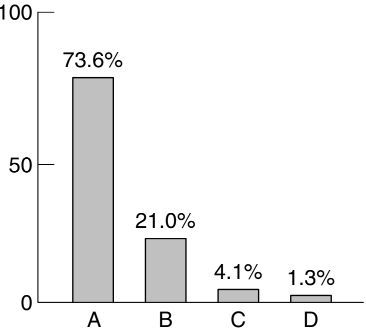

Fig. 36.2. A schematic representation of the overall frequency of the different causes of low platelets in pregnant patients. This figure was constructed from a large prospective study of some 15 000 mother–infant pairs[34].

physicians because there remains a risk, although it is less than 1%, that patients with ITP in pregnancy will have catastrophic outcomes. In utero death due to fetal hemorrhage is described, as is the occurrence of severe thrombocytopenia in the infant after delivery. Many studies have attempted to identify which infant will have thrombocytopenia. There is general agreement that the maternal platelet count and measurement of IgG in maternal plasma cannot be used to predict which infant will be thrombocytopenic[34,37–47]. The best predictor appears to be whether the mother had a previously thrombocytopenic infant[44,46,48,49]. Because of this dilemma, and the fact that some infants born to mothers with ITP will have severe thrombocytopenia, investigators have studied a number of approaches for measuring the infant's platelet count in utero. These have included percutaneous umbilical blood sampling (PUBS) and fetal scalp sampling. We do not favour either approach. Depending upon the centre and their experience, PUBS carries a 2 to 5% procedure-related complication rate[50]. We believe it is difficult to justify any diagnostic manoeuvre with a morbidity or mortality rate that is higher than the illness itself.

Fetal scalp sampling can be performed when the membranes are ruptured and the cervix has begun to dilate. However, our experience and that of others is that this test often produces an erroneously low infant platelet count, which could lead to unnecessary intervention.

During the pregnancy, we monitor the woman's platelet counts. The frequency of platelet count measurement is related to the severity of the maternal thrombocytopenia.

Cambridge Books Online © Cambridge University Press, 2009

Because the platelet count typically worsens later in the pregnancy, we increase the frequency of monitoring to once every one to two weeks in the later part of pregnancy. If intervention is required, we prefer RE blockade using high-dose IVIg over corticosteroids, since corticosteroids have been associated with hypertension in pregnancy. Our approach to the investigation and management of ITP in pregnancy is discussed at length elsewhere[36]. It is important to alert the neonatologists that a woman with ITP will soon deliver. A platelet count should be collected from the cord sample at the time of delivery with future monitoring related to this count. Most infants will have a further fall in their platelet count for several days following delivery, and the majority has the platelet nadir by day two. Treatment includes corticosteroids and high-dose IVIg. Platelet transfusions should be given if bleeding is present or if the thrombocytopenia is particularly severe.

Secondary immune thrombocytopenias

Immune thrombocytopenia can occur in association with a variety of systemic disorders. These diseases are typically disorders of immune dysregulation and include infections, collagen vascular diseases such as systemic lupus erythematosus, lymphoproliferative disorders, and other autoimmune diseases (Table 36.2). Treatment of the thrombocytopenia includes treatment of the underlying disease and therapies as described for ITP. In some conditions, notably Evan's syndrome, the thrombocytopenia is less responsive to therapies.

Table 36.2. Secondary associations of immune thrombocytopenia

Infections
Human immunodeficiency virus
Varicella
Epstein–Barr virus
Collagen vascular disease
Systemic lupus erythematosus
Rheumatoid arthritis
Progressive systemic sclerosis
Sjogren's syndrome
Lymphoproliferative disorders
Chronic lymphocytic leukemia
Hodgkin's disease
Non-Hodgkin's lymphoma
Other
Antiphospholipid antibody syndrome
Autoimmune thyroid dysfunction
Sarcoidosis
Post-bone marrow transplantation
Inflammatory bowel disease
Autoimmune hemolytic anemia (Evan's syndrome)
Bullous pemphigoid
Myasthenia gravis

Human immunodeficiency virus (HIV)-associated ITP

Thrombocytopenia is common, occurring in approximately 20% of patients with symptomatic disease and 9% of asymptomatic seropositive patients[51]. Thrombocytopenia may be the presenting manifestation of HIV infection and the risk of HIV should be assessed in any ITP patient with HIV risk factors. Patients have immune-mediated destruction of their platelets, similar to ITP. Other mechanisms also contribute to the thrombocytopenia including a defect in platelet production due to direct infection of megakaryocytes and sometimes the suppressive effects of medications. Patients with severe thrombocytopenia should be treated similarly to patients with ITP. Most patients respond to steroid therapy, however, only 10 to 20% will have a sustained response[52]. It has been suggested that the use of high-dose dexamethasome may actually be detrimental[53]. IVIg induces a transient improvement in the platelet count, but patients will require repeated treatments[54]. Splenectomy will induce improvement in most patients and there is no evidence that it increases the rate of progression to acquired immunodeficiency syndrome[55]. Treatment with retroviral medications also has a modestly beneficial effect on the thrombocytopenia[55,56]. Interferon-alpha may be a safe and effective treatment of zidovudine-resistant thrombocytopenia[57].

Thrombocytopenia complicating systemic lupus erythematosus

Thrombocytopenia can occur in up to 25% of patients with systemic lupus erythematosus (SLE)[58]. The thrombocytopenia is usually caused by autoantibodies. Some patients will also have concomitant platelet dysfunction characterized by increased bleeding and bruising. The treatment is similar to that for ITP, although the response to splenectomy may be lower with studies showing only 14% of patients not requiring additional treatment after splenectomy[59].

A subset of patients with SLE or SLE-like disorders have antibodies which interfere with phospholipid-dependent coagulation reactions, commonly detected by an unexplained elevation of the patient's prothrombin time (PT) or

Cambridge Books Online © Cambridge University Press, 2009

international normalized ratio (INR). These antibodies are immunoglobulins with specificity for negatively charged phospholipids and are termed as lupus anticoagulant antibodies. They tend to be heterogenous in their epitope specificity with most binding protein complexes including β_2-glycoprotein I[60]. Another class of antibodies, the anticardiolipin antibodies, is detected by an enzyme-linked immunosorbent assay (ELISA) using cardiolipin as the antigen. Cardiolipin is a lipid present in high concentrations in the inner membrane of mitochondria. This is the same antigen that is detected in the VDRL test for syphilis, which explains the false positive VDRL test in these patients. The two classes of antibodies are distinct, but likely have overlapping specificities. In fact, most anticardiolipin antibodies actually recognize an epitope on β_2-glycoprotein I. The term 'antiphospholipid antibodies' applies to both sets of antibodies.

Antiphospholipid antibodies can be associated with both venous and arterial thrombosis. The antiphospholipid antibody syndrome is a syndrome that can include any combination of arterial and venous thrombosis, recurrent fetal losses and thrombocytopenia. In the literature, thrombocytopenia has been found to occur in approximately 20 to 60% of patients with antiphospholipid antibody syndrome[61–63]. The diagnosis should be considered in patients who develop such events as idiopathic deep vein thrombosis, arterial thrombosis, or thrombosis in highly unusual sites. Many of these patients will also have an unusual vascular rash termed livedo reticularis. Patients can have hematologic abnormalities including mild thrombocytopenia, platelet dysfunction and, less commonly, autoimmune hemolytic anemia and leukopenia. As the thrombocytopenia is usually mild, treatment is rarely necessary. Many patients require long-term anticoagulation therapy to prevent recurrent thrombotic events.

Thrombocytopenia secondary to lymphoproliferative disorders

Immune thrombocytopenia commonly complicates chronic lymphocytic leukemia (CLL)[64]. This should be differentiated from thrombocytopenia of underproduction, which is seen in the spent stage of CLL. Immune thrombocytopenia is seen in 1 to 2% of patients with Hodgkin's disease and can predate or postdate the illness[65]. When it occurs after the illness, it does not necessarily indicate a relapse of disease. In some patients, the thrombocytopenia will resolve with treatment of the underlying malignancy. In others, the thrombocytopenia requires specific treatment. These patients should be treated similarly to patients with ITP.

Alloimmune thrombocytopenia

Alloimmune thrombocytopenia is caused by alloantibodies against specific platelet glycoproteins. Alloimmune thrombocytopenic disorders include alloimmune neonatal thrombocytopenia, post-transfusional purpura and refractoriness to platelet transfusions. Alloimmune thrombocytopenia has also been documented after organ transplantation[66].

Alloimmune neonatal thrombocytopenia

Alloimmune neonatal thrombocytopenia is mediated by alloantibodies in maternal plasma directed against paternal alloantigens on fetal platelets[67]. The most common and most important alloantibody to cause this disorder in the Caucasian population is targeted against a platelet glycoprotein termed PL^{A1} (also known as HPA-1a) located on platelet glycoprotein IIIa[68]. The risk of developing neonatal alloimmune thrombocytopenia appears to be associated with maternal HLA antigens, predominantly HLA DRB3*0101 or DQB1*02[69]. This disorder causes severe and often life-threatening fetal thrombocytopenia that can occur in utero. Intracranial hemorrhages occur in 10 to 15% of untreated infants with neonatal alloimmune thrombocytopenia with almost half of these hemorrhages occurring *in utero*[68]. To confirm the diagnosis of neonatal alloimmune thrombocytopenia, serological and genetic testing of both the father and the mother must be performed.

Post-transfusion purpura

Post-transfusion purpura (PTP) is a rare transfusion reaction. The patient, usually a woman, develops severe thrombocytopenia 5 to 12 days after receiving a transfusion of a blood product containing platelets. The thrombocytopenia is often very severe (platelet count less than 10×10^9/l). Post-transfusional purpura occurs when a patient produces an alloantibody to a specific platelet antigen that she lacks. The antigen usually implicated is PL^{A1}. Similarly to neonatal alloimmune thrombocytopenia, the risk for developing PTP is increased in HLA-DR3-positive individuals[70]. The syndrome most commonly occurs in multiparous women because previous pregnancies lead to their sensitization. Rarely, patients (including men) who have previously been transfused are also at risk.

Platelets of both the donor and the patient are destroyed. The destruction of the donor platelets occurs because of the presence of platelet-specific alloantibodies. There is no clear explanation for why the recipient's platelets are also destroyed.

Cambridge Books Online © Cambridge University Press, 2009

The diagnosis of PTP is made by the identification of a platelet-specific antibody in a patient with acute onset of thrombocytopenia five to twelve days after receiving a transfusion of a blood product. Although PTP is most commonly seen after transfusion of packed red blood cells, all blood products, including plasma, can cause the reaction. PTP is self-limited with recovery usually occurring within 1 to 3 weeks. However, because the condition can be lethal, treatment with plasmapheresis or IVIg should be considered. Platelet transfusions should be avoided except in cases of life-threatening hemorrhage.

Refractoriness to platelet transfusions

Alloimmunization is also seen in patients receiving repeated platelet transfusions. In these patients, development of alloantibodies, usually against HLA class 1 antigens, results in the patient being refractory to further platelet transfusions. If alloimmunization is suspected, the patient may have a better increment in platelet count if he is transfused with platelets from a HLA-compatible donor.

Drug-induced thrombocytopenia

Many drugs have been demonstrated to cause thrombocytopenia. The medications most commonly implicated include heparin, quinidine, sulfonamides and gold. However, virtually every medication has been associated with thrombocytopenia and the diagnosis should be considered in any patient who develops unexpected thrombocytopenia.

Patients with drug-induced thrombocytopenia typically have moderate to severe thrombocytopenia and can present with symptoms such as petechiae and mucosal bleeding. The thrombocytopenia is usually seen one to two weeks after beginning a medication, but it may occur unpredictably in patients who have been taking the medication for several years. The platelet destruction is usually IgG-mediated, although it can be mediated by IgM or complement. The thrombocytopenia usually resolves within days of stopping the causative drug. In cases of severe thrombocytopenia, the patient may be treated by reticuloendothelial blockade using either IVIg or intravenous Rho (D) immune globulin if the patient is Rh-positive. Treatment with corticosteroids is less effective. In cases of life-threatening hemorrhage, platelet transfusions may be required. Patients should be instructed to not take the drug causing the thrombocytopenia again as it will cause thrombocytopenia with subsequent exposure. If required, a structurally different drug should be substituted.

Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is the most important drug-induced thrombocytopenia. Heparin causes thrombocytopenia in 1 to 3% of patients exposed[71]. It usually develops between five and eight days after the initiation of heparin therapy but if the patient has been exposed to heparin within the last 3 months, the thrombocytopenia can occur earlier[72]. Patients develop mild to moderate thrombocytopenia, with platelet counts commonly ranging from 40 to 80×10^9/l. In addition, patients with HIT frequently develop thrombotic complications, especially deep venous thrombosis and pulmonary embolism. Other clinical associations include arterial thrombosis, skin lesions, and uncommon thrombotic events such as adrenal gland thrombosis and hemorrhage.

HIT is caused by an IgG antibody which recognizes a complex of heparin and platelet factor-4 (PF-4)[73,74]. Heparin itself is not immunogenic; rather, the immunogenicity arises from the conformational change in the PF-4 caused by heparin. The PF-4/heparin/IgG immune complexes bind to platelet Fc receptors causing platelet activation and microparticle formation with resulting activation of coagulation[75,76].

The frequency of HIT varies among clinical settings. The risk of thrombocytopenia also appears to be related to the type, dose and duration of heparin administration. For example, unfractionated heparin is more immunogenic than low molecular weight heparin preparations. As well, different patient populations have different risks of forming HIT-IgG. For example, the risk of HIT-IgG is higher in orthopedic patients than in medical patients[77].

The diagnosis of HIT should be considered in all patients receiving heparin therapy who develop thrombocytopenia or the clinical manifestations discussed previously. Other causes of thrombocytopenia should be excluded. Serological tests are used to confirm the diagnosis of HIT. The ELISA-based test was described by Amiral and colleagues[73]. This assay measures the binding of platelet antibodies to a complex of heparin and PF-4. The gold standard tests are biological assays, such as the ^{14}C-serotonin release assay[78]. In these assays, ^{14}C-serotonin labelled platelets from normal donors are incubated with the test serum. The amount of ^{14}C-serotonin released is quantified as a measurement of platelet activation. These assays are more complex and time consuming than the ELISA-based assays. Recent studies have shown that many patients who make the antibodies that cause HIT will not go on to develop the thrombocytopenia or thrombotic complications.

Treatment of HIT involves discontinuation of heparin.

Cambridge Books Online © Cambridge University Press, 2009

The patient should be treated with an agent that inhibits thrombin generation, such as hirudin or argatroban. Warfarin should not be used to treat acute HIT because it can trigger warfarin-induced limb gangrene. In addition to reducing the circulating concentrations of the vitamin K-dependent clotting factors, warfarin also reduces the levels of protein C and protein S, which act as natural anticoagulants.

Gold-induced thrombocytopenia

Gold-induced thrombocytopenia occurs in as many as 3% of patients treated with this medication[79]. There appears to be a genetic predisposition to the syndrome with HLA DR3 occurring in up to eighty percent of affected patients[80]. The thrombocytopenia usually occurs within the twenty weeks of therapy and can range from mild to severe. The initial management of gold-induced thrombocytopenia is to stop the drug and provide supportive treatment if required. Despite discontinuation of the medication, the thrombocytopenia can persist for many months or even years[81]. This is likely due to persistence of an autoantibody, but may also be due to the prolonged release of gold from tissue stores. Rapid correction of the thrombocytopenia may be achieved with IVIg; however, a relapse of the thrombocytopenia may occur in two to four weeks once the effects of the IVIg have worn off. Patients also respond to corticosteroids. Some patients with persistent thrombocytopenia may respond to splenectomy or immunosuppressive medications. Gold-chelating agents such as dimercaprol or N-acetylcysteine may promote gold excretion[82–84].

Quinidine-induced thrombocytopenia

Quinidine or quinine may cause thrombocytopenia in approximately 0.1 to 0.2% of patients, however, it is often difficult to establish a history of drug ingestion because quinidine is present in many tonics and beverages. Patients often present with severe thrombocytopenia and bleeding. In quinine-induced thrombocytopenia, the antibody recognizes a quinine-platelet complex or a drug-induced neoantigen on the platelet surface[85]. The antibody-bound platelets subsequently are rapidly cleared by the Fc receptors of the reticuloendothelial cells. The platelet count usually returns to normal within several days of stopping the medication.

Thrombocytopenia in childhood

C. Kaplan, M. Dreyfus, V. Proulle, G.Tchernia

Unité d'Immunologie Plaquettaire, INTS, Paris, France

Thrombocytopenia in children as in adults has a pleiomorphic expression, which may vary from a life-threatening hemorrhagic accident, to a biological finding in an apparently healthy child. In many patients clinical expression is absent or mild and thrombocytopenia will be fortuitously detected by blood cell counts during the course of a disease or prior to surgery. Neonatal thrombocytopenias also have special features requiring special diagnostic approach and management.

Platelet counting by blood cell automatic counters usually is reliable. However, in some situations, platelet counting can be erroneous; for example, circulating particles whose volume is within the platelet volume range can spuriously increase the platelet count and mask a thrombocytopenia; this can occur with extreme microcytosis or red cell fragmentation. On the contrary, in vitro platelet consumption, due to hemostasis activation during sampling or inefficient anticoagulation of the sample or to EDTA-induced platelet aggregation[1], can lead to spurious thrombocytopenia. In any case, an initial diagnosis of thrombocytopenia must be verified by phase contrast microscopy after microsampling, and by examination of the platelets' size, morphology and density on blood smears. There is no close correlation between clinical presentation and platelet count. Most patients will have minimal bleeding symptoms even with platelet counts below 50×10^9/l. Others can exhibit bruising and bleeding in spite of moderate thrombocytopenia due to associated platelet functional abnormalities. The search for a precise etiology, which can be either constitutional or acquired, needs a rigorous approach, as therapeutic decisions have to rely on certainties (Table 37.1).

In this chapter drug-induced thrombocytopenia and thrombocytopenia associated with malignancies will not be considered.

Diagnostic approaches to thrombocytopenia in infancy and childhood

Thrombocytopenia is defined by a platelet count less than 150×10^9/l. Due to the difficulties already described, blood smear examination, micro-sampling, phase microscopy, coagulation assessment and repeated platelet counts are mandatory to confirm the diagnosis, whatever the patient age. As in adults, thrombocytopenia results either from increased platelet destruction or decreased platelet production. This distinction can be difficult as in many disorders multiple factors can be involved in the etiology of thrombocytopenia.

Furthermore, the distinction between these two mechanisms may be difficult to achieve especially in neonates.

(i) Blood sampling is often difficult, and the small volume available allows limited biological studies.
(ii) Bone marrow aspiration and biopsy are technically difficult and megakaryocytes at birth can be located elsewhere than in the bone marrow. Being more and more aware of the importance of pain in very young infants, we are prone to avoid such investigations unless they appear absolutely necessary.
(iii) Radioactive studies of platelet kinetics are not usually performed in infants.

Determination of thrombopoietin (Tpo) levels can be of help for differential diagnosis of thrombocytopenia. Tpo, also known as Mpl ligand, is considered to be the major regulator of thrombopoiesis, promoting proliferation, growth and development of megakaryocytes from CD34+ cells, polyploïdization and proplatelet formation. Studies have been performed in the fetus and neonate to assess Tpo levels in normal and thrombocytopenic state. It has been shown that Tpo is present in higher concentrations in cord blood than in adults' serum samples and that the level does not correlate with either gestational age or platelet

Table 37.1. Etiology of thrombocytopenia in childhood

Acquired thrombocytopenias	Immunologic processes	Autoimmunity	AITP
			Neonatal thrombocytopenia due to maternal autoimmunity
		Alloimmunization	Neonatal alloimmune thrombocytopenia
	Non-immune processes	Infections	
		Increased platelet consumption	Disseminated intravascular coagulation
			Hemolytic uremic syndrome
			Thrombotic thrombocytopenic purpura
			Kasabach–Meritt syndrome
			Miscellaneous causes
Inherited thrombocytopenias		Small platelet size	Wiskott–Aldrich Syndrome
			X-linked thrombocytopenia
		Inherited giant platelet disorders	May–Hegglin disease, Alport syndrome, Fechtner syndrome
			Bernard–Soulier syndrome
			Grey platelet syndrome
			von Willebrand 2B syndrome
		Normal platelet volume	Thrombocytopenia with absent radii (TAR) syndrome
			Congenital amegakaryocytic thrombocytopenia
			Paris–Trousseau thrombocytopenia

count at birth[2]. A majority of neonates with hypogenerative thrombocytopenia have low levels of Tpo when compared to those reported in adults[3,4]. Appropriate references must be considered if Tpo assays are used for distinguishing thrombocytopenia associated with decreased platelet production from thrombocytopenia resulting from increased platelet destruction.

In these neonatal cases, it is therefore of prime importance to collect any available information, which may assist in diagnosis: maternal history of thrombocytopenia, recent bacterial infection or disseminated intravascular coagulation (DIC) must be searched for. Maternal platelet counts and neonatal coagulation tests should be available. A previous history of neonatal thrombocytopenia in the siblings or relatives is important and in some cases immunological tests for maternofetal alloimmunization should be carried out.

In childhood, acute autoimmune thrombocytopenic purpura (AITP) is the most frequent cause of thrombocytopenia and the diagnosis is usually made on clinical evidence after exclusion of other obvious causes:

(i) the sudden occurrence of a severe thrombocytopenia, associated with an extensive purpura and/or mucosal hemorrhage in an otherwise healthy child;
(ii) a recent viral infection/ vaccination in the child or a sibling.

The presence of an isolated, severe thrombocytopenia usually confirms the diagnosis. A bone marrow study is mandatory only in cases of atypical clinical or biological features, or for some authors before a steroid therapy is instituted in order to rule out a leukemia or a myelodysplasic syndrome.

The detection of specific autoantibodies using antigen-capture assays (Immunobead assay[5], MAIPA test[6,7]) is not mandatory, but may be of help in case of equivocal diagnosis. The indirect MAIPA is less likely to be positive in AITP than the direct MAIPA[8]. However, these assays are not easily available for routine diagnosis.

As in neonates, Tpo assays can be considered in the differential diagnosis to determine the mechanism of the thrombocytopenia[9]. The results must be compared to the normal range defined according to age.

In the case of chronic thrombocytopenia, other investigations, such as isotopic studies, are required to further confirm the diagnosis before therapeutic decisions such as splenectomy are made.

Platelet aggregation studies, vWF cofactor activity assays, platelet counts and vWF assessment in the parents and siblings, and platelet glycoprotein studies will be performed in cases of suspected inherited thrombocytopenia.

Acquired thrombocytopenia

Immunologic processes

Autoimmunity

Neonatal thrombocytopenia due to maternal autoimmune thrombocytopenic purpura

Autoimmune thrombocytopenic purpura (AITP) in pregnant women can induce moderate or severe thrombocytopenia in the fetus or in the newborn whatever the mother's disease status. It may occur notwithstanding splenectomy, in babies of thrombocytopenic mothers or of mothers with normal platelet counts due to compensated thrombocytolysis.

It is unpredictable and occurs in 30–40% of cases. For most authors none of the mother's clinical or biological parameters can predict the risk of thrombocytopenia in the newborn[10]. However, more recently studies have shown that severe neonatal thrombocytopenias are more often found in offspring of women with previous splenectomy[11]. Furthermore, mothers with AITP and HLA DRB3* phenotype seem to be protected against giving birth to a thrombocytopenic newborn; in contrast HLA DR02, DR5* could provide a higher risk. This last report, if confirmed by a multicentric study, could constitute a predictive factor useful in the management of pregnancy and of the newborn[12]. It has been shown that, despite the absence of prenatal bleeding in most cases, thrombocytopenia could be found as early as 20 weeks of gestational age and increases as gestation proceeds. Fetal thrombocytopenia cannot be prevented: intravenous immunoglobulins (IVIgG) or steroids, even if effective in raising the mother's platelet counts, do not appear to be able to decrease fetal platelet destruction[13].

The mode of delivery of mothers with AITP has evolved during the past years. Cesarean sections have been advocated to avoid potential intracranial hemorrhage in severely thrombocytopenic fetuses, whereas vaginal delivery has been suggested to bear a higher risk. In order to determine the mode of delivery and to decrease the rate of unnecessary cesarean sections, percutaneous umbilical blood sampling has been advocated. More recently the rationale for the assessment of fetal platelet counts has been subject to controversy.

(i) Up to now there is no prospective study showing that cesarean section is more effective in preventing intracranial hemorrhage than vaginal delivery.
(ii) In pregnant women with AITP, severe fetal thrombocytopenia is observed in only 10 to 15% of the cases.
(iii) Not all fetuses with severe antenatal thrombocytopenia will suffer intracranial bleeding.
(iv) Percutaneous umbilical blood sampling (PUBS) has a 0.5–1.5% complication rate.

Therefore PUBS is not recommended in this situation unless there has been severe bleeding in the offspring. In these cases, PUBS, if decided, must be performed in a referral centre and at the end of pregnancy. In our practice, in case of obstetrical complications and suspicion of severe fetal thrombocytopenia, we propose cesarean delivery as an alternative.

After birth, close monitoring of the newborn platelet count is recommended. Eventuality of an associated impairment of platelet function due to the interaction of autoantibodies with their epitope must not be ignored, and neonatal bleeding associated with moderate thrombocytopenia has been reported in such cases. Neonatal thrombocytopenia usually worsens during the first days of life with a nadir on day 3 to 5 and lasts from 10 to 60 days. Postnatal management includes IVIgG which has been shown to be effective most of the time, and low dose steroid therapy, which may be prescribed as an hemostatic agent. Exchange transfusion has only a moderate and transient effect but can be proposed in case of severe bleeding (Table 37.2).

Table 37.2. Neonatal thrombocytopenia due to maternal autoimmune thrombocytopenic purpura (AITP)

The fetal/neonatal thrombocytopenia is unpredictable:
30–40% of infants born to mothers with AITP will be thrombocytopenic
10–15% of infants will be severely thrombocytopenic but only 0–3% of infants with intracranial hemorrhage
No antenatal therapy to reverse fetal thrombocytopenia
Delivery:
vaginal delivery in most cases
cesarean section in case of obstetrical complications and suspicion of severe fetal thrombocytopenia
After birth:
close monitoring of the newborn platelet count
nadir of the neonatal thrombocytopenia on day 3–5
neonatal thrombocytopenia observed from 10 to 60 days
therapy: IVIgG, exchange-transfusion in case of severe bleeding

Acute AITP in childhood

Acute AITP is a frequent disease occurring in most cases between 2 and 8 years of age. It is generally a benign, self-limited condition with, in 80–90% of cases, a spontaneous

Cambridge Books Online © Cambridge University Press, 2009

recovery within a matter of days or weeks. The incidence has been reported to be 5.3 per 1 000 000 children under 15 years[14]. It often follows a seasonal viral illness, most often upper respiratory tract infection occurring within the 4 weeks before the child presents with thrombocytopenia. Vaccination, infectious mononucleosis, varicella, or various non-diagnosed erythemas can also be incriminated[15]. The male : female ratio is 1. Bruising and mucosal hemorrhage are often the first symptoms with an abrupt onset. The characteristic features are isolated thrombocytopenia and normal to increased numbers of megakaryocytes in the bone marrow[16]. The severity of thrombocytopenia reflects the balance between antibody-mediated platelet destruction and increased platelet production from megakaryocytes. The risk of severe bleeding is correlated with the clinical expression: nasal bleeds, menorrhagias in girls, hemorrhagic bullae inside the mouth on the internal face of the cheek, can alert to the potential severity of the disease.

The association with any coagulation abnormality can enhance the risk for bleeding and call for adapted management. Storing frozen serum samples can be of a great help for further immunological or viral investigations, which might not appear to be of interest at presentation. Bone marrow aspirate is recommended in all children with acute AITP if clinical presentation or laboratory features are atypical and in those children treated with IVIgG or short-term oral steroids who either fail to respond or require retreatment[17]. Approximately 10–20% of children with acute AITP will develop the chronic variety (Table 37.3).

Table 37.3. Autoimmune thrombocytopenic purpura (AITP) in childhood

Acute AITP
frequent disease between 2 and 8 years of age
generally benign with in 80–90% of cases a spontaneous recovery
viral infections have been incriminated
abrupt onset of bruising and mucosal hemorrhage
isolated thrombocytopenia with normal to increased numbers of megakaryocytes
bone marrow aspirate is recommended in all children if clinical presentation or laboratory features are atypical or in case of failure therapy with IVIgG or short-term oral steroids
therapy is controversial: steroids, IVIgG
Chronic AITP
disease persisting for more than 6 months
intracranial hemorrhage in less than 0.1% of the cases and in 0.5% of the cases with a platelet count persistently $<20\times10^9$/l 12 months after the diagnosis
therapy: IVIgG steroids; splenectomy has to be restricted to particular cases with refractoriness to all medical treatments, persistent bleeding tendency, risk for cerebral hemorrhage or unacceptable side effects of medical therapy
Emergency therapy
for patients with significant mucosal bleeding or extremely low platelet counts
hospitalization and therapy with a combination of IV steroids, IVIgG and platelet transfusion

Chronic AITP

Chronic AITP implies disease persisting for more than 6 months, which is an arbitrary threshold. The diagnosis of chronic AITP is mainly a process of exclusion, which is based on considering non-immune causes of long-term isolated thrombocytopenia such as various congenital thrombocytopenias and type 2B von Willebrand disease and also excluding immune-mediated thrombocytopenia associated with multisystem autoimmune disease or more generalized immune dysfunction[18]. A major difference will exist between children with repeated clinical manifestations and those who disclose only laboratory evidence of persistent antiplatelet autoimmunity, with no hemorrhagic symptoms[18]. Some features have been claimed to be predictive of the development of a chronic form of AITP, such as insidious presentation, female sex, age over 10 years, symptoms lasting for more than 2 weeks after diagnosis[19]. The incidence of life-threatening hemorrhage is lower than previously reported. Intracranial hemorrhage occurs in less than 0.1% of the cases and in 0.5% of the cases with a platelet count persistently $<20\times10^9$/l 12 months after the diagnosis[20]. There may be associated predisposing factors such as trauma or vascular malformations.

Most importantly, thrombocytopenia will resolve or switch from a severe to a mild form in the majority of children with chronic AITP, with an estimate of 30% at 2 years and 61% after 15 years[21] (Table 37.3).

Therapy of AITP in childhood

The therapeutic decision should mostly rely on clinical severity, but most surveys have shown a generalized tendency to treat platelet counts rather than bleeding symptoms[14,22] (Table 37.3).

Acute AITP

The aim of the treatment is only to shorten the risk period by increasing the platelet count before a spontaneous increase takes place. Initial treatment does not change the total duration of the illness and does not reduce the number of patients whose disease becomes chronic. Most

Cambridge Books Online © Cambridge University Press, 2009

authors consider that in AITP platelet counts above 30×10^9/l without overt cutaneous or mucosal hemorrhage do not require treatment in the absence of trauma or need for surgery. The decision of initial therapy is based individually on a combination of platelet count and clinical factors. Controversy exists about most published guidelines[18,23–25]. Owing to the rarity of intracranial bleeding, it has been suggested by some authors that initial treatment should not be prescribed in most cases, provided the patients are under close control until the platelet count begins to rise. A subgroup of children should, in any case, be treated: those with platelet count $<20 \times 10^9$/l, if additional risk factors such as head trauma or recent use of aspirin are identified. If a treatment is decided, the minimum therapy necessary to increase the platelet count to a safe level should be prescribed[26]. For many years, most pediatricians have used prednisone at a dose of 1–2 mg/kg as initial treatment for 10–28 days[27]. In most cases this leads to a stable increase in platelet counts within a few days and to a more rapid disappearance of petechiae and bleeding symptoms. When the dose is tapered, the platelet count can drop and clinical expression may reappear in some patients: in that case both evolution towards chronic AITP and subsequent spontaneous resolution can be observed. In any case, steroids should never be given for a prolonged period and, should the evolution be prolonged, other therapeutic approaches must be proposed. Short-term oral prednisone (4 mg/kg/day $\times$ 4 days) is probably a good alternative[28].

IVIgG has been shown to increase transiently the platelet count in patients with AITP[29,30]. The most frequently recommended dosage has been 0.8 g/kg/day[26]. The increase can occur in the 12–72 hours following the infusion. In most cases of acute AITP, a spontaneously favourable outcome is reached during the time of the therapeutic response. The major limitations are the price of the product, the time necessary for its administration in outpatients, the problems of viral safety, and some side effects such as meningitis or renal complications[26,31,32]. Platelet transfusions are not a treatment of immune AITP. However they may be considered, in conjunction with other treatments, for patients in whom a rapid rise in platelet count is deemed essential, that is before surgery, after significant trauma, or because of life-threatening mucosal or internal hemorrhage[25,27]. Intravenous rhesus antibodies have been shown to be less effective than steroid or IVIgG in acute AITP and should not be used as a first-line therapy[26].

Chronic AITP

Prior to any treatment, the diagnosis has to be firmly established in order to avoid potentially harmful therapy for other diseases, mostly constitutional thrombocytopenias[33], SLE- or HIV-related thrombocytopenias. In most cases a sharp rise is obtained with high dose IVIgG but the response duration will not exceed 1–6 weeks before relapse occurs. However, IVIgG is of major interest in two settings: (i) when a transient increase in platelet count is necessary, e.g. for surgery; (ii) in some patients regular IVIgG infusions can maintain a 'safe' platelet count and a normal life for several months, with an injection on an outpatient basis every 3–6 weeks. Moreover, in some of these patients the interval can gradually be increased. This strategy can provide the necessary time to learn the degree of tolerance and the natural history of the disease before discussing splenectomy or waiting for a favourable evolution.

Splenectomy results in a much higher cure rate than any medical regimen. The overall response rate averages 70%, with 14% relapse. An additional 12% of these patients achieve a stable partial response. Therefore, about 72% of patients have a beneficial response. According to various reports, several features could help to predict the result, such as previous steroid responsiveness, short survival and high turnover of labelled platelets[34] or high postoperative rise in platelet count. However, there is no foolproof way to predict which individual patient will have a stable response to splenectomy. Some surgical failures or relapses can be related to a persistent accessory spleen.

Operative morbidity of splenectomy is uncommon. If steroid therapy or IVIgG has previously been shown to be transiently efficient, they should be prescribed before surgery in order to allow a safe procedure. Otherwise, platelet concentrates should be ready for use and infused immediately if surgical hemostasis is difficult to achieve. However, the hazard of severe infections postsplenectomy has severely restrained the indications for splenectomy in all conditions including AITP. It should be emphasized that, in a large series of AITP in children, the mortality risk of overwhelming postsplenectomy infection can be as important as that of CNS hemorrhage[35]. In any case, all patients, whatever their age, should receive appropriate vaccination before surgery and regular oral penicillin prophylaxis should be prescribed. This particular risk explains why splenectomy, which everyone agrees to be the most frequently effective treatment, has been restricted to particular cases with refractoriness to all medical treatments, persistent bleeding tendency, risk for cerebral hemorrhage, or unacceptable side effects of medical treatments. Anti-D immunoglobulin in non-splenectomized Rhesus-positive patients with chronic ITP can result in a transient rise in the platelet count[17,36].

Cambridge Books Online © Cambridge University Press, 2009

Refractory chronic AITP

There is at present no definitive treatment for refractory chronic AITP. The plethora of suggested solutions simply reflects the fact that refractory idiopathic thrombocytopenic purpura often remains refractory[17,37].

Emergency therapy

Whatever the clinical course of AITP, acute or chronic, patients with significant mucosal bleeding or extremely low platelet counts ($<5\times10^9$–10×10^9/l) must be considered as at risk for severe bleeding, and immediately hospitalized and treated by a combination of IV steroids, IVIgG and platelet transfusion.

Alloimmunization

Immunization against platelet alloantigens or HPA (human platelet antigen) can occur either during pregnancy or after transfusion, leading, respectively, to neonatal alloimmune thrombocytopenia or post-transfusion purpura (PTP). However, PTP, which appears to be an anamnestic immune response, has not been described in children.

Neonatal alloimmune thrombocytopenia (NAIT) results from maternal allo-immunization against fetal platelet antigens inherited from the father, which she herself lacks. The incidence of feto-maternal alloimmunization (FMAIT) is estimated to be 1 per 800 to 1000 live births[38,39]. NAIT is considered to be the counterpart of Rh hemolytic disease of the newborn (HDN). In contrast to HDN, neonatal alloimmune thrombocytopenia may affect the first child. There may be severe bleeding in the central nervous system (CNS) and death or severe neurological sequelae.

Progress in platelet immunology and fetal medicine has led to the development of antenatal therapy and better management of this high-risk group, which are still evolving (Table 37.4).

The usual presentation is a neonate born to a healthy mother, who exhibits widespread purpura at or a few hours after birth. Otherwise, this infant is healthy, with no clinical signs of infection or malformation. Visceral hemorrhages are less common. The most serious complication is ICH leading to death in up to 10% of the reported cases, or to neurological sequelae in 20% of the cases[40,41]. Such hemorrhages may occur as early as 16 weeks of gestation and induce irreversible cerebral lesions. They may be present at birth or can occur as long as the newborn is thrombocytopenic. The risk of life-threatening hemorrhage necessitates prompt diagnosis and effective therapy.

The diagnosis of NAIT is made initially on clinical grounds and depends upon the exclusion of other causes of neonatal thrombocytopenia.

Table 37.4. Alloimmunization

Neonatal alloimmune thrombocytopenia results from maternal alloimmunization against a fetal platelet antigen inherited from the father, which she herself lacks

Incidence 1 per 800 to 1000 live births

Clinical presentation

neonate born to a healthy mother who exhibits widespread purpura at or a few hours after birth
no clinical sign of infection or malformation
visceral hemorrhages are less common
the most serious complication is intracranial hemorrhage leading to death in up to 10% of the reported cases or to 20% of neurological sequelae

Diagnosis

clinical grounds and exclusion of other causes of neonatal thrombocytopenia
isolated thrombocytopenia
platelet immunological testing: parental platelet alloantigen incompatibility with a corresponding maternal antibody

Therapy

transfusion of platelets compatible with the maternal alloantibody, the mother is the most reliable donor

Management of subsequent pregnancies

the optimal therapy is a matter of debate
recommendations based on our practice

* high-risk women must be followed in a referral centre with fetal blood sampling performed in case of incompatible fetus
* maternal therapy with IVIgG± corticosteroids in case of fetal thrombocytopenia
* cesarean section in case of therapy failure

The neonatal platelet count is low and anemia is only seen when secondary to bleeding. Platelet immunological investigations must be performed in a well-versed laboratory because of possible difficulties. The testing involves the detection of maternal circulating antibody and identification of the offending platelet antigen with the determination of the parents' platelet genotype. Detection of antibodies is usually done with antigen capture ELISA[6]. Molecular techniques are used for genotyping[42].

The diagnosis is straightforward when a parental antigen incompatibility with a corresponding maternal antibody are present. It could be equivocal in the absence of such an antibody or when a new, rare or private antigen is implicated. Any difficulties in confirming the diagnosis should not delay therapy when there are sufficient grounds for a provisional diagnosis.

Until there is a prospective screening programme for

Cambridge Books Online © Cambridge University Press, 2009

NAIT, most of the cases will be unexpected. Throughout the thrombocytopenic period, the infant is at risk of hemorrhage. The treatment of choice is the transfusion of platelets compatible with the maternal alloantibody. The most reliable donor is the mother. The maternal platelets must be washed, to remove the maternal plasma containing the antibody, and irradiated to eliminate the risk of graft-vs.-host-disease. In an emergency, exchange-transfusion, which removes a part of the circulating antibody, can be considered[43]. IVIgG can be considered, only when hemorrhages are not obvious, because the effect is delayed for 12–18 hours after injection[44].

The current management of subsequent pregnancies after a previous affected child is aimed at preventing ICH during pregnancy and delivery. The optimal antenatal therapy to reverse fetal thrombocytopenia is still a matter of debate[45]. At present, alternatives include weekly maternal injection of high doses of immunoglobulins (IVIgG), with or without corticosteroids, or weekly intrauterine platelet transfusions with antigen-negative platelets. The results obtained by the different teams in Europe and in the USA are somehow different and do not rely on randomized studies[46]. Thus, definite recommendations cannot be provided. Based on our data we recommend the following approach, high-risk pregnant women must be followed in a referral centre. In case of heterozygosity of the father for the offending antigen, fetal platelet genotyping must be performed on amniotic cells[47]. In case of incompatible fetus, a fetal blood sampling should be performed in order to determine the fetal platelet count at around 20–22 weeks of gestation. If the fetus is thrombocytopenic (platelet count $<150 \times 10^9$/l), maternal therapy with IVIgG (1 g/kg/week) should be considered. To assess the efficacy of therapy, a second fetal blood sampling should be performed at around 34 weeks of gestation. Corticosteroids could be added in case of therapy failure. For delivery we propose two options: cesarean section without control of the fetal platelet count or decided following the results of a third fetal blood sampling. In this last case vaginal delivery is allowed if the fetal platelet count is $>50 \times 10^9$/l after maternal therapy or after in utero platelet transfusion. We do not recommend weekly in utero platelet transfusion which seems to be too invasive, and may lead to destruction of the transfused platelets by maternal HLA-alloantibodies, or only in very severe familial cases, when the previous pregnancy was a therapeutic failure with in utero death or intracranial hemorrhage before 20 weeks of gestation.

In any case, pregnant women must be advised to avoid vigorous exercise, trauma, ingestion of drugs interfering with the platelet function (aspirin, antibiotics).

We also recommend the screening of the sisters of the affected woman in order to detect at risk individuals.

Non-immune processes

Infections

Bacterial and non-bacterial infection in the neonate

Thrombocytopenia in bacterial infection of maternal origin is usually moderate, transient and delayed making uncertain its usefulness in the diagnostic investigation. It is often the result of several mechanisms which interact.

Non-bacterial infections in the neonatal period are mostly due to the TORCH agents (Toxoplasmosis, other, rubella, CMV, herpes). Most of them occur after primary infestation during the first months of pregnancy. The typical clinical presentation involves intra uterine growth retardation and jaundice with hepatosplenomegaly. These symptoms prompt the clinician to look for other signs of fetal infection: hemolytic anemia or lesions of bone, eye, heart or cerebrum.

When viral or fungal infections are acquired during the birth process, clinical signs are delayed and depend on the organ affected (myocarditis, encephalitis). Moderate thrombocytopenia is often present at an early stage.

HIV-related thrombocytopenia has been described in infants as early as 3 months old, and has also been reported in neonates.

Neonatal malaria, whether it is a maternofetal or a transfusion-related infection, can lead to thrombocytopenia, probably due in part to low grade DIC.

Viral and bacterial infections in childhood

Viral infections are often associated with alterations of blood cells. Several mechanisms may produce thrombocytopenia[15]. Whereas data argue in favour of direct interactions between viruses and progenitor or peripheral blood cells, other findings support the direct effect of viral-induced autoantibodies on these cells. There are several reports concerning thrombocytopenia after the administration of live measles vaccine[48,49]. Thrombocytopenia has been observed in congenital and acquired rubella[50]. The thrombocytopenia occasionally associated with varicella typically develops 1 to 2 weeks after the rash[50]. Epstein–Barr virus, Cytomegalovirus and Human Parvovirus B19 infections[51] have been associated with thrombocytopenia. Thrombocytopenia is not a rare event in the natural history of HIV infection[52,53]. Thus in the presence of thrombocytopenia, especially the acute manifestations in childhood, it is important to look for viral infection.

Cambridge Books Online © Cambridge University Press, 2009

Thrombocytopenia can be associated with bacterial infection, especially with septicemia.

Increased platelet consumption

Disseminated intravascular coagulation (DIC)
It is frequently observed in distressed neonates or ill children. It usually leads to platelet consumption, typically associated with a decrease in coagulation factors, mostly factor V and fibrinogen, and to the presence of fibrin(ogen) degradation products. Repeated assessment of platelet counts and of coagulation status is mandatory. Usually thrombocytopenia occurs after the other biological signs and can persist a few days after coagulation factors have recovered normal values. The treatment of DIC-related thrombocytopenia relies on the treatment of the underlying cause of DIC itself and of associated symptoms such as hypovolemia, acidosis or shock. However, when the coincidence of coagulation factor consumption and severe thrombocytopenia leads to threatening hemorrhage, the most appropriate treatment has to be considered. Although rare during childhood, such pictures may be observed within the course of acute leukemias, specially at the initiation of the chemotherapy, due to the extensive lysis of hemoblastes, in cases of Kasabach–Merritt syndrome associated with giant hemangiomas, or in newborns who experienced acute, severe fetal distress. In such cases, thrombocytopenia is usually severe, and may account for the bleeding severity. A specific replacement therapy should therefore be undertaken in such cases, at the same time as the specific treatment directed against the DIC underlying pathology. This replacement therapy includes platelet concentrate transfusions or exchange transfusions with blood and platelet concentrates in neonates, transfusion of the missing coagulation factors, generally present in fresh frozen plasma together with coagulation inhibitors, and infusion of antiplasmin inhibitors such as aprotinin, aimed at replacing the alpha-2 antiplasmin consumed within the DIC process[54]. Prothrombin complex concentrates are contra-indicated in such cases as they may aggravate the DIC process. Furthermore, they are of no help in increasing the levels of FV, FVIII and fibrinogen that are consumed during the process.

Among the different causes of DIC, respiratory distress syndrome and perinatal asphyxia in neonates, leukemia or cancer, or bacterial infection, are pre-eminent.

Hemolytic uremic syndrome and thrombotic thrombocytopenic purpura
These two syndromes are characterized by common biological findings: microangiopathy with hemolytic anemia related to red cell fragmentation associated to variable degrees of thrombocytopenia.

The hemolytic uremic syndrome (HUS) described in 1955 could be observed in children[55] in association with a number of different infectious agents in the classic epidemic form. Sporadic and hereditary forms have also been described. Clinical manifestations, laboratory findings and therapy are quite similar to the adult forms. In contrast, thrombotic thrombocytopenic purpura also known as Moschcowitz disease[56] is essentially seen in adults.

Kasabach–Merritt syndrome
This syndrome was reported as the association of hemangioma and thrombocytopenia.

A local platelet consumption occurring locally in the hemangioma may lead to severe thrombocytopenia. Thrombocytopenia is associated with hypofibrinogenemia and red cell fragmentation, which can be seen on blood smears. Overt hemolysis can also be present. The diagnosis may be obvious if the angioma is apparent, but in other cases extensive X-ray and tomography must confirm it. Angioma-related thrombocytopenia can lead to a threatening hemorrhagic syndrome where specific intervention such as vascular embolization is needed. Recently, interferon alpha therapy, which has been shown to inhibit angiogenesis in vitro, has been successfully used in some cases of Kasabach–Merritt Syndrome[57].

Miscellaneous causes
(i) In the course of an extensive thrombosis, such as renal venous or catheter thrombosis, thrombocytopenia can be one of the most relevant biological signs.
(ii) Constitutional severe defects of coagulation inhibitors protein C and S have also to be considered: they may manifest as early as the first day of age by a life-threatening syndrome characterized by extensive necrotic hematomas purpura-fulminans-like, associated with retinal and cerebral thrombosis. Thrombocytopenia is usually severe, associated with schistocytosis and DIC. Due to the low physiological levels of these inhibitors at birth, and to their consumption in the DIC process, the diagnosis has to be confirmed by performing coagulation studies in the parents and siblings and by molecular analysis of the gene. However, due to the dramatic spontaneous aggravation in these cases, a replacement therapy must be initiated in emergency, without waiting for the results.
(iii) Platelet aggregation in the lung leading to thrombocytopenia has been suggested during the course of perinatal aspiration syndrome. A small amount of inhaled amniotic fluid may be a precipitating factor for

Cambridge Books Online © Cambridge University Press, 2009

formation of pulmonary microthrombi, leading to unresponsive persistent pulmonary hypertension.

Miscellaneous causes of acquired thrombocytopenia

In sick children, thrombocytopenia is more often easily related to causes extensively reviewed by Beardsley[58].

(i) Heparin-related thrombocytopenia has been reported in young infants, but not in the newborn. However, the potential hazards of the thrombocytopenia induced by platelet aggregation must be kept in mind, whatever the age at which heparin is prescribed, and must prompt discontinuation of therapy.

(ii) Thrombocytopenia has also been reported in infants who have experienced cold injury. It could be the combined result of a platelet splenic sequestration and of a decrease in megakaryocytopoiesis. Both mechanisms have been observed in hibernating animal models. The former has been reported in humans undergoing hypothermia for surgery and the latter occurs after a long exposure.

(iii) Neonatal thrombocytopenia is frequently observed during the first postnatal days of very small-for-date babies or in babies from pre-eclamptic mothers, often associated with erythroblastosis and granulocytopenia. In the most severe cases, hepatic insufficiency and multiorgan failure accompany neonatal thrombocytopenia, which can be fatal. Chronic hypoxia is likely to explain neonatal thrombocytopenia in these cases for it has been shown, in animal models, that prolonged hypoxia in pregnant females could lead to fetal thrombocytopenia[59]. This process could explain most cases of neonatal thrombocytopenia observed in neonatal intensive care units.

In a great number of other cases, peripheral destruction and impairment of megakaryocytopoiesis are combined, and there is no way to discriminate their respective involvement.

Neonatal thrombocytopenia has been observed in infants with inherited metabolic disorders leading to acidosis and after several therapeutic procedures such as phototherapy, which has been shown to shorten platelet life span, or exchange transfusion, where the magnitude of the transient fall observed during 2–3 days after the procedure could depend on the storage conditions of the blood used. Neonatal thrombocytopenia related to antenatal maternal treatment with agents such as thiazide and tolbutamide has been reported, but should be diagnosed with caution.

Inherited thrombocytopenias

Although its real incidence remains unknown, constitutional thrombocytopenia is not a rare event. The inherited origin of thrombocytopenia has to be systematically considered in children before the initiation of potentially harmful treatments, especially when thrombocytopenia is long lasting, moderate and silent and refractory to conventional AITP therapy. Achieving the diagnosis can need a careful collection of medical and familial data in search for consanguinity, thrombocytopenia or bleeding history in family member(s). A detailed pedigree could establish the inheritance pattern. Platelet abnormalities on blood smears can be observed as small, giant or agranular platelets. Other associated symptoms must be carefully searched for, such as immunodeficiency in Wiskott–Aldrich syndrome, deafness, nephritis, cataract or abnormalities in other hematopoietic cell lineages, e.g. presence of Döhle bodies in the neutrophils. Platelet functions must be assessed in order to detect associated thrombopathies.

Inherited thrombocytopenias can be classified according to the platelet size (Table 37.5).

Small platelet size

A small platelet size is the hallmark of Wiskott–Aldrich syndrome (WAS). It is a severe X-linked thrombocytopenia, associated with immunodeficiency and eczema. It has recently been related to mutations of the gene encoding WAS protein (WASP)[60], which is present in neutrophils, mononuclear cells and platelets, and mapping at Xp11.22–11.23. Thrombocytopenia and lymphocyte defects are severe in most children after the age of 6. Bleeding remains the major cause of death in these patients and may be alleviated by splenectomy in some cases. Bone marrow transplantation is the actual therapeutic option in severe cases with repeated infection. A mechanism has recently been proposed for the thrombocytopenia and small platelet size, which is based on the increased Ca^{2+} level in platelets, resulting in platelet activation, phosphatidylserine exposure at the platelet surface resulting in increased recognition and phagocytosis by the spleen macrophages, and microparticle release, leading to small platelet size[61].

Mutations of the WASP locus have also been reported in atypical WAS or in isolated X-linked thrombocytopenias (XLT) without immunodeficiency[62,63]. XLT may be misdiagnosed as chronic autoimmune thrombocytopenic purpura.

Small platelet size
Wiskott–Aldrich syndrome: X-linked thrombocytopenia associated with immunodeficiency and eczema
Isolated X-linked thrombocytopenia without immunodeficiency
Inherited giant platelet disorders
Autosomal dominant inheritance
May-Hegglin disease, Sebastian syndrome: basophilic inclusions in neutrophils (Döhle inclusions)
Alport syndrome: deafness, and nephritis
Epstein syndrome: Alport syndrome with severe thrombocytopenia
Fechtner syndrome: deafness, nephritis and congenital cataract with Döhle inclusions in neutrophils
Recessive disorder
Bernard–Soulier syndrome: defect in the platelet glycoprotein complex Ib–IX–V
Velocardiofacial (Digeorge) syndrome: heterozygous variant of Bernard–Soulier syndrome
Platelet-type von Willebrand syndrome: anomaly of the glycoprotein Ibα
Grey platelet syndrome: lack of alpha granules
Normal platelet volume
TAR syndrome: thrombocytopenia with absent radii, defective signal transduction in the c-Mpl pathway, autosomal recessive inheritance
Congenital amegakaryocytic thrombocytopenia (CAMT): Mpl mutations
Paris–Trousseau thrombocytopenia: giant alpha granules, 11q23.3 deletion, autosomal dominant inheritance

Inherited giant platelet disorders

A large platelet size is observed in inherited giant platelet disorders, recently reviewed[64]. Some are associated with basophilic inclusions in the neutrophils called Döhle bodies in May–Hegglin disease, and slightly different inclusions in Sebastian syndrome. Although thrombocytopenia may be severe, the low number of platelets seems to be balanced by their large size leading to a near-normal thrombocrit, and to a moderate bleeding tendency, occurring mostly after trauma and surgery. Their inheritance is autosomal dominant and thrombocytopenia has been suggested to result from an impaired megakaryocyte fragmentation. The May–Hegglin molecular anomaly has recently been located on MYH9, a region of chromosome 22q12–13 encoding non-muscle myosin heavy chain A. Mutations of this gene have been identified in 30 affected members of five unrelated families, whereas it was not found in 40 normal individuals[65].

(i) Giant thrombocytopenia associated with systemic manifestations, of autosomal dominant inheritance, characterizes Alport syndrome (deafness and nephritis), Epstein syndrome (Alport syndrome with severe thrombocytopenia), Fechtner syndrome (deafness, nephritis and congenital cataract, also associated with Döhle inclusions). Very little is known about the pathogenesis of these disorders, of which the molecular anomalies still have to be identified.

(ii) Giant thrombocytopenias associated with ultrastructural defects are better characterized:

Bernard–Soulier syndrome (BSS) is an autosomal recessive disorder due to a defect in the platelet glycoprotein (GP) Ib–IX–V complex, which is the receptor for von Willebrand factor (vWF) involved in platelet adhesion to the subendothelium. In most cases, a mutation of one of the genes coding for the GPIb α or β chains or GPIX leads to an abnormal assembly of the GP complex resulting in an impaired platelet adhesion. The clinical expression varies from mild to severe. Bleeding time may be normal in mild cases. Platelet half-life is decreased. Megakaryocytes may be abnormal, displaying vacuoles and abnormal demarcation membranes in ultrastructural study. The diagnosis relies on the absence of ristocetin induced platelet agglutination and on a decreased or undetectable GPIb–IX complex evidenced by flow cytometric analysis of the platelet glycoproteins[66].

(iii) Giant platelet with velocardiofacial (Digeorge) syndrome is an autosomal recessive disease. It is due to a 22q11 deletion including a GPIbβ gene deletion, and it is therefore considered a heterozygous variant of BSS.

(iv) Platelet-type von Willebrand syndrome, due to an anomaly of the GPIbα, is the platelet counterpart of the von Willebrand type 2B plasmatic disease, where the molecular anomaly is located on exon 28 of the vWF gene, encoding the vWF binding domain to GPIbα. Both anomalies induce an increased binding of vWF to its receptor, resulting in a decrease of circulating high molecular weight multimers of vWF and a bleeding tendency. The diagnosis relies on a highly fluctuating platelet count, ranging in the same individual from severe thrombocytopenia to normal platelet counts, an increased ristocetin-induced platelet agglutination, a decreased circulating vWF ristocetin cofactor activity, and the identification of the gene defect. Platelet ultrastructural study performed in three unrelated patients showed that vWF association to GPIb on the platelet surface and also inside the surface of the

Cambridge Books Online © Cambridge University Press, 2009

connected canalicular system does not result in platelet activation, which could provide an explanation for the bleeding tendency observed in these diseases. Furthermore, since GPIb integrity has been shown to be required for the normal platelet release from megakaryocyte proplatelet processes, abnormal occupancy of GPIb by vWF might interfere with platelet production, and account for thrombocytopenia[67].

Grey platelet syndrome is an autosomal recessive disease associating a moderate thrombocytopenia and a lack of alpha granules. Myelofibrosis is often observed, due to an abnormal release of platelet derived growth factor (PDGF) normally located inside the granules. The diagnosis relies on the platelet aspect on the blood smears and on a defective collagen induced platelet aggregation and secretion.

Other thrombocytopenias with giant platelets such as Mediterranean thrombocytopenia, resulting in moderate or no bleeding, are classified as 'benign'.

Normal platelet volume

Thrombocytopenia with absent radii or TAR syndrome is a rare, autosomal recessive disease characterized by a severe amegakaryocytic thrombocytopenia, associated with skeletal abnormalities such as radial aplasia, and a polymalformative syndrome extensively described by Hedberg[68]. Normal expression of c-Mpl on platelets with defective signal transduction in the c-Mpl pathway has been observed[69]. The platelet count may increase during the first months of life. On the other hand, the two main features of this rare syndrome may be isolated. Neonatal thrombocytopenia is probably the result of an arrest in the development of committed megakaryocyte progenitor cells, whereas production of megakaryocyte growth factors is normal. In early infancy thrombocytopenia is usually symptomatic, with life-threatening bleeding episodes. It has been shown that some megakaryocytic progenitors could respond to PEG-rHuMGDF, but this response could be incomplete.

Congenital amegakaryocytic thrombocytopenia (CAMT) has recently been shown to be due to Mpl mutations[70].

Paris–Trousseau is an autosomal dominant thrombocytopenia associated with a mild hemorrhagic presentation due to thrombopathy, and characterized by the presence of giant alpha-granules. There is an impaired megakaryocytopoiesis secondary to a 11q23.3 deletion[71].

During the last few years, many molecular abnormalities have been described, allowing secure diagnosis of constitutional thrombocytopenia. Investigations required for the diagnosis of inherited thrombocytopenia should be systematically performed in cases of non-acute thrombocytopenias. Thanks to the automated blood cell counters, the platelet count is nowadays systematically assessed together with leukocytes and erythrocytes, leading to the disclosure of silent, asymptomatic thrombocytopenias.

Alloimmune thrombocytopenia

E. Anders Kolb and James B. Bussel

Cornell University Medical Centre, New York Hospital, USA

Fetal and neonatal alloimmune thrombocytopenia (AIT) is the most common cause of severe thrombocytopenia in fetuses and neonates[1]. Maternal IgG alloantibodies against paternally derived fetal platelet antigens cross the placenta early in pregnancy and commonly result in severe thrombocytopenia. While the reported incidence varies somewhat with the assigned threshold of thrombocytopenia (50, 100, or 150×10^9/l), in most unselected populations, AIT affects 1 in 1000 to 1 in 2000 live births. Table 38.1 contains recent studies of AIT in unselected populations, systematically screened. In its severe form, AIT has the potential for significant morbidity (including intracranial hemorrhage) and mortality. In milder forms, there are either antibodies with no thrombocytopenia, or mild to moderate thrombocytopenia, which is identified only by a complete blood count obtained for another indication or in a screening study. While there have been extensive efforts made in the diagnosis and characterization of the disease, strategies for early detection and intervention remain controversial.

Pathogenesis

There are three requisite components of the pathogenesis of AIT. First, there must be an incompatibility between maternal and fetal 'platelet-specific' antigens, which are inherited from the father. The second requirement, alloimmunization, is a maternal humoral immune response specific to these 'foreign' fetal platelet antigens. Finally, maternal anti-platelet IgG alloantibodies must cross the placenta, bind to fetal platelet antigens, and cause fetal platelet destruction with resultant thrombocytopenia. The term alloimmunization, therefore, implies that there is a parental antigen incompatibility, and that maternal antibodies are produced and are specific to the paternally inherited (and foreign to the mother) fetal platelet antigen. The predictability of this process, and its ability to cause fetal or neonatal thrombocytopenia, is well characterized serologically but perplexing in a number of areas, and warrants careful discussion.

Table 38.1. Incidence of neonatal thrombocytopenia

Reference	Number and population screened	Incidence of AIT	Comments
	Pregnant women		
14	24 417	1 in 1285 pregnancies	
	Neonates		
1	15 932	1 in 5000 newborns	Platelet count $<50 \times 10^9$/l*
40	5 632	1 in 1000 newborns	
13	9 142	1 in 1800 newborns	Platelet count $<100 \times 10^9$/l
46	8 388	1 in 1700 newborns	
42	4 489	1 in 1200 newborns	
16	24 101	1 in 2400 newborns	Platelet count $<100 \times 10^9$/l
27	5 632	1 in 1000 newborns	

Notes:
* Unless otherwise specified, neonatal thrombocytopenia is defined as a cord blood platelet count less than 150×10^9/l.

Notes:
* NT = Not tested.
** 'W' indicates antigens for which only one allele is identified.

Human platelet-specific antigens

Platelets share several antigen systems with other cell types, including the HLA class I antigens, and the ABO blood group antigens[2,3]. However, these antigen systems are rarely, if ever, implicated in AIT. AIT secondary to an HLA antigen mismatch remains unproven and controversial. More commonly, AIT is caused by antibodies to platelet-specific antigens, which represent epitopes of the platelet surface glycoproteins. Currently there are at least fifteen human platelet-specific antigens listed by the Platelet Serology Working Party of the International Society of Blood Transfusion (ISBT), each with a different serologic frequency and ethnic distribution[2,4–6]. In 1990 the ISBT Working Party on Platelet Serology formulated a new nomenclature for the human platelet antigen system, as an attempt to standardize an otherwise confusing system of antigen names and descriptions. Platelet-specific antigens are designated HPA for Human Platelet Antigen. They are numbered in order of their original description, and the alleles labelled alphabetically in the order of their serologic frequency[2,4]. Recently, DNA sequencing has permitted the description of the specific amino acid changes associated with each allele. This DNA-based typing system provides an additional nomenclature for describing human platelet-specific antigens. Each HPA type is biallelic, and autosomal co-dominant, differing in only one amino acid. It is important to note that there is overlap of certain alleles, as discussed by Newman[7], and that the naming of a certain allele implies an understanding of the molecular identity of that glycoprotein. Table 38.2 contains the HPA type, the glycoprotein on which it is located, the previous

antigen designations, the associated amino acid changes for each allele, and the frequency of each antigen in selected populations.

AIT has been reported after alloimmunization to numerous human platelet antigens (see Table 38.3 and 38.4). In almost all large series, HPA1a incompatibility is the most common incompatibility resulting in AIT[8–16]. Newer studies suggest that HPA-5b incompatibility may be more common than HPA-1a incompatibility, but severe thrombocytopenia after HPA-5b alloimmunization is rare[17–19]. Of note, the initial description of a new human platelet antigen is frequently initiated by a patient with significant morbidity. Therefore, most non-HPA-1a incompatibilities have severe index cases, but incidences appear to be very low. Despite numerous reports of new, and potentially severe or frequent incompatibilities, it remains clear that HPA-1a incompatibility remains the most common cause of severe AIT in Caucasian populations.

Alloimmunization

Fetal platelet antigens may be expressed as early as 16 weeks gestation[20], and alloantibody formation with fetal platelet destruction may occur as early as 16 to 20 weeks of gestation[21,22]. Unlike hemolytic disease of the newborn, alloimmunization is reported in up to 50% of first pregnancies. However, antibodies have not been detected in primiparous women prior to 17 weeks gestation[14]. In a large series, Williamson et al.[14] reported that in 46 sensitized HPA-1a negative women, alloantibodies were detected before the 20th week of gestation in 59%, between 21 and 34 weeks in 17%, between 33 weeks and term in 6.5%, and on postnatal testing only in 6.5%.

Alloantibodies to fetal HPA-1a on GPIIIa is the most common cause of severe AIT in Caucasian populations[9]. Van Loghem et al.[23] initially reported that 97% of North American and European Caucasians react to anti-HPA-1a. The Hardy-Weinberg law predicts the allelic frequency to be 0.83 for HPA-1a and 0.17 for HPA-1b. Therefore, in Caucasians of European or North American descent, the genotypic distribution is calculated to be 68.9% homozygosity for HPA-1a, 2.9% homozygosity for HPA-1b, and 28.2% heterozygosity (HPA-1a/HPA-1b)[24,25]. The frequency of the HPA-1b genotype has been confirmed in several large population studies[14,15,26,27]. Both the predicted and actual frequency of mothers at risk for HPA-1a incompatibility, by virtue of being homozygous for HPA-1b, is 2–3%. The HPA-1b homozygous mother will be susceptible to alloimmunization in all cases if her partner is homozygous for HPA-1a (68.9%), or in half the offspring of a heterozygous partner (14.1%). Based on

Table 38.4. Less Common Antigen Incompatibilities in AIT

HPA type	Reference	Patients reported	Platelet Nadir ($\times 10^9$cells/l)	Hemorrhagic Sequelae	Maternal HLA Type
HPA-1b	38,115,116,117,118,119	6 total	10–13 duration up to 6 days	Petechiae (2 patients) Schizencephaly (1 patient) Prolonged thrombocytopenia 1 patient)	No consistent association
HPA-2b	42	3[a]	Mild	None	
HPA-3a	120	1	13	Purpura Death from ICH	None reported
HPA-3b	42 65	4[a] 14	Mild <20	None ICH (2 patients)	
HPA-4a	61,62	2 (siblings)	6–12	Petechiae (2 patients) Ecchymoses (2 patients) Scalp Hematoma (1 patient) In utero ICH (2 patients)	No consistent association
HPA-5b	121,17,9,10,13,18,40,46	39	<10 (4 patients) 10–30 (13 patients) >30 (22 patients)	No symptoms (59%) Purpura or hematoma (18%) Visceral hemorrhage (15%) ICH (8%) Death due to ICH (1 patient)	Associated with HLA-DR6
HPA-6b	42,122,123			Mild	Associated with maternal HLA DRB*1501; DQA1*0102; DQB1*0602 (Westerman,1997)

Notes:
[a] AIT suspected due to antigen incompatibility and thrombocytopenia, but there was no antibody detected.

these gene frequencies, alloimmune thrombocytopenia as a result of HPA-1a incompatibility may develop in 1 of 42 pregnancies[25]. The actual incidence, as stated above, is 1 in 1000 to 1 in 2000. Several prospective studies have shown that only 4–14% of mothers homozygous for HPA-1b will produce anti-HPA-1a antibodies[8,14,27,28].

The discrepancy between the expected and actual incidence of AIT can be explained, at least in part, by the efficiency of antigen presentation by different MHC subtypes. In 1981 Reznikoff-Etievant et al.[29] reported that the immune response to the HPA-1b antigen is associated with the maternal HLA type B8DR3*. Subsequently, several authors confirmed a strong association between the production of anti-HPA-1a antibodies and the HLADR3 locus[28,30–35]. de Waal et al.[36] later linked it to the supertypic HLA DRB3[1]0101 allele.

[1] The original description was of increased incidence of HLA type B8 in women producing anti-HPA-1a antibody. HLA B8 is in linkage disequilibrium with HLA DR3.[25]

The HLA DRB3*0101 locus has a binding affinity for the Leu33 substitution on HPA-1a, and not the Pro33 substitution on HPA-1b, demonstrating the importance of binding between fetal peptides expressed on the β-3 integrin and the maternal MHC locus[37]. This genetic maternal restriction on the immune response to foreign fetal antigens accounts, in large part, for the relatively low number of HPA-1a negative mothers who develop alloantibodies against their HPA-1a positive fetus.

Williamson et al.[14] studied HPA type, antibody production, and maternal HLA type in more than 24 000 consecutive pregnancies in Cambridge and East Anglia, England. Of the 2.5% of women homozygous for HPA-1b, anti-HPA-1a antibodies were detected in 12%. All but one of the antibody producers was HLA DRB3[1]0101 positive, while the overall frequency of the allele was 31.9%. The presence of the HLA DRB3[1]0101 phenotype did not predict alloimmunization (positive predictive value of 35%), but the absence of the HLA DRB3[1]0101 precludes alloimmuniza-

Cambridge Books Online © Cambridge University Press, 2009

tion with very few exceptions (negative predictive value 99.6%).

Although not as well studied, alloantibody formation in cases of HPA-5b incompatibility has been associated with maternal HLA DRw6 positivity[17,18,38]. Other HPA incompatibilities resulting in alloimmunization may have similar HLA associations[39], but the low incidence of AIT due to these antigens makes study difficult.

Allo-antibody mediated thrombocytopenia

Maternal alloimmunization to fetal platelet antigens is most likely necessary, and usually, but not always, sufficient for immune thrombocytopenia in the fetus or newborn. There are a number of reported cases of reasonably high titre maternal anti-platelet alloantibodies in infants with normal platelet counts[14,18,26,27,40]. Maternal alloimmunization without neonatal thrombocytopenia may be as high as 32%[40]. In addition to maternal HLA MHC class II modulation of alloimmunization, there appears to be another regulatory step in AIT. The process of antibody-mediated platelet destruction may be inhibited by unknown factors specific to certain maternal–fetal pairs. It is possible that this factor could be maternal, a so-called 'blocking' antibody.

Conversely, there are many reports of maternal–fetal HPA incompatibility with neonatal thrombocytopenia (presumed AIT), but no detectable maternal alloantibody[9,13,16,40–42]. Newer techniques of antibody detection have not entirely resolved this issue.

For the most part, careful and extensive study of AIT is limited to anti-HPA-1a antibodies. The role of alloantibodies to other fetal platelet antigens is less clear. There are reports of suspected AIT with anti-HLA antibodies[9,43–45], anti-blood group antibodies[9], and anti-platelet-specific glycoprotein antibodies[42]. Of these unconfirmed causes of AIT, anti-HLA antibodies are perhaps the most common. King et al.[45] found no significant relationship between the formation of anti-HLA antibodies and neonatal thrombocytopenia. It is possible that the presence of anti-HLA antibodies in infants with thrombocytopenia is coincidental, as anti-HLA antibodies will be absorbed by HLA antigens in the placenta, or on WBCs, thus minimizing their effect on fetal platelets. At best the role of ant-HLA alloantibodies is unclear, but, when present, they appear to have little effect on neonatal platelet counts[44,45]. It is impossible to exclude that they might have a thrombocytopenic effect in individual cases.

Clearly, the details of the genetic and immunologic controls governing the process of alloimmunization have yet to be completely described. Our ability to predict the occurrence of alloimmunization in cases of feto-maternal platelet antigen incompatibility is limited, as is our ability to predict the presence and severity of thrombocytopenia after alloimmunization occurs.

Clinical presentation

For newborns with unsuspected AIT, evaluation will commonly be initiated by the pediatrician or neonatologist after perinatal identification of petechiae or purpura, or by the incidental finding of thrombocytopenia on a screening complete blood count obtained for a different indication. When defined as either a cord blood platelet count of less than 100, or 150×10^9/l, neonatal thrombocytopenia is reported in 0.5–0.9% of newborns, with severe thrombocytopenia (platelet count less than $50\,000 \times 10^9$/l) in 0.14–0.24%[1,16,27,40,42,46,47] (See Table 38.1). Immune-mediated thrombocytopenia may account for as much as 30% of neonatal thrombocytopenias, occurring in 0.3% of all newborns[40]. A small additional subset of patients will be identified because of a sibling with AIT.

The frequency of hemorrhagic symptoms in AIT is likely overestimated in clinical studies not based on population screening, considering that a substantial proportion of patients with AIT will not have severe thrombocytopenia and may go undetected. For those patients with clinically significant disease, or with neonatal platelet counts less that 100×10^9/l, the incidence of minor hemorrhagic diatheses (petechiae, ecchymoses, or hematomas) is as high as 80%[9,12,16]. The most frequent bleeding symptoms for AIT with clinically significant disease are listed in Tables 38.3 and 38.4.

It is more likely that AIT identified through routine screening will follow a benign course. In the largest study of its kind to date, 65% of infants with persistent in utero exposure to maternal anti-HPA-1a alloantibodies had mild or no thrombocytopenia[14]. While petechiae and ecchymoses are important markers of clinically significant disease, they occur in a minority of patients with AIT. A negative family history of perinatal hemorrhagic symptoms should therefore not prevent the consideration of AIT in subsequent pregnancies. Additionally, 20–40% of thrombocytopenic infants with proven AIT will have other perinatal problems (e.g. poor feeding, low birthweight, cardiac problems, or respiratory problems), which may confuse the etiology of the thrombocytopenia[47].

Neonatal platelet counts can vary from normal to less than 10×10^9/l. When looking at all infants with AIT, as many as 35% may have platelet counts less that 50×10^9/l[14]. While this may represent a small proportion of AIT and an

Cambridge Books Online © Cambridge University Press, 2009

even smaller proportion of live births, when present, and when identified clinically rather than by screening, thrombocytopenia in AIT is usually severe[9,13,14]. In fact, AIT is the most common cause of severe thrombocytopenia in newborns in all studies to date[1,13,16].

Intracranial hemorrhage

The mortality rate with AIT has been reported as high as 15%, but this number does not include clinically unrecognized cases. Almost all deaths are associated with intracranial hemorrhage (ICH)[9,26]. ICH occurs in 10–20% of affected neonates[9,26,48]. In a series of almost 50 000 unselected term neonates, the incidence of ICH was 1 in 1500 live births. Twenty-five per cent occurred in infants with AIT, making it the most common cause of severe ICH in term newborns[49]. Intraventricular hemorrhages are most common, but unifocal, multifocal and large parenchymal hemorrhages have been reported[9,50–53]. The vascular distribution of ICH in alloimmune thrombocytopenia may be expected from the fact that normal hemostasis is maintained, in part, through interaction between platelets and the vascular endothelium. It is unclear if glycoprotein-bound antiplatelet antibodies interfere with the ability of platelets to support the vascular endothelium, but it is likely that decreased platelet numbers significantly compromise the integrity of vessel walls. It is equally possible that minimal trauma can lead to devastating vascular hemorrhage in the developing thrombocytopenic fetus or neonate.

Up to 50% of all reported intracranial hemorrhages in AIT will occur antenatally[9,26,54]. Severe thrombocytopenia may occur at the time of the initial fetal sampling in as many as 50% of affected fetuses, and as early as 16 to 20 weeks gestation[10,21,22,55]. In utero hemorrhages may present at any point in gestation, or even in the newborn period with fetal distress or demise[56,57], fetal or neonatal hydrocephalus[9,57,58], encephalomalacia, intracranial cysts[50,51,59], an abnormal neurological exam, or poor feeding[12,49,54,59,60]. ICH has been reported in association with almost all antigen incompatibilities[61,62], but it is most commonly associated with HPA-1a incompatibility[9,12,54].

In vitro binding of autoantibodies to GPIIb/IIIa may rarely result in an acquired disorder in platelet function[63]. In patients homozygotic for HPA-1a, alloantibodies to HPA-1a will completely eliminate platelet aggregation to all GPIIb/IIIa agonists (except ristocetin), but the effect is much less in heterozygous HPA-1a expression (as in all fetuses with AIT). The pathophysiology mediating this effect is not entirely clear. Glycoprotein IIb/IIIa is the most abundant glycoprotein on the platelet surface, and it is the site of fibrinogen binding. However, antibodies to HPA-1a do not appear to bind near enough to the fibrinogen-binding site to cause a steric hindrance[64]. The vascular distribution of some in utero hemorrhages has led to additional speculation about the possible role of endothelial GPIIb/IIIa in the pathogenesis of intracranial hemorrhages. However, the seemingly equivalent rate of ICH in HPA-3b (GPIIb) incompatibility suggests that this may not be a prominent factor since HPA-3b is not expressed on endothelial cells[65]. In summary, platelet counts less than 20×10^9/l in AIT are permissive but not sufficient for ICH. Anti HPA-1a antibodies do not cause substantial platelet dysfunction and the role of HPA-1a on endothelial cells is uncertain. Other factors that may contribute to the occurrence of ICH are unknown.

Predictors of disease

A goal of many recent screening protocols has been to define prognostic factors that may identify those patients at risk for ICH[14,15,66,67]. As discussed above, the presence of maternal alloantibody does not predict thrombocytopenia. However, recent studies have suggested that high (greater that 1:32) third trimester maternal antibody titre[14,15], and high titres of the IgG3 subclass[67] may predict severe thrombocytopenia. For HPA-5b incompatibilities, neither antibody titre nor subclass appears to predict disease[19].

There is a more than 90% recurrence rate of AIT among siblings. Mildly affected or undiagnosed first-born children may have severely affected siblings. Initial fetal platelet counts of less than 20×10^9/l are reported in 50% of siblings of affected children. Forty-five per cent of second siblings may have platelet counts of less than 20×10^9/l by 24 weeks gestation. However the only significant predictor of severe disease in subsequent affected siblings is antenatal ICH in the previous sibling[55].

Diagnosis

The diagnosis of AIT in a thrombocytopenic infant or fetus requires several laboratory observations. There must be HPA incompatibility between mother and child. Although not always identifiable, even with the most sensitive techniques, a firm diagnosis of AIT requires the identification of maternal antiplatelet alloantibodies. These antibodies should bind to paternal, but not maternal platelets, and they should be specific to the antigen incompatibility in question, including specificity for the glycoprotein on which the incompatible epitope is located.

Cambridge Books Online © Cambridge University Press, 2009

Antigen testing

Only a very few facilities can do both DNA-based and serologic testing for the most frequently encountered HPA antigens. With the development of oligonucleotide probes and the refinement of PCR techniques, it is possible to obtain platelet antigen typing on amniocytes and fetal leukocytes[68–70]. Techniques are also now available for platelet antigen genotyping from dried blood spots on cards to aide in rapid perinatal diagnosis[71].

Recently, several ELISA-based[72,73] and fluorescence-based[74] techniques have been developed for rapid antigen typing on large numbers of samples. ELISA-based kits are also available to screen for common HPA antigens, and to allow accurate testing of the common antigens at smaller centres[73].

Alloantibody testing

Early antibody testing was performed with the platelet suspension immunoflourescent test (PSIFT). The PSIFT technique detects antiplatelet antibodies bound to the surface of platelets, but is not specific for anti HPA alloantibodies[75,76]. In 1987, Kiefel et al.[77] reported accurate alloantibody detection with an enzyme immunoassay, the monoclonal antibody immobilization of platelet glycoprotein assay (MAIPA). This technique, and subsequent refinements, now allows for the identification and quantification of glycoprotein-specific alloantibodies[77–79]. MAIPA can be both utilized during pregnancy to monitor antibody levels, and possibly adapted for large-scale screening programs[80]. Other techniques show promise for large-scale screening programs[5,81].

Who to test

When evaluating the thrombocytopenic newborn, it is important to carefully consider the diagnosis of AIT. We believe that all infants with platelet counts less than 50×10^9/l should be tested for AIT and managed accordingly. Even in patients with mild thrombocytopenia, it is always important to identify those with AIT, because of the implication for subsequent offspring, who may be more severely affected. In general, any thrombocytopenic infant, even with a platelet count greater than 50×10^9/l, without evidence of asphyxia or sepsis, is deserving of evaluation. As many as 30% of infants with AIT will have other neonatal medical problems, which can confuse the diagnosis of AIT. Therefore the diagnosis of other newborn disease, regardless of whether or not they are independent causes of thrombocytopenia, should not prevent an evaluation for AIT, especially with severe thrombocytopenia or ICH. Severe thrombocytopenia and ICH are strongly associated with AIT. In premature infants, where an ICH is likely due to an underdeveloped germinal matrix, AIT should be considered if the ICH is associated with thrombocytopenia, or if there is a parenchymal bleed. Finally, any familial or transient neonatal thrombocytopenia should also be evaluated[47].

Screening programs

Currently there is no consensus on the need for routine, prenatal, maternal platelet antigen phenotyping, or on obtaining routine neonatal platelet counts. AIT is a significant cause of prenatal and perinatal morbidity and mortality, the pathogenesis is relatively well understood, and early intervention can prevent adverse outcomes. Unfortunately, we lack adequate biological markers of severe disease to justify the risk associated with fetal blood sampling and, for the same reasons, it is difficult to justify treating blindly without fetal blood sampling to know that the fetus is or will be severely affected.

The financial and technical burden of screening for all maternal platelet antigens would certainly exceed the resources of any large-scale screening program. Testing would have to be based on the ethnic distribution of the most likely antigen incompatibilities, and the severity of the associated thrombocytopenia. For most populations this would require testing for the HPA-1a antigen. However, such a program would miss incompatibilities among the less common human platelet antigens, some of which can lead to severe disease.

If a screening programme were to identify a woman with the HPA-1b phenotype, what would be the next step to determine the need for treatment? Both anti-HPA-1a antibody and HLA-typing for DRB[1]30101 have been suggested. While high anti-HPA-1a antibody titres may predict severe AIT, low or undetectable titres are not at all predictive of the severity of the thrombocytopenia. In most cases of AIT, alloimmunization is eventually detected but it may require multiple antibody assays throughout the pregnancy and postnatal period. Additionally, there are at least three reported cases (including those in unpublished communications) of alloimmunization to HPA-1a in mothers that do not have the HLA DRB[1]30101 subtype.

Screening programs have the potential to prevent the devastating or fatal hemorrhagic complications of AIT. However, without better markers for severe thrombocytopenia in affected maternal–fetal pairs, we have to rely on fetal blood sampling (FBS) to confirm the diagnosis. Until there is better data on the incidence and significance of the

Cambridge Books Online © Cambridge University Press, 2009

biological markers for alloimmunization and thrombocytopenia, it is difficult to justify the number of unnecessary fetal blood samplings that would result from a screening programme using the current technology. For example, a reasonable screening programme might suggest FBS for any maternal–fetal pair with HPA-1a antigen incompatibility and a detectable maternal antibody. If we assume that there is a human–platelet antigen incompatibility in 1 in 40 pregnancies, and that 2% of these will have detectable alloimmunization[14,26–28] then 1 in 2000 pregnancies will result in alloimmunization, and require FBS. Only 35% of infants exposed to antiplatelet alloantibodies will develop moderate to severe thrombocytopenia[14], while only 10–20% of these neonates with suffer an intracranial hemorrhage[9,12,48]. If the fetal loss rate after FBS is 1–2%[82–84], then a screening program will result in fetal loss from FBS in as many as 1 in 100 000 to 1 in 200 000 pregnancies, while potentially preventing ICH in 1 in 28 500 to 1 in 57 000 pregnancies. In other words, in the setting of routine screening of first pregnancies, the best technology available still requires that one in three infants will undergo unnecessary FBS. Additionally, for every infant that suffers a fatal complication of FBS (assuming only one FBS per patient), we will only have the opportunity to potentially prevent ICH in two to five infants.

There are two large, multi-centred studies nearing completion in Northern Europe to help better define these issues.

Management

Ideally, the goal in the management of AIT is to prevent antenatal or perinatal intracranial hemorrhage, and the associated neurologic sequelae or mortality. For those patients diagnosed in the newborn period, prompt diagnosis and treatment is necessary to restore normal hemostasis. However, often the damage is already done and optimal neonatal management merely serves to limit the extent of damage by preventing further progression of the ICH[54]. A number of cases may be diagnosed antenatally because of a history of AIT in a first or second degree relative, or, infrequently, because of an in utero intracranial hemorrhage diagnosed by prenatal ultrasound. Antenatal management of affected fetuses identified because of previously affected siblings can significantly reduce the morbidity and mortality associated with AIT. While severe thrombocytopenia and ICH occur in a minority of patients with AIT, the sequelae are potentially devastating and warrant aggressive preventative efforts.

Antenatal management

There are several important considerations in developing antenatal management strategies for fetuses suspected of having fetal AIT: the potential severity of the thrombocytopenia; the natural history of fetal AIT; the risk of ICH at a given fetal or neonatal platelet count; the mode of delivery; the morbidity and mortality associated with therapy and therapeutic procedures; and the efficacy of available therapies. The appropriate use of antenatal therapies is best defined in second-affected siblings. In the absence of routine maternal human platelet antigen typing, first-born children are rarely diagnosed before the newborn period.

Severity of disease

Other than antenatal ICH in an older affected sibling, there are no reliable predictors of severe thrombocytopenia in subsequent pregnancies. However, if an older sibling had severe AIT, subsequent infants will have disease that is at least as severe[55,59,61]. To our knowledge there are no reports of untreated fetuses with disease less severe than older affected siblings. As many as 40% of initial fetal platelet counts between 20 and 30 weeks gestation will be lower than the platelet nadir of an older affected sibling[55]. Furthermore, there are no reported cases of ‘spontaneous’ increases in the fetal platelet count, and affected fetuses, who are not initially treated because of adequate fetal platelet counts, will probably have a predictable decrease in their platelet counts. If previous pregnancies resulted only in mild disease, the severity of disease in subsequent pregnancies is impossible to predict.

ICH

‘Spontaneous’ fetal ICH is rare at platelet counts greater than 20×10^9/l. However, the risk of ICH at a given platelet count after vaginal births and after cesarean section has not been studied in randomized controlled trials in AIT. Several early reports of ICH in thrombocytopenic infants after vaginal delivery prompted authors to advocate for scheduled ‘elective’ cesarean section in severely thrombocytopenic infants[85,86]. However, it is still not clear if vaginal delivery is an independent risk factor for ICH in thrombocytopenic neonates[87,88]. While in theory it may seem that cesarean section is safer for thrombocytopenic neonates, this is unproven. Successful antenatal therapy may increase fetal platelet counts to greater than 50×10^9/l, the generally accepted, but unproven, threshold for ‘safe’ vaginal delivery.

Therapeutic procedures

Monitoring the efficacy of therapeutic interventions in fetuses with AIT requires fetal blood sampling using the

Cambridge Books Online © Cambridge University Press, 2009

technique of cordocentesis. There is a reported fetal loss rate of 0.2% to 7.2%, depending on the technique (free-hand technique, fixed-needle technique, or combined technique), operator experience, and underlying fetal disease[67,89–92]. In otherwise healthy but thrombocytopenic fetuses, the risk of fetal loss is likely closer to 1%[82,84]. While some authors report no association between fetal loss and fetal platelet count[67], thrombocytopenic fetuses appear to be at higher risk for exsanguination after FBS[84] and therefore transfusion of maternal or other matched antigen negative platelets is the standard of care.

Efficacy of selected therapies

Intrauterine platelet transfusions

Shortly following the description of the cordocentesis procedure, Daffos et al. described the use of washed maternal platelets injected into the umbilical vein of an infant with AIT[93]. Subsequent reports showed the efficacy of prophylactic HPA-1a negative platelet transfusions in maintaining fetal platelet counts and avoiding hemorrhagic complications[22,94–96]. Unfortunately, transfused platelets have a short half-life and repeat transfusions are required every 5 to 7 days to maintain an adequate platelet count ($>20\times 10^9/\mu l$) in a fetus with severe AIT. Repeated weekly fetal blood samplings for the purpose of platelet transfusions, carry a greatly increased risk of fetal loss or distress.

Intravenous immunoglobulin and corticosteroids

While corticosteroids have shown limited benefit in AIT[83], they do have some efficacy both as primary treatment and as adjunctive treatment to the use of intravenous infusions of gammaglobulin (IVIG). However, the use of maternally administered intravenous immunoglobulin has had the greatest impact on the restoration of adequate fetal platelet counts and the prevention of ICH[97–101]. The mechanism of effect of IVIG is unclear, although IVIG is thought to most likely work by competitively inhibiting the binding of alloantibodies to the $F_c\gamma$ receptor[100,102]. Sufficient doses of IVIG will bind to the $F_c\gamma$ receptors in both the placenta, preventing endocytotic uptake of alloantibodies[103], and fetal mononuclear-phagocytic system, preventing alloantibody mediated platelet destruction[100,102]. The former mechanism, in particular, has indirect support in that the levels of IgG in the maternal circulation are in the range that was shown to competitively inhibit the transport of 90% of anti-D[101,103]. Direct infusion of IVIG into the fetal circulation[104,105] and peritoneum[22] has been reported without great success. Given the efficiency of maternal IVIG transfer across the placenta, and the theoretical benefit of $F_c\gamma$ receptor blockade in the placenta, it is most likely unnecessary to directly infuse IVIG into the fetus. However data on this approach is limited.

Fifteen of the first eighteen maternal–fetal pairs treated with maternally administered IVIG (1gram/kg/week) demonstrated a substantial increase in fetal platelet counts. None of the fetuses or newborns suffered an ICH, even when an antenatal ICH was reported in an older sibling. Almost all of the infants had higher birth platelet counts than did their older siblings. When IVIG was used in combination with 3 to 5 mg/kg/day of dexamethasone, 4 of 5 patients developed oligohydramnios[98,100]. In 1992, Lynch et al.[100] reported that the use of IVIG alone seemed inferior to that of IVIG and steroids. Therefore, a treatment protocol with IVIG plus 1.5 mg/kg/day of dexamethasone was piloted. At this lower dose of dexamethasone, there was no reported oligohydramnios[47,100]. A larger randomized trial then analysed whether there was benefit of this lower dose of steroids in combination with IVIG, but the effect of combined IVIG and dexamethasone 1.5mg/kg was no better than IVIG alone[47].

There are a number of reports of refractory fetal thrombocytopenia despite administration of maternal IVIG[22,100,106–108]. The addition of high dose prednisone (60 mg/day) to weekly IVIG may be effective in patients who do not respond to IVIG alone. This dose of prednisone in combination with IVIG did not cause oligohydramnios[47].

Weekly antenatal IVIG appears to be an effective therapy in preventing in utero and perinatal ICH. However, the variable responses of patients to IVIG necessitates that fetal platelet counts be monitored during the pregnancy by cordocentesis. FBS should be used judiciously for the diagnosis and monitoring of AIT. Operators should be experienced (at least 50 procedures)[47,92,109], and concentrated maternal platelets should be transfused into all fetuses with a platelet count less than $50\times 10^9/l$ prior to the removal of the needle. However in the great majority of centres, a platelet count requires 3–5 minutes to be obtained. Therefore, 3 to 10 millilitres of platelets are usually administered prior to knowledge of the fetal platelet count.

Specific management strategies

For the purpose of defining the most safe and effective management strategies for fetuses with known AIT, it is helpful to consider the following: second affected fetuses from the same parents have comparable or more severe disease than their older sibling; thrombocytopenia worsens as the pregnancy progresses; fetal blood sampling

Table 38.5. Risk Stratification and initial therapy

	Unknown risk	Standard risk	High risk	Very high risk	Extremely high risk
Antigen incompatibility, but other factors unknown?	**Yes**	No	No	No	No
Known AIT, platelet count $>20\times10^9$, and no history of sibling* with ICH?	No	**Yes**	No	No	No
Platelet count on FBS is $<20\times10^9$, or a history of sibling with perinatal ICH?	No	No	**Yes**	No	No
Sibling with ICH between 28 and 36 weeks gestation?	No	No	No	**Yes**	No
Sibling with ICH occurring before 28 weeks gestation?	No	No	No	No	**Yes**
First fetal blood sampling	See text	20 weeks gestation**	20 weeks gestation	20 weeks gestation	20 weeks gestation
Treatment***	See text	IVIG 0.5g to 1g/kg/week	IVIG 1g/kg/wk, and consider prednisolone 1mg/kg/day	IVIG 1g/kg/wk, to start at 12 weeks gestation	IVIG 1g/kg/wk, to start at 12 weeks gestation, but consider IVIG 2g/kg/wk in 2 divided doses

Notes:
* Refers to antigen positive sibling with suspected or confirmed AIT.
** 20 weeks gestation represents the earliest recommended time for FBS in AIT. For standard risk patients, sampling at 20–24 weeks is probably sufficient. See text for more details regarding timing of FBS.
*** Treatment refers to therapy administered to the mother after the first fetal blood sampling, unless otherwise specified.

is the only way to document a response to therapy; maintenance of a fetal platelet count above 20×10^9/l is likely necessary to reduce the risk of ICH; and maintenance of a platelet count above 50×10^9/l is likely necessary for a safe vaginal delivery. To translate these considerations into specific management strategies, our current protocol employs the following grading system: extremely high risk, very high risk, high risk, standard risk and unknown risk (see Table 38.5).

Extremely high risk
Patients are at extremely high risk for an adverse outcome if they are the antigen positive sibling of a fetus who suffered an antenatal ICH before 28 weeks gestation. For this group, 2 g/kg/week (in 2 doses) of maternal IVIG starting at 12 weeks gestation may be more effective than 1 g/kg/week with prednisone.

Very high risk
Fetuses are at very high risk for an adverse outcome if they are antigen positive and have a sibling who suffered an antenatal ICH between 28 and 36 weeks gestation. IVIG at 1g/kg/week starting at 12 weeks gestation may be sufficient in preventing ICH in this group. Monitoring of the fetal platelet count is crucial and in our experience, most patients will later require the addition of 1mg/kg/day of prednisone.

High risk
Fetuses with a sibling who suffered a perinatal ICH, *or* fetuses with a platelet count less than 20×10^9/l, are defined as being at high risk for an adverse outcome. Our ongoing study asked for an initial FBS at 20 weeks gestation and randomized treatment in this group between IVIG alone and IVIG combined with 1 mg/kg of prednisone. It appears that IVIG and prednisone is more effective for the fetus, but also more toxic for the mother.

Standard risk
Fetuses affected by AIT who have no history of a sibling ICH, and have a platelet count greater than 20×10^9/l, have a lesser risk of an adverse outcome. Treatment after FBS is randomized between 1 g/kg/week of maternal IVIG and prednisone 0.5 mg/kg/day.

Unknown risk
When there is maternal–fetal antigen incompatibility, with or without alloantibody formation, there is an unknown risk of an adverse outcome. The literature is fairly clear about the need for close observation of siblings of children

Cambridge Books Online © Cambridge University Press, 2009

with severe AIT. However, there are no absolute indications for antenatal intervention in patients referred with a history of a first or second degree relative with AIT, or in HPA-1a negative primaparous women, even with an affected fetus, unless the fetal platelet count is known to be low. Given the low incidence of alloimmunization in HPA-1a negative mothers, the low incidence of severe thrombocytopenia after alloimmunization[14], and, consequently, the low incidence of ICH, we do not recommend FBS for all such cases. The optimal management remains unknown for the primiparous woman. Paternal phenotype should be ascertained to determine the potential fetal genotypes. If the father is heterozygous for the HPA-1a antigen, fetal genotype should be determined by amniocentesis. FBS should be performed, as early as 20 to 24 weeks gestation, if the following conditions are met (in the absence of a history of AIT in a first degree relative): there is a HPA-1a antigen incompatibility between mother and fetus (by amniocentesis, or if the mother is HPA-1b positive and the father is homozygous for HPA-1a); and maternal alloantibody is detected, irrespective of titre. Maternal alloantibody titres should be tested every 1–3 months until positive, or until 1–2 months postpartum. Alloimmunization may occur at delivery, in which case antibody titres will not rise until the postpartum period, will be subsequent siblings at great risk for thrombocytopenia.

Special considerations

Failure of treatment

After initiation of 1 g/kg/week of maternal IVIG, repeat platelet counts that are lower than previous samplings, or that are below 20×10^9/l, represent refractory disease, and deserve intensification of therapy. In an ongoing clinical trial, our early data suggests that intensification of therapy to 2 g/kg/week of maternal IVIG with or without the addition of 1 mg/kg/day of maternal prednisone may be effective in such refractory cases (unpublished data).

Platelet count less than 10×10^9/l

A platelet count of less than 10×10^9/l, especially if obtained on the first FBS, places the fetus at substantial risk for an adverse outcome. The combination of 1 mg/kg/day prednisone and 1g/kg/week IVIG seems to be more effective in these patients than IVIG alone (preliminary data).

Frequency of fetal blood sampling

The natural history of AIT predicts that the platelet count in an untreated, affected infant will drop by 20 to 25×10^9/l/week. Consequently, for fetal platelet counts of $100–150 \times 10^9$/l, it is reasonable to perform the next FBS within 4 to 6 weeks, and in 3–4 weeks for fetal platelet counts less that 100×10^9/l. FBS cannot be consistently, safely performed prior to 20 to 24 weeks gestation. If the patient is at very high or extremely high risk for an adverse outcome, it is likely that the platelet count will be very low early in gestation, and therapy should be initiated at 12 weeks gestation, 8 weeks prior to the first FBS.

Treatment in the newborn

Early attempts to treat AIT consisted primarily of maternal platelet transfusion[110]. Maternal platelet transfusion or transfusion of HPA-1a negative platelets are still used in severe cases. In the early 1980s there were reports of the successful use of IVIG to treat immune thrombocytopenia in the newborn[111–113]. Corticosteroids are a third option, but are most effective when used in combination with IVIG. Random donor platelets are effective only for brief periods due to rapid alloimmune destruction.

For most infants with presumed AIT, IVIG (1g/kg/dose) will be sufficient in restoring a normal platelet count. The addition of methylprednisolone (1 mg IV every 8 hours) to IVIG may be better than IVIG alone. Recovery of the platelet count can usually be seen within 24 to 72 hours[9,55,114]. For visceral bleeding, including ICH, patients should receive HPA-1a negative platelets (maternal or single donor) in combination with IVIG and methylprednisolone. If HPA-1a negative platelets are not immediately available, random donor platelets may be substituted with frequent assessments of platelet recovery. Most large centres have identified HPA-1a negative donors, and can likely have HPA-1a negative platelets available on short notice.

Conclusions

Alloimmune thrombocytopenia is a disease of varied presentation and course that may have a devastating impact on severely affected infants and their families. While early treatment and intervention may prevent many of the potential adverse sequelae, the prescribed therapy itself is not without significant risk. The capacity exists to effectively treat a great majority of affected fetuses, but we, unfortunately, lack sensitive, reliable and non-invasive indicators of disease severity, and response to therapy.

As understanding of the pathogenesis of this disease broadens, more effective and specific intervention will become available. Future efforts in the study of AIT must focus on: mechanisms of immune modulation in affected

Cambridge Books Online © Cambridge University Press, 2009

and unaffected mismatched maternal–fetal pairs; biologic markers that better define the disease and risk groups; and effective, non-toxic, risk-based therapeutic interventions.

Drug-induced and drug-dependent immune thrombocytopenias

Andreas Greinacher, Petra Eichler and Norbert Lubenow

Institute for Immunology and Transfusion Medicine, Ernst-Moritz-Arndt-University, Greifswald, Germany

Introduction

This chapter will focus on pathological conditions of enhanced platelet destruction mediated by drug-induced and drug-dependent immune mechanisms. Drug-induced thrombotic thrombocytopenic purpura (TTP) will be outlined in Chapter 40.

Drugs may induce various immune-mediated hemocytopenias, immune hemolytic anemia[1], neutropenia[2,3] and thrombocytopenia (Table 39.1).

Table 39.1. Immune thrombocytopenias induced by drugs

1. drug induced autoimmune thrombocytopenia
2. drug dependent immune thrombocytopenia
3. GPIIb/IIIa-antagonist induced thrombocytopenias
4. heparin-induced thrombocytopenia (HIT)
5. drug-induced thrombotic thrombocytopenia (TTP)

Drug-induced autoimmune thrombocytopenia

Von dem Borne et al.[4] reported gold therapy-induced antibodies that bind to platelet membrane targets even when the drug is absent. This has been confirmed by several other groups[5]. The clinical presentation of these patients is indistinguishable from autoimmune thrombocytopenia. Even after cessation of gold therapy, the autoantibodies cause destruction of platelets, usually by phagocytosis in the reticulo-endothelial system (RES). Autoantibody titres may decrease slowly, within months, after cessation of gold therapy paralleled by an increase in platelet counts. Laboratory diagnosis of these antibodies does not differ from other platelet autoantibodies (see Chapter 36). The same is true for treatment. However, gold should be avoided in these patients[6].

Drug-dependent immune thrombocytopenias (ddtp)

Pathogenesis

In ddtp the antibodies only bind to platelets in the presence of the drug or of one of its metabolites. Several models of pathogenesis have been debated[7] (Figure 39.1). According to the hapten-theory[8–10] the antibodies recognize an epitope on the drug. If the drug binds to the platelet surface, the antibodies also bind to the surface bound drug which results in platelet destruction in the RES. This mechanism can be responsible for penicillin-induced thrombocytopenia,[9] but is very unlikely to be the mechanism of other ddtps. Haptens usually bind strongly to proteins and cells[9]; binding of most drugs to platelets, however, is weak. They can be washed off cells rather easily[11,12]. Furthermore, in the test tube, high concentrations of the drug in the supernatant do not block antibody binding[6].

As early as 1963 Shulman and Reid[13] presented an immune-complex mechanism, according to which the drug binds to a protein. The multimolecular complex of protein, drug and antibodies should bind to platelets, causing platelet destruction[14]. Ddtp-antibodies, however, bind to platelets by their Fab-parts and not via their Fc-part[15,16].

According to the trimolecular-complex theory the epitope in ddtp is formed after binding of a drug to a platelet glycoprotein. It still remains unresolved whether the antibodies recognize a change of protein conformation, or the complex of protein and drug. Ddtp-antibodies typically react with monomorphic epitopes on platelet glycoproteins but only in the presence of the drug or a

metabolite. Although several platelet glycoproteins (GPs) have been identified as the antibody target in ddtp (GPIb/IX[17–19], GPV[20], GP IIb/IIIa[21–25]) antibodies in an individual patient are highly specific for a single GP.

Kroll et al.[26] investigated sera of 5 patients with carbimazole-dependent platelet reactive antibodies. They identified a complex of PECAM-1 (platelet endothelial cell adhesion molecule-1, CD 31) and carbimazole to be the antibody binding site.

Drugs causing ddtp

Many drugs in numerous case reports have been suspected to cause ddtp (for a reference list of all case reports until 1998 see: *http: //www.acponline.org/journals/annals/01dec98/drugdata.htm*

http: //www.acponline.org/journals/annals/01dec98/drugindu.htm

George et al.[5,27], but only a few have been documented by appropriate laboratory studies[28]. In some cases a metabolite rather than the drug itself mediates ddtp antibody binding to platelets[12,29–31]. Table 39.2 summarizes all drugs suspected to induce ddtp.

During a time period of 5 years, our laboratory had 153 requests to test for ddtp antiplatelet antibodies. In 11 of them a clear positive result could be obtained: in six patients with carbamazepine, and in one patient each with ceftriaxone, trimethoprim, sulfamethoxazole, perazin, piperacilline/tazobactam. To put these data in perspective, during the same time period, heparin-induced thrombocytopenia antibodies had been confirmed in 1189 patients in our laboratory.

Clinical presentation

Clinical symptoms of ddtp typically occur after an interval of at least 7–10 days after start of medication. As ddtp antibodies may persist for years, in case of re-exposure symptoms can manifest within hours. Platelet counts typically decrease to values below 20 000/μl, petechiae and hemorrhagic blisters of the mucosa are frequent[5,32]. An exception are carbimazole-dependent antibodies[26], which cause a moderate decrease of platelet counts only. The most likely reason is that PECAM-1, which is involved in antigen presentation, also is expressed on leukocytes and endothelial cells. Thus the drug-induced antibodies bind to non-platelet epitopes, too. Whether this mechanism is restricted to carbimazole or applies to other drugs as well is unresolved.

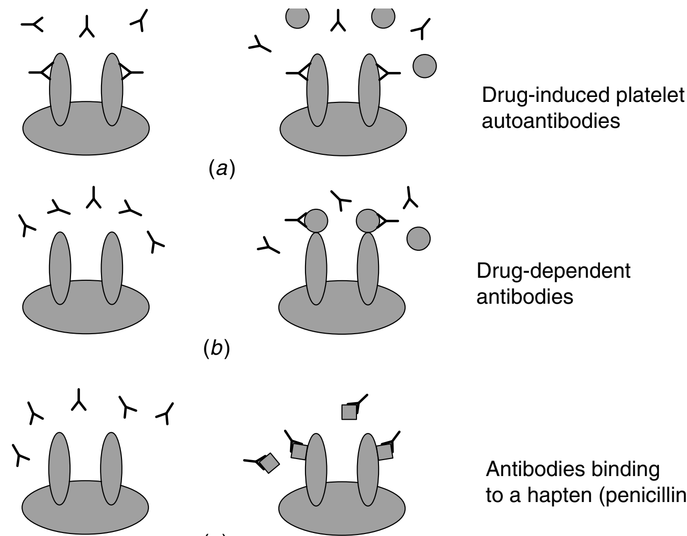

Fig. 39.1. Different hypotheses for drug dependent immune thrombocytopenias (ddtp) are described. (*a*) Drug-induced platelet autoantibodies bind to platelets in the absence (left side) as well as in the presence of the causative drug (right side). (*b*) In the absence of the causative drug, ddtp-antibodies are not able to bind to platelets (left side) but in the presence of the drug the antibodies form a labile trimolecular complex with the drug and platelet membrane structures (right side). (*c*) In the classical hapten reaction, ddtp-antibodies bind to haptens in plasma or to haptens on the cell membrane. In vitro antibody-binding to platelets is inhibited by excess drug.

Treatment

The most important measure in ddtp is cessation and future avoidance of the responsible drug. In the experience of the authors, platelet counts usually rise after 4–5 drug half-life times to values above 50,000/μl. In the meantime, general measures to avoid high intracranial pressure are indicated. If hemorrhage is life-threatening, massive platelet transfusions and i.v. IgG should be considered.

Diagnosis of ddtp

Most important for the diagnosis of ddtp is the clinical judgement and a carefully taken history. Drugs taken by the patient for months or even years are rarely the cause for the immune response. Drugs taken during the last 2 weeks are much more likely to be the trigger. In general drugs taken before, not after, onset of symptoms, are of major relevance.

Laboratory diagnosis

Ddtp-antibodies can be confirmed by a variety of assays[33]. Whole platelet-[34] and GP-specific ELISAs[35] have been employed as well as flow cytometry[36], or immunoblot[37]. Due to labile binding of the drug to platelet GPs and the potential dependency of the antigen on protein conformation, assays not altering the GP structure, e.g. flow cytometry are usually more sensitive than immunoblot. In all assays it is absolutely crucial to add to all reaction media, including all washing buffers, with the same concentration of the suspected drug or the metabolite. Appropriate controls are also mandatory (Table 39.3). In case a metabolite of a drug is suspected to be causative, a practical source for some metabolites is the use of urine (pH buffered) obtained from an individual who takes the suspected drug. The clinical importance of negative in vitro tests for drug-dependent antibodies remains uncertain. In some reports, patients with apparent quinidine-induced thrombocytopenia had no demonstrable drug-dependent antibodies using different assays. Therefore, in the absence of promptly available and clinically validated laboratory assays, judgement about ddtp must continue to be based on clinical criteria[38].

GP IIb/IIIa receptor antagonist-induced thrombocytopenias

Frequency

GP IIb/IIIa receptor antagonists are a heterogeneous group of anti-integrilins[39] (Table 39.4) gaining increasing importance in the treatment of acute cardiac syndromes. Thrombocytopenias have been observed in all studies with these drugs, but also occurred in the control populations (Table 39.5). Currently abciximab, tirofiban and oral GPIIb/IIIa antagonists seem to be associated with an increased risk for severe thrombocytopenias, whereas in eptifibatide-treated patients the risk for severe thrombocytopenias was not enhanced as compared to the control population (Table 39.5). In abciximab treated patients severe thrombocytopenias ($<$20 000/μl) occurred in 0.3–1.6 % of patients who received the drug for the first time. If the EPIC, EPILOG and CAPTURE studies are pooled the incidence of severe thrombocytopenias was higher in abciximab treated patients as compared to placebo treated patients (1.1% vs. 0.5%, $P = 0.017$)[49–51].

Clinical presentation and treatment

GP IIb/IIIa inhibitor induced thrombocytopenias typically occur within the first 24 hours after start of treatment. Platelet counts decrease to values below 50 000/μl and

often below 20 000/µl[52]. Patients are at an increased risk to develop bleeding complications. Therefore it is recommended that platelet counts be monitored during treatment with GP IIb/IIIa receptor antagonists. For abciximab, platelet counts are recommend by the manufacturers after 2, 4 and 24 hours.

In our own series of 34 of these patients, hematomas, petechiae, mucosal and urine tract hemorrhages were the most frequent bleeding symptoms. After cessation of the drug, platelet counts normalized rapidly, usually within 2–3 days. Treatment of thrombocytopenia is symptomatic, but the heparin dose should be reduced. In case of bleeding complications, platelet transfusions are the treatment of choice. Steroids or i.v. IgG are not sufficient[53,54]. For

platelet transfusion therapy, the different half-lives of the GP IIb/IIIa antagonists and their different pharmacology should be considered. The direct antagonists like abciximab have a high binding affinity to GP IIb/IIIa. Therefore the drug is rapidly cleared from the circulation and redistribution to transfused platelets occurs slowly[55,56]. Eptifibatide and tirofiban, however, have a much lower affinity for the receptor and are given in excess. The GP IIb/IIIa complexes of transfused platelets will be rapidly covered with the drug. Platelet transfusions should therefore be given after several half-lives of the drug have passed following cessation of the drug (4–6 hours). Before heparin dosage is reduced or platelet transfusions are given prophylactically, pseudothrombocytopenia must be excluded.

Pseudothrombocytopenia

This artefact seems to be frequent in abciximab treated patients. Several cases of abciximab induced pseudothrombocytopenia have been described[57–59]. Sane et al.[60] determined incidences of pseudothrombocytopenia and thrombocytopenia in the EPIC-, EPILOG-, EPISTENT- and CAPTURE studies. Pseudothrombocytopenia occurred in 2.1% of abciximab treated patients as compared to 0.6% in placebo treated patients. In our laboratory, in 5 of 34 patients (14.7%) with the clinical suspicion of GP IIb/IIIa antagonist-induced thrombocytopenia, pseudothrombocytopenia was the underlying reason. All these patients had been treated with abciximab.

In our view, pseudothrombocytopenia is the most dangerous side effect of GP IIb/IIIa antagonists. In case of misinterpretation as real thrombocytopenia not only the drug itself but also heparin are often withdrawn and sometimes even platelet transfusions are given. These measures increase the risk of developing a new arterial occlusion. As pseudothrombocytopenia may occur independently of the anticoagulant used, i.e. in EDTA-, citrate- and heparinized blood, a microscopical assessment of a blood smear should always be included in the diagnostic procedure to distinguish between the typical large platelet aggregates and genuine thrombocytopenia. The impressively huge platelet aggregates as seen on blood smears in patients

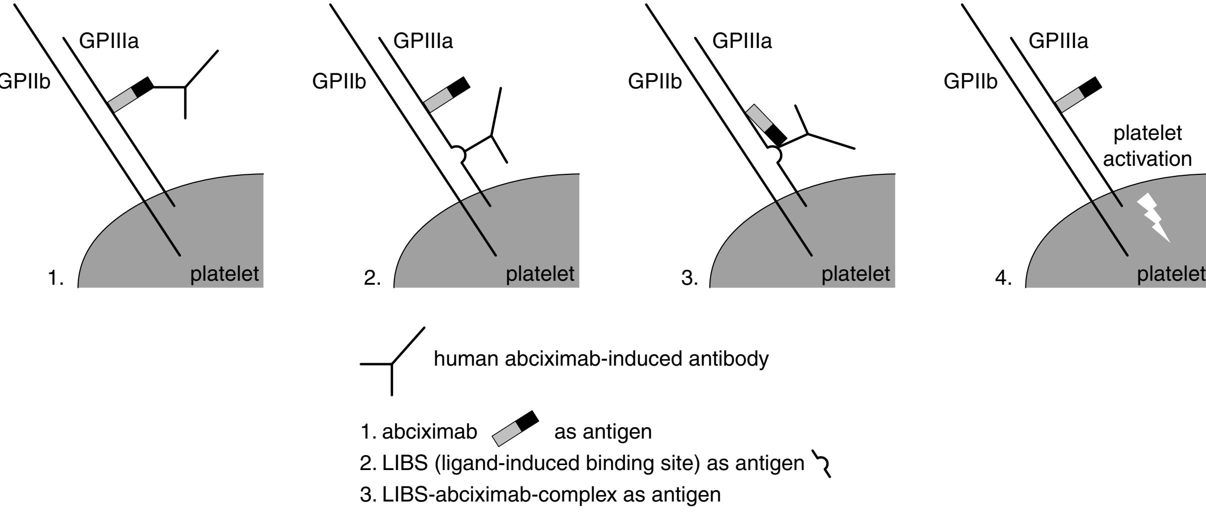

Fig. 39.2. Hypotheses for development of GP IIb/IIIa-induced thrombocytopenia.

with pseudothrombocytopenia, and the still unexplained fact that the large trials of oral GPIIb/IIIa antagonists had to be terminated because of an excess of thrombotic events may be causally related. The exact mechanism of pseudothrombocytopenia in GPII/IIIa treated patients is unknown; however, there is no evidence that other patients with pseudothrombocytopenia, who are not treated with GPIIb/IIIa antagonists, have any clinical sequelae associated with this in vitro phenomenon.

In addition, owing to the concomitant use of heparin and GP IIb/IIIa receptor antagonists, heparin-induced thrombocytopenia should also be considered, if the patient received heparin within the last 3 months before the acute episode.

Pathogenesis

The pathogenesis of GP IIb/IIIa-induced thrombocytopenias is still unresolved. The hypothesis most often presented is that a neoepitope is generated on the platelet surface after binding of the drug. This neoepitope is recognized by preformed antibodies in the patient serum. After binding of these antibodies, platelets are phagocytosed by the RES. Hereby, (i) the drug itself may be recognized as the antigen (Fig. 39.2), (ii) the GP can undergo a conformational change after binding of the drug resulting in a new ligand induced binding site (LIBS)[7,38,61], or (iii) a complex of the drug and the LIBS could be the antigen[38,62].

An alternative theory is that binding of the drug may induce an outside–in signalling which causes platelet activation. The activated platelets would then be destroyed in the RES[63,64].

It seems to be very unlikely that a specific immune response induced by the GP IIb/IIIa antagonists is the reason for the acute thrombocytopenias, as the time interval between start of treatment and onset of thrombocytopenia is too short.

Cines[65] speculated that only in patients with a certain polymorphism of the GP IIb/IIIa complex is a neoepitope expressed after binding of the drug to which preformed antibodies bind by crossreactivity. This model could provide an explanation why only a minority of GP IIb/IIIa receptor antagonist-treated patients develops thrombocytopenia. To test this hypothesis, we screened DNA of 34 affected patients for polymorphisms in the GP IIb/IIIa complex but could not find mutations associated with the occurrence of thrombocytopenia (unpublished).

Curtis et al.[66] used flow cytometry and demonstrated antibodies which bind to abciximab preincubated platelets in 94% of patients with acute thrombocytopenia during abciximab therapy. However, in sera of 10% of normal controls, these antibodies were also present. Whereas the antibodies in the control sera could be neutralized by preincubation with normal Fab fragments, antibodies in patient sera could not. The titres of these antibodies increased tenfold after re-exposure with abciximab.

Kecskes et al.[67] and Cines[65] also described preformed antibodies directed against a conformation-dependent epitope on the GP IIb/IIIa complex. Kroll et al.[68] found

Cambridge Books Online © Cambridge University Press, 2009

abciximab dependent antibodies in 7/7 patients using flow cytometry and the MAIPA technique. However, they found these antibodies also in 17/100 sera of normal blood donors, not pre-exposed to abciximab. We find an even higher percentage of positive results in normal controls. The monoclonal antibody anti-CD41, clone P2 (recognizing GP IIb in the intact GPIIb/IIIa complex) blocks human antibody binding, whereas the moab anti CD-61, clone PM 6/13 (specific for GP IIIa) does not. The epitope involved therefore seems related to the binding site of moab anti-CD41, clone P2. The high percentage of positive results in normal controls, however, raises the question about the diagnostic and pathogenetic relevance of those antibodies.

Kozak et al.[59] demonstrated in vitro platelet aggregation in a patient with abciximab related pseudothrombocytopenia after addition of abciximab, eptifibatide or tirofiban, which they interpreted as crossreactivity of the antibodies.

In our laboratory, antibodies which bound to platelets after preincubation with abciximab did not bind after preincubation with tirofiban. Whether this excludes cross-reactivity, or is a result of the different affinities of the two drugs, is unresolved.

Human antichimeric antibodies (HACAs)

HACAs are induced by the chimeric, humanized Fab fragments of abciximab. Between 4.7 and 6.5% of all patients treated in the EPIC, EPILOG, and CAPTURE studies developed these antibodies, which are directed against the human part of the Fab-fragment. As to be expected from primary immune response, these antibodies occur 2–4 weeks after treatment with a maximal titre after 4–6 weeks[69]. The percentage of patients with HACAs increases after re-exposure to abciximab[70]. However, these antibodies seem to be of very minor, if any, clinical relevance and are not correlated to the risk of occurrence of thrombocytopenia.

Heparin-induced thrombocytopenia

The first case reports of ‘paradox’ thromboembolic complications (TECs) during heparin medication were published in 1958[71]. Today, heparin-induced thrombocytopenia (HIT) is the most important and most frequent drug-induced, immune-mediated thrombocytopenia. This immune HIT has to be distinguished from non-immune interactions between heparin and platelets. In our laboratory confirmed HIT was 100 times more frequent than all other drug-induced thrombocytopenia during the last 5 years.

Non-immune heparin-associated thrombocytopenia

Due to its negative charge, heparin binds to platelets in a saturable manner[72–75]. No unique platelet structures have been identified for this binding and different polysaccharides can displace each other from platelet binding directly dependent on their charge density and chain length[73,76,77]. Numerous in vitro experiments addressed the effects of heparin on platelets[75]. Although results are not always consistent, it is generally agreed that in vitro heparin has a pro-aggregatory effect on platelets[78–80], which is correlated to its grade of sulfation and chain length[81].

These direct heparin–platelet interactions are thought to cause the frequent phenomenon of early onset thrombocytopenia in patients receiving unfractionated heparin (UFH), typically in therapeutic dosage i.v. In a consensus paper[82] it had been suggested to use the term heparin-associated thrombocytopenia to distinguish this syndrome from immune mediated HIT.

Clinically non-immune heparin–platelet interactions cause a mild and transient decrease of platelet counts, rarely $<100\,000/\mu l$[83,84]. In case of certain underlying diseases like anorexia nervosa, burns, arterial disease, or concomitant DIC, platelet counts can decrease to much lower levels[81,85,86].

Diagnosis of non-immune heparin-associated thrombocytopenia is an exclusion diagnosis. Special treatment is usually not required. In patients with a dramatic reduction in platelet counts, low molecular weight heparins (LMWH) may be a therapeutic option for anticoagulation.

These heparin–platelet interactions are of relevance for the development of immune HIT[87]. Binding of platelet factor 4 (PF4) heparin complexes is mediated by the heparin binding site rather than a PF4 binding site[77,88]. Smaller heparin molecules bind less strongly to platelets, cause less platelet activation, less release of PF4 either from platelet alpha granules or from endothelial cell heparan sulfate, and form smaller (less immunogenic) complexes with PF4[89,90].

Immune heparin-induced thrombocytopenia

Pathogenesis of HIT

The pathogenesis of HIT is rather unique. Two compounds which are normally present in the human body, heparin and PF4, complex with each other and induce an immune response.

The proteins involved

Amiral et al.[91,92] were the first who identified PF4 as the most important protein involved in the immune response

Cambridge Books Online © Cambridge University Press, 2009

of HIT and who characterized other involved chemokines as interleukin 8 (IL8) or neutrophil activating peptide-2 (NAP-2)[93] Their finding has been confirmed by several other groups[94–97]. PF4 is a positively charged tetrameric glycoprotein formed by two self-assembling dimers, each consisting of two non-covalently bound monomers. These PF4 tetramers bind to glycosaminoglycans. The amino-acid sequence of PF4 and the encoding DNA sequences are resolved[98,99]. In patients with HIT no mutations of the PF4 gene could be identified[100], thus the antigen is considered to be a cryptantigen or autoantigen exposed after binding of heparin to the tetramer[101]. Horsewood et al.[102] used reduced or alkylated PF4 to map the binding region of HIT antibodies. Of 29 sera, 5 contained antibodies which bound to these modified PF4 proteins and which recognized a 19 COOH-terminal amino acid peptide. By using chimeric PF4[103], PF4 mutants,[104–106] and inhibition experiments[104], the PF4 region between the third and the fourth cysteine residues has been identified as most important for formation of at least three recognition sites for HIT-antibodies. However, as peptides of these regions alone are not able to bind HIT-antibodies, the antigenic site seems to be dependent on the three-dimensional structure of the complex.

The polysaccharides involved

In platelets, eight PF4 tetramers are bound to a chondroitin sulfate proteoglycan[107]. PF4 is released from platelets during platelet activation and can then bind to heparan sulfate containing proteoglycans at the surface of endothelial cells[108]. Polysaccharides with higher sulfation than heparan, e.g. heparin, can displace PF4 from endothelial bound heparan sulfate[109]. The interaction between heparin or other polysaccharides and PF4 has been extensively studied[110]. In essence, the interaction is not dependent on the primary sugar sequence, the type of glycosidic linkage, or the antithrombin binding capacity of a polysaccharide[98,111–113], but on the degree of sulfation and the molecular weight. If the degree of sulfation (number of sulfate groups per monosaccharide) is below 0.5, or the chain length is below 2.4 kDa (~7 monosaccharides) formation of the HIT antibody recognition site after complexing of the polysaccharide with PF4 is very unlikely[111]. Thus the pentasaccharide (1727 kDa)[114], a mixture of low sulfated glycosaminoglycans (danaparoid)[115], or certain synthetic polysaccharides[116] will potentially reduce the risk of immune-mediated HIT.

The concentrations required

Because complexes of PF4 and heparin bind to platelets via the heparin binding site, they have to compete with free heparin[88,117]. If free heparin is in excess, the pathogenic complexes are displaced from the platelet surface. Therapeutic concentrations of heparin reach 0.2–0.4 U/ml, which corresponds to 100–200 nmol/l, whereas the normal PF4 concentration reached after application of heparin is only 8 nM[118] which corresponds to ~0.2 μg/ml. Under in vitro conditions, using 0.2–0.4 IU heparin/ml, the amount of PF4 required to reach the stoichiometric concentrations for the antigenic complex is about 6–20 μg/ml. Thus the HIT antigen is only formed under extreme conditions in which very high amounts of PF4 are released. The situation is very different if small amounts of heparin are given in clinical settings with enhanced platelet activation and higher than normal PF4 concentrations, e.g. during thrombosis prophylaxis after major hip-joint replacement surgery, or in patients with major arterial vessel disease. This seems to be exactly the situation where patients are at the highest risk to develop HIT (Fig. 39.3). Furthermore, this concentration dependency may give an explanation for the differences in the frequency of HIT in different patient populations[75,101].

The antibodies involved

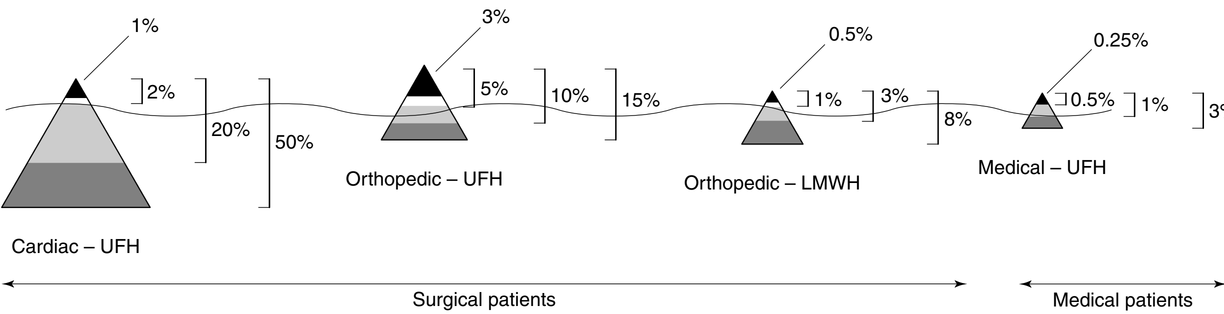
In symptomatic HIT patients, the antibodies involved are of the IgG class in 80% of cases. Antibodies of the IgG1 class were found to be predominant among HIT-IgG[120–122] but patients with HIT antibodies of the IgM or IgA class only have also been described[123]. There is increasing evidence that the percentage of patients developing the immune response of HIT, i.e. a positive HIT-antibody test but no clinical symptoms, is much higher than the percentage of patients who develop clinical HIT. Antibody concentration, antibody affinity, and most importantly the clinical conditions of the patient seem to be relevant for a 'clinical breakthrough' of HIT[101]. Empirically, we have the impression that anti-PF4/heparin antibodies, which activate platelets in an in vitro assay, are more likely to cause clinical HIT than those only detectable by ELISA.

There are pre-existing antibodies against chemokines (IL-8, NAP-2, PF4)[124–126]. Whether they have any pathogenic role in HIT is unresolved.

Platelet receptors and HIT

The most important platelet glycoprotein involved in HIT is the platelet FcγIIa receptor[127]. Binding of HIT antibodies to the PF4–heparin complexes results in large multimolecular immune complexes[94,96]. The Fc-parts of the IgG in the immune complexes crosslink the FcγRIIa. The resulting platelet activation can be completely blocked by a monoclonal antibody against the FcγRIIa[79,128]. The number of FcγRIIa copies on the platelet surface is increased in

Cambridge Books Online © Cambridge University Press, 2009



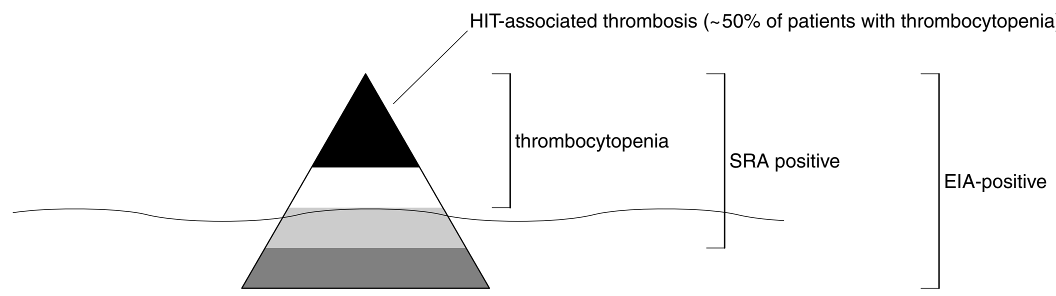


Fig. 39.3. Iceberg-model of heparin-induced thrombocytopenia[119]. SRA: serotonin release assay; EIA: enzyme linked immune assay.

HIT[129], most likely as a marker of increased platelet activation. Soluble FcγRIIa, produced by alternative splicing[130,131], reach about 10% of the total number of the platelet membrane bound receptors. They are not able to saturate the Fc-parts of the immune complexes. As a marker of increased platelet activation, soluble FcγRIIa is found in increased concentrations in HIT patients[132].

The FcγRIIa has a functionally relevant polymorphism, FcγRIIa–Arg/His131, which results in different affinities for human IgG2[133–135]. In vitro, washed platelets with the FcγRIIa His131 variant are preferentially activated by HIT antibodies[121,136]. Several studies investigated the role of this polymorphism in HIT. Burgess et al.[137] ($n=19$), Brandt et al.[138] ($n=96$), Denomme et al.[121] ($n=84$) found the His131 variant overrepresented whereas Arepally et al.[120] ($n=36$) and Bachelot-Loza et al.[136] ($n=25$) found no association between Fcγ RIIa genotype and HIT. Carlsson et al.[139] ($n=389$) showed an increase in the frequency of Arg131. This increase occurred only in the subset of patients with HIT and thrombosis. They hypothesize that the PF4–heparin–HIT–IgG immune complexes and platelets covered with these immune complexes are cleared by the FcγRIIa of the RES more efficiently in individuals with the His131 genotype. Therefore, platelet activating immune complexes circulate longer in patients with the Arg 131 phenotype, thereby enhancing thrombin generation and increasing the risk for HIT-related thrombosis.

Apart from the FcγRIIa, at least one of the platelet ADP receptors seems to be of major importance in HIT, as blocking of the receptor completely inhibits FcγRIIa-mediated platelet activation[140].

Endothelial cells in HIT

HIT antibodies of the IgG, IgA, and IgM class bind to endothelial cells[141], dependent on endothelial cell heparan sulfate and on addition of PF4[96,141]. Activation of endothelial cells by HIT antibodies, however, seems to require cofactors released by activated platelets and can be inhibited by addition of apyrase or a GPIIb/IIIa inhibitor[142]. Although endothelial cells should have an important role in HIT, the exact mechanism is still unresolved.

Thrombin in HIT

Thrombin plays a central role in HIT-related thromboembolic complications (TECs) (Fig. 39.4). Thrombin generation is enhanced in HIT[143,144] by concomitant activation of platelets[145], generation of platelet microparticles[146], and alteration of endothelial cells[141]. Activated endothelial cells

Cambridge Books Online © Cambridge University Press, 2009

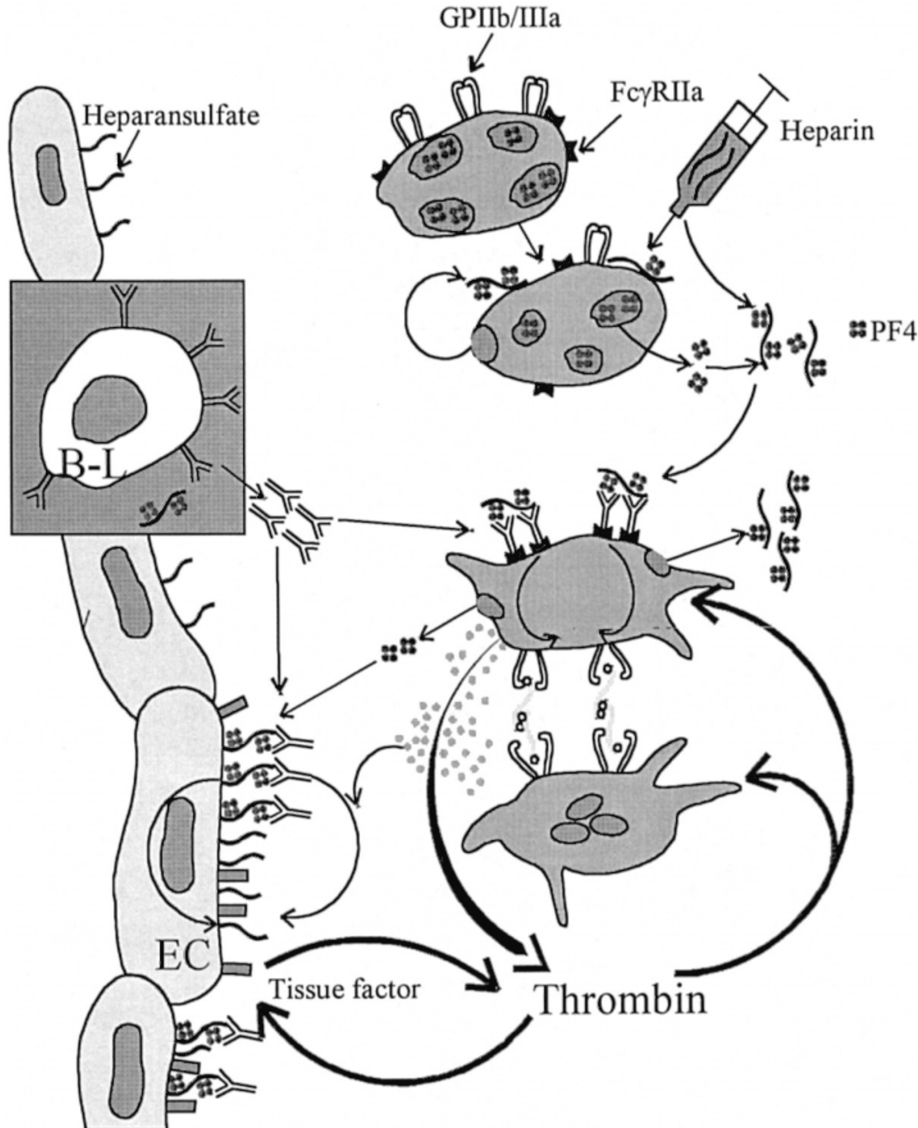

Fig. 39.4. Pathophysiology of heparin-induced thrombocytopenia[82]. Platelets activated by PF4/heparin–HIT–antibody complexes trigger a cascade of events that eventually lead to activation of the coagulation pathways, resulting in thrombin generation. The released PF4 also binds to endothelial cell heparan sulfate, forming antigen complexes to which HIT-antibodies can bind.

upregulate tissue factor expression. It is very likely that platelet microparticles and anti-PF4 heparin antibodies, known to be able to activate monocytes, also cause expression of tissue factor on monocytes[147].

Genetic polymorphisms of clotting factors causing enhanced thrombin generation such as Factor V Leiden[148] or prothrombin G20210A[149] or MTHFR C677T[149] do not seem to be risk factors for the development of clinical HIT.

Frequency of HIT

It is important to distinguish patients with HIT-antibodies only from patients with clinical HIT: studies screening symptomatic as well as asymptomatic patients[150–159] showed that most patients who form HIT antibodies do not develop clinical HIT. Clinical HIT however can occur in up to 3% of patients treated with unfractionated heparin[150]. Different patient populations can have greatly differing incidences of clinically inapparent HIT antibodies as well

Cambridge Books Online © Cambridge University Press, 2009

as clinically manifest HIT. Fig. 39.3 shows the cardiosurgical patients treated with UFH to be at highest risk of developing HIT-antibodies but associated thromboembolic complications are more frequent in patients undergoing orthopedic hip replacement surgery. Despite the fact that LMWHs cause HIT less often compared to UFH[150–160], this is only true within the same patient population: medical patients on UFH have a lower risk of developing HIT compared to orthopedic patients on LMWH.

Diagnosis of HIT

Clinical diagnosis

In HIT platelet counts usually drop by >50% or below 100 000 Gpt/l after day 5 of heparin treatment. In case of reexposure to heparin this drop can occur earlier[161,162]. Thrombocytopenia of <20 000 Gpt/l occurs in less than 10% of HIT-patients. Typical TECs associated with HIT are deep venous thrombosis, pulmonary embolism[163], venous limb gangrene (caused by temporary acquired protein C deficiency during initiation of coumarin anticoagulation)[143], cerebral vein thrombosis/adrenal hemorrhagic necrosis[164–166], arterial thrombosis,[119] heparin-induced skin lesions[167,168] and acute systemic reactions[169–171].

Differential diagnosis

Differential diagnoses include non-immune heparin associated thrombocytopenia, autoimmune thrombocytopenia, drug-dependent thrombocytopenias (see above), consumptive thrombohemorrhagic disorders like disseminated intravascular coagulopathy, post-transfusion purpura[172], and a variety of diseases accompanied by a substantial decrease of platelet counts[173]. In patients with adenocarcinoma, DIC can be triggered secondary to procoagulant material produced by neoplastic cells. This is typically enhanced when oral anticoagulation is started, most likely due to the induced protein C deficiency[168,173]. In severe pulmonary embolism, platelet activation by clot bound thrombin can result in a substantial decrease of platelet counts. Both syndromes can easily be misdiagnosed as HIT, because thrombocytopenia and the new thrombotic complication may occur after several days of heparin treatment. Although drug-dependent thrombocytopenia and post-transfusion purpura[172] occur with a time delay typical for HIT, they are characterized by very low platelet counts and are often associated with bleeding complications which would be atypical for HIT. Also, in clinical situations with acute platelet activation, the platelet count decrease occurs early and not with the time delay of 5–9 days as in HIT, i.e. in diabetic ketoacidosis, causing hyperaggregable platelets; in thrombolytic therapy potentially due to thrombin bound to fibrin split products; in infective endocarditis, by infection-related platelet activation sometimes accompanied by septic emboli; and in paroxysmal nocturnal hemoglobinuria, by platelet hypoproduction and complement mediated platelet destruction. Differentiation of antiphospholipid syndrome from HIT is sometimes difficult[174].

Laboratory testing

In vitro demonstration of HIT-antibodies by functional (or activation) and immunological assays[175] can help securing the clinical suspicion of HIT.

Activation assays are usually performed with washed donor platelets, incubated with heparin and patient serum. Whereas the serotonin release assay (SRA) is regarded the gold standard, it involves the need for radiolabels[176]. The heparin-induced platelet activation assay – while still technically demanding – is better suited for routine testing[177,178]. Other endpoints as luminography[179], platelet derived microparticle generation[180], or annexin V expression[181] may also be used. In the hands of the authors, results between these assays do not differ largely as long as washed platelets are used. However, sensitivity is reduced, if performed with platelet-rich plasma[182–185].

Antigen assays use surface-bound target antigen (PF4/heparin- or PF4/polyvinylsulfate-complexes, respectively) to detect the antibodies[91,96,186]. The fluid phase EIA for HIT antibodies[187] is a modification of the protein A antibody capture method[188]. The latter assay has several technical advantages such as lower background by removal of non-HIT IgG and less interaction of the microtitre plate surface with the antigen structure, but it only allows detection of antibodies of the IgG class. An assay using the microcolumn technique known from red blood cell serology for detection of HIT antibodies[189] is currently under evaluation.

Regardless which assay is used, it is important to incorporate clinical information in the interpretation of test results and to combine a sensitive functional assay and an antigen assay. Whereas functional and antigen assays have similar sensitivities for clinical HIT, antigen assays may have greater sensitivity for HIT antibody seroconversion. Thus the functional assays' positive predictive value for clinical HIT could be greater[153]. False negative results are estimated to be less than 5% if both test systems are applied.

Therapy

Immediate cessation of heparin is necessary when HIT develops. However, thrombin generation continues[190]. Up to 50% of patients with HIT who do not have a new

Cambridge Books Online © Cambridge University Press, 2009

HIT-associated thrombosis at the time HIT is clinically suspected on the basis of isolated thrombocytopenia will develop a new thrombotic complication during the next weeks[163,191–193]. Therefore, these patients should be treated with an alternative anticoagulant until recovery of platelet counts[194,195].

Prospective studies with lepirudin revealed that patients were at the highest risk of experiencing new thromboembolic complications in the acute phase of HIT despite cessation of heparin[192,193]. Thus, in cases of strong clinical suspicion of HIT, patients should immediately be treated with an alternative anticoagulant. Awaiting laboratory confirmation of HIT before alternative anticoagulation is started would cause a significant delay in most cases, enhancing the risk for the patient substantially.

There is clinical experience as well as approval by the authorities in several countries for the treatment of HIT with the direct thrombin inhibitors hirudin and argatroban as well as the heparinoid danaparoid.

Hirudin

Pharmacology

Unlike heparin, hirudin inhibits not only free but also clot-bound thrombin[196–199].

Terminal plasma elimination half-lifes ($t_{1/2}$ß) of 0.8–1.7 hours after intravenous (i.v.) injection of bolus lepirudin doses of 0.01–0.5 mg/kg, and 1.1–2.0 hours for continuous i.v. infusions over 6 hours are observed[200]. With subcutaneous (s.c.) administration, bioavailability is nearly 100%. After s.c. injection of 0.75 mg/kg, a peak lepirudin concentration of approximately 0.7 μg/ml occurs in 3 to 4 hours[201] (dosing schedules Table 39.6).

Renal clearance accounts for approximately 90% of the systemic clearance. The $t_{1/2}$ß of lepirudin is lengthened with deterioration of renal function[204–208]; in nephrectomized humans it is prolonged to up to 200 hours[209].

For monitoring, the aPTT[210,211] shows considerable variability between patients[212–215] and at higher hirudin plasma levels (aPTT values >70 seconds), the concentration-aPTT curve flattens and the correlation becomes poor[215–218]. A new tool for monitoring hirudin treatment is the ecarin clotting time (ECT)[219–222] especially in patients requiring a high hirudin dose, for example during cardiopulmonary bypass[223]. There is no antidote available for hirudin.

Clinical studies with hirudin in HIT

After a small pilot study[224] and several case reports showed the feasibility of lepirudin treatment in HIT patients[225–231], two prospective, multicentre, historically controlled trials, HAT-1 ($n = 82$)[192] and HAT-2 ($n = 112$)[193] were conducted in patients with laboratory confirmation of the clinical diagnosis of HIT.

Both studies had similar mortality rates (7.3% and 9.8%); however, limb amputations (3.7% and 8.9%) and new thromboembolic complications (9.8% and 17.9%) differed between the studies. All fatalities were judged to be due to the underlying disease, rather than use of lepirudin.

The combined endpoint (new TECs, limb amputation, death) at day 35 was 52.1% in a historical control ($n = 120$) and 25.4% in the HAT-1– ($P = 0.014$; adjusted risk ratio 0.508; 95% CI, 0.290–0.892) and 31.9% in the HAT-2 study ($P = 0.15$; adjusted risk ratio 0.709; 95% CI, 0.44–1.14).

In both studies there were more bleeding events in the lepirudin-treated group compared to controls (39.1% [HAT-1], 44.6% [HAT-2] vs. 27.2%), but not more bleedings requiring transfusion (9.9% [HAT-1], 12.9% [HAT-2] vs. 9.1%).

In a recent meta-analysis of both studies, patients with HIT and ongoing thrombosis treated with lepirudin showed a clear reduction of the combined endpoint compared to the historical control group ($P = 0.004$)[144]. Low aPTT ratios (1.0 to 1.5) were clearly subtherapeutic, with minimal effects on both clinical events and bleeding. In contrast, medium aPTT ratios (1.5 to 2.5) were associated with a pronounced reduction in clinical events (RR = 0.42) and a moderately increased risk of bleeding (RR = 3.21). Higher aPTT ratios (>2.5) did not further reduce clinical events, but doubled the risk ratio of bleeding (RR = 6.03). Thus, an aPTT ratio of 1.5 to 2.5 is the recommended target range[144].

Whereas a change in the prothrombin time at the start of treatment with lepirudin is of minor clinical relevance, no evidence was found indicating that cessation of lepirudin causes a change of the INRs[144].

Induction of antibodies

As a non-human protein, recombinant hirudin has immunogenic properties that can cause antihirudin antibody formation[232–235]. Of 198 HIT patients treated for ≥5 days with lepirudin, 45% developed antihirudin antibodies of the immunoglobulin G (IgG) class[232]. In 2–3% of patients with antihirudin antibodies, the hirudin dose had to be decreased by more than 60% to maintain the aPTT within the target range[232]. This enhanced anticoagulant effect may be caused by decreased renal elimination of the hirudin–antihirudin complexes. In a few patients, development of antihirudin antibodies was paralleled by a decrease of the aPTT.

Notes:

Due to lack of systematic data, hirudin cannot be recommended during pregnancy and lactation or in children as long as other treatment options are available.

During concomitant treatment with aspirin, GPIIb/IIIa inhibitors, fibrinolysis, or in patients with platelet counts <100 000/μl, the bleeding risk is increased and dosage may have to be reduced.

In patients with renal impairment, dosage must be reduced to avoid overdosage.

Abbreviations: aPTT = activated partial thromboplastin time; HIT = heparin-induced thrombocytopenia; TEC = thromboembolic complication; i.v. = intravenous; s.c. = subcutaneous; b.w. = body weight; CVVH = chronic-veno-venous hemofiltration; ECT = ecarin clotting time; HLM = heart–lung machine; CPB = cardiopulmonary bypass; bid = two times daily.

[a] If Actin FS or Neothromtin reagents are used in Europe, different ranges may apply (e.g., 1.5–3.0).

[b] Approved indication in the EU and the USA reduce bolus by 50% in elderly patients (compensated renal insufficiency).

[c] Maximum body weight for calculation of dosage: 110 kg.

[d] Desirudin has been shown to be effective in a dosage of 15 mg s.c. bid following orthopedic hip replacement surgery (d).[202,203]

[e] Stop 15 min before end of CPB. Put 5 mg lepirudin into CPB-machine after disconnection to avoid clotting.

Levels of evidence for the recommendations:

(a) prospective randomized double-blind trials.

(b) prospective randomized open trial.

(c) uncontrolled (due to ethical reasons), prospective multicentre trials.

(d) crossover study, prospective dose escalation trial.

(e) case observations.

Argatroban

Pharmacology

Argatroban is a small (anhydrous, MW 508.7) synthetic direct thrombin inhibitor that specifically and reversibly binds to the catalytic site region of thrombin[236].

In healthy volunteers the pharmacodynamic steady-state was reached after 161–268 minutes in doses from 1.25 to 10 μg/kg/min without bolus and 150–268 minutes with a bolus of 250 μg/kg.

The main route of elimination is hepatic metabolization, the pharmacodynamic half- life is 36 minutes and severe renal impairment does not affect the elimination of argatroban (at a dose of 5.0 μg/kg/min for 4 hours). This is a major advantage in HIT patients with renal impairment in whom quickly adjustable anticoagulation is required.

Initial dosing in adults without hepatic impairment is 2 μg/kg/min as a continuous intravenous infusion. Steady state levels are typically reached after about 2.5 hours. Monitoring using the aPTT should be started at that time aiming at 1.5–3.0 times baseline values, not to exceed 100 seconds. Adjusted doses should be lower than 10 μg/kg/minute.

There are combined effects of oral anticoagulants and argatroban on the INR, causing artificially increased INR values. Therefore, INR values should be monitored daily. No loading dose of the oral anticoagulant should be given, instead therapy should be started with the expected daily dose. With doses of argatroban of up to 2 μg/kg/min, argatroban can be discontinued once the INR is >4. INR should then be checked every 4–6 hours. If a repeat INR is below the therapeutic range, the argatroban infusion should be resumed and the procedure repeated daily until the therapeutic INR level is reached on oral anticoagulation alone. With oral anticoagulation and argatroban doses >2 μg/kg/min, dosing should be temporarily reduced to 2 μg/kg/min and the INR checked 4–6 hours later.

Clinical studies with argatroban in HIT

Argatroban has been assessed in a prospective trial in patients with HIT with a similar design as the lepirudin studies. A major difference to the lepirudin studies was that patients with a clinical suspicion of HIT only were also included. In brief argatroban was associated with a lower composite event rate (death, limb amputation, new thrombosis) compared to historic control subjects (patients with isolated HIT 25.6 vs. 38.8%, $P = 0.014$ and patients with HIT and thrombosis 43.8 vs. 56.5%, $P < 0.130$)[237]. Significant between-group differences by time-to-event analysis of the composite end point favoured argatroban treatment in HIT ($P = 0.010$) and HIT and thrombosis ($P = 0.014$).

Danaparoid

Pharmacology

The heparinoid danaparoid-sodium[238–240] consists of 84% heparan sulfate, 12% dermatan sulfate and 4% chondroitin sulfate[241].

Danaparoid mainly exhibits anti-Xa activity, with a half life of approx. 24 hours. Its antithrombin activity has a half-life of about 2–4 hours. Danaparoid is mainly eliminated renally[242]. In patients with renal failure a dose reduction of about 30% is required to maintain aFXa levels within the therapeutic range[115].

Danaparoid does not significantly prolong aPTT, activated clotting time or INR, thus anti-FXa-activity has to be used for monitoring. It is important to use a danaparoid-calibration curve[243].

Bioavailability is nearly 100% after s.c. injection and plasma levels are usually predictable. Monitoring is recommended in substantial renal impairment, unusually high or low body weight, life- or limb-threatening thrombosis, unexpected bleeding and critically ill or unstable patients[115].

Clinical studies with danaparoid in HIT

Danaparoid has been assessed in a compassionate use programme and one prospective, randomized clinical trial. In the named patient programme, 667 HIT patients with 708 treatment episodes were included[239] (for doses see Table 39.7). The treating physicians judged treatment to be successful in 93% because of platelet count recovery or clinical improvement of patients. In 1.7% of patients, new thromboembolic complications occurred. Of 114 (17.1%) deaths, 14 (12.2%) were thought to be related to the danaparoid treatment.

In a prospective, randomized controlled study comparing danaparoid plus warfarin with dextran 70 plus warfarin, 42 HIT patients with acute thrombosis were stratified depending on the severity of their thrombosis[240]. The treatment consisted of a danaparoid 2400 IU bolus, followed by 400 IU/h for 2 hours, then 300 IU/h for 2 hours and then 200 IU/h for 5 days. In patients with 'mild' thrombosis improvement was seen in a slightly higher proportion of the danaparoid-treated patients (92% vs. 71%, non-significant). A significant difference in favor of the danaparoid-treated patients was seen in the group with 'severe' thrombosis: 85% vs. 30%, $P = 0.03$.

Cross-reactivity with HIT antibodies

Danaparoid cross-reacts with HIT-antibodies in vitro at a rate of 7–50%, depending on the sensitivity of the assay used[115,187]. Despite anecdotal reports of unfavourable out-

Cambridge Books Online © Cambridge University Press, 2009

comes[244], two studies found no difference in clinical outcomes comparing HIT patients treated with danaparoid with or without in vitro cross-reactivity[187,245]. It therefore seems reasonable to limit testing for in vitro cross-reactions to patients who develop new, progressive or recurrent thrombocytopenia or thrombosis during treatment with danaparoid[115]. Should a positive result occur in such a patient, anticoagulation should be switched to a different drug[246].

Clinical experiences with treatment of HIT in special circumstances

Dialysis

The feasibility of hirudin for hemodialysis has been shown in small patient groups[205–208,247,248] (Table 39.7). In critically ill patients, a reduced dosage is often sufficient to enable hemodialysis or hemofiltration (continuous i.v. infusion of 0.005 mg/kg/h immediately before the filter, adjusted to ECT or to aPTT)[249].

Argatroban has been used successfully in hemodialysis[250], but systematic data are lacking at present.

Danaparoid has also been successfully used in intermittent as well as in continuous hemodialysis[115,251,252] (Table 39.7).

Extracorporeal circulation

In patients undergoing cardiac surgery with lepirudin[223,253,254,255], close bedside monitoring using the ECT is essential[217,218,223,255–258].

A pre-CPB lepirudin bolus of 0.25 mg/kg should be given and 0.2 mg/kg added to the priming solution. Plasma levels at the start of CPB should be >2.5 μg/ml (if lower, an additional 10 mg bolus should be given). During CPB, 0.5 mg/min should be infused continuously, and adjusted using ECT measurements every 15 min (target range 3.5–4.5 μg/ml). The infusion should be stopped 15 min before the anticipated end of CPB. Patients with impaired renal function usually require hemofiltration to reduce lepirudin plasma levels, but are still at high risk of developing bleeding complications[223].

Experiences with danaparoid and CPB in 47 patients[259] were judged successful in 95.7% at the time of postoperative wound closure. Because of clotting as well as bleeding problems in this and in other studies using a fixed danaparoid dose regimen, Pötzsch and Madlener[223] developed an algorithm using dose adjustments according to aFXa-measurements intraoperatively: 3000 aFXaU should be added to the priming solution with a bolus of 100 aFXaU/kg given to the patient 15–20 min before start of CPB. aFXa target level is >1.5 U/ml. During CPB a danaparoid infusion of 200 U/h should be started with a target range of 1.2–1.8 U/ml. aFXa activity monitoring every 15 min is mandatory. Thirty minutes before anticipated end of CPB, the infusion should be stopped.

In patients with a history of HIT and no circulating HIT-antibodies, short-term re-exposure with heparin is probably a safer treatment alternative (see below)[260,261].

Children

Schiffmann et al.[225] described a 12-year-old patient with HIT and multiple TECs. Using a bolus of 0.2 mg/kg lepirudin followed by a continuous infusion of 0.1–0.7 mg/kg/h, the aPTT was prolonged to 45–85 s. Planned surgical interventions were possible after discontinuing lepirudin for 4 hours.

Danaparoid has been used in children successfully[262]. For thrombosis prophylaxis in children below 55 kg, the manufacturer[263] recommends subcutaneous injections of 10 aFXaU/kg bid, in acute thrombosis a bolus of 30 aFXaU/kg followed by 1.2–4.0 aFXaU/kg/h with a target range of 0.4–0.6 aFXaU/ml or 0.5–0.8 aFXaU/ml, respectively.

Pregnancy

In rabbits, the hirudin plasma concentration in the fetuses was 1/60 of the respective maternal concentration[264]. Embryotoxic effects were seen at high, but not at low doses in rabbits (30 mg/kg/day and 1 and 10 mg/kg/day, respectively)[200].

Subcutaneous r-hirudin (15 mg twice daily) was used successfully from week 25 in a pregnant woman with HIT and cross-reactivity to danaparoid[265]. Lindhoff-Last et al.[266] detected no hirudin in the breast milk of a woman treated with lepirudin 50 mg s.c. bid.

Danaparoid has been used successfully in therapeutic and prophylactic doses in pregnancy[115]. Studying aFXa activities in maternal and placental blood, no evidence was found for danaparoid crossing the placenta[267].

Adjunctive treatments

Adjunctive treatments in HIT have not been assessed systematically. They may be considered as additional treatment options in individual patients[195].

Regional or systemic thrombolysis should be considered in patients with limb-threatening thrombosis or pulmonary embolism with severe cardiovascular compromise; surgical thrombectomy for limb-threatening large-vessel arterial thromboembolism is not contraindicated, even in thrombocytopenic patients. Intravenous gammaglobulin can be used in selected patients to block Fc-receptor dependent platelet activating effects of HIT antibodies.

Table 39.7. Danaparoid dosing schedules[115]

Clinical indication	Danaparoid dosing schedule
Venous thromboembolism: prophylaxis	750 U s.c. bid or tid
Venous thromboembolism: treatment	2250 U i.v. bolus[a], followed by 400 U/h for 4 h, 300 U/h for 4 h, then 150–200 U/h for ≥5 days, aiming at a plasma anti-Xa level of 0.5–0.8 U/ml *Subcutaneous administration schedule*: 1500–2250 U s.c. bid (bioavailability is almost 100% when given by s.c. injections; thus, 2250 U s.c. bid is approximately equal to an i.v. infusion rate of 200 U/h (4500 U/24 h vs. 4800 U/24 h, respectively))
Arterial thromboembolism: treatment	See venous thromboembolism treatment schedule
Embolectomy or other peripheral vascular surgery	*Preoperative*: 2250 U i.v. bolus[a]; *intraoperative flushes*: 750 U in 250 ml saline, using up to 50 ml; *postoperative*: 750 U s.c. tid (low-risk) or 150–200 U/h (high-risk) beginning at least 6 h after surgery
Hemodialysis (on alternate days)	3750 U i.v. before 1st and 2nd dialyses; 3000 U for 3rd dialysis; then 2250 U for subsequent dialyses, aiming at plasma anti-Xa level of <0.3 U/ml before each dialysis and 0.5 –0.8 U/ml during dialysis
Hemofiltration	2250 U i.v. bolus, followed by 600 U/h for 4h, then 400 U/h for 4 h, then 200–400 U/h aiming at a plasma anti-Xa level of 0.5–1.0 U/ml
Cardiopulmonary bypass surgery (CPB)	125 U/kg i.v. bolus after thoracotomy 3 U/ml in priming fluid of CPB apparatus 7 U/kg/h i.v. infusion commencing after bypass hookup, and continued until 45 min prior to expectation of stopping bypass
Cardiac catheterization	*Preprocedure*: 2250 U i.v. bolus (3000 U if 75–90 kg and 3750 U if >90 kg)
Percutaneous transluminal coronary angioplasty (PTCA) or intra-aortic balloon pump	*Preprocedure*: bolus as per above row; *post-procedure*: 150–200 U/hr for 1–2 days after PTCA (or until removal of balloon pump)
Catheter patency	750 U in 50 ml saline, then 5–10 ml per port, or as required
Pediatric dosage considerations:	*Prophylaxis*: 10 U/kg s.c. bid *Treatment:* 30 U/kg b.w., then 1.2–2.0 U/kg b.w./h depending upon severity of thrombosis

Notes:
[a] Adjust i.v. danaparoid bolus for body weight: <60 kg, 1500 U; 60–75 kg, 2250 U; 75–90 kg, 3000 U; >90 kg, 3750 U.

Plasmapheresis is only recommended when acquired deficiency of one or more natural anticoagulant proteins is suspected. Antiplatelet agents such as aspirin might be beneficial in patients with HIT and an increased risk for arterial thromboembolism, enhancing bleeding risk as well. Platelet glycoprotein IIb/IIIa inhibitors should be considered as experimental in this clinical setting.

Re-exposure of patients with a history of HIT to heparin

Even though not all patients with a history of HIT show an anamnestic response when reexposed to heparin[161], both UFH and LMWH should be avoided in patients with a history of HIT. Short-term re-exposure may be considered in special clinical settings (such as need for cardiopulmonary bypass) after a careful risk/benefit analysis.

Warkentin and Kelton[161], in a study including 260 patients, analyzed the timing of onset of HIT in relation to a recent (≤100 days) or remote (>100 days) prior heparin use. Two patterns were observed: 77 patients developed immediate onset of HIT with a platelet count fall within 36 h after starting heparin. All 77 patients had received heparin within the past 100 days. In a similar study we also identified heparin re-exposure within 3 months as a risk factor for early onset of HIT[162].

This temporal pattern may offer treatment options in patients with a history of HIT who are in need of surgery necessitating CPB. Provided no circulating HIT-antibodies are detectable, these patients can receive heparin during CPB if heparin exposure is strictly avoided pre- and post-operatively. With this strategy, complications using anticoagulants without an antidote during CPB, i.e. hirudin, argatroban or danaparoid, can be avoided[223,261,268].

Thrombotic thrombocytopenic purpura and hemolytic uremic syndrome

Miha Furlan

Central Hematology Laboratory, University Hospital, Inselspital, Bern, Switzerland

Introduction

Thrombotic thrombocytopenic purpura (TTP) is a disseminated form of thrombotic microangiopathy that was initially described by Moschowitz in 1924 as a new disease[1]. He reported an abrupt onset of petechiae, anemia and microscopic hematuria in a 16-year-old girl, who presented with fever and malaise and died 13 days later. He observed widespread hyaline microthrombi in the terminal arterioles and capillaries and interpreted them as agglutinated and hyalinized erythrocytes caused by 'a powerful poison which had both agglutinative and hemolytic properties'[2]. A congenital form of TTP was reported[3] by Schulman et al., who suggested that the pathogenesis was due to deficiency of a platelet-stimulating factor in the patient's plasma. A similar congenital deficiency of a plasma factor, important in platelet and red-cell survival, was later described by Schulman in another patient with chronic relapsing TTP[4]. Familial predisposition to TTP was implicated from observations of siblings suffering from recurrent TTP[5,6]. The congenital form of TTP has been occasionally described in the literature as Upshaw–Schulman syndrome.

TTP is characterized by the pentad of severe thrombocytopenia, microangiopathic hemolysis with erythrocyte fragmentation, neurologic deficit, renal dysfunction, and fever[7,8]. A TTP-like disorder, the hemolytic uremic syndrome (HUS), usually occurs in children, and is characterized by the triad of thrombocytopenia, microangiopathic hemolytic anemia and renal dysfunction[9]. The diagnosis of TTP is usually made in adult patients with neurologic dysfunction, whereas children with predominant glomerular damage are preferably diagnosed as having HUS. However, only about 40% of patients with acute TTP episodes have manifested the complete classic pentad[10]. All patients with HUS had an impairment of the kidneys, but renal abnormalities were also observed in 44% of patients with TTP; on the other hand, neurologic dysfunction was reported in 78% of patients with TTP, but also in one-third of patients with HUS[10]. Therefore, distinguishing between TTP and HUS clinically is difficult and somewhat arbitrary. TTP and HUS are often regarded as variants of one syndrome denoted as TTP/HUS. Since siblings of patients with TTP have been diagnosed to have HUS[11,12] and since acute episodes of TTP and HUS have been reported to occur sequentially even in the same patient, it has been suggested that the two disorders may be different manifestations of the same pathophysiologic process[13,14].

Epidemiology of thrombotic thrombocytopenic purpura and hemolytic uremic syndrome

TTP is believed to occur in 2–10 cases per million per year. In a study covering the 4523 TTP-associated deaths between 1968 and 1991 in the United States[15], the incidence of TTP was estimated to be approximately 3.7 cases per million residents, and the trend in mortality suggested that the incidence is increasing. Deaths were rare below the age of 20 years, and the mortality rate for patients older than 20 years increased steadily with increasing age. Numerous epidemic outbreaks of HUS in children have been reported[16], especially during the warmer months. The average annual incidence in the United States is about 1–2 per million, but it may be several times greater in some other countries, e.g. Scotland[17] or Argentina[18].

Pathogenesis of thrombotic thrombocytopenic purpura

The hypotheses concerning the etiology of TTP are controversial and suggest different pathogenetic mechanisms being responsible for development of the disorder[7,8]. Microvascular endothelial injury is generally considered as the primary event. Most commonly, patients with TTP have no discernible underlying disease or pathologic condition. However, in some patients TTP has been associated with the presence in plasma of platelet aggregating agents, viral or bacterial infection, bone marrow transplantation, cancer and cancer chemotherapy, use of the antiplatelet agent ticlopidine, alcohol abuse, pregnancy, and autoimmune disorders. Oxidative injury, free radical formation, reduced production of prostacyclin (PGI_2), impaired fibrinolysis and abnormal processing of von Willebrand factor (vWF) multimers have been proposed to be pathogenetically relevant for the development of TTP.

Platelet aggregating agents in thrombotic thrombocytopenic purpura

Several groups have attempted to identify in plasma samples from patients with TTP, a platelet aggregating factor responsible for formation of disseminated microvascular platelet thrombi. A 37 kD protein that caused aggregation of normal platelets was isolated from plasma of patients with acute TTP[19].

A calcium-dependent cysteine protease, capable of inducing platelet aggregation, was established in the sera of 15 patients with TTP during the acute phase of the disease but not in remission[20]. Moore et al.[21] have shown that the calpain from human platelets degraded vWF subunits to 205 kD and 85 kD fragments, with complete loss of large vWF multimers; calpain-degraded vWF was found to bind to platelet glycoproteins IIb/IIIa on activated platelets and to cause their aggregation. Active calpain in plasma of patients with TTP was associated with platelet microparticles protecting it from plasma inhibitors[22] such as α_2-macroglobulin and high molecular weight kininogen. While purified calpain is readily inhibited by plasma from normal subjects, there was no inhibition of microparticle-bound calpain from TTP patients by normal plasma[22]. It appears that microparticles released from thrombin-activated normal platelets, displaying procoagulant phospholipids for the process of blood coagulation, are different from those found in patients with TTP, since there was no calpain activity present in the serum of control subjects, in contrast to serum from TTP patients. This lack of calpain containing microparticles in the serum of normal individuals cannot be explained by their consumption in the fibrin clot, because the same levels of calpain activity were found in plasma and in serum of patients with TTP[22].

Unusually large von Willebrand factor in thrombotic thrombocytopenic purpura

Unusually large vWF multimers have been observed in plasma from patients with chronic relapsing forms of TTP[23,24] and HUS[25]. vWF is a multimeric plasma glycoprotein synthesized in endothelial cells and megakaryocytes. vWF mediates the initial platelet adhesion to the subendothelium of the damaged vessel wall at high shear rates. Only the highly polymeric forms of vWF are hemostatically active. While the circulating vWF in normal plasma shows only weak binding affinity for platelets, these interactions can be amplified by non-physiologic modulators, such as ristocetin and botrocetin. Electron microscopic studies[26] showed that about 90% of vWF in a resting solution is present in the form of linear polymers coiled upon itself in a ‘ball of yarn’ form. It is conceivable that the vWF undergoes a shear stress-induced conformational transition from a globular state to an extended chain conformation with exposure of intramolecular globular domains[27]. At sites of high fluid shear stress, encountered in arterioles and capillaries, the large vWF filaments apparently unfold and establish multiple interactions with platelets. Even though the affinity of the individual vWF subunits for platelet receptors is very low, multiple interactions of repeating binding sites on extended filaments of vWF with receptor glycoproteins Ib on the platelet surface may dramatically increase the stability of the bonds between platelet and vWF, and thus lead to platelet agglutination. Binding affinities of the large vWF multimers for platelets were shown to be up to ten times higher than those of the smaller molecular forms of vWF[28].

From the storage organelles (Weibel–Palade bodies) of the activated endothelial cells, vWF is secreted in the form of extremely large vWF multimers[29,30]. The length of these unusually large polymeric filaments, if stretched, would surpass the diameter of an intact platelet. These very large vWF multimers, released from the endothelial cells, are even more effective than the largest vWF forms, circulating in normal plasma, in inducing platelet agglutination under conditions of high fluid shear[31].

Cambridge Books Online © Cambridge University Press, 2009

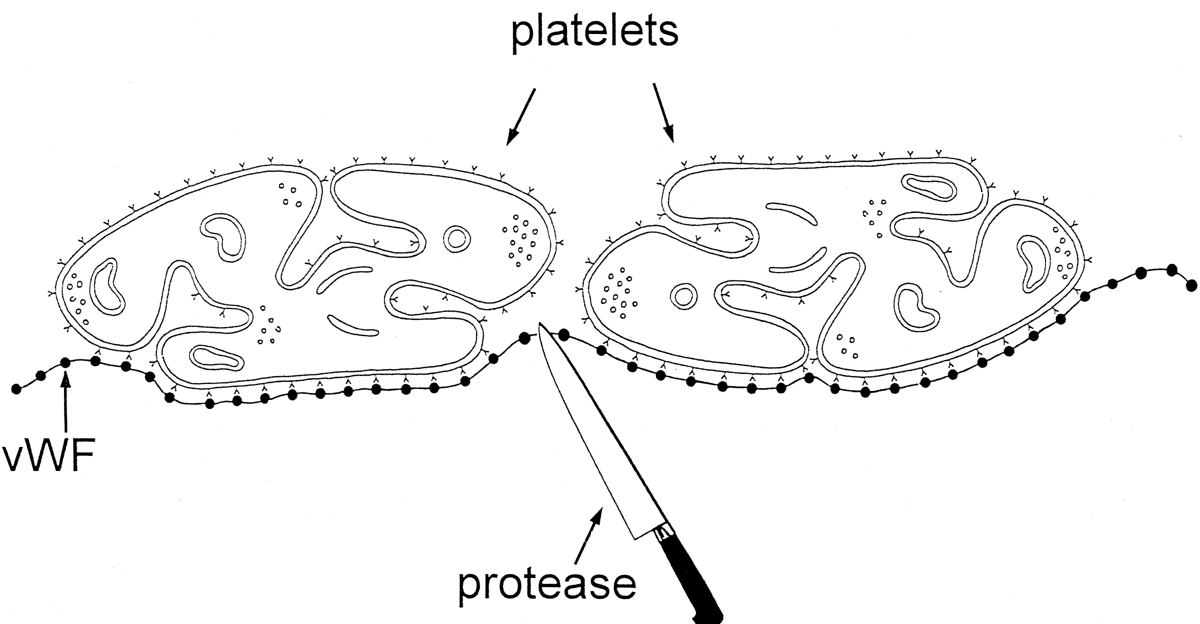

Fig. 40.1. Aggregation of platelets by unusually large multimers of vWF. In this model, the extended filament of an extremely large vWF multimer adheres to and joins a pair of circulating platelets. Multiple interactions of vWF with platelet glycoprotein Ib lead to an increased binding affinity that is required to resist high shear forces in the blood circulation. Cleavage of vWF multimers by a protease leads to smaller forms of vWF having an impaired ability to adhere firmly to the surface of two platelets.

Deficiency of vWF-cleaving protease in thrombotic thrombocytopenic purpura

Multimeric vWF is slowly but continuously attacked by protease(s) in the circulation[30,32–34]. Proteolytic cleavage of the vWF subunit between residues tyrosine at position 842 and methionine at position 843 is responsible for the post-translational processing of vWF[32].

Moake et al.[23] suggested that the presence of unusually large vWF multimers in plasma of patients with chronic relapsing forms of TTP may be due to an excessive release of vWF from endothelial cells and/or to an impaired degradation of the highly multimeric forms of vWF by a 'depolymerase'. A specific protease (Fig. 40.1), cleaving purified vWF in vitro to the same fragments as those produced in vivo, has been isolated from normal human plasma[35,36]. This protease is not inhibited by inhibitors of serine proteases, cysteine proteases, or matrix metalloproteases. It requires calcium ions (or barium ions) for full activity, but it is different from calpain. Normal human vWF appears to be resistant against proteolytic cleavage in a physiologic saline solution but becomes susceptible to degradation at low ionic strength or in the presence of 1.0–1.5 mol/l urea[35] or 1.1–1.2 mol/l guanidinium chloride[36]. Tsai et al.[37] also observed that the proteolytic degradation was enhanced under conditions of high fluid shear stress. It is apparent that the hypotonic salt concentration, urea, guanidinium chloride or shear stress cause a conformational change in the vWF molecule resulting in exposure of the cleavage site 842 Tyr–843 Met.

Impaired degradation of vWF, that had been suspected in patients with TTP[23], was first established in two brothers with chronic relapsing TT by Furlan et al.[38], who confirmed the presence in plasma of unusually large vWF multimers. The latter were absent in plasma samples of their asymptomatic parents and sister. Both affected patients showed complete deficiency of vWF-cleaving protease activity, whereas their parents had about half normal protease activity, and the sister had normal activity[38]. No inhibition of the protease activity in normal plasma was found after incubation with an equal volume of patient plasma. The in vivo recovery of vWF-cleaving protease following plasma exchange was about 100% and its biologic half-life was 2–4 days[39]. This half-life is uniquely long for a proteolytic enzyme, since the majority of proteases are rapidly inactivated in plasma by circulating inhibitors; thus, the activated forms of most proteases have plasma half-lives measured in seconds to minutes. It appears that, in patients with recurring TTP and severe congenital deficiency of vWF-cleaving protease, plasma exchange or even

Cambridge Books Online © Cambridge University Press, 2009

plasma infusion alone may be effective in suppressing the acute TTP episodes and in preventing TTP relapses[39].

The lack of vWF-cleaving protease activity in another patient with recurrent severe episodes of TTP was shown to be due to an acquired inhibitor of the protease activity[40]. Treatment with plasma, corticosteroids and vincristine led to a transient disappearance of the autoantibody and appearance of the protease activity. Three months after remission from the initial TTP event, the protease inhibitor returned, vWF-cleaving protease activity disappeared, and the platelet count gradually decreased. Severe relapses of TTP occurred 7 and 11 months after the first acute TTP event. Treatment with vincristine, that had been recommended for plasma-resistant patients[41–43], resulted in a transitory improvement of the platelet count even though the inhibitor did not vanish[40], suggesting a direct effect of vincristine on platelets rather than an immunosuppressive mode of action. An increased titre of the autoantibody was noted following treatment with fresh frozen plasma (FFP)[40]. This observation suggests that plasma exchange and replacement with FFP alone may not be sufficient in patients with acquired TTP. Splenectomy, performed 1 year after the first TTP event, resulted in disappearance of the autoantibody and normalization of the protease activity and of the platelet count[40]. No clinical relapse occurred and no protease inhibitor was detected as of the last visit, more than 4 years following splenectomy. The therapeutic effect of splenectomy appears to be due to removal of the B cells responsible for production of autoantibodies inhibiting vWF-cleaving protease, and corroborates the empirically observed beneficial effect of splenectomy in patients with TTP[44–46]. It is conceivable that splenectomy should primarily be reserved for plasma-refractory patients showing an antibody against vWF-cleaving protease.

Association of TTP with constitutional as well as with acquired deficiency of vWF-cleaving protease was subsequently confirmed in a multicentre retrospective study on the prevalence of protease deficiency in patients with familial and acquired TTP/HUS[47]. Lacking or strongly decreased protease activity ($<$5% of normal plasma) was found in 26 of 30 examined patients during an acute TTP event (6 familial and 24 non-familial TTP cases) (Fig. 40.2) while the protease activity was higher than 50% of pooled normal plasma in 120 healthy subjects. An inhibitor of vWF-cleaving protease was established in 20 of 24 patients with non-familial TTP but in none with familial TTP. The protease inhibitor is an IgG autoantibody that usually disappears, at least temporarily, in remission. Normal protease activity was found in 21 of 23 patients with an acute episode of HUS (10 familial and 13 non- familial cases). The difference in vWF-cleaving protease activity between TTP and HUS permits a differential diagnosis of these two similar disorders that are often difficult to distinguish clinically.

The acquired deficiency of vWF-cleaving protease in patients with TTP was independently confirmed by Tsai and Lian[48], who found no activity in plasma samples of 37 patients during the acute episode. IgG antibodies with protease inhibitory activity were detected in two-thirds of samples collected during the acute event. No inhibitor was found in 16 plasma samples obtained during the remission of TTP, or in 74 plasma samples from normal subjects or patients with hemolysis, thrombocytopenia or thrombosis from other causes[48]. Complete absence or severe reduction of vWF-cleaving protease activity was described in seven patients with ticlopidine-associated TTP[49]. An inhibitor of the protease was found in 6 of these patients within 2 to 7 weeks after the initiation of ticlopidine therapy. The protease deficiency resolved after ticlopidine therapy had been discontinued and plasmapheresis instituted. vWF-cleaving protease was assayed in 2 of 11 patients with clopidogrel-associated TTP[50]; in both patients, vWF-cleaving protease was undetectable during the acute episodes of TTP, and IgG inhibitors of the protease were present.

In contrast to the above patients with autoimmune deficiency of vWF-cleaving protease, normal protease activities were found in patients with bone marrow transplantation (BMT)-associated TTP[51]. It appears that BMT-associated thrombotic microangiopathy should be classified as atypical HUS, in which the protease activity is usually in the normal range, rather than as TTP. It has been recently reported by Mammucci et al.[52] that the activity of vWF-cleaving protease may be depressed below the normal range (50–200%) in healthy newborns and in pregnant women during the third trimester, in patients with liver cirrhosis or inflammatory diseases. Therefore, only complete deficiency of vWF-cleaving protease should be regarded as a reliable marker for TTP.

Assays of vWF-cleaving protease

Immunoblotting of degraded vWF substrate following electrophoresis in SDS-agarose gel

Purified vWF, prepared from cryoprecipitate of normal human plasma by gel filtration on Sepharose CL-2B, is used as substrate for protease activity[35]. The protease in diluted test plasma is activated with barium ions. The reaction mixture is dialysed using a hydrophilic filter floating on the surface of the dialysis solution (1.5 mol/l urea,

Cambridge Books Online © Cambridge University Press, 2009

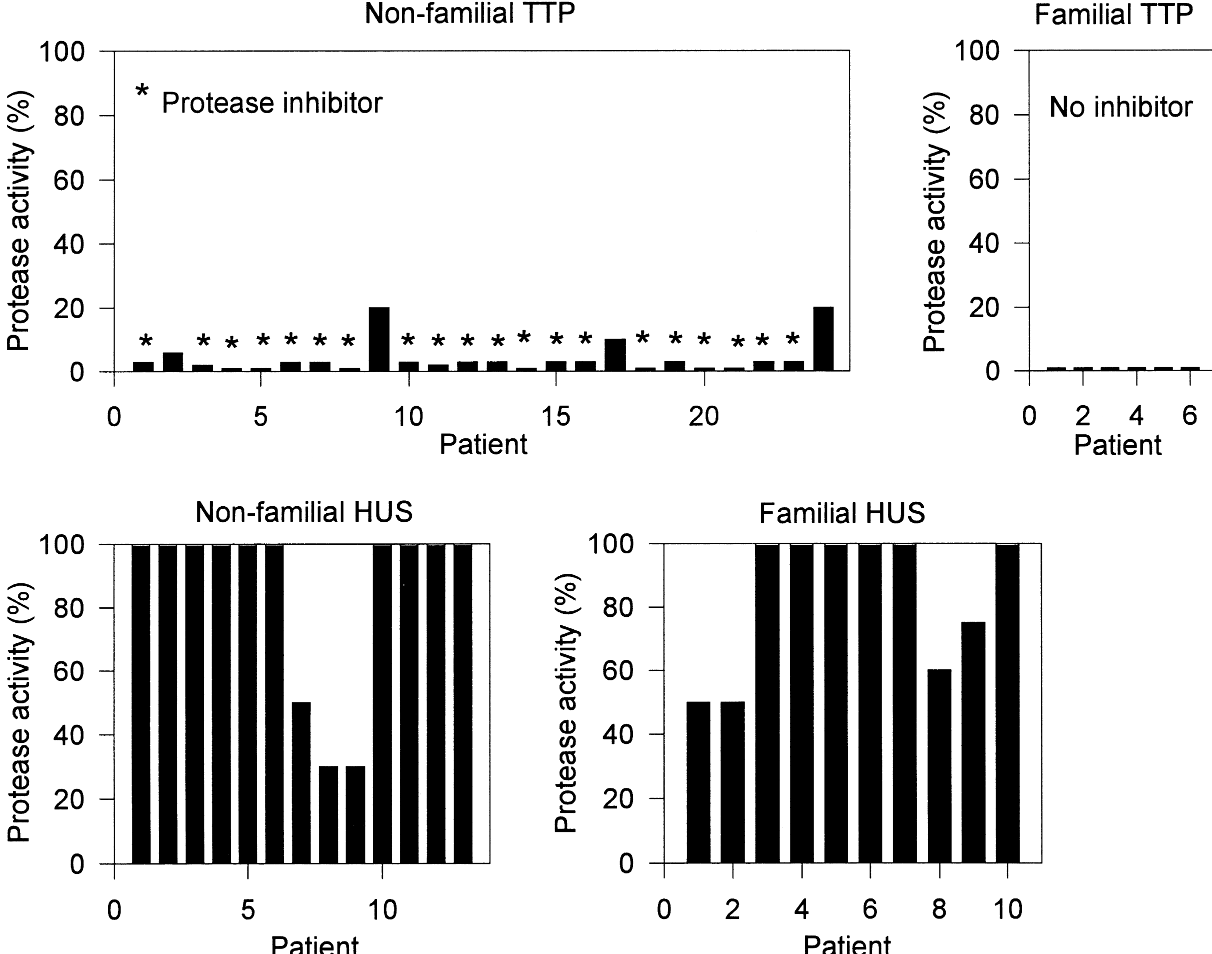

Fig. 40.2. Activity of vWF-cleaving protease in patients with TTP or HUS. In 20 of 24 patients with non-familial TTP, an inhibitor of vWF-cleaving protease was found, whereas no patient with familial TTP had an inhibitor. None of 13 patients with non-familial HUS or 10 patients with familial HUS had a severe deficiency (<5%) of vWF-cleaving protease which was found in 26 of 30 patients with TTP.

5 mmol/l Tris, pH 8.0) for 24 h at 37 °C. The reaction is stopped by addition of EDTA, and the extent of vWF degradation is assessed by multimer analysis in SDS–1.4% agarose gel. After electrophoresis, the proteins are electroblotted to nitrocellulose and stained with peroxidase-conjugated rabbit antibodies against human vWF. The method is very sensitive in the range of low protease activity and can discriminate between 0% and 1% activity. On the other hand, its accuracy is only moderate in the subnormal and normal range of protease activity. The inhibitor assay is performed by measuring the residual activity in the normal plasma after preincubation with the patient plasma[40].

Analysis of protease-digested vWF substrate by SDS-polyacrylamide gel electrophoresis (PAGE)

Purified vWF is preincubated in 1.5 mol/l guanidine and used as substrate for the protease assay[48]. After incubation of vWF substrate with diluted patient plasma in the presence of calcium chloride for 1 h at 37 °C, the reaction is terminated by addition of SDS and EDTA. The resulting fragments of vWF are electrophoresed in SDS–6% PAGE under non-reducing conditions. Following electrotransfer to nitrocellulose, vWF is visualized by probing the blots with ^{125}I-labelled rabbit IgG against human vWF and autoradiography. This assay is based on the generation, from the purified vWF, of dimers of carboxy terminal 176 kD fragments and of dimers of amino terminal 140 kD frag-

Cambridge Books Online © Cambridge University Press, 2009

ments, migrating in the SDS–PAGE as 350 kD and 200 kD bands, respectively. The radioactivity of the 350 kD band, measured by optical densitometry of the autoradiograms, represents the protease activity in the test sample.

Collagen binding assay for quantitating the proteolysis of vWF

Both assays of vWF-cleaving protease activity described above are very cumbersome and require expertise available only in laboratories familiar with immunoblotting. In a recently described method[53], the electrophoretic analysis of vWF multimers or its fragments is replaced by an ELISA based on preferential binding of large vWF multimers to collagen. This method also avoids preparation of protease-free vWF: purified vWF is replaced as substrate by normal plasma in which the vWF-cleaving protease has been irreversibly inactivated by 3 h exposure to EDTA. EDTA in the substrate plasma preparation is then removed by exhaustive dialysis against 5 mmol/l Tris, pH 8.0. 1.5 mol/l urea. Incubation with diluted test plasma samples is performed in the presence of urea and barium ions for 2 h at 37 °C, and the reaction is terminated by addition of sodium sulfate. The binding of degraded vWF to microtitre plates coated with collagen type III is measured using a peroxidase-conjugated anti-vWF antibody. The assay can be completed within 6 hours, requires no complex equipment and can be performed in a routine hospital laboratory.

Assay of vWF-cleaving protease using monoclonal antibodies to vWF

Another approach to measuring vWF-cleaving protease has been described by Obert et al.[54]. Wild-type recombinant vWF, devoid of vWF-cleaving protease, is used as substrate. The protease in test plasma samples is activated with barium ions and incubated with vWF substrate for 18 h at 22 °C on filter membranes floating on the top of 5 mmol/l Tris buffer containing 1.5 mol/l urea. The extent of vWF degradation is estimated by a two-site immunoradiometric assay, using the monoclonal antibody to a C-terminal epitope of vWF as the coating antibody, and a mixture of ^{125}I-labelled monoclonal antibodies to N-terminal epitopes as second antibody.

The latter three methods are more accurate in the normal and subnormal range but less sensitive in the very low range of protease activity than SDS-agarose electrophoresis of degraded vWF multimers. A simplified scheme for differential diagnosis of TTP, following the assay of vWF-cleaving protease, is presented in Fig. 40.3. Patients with signs and symptoms of TTP/HUS, who have no measurable protease activity during the acute episode, may be diagnosed as having classic TTP, whereas normal activity is compatible with the diagnosis of HUS. Since the half-time of vWF-cleaving protease in patients without inhibitor is 2–4 days[39], the blood sample has to be collected before, or at least 10 days after any plasma treatment. Patients with congenital protease deficiency are protease deficient during the acute TTP event as well as in the remission. Their platelet count is normalized within 2–3 days after a single plasma infusion, without any additional treatment, but tends to decrease 1–2 weeks later. On the other hand, patients with acquired TTP, due to an autoantibody, will hardly recover after a single plasma treatment. Immune suppression and other supportive measures lead to disappearance of the inhibitor and to reappearance of vWF-cleaving protease in the remission. Therefore, normal protease activity from a patient in remission does not exclude an acquired form of TTP during the preceding acute episode.

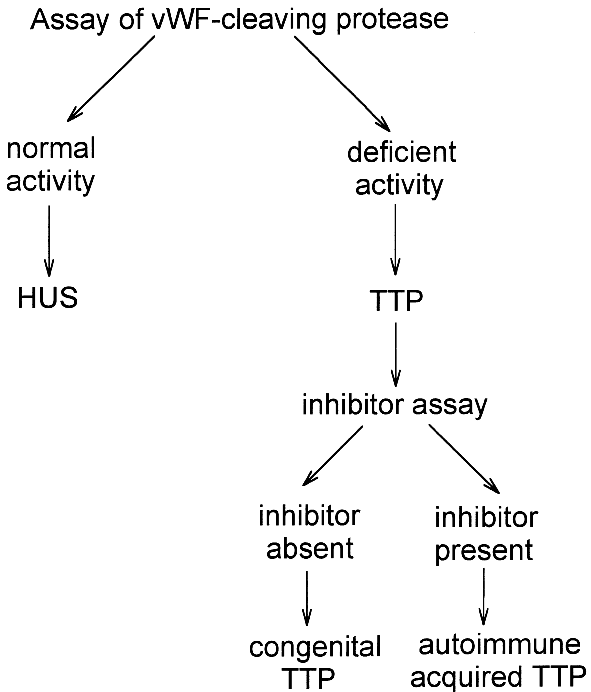

Fig. 40.3. Differential diagnosis in patients with TTP/HUS. Interpretation of results obtained by the assays of vWF-cleaving protease and of its inhibitor has to be performed with appropriate consideration of the clinical data.

Pathophysiologic mechanisms of hemolytic uremic syndrome

The question regarding the involvement of unusually large vWF multimers in the pathogenesis of HUS remains open. Infection by shiga toxin-producing *Escherichia coli* (most common serotype O157: H7) has been recognized as the predominant etiology of HUS in children. In these cases, endothelial damage induced by shiga-like verotoxins is widely assumed to be the primary cause of renal dysfunction. Verocytotoxin was shown to be cytopathic to renal microvascular endothelial cells in culture, supporting the hypothesis that the vasculopathy of HUS is caused directly by the toxic action of verotoxins on endothelial cells[55,56]. Uchida et al.[57] showed the deposition of shiga toxins in the distal tubular epithelium of the kidney. Distal tubular epithelial cells were found to express a functional receptor (Gb3/CD77) for shiga toxins and to be susceptible to its cytotoxicity[58]. Verotoxin 1 was internalized in cultured human glomerular epithelial cells, mesangial cells and cortical tubular epithelial cells[59]. These observations suggest that endothelial cells may not be the sole target for shiga toxin-mediated cell injury.

According to the tentative scheme of the pathogenesis of enterohemorrhagic *E. coli*-induced HUS, proposed by Taylor & Monnens[60], the initial reaction is binding of the toxin to the monocytes followed by release of interleukins IL-1β, IL-6, IL-8, and tumour necrosis factor-α (TNFα). Thus, inflammatory mediators, locally produced by toxin-stimulated monocytes, may contribute to the pathogenesis of HUS[61]. Moreover, incubation of verotoxin-loaded polymorphonuclear leukocytes (PMNs) with human glomerular microvascular endothelial cells resulted in toxin transfer to the endothelial cells, inhibition of protein synthesis and cell death[62], suggesting that PMNs participate in the development of acute HUS.

Reduced serum levels of the third component (C3) of the complement system have been reported in familial and atypical HUS[63,64]. It appears that decreased serum concentrations of C3 in patients with hereditary or sporadic HUS are due to the deficiency or a functional abnormality of the complement factor H[65–68], the most important plasma regulator of the alternative complement activation pathway. Thus, a complement-mediated mechanism of endothelial cell activation, leading to massive release of unusually large vWF multimers, seems to be a plausible hypothesis of familial and sporadic HUS etiology.

vWF-cleaving protease deficiency alone is not sufficient to cause clinical thrombotic thrombocytopenic purpura

The age distribution of patients with constitutional protease deficiency, shown in Fig. 40.4 (M. Furlan, unpublished data), demonstrates a striking age-dependent clustering of the first acute TTP episode. One-half of the 20 patients with complete constitutional deficiency of vWF-cleaving protease had their first TTP event between the neonatal period and the age of 5 years; this acute episode was then often followed by chronic relapsing TTP unless the patients received prophylactic plasma therapy at regular intervals of about 3 weeks. The other half of the patients with severe constitutional protease deficiency remained apparently asymptomatic until the age of about 20–30 years. Two sisters with hereditary protease deficiency (denoted in Fig. 40.4 as patients 14 and 15) had their first acute TTP episode during their first pregnancies while their brother, aged 44 years, has never had any symptoms of TTP. Similarly, another pair of sisters (patients 13 and 18) were asymptomatic until their first pregnancy; they also have a protease-deficient brother, aged 37 years, who has never had an acute event of TTP.

These results indicate that most, if not all, patients with classic TTP have severe protease deficiency but not all individuals with constitutional protease deficiency develop acute TTP. The first acute episode of TTP in a patient with constitutional deficiency of vWF-cleaving protease tends to be followed by a chronic relapsing form of the disease. Patient 11 had no signs or symptoms of TTP before the age of 20 years, but experienced several relapses in the years following the first acute bout of TTP (M. Furlan, unpublished data). The last acute episode, at the age of 36 years, led to the institution of regular plasma infusion, starting with 2 units of FFP every third week, as recommended elsewhere[3,69–72]. The estimated initial concentration of vWF-cleaving protease in patient 11, after infusion of 2 units of FFP, was estimated to be about 15% of normal plasma. The platelet count in this patient increased steadily during the first 10 days after each plasma infusion, although the circulating protease concentration had been reduced to less than 5% within the same time interval (M. Furlan, unpublished data). We conclude tentatively from this observation that 5% protease activity may be sufficient to degrade the very large and adhesive vWF multimers to smaller vWF forms, which do not spontaneously agglutinate platelets. Since the kinetics of platelet consumption at very low protease concentrations appears to vary from patient to patient, we suggest that, in each patient with constitutional protease deficiency, the optimum infusion intervals

Cambridge Books Online © Cambridge University Press, 2009

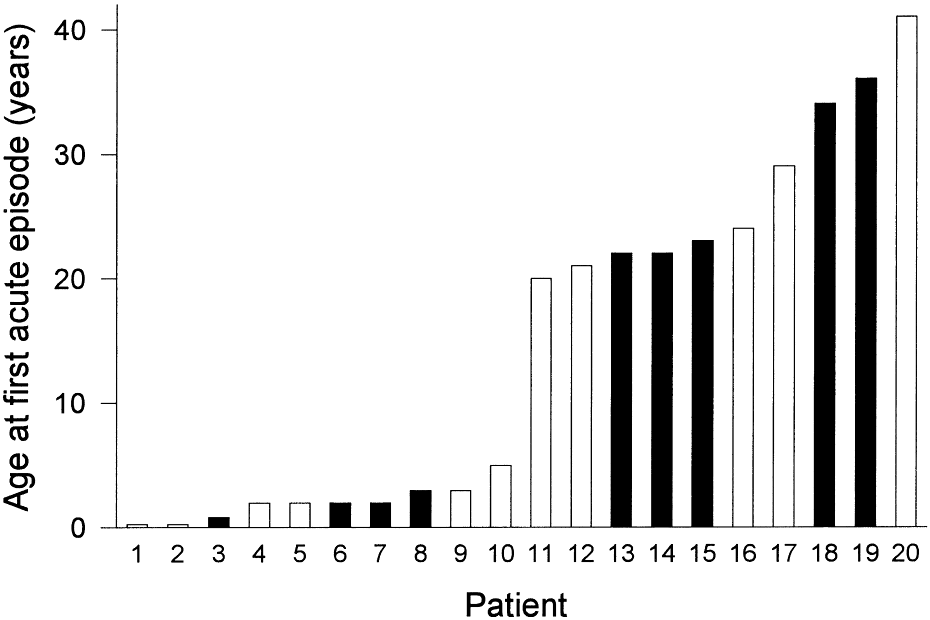

Fig. 40.4. Age distribution of the first acute TTP episode in 20 patients with complete congenital deficiency of vWF-cleaving protease. Empty bars, male patients; full bars, female patients.

and the infused plasma volumes be empirically established from the individual time course of the platelet count.

Data presented in Fig. 40.4 suggest that the prevalence of congenital vWF-cleaving protease deficiency may be higher than diagnosed, since some severe protease-deficiencies remain undetected in asymptomatic subjects. It is not improbable that individuals with an acquired protease deficiency may also escape detection, because the autoantibodies against the protease may disappear before the development of an acute TTP. As reported elsewhere[40], a patient with acquired TTP had his first relapse 3 months after the antibody-mediated disappearance of the vWF-cleaving protease, suggesting that a specific pathophysiologic condition was required to trigger the onset of the acute episode. It was also observed[47] that some patients with acquired TTP progressed to remission before the complete disappearance of the inhibitor and normalization of the vWF-cleaving protease. The above considerations regarding the occurrence of acute TTP in severely protease-deficient patients are reminiscent of venous thrombophilia in patients with genetic (e.g. factor V Leiden, deficiencies of antithrombin III, proteins C and S) or acquired (antiphospholipid antibodies, oral contraceptives, pregnancy, trauma, surgery, malignancy, previous thrombotic episodes) risk factors: a single risk factor alone is hardly sufficient to induce venous thrombosis in these patients, but the likelihood of an acute thrombotic event increases if several risk factors accumulate and recurrence rate is high after a first thromboembolic event.

It remains unclear why some individuals with severe congenital protease deficiency experience acute episode(s) of TTP during childhood while others remain asymptomatic for decades, as shown in Fig. 40.4. The vWF-cleaving protease deficiency is a very strong risk factor for TTP, but the development of an acute thrombotic microangiopathy requires a trigger, such as pregnancy, alcohol abuse, viral or bacterial infection. It is generally assumed that this trigger leads to activation or death of the microvascular endothelial cells releasing the unusually large vWF multimers from the storage organelles.

Antibodies against platelets and endothelial cells in patients with thrombotic thrombocytopenic purpura

Several attempts have been undertaken to pinpoint the mechanism of endothelial cell damage and death. Lytic antiendothelial cell antibodies were detected in plasma of patients with TTP[73] and HUS[74]. Endothelial cell-reactive plasmas were found to induce aggregation of human platelets in vitro[73], suggesting that TTP plasma may account for both endothelial cell damage and direct thrombotic vascu-

Cambridge Books Online © Cambridge University Press, 2009

lar occlusion in TTP. More recently, much attention has been devoted to the presence in TTP of antibodies directed against the human CD36[75,76], an integral membrane protein (also known as platelet glycoprotein IV), expressed by platelets as well as by some other cells including endothelial cells. It is interesting that CD36 expression on endothelial cells is restricted to capillary endothelial cells and is not observed on large vessel endothelial cells[77]. CD36 is the receptor of the platelet-agglutinating 37 kD protein[78], a previously recognized platelet aggregating factor present in plasmas of patients with TTP[19].

It is unknown whether antiendothelial cell and antiplatelet autoantibodies are directly involved in formation of microvascular platelet aggregates or whether they rather induce damage or apoptosis of endothelial cells and subsequent release of very large vWF multimers from intracellular stores. Antibodies against endothelial cells and platelets might arise as a secondary response of the immune system to inflammatory events in TTP patients, leading to expression of cellular neoantigens or exposure of cryptoantigens[79]. Antibodies against endothelial cells were also found in patients with disorders unrelated to TTP[80]. A recent study suggested that antibodies reactive against platelet or endothelial cell antigens are not prevalent in TTP, and that more than a third of reactive antibodies were human leukocyte antigen alloantibodies[81]. In addition, complement is not depleted in acute TTP[82], a feature that would be expected if circulating antibodies, directly toxic to endothelial cells, were involved. Thus, the evidence that antibody-mediated injury of endothelial cells is a primary etiologic factor in TTP remains controversial.

Inflammatory cytokines and apoptosis of endothelial cells in thrombotic thrombocytopenic purpura and the hemolytic uremic syndrome

Ultrastructural alterations in microvascular endothelial cells have been found in TTP by electron microscopy showing cytoplasmic vacuoles and swollen mitochondria. These changes, reflecting early apoptotic lesions, have been noted even in the absence of platelet microthrombi, suggesting that they are not simply a consequence of vessel occlusion. Plasmas of patients with either idiopathic TTP or HIV-associated microangiopathy were shown to induce apoptosis of primary human endothelial cells of dermal microvascular but not of umbilical vein origin[83]. Detachment of endothelial cells from renal microvasculature and their appearance in the circulation[84] are consistent with an apoptotic process. Furthermore, plasmas from TTP and sporadic HUS patients, but not from D+ diarrhea positive HUS patients, induced apoptosis and expression of the apoptosis-associated protein Fas (CD95), a type I plasma membrane receptor involved in the regulation of programmed cell death, in microvascular endothelial cells of renal, cerebral and dermal origin but not in those of pulmonary and hepatic origin[85]. This difference parallels the in vivo pathology of TTP/sporadic HUS, with notable sparing of the pulmonary and hepatic microvasculature.

The primary apoptosis-inducing agents have not yet been identified. It has been tentatively proposed that the impaired endothelial cell survival might be associated with the loss of extracellular matrix proteins[86]. Cytokines might also play a pathogenetic role. Fas was shown to become upregulated on endothelial cells by exposure to TNF-α[83] and its upregulation was accompanied by induction of the cell cycle protein Cdc2 in the dermal microvascular endothelial cells, but not in large vessel endothelial cells[87]. However, induction of Fas by the reactive components of TTP and HUS plasmas could simply reflect an activated cell phenotype and be irrelevant to apoptosis[87]. TNF-α can initiate apoptosis of endothelial cells, but the TTP plasma-mediated apoptosis could not be blocked with anti-TNF-α antibodies[83]. The finding that TTP plasma induces endothelial cell apoptosis has recently been confirmed by other authors[88]; nevertheless, Fas did not seem to be involved. Karpman et al.[89] reported apoptosis of renal cortical cells in children with postenterohepatic (D+) HUS. They also found apoptosis in cultured renal tubular cells incubated with shiga-like toxin from *E. coli*. Interleukin-6 (IL-6) was elevated in the serum of 33 of 35 children with HUS (31 diarrhea-associated and 4 non-diarrhea-associated) and in 2 of 2 children with recurrent TTP[90]; the latter two patients have been found to have constitutional protease deficiency. The same study showed increased levels of TNF-α in the serum from 7 of 35 HUS patients and from both children with TTP. Circulating levels of pro-inflammatory IL-6 were also increased in another study of children with HUS due to *E. coli* infection; the concentrations of the anti-inflammatory IL-10 were also increased, but to a lesser extent than IL-6[91], suggesting that an imbalance of pro- and anti-inflammatory cytokines may be involved in the pathophysiology of verotoxin-associated HUS. IL-6 was found to activate normal human platelets in vitro[92]. In addition to the above, sometimes discordant models of the apoptotic endothelial cell death in TTP/HUS, another study reported that calpain is involved in apoptosis-like events in washed human platelets[93]. Although platelets were found to contain the pro-apoptotic caspases 3 and 9, it was found that calpain, and not

Cambridge Books Online © Cambridge University Press, 2009

caspases, promoted the apoptosis-like events in platelets during their activation.

Need for a new classification of thrombotic microangiopathies (TMA)

The progress in our understanding of the pathogenesis of TMAs in recent years calls for establishment of a new classification that would probably be helpful for therapeutic purposes. This classification should recognize the differences in the congenital and acquired (due to autoantibodies) deficiencies of vWF-cleaving protease. The classic TMA, thus far frequently denoted as idiopathic TTP, may be triggered by different precipitating factors such as pregnancy, infection or drugs (ticlopidine), and is usually mediated by an autoimmune process abolishing vWF-cleaving protease activity. Furthermore, the deficiency of the complement factor H is a special type of TMA including many cases of familial HUS. Diarrhea-associated HUS is a major well-established form that represent a distinctive class of TMA. In addition, bone marrow transplantation-associated, neoplasia-associated, and autoimmune disease-associated TMA appear to represent special types of TMA with similar clinical symptoms but different course and prognosis. A new classification should be helpful in devising the specific patient treatment which may be strikingly different in the different forms of TMA.

Thrombocytosis and thrombocythemia

Tiziano Barbui and Guido Finazzi

Division of Hematology, Ospedali Riuniti, Bergamo, Italy

Definition

A thrombocytosis is defined as a platelet count above the upper limit of the reference range[1]. By convention, the normal range of blood platelet count in humans is considered to be 150 to 400×10^9/l. It is likely that this wide variation includes healthy individuals who have modest degrees of reactive thrombocytosis, such as young women with iron deficiency secondary to excessive menstrual blood loss. Consequently, although this is not well documented, the upper limit of the normal range in truly healthy people may be less than 400×10^9/l. Platelet values in the upper normal range should be interpreted in the clinical context of the individual patient who should be followed for eventual clear diagnostic evaluation.

Table 41.1. Classification of thrombocytosis

Reactive thrombocytosis
Infectious or inflammatory diseases
Malignancy
Iron deficiency anemia, hemolytic anemia, acute blood loss
Splenectomy
Rebound effect after chemotherapy or immune thrombocytopenia
Clonal thrombocytosis
Essential thrombocythemia
Polycythemia vera
Idiopathic myelofibrosis
Chronic granulocytic leukemia
Myelodysplastic syndromes
5q- syndrome
Idiopathic refractory sideroblastic anemia

Classification and differential diagnosis

Based on the mechanisms inducing the increased platelet production, two major types of thrombocytosis, i.e. platelet count 400×10^9/l can be found: reactive and clonal[3]. Reactive thrombocytosis (RT) is the commonest cause of an elevated platelet count and includes an heterogeneous group of disorders characterized by increased megakaryopoiesis produced by an intrinsecally normal megakaryocyte compartment. This is thought to be due to an increased cytokine production secondary to several pathological events (Table 41.1).

On the other hand, essential thrombocythemia (ET) and the thrombocythemic states found in the myeloproliferative disorders (MPDs) are usually characterized by a clonal thrombocytosis[4]. In this situation, a single hematopoietic precursor or stem cell and its progeny gain a growth advantage over their normal counterparts, so that the proliferation of the latter is suppressed. This growth advantage is derived, at least in part, from increased sensitivity of megakaryocytes and other hematopoietic precursors to the stimulatory effect of thrombopoietin (TPO), erythropoietin and several others growth factors[5,6]. The crucial role of TPO is supported by recent findings in families with hereditary thrombocythemia, where mutations in the TPO gene resulted in derepression of TPO mRNA translation, overproducton of TPO protein and thrombocytosis in the affected family members[7–9].

TPO is the primary regulator of megakaryocyte development and platelet number[10,11]. Produced predominantly by the liver and the kidney, the rate of TPO production is thought to be relatively constant, with no changes in mRNA levels or isoforms during thrombocytopenia or thrombocytosis[12]. TPO circulating levels are controlled by specific binding to its receptor, c-mpl, expressed on the surface of megakaryocytes and platelets, leading to its

internalization and degradation[13]. In thrombocytopenia due to hypoproductive states, as for example in aplastic anemia, blood TPO levels are inversely proportional to the platelet mass. In contrast, in thrombocytosis this relationship is not maintained. A number of studies have reported either normal or slighly elevated blood TPO levels in patients with both primary and secondary thrombocytosis[14,15] and no correlation between TPO levels and platelet count was demonstrated. Therefore, measurement of TPO cannot be used to discriminate between RT and ET or other MPDs. A possible explanation for elevated TPO levels in spite of elevated platelet count in MPDs has been suggested by the recent demonstration of reduced c-mpl expression on platelets from these patients[16]. Since c-mpl reduction was found restricted to clonal thrombocytosis, this finding has been proposed as a positive marker for these disorders[17,18], even though this remains to be confirmed in further studies. In spite of this new information, to date, the differential diagnosis between RT and ET still rests on the exclusion criteria discussed below[19].

Reactive thrombocytosis

In RT, the level of platelet counts is variable and may be very high. In a study of 280 cases with extreme thrombocytosis, i.e. platelet counts greater than or equal to 1000×10^9/l, 231 (82%) had RT and only 38 (14%) had a myeloproliferative disorder[20]. Characteristically, in this study, the proportion of patients with clonal thrombocytosis increased with age and a peak was reached in the highest age groups. In over 16000 platelet counts performed on 7916 children, it was found that 36 (0.5%) produced at least one count of $>800 \times 10^9$/l and seven (0.1%) had platelet counts $>1000 \times 10^9$/l. Most of them had an acute infection, although two were also recovering from antineoplastic chemotherapy and one was concomitantly iron deficient[21].

The great majority of patients with RT can be included in four groups, namely inflammatory disease, malignancy, splenectomy and iron deficiency anemia.

Inflammatory disease and malignancy

Thrombocytosis has long been recognized to accompany acute and chronic infections and also non-infectious inflammatory states. Early reviews stressed that thrombocytosis was commonly present during the course of bacterial pneumonia, pyelonephritis, osteomyelitis, pyogenic arthritis, chronic wound infections, and other bacterial infections[22]. Subsequently[23], 76% of patients with active pulmonary tuberculosis were reported to have elevated platelet counts, with 11% having platelet counts greater than 1000×10^9/l. In contrast, thrombocytosis is rare during the course of viral infections. The platelet count often falls to some degree along with the leukocyte count.

A similar degree of thrombocytosis accompanies a wide variety of noninfectious, inflammatory illnesses such as rheumatoid arthritis[24], vasculitis (including polyarteritis nodosa and polymyalgia rheumatica)[22], inflammatory bowel disease, hepatic cirrhosis[22], and nephritis[22]. In general, the degree of thrombocytosis parallels the activity of disease, and the elevated platelet count returns to normal levels with effective therapy.

An increase in platelet count is frequently seen in patients with advanced malignancy[22,25–27]. Ninety per cent of patients with thrombocytosis secondary to malignancy have platelet counts in the range of 400×10^9/l to 1000×10^9/l; occasional patients have been reported[25] with counts as high as 6000×10^9/l. The pathophysiologic mechanisms of the thrombocytosis of malignancy and inflammation may be similar. In a study of patients with carcinoma of the lung and colon[27], the platelet count correlated directly with the leukocyte count and the fibrinogen level and inversely with the hemoglobin, again suggesting that the platelet count may be regarded as an acute-phase reactant. Thrombocytosis has been reported with most types of tumours. The literature has stressed its frequency in carcinoma of the lung[27] and in mesothelioma[26].

Splenectomy

Approximately one-third of the total body platelet mass normally resides in a pool in the spleen. Therefore, the platelet count should theoretically rise by approximately 50% after splenectomy. The inflammation related to surgery might transiently increase the platelet count by approximately another 50%. However, if splenectomy is performed in a hematologically normal person, the platelet count often rises far in excess of that predicted by these two considerations, sometimes reaching in excess of 1000×10^9/l

Therefore, the removal of the spleen may stimulate platelet production. Thrombocytosis generally subsides over weeks to months and rarely persists for more than 2 years following splenectomy. Thus, the stimulation must be transient or compensated for in some circulating factor that suppresses platelet production, but this is not well established. It is generally accepted that such transient, self-limited postsplenectomy thrombocytosis is not associated with thrombotic or hemorrhagic complications[28] and that therapy for it is not necessary. Following splenec-

Cambridge Books Online © Cambridge University Press, 2009

tomy (even many years later), infectious or inflammatory thrombocytosis may be exaggerated considerably.

Postsplenectomy thrombocytosis can be expected to persist under two circumstances. A patient with MPD who has splenomegaly and a normal platelet count may, in fact, have a marked increase in the rate of platelet production which is masked by an increase in the size of the pool of platelets in the spleen. If the spleen is removed under these circumstances, there may be a massive increase in the platelet count, often to ten times the pre-splenectomy value. There are many reports of thrombotic complications in this situation[29]. The second circumstance occurs when the spleen is removed in patients with anemia secondary to hemolysis or ineffective erythropoiesis and the splenectomy does not completely correct the anemia[30]. Typical situations in which this might occur are hereditary, nonspherocytic hemolytic anemia and thalassemia major. In such patients, it is typical for the platelet count to persist indefinitely in the range of 600×10^9/l to 1000×10^9/l. In addition, such patients have an increased incidence of deep vein thrombosis[30].

Iron-deficiency anemia

Patients with anemia secondary to simple iron deficiency typically have an elevated platelet count, not uncommonly to levels in excess of 1000×10^9/l. In adults in the Western world, blood loss is the most common cause of iron deficiency, and bleeding itself can cause thrombocytosis. However, in experimental animals, iron deficiency produced by an iron-deficient diet also leads to thrombocytosis[31]. The mechanism is not known, and there is no explanation for the observation that some patients develop marked thrombocytosis while others with equally severe anemia have only modest elevations in platelet count. The platelet count falls rapidly as soon as iron replacement is begun, so that normal or even low levels may be reached within 7–10 days[32]. Thus the increased rate of platelet production appears to be secondary to iron deficiency *per se* and not to the erythroid hyperplasia in the marrow, which continues until the anemia is corrected. Although there have been case reports of thrombotic complications in this setting[32,33], the response of the thrombocytosis to iron replacement is so rapid that no other therapy is required.

Essential thrombocythemia

Within the category of clonal thrombocytosis, ET represents the most characteristic disease. Clonal hemopoiesis in ET was originally shown by studying glucose-6-phosphate deydrogenase (G6PD) isoenzymes in females who were coincidentally heterozygous at this C-linked locus[4]. More recent methods of DNA and RNA analysis have made it possible to assess clonality in the nucleated cells of up to 50% of women with these illness[34]. These analyses have confirmed the previous G6PD studies in most, but not in all patients. For example, 14 out of 46 patients (30%) studied by El-Kassar et al.[35] and 13 out of 46 patients (28%) studied by Harrison et al.[36] who had a diagnosis of ET according to the Polycytemia Vera Study Group (PVSG) criteria had polyclonal myelopoiesis. These results indicate that ET is a heterogeneous disease[37] and raise a number of issues, in particular whether etiology and clinical course in the two groups are different. It is possible that patients with monoclonal myelopoiesis represent those who have progressed from a polyclonal disease by acquiring a pathogenic alteration that provides cells with a growth or survival advantage[34]. This process may not necessarily reflect a truly ‘transformed’ state, since progression to acute leukemia is observed in only 6–7% of ET patients[19,38] and further hits may be required for transformation to occur. However, it should be recognized that there is no known experimental model to support such an hypothesis. From a clinical point of view, no difference between patients with monoclonal and polyclonal myelopoiesis was observed with respect to age or platelet count at diagnosis, incidence of hepatosplenomegaly or bleeding complications. However, monoclonal patients were more likely to have experienced thrombotic events[36,39]. This information is noteworthy and requires confirmation in larger and prospective studies since, as will be discussed in greater detail subsequently, the ability to categorize patients as potentially either ‘low risk’ or ‘high risk’ for thrombosis is the current basis for treatment recommendations.

Diagnostic criteria

There is no single clinical or laboratory finding that permits a positive diagnosis of ET. Rather, many clinicians have concluded that the diagnosis must be reached by excluding other myeloproliferative or myelodysplastic disorders or the conditions which are associated with a reactive thrombocytosis. This principle was used in the development of the criteria of the PVSG[40] that have been recently updated[19] (Table 41.2). A flow diagram for diagnosis of ET according to these criteria is presented in Fig. 41.1. The individual components will be discussed, including some investigations aimed at providing positive diagnostic tests for ET.

Table 41.2. Updated diagnostic criteria for essential thrombocythemia[19]

I	Platelet count>600 000/μl
II	Hematocrit <40%, or normal RBC mass (Males <36 ml/kg, females <32 ml/kg)
III	Stainable iron in marrow or normal serum ferritin or normal RBC mean corpuscular volume[a]
IV	No Philadelphia chromosome or *bcr/abl* gene rearrangement
V	Collagen fibrosis of marrow A. Absent or B. <1/3 biopsy area without both marked splenomegaly and leukoerythroblastic reaction
VI	No cytogenetic or morphologic evidence for a myelodysplastic syndrome
VII	No cause for reactive thrombocytosis

Note:
[a] If these measurements suggest iron deficiency, PV cannot be excluded unless a trial of iron therapy fails to increase the RBC mass into the polycythemic range

Platelet count

The current criteria for ET give a persistent platelet count of 600×10^9/l[19]. However, it has been suggested that the platelet count criterion should be reduced to 400×10^9/l[41] since, in long-term follow-up studies, the clinical course of patients with platelet counts between 400 and 600×10^9/l was found to be indistinguishable from that of patients with a clearly diagnosed essential thrombocythemia[42,43]. The major problem with this approach is that platelet counts above these levels are commonly encountered in hospital practice and many individuals at the extreme end of the physiological range may be included. In other words, lowering the threshold of platelet count will improve the sensitivity but reduce the specificity of ET diagnosis. Therefore, the selection of a cut-off of 600×10^9/l is probably the most appropriate for the selection of ET patients to be put in therapeutic trials. In the current clinical practice, a lower platelet count can be taken for an initial screening but then a highly specific test, such as bone marrow histology (see below) should be suggested for establishing the correct diagnosis avoiding false-positive cases. In any case, these borderline patients deserve to be carefully followed up.

Platelet morphologic and functional abnormalities

ET platelets may be normal in size but more often their volume is highly variable with micro and giant platelets coexisting in the same patient[44,45]. The mean platelet volume (MPV) and size heterogeneity, reflected by the platelet distribution width (PDW), are easily measured by electronic cell counter, but their usefulness in the differential diagnosis with RT is questionable. The PDW is higher in ET than in RT but the overlap between groups makes it unreliable as the sole citerion[1]. The MPV is an unhelpful marker[46].

ET platelets are characterized by several biochemical and functional abnormalities[47]. Many defects are related to reductions of specific glycoproteins with impairment of the associated receptor functions[48,49]. Glycoprotein changes most commonly described are the reduction of GPIb[48] and GP IIb–IIIa complex[50] and/or modification of their glycosylation[51]. Binding sites for von Willebrand factor and fibrinogen are present on GPIb and GPIIb–IIIa, respectively, and this explains some loss of the binding capacity for these molecules[50]. In ET patients with extreme

Cambridge Books Online © Cambridge University Press, 2009

thrombocytosis a plasma deficiency of von Willebrand large multimers has been described[52,53]. This deficiency, along with the decrease of platelet receptors for that factor, may explain the bleeding observed in thrombocythemic states (see also below).

Several alterations in arachidonic acid metabolism have been reported. These include reduced arachidonic acid content in platelet membranes[54] defective substrate mobilization in response to stimuli and abnormalities in its conversion through the PGH-synthase and 12-lipoxygenase pathways[55–57]. However, the relevance of these findings for diagnostic or prognostic purposes remains to be established.

Many functional studies on ET platelets have been performed by measuring platelet aggregation. The two most consistent findings refers to the loss of ET platelet aggregating response to epinephrine[58] and the phenomenon of spontaneous aggregation[59]. Intrinsic limitations of this technique have been reported, however[45], and its use in ET can be also associated with potential artefacts arising from variable ex vivo activation of ET platelets and modification of platelet morphology and size.

Other qualitative platelet changes include reduced ADP levels, leading to a higher ATP/ADP ratio in ET than in RT[46], and increased plasma levels of β-thromboglobulin[60,61] and platelet factor 4[62], suggesting enhanced platelet activation in vivo in ET subjects. However, again, these tests are of limited value because of the lack of standardization, limited availability and cost. Overall, despite the identification of a broad array of specific structural, biochemical and metabolic platelet defects, no parameter of hemostasis has been shown to reliably distinguish between ET and RT or herald a thrombotic or bleeding tendency in ET patients.

Exclusion of PV

If the patient's hematocrit is $>$51% for males or 48% for females the total body red cell mass should be measured. If it is elevated, the diagnosis should be PV[1,63]. If the red cell mass is not elevated, the possibility of PV, masked by bleeding or iron deficiency, should be considered. For practical purposes, a normal or increased serum ferritin level along with a normal red blood cell mean corpuscolar volume suffices to exclude both reactive thrombocytosis secondary to iron deficiency and the possibility that one may be dealing with PV masked by iron deficiency. When iron-deficiency erythropoiesis is present or cannot be excluded, the distinction between PV and ET cannot be made with certainty until re-valuation is performed after 1–2 months of iron replacement therapy.

Exclusion of other MPDs or myelodysplasia

During the initial evaluation of a patient suspected of having ET, it is advisable to perform a bone marrow aspiration, biopsy, and karyotype analysis[64–66]. If frank fibrosis on the bone marrow biopsy is found, the diagnosis of myelofibrosis can be made, particularly if other ancillary signs are present, such as marked splenomegaly on physical examination, teardrop poikilocytosis and a leukoerythroblastic reaction in the peripheral blood smear. The bone marrow karyotype is critical to exclude the Philadelphia (Ph) chromosome and, therefore, CML. In some circumstances in which the clinical picture is atypical for ET, the *bcr/abl* rearrangement, diagnostic of CML should be sought. Recently, an intriguing report suggested the presence of BCR-ABL transcripts in the bone marrow of a high proportion (48%) of Ph-neg ET patients[67]. However, this finding was not confirmed[68,69] and therefore its clinical significance of this finding remains to be determined. Sometimes, myelodysplastic syndromes (MDS) may present with thrombocytosis[70], particularly in the 5q- syndrome[71]. If present, this karyotypic abnormality would place the patient in the MDS category. However, it should be borne in mind that a proportion of patients with clinical and laboratory features overlapping between ET and other MPDs or MDS remains unclassified. Reliable prognostic information about such patients is not available and a careful follow-up to establish the clinical evolution is probably the most reasonable approach.

Exclusion of reactive thrombocytosis

The causes of RT are listed in Table 41.1 and discussed above. Clinical evaluation and laboratory studies designed to detect iron deficiency and occult inflammatory or malignant disease are generally sufficient to exclude RT. In addition, a study[72] suggested that most patients with RT have elevated serum levels of interleukin-6 and C-reactive protein while patients with MPD and thrombocytosis have normal levels.

Positive criteria for diagnosing ET

The approach to ET as a diagnosis of exclusion is intrinsically unsatisfactory, and positive criteria that would distinguish ET from RT and other MPDs have been proposed[46,73]. The role and limits of clonality studies and measurement of TPO and TPO receptor in this setting has been discussed above. Some authors have shown that endogenous erythroid colonies (EEC)[74] or culture examining CFU-Mk growth may be reliable markers of the disease[75,76]. However, these investigations are not widely available, are expensive and technically demanding and, therefore, may

Cambridge Books Online © Cambridge University Press, 2009

be suitable for the research purposes in the occasional patient but not for general use.

It has been suggested that ET can be positively diagnosed by careful, quantitative examination of the bone marrow biopsy[64–66]. Typical clustering of enlarged megakaryocytes with multilobated nuclei has been advocated to represent the hallmark feature of the disease. Histologic background of hematopoiesis in ET is featured by a discrete pattern of minimal or no prominence of erythropoiesis, no change in granulopoiesis, almost no fibrosis and reduction of stainable iron. A detailed evaluation of bone marrow features may also help to distinguish 'true' ET from the initial stages of idiopathic myelofibrosis[66] or myelodysplasia[65]. 'Early' myelofibrosis is characterized by increasing cellularity with prominent neutrophil granulopoiesis, borderline to slight reticulin fibrosis and pronounced abnormalities of megakaryocyte differentiation, including hyperchromasia and marked nuclear cytoplasmatic deviation. Notably, patients with these morphological features frequently develop an overt myelofibrosis and have a significantly worse life expectancy. However, an experienced observer and a well-standardized procedure are required to diagnose ET by examination of the bone marrow biopsy. This is one of the major limits of the diagnostic classifications of ET based on bone marrow histology.

Clinical features and prognostic factors

A diagnosis of ET, based on a careful pathologic and cytogenetic review, is associated with a very low risk of either leukemic transformation or occurrence of other life-threatening complications. As a result, life expectancy is near normal[77]. However, the clinical course of these patients is characterized by frequent thrombotic and hemorrhagic events. Thus, once the diagnosis is adequately established, the next step is to evaluate for the presence or absence of risk factors for thrombohemorrhagic complications.

Bleeding and thrombosis in ET

Reported rates for thrombosis and hemorrhage range from 8 to 84% and 13 to 63%, respectively[78–83]. This wide range reflects the referral bias in the reported series, which are almost all retrospective and based on relatively small numbers of patients. The vascular occlusive events either occur in the microvasculature, with symptoms such as transient cerebral ischemia, migraine and visual dysfunction[84] digital ischemia and erythromelalgia[85] or in larger vessels usually cerebral, peripheral and coronary arteries[45]. Major venous occlusions can also occur and thromboses in unusual sites such as hepatic (Budd–Chiari syndrome)[86,87], portal[87,88] and mesenteric veins[89] and of intracranial sinuses[90] are not infrequently encountered. Bleeding involves more frequently mucocutaneous sites rather than joints or soft tissues. Common manifestations are represented by easy bruising, epistaxis and gingival bleeding. Severe hemorrhages requiring transfusion and/or hospitalization are relatively infrequent and generally involve the gastrointestinal tract[45]. Due to this heterogenous clinical presentation, several studies have focused on the search for factors possibly associated with an increased risk of thrombotic and hemorrhagic complications[78–83].

Risk factors for major bleeding

Hemorrhagic symptoms have been found more frequently in patients with platelet counts in excess of 1000×10^9/l and this may be related to an acquired deficiency of vonWillebrand's factor[52,53]. The number of circulating platelets directly affects the concentration of plasma large vWF multimers, which may compromise hemostasis at high platelet counts. In a series of 44 ET patients under the age of 45, 6 (13%) experienced bleeding complications which for the most part were mild and mucosal in nature. In two cases, however, deep-seated hemorrhage occurred into muscle and one of these individuals was found to have an acquired von Willebrand's disease[91]. In these patients, serious bleeding may be spontaneous or triggered by contemporaneous aspirin treatment[92]. Therefore, caution is recommended in giving platelet inhibiting agents to ET patients with platelet counts above 1000×10^9/l. Bleeding time measurement performed by the Ivy's method have been widely used in ET patients in order to identify patients with impaired platelet function and increased hemorrhagic risk[93]. However, there is no established evidence that bleeding time has any predictive value for the evaluation of the hemorrhagic risk associated with surgical procedures[94], antiplatelet therapy or in patients with congenital platelet defects[95–96]. Thus, bleeding time measurement seems of uncertain clinical usefulness in ET patients[47].

Risk factors for thrombosis

A clear correlation between ageing and thrombosis has been reported by many authors[80,97–100]. In a cohort study of 100 consecutive patients with ET diagnosed between 1978 and 1988, the rate of thrombosis was 1.7% per year in patients younger than 40, versus 6.3% per year in those from 40–60 years and 15.1% per year in subjects over 60 years old[80]. In another series of 56 young thrombocythemic subjects the incidence of severe thromboses was only about 1% per year after a mean follow-up of 4.7 years[97].

Cambridge Books Online © Cambridge University Press, 2009

However, isolated reports indicate the possibility of life-threatening thromboses also in young ET patients[91,101–104]. Most ischemic complications in this group were represented by migraine, headache and erythromelalgia. The thrombotic nature of these neurological symptoms is uncertain, however. In a study of transient neurological and ocular ischemias in patients with ET, Michiels et al. reported that poorly localized symptoms such as dysarthria, transient unsteadiness, and scintillating scotomata were more common than focal symptoms such as transient monocular blindness or transient mono- or hemi paresis[105]. These clinical manifestations were uniformly sensitive to aspirin (see also below) and often preceded or followed by erytromelalgia or large vessel thrombosis.

A previous history of thrombotic events is an important risk factor for subsequent vascular occlusions, despite the fact that most symptomatic patients are treated with cytoreductive drugs. In one study, the prevalence of thrombosis was increased by the presence of a prior thrombotic event from 3.4% per year to 31.4% per year[80] and in another, from 16 to 57%[83].

Disease transformation

In rare cases of ET, transformation to polycythemia vera or myelofibrosis may occur as part of the natural history of disease. This is consistent with the well-known overlap between different Philadelphia-negative CMDs. In a long-term study of young women with ET, transformation into polycythemia vera and myelofibrosis was observed in 2.7% and 4% of the patients, respectively[106]. Sporadic reports of the transformation of ET to acute leukemia have been recorded, although the incidence appears less than in the related MPDs. Retrospective studies with median duration follow-up of 3 to 7 years have reported incidence rates of leukemic conversion ranging from 0.6 to 5%[79,82,83,107,108]. Most patients who had transformation were previously managed with cytoreductive therapy (see below). However, leukemic transformation in ET has occasionally occurred in the absence of previous therapy, suggesting that the event may also be a natural, albeit very rare, sequela of the disease.

Table 41.3. Risk stratification in essential thrombocythemia

Low-risk
Age <60 years, and
No history of thrombosis, and
Platelet count $<1500\times10^9$/l
High-risk
Age 60 years, or
A previous history of thrombosis, or
Platelet count 1500×10^9/l

Note:
Correction of cardiovascular risk factors (smoking, obesity) is recommended in all patients.

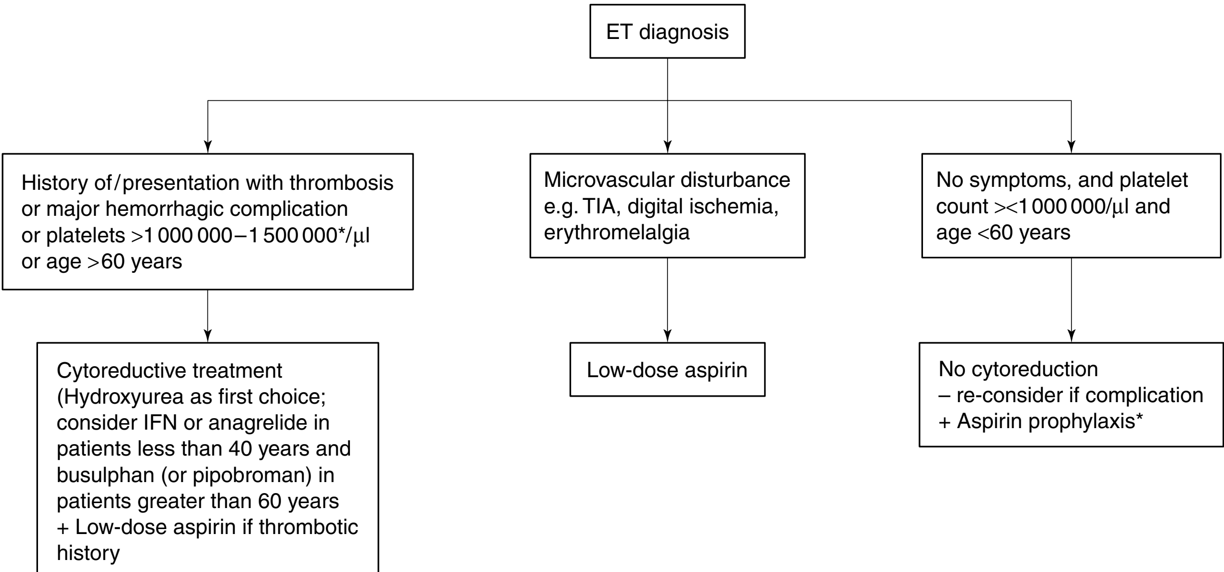

Fig. 41.2. Flowchart of recommended treatment for patients with essential thrombocythemia. Areas of uncertainty are marked with the asterisk (*). IFN, interferon; TIA, transient ischemic attack.

Treatment

The management of patients with ET is based on a careful evaluation for the presence or absence of risk factors for thrombohemorrhagic complication and should take into consideration the issue of potential leukemogenicy associated with myelosuppressive drugs (Table 41.3 and Fig. 41.2).

Management of 'lower-risk' patients

The natural history of untreated, 'lower-risk' ET patients was evaluated in a prospective, controlled study[109]. Sixty-five ET patients with age below 60 years, no history of thrombosis or major bleeding and platelet count below 1500×10^9/l were compared to 65 age- and sex-matched normal controls. Patients were not treated with cytoreductive therapy, until the occurrence of major clinical events. After a median follow-up of 4.1 years, the incidence of thrombosis in patients and controls was 1.91 and 1.5% patient–year, respectively. The age and sex adjusted risk rate ratio was 1.43 (95% c.i. 0.37–5.4). No major bleeding was observed. This study indicates that the thrombotic risk of young, asymptomatic ET patients is not significantly increased compared to the normal population. These findings have been recently confirmed in another Italian cohort of 28 patients below 40 years of age followed for a median of 4 years[100]. However, it should be recognized that the number of patients included in these studies is relatively small and further data from large, currently ongoing clinical trials are warranted. Thrombotic deaths have been only occasionally reported in young patients with ET[91] and data showing that fatalities can be prevented by starting cytoreductive drugs early have not been produced. Therefore, one can conclude that, to date, withholding cytoreductive therapy might be justifiable in asymptomatic, young ET patients with a platelet count below 1000 $\times 10^9$/l, based on their very low risk of developing fatal thrombotic or bleeding events and for the concern about the potential leukemogenicity of cytotoxic drugs (see below).

Having made this generalization concerning myelosuppressive therapy, it may be wise to propose a primary antithrombotic prophylaxis with aspirin for reducing the rate of vascular complications in these asymptomatic patients. Aspirin was found to be effective in ET patients with microvascular disturbances, such as erythromelalgia[85] or transient cerebral or ocular ischemia[84]. In the absence of contraindications and/or side effects, a dose of 100–300 mg/day is recommended in the acute management of these patients, and 75–100 mg/day are also recommended as secondary prophylaxis for major arterial thrombosis[45]. However, in the absence of clinical trials in the specific setting of ET, this recommendation is largely based on the assumption that the use of platelet antiaggregating agents is associated with a risk reduction comparable to that achievable in patients not having ET. In prescribing antiaggregating agents one should consider the risk of bleeding, an issue particularly important in ET patients, who very often have platelet functional defects and a possible abnormal hypersensitivity to aspirin[47,92].

Management of 'high-risk' patients

Patients aged more than 60 years or with platelet count exceeding 1500×10^9/l, or with a previous history of thrombosis or major bleeding are candidates to receive a cytoreductive drug[106,110].

Hydroxyurea

Hydroxyurea (HU) has emerged as the treatment of choice in patients with ET because of its efficacy and only rare acute toxicity[111]. The drug is given at an initial dose of 15–20 mg/kg/day, with adjustments to maintain reduced platelet values, ideally to less than 400×10^9/l without excessive lowering of the neuthrophil count. Treatment with HU has been shown to reduce the platelet count to below 500×10^9/l within 8 weeks in 80% of patients. Hematopoietic impairment, leading to neutropenia and macrocytic anaemia, is the major short-term toxic effect of HU. Neutropenia is dose related and generally quickly reversible if the drug is discontinued for a few days. Withdrawal is followed by a rebound of platelet counts, so that continuous treatment is necessary. Failure of HU to provide adequate control of the platelet count was reported in 11% to 17% of patients[19,112]. Additional side effects of the drug may include skin changes[113,114], nail staining[115] and leg ulcerations[114,116]. In occasional patients, these dermatological symptoms may be severe enough to withdraw the drug.

Lowering the platelet count by HU is associated with significant improvement in acute ischemic or hemorrhagic symptoms. In a randomized clinical trial, the efficacy of HU in preventing thrombosis in ET patients aged >60 years, or with a history of previous thrombosis, or with a platelet count above 1500×10^9/l was clearly demonstrated[117].

Is hydroxyurea leukemogenic?

HU, being a non-alkylating agent, was generally thought to be non-mutagenic, but long-term follow-up studies of HU-treated patients with PV and ET revealed that some cases developed acute leukemia[118–120]. Even when used as a single agent in the treatment of PV and ET, the reported

Cambridge Books Online © Cambridge University Press, 2009

rate of acute leukemia ranges between 3.5 and 10% and this fatal complication is encountered 4–10 years after the start of treatment[121]. In other clinical conditions, the use of HU was rarely associated with secondary malignancies. However, it should be mentioned that at least three patients with sickle cell disease treated with HU developed leukemia, after 6–8 years of treatment[122].

The incidence of leukemic transformation is enhanced in patients with ET carrying cytogenetic abnormalities[123]. About 5% of ET patients have alterations, mostly involving chromosomes 1, 2, 5, 17, 20 and 21. The 17p deletion has been recently described in a high proportion of ET patients who developed acute myeloid leukemia and myelodysplasia following treatment with hydroxyurea[120].

The importance of avoiding multiple cytotoxic drugs with different mechanisms of action (antimetabolites, alkylating agents) in ET patients has been emphasized[19,38,124]. In a follow-up study of the unique randomized clinical trial hitherto performed, 56 high-risk ET patients randomized to receive HU and 58 to receive no cytoreductive therapy have been observed for a median observation period of 73 months (range 3–94). Before randomization, 15 patients had been treated with busulphan. When analyzed by intention to treat, seven patients (13%) in the HU group developed secondary acute leukemia, myelodysplastic syndromes or solid tumours, but only one control (1.7%) ($P = 0.032$). The occurrence of secondary malignancies was also analysed by treatment: none of 20 patients never treated with chemotherapy developed neoplasia vs. 3 of 77 given HU only (3.9% n.s.) and 5 of 15 given busulfan plus HU (33% $P < 0.0001$). Thus, the sequential use of busulfan and HU significantly increased the risk of second malignancies[38]. These findings are consistent with those of other studies. Sterkers et al. reported 14% rate of leukemia when HU was combined with other cytotoxic agents, generally pipobroman[120]. Six cases of AML (21%) out of 28 ET patients treated with HU plus alkylating agents or 32P were observed by Murphy et al[19].

The reason why sequential cytotoxic therapy is associated with an high rate of second malignancies is uncertain. One reason could be that an inadequate disease control with the first drug selects a subset of patients with a resistent disease and an increased tendency to develop leukemia. Murphy et al[19]. suggested another possible explanation, that is more consistent with our data. The first myelosuppressive drug can act as a ‘sensitizer’ such that exposure to it followed by a ‘second hit’ is highly leukemogenic. Supporting this hypothesis, Sterkers et al[120]. observed that any combination of cytotoxic agents was associated with an increased rate of second leukemia.

In conclusion, the definite proof that HU is leukemogenic is still lacking. However, there is increasing evidence that the drug may accelerate the progression to acute leukemia in predisposed patients, such as those with cytogenetic abnormalities[120] or given multiple cytotoxic drugs[38].

Busulphan

Busulphan is an alkylating agent interfering with the megakaryocyte proliferation[125]. It should be given in a dose of 2–4 mg daily, according to hematological response, under weekly control of platelet count. After normalization of the platelet count, adequate long-term control of thrombocytosis can be obtained with intermittent courses of the drug, allowing long intervals without the need for therapy. With this schedule, the secondary effects of the drug usually observed at higher doses, such as bone marrow aplasia, skin pigmentation, amenorrhea and pulmonary fibrosis, can be avoided[125,126]. Alkylating agents, such as chlorambucil, were associated with an excess incidence of malignancies in polycythemia vera[127]. Although busulphan was not found to induce leukemia or other cancers in PV and ET patients[125,126,128], concerns about leukemogenicity suggest to limit its indication to elderly patients, where the convenience of its use outweigh the potential leukemogenic risk.

Interferon

Recombinant interferon-α (IFN) is an active agent in myeloproliferative disorders with cytoreductive activity that is virtually devoid of mutagenic risk and is being used both in ET and PV[129]. The rationale for this drug includes its myelosuppressive activity and its ability to antagonize the action of platelet-derived growth-factor (PDGF), a product of megakaryopoiesis which initiates fibroblast proliferation. The precise mechanism of action, however, has not yet been fully elucidated. In ET patients, IFN has been evaluated in several cohort studies[130]. Overall results indicate that reduction of platelet count below 600×10^9/l can be obtained in about 90% of cases after about 3 months with an average dose of 3 million IU daily. Time and degree of the platelet reduction during the induction phase were dose dependent. During maintenance the IFN dose could be tapered, but if IFN is suspended platelet count rebounds in the majority of patients. IFN is not known to be teratogenic and it does not cross the placenta. Thus, it has been used successfuly throughout pregnancy in some ET patients with no adverse fetal or maternal outcome.

Side effects are a major problem with this drug[130–132]. Fever and flu-like symptoms are experienced by most patients and usually require contemporaneous administration of paracetamol. Signs of chronic IFN toxicity, such as weakness, myalgia, weight and hair loss, severe depres-

Cambridge Books Online © Cambridge University Press, 2009

sion and gastrointestinal and cardiovascular symptoms, necessitate drug cessation in a relevant proportion of patients. In 273 cases published in the literature[130], IFN therapy was terminated in 25% (67 cases) against the primary treatment plan. The rate of withdrawal ranged between zero and 66% in the different studies. The wide range may be partly explained by the difference in the observation time lasting from 1 month to 4 years in the reported patients. The most common reasons for withdrawal were IFN-related side effects in 55% and patient refusal in 10%. Thus far, no leukemogenic effects have been reported. Therefore, despite high cost and toxicity, IFN remains a promising agent in cytoreductive treatment of ET, especially in younger patients.

A new interesting development is represented by the pegylated form of IFN[133]. This recent formulation may be one step forward because of its slower clearance, permitting once-weekly dosing. Clinical studies comparing IFN (also in its pegylated form) to HU or anagrelide are currently ongoing.

Anagrelide

Anagrelide is a member of the imidazo(2,1-b)quinazolin-2-one series of compounds with an inhibitory activity on platelet aggregation in both humans and animals. In addition, it has in humans a species-specific platelet-lowering effect observed at dose levels lower than those required to inhibit platelet aggregation. Because of this, the drug has been tested in patients with clonal thrombocytosis and has been shown to have potent platelet reducing activity[131,134]. The mechanism whereby anagrelide reduces platelet count without affecting the white count or normally the red blood cells is not yet completely understood, but there are data showing that its major action is the inhibition of megakaryocytic maturation. No chromosomal damage has been reported in relation to its use. The efficacy of anagrelide in ET has been assessed in non-comparative clinical studies[134]. Response was defined as a platelet count <500 or 600×10^9/l or a 50% drop in platelet count. A response rate of 60 to 93% was reported, irrespective of age, sex, spleen size, bleeding time, clinical symptoms or prior treatment. The average dose required to control platelet count was 2 to 2.5 mg per day and, in most cases, the median time for response was 3–4 weeks, although delayed responses of up to 24 months were described. Patients refractory to HU responded to anagrelide in 68% of cases. Continuous therapy is required because the platelet count rebounds in a few days after withdrawal of the drug.

The most serious complications of anagrelide are cardiac, including palpitations or forceful heart beats (27% of patients) tachycardia and other arrhythmias ($<10\%$) and congestive heart failure (2%)[131]. In addition, the vasodilating effect of the drug is the underlying cause of headache, which is the more frequent side effect (occurring in more than one-third of patients), fluid retention or edema (24% of cases), dizzness (15%) and postural hypotension. Gastrointestinal complications (nausea, abdominal pain and diarrhea) and transient rash have been reported less frequently. Sudden death was observed in two patients given anagrelide: one death was related to a pulmonary infiltrate and the other to congestive heart failure. Overall, 16% of 424 evaluable thrombocythemic patients with MPDs, including 262 with ET, discontinued anagrelide treatment because of side effects. Leukemic transformation has not been observed for up to 55 months of treatment.

The long-term efficacy and safety of Anagrelide has been recently analysed in 35 young patients with ET (median age 38 yrs, range 17–48) followed in a single Institution for a median follow-up period of 10.8 years (range 7–15.5)[135]. The overall initial response rate was 94% and the reduction of platelet count was maintained in 66% of patients over the study period. Eight patients (24%) experience a more than 3 g/dl decrease in hemoglobin level and three (9%) discontinued treatment because of toxicity. Most importantly, 7 patients (20%) experienced a total of 10 thrombotic episodes, while on therapy, and a similar proportion experienced major bleeding complications. None of the patients developed acute leukemia. Thus, long-term therapy with anagrelide appears to be relatively well tolerated but thrombohemorrhagic complications continue to occur. The final place of this drug in the therapeutic strategy of ET patients remains to be established in controlled clinical trials, such as the PT1 trial currently ongoing in UK and Germany.

Special situations (pregnancy, surgery, children)

Some special clinical situations in ET patients deserve consideration. Approximately 50% of pregnancies develop obstetric complications, including recurrent abortion, particularly in the first trimester, premature delivery, fetal growth retardation, and abruptio placenta[136]. The likely mechanism of these complications is placental infarction, so that some authors recommend the use of aspirin[137] or subcutaneous heparin[138], particularly in individuals who have had previous fetal losses. By reviewing the relevant literature, it would appear that aspirin was associated with a more successful outcome of pregnancy than in those managed without the drug[137]. Thus, aspirin, 75 mg/day, throughout the pregnancy and for at least 6 weeks after delivery is recommended in all women enrolled in a prospective, follow-up study currently ongoing in UK (T.C.

Cambridge Books Online © Cambridge University Press, 2009

Pearson, personal communication). However, in a single institutional experience from Mayo Clinic[139], specific therapy during 34 pregnancies did not appear to modify the clinical outcome. In symptomatic patients, the use of α-interferon has been proposed[140] even though only very few anecdotal reports support this recommendation. Thus, some uncertainty still remains in the management of pregnant patients with ET and we recommend considering therapy on an individual basis.

Considering major surgery, patients with uncontrolled PV and ET have an increased risk of thrombosis and hemorrhage in the postoperative period. Based on this rationale, a course of myelosuppressive therapy to lower the platelet count of patients with MPD should be considered prior to elective surgery. Myelosuppressive therapy is particularly indicated in patients with myeloproliferative disorders who require splenectomy, since such patients may have severe thrombo-haemorrhagic complications associated with massive postsplenectomy thrombocytosis.

ET may be observed in children[141–144]. These very young patients are generally characterized by a persistently elevated platelet count above 900×10^9/l and frequent headache, thrombosis and hemorrhagic episodes often leading to the discovery of the disease. There is some uncertainty to consider these thrombocytoses as 'true' myeloproliferative diseases and the term 'idiopathic thrombocytosis' has been suggested to emphasize this point. A careful long-term follow-up of all these cases is recommended to answer this question and establish the natural history of ET beginning in childhood.

Thrombocytosis in polycythemia vera and other MPDs

Increased platelet count is a frequent finding in PV and is currently included among the criteria for diagnosis[145]. Whether thrombocytosis should be considered as a risk factor for thrombosis is uncertain, however[146]. In a nested case-control analysis performed in the setting of the PVSG-01 protocol[147], each patient who suffered a thrombosis was matched with a thrombosis-free control of similar age, sex, treatment group and duration of study. Platelet counts at the nearest time before the thrombotic events of the index cases were not significantly different from those of the matched controls, suggesting that the level of the platelet count itself is not responsible for thrombosis.

Yet many clinicians believe that lowering of the platelet count in patients with PV leads to a reduction in thrombotic complications. This is supported by the finding that myelosuppressive therapy is associated with fewer thrombotic complications than therapy with phlebotomy alone[127]. However, one must ask whether myelosuppressive therapy reduces the incidence of thrombosis because of reduction of platelet count or whether thrombosis results from some other aspect of PV which is yet ill defined. In this regard, a recent study showed that in ET and PV an in vivo activation of the polymorphonuclear leukocytes occurs and is associated with laboratory signs of endothelium and coagulation system activation[148]. Nevertheless, there is no information, to date, on the effect of myelosuppressive therapy on this pathophysiologic mechanism.

Another important issue relates to the potential profibrotic effect of uncontrolled thrombocytosis in ET and other MPDs, driven by platelet-derived growth factor (PDGF) and other cytokines produced by platelets and megakaryocytes. In a French trial comparing hydroxyurea and pipobroman for the treatment of PV, a significant increase in the risk of progression to myelofibrosis was seen in the HU-treated patients[149]. Three-quarters of the patients developing myelofibrosis had permanently raised platelet counts ($> 400 \times 10^9$/l), particularly in the HU arm.

In idiopathic myelofibrosis, elevated platelet count is frequently observed after splenectomy, when major thrombotic and bleeding complications are more likely to occur[111]. In these cases, the risk of perioperative thrombosis may be reduced by judicious prophylactic use of drugs that lower the platelet count[150].

Platelet adhesive protein defect disorders

Kenneth J. Clemetson and Jeannine M. Clemetson

Theodor Kocher Institute, University of Berne, Freiestrasse 1, CH-3012 Berne, Switzerland

Introduction

The investigation of platelet defects causing bleeding disorders has been an important step in determining the roles of the major glycoproteins in platelet function. In particular, Bernard–Soulier syndrome and Glanzmann's thrombasthenia have provided the basis for studying the function of the GPIb complex and $\alpha_{IIb}\beta_3$, respectively. More recently, some generally milder bleeding disorders have been related to the absence or deficiency of other platelet receptors. With the development of techniques to produce mice in which specific gene expression has been deleted, these defects can also be reproduced and can be corrected by gene therapy. Have the disorders in humans still lessons to teach us? Probably the main diseases have already been discovered but we cannot exclude that a detailed screening of patients with mild, platelet related, bleeding disorders might disclose defects in previously unknown minor platelet receptors or new mutations with different effects in known receptors. Many patients with mild bleeding problems related to platelets are seen in hematology departments and cannot yet be diagnosed at a molecular level. Achieving the ability to diagnose the defects in these patients is still a major goal in platelet studies and may be amenable to proteomics approaches. Until X-ray crystallographic structures are available for the GPIb complex and $\alpha_{IIb}\beta_3$, information provided by the molecular diagnosis of Bernard–Soulier syndrome and Glanzmann's thrombasthenia will continue to provide important data on structure–functional relationships.

GPIb-V–IX complex

Bernard–Soulier syndrome

Bernard–Soulier syndrome (BSS) is caused by genetic defects in the genes of GPIbα, GPIbβ or GPIX[1–3]. First reported in 1948[4] the molecular diagnosis of this disorder began in the 1970s[5,6] with the discovery of the major platelet glycoprotein GPIb, later shown to consist of two subunits[7]. The involvement of two other components, GPIX and GPV, in BSS and also in the GPIb complex, was demonstrated in the early 1980s[8,9]. Absence or defects in the fourth component of the complex, GPV[10], do not lead to BSS[11] and expression of GPV is not essential for the expression of the other three subunits although expression of GPV depends on the expression of the other subunits. Recent studies with GPV-null mice indicate that a defect in GPV might rather lead to a thrombotic disorder than a bleeding disorder[12,13]. Patients with BSS have a prolonged bleeding time, large, often giant, platelets and thrombocytopenia[14,15]. In fact, because of the size of the platelets, the total platelet mass may be normal. Platelet counts as well as platelet size vary considerably between different cases. The characteristic platelet defect in BSS is lack of response to ristocetin/von Willebrand factor, which is not corrected by addition of normal plasma, while responses to other agonists, with the exception of low doses of thrombin, are normal. The inheritance of BSS is normally autosomal recessive and when homozygous is often due to consanguinity, only one case has been described as autosomal dominant[16]. Typical symptoms include nose bleeds, bleeding from the gums and from minor scratches as well as a noticeable tendency to bruise easily. Severe, life-threatening, bleeding is associated with surgery or with major trauma and is normally controlled by platelet or

blood transfusions. In the past BSS was often misdiagnosed as idiopathic thrombocytopenia purpura and treated by splenectomy or steroids. Most older patients have undergone a splenectomy. Women with BSS require special attention because of menorrhagia and childbirth. Associated problems may be prevented by oral contraceptives and appropriate transfusions, respectively. Nowadays, most patients, in taking adequate precautions, can live relatively normal lives. Members of patients' families who are heterozygous for BSS normally show few, if any, symptoms. Occasionally, they have been reported to have larger than normal platelets or to show some mild signs such as easy bruising[17] but not all heterozygotes have these and it is not clear if these symptoms are only apparent because of a combination with a further partial defect, e.g. in a coagulation factor (however, see the A156V mutation, below).

In addition to their large size and lack of binding to vWf, platelets from patients with BSS show some further characteristics; they have a reduced response to low doses of thrombin[18] and they have abnormal procoagulant responses[19]. On the one hand, they have an increased resting procoagulant state and on the other they do not show a normal increase in procoagulant activity after stimulation. These phenomena have been at least partly explained by a recent series of studies showing a critical role for GPIbα in the platelet response to thrombin in general[20,21] and in the procoagulant response in particular[22]. The reason for the large platelets is still not satisfactorily explained. An obvious possibility that has been proposed several times is a reduced association between the membrane and the submembranous cytoskeleton which might also explain the increased membrane deformability found in BSS platelets[23].

The basic types of BSS are less varied than in Glanzmann's thrombasthenia (GT) because most molecular defects lead to lack of expression of the complex rather than to expression of a dysfunctional complex. Identified mutations or deletions affecting GPIbα are listed in Table 42.1 and those affecting GPIbβ and GPIX in Table 42.2. Molecular defects causing BSS can be classed as:

(i) Glycoproteins totally absent – caused by frame shifts, deletions and folding defects in any of the three chains GPIbα, GPIbβ, or IX followed by a failure to form a complex or of the complex to translocate to the membrane. Major categories within this type are caused by frame shifts or deletions in any of the three chains leading to premature termination and therefore lack of the transmembrane domain and production of soluble fragments. Typical examples in GPIbα are: deletion of T in codon 76 leading to frame shift and premature truncation[24]; W343stop[25]; S444stop[26]; W498stop[27]; one base deletion leading to frame shift and premature truncation[28]; one base deletion in codon 19 leading to frame shift and premature truncation at codon21[29]; two base deletion at 972–975 of gene leading to frame shift after T294 and premature termination[30]; base insertion at 1418, and deletion at 1438–1444 both leading to frame shift and premature termination[30]; deletion of two bases of codon 492 producing a truncated molecule detectable in plasma[31]. In GPIX these are W126stop[28,32] and in GPIbβ a base deletion in A80 resulting in a frame shift and premature termination[33] as well as a W21stop mutation[34].

(ii) Variants of these may be mutations in or near the transmembrane region leading to frame shifts within this domain or in the cytoplasmic domain. These can lead to partial expression of functional or dysfunctional molecules. Folding problems can also lead to failure to translocate to the membrane. Such problems are often caused by mutations leading to replacement of cysteine residues or to the introduction of abnormal cysteine residues (Fig. 42.1). These types of mutations have been seen in all three subunits, for example in GPIbα C209S[35], in GPIX C8R[36] C73Y[37], C97Y[38] and in GPIbβ Y88C[39]. Folding problems are also typically caused by mutations within the leucine-rich repeat (LRR) domains (Fig. 42.1). Examples in GPIbα are L129P[40], in GPIX L40P[41], N45S[17,42], F55S[43] and in GPIbβ N63T[44]. This last mutation in GPIbβ is particularly significant in confirming the presence of two LRR in this subunit (and most likely in GPIX also) as predicted by protein modelling, and not one LRR with 'flanking domains' which would not fold stably. The N45S mutation is particularly common in populations of northern European origin, e.g.[45] and has also been found in many unpublished cases.

(iii) There are a few mutations in the LRR domains that appear to affect folding less radically and result in partial expression of a molecule, which does not function normally. The cases so far described of these variants were all mutations of GPIbα: L57F[16], A156V[46], L179 deletion[47]. The A156V mutation[48] is particularly common in southern Italian populations and, like L57F, shows autosomal dominant inheritance characteristics. It should be noted that most of the mutations leading to single amino acid substitutions in the LRR domains causing BSS are in the β-sheet part of the repeat (see Fig. 42.1). An exception to this is F55S in GPIX. Presumably the α-helix is more forgiving of single amino acid substitutions. A few other cases of BSS are known where the mutations lie outside these domains or defects. These include mutations within the disulfide loops at each end of the LRR, again presumably causing problems by preventing the loops from folding correctly. In GPIbα mutations in the C-terminal loops can lead to

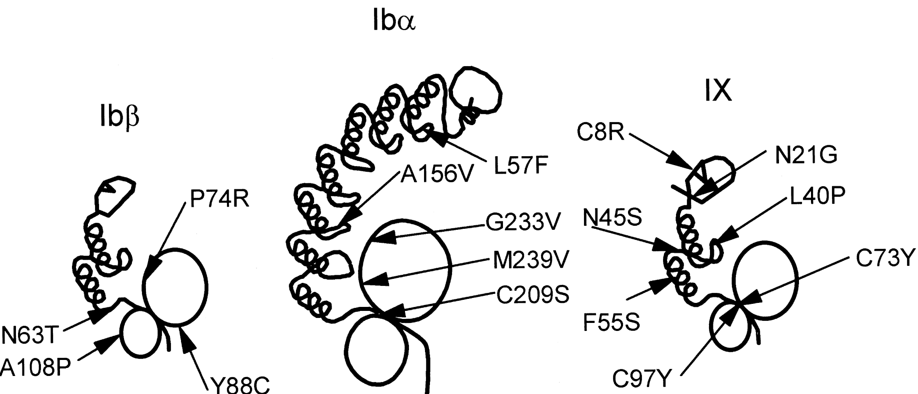

Fig. 42.1. Diagram of the outer, ligand-binding domains of GPIbα, GPIbβ and GPIX, consisting of leucine-rich repeats and disulfide bond linked loops, and indicating the position of amino acid substitution mutations involved in Bernard–Soulier syndrome and platelet-type von Willebrand disease.

platelet-type von Willebrand disease (see below). In GPIX mutations are found in N21G[42] and in GPIbβ in P74R[49], Y88C and A108P[39]. These last two mutations were characterised by the lack of disulfide bond formation between GPIbα and GPIbβ in most of the GPIb molecules. No functionally related mutations have so far been described within the macroglycopeptide region of GPIbα or in the region between the LRR C-terminal disulphide loops and the membrane surface in GPIbβ or GPIX.

(iv) All of the mutations listed above cause the disorder by inheritance in a recessive mode. The only example described as being dominant was a L57F mutation present in one allele of GPIbα[16]. More recently, the A156V mutation has been shown to have some autosomal dominant inheritance characteristics for a mild to moderate bleeding problem and larger than normal platelets as well as thrombocytopenia[48]. Since the other allele is normal in these patients, the phenotype could only be explained if a defective, expressed GPIbα interferes with the function of the normal molecule. No satisfactory mechanism to explain this has been suggested yet.

(v) Mutations within the promoter region may also affect expression levels leading to BSS. A typical example is a mutation in the GATA-1 sequence of the GPIbβ promoter in one allele which, combined with deletion of the other allele in DiGeorge syndrome, reduced expression of the complex to produce BSS[50].

Although still a rare disease and less common than GT, BSS is probably at least 2–3 times more common (2–3 cases per 1 000 000 population) than once thought. One reason for this is that recurrent mutations are not sufficiently novel to be published in the literature and are therefore underreported. An approach to solving this problem will be to provide a registry as has been done for GT (see below) to be able to collect information on all patients.

Platelet-type (or pseudo) von Willebrand's disease

Platelet-type von Willebrand's disease (vWd) is a dominant inherited bleeding disorder caused by mutations in GPIbα leading to an increased avidity for vWf in the resting platelet. This leads to platelet activation and aggregation, removal from the circulation by the spleen and periodic thrombocytopenia. Because the most active, larger multimers of vWf are preferentially removed, this causes defective hemostasis and hence bleeding risk. So far, two naturally occurring mutations, G233V[51] and M239V[52,53], leading to this disorder have been found (Table 42.1), both lying within the complex double-loop region between the LRR domain and the macroglycopeptide domain (Fig. 42.1). In vitro mutagenesis and expression of recombinant molecules have indicated that other mutations within this domain could also lead to changes in resting avidity[54] so that it remains possible that some of these mutations will be detected in vivo in the future. Nevertheless, it must be stressed that this is an extremely rare disorder probably because of the life threatening bleeding which is associated with it, which may well have been an evolutionary handicap in the past. Platelet-type vWd is generally treated very conservatively. Some cases may have been diagnosed as idiopathic thrombocytopenia purpura or as Type IIB vWd and it is important to differentiate these.

Size polymorphisms in GPIbα and their relation to bleeding disorders

At least three patients are known who have mild bleeding disorders related to size variation in GPIbα[55–57]. All three of these showed two bands for GPIb on polyacrylamide gels with an abnormally high upper band compared to the known size polymorphisms. However, only one of these patients has been investigated in any detail. Polymorphisms in the size of GPIbα are due to different repeats of a 13-amino acid sequence present in the macroglycopeptide domain[58]. The commonest of these are the single copy or the duplicate but triple and quadruple repeats are also known from European and East Asian populations[59], respectively. More recently, a variant where this repeat is completely missing has also been described[60]. In the patient with the bleeding problem one of the alleles for GPIbα is normal whereas the other has six copies of the 13 amino acid repeat. The disorder is inherited in a dominant pattern and appears to be linked to the size polymorphism. It is not clear why this leads to a bleeding problem since the GPIb binding sites should stick out more from the membrane. Possible reasons might be the discordance in size between the normal and abnormal GPIb molecules affecting efficient binding to vWf. There have been several studies examining a possible role of size polymorphisms in GPIbα in cardiovascular disease[61–64] but no clear tendency has emerged unlike the situation with other platelet receptors.

$\alpha_{IIb}\beta_3/\alpha_v\beta_3$

Glanzmann's thrombasthenia

Glanzmann's thrombasthenia (GT) is at the same time the commonest and among the most complex of disorders caused by defects in platelet adhesive receptors. It was the first such bleeding disorder to be described in 1918[65] and a molecular explanation had to wait until 1974–5 when the glycoproteins called GPIIb–IIIa were first implicated[66,67]. It is now clear that this disorder is caused by a defect or lack of expression in these two glycoproteins forming the integrin $\alpha_{IIb}\beta_3$. This disorder is characterized by a lack or reduction in platelet aggregation to all agonists. A further typical symptom is the lack of fibrinogen in the platelet alpha granules in the extreme form of this disease. As in BSS the problem can be caused by mutations or deletions, which prevent expression of one or the other of the subunits by premature termination before the transmembrane region but there are also a great many variants with different levels of expression caused by mutations which also affect folding[15,68]. Both homozygous as well as compound heterozygous mutations have been reported. Unlike BSS, because of the larger number of introns/exons making up the α_{IIb} and β_3 genes, splicing errors also contribute to the known defects. Identified molecular defects in the gene for GPIIb are listed in Table 42.3 and those in GPIIIa in Table 42.4. Although there is still no X-ray crystallographic structure available for $\alpha_{IIb}\beta_3$, computer modelling by homology with structures available from other integrins starts to give some insight into a general structure for $\alpha_{IIb}\beta_3$ and how it might function[69]. Thus, many of the mutations in α_{IIb} that lead to absence of expression or to defective function while partial expression of the complex is maintained are in a seven blade β-propeller structure[70] which is predicted to be the ligand binding site of this subunit (Fig. 42.2). Some of these involve calcium binding domains which are in the fourth to seventh blades of the propeller. The mutations often change the charge of a residue. These mutations include G273D (numbering based on the mature protein), before the first calcium binding domain[71], E324K[72] and R327H[73] between the second and third calcium-binding domains, G418D before the fourth calcium-binding domain[74] and a V425D426 deletion at the beginning of the fourth calcium-binding domain[75]. A cluster of mutations (P145A, P145L[76], T176I[77] and L183P[78]) lie in the third blade of the propeller implicated to participate in ligand-binding and cause receptor dysfunction. A further engineered mutation, D224V, in a connecting strand within this structural domain also led to GT[79].

While α_{IIb} subunit expression is restricted to $\alpha_{IIb}\beta_3$ and mutations and deletions of this subunit only affect this integrin, mutations and deletions of the β_3 subunit affect both $\alpha_{IIb}\beta_3$ and $\alpha_v\beta_3$. A large number of mutations and deletions lead to frame shifts and premature termination and hence to failure to express the integrin complex. One might expect that patients with GT caused by β_3 defects could show additional problems. In a mouse model, where the β_3 gene was ablated, an osteosclerotic phenotype was observed in ageing mice with marked bone thickening, presumably due to loss of $\alpha_v\beta_3$ on osteoclasts[80]. No additional effects on platelet function or on angiogenesis were detected. Within the β_3 subunit two major structural units have been identified. One of these is the cation-binding domain, classed as a MIDAS structure or I-domain-like structure[81] and the other is the region rich in disulfide bonds recently recognized as having a protein disulfide isomerase function[82]. Within the MIDAS domain eight point mutations leading to amino acid replacements causing GT have been identified (Fig. 42.3). Two of these, D119Y[83] and D119N[84] are in the DXSXS motif, which is highly conserved. Three mutations, R214W[85], R214Q[86] and

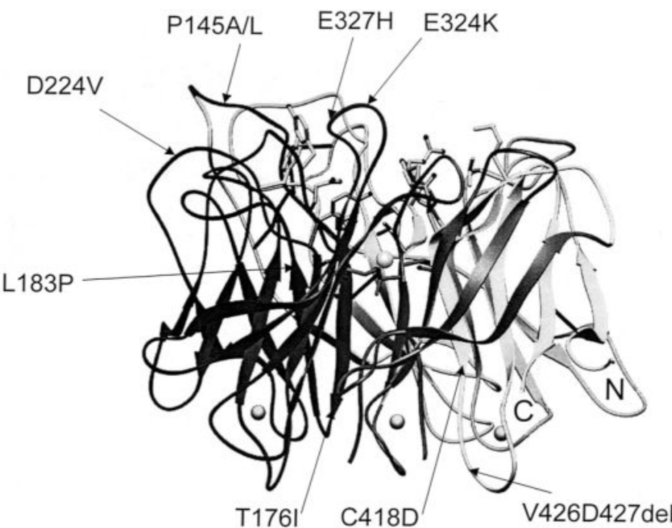

Fig. 42.2. Model of the outer domain of the α_{IIb} subunit as a β-propeller, indicating the position of amino acid substitutions/deletions involved in Glanzmann's thrombasthenia. This domain is predicted to be the ligand binding region of the IIb subunit. There are seven blades, consisting of antiparallel β-folds connected by loops, which include four calcium binding domains towards the bottom of the structure.

R216Q[87] are near cation coordinating sites, and three mutations, D117W[88], S162L[89] and L262P[90] are in the MIDAS structural unit. It is interesting that while the mutations D119Y and D119N affect function but have little effect on expression that at D117W prevents surface expression. The mutations near the cation coordinating sites, R214W, R214Q and R216Q, increase susceptibility of $\alpha_{IIb}\beta_3$ complexes containing these mutated β_3 subunits to dissociation by calcium chelating agents. The mutations at S162L and L262P cause both reduced surface expression (~30%) as well as increased sensitivity of $\alpha_{IIb}\beta_3$ to dissociation by calcium. The S162L mutation results in a complex which does not bind fibrinogen but does support clot retraction, implying that the complex recognizes fibrin. The recently described L262P mutation caused reduced expression and easily dissociated complexes. Again, cells expressing the mutant complex were able to sustain clot retraction while failing to bind to immobilized fibrinogen. Mutations in cysteine residues within the β_3 subunit are also critical for folding and complex formation. These include C374Y[91] and C457R[15] which lead to decreased amounts of expression and C542R[92] where no surface expression was detected.

A great deal of interest has been raised by mutations in the cytoplasmic domain of β_3 which affect inside-out signalling and activation of the receptor for ligand binding. One of these in the codon for R724 to a nonsense triplet causes premature termination and deletion of the C-terminal 39 amino acids[93]. Another is an S752P mutation[94]. Although platelets from both patients express $\alpha_{IIb}\beta_3$ they do not aggregate in response to platelet agonists. Nevertheless, they adhere to immobilized fibrinogen but do not spread on this surface. These mutations do not affect fibrinogen uptake suggesting that outside-in signalling via $\alpha_{IIb}\beta_3$ is not necessary for this function.

GT is the commonest of the platelet receptor related disorders and one of the best documented. An Internet database has been established with data on patients and the possibility of contributing new data (*http://med.mssm.edu/glanzmanndb*). It is to be hoped that, in the future, this will be extended to cover other platelet-related defects.

$\alpha_2\beta_1$ deficiency

In the 1980s two patients were described with mild bleeding problems related to a deficient expression of $\alpha_2\beta_1$[95,96]. These patients had a defective response to collagen but not to other agonists and both surface labelling studies as well as two-dimensional gel electrophoresis studies demonstrated low levels or absent $\alpha_2\beta_1$. In one case further studies showed decreased adhesion to vascular subendothelium as well as poor activation and spreading. Both patients were women and one passed through the menopause soon after these studies which was linked to a recovery of responses to collagen. The other was younger at that time, but has also recently passed the menopause and also showed a recovery of platelet function. It is also seems likely that both these patients started to show symptoms only after their menarche. Other studies found a wide distribution of levels of $\alpha_2\beta_1$ expression among normal donors linked to silent polymorphisms in the gene for α_2[97] so it remains unclear to what extent the two patients were abnormal. It is possible that they represent extreme levels within the 'normal' range perhaps coupled to a low 'normal' value of a coagulation factor, together leading to an enhanced bleeding tendency. The recovery after the menopause suggests a role of hormones in expression levels which is not implausible given the hormone dependency of some transduction factors. These studies suggest that loss of, or inhibition of, $\alpha_2\beta_1$ might not cause major bleeding problems and that inhibition of this receptor might be a possible antithrombotic strategy. However, $\alpha_2\beta_1$ is expressed on vascular cells such as endothelial and smooth muscle cells as well as platelets and it is not known

Fig. 42.3. Model of the outer domain of the β_3 subunit as a MIDAS/I-domain, indicating the position of amino acid substitutions involved in Glanzmann's thrombasthenia. The structure is based upon the folding pattern found in several such domains including the A domain of von Willebrand factor and the I-domain of the α_2 integrin subunit.

if these were affected in the patients, presenting an additional complication.

In 1995 a patient suffering from a myeloproliferative disorder was shown to have a specific deficiency in platelet $\alpha_2\beta_1$ and lacked aggregation and adhesion responses to collagen[98]. The patient had a prolonged bleeding time and marked thrombocytosis.

GPVI deficiency

The detection of patients lacking or deficient in GPVI was an important step in identifying this glycoprotein as a critical collagen receptor. Although GPVI was recognized earlier on platelets its function was obscure. The first patient to be identified had platelets with a specific collagen-response defect and her plasma contained antibodies that recognized GPVI in normal platelets[99]. It is still not clear why this patient developed an antibody to an absent receptor but results from mouse model studies start to cast some light on possible explanations. The antibodies from this patient were extremely useful in further characterization of GPVI but also helped to identify other Japanese patients with a defect in this receptor. At least three other patients were found, of whom two also completely lacked surface expression of GPVI while the third had 10% of normal amounts[100,101]. Although both the gene sequence[102] as well as the genomic structure of GPVI[103] are now established, the molecular reason for the absence of GPVI in these patients has not yet been established. Since expression of GPVI and its signalling subunit Fcγ are closely linked[104], it cannot be excluded that the defect may lie in

Cambridge Books Online © Cambridge University Press, 2009

the gene for Fcγ. Some recent studies in mice with a rat monoclonal antibody to GPVI may also provide an explanation for the patient with the autoantibodies by showing that there is down-regulation of GPVI expression on normal mouse platelets in the presence of this antibody[105]. Patients with GPVI deficient platelets have so far only been detected in Japan. Although this may mean that the deficiency is restricted to, or more common, in the Japanese, it is also possible that the mild bleeding tendency, that has permitted its detection, is not present in other ethnic groups with more thrombogenic diets and lifestyles. A wider screening of other population groups may detect more GPVI deficient individuals.

CD36 deficiency

CD36 is the general name for a molecule that was also named GPIIIb or GPIV in platelets. Many early studies on this glycoprotein were also carried out on platelets. There was considerable interest when CD36 was found to be absent in a small population (4–7%) of healthy donors. At first this deficiency was thought to be confined to the Japanese but then other deficient individuals were found in different East Asian populations. More recent studies showed that CD36 is also absent in a minority (7–10%) of the sub-Saharan populations of Africa and in a very small part (~0.3%) of populations in other parts of the world. Is CD36 an adhesive receptor? This has been a controversial area and is even now not completely resolved. Two major adhesive proteins, collagen[106] and thrombospondin[107] have been suggested as ligands for CD36, but it is clear that other proteins also bind to this receptor, including *Plasmodium*-infected erythrocytes and that its main function may be as a scavenger for oxidised lipoproteins[108] or a transporter of long-chain fatty acids[109]. Other authors found little evidence for a role of CD36 as a collagen receptor[110,111]. The molecular basis of CD36 deficiency has been identified as a polymorphism in codon 90 which, if expressed, would lead to a Ser$\rightarrow$Pro shift[112].

Other putative candidates for adhesive receptor defects

Platelets have a number of other receptors which are thought to have either a direct role in adhesion such as $\alpha_5\beta_1$ and $\alpha_6\beta_1$, or a supporting role, such as CD9 or CD47 but so far no bleeding disorders have been linked to a defect in any of these. This may be because they have relatively minor roles in platelet function or, alternatively, because they have major functions on platelets or other cells during embryonal development. Targeted ablation of the genes for these receptors in a tissue-specific way will provide more information about the possible consequences of natural defects. In the long-term proteomic approaches to the analysis of platelets from patients with mild bleeding disorders, related to platelet defects, may be expected to identify a variety of new receptor-linked disorders, whether in the receptors themselves or in downstream signalling pathways.

Congenital disorders of platelet secretion

Marco Cattaneo

Angelo Bianchi Bonomi Hemophilia and Thrombosis Centre, IRCCS Ospedale Maggiore, University of Milano, Italy.

A brief introduction on platelet secretion (see Fig. 43.1)

The essential role played by platelets in hemostasis, thrombosis and vascular remodelling is, to a large extent, mediated by effector molecules that they secrete at sites of vascular injury. These molecules are contained in the platelet dense (or δ-) and α-granules. Dense granules are small organelles (200–300 nm in diameter) that are dense to electrons in osmium-stained platelets. They mostly contain small molecules, such as nucleotides, serotonin, catecholamines, Ca^{2+}, Mg^{2+} and pyrophosphate. More recent studies have demonstrated the presence of P-selectin, granulophysin, glycoprotein (GP) Ib and GPIIb/IIIa bound to their membrane[1–3]. Alpha granules, at variance with δ-granules, are moderately electron-dense and have a diameter of about 200–500 nm. The most numerous of the platelet storage organelles, they contain membrane-bound proteins (GPIb/IX/V, GPIIb/IIIa, P-selectin, GPIV, osteonectin, PECAM1, GMP33, CD9) and are the storage site for proteins which are synthesized in the megakaryocytes (von Willebrand factor, thrombospondin, fibronectin, coagulation factor V, platelet-derived growth factor and other growth factors), or acquired from plasma either by receptor-mediated endocytosis (e.g., fibrinogen) or by fluid-phase pynocytosis (e.g., albumin and immunoglobulin G)[4,5].

While δ-granules function primarily for the amplification of platelet activation through the secretion of platelet agonists such as serotonin and adenosine diphosphate (ADP), α- granules enhance the adhesive process, promote cell–cell interactions and stimulate vascular repair. The combined action of molecules secreted by δ- and α-granules contribute to the stabilization of platelet aggregates[6,7].

Other platelet organelles that release their contents in the extracellular fluid upon activation are the lysosomes,

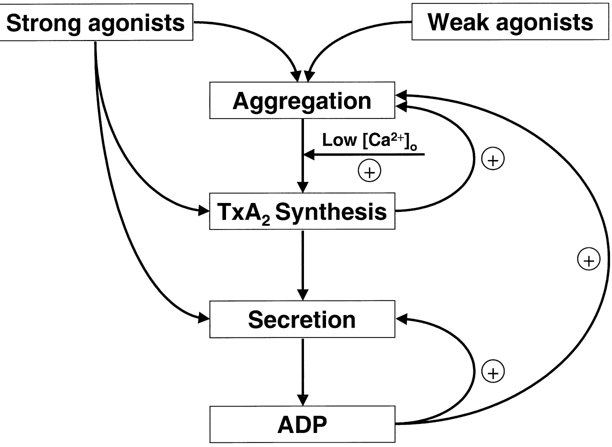

Fig. 43.1. Schematic representation of the amplification pathways of platelet aggregation and secretion. Being a weak agonist, ADP does not induce platelet secretion directly when it interacts with resting platelets. However, once platelet secretion has been triggered by a strong agonist, released ADP potentiates platelet secretion independently of the formation of large platelet aggregates and thromboxane A_2 production[16]. This function of released ADP is mediated by its interaction with the platelet $P2Y_{12}$ receptor[17] (see also Fig. 43.2). ADP, adenosine diphosphate; TxA_2, thromboxane A_2; $[Ca^{2+}]_o$, concentration of external ionized calcium; (+) = potentiation.

which contain degradative enzymes, including acid phosphatases, aryl sulfatase, β-glucuronidase, cathepsin, heparitinase, β-hexosaminidase and β-galactosidase. Their membrane contains several glycoproteins, including CD63, LAMP-1 and LAMP-2. Recent data suggest that lysosome release requires the same membrane fusion machinery that is necessary for δ- and α-granule release[8]. Although lysosome secretion can be easily induced *in vitro* and can occur *in vivo* upon stimulation[9], its physiological relevance is controversial[10]. They may have a role in the

amplification of platelet activation[11] and in vascular remodelling.

Very briefly, the molecular mechanisms of platelet secretion involve the interaction of agonists with their receptors, which are coupled to second messengers, including Ca^{2+}, diacylglycerol and protein kinase C that signal to the SNARE (soluble NSF attachment protein receptor) machinery through yet unknown linkages[12,13] (Chapter 24 in this book). The platelet granules fuse with the membranes of the open canalicular system (OCS), into which they release their contents.

Platelet agonists are usually subdivided in two categories: weak and strong agonists. Weak agonists, such as ADP and epinephrine, induce platelet aggregation, but do not cause platelet secretion directly. However, in a minority of individuals[14], the close platelet-to-platelet contact brought about by platelet aggregation triggers the formation of trace amounts of thromboxane A_2 (TxA_2) which stimulates platelet secretion and, together with substances released from platelet granules, reinforces aggregation. This effect is greatly enhanced and can be observed in most individuals, when the concentration of ionized calcium in the extracellular medium is artefactually decreased to the micromolar level, such as in citrated PRP[14,15]. It must be noted, however, that recent studies have shown that, once platelet secretion has been triggered by a strong agonist, ADP or epinephrine potentiates platelet secretion directly, independently of platelet aggregation and TxA_2 formation[16,17]. In contrast to weak agonists, strong agonists, such as thrombin and collagen, trigger platelet secretion directly, i.e. independently of platelet aggregation and TxA_2 production. With medium-low concentrations of strong agonists, however, some aggregation- and TxA_2-dependent amplification of platelet secretion can be observed, especially at low concentrations of external Ca^{2+}[18,19].

Defects of platelet secretion

Definition

Since platelet secretion and aggregation are intimately related and both depend on platelet activation, a clear distinction between disorders of platelet aggregation, platelet activation and platelet secretion is in many instances problematic. For example, when citrated PRP from patients with Glanzmann's thrombasthenia are stimulated in the aggregometer with ADP, they do not undergo aggregation and, as a consequence, do not undergo the aggregation-dependet secretion. However, Glanzmann's thrombasthenia is generally, and correctly, considered a typical defect of platelet aggregation. This chapter will review those congenital disorders of platelet function in which a secretion defect appears to be the primary or the more relevant abnormality. As a consequence of the secretion defect and the lack of the potentiating effect of released δ-granule constituents, these disorders usually have as a common characteristic an abnormal pattern of aggregation responses to many agonists: (i) absent secondary waves of aggregation, after normal primary waves stimulated by the weak agonists ADP, epinephrine and platelet activating factor (PAF)[20], (ii) impaired aggregation induced by low concentrations of collagen or thrombin. It must be noted, however, that these abnormalities of platelet aggregation, albeit typical, are not to be considered the diagnostic hallmark of defects of platelet secretion, because platelet aggregation is not a sensitive diagnostic test for these abnormalities of platelet function (see later).

Classification

In an attempt to make some order among the very heterogeneous disorders of platelet secretion, they are here subdivided in three groups (Table 43.1): (i) defects of the platelet granules, which could be considered 'pure' defects of platelet secretion; (ii) defects of the two main amplification pathways of platelet activation, the arachidonate-TxA_2 pathway and the ADP pathway; (iii) miscellaneous abnormalities of platelet secretion ('primary secretion defects'): this group encompasses heterogeneous disorders of platelet secretion that cannot be explained by abnormalities of platelet organelles or of the two amplification pathways. Parts of this chapter will inevitably overlap with parts of the following chapter on defects of platelet signal transduction.

Defects of the platelet granules

Defects of the platelet granules comprise a heterogeneous group of disorders, including deficiencies of the δ- and/or α-granules, or their consituents (δ-, α,δ- and α-Storage Pool Deficiency, Table 43.2) and other, less common defects of the α-granules. It must be noted that pure defects of the α-granules do not cause the abnormalities of platelet aggregation that are typical of defects of platelet secretion.

Cambridge Books Online © Cambridge University Press, 2009

Table 43.1. Classification of congenital defects of platelet secretion

Abnormalities of the platelet granules ('Pure' platelet secretion disorders)
δ-storage pool deficiency (δ-SPD)[a]
δ-SPD (not associated to other congenital disorders)
Hermanski–Pudlak syndrome
Chediak–Higashi syndrome
α,δ-storage pool deficiency (α,δ-SPD)
α-storage pool deficiency, or Gray Platelet syndrome (GPS)
Quebec platelet syndrome
Jacobsen or Paris-Trousseau syndrome
Platelet secretion disorders due to abnormalities of the amplification pathways
Abnormalities of the arachidonate/TxA_2 pathway
impaired liberation of arachidonate from membrane phospholipids
defects of cyclooxygenase (aspirin-like defects)
defects of thromboxane synthetase
defects of the platelet TxA_2 receptor
Abnormalities of the ADP pathway
defects of the platelet $P2Y_{12}$ receptor[b]
Miscellaneous abnormalities of platelet secretion ('Primary secretion defects')
Miscellaneous disorders of platelet secretion not due to defects of the platelet granules or of the amplification pathways

Notes:
[a] δ-SPD has also been described in some cases of thrombocytopenia with absent radii (TAR) syndrome and Wiskott–Aldrich syndrome (WAS) (see Chapter 34).
[b] Patients who are homozygous for $P2Y_{12}$ defect, in addition to a secretion defect, have a severe impairment of platelet aggregation induced by ADP.

Defects of the δ-granules (δ-storage pool deficiency)

δ-storage pool deficiency

The term δ-storage pool deficiency, or δ-storage pool disease (δ-SPD) defines a congenital abnormality of platelets characterized by deficiency of dense granules in megakaryocytes and platelets. It is characterized by a bleeding diathesis of variable degree, mildly-to-moderately prolonged skin bleeding time, abnormal platelet secretion induced by several platelet agonists, impaired platelet aggregation and decreased platelet content of dense granules. It may present as an isolated platelet function defect or it may associate with a variety of congenital disorders.

First described in 1969 in a family with impaired platelet aggregation and reduced release of ADP[21], it was later shown to be caused by a deficiency in the nonmetabolic pool of adeninenucleotides contained in the platelet δ-granules[22,23]. Several other patients have been described since then. Between 10% and 18% of patients with congenital abnormalities of platelet function have SPD[24,25]. The inheritance is autosomal recessive in some families and autosomal dominant in others.

Clinical features

Patients with δ-SPD have mild to moderate bleeding diathesis, characterized mainly by mucocutaneous bleedings, such as epistaxis, menorrhagia and easy bruising. Patients with the most severe forms may also experience postsurgical hemorrhagic complications, especially after tooth extraction and tonsillectomy. Only one case with intracranial bleeding has been reported[26]. Hemarthrosis has never been reported in these patients. The bleeding time is usually prolonged, and the extent of its prolongation is inversely related to the amount of ADP or serotonin contained in the granules[27,28].

Studies of a family which includes several members with autosomal dominant δ-SPD showed an association between δ-SPD and the development of acute myelogenous leukemia: on this ground, the hypothesis was raised that a gene coding for a protein important for the formation of dense granules is located adjacent to a gene which, when abnormal, may predispose to the development of leukemia[29,30]. An association of δ-SPD with primary pulmonary hypertension was described in a patient, suggesting a role for the high plasma serotonin levels found in δ-SPD in the pathogenesis of this disorder[31]. The association between pulmonary hypertension and δ-SPD was also described in fawn-hooded rats[32].

Laboratory findings

Studies of δ-granules with uranaffin reaction (staining by uranyl ions of both the δ-granule membrane and core)[33], with the fluorescence probe mepacrine (which concentrates in the δ-granules)[34], or with electron microscopy[35], revealed that platelets from patients with isolated δ-SPD have slightly reduced number of uranaffin-positive and mepacrine-positive granules, but a shift in uranaffin-positive distribution towards those lacking a dense core ('empty granules'), suggesting a more qualitative than quantitative type of δ-granule defect[36]. In accordance with these findings, platelets from patients with isolated

Chediak–Higashi syndrome	Bleeding diathesis Oculocutaneous albinism Recurrent infections (neutropenia) [accelerated phase: lymphoid infiltration of multiple organs]	Aut/recessive	Decreased	Decreased	Normal	Normal
α,δ-storage pool deficiency	Bleeding diathesis	Aut/recessive	Decreased	Normal (?)	Decreased	Normal (?)
Grey platelet syndrome (α-storage pool deficiency)	Bleeding diathesis Thrombocytopenia Myelofibrosis (splenomegaly)	Aut/recessive Aut/dominant	Normal	Normal	Decreased	Normal

platelet δ-SPD had normal amounts of the δ-granule membrane protein granulophysin[37,38].

δ-SPD platelets have decreased levels of δ-granule constituents: ATP and ADP[22,23], serotonin, calcium and pyrophosphate[39,40]. ADP and ATP are contained in platelets in a metabolic pool, which represents about 1/3 of the total content, and the δ-granules, which represent the storage pool. ADP is present in greater amounts in the storage pool, while the concentration of ATP is higher in the metabolic pool. The ratio of total ATP: ADP in normal platelets is $<2.5:1$, while that of the metabolic pool is about 10: 1. Due to the deficiency of δ-granules, the ratio of total ATP: ADP in δ-SPD platelets typically rises to values >2.5–3: 1[41].

Platelets are the main storage site for serotonin of the human body. Normal platelets avidly uptake serotonin from the bloodstream and store it in the δ-granules, where it is protected from the action of mitochondrial monoamino oxidases. When radioactive serotonin is incubated with normal platelets in vitro, more than 90% of it is rapidly incorporated. In contrast, when it is incubated with δ-SPD platelets, the initial rate of uptake (through the platelet plasma membrane) is normal, but the saturation level is decreased, due to the catabolism of serotonin, resulting in the loss of the radioactive label from the platelets[42].

In citrated platelet-rich plasma, primary aggregation induced by ADP or epinephrine and the agglutination response to ristocetin are normal in these patients, but the second wave of aggregation and the aggregation in response to collagen are generally absent or greatly reduced[23,43]. The production of arachidonate metabolites can be defective after stimulation with epinephrine or collagen, but normal with arachidonate[44]; however, the aggregation induced by sodium arachidonate or prostaglandin endoperoxides may be normal or decreased[43–47], depending on the severity of ADP deficiency in platelet granules[44]. Normal responses to ADP or epinephrine have been observed in some patients[48], indicating that there is a large variability in platelet aggregation in patients with δ-SPD, which has been well documented in a large study of 106 patients with δ-SPD (congenital in ref. 51 and acquired in ref. 55), which showed that about 25% of the patients had normal aggregation responses to ADP, epinephrine and collagen, while only 33% had aggregation tracings typical for a platelet secretion defect[24]. In agreement with these findings, it was later shown that, among 46 patients with prolonged bleeding times, normal vWF levels and normal platelet aggregation 17 (35%) had δ-SPD[49]. Lumiaggregometry, which measures platelet aggregation and secretion simultaneously, may prove a more accurate technique than platelet aggregometry for diagnosing patients with δ-SPD and, more generally, with platelet secretion defects.

Cambridge Books Online © Cambridge University Press, 2009

High concentrations of thrombin induced normal extent of aggregation of δ-SPD platelets, but the aggregates deaggregated more easily than normal[7]. This defect was corrected by the addition of exogenous ADP immediately after thrombin stimulation, suggesting that released ADP plays a role in the stabilization of platelet aggregates[7]. Other platelet function abnormalities described in δ-SPD patients include abnormal secretion of acid hydrolases[50], which was corrected by exogenous ADP[51], and defective aggregation at high shear[28,52].

The in vitro interaction of δ-SPD platelets with the subendothelium was impaired in an experiment of perfusion of citrated blood through a chamber containing everted segments of rabbit aorta[53]. Subsequent experiments performed at different flow conditions (shear rates varying from 650 to 3300 s^{-1}) with non-anticoagulated blood showed that thrombus formation was decreased in δ-SPD patients in proportion to the magnitude of the granule defect[54].

Weiss and Lages showed that the prothrombinase activity induced by collagen, thrombin, or collagen plus thrombin was impaired in δ-SPD platelets and was corrected by the addition of ADP[55]. However, a previous study failed to demonstrate an abnormal procoagulant activity of δ-SPD platelets under slightly different experimental conditions[56].

Diagnosis

The diagnosis of δ-SPD is essentially based on the finding of defective platelet secretion induced by several agonists, decreased platelet content of total ADP and ATP, increase in the ATP/ADP ratio >2.5–3.0, and normal serum concentration of the stable TxA_2 metabolite, TxB_2. Methods involving the identification of mepacrine-loaded platelets by flow cytometry[57,58] or studying platelet aggregation at high shear[28] may also prove to be useful for the diagnosis of this disorder.

The Hermansky–Pudlak syndrome

Clinical features

Hermansky–Pudlak syndrome (HPS) is a rare autosomal recessive disease of subcellular organelles of many tissues, involving abnormalities of melanosomes, platelet δ-granules and lysosomes. It is characterized by tyrosinase-positive oculocutaneous albinism, a bleeding diathesis due to δ-SPD and ceroid-lypofuscin lysosomal storage disease[59]. The oculocutaneous albinism manifests as congenital nystagmus, iris transillumination, decreased visual activity and various degrees of skin and hair hypopigmentation. Ceroid lypufuscin is a lipid–protein complex accumulating in lysosomal organelles, which is believed to be responsible for the development of progressive pulmonary fibrosis[60,61] and granulomatous colitis[62] in affected patients. The pulmonary fibrosis is particularly frequent in patients homozygous for the 16-bp duplication in HPS gene (see below)[63] and usually leads to death within the fourth or fifth decade. In albino patients, the absence of visible δ-granules in the platelet cytoplasm under the electron microscope and/or the deficiency of platelet adenine nucleotides is pathognomonic for the disease. The bleeding diathesis of HPS patients, similarly to that of other types of δ-SPD, manifests with easy bruising, epistaxis, gum bleeding, menorrhagia and postsurgical bleeding. Just as the degree of hypopigmentation is not uniform in all patients, the severity of the bleeding diathesis varies substantially. It has been suggested that the bleeding risk increases in patients with low plasma vWF levels[64], although a more recent study did not confirm this association[65]. A recent report documented that major bleedings, some of which were life-threatening, occurred in 40% of the patients studied[63].

Prevalence

HPS is rare in the general population, but occurs with relatively high frequency in certain isolated groups, such as in the northwestern region of Puerto Rico, where its prevalence is 1 in 1800[66], and in an isolated village in the Swiss Alps[67].

Laboratory findings

The number of δ-granules in platelets from 7 HPS patients was markedly diminished when studied with electron microscopy, loading of the fluorescent probe mepacrine or the uranaffin reaction[36], indicating that the basic defect of HPS, at variance with that of isolated platelet δ-SPD, is a specific abnormality in organelle development which prevents the formation of an intact granule structure. In accordance with these findings, the platelet content of the δ-granule membrane protein granulophysin was shown to be very low in HPS patients[37].

The bleeding time is prolonged in most, but not all HPS patients. A variable degree of abnormalities of tests of platelet function can be observed in HPS patients as well as in patients with isolated δ-SPD. The release of α-granule proteins induced by thrombin was impaired in one patient, and was normalized by the simultaneous stimulation of platelets with ADP[68]. These findings are consistent with the recent demonstration that released ADP directly potentiates platelet secretion induced by U46619 or thrombin by interacting with the platelet $P2Y_{12}$ receptor[16,17,69]. In a group of 30 HPS patients, both plasma and

Cambridge Books Online © Cambridge University Press, 2009

platelet vWF levels tended to be slightly reduced compared to normal controls[65].

Molecular aspects

The molecular basis for HPS has only recently begun to be unravelled. HPS can arise from mutations in different genetic loci[70–72]. The Puerto Rican variant of HPS, termed HPS-1, is associated with a 16-bp duplication in exon 15 of the HPS gene, mapped to chromosome 10q23, which encodes for a cytosolic protein (HPS1p) of 79.3 kDa[73]. Another form of HPS, termed HPS-2, is characterized by mutations in the ADTB3A gene encoding the β3A subunit of the heterotetrameric protein complex, adaptor complex-3 (AP-3)[72]. The reduction in AP-3 cellular content in cells of HPS-2 patients is associated with increased routing of lysosomal proteins through the plasma membrane[72]. In contrast, cells from HPS-1 patients, which are deficient in HPS1p, display normal distribution and trafficking of lysosomal proteins[74]. It is therefore likely that HPS-2 arises from impairment of protein transport to lysosomes and related organelles, such as the platelet δ-granules, while HPS-1 arises from mechanisms that are independent of mistargeting of lysosomal membrane proteins[72,74]. Some HPS patients do not bear any detectable mutation in HPS1, ADTB3A or any other subunit gene[72]. This phenomenon, called locus heterogeneity, is also found in mouse animal models of HPS (see following section).

Animal models

Fifteen different mouse strains manifest a type of HPS (pigment dilution and platelet δ-SPD), each due to a different gene[75]. To date, three different genes have been cloned. *Pale ear* is the murine analogue of patients with HPS-1 mutations[76,77], and *pearl*[78] and *mocha*[79] have defects in AP-3. One protein subunit of AP-3, called β-3A, is mutated in the *pearl* mouse, while another protein, called δ, is mutated in the *mocha* mouse. More recently, a new mouse HPS mutation was identified, termed cappuccino (*cno*), of a gene in chromosome 5 which is not a component of the AP-3 family, confirming that there are defects in multiple pathways in the pathogenesis of HPS[80]. The mouse models of HPS show striking clinical correlations to human HPS. All have an autosomal recessive inheritance, prolonged bleeding times and suffer a bleeding diathesis.

Additional animal models of δ-SPD have been described in dogs[81], pigs[82,83] and rats[84,85].

Chediak–Higashi syndrome

Clinical and laboratory features

Chediak–Hygashi syndrome (CHS) is a rare autosomal recessive disorder characterized by variable degrees of oculocutaneous albinism, very large peroxidase-positive cytoplasmic granules in a variety of hemopoietic (neutrophils) and non-hematopoietic cells, easy bruisability due to δ-SPD, and recurrent infections, associated with neutropenia, impaired chemotaxis and bactericidal activity, and abnormal NK function[86]. Many patients may undergo an accelerated phase, characterized by non-malignant lymphoid infiltration of multiple organs. The syndrome is lethal, leading to death usually in the first decade of life.

The bleeding diathesis and the abnormalities of platelet aggregation and secretion are similar to those of other forms of δ-SPD[87,88]. The levels of the δ-granule membrane protein granulophysin are very low in CHS platelets[37], as expected in platelets lacking δ-granules[89]. The pathognomonic feature of CHS is peroxidase-positive granules that can be seen in polymorphonuclear leukocytes, as well as in megakaryocytes, neurons and other cells.

Molecular aspects

The gene responsible for CHS has been cloned[90] and mapped to the chromosome segment 1q42–44[91,92]. The gene is very large and several mutations have been described[86]. Like HPS, CHS may prove to be a genetically heterogeneous disorder, with mutations at different loci resulting in a similar phenotype.

Animal models

Among the several reported animal models for CHS[86], the *beige* mouse has been well characterized[93]. In addition to other features resembling human CHS, the *beige* mice have markedly reduced constituents of the δ-granules and prolonged bleeding times[94]. Normal bone marrow transplantation in these mice corrected the prolonged bleeding times and the platelet serotonin levels, while transplantation of *beige* mouse bone marrow into normal mice caused the development of prolonged bleeding times and low levels of δ-granule constituents[95]. The *beige* gene is located on the mouse chromosome 13, which is syntenic to human chromosome 1q42–43.

Additional animal models for the CHS have been described in cattle[96], blue foxes[97] and cats[98]. Allogeneic bone marrow transplantation successfully corrected the neutrophil migration defect and the platelet δ-SPD, but had no effect on lysosome distribution in liver and kidney cells of CHS cats[98].

Cambridge Books Online © Cambridge University Press, 2009

Hereditary thrombocytopenias

Two types of hereditary thrombocytopenia may be associated with δ-SPD: the Thrombocytopenia and absent radii syndrome (TAR)[99] and the Wiskott–Aldrich syndrome[100,101]. They are described in detail in Chapter 34 of this book.

Defects of the α-granules

α-storage pool deficiency (Grey platelet syndrome)

The first patient with this disorder was described by Raccuglia in 1971[102]. The condition owes its name to the grey appearance of the patient's platelets in peripheral blood smears as a consequence of the rarity of platelet granules. Since its first description, about 40 new cases have been reported in the literature, many of whom belonging to a single family in Japan[103]. The inheritance pattern seems to be autosomal recessive, although in a single family from Japan, it seemed to be autosomal dominant[103].

Clinical features

Affected patients have a lifelong history of mucocutaneous bleeding, which may vary from mild to moderate in severity, prolonged bleeding time, mild thrombocytopenia, abnormally large platelets and isolated reduction of the platelet α-granule content. Occasional patients may have more severe bleeding symptoms, including intracranial hemorrhage and postsurgical bleeding[104–106]. Mild to moderate myelofibrosis, which seems to be non-progressive, has been described in some patients[107] and hypothetically ascribed to the action of cytokines that are present in abnormally high concentrations in the bone marrow, as a consequence of their release by the hypogranular platelets and megakaryocytes[108]. Splenomegaly may be present[102,107,109] and splenectomy may be followed by normalization of the platelet count, but not by an amelioration of the bleeding diathesis[107]. A case report describing a GPS patient with idiopathic pulmonary fibrosis suggested the intriguing hypothesis that the abnormal megakaryocytes of GPS may have a role in the pathogenesis of this condition[106].

Laboratory findings

Gray platelets are severely and selectively deficient in soluble proteins contained in the α-granule: platelet factor 4, β-thromboglobulin, von Willebrand factor, thrombospondin, fibrinogen, albumin, etc. The extent of the deficiency is more severe for proteins that are endocytosed from plasma, such as albumin and immunoglobulins, than for proteins that are synthesized by the megakaryocytes[110–113]. In contrast to soluble proteins, the α-granule membrane proteins are normal in GPS[112,114–116], consistent with the demonstration of the presence of empty α-granules in the GPS platelets[117] and the normal production of precursors of α-granules in GPS megakaryocytes[118]. It is therefore conceivable that the basic defect in GPS is the defective targeting and packaging of endogenously synthesized proteins in platelet α-granules. This hypothesis is also consistent with the finding of increased plasma levels of β-thromboglobulin in GPS patients[119]. The targeting defect seems to be specific to the megakaryocyte cell line, as GPS patients have normal Weibel–Palade bodies, the endothelial cell storage granules equivalent to the platelet α-granules[120].

Circulating platelets are reduced in number, are relatively large, vacuolated, and contain normal numbers of mitochondria, δ-granules, peroxisomes and lysosomes but specifically lack α-granules[121]. The degree of thrombocytopenia is usually mild, although cases with platelet counts as low as 20 000 per μl have been described. Platelet aggregation studies show variable results in GPS patients. Platelet aggregation induced by ADP and adrenaline in citrated plasma were usually normal, but impaired aggregation responses induced by ADP or low concentrations of thrombin or collagen have been described in some patients[106,107,110,111,122,123]. The secretion of ^{14}C- serotonin was impaired in some patients[119], but not in others[122].

Bevers et al. reported normal platelet prothrombinase activity in three patients with GPS[56]. In contrast, a more recent study showed that the collagen plus thrombin-induced prothrombinase activity of platelets from one GPS patient was greatly impaired and was not corrected completely by the addition of exogenous factor Va[55]. The results of the latter study are consistent with the demonstration that α-granule factor V bound to the surface of platelets that had been stimulated simultaneously with thrombin and collagen, plays a unique role in generating prothrombinase activity[124].

Animal models

Rats of the Wistar Furth (WF) strain have hereditary macrothrombocytopenia, resulting from erratic subdivision of megakaryocyte cytoplasm into platelets. WF platelets have decreased levels of thrombospondin, fibrinogen and platelet factor 4, and have smaller α-granules than normal[125]. Therefore, they represent an animal model resembling GPS. The autosomal recessive pattern of inheritance of macrothrombocytes and platelet α-granule protein deficiencies suggests that a component common to formation of platelet α-granules and subdivision of megakaryocyte cytoplasm into platelets, is abnormal in WF rat megakaryocytes and platelets. WF rats have markedly prolonged bleeding times, impaired clot formation at wound sites

Cambridge Books Online © Cambridge University Press, 2009

and abnormal platelet spreading and filopodia formation after adhesion onto Formvar-coated, carbon-stabilized grids[126]. Disruption of microtubules in vivo by vincristine in normal rats caused the formation of large membrane complexes in the cytoplasm of megakaryocytes, identical to those found in megakaryocytes of human hereditary macrothrombocytopenias (including GPS) and the Wistar Furth rat[127]. Therefore, intact microtubules seem to play a major role in the organization of the megakaryocyte demarcation membrane and the stability of α-granules.

Quebec platelet disorder

The Quebec platelet disorder is an autsomal dominant qualitative platelet abnormality, characterized by severe post-traumatic bleeding complications unresponsive to platelet transfusion, abnormal proteolysis of α-granule proteins, severe deficiency of platelet factor V, deficiency of multimerin, reduced to normal platelet counts and markedly decreased platelet aggregation induced by epinephrine[128,129]. Multimerin, one of the largest proteins found in the human body, is present in platelet α-granules and in endothelial cell Weibel–Palade bodies[130–132]. It binds factor V and its activated form, factor Va. Its deficiency in patients with the Quebec platelet disorder is probably responsible for the defect in platelet factor V, which is likely to be degraded by abnormally regulated platelet proteases. Other α-granule proteins are degraded along with factor V in this disorder, including von Willebrand factor, fibrinogen, osteonectin, fibronectin, P-selectin and thrombospondin[131,133,134]. However, platelet factor 4, β-thromboglobulin, albumin, IgG, CD63 and external membrane glycoproteins are normal in these patients, indicating that there is restriction in the platelet proteins degraded[131,133,134]. In addition, electron microscopic and immunoelectron microscopy studies indicated preserved α-granular ultrastructure and normal to reduced labelling for platelet α-granule proteins, suggesting that the pathologic proteolysis of α-granule proteins is not secondary to a defect in targeting proteins to α-granules[134].

Jacobsen or Paris–Trousseau syndrome

This is rare syndrome that is associated with a mild hemorragic diathesis and is characterized by congenital thrombocytopenia, normal platelet lifespan, increased number of marrow megakaryocytes, many of which present with signs of abnormal maturation and intramedullary lysis. A fraction of the circulating platelets has giant α-granules, which are unable to release their content upon platelet stimulation with thrombin. A deletion of the distal part of one chromosome 11 [del(11)q23.3 $\rightarrow$ qter] was found in the affected patients[135,136].

Defects of the α- and δ-granules

α,δ-storage pool deficiency

Clinical and laboratory features

α,δ-storage pool deficiency is a heterogeneous congenital disorder of platelet secretion characterized by deficiencies of both α- and δ-granules[36,39]. It is important to note that blood samples should be collected in sodium citrate for measurement of platelet granule contents, because platelets from some individuals may undergo degranulation *in vitro* when blood is collected into EDTA, resembling α,δ-SPD[137]. The phenotypic heterogeneity of this disorder is illustrated by the finding that the platelet content of GMP-140 (P-selectin) was normal in three members of a family with mild α,δ-SPD, while it was approximately halved in a patient with severe α,δ-SPD[138]. Approximately 80% of platelets from the patient with severe α,δ-SPD expressed little or no GMP-140 after stimulation, whereas the remaining 20% expressed normal amounts of it. No such heterogeneity was found among platelets of the three patients with mild α,δ-SPD. Compared to δ-SPD platelets, which have a normal density, α,δ-SPD platelets show a shift to the left of the density distribution, suggesting that α-granules are a major determinant of platelet density[139].

The clinical picture and the platelet aggregation abnormalities are similar to those of patients with GPS or δ-SPD. As in GPS, the platelet prothrombinase activity in response to collagen plus thrombin was impaired in a patient with severe α,δ-SPD and was not completely corrected by added factor Va[55]. Platelet thrombus formation on everted rabbit vessel segments under various flow conditions was severely impaired[54], as well as the production of arachidonate metabolites after stimulation with arachidonate, epinephrine or collagen[44].

Animal models

Hereditary macrothrombocytopenia and prolonged bleeding times are associated with the recessive mouse pigment dilution mutant gene gunmetal (*gm/gm*). Like human α,δ-SPD, the mutant phenotype has reduced platelet levels of both δ-granule and α-granule components (serotonin, fibrinogen, platelet factor 4, von Willebrand factor)[140]. In addition, *gm/gm* platelets express two additional low molecular weight guanosine triphosphate (GTP)-binding proteins, which might be responsible for both the abnormal platelet production and the impaired organelle formation in *gm/gm* mice[139]. Further studies suggested that the gunmetal gene acts intrinsically in megakaryocytes and that an abnormality in this gene causes

Cambridge Books Online © Cambridge University Press, 2009

significant qualitative and quantitative effects on platelet production[141].

Defects of the amplification pathways of platelet activation

Defects of the arachidonate/thromboxane A_2 pathway

Impaired liberation of arachidonic acid from membrane phospholipids

Liberation of arachidonic acid from membrane phospholipids occurs under the action of phospholipase A_2 (PLA_2), a Ca^{2+}-dependent enzyme. Abnormalities of arachidonic acid liberation have been described in patients with other platelet defects, including defects of GPIIb/IIIa and procoagulant activity[142] and Hermansky–Pudlak syndrome[68]. Four patients were described with abnormal thrombin-induced liberation of ^{3}H-arachidonic acid from prelabelled platelets. TxB_2 production after stimulation with ADP or thrombin was impaired, while it was normal with arachidonic acid[143]. However, subsequent studies of one of these patients showed that his platelets contained normal amounts of PLA_2, while agonist-induced Ca^{2+} mobilization[144] and G protein activation were reduced[145].

Defects of cyclooxygenase (aspirin-like defect)

Many patients with congenital abnormalities in cyclooxygenase, the enzyme catalysing the first step in prostaglandin synthesis from arachidonate, have been described[146–155]. The platelets from these patients have the same functional defect of normal platelets that had been treated in vitro or in vivo with aspirin, which irreversibly acetylates the platelet cyclooxygenase[156,157]: impaired aggregation and secretion induced by ADP, epinephrine, collagen or arachidonic acid, normal responses to TxA_2/endoperoxides analogues, and absent platelet TxA_2 production. The actual concentration of cyclooxygenase antigen in platelet lysates, measured with an immunoassays, was found to be defective in some patients only[146,158]. It has therefore been proposed that the platelet cyclooxygenase defect can be subdivided into *type 1*, characterized by undetectable levels of the enzyme protein, and *type 2*, characterized by the presence of normal levels of a dysfunctional protein. However, before a diagnosis of *type 2* cyclooxygenase deficiency can be safely made, caution should be taken to rule out the possibility of surreptitious or inadvertent ingestion of acetylsalicylic acid, which is contained in several generic medications.

In one patient, the synthesis of both platelet TxA_2 and vessel wall PGI_2 were measured and found to be severely impaired[148]. Since that patient had a mild bleeding diathesis, the finding suggested that the contemporary abolition of TxA_2 and PGI_2 synthesis results in a hemorrhagic diathesis, rather than in a thrombotic tendency, as was previously hypothesized[159].

Defects of thromboxane synthetase

Two reports of patients with congenital defects of platelet thromboxane synthetase have been published[160,161]. Defreyn et al. described three family members of three successive generations with moderate bleeding tendency, markedly prolonged bleeding time, absent aggregation induced by arachidonic acid, and monophasic aggregation induced by ADP or epinephrine. The platelet production of TxB_2 was decreased, while that of $PGF_{2\alpha}$, PGE_2 and PGD_2 were increased. The plasma levels of the PGI_2 metabolite 6-keto $PGF_{1\alpha}$ were raised. These findings are compatible with a partial platelet thromboxane synthetase defect and reorientation of cyclic endoperoxide metabolism to increased production of the inhibitory prostaglandins PGI_2 and PGD_2, which would contribute, in conjunction with the reduced synthesis of TxA_2, to the abnormality of primary hemostasis.

Defects of the platelet thromboxane A_2 receptor

Clinical and laboratory features

In 1981, three reports of impaired platelet responses to TxA_2 in patients with bleeding disorders were published[162–164]. The platelets from these patients could synthesize TxA_2 from exogenous arachidonate, but were unable to undergo normal TxA_2-dependent aggregation and secretion in response to a variety of agonists. In one patient only, however, the stable TxA_2 mimetic U46619 was tested and found to be unable to elicit normal platelet responses[164], providing convincing evidence that his platelets had a defect at the receptor level.

In 1993, a similar patient with a mild bleeding disorder was described, whose platelets did not undergo shape change, aggregation and secretion in response to the synthetic TxA_2 mimetic STA_2[165]. Binding studies of radiolabelled TxA_2 agonists and antagonists revealed that the patient platelets had a normal number of TxA_2 binding sites and normal equilibrium dissociation rate constants. Despite the normal number of TxA_2 receptors, the TxA_2-induced IP3 formation, Ca^{2+} mobilization and GTPase activity were normal, suggesting that the abnormality of these platelets was impaired coupling between TxA_2 receptor, G protein and PLC. The platelet aggregation and secretion responses to several agonists were impaired. A similar

Cambridge Books Online © Cambridge University Press, 2009

patient, who was also affected by polycythemia vera, had previously been described by Ushikubi et al.[166].

Molecular aspects
These two last patients were subsequently found to have an Arg60 to Leu mutation in the first cytoplasmic loop of the TxA_2 receptor[167], affecting both isoforms of the receptor[168,169]. The mutant receptor expressed in Chinese hamster ovary cells showed decreased agonist-induced second messenger formation despite its normal ligand binding affinities. The mutation was found exclusively in the affected members of the two unrelated families and was inherited as an autosomal dominant trait. Although the heterozygous patients did not differ from the homozygous patients in terms of aggregation and secretion responses of platelets to TxA_2, subsequent studies showed that in heterozygous patients, the mutant TxA_2 receptor suppresses the wild-type receptor-mediated platelet aggregation and secretion by a mechanism independent of inhibition of PLC activation[170,171].

Animal models
Most dogs have blood platelets that do not aggregate or secrete in response to TxA_2, although they form normal amounts of it[172–175]. TxA_2 unresponsive dog platelets have impaired TxA_2 receptor-G protein coupling, and abnormal binding parameters of the TxA_2 analogue BOP; all platelet abnormalities could be corrected by platelet treatment with epinephrine[176].

In contrast to dog, in whom the platelet insensitivity to TxA_2 is the rule, normal mice have TxA_2 platelet receptors. TxA_2 knockout mice have a mild bleeding disorder and altered vascular responses to TxA_2 and arachidonate[177].

Congenital defects of the ADP pathway (see Fig. 43.2)

Platelets possess at least three different purinergic receptors[178–183]: the $P2X_1$ ionotropic receptor responsible for rapid influx of ionized calcium into the cytosol; the $P2Y_1$ metabotropic receptor responsible for mobilization of ionized calcium from internal stores which initiates ADP-induced aggregation, and a third receptor coupled to adenylyl cyclase inhibition, essential for the full aggregation response to ADP, which has recently been identified[184,185] and named $P2Y_{12}$[184]. Although $P2X_1$ may be important for normal hemostasis, since a dominant negative mutation in its gene has been reported in a patient with a severe bleeding disorder[186], recent data have provided convincing evidence that it is activated by ATP, rather than ADP[187]. Therefore, platelets seem to have only two purinoceptors for ADP: $P2Y_1$ and $P2Y_{12}$. Only patients with congenital

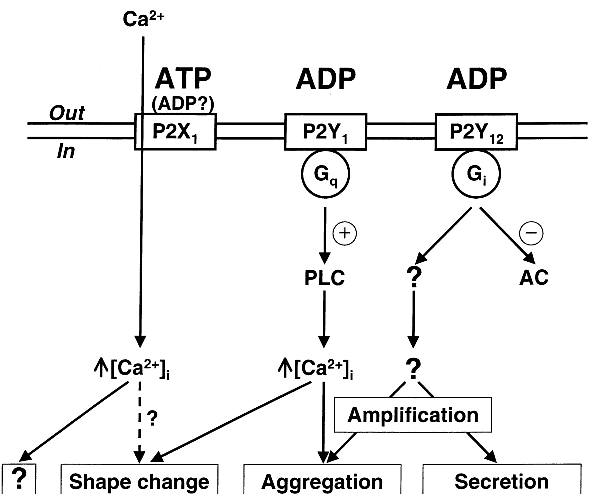

Fig. 43.2. Effects of platelet purinoceptors on platelet function. The role of $P2X_1$ is unclear: although many studies failed to find any effect of $P2X_1$ on platelet function, a recent report showed that it mediates the platelet shape change triggered by the ATP analogue α,β-methylene ATP[214]. ADP, adenosine diphosphate; ATP, adenosine triphosphate; $[Ca^{2+}]_i$, concentration of cytoplasmic ionized calcium; AC, adenylyl cyclase; PLC, phospholipase C; cAMP, cyclic adenosine monophosphate.

abnormalities of $P2Y_{12}$ have been described so far[183]. The platelet function abnormality of patients who are heterozygous for the defect of $P2Y_{12}$ receptors is typical of disorders of platelet secretion[69], since $P2Y_{12}$ is the mediator of the described potentiating effect of ADP on platelet secretion[16,17,183]. Patients who are homozygous for $P2Y_{12}$ defect, in addition to a secretion defect, have a severe impairment of platelet aggregation induced by ADP.

Congenital defects of the $P2Y_{12}$ receptor for ADP

In 1992, the first patient with a selective defect of platelet responses to ADP was described[188]. He is a man of Caucasian origin who had a lifelong history of excessive bleeding, prolonged bleeding time and an abnormality of platelet aggregation that was similar to that observed in patients with defects of platelet secretion, except that the aggregation response to ADP was severely impaired. This platelet aggregation profile is compatible with a selective impairment of responses to ADP, which also affects the full aggregation response to release-inducing agonists, as a consequence of the loss of the potentiating effect of released ADP on platelet aggregation. Other abnormalities of platelet function found in this patient were: (i) no inhibition by ADP of PGE_1-stimulated platelet adenylate cyclase, but normal inhibition by epinephrine; (ii) normal shape change and normal-to-mildly reduced mobilization

Cambridge Books Online © Cambridge University Press, 2009

of cytoplasmic ionized calcium induced by ADP; (iii) presence of about 30% of the normal number of platelet binding sites for $[^3H]ADP$[188] or $[^{33}P]2MeSADP$[189]. Three additional patients, one male[190] and two females[69] with very similar characteristics were subsequently described; in one of them it was shown that the ADP receptor pathway that is defective in this condition is linked to a defective tyrosine phosphorylation response[191]. The many similarities among the patients suggest that they are affected by the same type of disorder of platelet function[192], associated with defective interaction between ADP and the recently cloned $P2Y_{12}$ receptor. The deletion of two nucleotides causing a shift in the reading frame of the coding region of one allele and repression of the expression of the wild-type allele were described in one of the patients[190] with $P2Y_{12}$ deficiency[184]. The defect is probably inherited as an autosomal recessive trait, because all patients so far described were born from consanguineous parents.

The heterozygous son of one of these patients bound intermediate levels of 2MeS–ADP[69]. His bleeding time was mildly prolonged (13 min) and his platelets underwent a normal first wave of aggregation after stimulation with ADP, but did not secrete normal amounts of ATP after stimulation with different agonists. The secretion defect of his platelets could not be ascribed to impaired production of thromboxane A_2 or low concentrations of platelet granule contents, which were normal and was therefore attributed to the partial defect in the potentiation of platelet secretion mediated by $P2Y_{12}$. His phenotype is therefore similar to that of some previously described patients with secretion defects of unknown cause, who proved to be partially deficient in $P2Y_{12}$ receptors[16].

Miscellaneous abnormalities of platelet secretion (primary secretion defects)

Definition

The term primary secretion defect was probably used for the first time by Weiss, to indicate all those ill-defined abnormalities of platelet secretion not associated with platelet granules deficiencies[193]. The term was later used to indicate the platelet secretion defects not associated to platelet granule with deficiencies and abnormalities of the arachidonate pathway[16,69], or, more generally, all the abnormalities of platelet function associated with defects of signal transduction[194,195]. With the progression of our knowledge in the platelet pathophysiology, this heterogeneous group, which lumps together the majority of patients with congenital disorders of platelet function[194], will become progressively smaller, losing those patients with better defined biochemical abnormalities responsible for their platelet secretion defect. An example is given by patients with heterozygous $P2Y_{12}$ deficiency who were included in this group of disorders until their biochemical abnormality was identified[16,69,183].

Only those abnormalities of platelet secretion that exhibit normal primary waves of aggregation induced by ADP, epinephrine or PAF will be described here.

Clinical and laboratory features

In 1981, Wu et al. described a large family with a hereditary bleeding disorder associated with defective platelet secretion, despite normal platelet granules contents and normal TxA_2 production[196]. Although the platelets of these patients might have had an abnormality of TxA_2 receptors, because they did not respond to a PGH_2 analogue, their biochemical abnormality has not been further elucidated. Hardisty et al. later reported a patient with similar platelet abnormalities, including the lack of reponse to PGH_2 and TxA_2[197]. Of interest are some abnormalities of platelet secretion described in patients with psychiatric disorders, such as the attention deficit disorder[198] and conduct disorder[199]: these reports emphasize the role of platelets as a model for neurons in functional disorders. In 1989, Rao et al. described a 42-year-old white woman and her 23-year-old son who suffered from a mild hemorrhagic diathesis, whose platelets underwent abnormal secretion and aggregation induced by ADP, epinephrine, PAF, arachidonic acid and ionophore A23187[200]. In both patients, the platelet ADP and ATP contents and TxA_2 synthesis were normal, while the concentration of cytoplasmic Ca^{2+} $[Ca^{2+}]i$ in resting platelets, peak $[Ca^{2+}]i$ concentrations stimulated by ADP, PAF, collagen, the prostaglandin endoperoxides analogue U46619 and thrombin were impaired. Subsequent studies indicated that, upon platelet activation, the formation of inositol 1,4,5-trisphosphate (In1,4,5–P_3) and diacylglycerol, and the phosphorylation of pleckstrin were abnormal[201]. These data suggested that the patient platelets had a defect in phospholipase C (PLC) activation. This hypothesis was confirmed by the finding that platelets from one of these patients had a selective decrease in one of the seven PLC isoforms present in platelets, PLC-β2, suggesting that this isoenzyme may have an important role in platelet activation[202].

Generally included in the group of Primary Secretion Defects are patients with abnormal secretion, normal platelet granules and TxB_2 formation, but decreased initial rate and extent of aggregation to one or more weak

Table 43.3. Therapeutic options for congenital defects of platelet secretion

Desmopressin (DDAVP)
0.3 μg per kilogram b.w., intravenously or subcutaneously
300 μg (adults) or 150 μg (children), intanasally

Antifibrinolytic agents
Tranexamic acid: 15–25 mg per kilogram b.w every 8 hours, orally or intravenously
ε-aminocaproic acid: 50–60 mg per kilogram b.w every 4 hours, orally or intravenously

Transfusion of platelet concentrates
Required only for the control of severe bleeding episodes, which are very rare in patients with platelet secretion defects.

agonists[203]. These defects will be described in detail in the following chapter of this book.

Therapy (see Table 43.3)

The mainstays of therapy of patients with congenital disorders of platelet secretion are platelet transfusions, the vasopressin analogue 1-deamino-8–D-arginine vasopressin (desmopressin, or DDVAP) and antifibrinolytic agents.

Bleeding complications in patients with disorders of platelet secretion are rarely severe enough to require the transfusion of platelet concentrates, which are effective but are expensive and carry the risks that are associated with the use of blood products.

Desmopressin, which causes the increase in plasma vWF and FVIII levels, has been shown to be effective in shortening the prolonged bleeding times of most patients with disorders of platelet secretion, including patients with Hermansky–Pudlak syndrome[204] and other platelet function abnormalities, including Bernard–Soulier syndrome and drug-induced platelet dysfunction[52,205–210]. Since the bleeding time response to DDAVP infusions varies very much among subjects and tends to be rather consistent after repeated infusions, a test dose of DDAVP should be administered in order to test the degree of responsiveness to the drug of each patient. Although the effect of desmopressin on the bleeding times of patients with platelet function disorders is well established, its efficacy in reducing the incidence and severity of bleeding complications in these patients is based on anecdotal reports only[210–212]. Despite the absence of controlled clinical trials documenting its efficacy, desmopressin can be recommended for the prophylaxis and treatment of bleeding episodes in patients with platelet function disorders, in consideration of the absence of serious side effects associated with its infusion[205,211]. The mechanisms by which desmopressin shortens the prolonged bleeding times of patients with normal plasma vWF levels are not well understood: both mechanisms that are dependent[28,52] and independent[213] on the induced increase in plasma vWF levels have been hypothesized.

Other approaches used to reduce the bleeding episodes in patients with platelet secretion defects include the administration of antifibrinolytic agents, such as ε-aminocaproic acid and tranexamic acid[205,211]. Tranexamic acid reduces menstrual bleeding by 40 to 50 percent. It should be used only when organic lesions in the uterus have been excluded, at the oral doses of 10 to 15 mg per kilogram of body weight every 8 hours, from the onset until the arrest of menstrual bleeding. Antifibrinolytic agents may also be useful in the control of oral bleeding in these patients.

Temple University School of Medicine, Philadelphia, PA 19140 USA

Platelets play a major role in hemostasis, and alterations in platelet mechanisms may lead to a bleeding diathesis. When the blood vessel is injured, platelets adhere to exposed subendothelium by a process (adhesion) which involves the interaction of a plasma protein, von Willebrand factor (vWF), and a specific protein on the platelet surface, glycoprotein Ib (GPIb) (Fig. 44.1). Adhesion is followed by recruitment of additional platelets which form clumps, a process called aggregation (cohesion). This involves binding of fibrinogen to specific platelet surface receptors, a complex composed of glycoproteins IIb–IIIa (GPIIb–IIIa). Activated platelets release contents of their granules (secretion or release reaction), such as adenosine diphosphate (ADP) and serotonin from the dense granules, which cause recruitment of additional platelets. In addition, platelets play a major role in coagulation mechanisms; several key enzymatic reactions occur on the platelet membrane lipoprotein surface. A number of physiological agonists interact with specific receptors on platelet surface to induce responses including a change in platelet shape from discoid to spherical (shape change), aggregation, secretion, and thromboxane A_2 (TxA_2) production. Other agonists, such as prostacyclin, inhibit these responses. Ligation of the platelet receptors initiates the production or release of several intracellular messenger molecules including Ca^{2+} ions, products of phosphoinositide (PI) hydrolysis by phospholipase C (diacylglycerol, DG, and inositol 1,4,5-triphosphate, $InsP_3$), TxA_2 and cyclic nucleotides (cAMP) (Fig. 44.1). These induce or modulate the various platelet responses of Ca^{2+} mobilization, protein phosphorylation, aggregation, secretion and liberation of arachidonic acid. The interaction between the agonist receptors and the key intracellular effector enzymes (e.g. phospholipases A_2 and C, adenylyl cyclase) is mediated by a group of GTP-binding proteins which are modulated by GTP. As in most secretory cells, platelet activation results in a rise in cytoplasmic ionized calcium concentration; $InsP_3$ functions as a messenger to mobilize Ca^{2+} from intracellular stores. Diacylglycerol activates protein kinase C (PKC) and this results in the phosphorylation of a 47 kD protein pleckstrin. PKC activation is considered to play a major role in platelet secretion and in the activation of GP IIb–IIIa. Numerous other mechanisms, such as phosphorylation of proteins by non-receptor tyrosine kinases, also play a role in signal transduction. A detailed description of the platelet activation mechanisms is provided elsewhere in this book. Inherited defects in the above platelet mechanisms may lead to impaired platelet role in hemostasis and are described in this chapter.

Congenital disorders of platelet function

In general, congenital disorders of platelet function are characterized by highly variable mucocutaneous bleeding manifestations and excessive hemorrhage following surgical procedures or trauma. A majority of patients, but not all, have a prolonged bleeding time. Platelet aggregation and secretion studies provide evidence for the defect, but are not always predictive of the severity of clinical manifestations. The platelet dysfunction in these patients arises by diverse mechanisms[1,2]. Table 44.1 provides a classification based on the platelet functions or responses that are abnormal (Fig. 44.1). In patients with defects in platelet–vessel wall interactions, adhesion of platelets to subendothelium is abnormal. The two disorders in this group are the von Willebrand disease (vWD), due to a deficiency or abnormality in plasma vWF[3], and the Bernard–Soulier syndrome, where platelets are deficient in GPIb (and GPV and

IX) and the binding of vWF to platelets is abnormal[4]. Disorders characterized by abnormal platelet–platelet interactions (aggregation) arise because of an absence of plasma fibrinogen (congenital afibrinogenemia) or because of a quantitative or qualitative abnormality of the platelet membrane GPIIb–IIIa complex (Glanzmann thrombasthenia)[5]. Patients with defects in platelet secretion and signal transduction are a heterogeneous group lumped together for convenience of classification rather than on the basis of an understanding of the specific underlying abnormality. The major common characteristic in these patients, as currently perceived, is an inability to release intracellular granule (dense) contents upon activation of platelet-rich plasma with agonists such as ADP, epinephrine and collagen. In aggregation studies the second wave of aggregation is blunted or absent. A small proportion of these patients have a deficiency of dense granule stores (storage pool deficiency). In some of the other patients, the impaired secretion results from aberrations in the signal transduction events that govern end responses such as secretion and aggregation. This review will focus on these patients who are encountered more often than thrombasthenia or the Bernard–Soulier syndrome. Lastly, are the patients who have an abnormality in interactions of platelets with proteins of the coagulation system; the best described is the Scott syndrome[6]. In addition to the above groups, there are patients who have abnormal platelet function associated with systemic disorders such as Down syndrome and the May–Hegglin anomaly where the specific aberrant platelet mechanisms are still unclear.

Disorders of platelet secretion and signal transduction

As an unifying theme, patients lumped in this remarkably heterogeneous group generally manifest impaired secretion of granule contents and absence of the second wave of aggregation upon stimulation of platelet-rich plasma with ADP and epinephrine; responses to collagen, thromboxane analogue (U46619), arachidonic acid, and platelet-activating factor (PAF) may also be impaired. Platelet function is abnormal in these patients either when the granule contents are diminished (storage pool deficiency, SPD) or when there is an aberration in the activation mechanisms governing aggregation and secretion, the easily discernible end-responses following platelet activation by a diverse group of agonists. (Table 44.1).

Deficiency of granule stores: storage pool deficiency

Patients with storage pool deficiency (SPD) have deficiencies in platelet content of dense granules (δ-SPD), alpha-granules (α-SPD) or both types of granules ($\alpha\delta$-SPD)[7,8]. The Quebec platelet disorder is an autosomal dominant disorder associated with abnormal proteolysis of α-granule proteins, deficiency of platelet α-granule multimerin (a factor V binding protein), and markedly

Cambridge Books Online © Cambridge University Press, 2009

impaired aggregation with epinephrine as a striking feature[8]. These disorders are discussed elsewhere in detail.

Defects in platelet signal transduction (primary secretion defects)

Signal transduction mechanisms encompass processes that are initiated by the interaction of agonists with specific platelet receptors and include responses such as G-protein activation and activation of effectors such as phospholipase C and phospholipase A_2. If the key components in signal transduction are the surface receptors, the G-proteins, and the effectors, evidence now exists for specific platelet abnormalities at each of these levels. It is only a matter of time before deficiencies are documented in the various specific mechanisms involving other proteins, for example, the kinases and phosphatases, that are activated on platelet receptor ligation.

Defects in platelet–agonist interaction: receptor defects

These patients are characterized by impaired platelet responses resulting from an abnormality at the level of platelet surface receptors for a specific agonist. Such receptor defects have been documented for TxA_2, collagen, ADP and epinephrine. One patient has been described with diminished responses to PAF alone[9]. Because ADP and TxA_2 play a synergistic role in the platelet responses to several agonists, it is not surprising that patients with specific defects at the ADP or TxA_2 receptor have impaired responses to multiple agonists, particularly the weaker ones.

Thromboxane A2 receptor defect

In some patients with platelet dysfunction[10–12] the abnormal aggregation responses have been attributed to an impaired platelet responsiveness to TxA_2, although it is synthesized in normal amounts. Because TxA_2 is highly unstable, these studies have used a system in which TxA_2 was generated by incubating normal platelets with arachidonic acid and aliquots of the stimulated platelet suspension or its supernate were transferred to the patient's platelets as a source of TxA_2. Based on a diminished response to stimulation with such aliquots, the platelet dysfunction has been attributed to an impaired platelet responsiveness to TxA_2 or to a TxA_2 receptor defect[10–12]. However, in such a test system, the responses induced in the recipient platelets occur due to a synergism between TxA_2 and ADP and not due to the former alone, and they are dependent on the ability of the test platelets to secrete ADP[13]. Therefore, the primary defect in these patients[10,11] is not established to be a specific impairment in the response to TxA_2. In one of these patients[12], TxA_2 analogue U46619 failed to suppress PGI_2 induced cAMP levels, suggesting that this patient may have a defect at the TxA_2 receptor level. In another patient[10], subsequent studies[14] have revealed abnormalities in the phosphatidylinositol metabolism on platelet activation with thrombin and collagen.

The existence of specific mutations in the platelet TxA_2 receptor has been established by Hirata et al.[15] who described an Arg^{60} to Leu mutation in the first cytoplasmic loop of the TxA_2 receptor in two unrelated patients. This Arg^{60} corresponds to a highly conserved basic residue among G-protein coupled receptors[15]. These patients had a mild bleeding disorder with an autosomal dominant pattern of inheritance. Aggregation responses to several agonists were impaired with the exception of thrombin[16]. The binding of TxA_2 analogues to platelets was normal[16,17]. GTPase activity on activation with a TxA_2 analog, but not thrombin, was diminished[17,18] suggesting a defect in TxA_2 receptor-G-protein coupling. TxA_2-induced activation of PLC (measured as Ca^{2+} mobilization, inositol trisphosphate, and phosphatidic acid formation) was impaired while PLA_2 activation and TxA_2 production were normal. Less than half the number of TxA_2 receptors are sufficient for irreversible aggregation with TxA_2 agonist[19]. The finding that the aggregation responses were impaired in the heterozygous family members[15] suggest a dominant negative effect of the mutation. It needs to be noted that absent aggregation responses to TxA_2 have been observed in patients who do not have evidence for a defect of TxA_2 receptor level[20]. Lastly, thromboxane receptor knockout mice have a mild bleeding disorder and their platelets have impaired aggregation responses to TxA2 analogues as well as collagen[21].

Collagen receptor defects

Several patients have been reported with mucocutaneous bleeding manifestations and selective impairment in platelet-collagen interaction. Platelets from the patient described by Nieuwenhuis et al.[22,23] had ~ 15 to 25% of normal amount of platelet GPIa and failed to aggregate with collagen, or adhere and spread normally to subendothelial surfaces. In another patient described by Kehrel et al.[24], collagen-induced platelet aggregation was markedly reduced, and the platelets were deficient in GPIa and thrombospondin. In both of these patients, the bleeding times were prolonged and platelet aggregation responses to other agonists were preserved. Selective impairment in collagen responses and a mild bleeding disorder have also

Cambridge Books Online © Cambridge University Press, 2009

been related to a deficiency of platelet GP VI[25–27]. GP VI deficient platelets have been reported to have impaired collagen activation of Syk but not c-Src[28]. In the current models of platelet–collagen interactions, collagen binds initially to either the GPIa–GPIIa ($\alpha 2\beta 1$) or GPVI, leading to subsequent binding to the other receptor which serves to reinforce adhesion and generation of intracellular signals[29].

GP IV (CD 36) has also been implicated in platelet–collagen interactions[30]. Platelets lacking GP IV have been reported to have reduced adhesion to collagen in flowing whole blood[31]. However, individuals lacking platelet GP IV in the Japanese population (approximately 3% of the population) and the US population (approximately 0.3%) have not had a bleeding disorder[32] and collagen-induced platelet aggregation[32], Ca^{2+} mobilization, and tyrosine phosphorylation[33] have been normal. In other studies[34] GP IV deficient platelets aggregated normally in response to collagens type I and III but not to type V collagen. Moreover, adhesion and subsequent aggregate formation of GP IV deficient platelets on types I, III and IV collagens were normal under static or flow conditions whereas adhesion to type V collagen was reduced under static conditions[35]. In several GP IV deficient subjects a Pro^{90} to ser mutation has been reported in the GP IV gene[36] and GP IV mRNA has been detected in platelets from all subjects studied[36,37]. Kehrel et al.[34] have described platelet responses to collagen-related peptides; platelets deficient in GP VI but not GP IV failed to aggregate in response to these peptides.

Defect in platelet ADP receptors

ADP interaction with platelets is mediated by multiple receptors (P2Y1, $P2T_{AC}/P2Y_{12}$, P2X1) which elicit distinct responses[38–40]. Cattaneo et al.[41] and Nurden et al.[42] have described two patients in whom platelet aggregation response to ADP was blunted (but not absent) and the ability of ADP to suppress PGE_1-induced elevation in cAMP levels was impaired; ADP stimulated shape change was normal. ADP stimulated Ca^{2+} mobilization and tyrosine phosphorylation in response to ADP and TxA_2 have been reported to be abnormal in the patients studied[41,43]. Aggregation in response to a TxA_2 analogue and lower concentrations of collagen were also impaired. The binding of radiolabelled ADP[41] or the ADP analogue 2-methylthio-ADP[42] to platelets was decreased in these patients. Recent studies[44] in one of these patients,[42] provide evidence of a mutation in the $P2T_{AC}$ ($P2Y_{12}$) ADP receptor linked to inhibition of adenyl cyclase. Electron microscopic studies in one patient with the ADP receptor defect[45] showed that the aggregates formed following stimulation with high dose ADP were composed of loosely bound platelets with few contact points. A decreased platelet 2-methylthio-ADP binding has been reported[46–48] in additional patients with impaired aggregation and secretion in response to several agonists including ADP. In addition to the patients mentioned above, who have a defect in the $P2T_{AC}$ ($P2Y_{12}$) ADP receptor, one patient has been briefly described[49] with a defect in the P2Y1 platelet receptor which is coupled to ADP induced calcium mobilization. This patient also had impaired platelet aggregation in response to ADP and other agonists. P2Y1-deficient mice have been reported to have decreased platelet aggregation and resistance to thromboembolism[50,51], with a prolonged bleeding time[50]. Lastly, Oury et al.[52] have recently reported a patient with a selective impairment of the ADP-induced aggregation associated with a dominant negative P2X1 receptor due to deletion of a single leucine residue in the second transmembrane domain. P2X1 receptor is an ATP-gated ion channel, and the association of a bleeding disorder with alterations in this receptor suggests its hitherto unrecognized physiological role in hemostasis.

Selective impairment in platelet responsiveness to epinephrine

Aggregation responses to epinephrine, mediated by α_2-adrenergic receptors, may be variable even in otherwise normal individuals[53] and it is impaired in some presumably normal individuals. In one study[54], the second wave of aggregation was noted to be absent in 10–15% of normal subjects. Studies in twins suggest that platelet adrenergic receptors are under genetic control[55]. Scrutton et al.[56] reported depressed platelet aggregation response to epinephrine in five apparently normal volunteers and indicated that the defect was familial. However, in four of the index cases platelet responses to other agonists such as collagen, vasopressin, and ADP were also impaired. Rao et al.[57] have described a family whose several members had impaired aggregation and secretion responses only to epinephrine associated with decreased number of platelet α_2-adrenergic receptors. Three of the family members had a history of easy bruising with minimally prolonged bleeding times. Although aggregation response was impaired, epinephrine inhibition of adenylate cyclase was normal indicating that the receptor requirements for these two platelet responses are different. Although other families with an epinephrine defect have been reported,[58] the relationship of the selective epinephrine defect to bleeding manifestations still needs to be defined. It is tantalizing to speculate that, in some of these patients with bleeding symptoms, the isolated impaired aggregation response to epinephrine may be related to the Quebec platelet syndrome[59]. Mice deficient in Gz, a member of the Gi family of

Cambridge Books Online © Cambridge University Press, 2009

G-proteins, have impaired platelet aggregation and ability to inhibit cAMP formation in response to epinephrine, and are resistant to fatal thromboembolism[60].

Defects in GTP-binding protein activation

GTP-binding proteins are a group of heterotrimeric (consisting of α, β and γ subunits) proteins that constitute the link between surface receptors and intracellular enzymes, although the specific Gα subunits mediating different agonist responses may be different[61]. Because of their modulating role as molecular switches, G-proteins constitute an important potential locus for aberrations leading to platelet dysfunction. Convincing evidence for the existence of such a defect has been provided by Gabbeta et al.[62] in a patient with a mild bleeding disorder, abnormal aggregation and secretion in response to a number of agonists, and diminished GTPase activity (a reflection of α-subunit function) on activation. The binding of ^{35}S-GTPγS to platelet membranes was diminished, and there was a selective decrease in platelet membrane Gαq with normal levels of Gα_i, Gα_{12}, Gα_{13} and Gα_z. This patient was found to have abnormalities in other downstream signalling events: Ca^{2+} mobilization[63], and release of arachidonic acid from phospholipids on platelet activation[64] despite presence of normal levels of phospholipase A2[62]. Recent studies suggest that this patient has a hematopoietic-lineage restricted defect in Gαq gene expression, characterized by decreased Gαq mRNA and protein levels in platelets but not in neutrophils[64a]. These findings have been corroborated by essentially identical abnormal platelet responses in the Gαq deficient 'knockout' mice[65]. Impaired G-protein activation has also been observed in patients with TxA_2 receptor defect[17,18].

Defects in phospholipase C activation, calcium mobilization, pleckstrin phosphorylation

Several reports have documented patients with a relatively mild bleeding diathesis, and impaired aggregation and dense granule secretion, even though their platelets have normal granule stores and synthesize substantial amounts of TxA_2[66–68]. These heterogenous patients have abnormalities in aggregation and secretion particularly in response to weaker agonists (ADP, epinephrine, PAF); the responses to relatively stronger agonists such as arachidonate and high concentrations of collagen are often normal. Such patients are far more common than those with the storage pool deficiency or defects in TxA_2 synthesis. Lages and Weiss[66] have described eight such patients who had decreased initial rates and extents of aggregation in response to ADP, epinephrine, and U44069; they postulated defects in early platelet activation events to explain the abnormal responses. They subsequently demonstrated a defect in phosphatidylinositol hydrolysis and phosphatidic acid formation[14], and in pleckstrin phosphorylation[69] in one patient.

Koike et al.[67] described platelet dysfunction in 12 patients with the behavioral disorder attention deficit disorder (ADD) and a mild bleeding disorder characterized predominantly by easy bruising. Platelet aggregation and ^{14}C-serotonin secretion responses during stimulation of platelet-rich plasma with ADP, epinephrine, and collagen, revealed only minor abnormalities. In contrast, the aggregation responses of gel-filtered platelets to a divalent cationophore A23187 were markedly impaired in ADD patients. Upon stimulation with A23187 and thrombin (at low concentrations), dense granule and acid hydrolase secretion was impaired whereas α-granule secretion was normal. The platelet contents of all granule constituents were normal, thereby excluding a SPD, and platelet TxA_2 production was intact. The ADD patients and those indicated above[66–68] attest to the existence of a group of patients who have platelet dysfunction despite the presence of normal granule stores and normal TxA_2 synthesis; such patients have been referred to as having primary secretion defects[70].

Platelet receptor ligation results in a rise in cytoplasmic ionized Ca^{2+} concentration which is an early response to platelet stimulation. Attention has, therefore, been focused on this process to explain the impaired platelet aggregation and secretion. In several patients, defects in calcium mobilization have been proposed based on impaired platelet responses to the calcium ionophore (A23187)[10,70]; however, this evidence is indirect, at best. Direct evidence has been provided that some of these patients indeed, have impaired Ca^{2+} mobilization upon platelet activation[63,68,71]. Detailed studies in two related patients[71] with impaired aggregation and secretion responses revealed that resting cytoplasmic Ca^{2+} concentration was normal, but the peak Ca^{2+} concentrations following activation with ADP, collagen, PAF or thrombin were diminished; both the release of Ca^{2+} from intracellular stores and the influx of extracellular Ca^{2+}[63] were decreased. Formation of $InsP_3$, the key intracellular mediator of Ca^{2+} release, as well as diacylglycerol formation and pleckstrin phosphorylation, were diminished upon platelet activation[72], indicating a defect in PLC activation. Human platelets contain at least seven PLC isozymes in the quantitative order PLC-γ2 > PLC-β2 > PLC-β3 > PLC-β1 > PLC-γ1 > PLC-δ1 > PLC-β4[73]. Studies in one of these patients with impaired PLC activation revealed a selective decrease in PLC-β2 isozyme with

Cambridge Books Online © Cambridge University Press, 2009

normal levels of other PLC isoforms[73]. Recent studies show that the decreased platelet PLC-β2 protein levels are associated with diminished platelet PLC-β2 mRNA levels suggesting a defect in gene regulation[74]. Moreover, PLC-β2 protein and mRNA levels in neutrophils were found to be normal suggesting that the defect is hematopoietic lineage restricted. PLC-β isozymes are activated by G-protein mediated pathways while PLC-γ isozymes are activated by tyrosine kinase-dependent mechanisms[75,76]; the relative importance of the various PLC isozymes in normal platelet responses remains unknown. The platelet dysfunction in this patient indicates that PLC-β2, the predominant G-protein linked PLC isozyme in platelets, plays a major role in platelet activation responses involved in hemostasis. In line with the above findings in platelets, agonist-induced calcium mobilization is diminished in neutrophils of knockout mice deficient in PLC- β2[77].

Other studies have also provided evidence for abnormalities in signal transduction pathways in patients with diminished platelet aggregation and secretion responses. Defects in phosphatidylinositol metabolism and protein phosphorylation have been described in such patients[14,17,69,78–80]. Holmsen et al.[78] described a patient with abnormalities in platelet aggregation and dense granule secretion who had impaired phosphoinositide hydrolysis and release of free arachidonic acid from phospholipids on thrombin activation. This patient had significant reduction in membrane GPIIb and GPIIIa as well; however, no studies were performed on Ca^{2+} mobilization or Ins(1,4,5)P_3 production. Another patient has been described with impaired platelet responses and diminished phosphoinositide metabolism in whom the altered stimulus-response coupling has been attributed to abnormal membrane phospholipid composition[79]. Fuse et al.[17] have reported a patient with a mild bleeding disorder whose platelets had impaired aggregation, secretion, $InsP_3$ formation, and Ca^{2+} mobilization in response to a TxA_2 mimetic (STA_2) associated with normal TxA_2 formation. Interestingly, GTPase activity upon activation with STA_2 was also impaired leading to the conclusion that the platelets had an abnormality in coupling between TxA_2 receptor and PLC. In the patient described by Mitsui et al.[80], the abnormal platelet aggregation was associated with decreased TxA_2-induced $InsP_3$ formation but with normal GTPase activity on TxA_2 activation and normal platelet TxA_2 receptors (including their cDNA sequence), suggesting that the abnormality in PLC activity was downstream of the surface receptor. In an analysis of five patients with absent aggregation in response to TxA_2, (but with abnormal responses to ADP and collagen), Fuse et al.[20] found evidence for a defect in the TxA_2 receptor in three patients; in the other two patients TxA_2-induced GTPase activity, IP3 formation and Ca^{2+} mobilization were normal, suggesting a primary abnormality distal to the TxA_2 receptor and unrelated to PLC activation. Overall, these patients provide evidence for aberrations in the signal transduction pathways in patients with diminished platelet aggregation and secretion responses.

Yang et al.[68] have summarized detailed studies on signalling mechanisms in eight patients with abnormal aggregation and secretion in response to several different surface receptor-mediated agonists despite presence of normal dense granule contents. Both protein kinase C induced pleckstrin phosphorylation and cytoplasmic Ca^{2+} mobilization play a major role in secretion on activation[81]. Receptor-mediated Ca^{2+} mobilization and/or pleckstrin phosphorylation were abnormal in seven of the eight patients. It was postulated that combined platelet activation with a direct PKC activator DIC_8 (1,2, dioctonoyl-sn-glycerol) and ionophore A23187, which possibly bypass two major intracellular mediators (inositol trisphosphate, diacylglycerol), may induce normal dense granule secretion in these patients with diminished secretion on activation with receptor mediated agonists. Platelet activation with a combination of ADP with DIC_8 or A23187 improved secretion in four patients. However, combination of DIC_8 and A23187 induced normal secretion in platelet-rich plasma in all patients. These studies indicate that the ultimate process of exocytosis or secretion *per se* is intact in these patients and impaired secretion results from abnormalities in early signal transduction events.

Protein phosphorylation by tyrosine kinases (members of the Src-kinase family, focal adhesion kinase (FAK) family, pp72[syk], and Janus (JAK) kinase family) play an important role in platelet signal transduction[82]. In thrombasthenia[83,84] and the Scott syndrome[85], tyrosine phosphorylation of several proteins is impaired on platelet activation. In these disorders, this defect is a result of the primary abnormality in the GPIIb-IIIa complex and in phospholipid scrambling, respectively[82,84,85]. Interestingly, in patients with the thrombocytopenia with absent radii (TAR) syndrome thrombopoietin-induced tyrosine phosphorylation has been reported to be markedly abnormal[86].

Signal transduction defects and activation of GPIIb–IIIa

Platelet activation induced conformational change in the GPIIb–IIIa complex and fibrinogen-binding to platelets, is a signal transduction dependent process, and has been linked to pleckstrin phosphorylation[87,88]. Therefore, it is likely that abnormalities in signalling mechanisms would

Cambridge Books Online © Cambridge University Press, 2009

impair activation of GPIIb–IIIa, a prerequisite for aggregation. Evidence for this is provided by the report[89] of a patient with markedly abnormal platelet aggregation and receptor activated pleckstrin phosphorylation who had decreased activation of the platelet GPIIb–IIIa complexes despite the presence of a normal number of these platelet receptors with intact ligand (fibrinogen) binding capacity. The implication is that defects in upstream signalling events that modulate activation of the GPIIb–IIIa complex may manifest with decreased platelet aggregation on exposure to receptor-mediated agonists. A similar abnormality in the activation of GPIIb–IIIa has also been observed in the patient with Gαq deficiency[62] attesting to the role of the G-protein-mediated signalling mechanisms in modulating GPIIb–IIIa on activation (Fig. 44.2). Such a defect in GPIIb–IIIa activation, secondary to abnormalities in upstream signal transduction events may be a more common mechanism for blunted aggregation (particularly primary wave) than specific defects in the GPIIb–IIIa complex *per se*[90], and may explain the diminished initial aggregation responses noted by Lages and Weiss[66] in several patients.

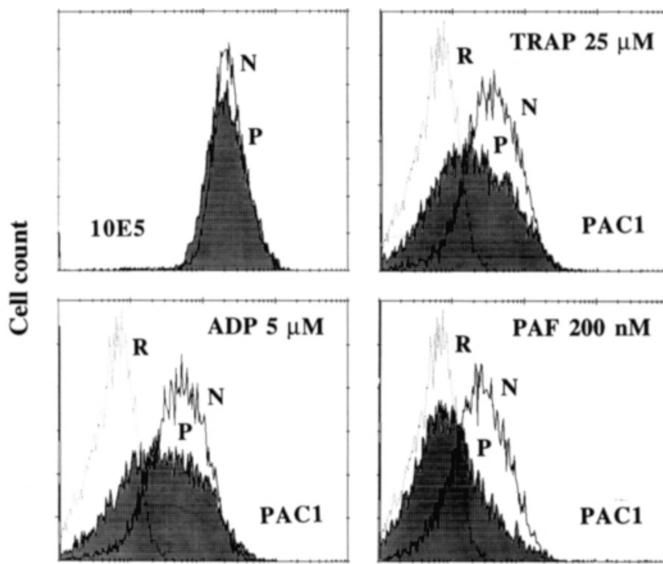

Fig. 44.2. Impaired receptor-mediated activation of GPIIb–IIIa complex on platelets in a patient with Gαq deficiency. Shown is the flow cytometry analysis of GPIIb–IIIa complex on platelets from a normal donor (N) and patient (P) in the resting state (R) and after activation. Top left panel: Binding of monoclonal antibody 10E5 which recognizes both activated and resting forms of GPIIb–IIIa. This panel shows that the GPIIb–IIIa complexes on platelets from the patient and normal are comparable. Top right and lower panels: Binding of antibody PAC-1 which binds only to the activated form of GPIIb–IIIa after activation with thrombin receptor activating peptide (TRAP, SFLLRN), ADP and platelet activating factor. These studies show that despite the presence of a normal complement of GPIIb–IIIa receptors on the patient's platelets, their activation is diminished as revealed by decreased binding of PAC-1. Antibody binding to platelets was measured as fluorescence intensity shown on abscissa and platelet count is on the ordinate. (Reprinted with permission[62].)

Abnormalities in platelet arachidonic acid pathways and thromboxane A_2 production

Platelet activation results in the liberation of arachidonic acid from phospholipids and its subsequent conversion to TxA_2, which forms an important positive feedback enhancing the activation process. TxA_2 synthesis is required for dense granule secretion during stimulation of platelet-rich plasma with ADP, epinephrine, and low concentrations of collagen and thrombin. In general, most patients with defects in the platelet arachidonic acid pathways have had mild to moderate bleeding manifestations.

Defects in the liberation of arachidonic acid from phospholipids

Mobilization of free arachidonic acid from membrane-bound phospholipids PLA_2, a Ca^{2+} dependent enzyme, constitutes the initial and rate-limiting step in TxA_2 synthesis. Four patients have been described[64] with abnormal aggregation and secretion associated with impaired liberation of arachidonic acid from membrane phospholipids during platelet stimulation. In these patients the dense granule contents were normal. Platelet TxA_2 production, measured using a radioimmunoassay, was diminished during stimulation with ADP and thrombin but was normal with free arachidonic acid. In ^{3}H-arachidonic acid labelled platelets, thrombin-induced mobilization of free arachidonic acid from phospholipids was impaired in these patients. Subsequent studies in one of the patients showed that the platelet PLA_2 levels (both membrane and cytosolic) were normal but agonist-induced Ca^{2+} mobilization[63] and G-protein activation[62] were decreased. The impaired arachidonate liberation in this patient is likely secondary to the defect in Ca^{2+} mobilization, preventing full expression of PLA_2 activity. Other reports have also documented patients with an impaired release of arachidonic acid[78,91,92]. In one study[78], the platelets were deficient in GPIIb–IIIa as well; while in another[92], the patient platelets had SPD in addition to diminished platelet uptake of ^{14}C-arachidonic acid and PLA_2 activity.

Deficiencies of cyclooxygenase and thromboxane synthase

In 1975, Malmsten et al.[93] reported platelet cyclooxygenase deficiency in a patient with a mild bleeding disorder and impaired aggregation responses to ADP, epinephrine, collagen and arachidonic acid but with normal response to PGG_2. Subsequently, several other patients have been described with a similar defect in TxA_2 synthesis[94–99]. Because cyclooxygenase mediates the endothelial PGI_2 production, the patient described by Pareti et al.[96] had impaired PGI_2 production as well. Interestingly, this patient with defects in both platelet and vessel wall cyclooxygenase had predominantly bleeding symptoms and not thrombotic events. The patient reported by Rak and Boda[97] had progressive arteriosclerosis as evidenced by cerebrovascular and cardiac events. Using a radioimmunoassay, Roth and Machuga[98] found normal cyclooxygenase levels in five of six patients suspected to have a deficiency, suggesting that these patients may have a functionally abnormal molecule. More recently, three patients have been described[99] with impaired platelet responses and markedly decreased ability to convert arachidonic acid, but not of PGH_2, to TxA_2. Using specific antibodies, the authors demonstrated decreased platelet cyclooxygenase-1 levels in two patients and normal levels in the third; levels of thromboxane synthase were normal in all three. Thus, platelet cyclooxygenase deficiency is manifested either by undetectable enzyme protein levels (Type 1) or as an antigenically detectable but functionally abnormal molecule (Type 2)[99].

Thromboxane synthase deficiency has been described in two patients[100,101]. Another patient has been described[102] with bleeding manifestations, whose platelets had impaired aggregation, dense granule secretion and TxA_2 production upon activation. Liberation of arachidonic acid from phospholipids was normal and TxA_2 synthesis was markedly diminished during stimulation of platelet-rich plasma with thrombin, but substantial TxA_2 production was noted on activation of patient's platelets suspended in a buffer containing no albumin. These findings suggest that the platelets had diminished levels of enzyme activity which could express itself adequately only in the absence of albumin, which binds free arachidonic acid avidly. Although the exact site of the enzyme defect was not elucidated, these studies reflect the modulating role of albumin on platelet arachidonate metabolism.

Defects in cytoskeletal assembly

The Wiskott–Aldrich syndrome (WAS) is an X-linked inherited disorder affecting T-lymphocytes and platelets and characterized by thrombocytopenia, eczema, and immunodeficiency. The platelets are smaller than normal with a shortened survival, and several platelet abnormalities have been reported including dense granule SPD[103], deficiencies of GPIb and GPIa, impaired aggregation responses and abnormalities in platelet energy metabolism[103–106]. WAS and the related X-linked thrombocytopenia (XLT) arise from mutations of the X-chromosome gene (location Xp11.22) called WASP which encodes a novel intracellular proline-rich 53-kD protein of 502 amino acids[103,107]. This multifaceted WASP protein appears to constitute a link between the cytoskeleton and signal transduction pathways. WASP has been shown to bind to $p47^{nck}$, a SH3-containing adapter protein, and to active GTP-complexed form of Cdc42, a member of the small GTP-hydrolyzing proteins (GTPases) which is involved in actin remodelling[103,108,109]. WASP has an actin-binding region at the carboxyl end, and an amino terminal pleckstrin homology (PH) domain which plays a role in the binding of the protein to phospholipids (PIP_2). Overall, WASP appears to be a key cytoplasmic regulator of cytoskeletal assembly in the affected WAS cells leading to the unifying concept of WAS as a cytoskeletal disease[103,109]. However, specific abnormalities in platelet cytoskeletal assembly state need to be documented in WAS. In terms of therapy, patients with WAS respond to splenectomy with an increase in platelet number and size and WAS has been successfully managed with bone marrow transplantation[103,110–112]. Serious infections remain a major issue in individuals who undergo splenectomy[111,112].

Miscellaneous disorders associated with platelet function defects

Platelet function abnormalities have been reported in inherited connective tissue disorders such as osteogenesis imperfecta, the Ehlers–Danlos syndrome, and the Marfan's syndrome[113–116] which are associated with bleeding manifestations more likely due to the underlying connective tissue defect rather than the platelet dysfunction. Abnormal platelet responses have been reported in patients with hexokinase deficiency[117], glucose-6 phosphatase deficiency (glycogen storage disease, type I)[118,119], Epstein's syndrome characterized by thrombocytopenia, hereditary nephritis and nerve deafness[120,121], and Down's syndrome[122]. In glucose-6 phosphatase deficiency the platelet abnormalities were reversed following total parenteral nutrition in these patients for 10–12 days[118,119] indicating that the platelets may be intrinsically normal. The May–Hegglin anomaly is characterized by giant platelets,

Cambridge Books Online © Cambridge University Press, 2009

thrombocytopenia and basophilic granulocyte inclusions. Some patients with this anomaly have platelet function and ultrastructural abnormalities[123,124]. Despite the large platelet size, the surface membrane glycoproteins appear to be normal[125]. In all of the disorders described here, the precise mechanisms leading to the impaired platelet responses are poorly understood.

Relative frequency of various platelet abnormalities

Thrombasthenia, the Bernard–Soulier syndrome and afibrinogenemia are rare disorders. It is generally considered that vWD is the most common congenital platelet function disorder, although the severe forms are rare. Patients currently classified in the heterogeneous category of abnormalities in platelet secretion and signal transduction are probably the most frequently encountered inherited platelet defects. In our experience, the SPD is present in less than 10–15% of patients with congenital platelet defects. Abnormalities in TxA_2 production occur in about 10–20% of patients. A large proportion of the remaining patients with abnormal aggregation and secretion responses demonstrate adequate dense granule stores and produce substantial amounts of TxA_2. They may have defects in the early signalling mechanisms. In this highly heterogeneous group, the underlying mechanisms still need to be established.

Therapy of patients with congenital platelet function disorders

The mainstays of therapy of patients with vWD and afibrinogenemia during bleeding episodes and surgical procedures are methods aimed at elevating the deficient factor levels in plasma. Platelet transfusions and 1-desamino-8D-arginine vasopressin (DDAVP) are the main therapy of patients with inherited platelet defects. Because of the wide disparity in bleeding manifestations therapeutic approaches need to be individualized. Platelet transfusions are effective in controlling the bleeding manifestations but come with potential risks associated with blood products, including alloimmunization. Patients with thrombasthenia may develop antibodies[126,127] against GPIIb-IIIa that compromise the efficacy of subsequent platelet transfusions. A viable alternative to platelet transfusions is intravenous administration of DDAVP which shortens the bleeding time in a substantial number of patients with platelet function defects[128–131]. This response appears to be dependent on the defects leading to the platelet dysfunction[128,130,131]. Most patients with thrombasthenia have not responded to DDAVP infusion with a shortening of the bleeding time[128,130–132] with exceptions[133]. However, it is unknown whether DDAVP improves hemostasis in these patients despite a lack of shortening of the bleeding time. Responses in patients with SPD have been variable with a shortening of the bleeding time in some patients[131,134,135] but not others[128,130]. A substantial number of patients with the primary secretion defects appear to respond to DDAVP with a shortening of the bleeding time[130]. In uncontrolled studies it has been feasible to manage selected patients with congenital platelet defects undergoing surgical procedures with DDAVP alone[128,130]. However, this approach needs to be individualized based on the nature of the surgery and the intensity of bleeding symptoms, and platelet transfusions need to be readily available for use in the event of excess hemorrhage. The mechanisms by which DDAVP enhances hemostasis in patients with platelet defects are unclear[128,129]. Its administration induces a rise in plasma vWF, FVIII and tissue plasminogen activator. The abnormal in vitro platelet aggregation or secretion responses in patients with platelet defects are not corrected by DDAVP[130]. Enhancement of aggregation responses by DDAVP or a direct stimulatory effect has been noted in some studies[136] but not others[137,138].

The other approaches that have been utilized to improve hemostasis in patients with inherited platelet defects include a short 3–4 day course of prednisone (20–50 mg)[139] and the administration of antifibrinolytic agents epsilonaminocaproic acid or tranexamic acid which have been successfully used in patients with coagulation disorders[129,140,141]. Although allogeneic bone marrow transplantation has been successfully performed with complete correction in patients with thrombasthenia[142] and the Wiskott–Aldrich syndrome[103,110], such a drastic therapy is rarely required in patients with congenital platelet function disorders.

Acquired platelet function defects

Joel S. Bennett

University of Pennsylvania School of Medicine, Philadelphia, USA

Platelet function can be impaired by medications and by non-hematologic and hematologic disorders (Table 45.1). Although the effect of these drugs and disorders on platelet function is usually mild, it can be substantial when it is associated with other hemostatic disorders.

Medications that affect platelet function

The effect of medications is the most common cause of acquired platelet dysfunction (Table 45.2)[1]. While some medications simply prolong the bleeding time without causing bleeding, others prolong the bleeding time and either cause or exacerbate a bleeding diathesis. Moreover, it is important to recognize that many drugs affect ex vivo and in vitro platelet function but without obvious clinical consequences.

Table 45.1. Acquired qualitative platelet disorders

1. *Drugs that affect platelet function*
2. *Systemic disorders associated with abnormal platelet function*
   - Uremia
   - Antiplatelet antibodies
   - Cardiopulmonary bypass
   - Miscellaneous disorders
     - Liver disease
     - Disseminated intravascular coagulation
     - Bartter syndrome
3. *Hematological disorders associated with abnormal platelet function*
   - Chronic myeloproliferative disorders
   - Leukemias and myelodysplastic syndromes
   - Dysproteinemias
   - Acquired von Willebrand disease

Table 45.2. Drugs that inhibit platelet function

Non-steroidal anti-inflammatory drugs
Aspirin; reversible cyclooxygenase inhibitors such as indomethacin, ibuprofen, sulindac, and naproxen

Antibiotics
Penicillins, cephalosporins, nitrofurantoin, Miconazole

Thienopyridines
Ticlopidine, clopidogrel

GPIIb/IIIa antagonists
Abciximab, tirofiban,eptifibatide

Drugs that affect platelet cAMP levels
Prostacyclin, iloprost, dipyridamole, cilostazol,

Anticoagulants and fibrinolytic agents
Heparin, streptokinase, tissue plasminogen activator, urokinase, ε-aminocaproic acid

Cardiovascular drugs
Nitroglycerin, isosorbide dinitrate, propranolol, nitroprusside, nifedipine, verapamil, diltiazem, quinidine

Volume expanders
Dextran, hydroxyethyl starch

Psychotropic drugs and anesthetics
Psychotropic drugs: imiprimine, amitriptyline, nortryptaline, chlorpromazine, promethazine, flufenazine, trifluoperazine, haloperidol

Anesthetics: dibucaine, tetracaine, metycaine, cyclaine, butacaine, nepercaine, procaine, cocaine, plaquenil, halothane

Chemotherapeutic agents
Mithramycin, daunorubicin, BCNU

Miscellaneous drugs
Serotonin antagonists
Antihistamines
Radiographic contrast agent
Foods and food additives

Aspirin and other non-steroidal anti-inflammatory drugs

Aspirin

Aspirin inhibits platelet function by irreversibly inactivating the enzyme prostaglandin endoperoxide H synthase-1 (PGHS-1, cyclooxygenase-1, COX-1)[2], thereby preventing the conversion of arachidonic acid to the thromboxane synthase substrate prostaglandin H_2. The resulting inability to synthesize thromboxane A_2, a platelet agonist and vasoconstrictor, impairs platelet responses to ADP, epinephrine, arachidonic acid, and to low doses of collagen and thrombin, although responses to higher doses of collagen or thrombin are unaffected[3,4]. A single 100-mg dose of aspirin almost completely inhibits platelet cyclooxygenase, as does a 30 mg dose taken daily for 7–10 days[5]. Aspirin irreversibly inhibits cyclooxygenase in endothelial cells[6], but has no lasting effect on prostacyclin production by these cells because they can synthesize additional enzyme[7,8].

Aspirin is one of the few drugs that prolongs the bleeding time in humans. In normal subjects, aspirin prolongs the bleeding time to no more than 1.2 to 2.0 times the baseline[9,10]. The bleeding time may remain prolonged for 1 to 4 days after aspirin administration has been discontinued and ex vivo platelet aggregation may be abnormal for up to a week, until the affected platelets are replaced by unaffected ones[11].

In normal subjects, aspirin has a minimal effect on hemostasis, although chronic aspirin ingestion has been reported to increase bruising, epistaxis and gastrointesinal blood loss[12]; the latter likely due to a direct effect on the gastric mucosa[13,14]. When aspirin was taken as primary prophylaxis against myocardial infarction, there was a slight increase in hemorrhagic strokes [12]. Aspirin may also increase maternal and neonatal bleeding during parturition [15] and some studies suggest that preoperative aspirin administration increases blood loss following cardiothoracic and general surgery[16–18]. On the other hand, retrospective analysis indicates that aspirin administration does not affect the safety of epidural and spinal anesthesia[19]. Aspirin markedly prolongs the bleeding time and can precipitate hemorrhage in individuals with preexisting hemostatic defects such as von Willebrand disease, hemophilia, warfarin ingestion, uremia, and disorders of platelet function[20–22]. Ethanol has been reported to potentiate the effect of aspirin[23,24], whereas DDAVP can shorten a prolonged bleeding time due to aspirin[25,26].

Other non-steroidal anti-infammatory drugs (NSAIDS)

NSAIDS such as indomethacin, ibuprofen, naproxen, phenylbutazone, and sulfinpyrazone reversibly inhibit platelet cyclooxygenase by competing with arachidonic acid for binding to the active site of the enzyme[2]. Therapeutic doses of NSAIDS may cause a transient prolongation of the bleeding time; however, this is usually not clinically significant[27–29]. Ibuprofen has been given safely to patients with hemophilia A[30,31]. Analgesics such as acetaminophen, sodium or choline salicylate, and narcotics neither inhibit cyclooxygenase nor prolong the bleeding time[30,32,33].

Antibiotics

Large doses of penicillin can impair ex vivo platelet aggregation and secretion, inhibit ristocetin-induced platelet agglutination, and prolong the bleeding time[34–36] by impairing the interaction of agonists and von Willebrand factor (vWf) with the platelet membrane[37,38]. Thus, penicillin may bind to membrane components necessary for platelet adhesion and/or signal transduction. Consistent with this possibility, the relative antiplatelet activity of various penicillins correlates with their lipid solubility and with the inhibitory potency of the isolated side chains[39,40].

The maximal effect of penicillin on platelet function is seen after 1 to 3 days of administration and may persist for several days after the antibiotic is stopped. Although clinically significant bleeding has been reported with carbenicillin, penicillin G, ticarcillin, and nafcillin, it is far less common than prolongation of the bleeding time[34,41]. Patients with coexisting hemostatic defects may be prone to bleeding. A similar pattern of platelet dysfunction has been reported with cephalosporins moxalactam and cefoxitin, but not with ceftizoxime, cefoperazone, and ceftriaxone[34,42,43]. Moxalactam, cefamandole, and cefoperazone also induce hypothrombinemia, either by decreasing the amount of vitamin K synthesized by the intestinal microflora or by directly inhibiting the vitamin K-dependent carboxylase[34,44]. Nitrofurantoin, a structurally unrelated antibiotic, may cause a mild prolongation of the bleeding time and impair platelet aggregation when blood levels of the drug are higher than 20 μM[45]. Miconazole, an antifungal agent, has been shown to inhibit human and rabbit platelet cyclooxygenase in vitro and rabbit platelet cyclooxygenase after intravenous infusion[46].

Thienopyridines

The thienopyridines ticlopidine and clopidogrel inhibit platelet function by irreversibly antagonizing the G_i-

Cambridge Books Online © Cambridge University Press, 2009

coupled platelet ADP receptor $P2Y_{12}$[47–49]. Thus, ADP-induced platelet shape change and calcium transients are unimpaired, whereas the ability of ADP to inhibit PGI_2-stimulated increases in cAMP is inhibited. Both drugs are prodrugs; hepatic metabolism is required to generate the active agents[50]. Thus, although inhibition of platelet aggregation and prolongation of the bleeding time may be seen within 24–48 hours of the first dose, the effects are not maximal for 4–6 days and may last for 4–10 days after the drugs have been discontinued.

Ticlopidine administration is associated with potentially serious hematological complications, including a 2% incidence of neutropenia[50–52], and less commonly, aplastic anemia, thrombotic thrombocytopenic purpura, and thrombocytopenia[53–57]. Results from the CAPRIE trial suggest that these complications are far less common with clopidogrel[58]. However, 20 cases of TTP have been reported since clopidogrel was approved by the US FDA in 1998[59,60].

GPIIb/IIIa receptor antagonists

Three intravenous GPIIb/IIIa antagonists – abciximab, eptifibatide, and tirofiban – have been approved for use in the treatment of acute coronary artery disease and a number of orally-active GPIIb/IIIa antagonists are undergoing development. As would be expected, these drugs predispose to bleeding. In the EPIC trial, 14% of patients given abciximab (a chimeric human-murine anti-GPIIb/IIIa monoclonal antibody Fab fragment) plus heparin and aspirin during percutaneous coronary angioplasty experienced major bleeding compared to 7% of patients receiving only heparin and aspirin[61]. In the subsequent EPILOG trial, in which the dose of heparin was decreased, the incidence of major bleeding in patients receiving abciximab decreased to 2.0% compared to 3.1% in the control group[62], implying that bleeding in patients given GPIIb/IIIa antagonists can be minimized by paying careful attention to other factors that impair hemostasis[63]. Platelet transfusions readily reverse GPIIb/IIIa antagonism by abciximab by decreasing the extent of GPIIb/IIIa blockade. The ability of platelet transfusion to reverse the effects of the other GPIIb/IIIa antagonists is less clear, but these drugs have short half-lives when renal and hepatic function are normal.

Thrombocytopenia has been observed in small numbers of patients given GPIIb/IIIa antagonists[64–67] and must be differentiated from pseudothrombocytopenia that accounts for approximately 30% of the thrombocytopenia observed in patients receiving these drugs[68]. Rarely, acute profound thrombocytopenia with platelet counts below 20 000/μl occurs within 2–4 hours after initiating therapy[69,70]. The pathogenesis of this thrombocytopenia is uncertain, but it readily reverses when the drugs are stopped and may be reversed more rapidly by platelet transfusion[63].

Drugs that affect platelet cyclic nucleotide levels

Increasing the platelet content of cAMP impairs platelet function. Although the pyrimidopyrimidine derivative dipyridamole increases platelet cAMP by inhibiting its degradation by cyclic nucleotide phosphodiesterase (PDE), its utility at clinically achievable concentrations is controversial[71,72]. On other hand, treatment with a sustained release dipyridamole preparation plus aspirin may be beneficial in the secondary prevention of stroke and transient ischemic attack[73]. Cilostazol, a specific inhbitor of PDE3, the most abundant PDE in platelets[74], has been approved for the treatment of peripheral vascular disease[75] and may be useful in the prevention of cardiac stent occlusion[76]. Intravenous infusions of prostaglandin E_1 (PGE_1), prostacyclin, or stable analogues of prostacyclin decrease platelet responsiveness by stimulating platelet adenylyl cyclase[77–79]. Their clinical utility is limited by their short half-life and side effects due to peripheral vasodilatation[77,80]. Nitric oxide and organic nitrates such as nitroglycerin inhibit platelet function in vitro by activating guanylyl cyclase[81]. Their effect on platelet function in vivo is uncertain. High concentrations of caffeine and theophylline also inhibit platelet phosphodiesterases in vitro.

Anticoagulants and fibrinolytic agents

Heparin can impair platelet function by inhibiting the generation of thrombin, a potent platelet agonist, and perhaps by inhibiting thrombin binding to GPIb[82]. Conversely, in vitro studies suggest that heparin can enhance platelet aggregation induced by other platelet agonists[83]. Large doses of heparin can also impair vWf-dependent platelet function, possibly by binding to the heparin-binding domain of vWf[84]. Whether any of these observations contribute to the bleeding complications of heparin therapy is uncertain. Pharmacologic doses of streptokinase, urokinase, and tissue plasminogen activator (t-PA) can affect platelet function[85]. High concentrations of plasmin in vitro cause platelet aggregation[86] and increases in the urinary excretion of thromboxane A_2 metabolites have been observed in patients receiving streptokinase or t-PA, implying that platelet activation had occurred[87,88]. On the other hand, a number of studies suggest that plasmin can inhibit platelet function. For example, high levels of plasmin-generated fibrin(ogen) degradation products

Cambridge Books Online © Cambridge University Press, 2009

impair platelet aggregation[89] and plasmin enzymatically degrades platelet GPIb[90,91], inhibits platelet arachidonic acid metabolism[92], and promotes the disaggregation of platelet aggregates by lysing GPIIb/IIIa bound fibrinogen[93]. Whether these observations are clinically significant is uncertain[94].

Miscellaneous agents

A number of other medications have been reported to affect in vitro platelet function, but this appears to be of little clinical significance. Drugs in this category include the cardiovascular drugs nitroprusside[95,96], nitroglycerine[97], nitric oxide[98–100], propranolol[101,102] and calcium channel blockers such as verapamil, nifedipine, and diltiazem[103,104]. The volume expander dextran can prolong the bleeding time of patients with von Willebrand disease, but this has not been observed in most normal subjects[105–107]. Hydroxyethyl starch, while generally safe, may prolong the bleeding time and predispose to hemorrhage, particularly if it is administered in doses exceeding 20 ml/kg of a 6% solution[108–110]. Antidepressants and phenothiozines can impair platelet aggregation ex vivo, but this is not associated with bleeding[111,112]. The general anesthesic halothane can cause a slight bleeding time prolongation, but this has no adverse effect on surgical hemostasis[113]. Cocaine has been reported to either inhibit platelet function[114,115] or to induce platelet activation[116].

The chemotherapeutic drug mithramycin has been associated with mucocutaneous bleeding, increased bleeding times, and decreased platelet aggregation[117]. An ex vivo defect in platelet secretion and secondary aggregation has been observed in patients receiving autologous bone marrow and high dose chemotherapy with cisplatin, cyclophosphamide, and either BCNU or melphelan[118]. Daunorubicin and BCNU inhibit platelet aggregation and secretion in vitro, but do not induce clinically significant platelet dysfunction[119–121]. Cyclosporine A may enhance ADP-stimulated platelet aggregation ex vivo and in vitro[122–124]. Antihistamines[125], the serotonin antagonist ketanserin[126], and some radiographic contrast agents[127,128] impair platelet aggregation ex vivo by unknown mechanisms.

Diets rich in ω-3 fatty acids cause a slight prolongation of the bleeding time[129] by reducing the platelet content of arachidonic acid and by competing with arachidonic acid for cyclooxygenase[130,131]. Easy bruising noted after eating Chinese food has been attributed to an effect of the black tree fungus[132]. An onion extract can inhibit platelet arachidonic acid metabolism[133]. The garlic component, ajoene, inhibits platelet aggregation[134,135]. Extracts of two commonly used spices, cumin and turmeric, inhibit platelet aggregation and eicosanoid biosynthesis[136].

Systemic disorders associated with abnormal platelet function

Uremia

Bleeding can be a serious complication of acute and chronic renal failure[137], although the frequency of severe, spontaneous hemorrhage decreased with the advent of dialysis. Moreover, experience with percutaneous renal biopsy in several thousand patients with renal disease indicates that their hemostatic defect is usually mild[138,139].

The hemostatic defect in uremia has been attributed to abnormal platelet function[140]. Platelet adhesion is defective in uremia[141–143]. One major factor may be anemia. Lowering the hematocrit causes an ex vivo platelet adhesion defect that can be corrected by increasing the hematocrit to $\geq$30%[141]. In uremic patients, increasing the hematocrit to 27–32% by red blood cell transfusion or erythropoietin administration either partially or completely normalizes the bleeding time[140,144–148]. However, the effect of anemia on the bleeding time is not unique to uremia. In normal subjects, the bleeding time correlates with the hematocrit, even though both sets of values are in the normal range[149]. Furthermore, bleeding times can be prolonged in patients with severe anemia of any etiology[149,150].

Because increasing the hematocrit does not shorten the bleeding time in all uremic patients, other factors likely impair platelet adhesion as well[141]. Abnormal ristocetin-induced platelet aggregation suggests that uremia induces a quantitative or qualitative abnormality in vWf or in its platelet receptor GP Ib–IX–V. However, the plasma concentration of vWf in patients with renal failureis either normal or elevated and qualitative vWf abnormalities have not been uniformly observed[142,151,152]. Nonetheless, uremic plasma can inhibit platelet adhesion to de-endothelialized human umbilical artery segments[142]. Uremic platelets also spread poorly on the subendothelium of rabbit blood vessels[153], an abnormality attributed to impaired vWf binding to activated GPIIb/IIIa, suggesting that platelet activation may be defective in uremia.

Additional observations suggest that a platelet activation defect is present in uremia. For example, uremia, and uremic plasma, can reduce agonist-stimulated fibrinogen binding to GPIIb/IIIa, platelet aggregation, and platelet secretion[154]. Platelet procoagulant activity is consistently reduced in uremia[155]. Agonist-induced biochemical

Cambridge Books Online © Cambridge University Press, 2009

responses, including a rise in cytoplasmic free calcium levels[156], release of arachidonic acid from platelet phospholipids[157], and conversion of arachidonic acid to prostaglandin endoperoxides and thromboxane A_2 can be reduced in platelets from uremic patients[158–160]. A decrease in the dense-granule content of ADP and serotonin has been observed in uremia[161], as has an increase in the concentration of cAMP[162].

Both dialysable and non-dialysable substances may be responsible for the platelet activation defect in uremia. These include small molecules such as guanidinosuccinic acid, phenolic acids, and a poorly characterized 'middle molecules'[163]. In uremic rats, prolonged bleeding times were normalized by an inhibitor of nitric oxide formation[164], suggesting that nitric oxide may be partly responsible for the defective function of uremic platelets[165]. Impaired platelet aggregation may improve following dialysis[166,167], but venous and arterial segments from uremic patients produce more prostacyclin than their normal counterparts and this is not corrected by dialysis[168,169].

When bleeding complicates a surgical procedure in a patient with renal failure or occurs spontaneously and cannot be attributed to an etiology other than uremia, there are several therapeutic maneuvers that can undertaken (Table 45.3). These manoeuvres are not uniformly effective and the choice of therapy should be based on considerations such as the severity of the bleeding, the predicted duration of therapeutic effect, and the risks of therapy.

Table 45.3. Treatment of platelet dysfunction in patients with uremia

Dialysis
Desmopressin
Red cell transfusion
Conjugated estrogens
Cryoprecipitate

Dialysis

Intensive dialysis can correct the bleeding time and bleeding diathesis in many patients, but is only partially effective in others[167,170]. Peritoneal dialysis and hemodialysis are equally effective[171,172]. If a patient undergoing dialysis bleeds, it may be worthwhile to increase the intensity of the dialysis.

Desmopressin (1-desamino-8-D-arginine vasopressin, DDAVP)

This vasopressin analogue has been reported to shorten the bleeding time in 50 to 75 per cent of patients with uremia. In many cases, surgery has been carried out safely after administration of this drug, although no controlled trial has been performed[173]. DDAVP is usually administered intravenously in a dose of 0.3 μg/kg over 15 to 30 min (maximum dose 20 μg), but it is also effective at this dose when given subcutaneously[173] or intranasally[174]. Improvement in the bleeding time is seen within 30 to 60 min of administration, lasts for approximately 4 h, and roughly correlates with the rise in the plasma levels of vWf and the appearance in the circulation of high molecular weight vWf multimers[175]. In some patients, the drug has been given repeatedly at 12– to 24-h intervals, although tachyphylaxis can occur[176].

Side effects of DDAVP administration are uncommon and generally mild. A 10 to 15% decrease in mean arterial pressure, a 20 to 30% increase in pulse rate, facial flushing, water retention, and hyponatremia leading to seizures can occur[173,177]. The latter has not been observed in patients whose kidneys cannot respond to the hormone. Rarely, stroke and myocardial infarction have been reported in uremic and non-uremic individuals with atherosclerosis after DDAVP administration[178–180]. If dialysis is not effective, DDAVP is the treatment of choice for uremic bleeding, particularly if only a short-term effect is required[175].

Red cell transfusion

Increasing the hematocrit to 27–32%, either by red blood cell transfusion or treatment with erythropoietin, is associated with correction of the bleeding time in uremic individuals[140,145–148]. The beneficial effects of red cells and DDAVP may be additive[181]. Correction of the bleeding time by increasing the red cell mass would be expected to be more durable than correction with DDAVP. A number of reports suggest that erythropoietin has an effect on platelets that is independent of an increase in hematocrit[144], perhaps by increasing the number of young platelets in the circulation[182].

Conjugated estrogens

Conjugated estrogens, at dose of 0.6 mg/kg intravenously for 5 days, have been reported to shorten the bleeding time in most uremic individuals[151,183–185] and appear to be useful in uremic patients who bleed from gastrointestinal telangiectasia[186]. Shortening of the bleeding time may be seen within 72 hrs, but the maximal effect occurs within 5 to 7 days and can persist for up to 14 days.

Cryoprecipitate

Infusion of cryoprecipitate has been reported to correct the bleeding time and to ameliorate bleeding[187,188], but

Cambridge Books Online © Cambridge University Press, 2009

others have reported inconsistent results[189]. Hemostasis may be promoted by either vWf or the platelet microparticles found within cryoprecipitate preparations[190].

Anti-platelet antibodies

Antibody binding to platelets occurs in several pathologic conditions, such as idiopathic thrombocytopenic purpura (ITP), system lupus erythematosus (SLE), and platelet alloimmunization, usually resulting in platelet destruction. In most instances, surviving platelets function normally, but in some cases of ITP, bleeding times may be shorter than expected for the degree of thrombocytopenia[191]. Conversely, some individuals with circulating antiplatelet antibodies have impaired platelet function.

The mechanism by which auto- or alloantibodies inhibit platelet function is usually not apparent, although antibody binding to specific platelet membrane proteins has been shown to be responsible in several cases. Most autoantibodies are directed against the GPIIb/IIIa complex, but antibodies directed against GPIb–IX–V, GPIa/IIa, and GPIV have been detected as well[192]. Thus, the platelets of some patients with antiplatelet antibodies may exhibit impaired platelet aggregation to ADP, epinephrine, or collagen[193–196]. Two IgG autoantibodies against GPIb have been reported that selectively inhibited ristocetin-induced platelet aggregation[197,198]. Impaired collagen-induced platelet aggregation has been associated with autoantibodies against a platelet collagen receptor, GPIa/IIa[199,200]. Antibodies have also been observed to activate platelets and induce aggregation and secretion via immune complex binding to the platelet Fc receptors, by depositing sublytic quantities of the complement C5b–9 complex on the platelet surface[201], and by binding to a specific membrane antigen[202]. This may explain the acquired storage pool disease occasionally seen in ITP or SLE[203,204].

Platelet dysfunction should be suspected in a patient with ITP or SLE who has mucocutaneous bleeding with a platelet count that is not ordinarily associated with bleeding. In these cases, the bleeding time may be longer than expected for the platelet count[203,205]. Patients (usually women) have also been reported with ‘easy bruising’ a normal platelet count, circulating antiplatelet antibodies and megathrombocytes[206]. These patients may have ITP with ‘compensated thrombocytolysis’.

Cardiopulmonary bypass

Thrombocytopenia and platelet function defects are consistent consequences of circulating blood through an extracorporeal bypass circuit[207,208]. Platelet counts typically decrease to 50% of presurgical levels and can persist for as long as several days[207,209,210]. The thrombocytopenia can be attributed to hemodilution from priming the pump with colloid or crystalloid solutions[209–211], but it also can result from platelet adhesion to artificial surfaces in the circuit, as shown in scanning electron micrographs[212–214]. Other factors include disseminated intravascular coagulation, sequestration of damaged platelets in the liver, and heparin-induced thrombocytopenia[215].

Qualitative platelet defects manifest as prolonged bleeding times, abnormal ex vivo platelet aggregation, decreased ristocetin-induced platelet agglutination, α and dense granules deficiency, and generation of platelet microparticles[207,209,210,214,216–218]. Their severity correlates with the duration of extracorporeal bypass and they generally resolve within 2 to 24 hours[219]. Bypass-induced platelet function defects likely result from platelet activation and fragmentation[218,220] due to hypothermia, contact with fibrinogen-coated synthetic surfaces, contact with the blood–air interface, cardiotomy suction, and exposure to traces of thrombin, plasmin, ADP or complement[214,221–224]. Drugs such as heparin, protamine and aspirin, as well as fibrin degradation products, can also impair platelet function[208,225,226].

The most important determinant of blood loss following cardiopulmonary surgery is the surgical procedure itself. If excessive non-surgical postoperative bleeding occurs, one should verify that the patient is no longer hypothermic and that heparin has been fully reversed. If neither of these is a factor, then administration of pharmacologic agents, along with judicious transfusions of platelets, cryoprecipitate, fresh frozen plasma and red blood cells, is appropriate. Several pharmacologic agents have been tried to assist in the management of postoperative bleeding. Although patients with excessive post-operative blood loss can respond to DDAVP, as evidenced by a shortening of the bleeding time, the results of trials using DDAVP have been contradictory, some studies showing a reduced blood loss and others showing no benefit[227,228]. Because platelet activation during bypass could be a major cause of postoperative platelet dysfunction, infusions of PGE_1, prostacyclin, or stable prostacyclin analogues have been tried in animal and humans to increase platelet cyclic AMP and reduce platelet responsiveness. Randomized trials using prostacyclin and its analogue, Iloprost, did not show a clear overall benefit[77,80]. The protease inhibitor aprotinin can reduce mediastinal blood loss and transfusion requirements[229,230]. Some studies suggest that aprotinin exerts a protective effect on platelets[229,231], but others do not[232,233]. Aprotinin does inhibit hyperfibrinolysis and this may be its sole beneficial activity at low dosage[232,234]. Other anti-

Cambridge Books Online © Cambridge University Press, 2009

fibrinolytic agents that may have a role in minimizing post-operative blood loss include ε-aminocaproic acid and tranexamic acid[235,236].

Miscellaneous disorders

Chronic liver disease has been reported to cause a prolonged bleeding time and reduced platelet aggregation and procoagulant activity[237,238]. The prolonged bleeding time in such patients may respond to infusion of DDAVP[239]. A number of defects in platelet function have been reported in patients with cirrhosis including dense granule deficiency[240], increases in the platelet content of cAMP and cGMP[241], degradation of von Willebrand factor with loss of high molecular weight multimers[242], and paradoxically, platelet hypersensitivity to botrocetin[243]. However, these defects are not specific for liver disease and the basis for the hemorrhagic diathesis associated with liver disease is multifactorial[244,245]. Patients with disseminated intravascular coagulation (DIC) can exhibit reduced platelet aggregation and acquired storage pool deficiency[246,247]. These result from platelet activation in vivo by thrombin or other agonists. In addition, elevated levels of fibrin(ogen) degradation products and low fibrinogen levels contribute to the platelet defect. However, it is difficult to assess the significance of platelet dysfunction in most patients with DIC due to the simultaneous presence of thrombocytopenia and other hemostatic defects. Platelet function abnormalities have been described in Bartter syndrome, possibly due to an inhibitory prostaglandin[248]. There are isolated reports of a slight prolongation of the bleeding time and/or ex vivo platelet function defects in a number of other conditions, including nonthrombocytopenic purpura with eosinophilia[249,250], atopic asthma and hay fever[251], acute respiratory failure[252], and Wilms tumour elaborating hyaluronic acid[253].

Hematologic disorders associated with abnormal platelet function

Chronic myeloproliferative disorders

Several factors contribute to abnormal hemostasis in the chronic myeloproliferative disorders essential thrombocythemia, polycythemia rubra vera, myelofibrosis with myeloid metaplasia, and chronic myelogenous leukemia[254]. These include the increased whole-blood viscosity characteristic of polycythemia vera[255,256], intrinsic defects in platelet function that generally do not prolong the bleeding time[257], and thrombocytosis[258–262].

Table 45.4. Biochemical abnormalities reported in platelets of patients with myeloproliferative disorders

Decreased arachidonic acid release from membrane phospholipids
Reduced cyclooxygenase and/or lipoxygenase activity
Reduced responsiveness to thromboxane A_2
Dense- and/or α-granule deficiency
Decreased membrane proteins
$\alpha 2\beta 1$ (GPIa/IIa)
α_2-adrenergic receptors
GPIb–IX–V
PGD_2 receptors
Thrombopoietin receptors
Increased membrane proteins
Platelet Fc receptors
GPIV
Reduced platelet procoagulant activity
Acquired von Willebrand disease

Bleeding occurs in about one-third of patients with myeloproliferative disorders and contributes to mortality in 10 percent. Thrombosis also occurs in one-third of cases, contributing to mortality in 15 to 40 percent[263]. Bleeding usually involves the skin or mucous membranes, but may also occur after surgery or trauma. Thrombosis can involve arteries or veins and may occur in unusual locations such as the hepatic, portal, and mesenteric circulations[263–265]. It has been difficult to predict the risk of bleeding or thrombosis in an asymptomatic patient[266], but an increased number of reticulated platelets in patients with thrombocytosis, thought to reflect an increase in platelet turnover, has been associated with an increased risk for thrombosis[267]. Vascular complications are also more likely to occur in patients older than 60 and in patients with other risk factors for vascular disease[268].

A number of functional and biochemical abnormalities have been described in the platelets of patients with myeloproliferative disorders[257] (Table 45.4). These include decreased release of arachidonic acid from membrane phospholipids[269,270], reduced conversion of arachidonic acid to prostaglandin endoperoxides or lipoxygenase products[271], reduced responsiveness to thromboxane A_2 [272,273], deficiency of dense- or α-granules[274,275], unresponsiveness to collagen due to GPIa/IIa deficiency[276], and decreased numbers of α_2-adrenergic receptors[277,278]. The latter results in a defect in epinephrine-induced aggregation, often including absence of the primary wave of aggregation, which is unusual in other conditions. In

Cambridge Books Online © Cambridge University Press, 2009

addition, reduced platelet procoagulant activity has been reported in some patients[279], as have specific platelet membrane abnormalities, including decreased amounts of GPIb–IX–V[280], decreased numbers of PGD_2 receptors[281], increased numbers of platelet Fc receptors[282], an increased amount of GPIV (CD36)[283–285], and decreased expression of thrombopoietin receptors[286]. An acquired form of von Willebrand disease has been reported in several individuals with chronic myelogenous leukemia and other myeloproliferative syndromes[287]. In these cases, there was a reduction in high molecular weight vWf multimers[288]; in some, the vWf abnormality was corrected transiently by infusion of DDAVP[284,289]. In others, the abnormalities were partially or completely corrected by cytoreductive therapy[287,290].

Leukemias and myelodysplastic syndromes

Although thrombocytopenia is the overwhelming cause of bleeding in patients with leukemia, abnormal platelet function has been described in acute myelogenous leukemia. Besides morphologic abnormalities, there may be platelet aggregation and secretion abnormalities, as well as decreased platelet procoagulant activity[291–293]. These defects are intrinsic to the platelet and probably relate to the fact that the megakaryocytes from which platelets are derived have originated from a leukemic stem cell. Identical platelet abnormalities may be seen in the myelodysplastic syndrome[291,294]. Reduced platelet aggregation has also been reported in children with acute lymphocytic leukemia[292]. The platelets of some patients wth hairy-cell leukemia exhibit storage pool deficiency or a defect in platelet activation[295–300]. A single case of acquired von Willebrand disease in association with hairy-cell leukemia has been reported[301].

Dysproteinemias

Platelet dysfunction is observed in approximately one-third of patients with IgA myeloma or Waldenström macroglobulinemia, 15% of patients with IgG multiple myeloma, occasionally in patients with monoclonal gammopathy of undetermined significance[302] and can be associated with a prolonged bleeding time, even in the absence of clinical bleeding. The platelet defect is caused by the monoclonal protein, perhaps because it interacts with the platelet surface to non-specifically inhibit platelet adhesion or stimulus–response coupling. In some cases, however, specific interactions of a monoclonal protein with platelets have been described[303,304]. Several patients with myeloma, benign monoclonal gammopathy, or chronic lymphocytic leukemia have been reported to have an acquired form of von Willebrand disease[305–307].

When clinically significant platelet dysfunction occurs in a patient with a dysproteinemia, cytoreductive therapy should be considered to reduce the production and plasma level of the monoclonal immunoglobulin[302]. Plasmapheresis can also control bleeding by reducing the level of the abnormal protein[308,309].

Valproic acid
Ciprofloxacin
Wilm's tumour

Acquired von Willebrand disease

Acquired von Willebrand disease[310] is a relatively rare disorder that has been seen in patients with a variety of conditions including autoimmune disorders such as systemic lupus[311] and scleroderma[312]; plasma cell dyscrasias such as multiple myeloma[313,314], Waldenstrom's macroglobulinemia[315] and MGUS[316]; lymphoproliferative disorders such as non-Hodgkin's lymphoma[317,318], chronic lymphocytic leukemia[319], and hairy cell leukemia[320]; myeloproliferative disorders[287]; hypothyroidism[321]; gastrointestinal angiodysplasia[322]; Wilm's tumour[323]; and ciprofloxacin[324] or valproic acid administration[325] (Table 45.5). In these disorders, antibodies againt vWf are present[313,314,326–328]. When acquired von Willebrand disease occurs in patients with cancer or hypothyroidism, it may result from the non-specific direct absorption of vWf onto tumour cells[301,323,329], or decreased vWf production[330,331]. The presence of an in vitro inhibitor of vWf may, or may not, be detectable depending on whether the antibody neutralizes Wf function or merely

Cambridge Books Online © Cambridge University Press, 2009

leads to accelerated vWF clearance[332]. Patient management includes infusions of desmopressin[314,319,328], vWf-containing factor VIII concentrates[333], or high dose intravenous immunoglobulin[334,335]. The latter has been efficacious in patients when acquired von Willebrand disease is associated with a lymphoproliferative disorder or monoclonal paraprotein and most likely acts by delaying vWf clearance via reticuloendothelial cell blockade[336–338]. Treatment of the underlying associated disease is only sometimes helpful[332].

Platelet storage and transfusion

Scott Murphy, MD

Chief Medical Officer, American Red Cross Blood Services, Penn-Jersey Region and Department of Medicine, University of Pennsylvania, Philadelphia, USA

Introduction

Platelet transfusion has become a routine component of modern medical care. Each year, approximately 2 000 000 such transfusions are administered in the United States[1]. This chapter will review the preparation, storage, clinical use and complications of platelet transfusion.

Platelet preparation

Platelet concentrates (PC) for transfusion may be obtained from routine donations of whole blood or by apheresis (AP–PC), using citrate as the anticoagulant. There are two methods for preparing PC from whole blood, the platelet-rich-plasma method (PRP–PC) and the buffy coat method (BC–PC)(Fig. 46.1).

In evaluating the quality of PC, much attention is now being given to the number of contaminating leukocytes as well as to the appropriate platelet content. Problems related to contaminating leukocytes will be discussed in the section on complications of platelet transfusion. Many now recommend a totally leuko-reduced blood supply to reduce the frequency of these complications[2]. Platelets can be filtered during infusion at the bedside, but, for reasons to be discussed, it is probably preferable to perform leuko-reduction at the time of preparation of the PC. In the United States, an AP–PC or a pool of PRP–PC is considered leukoreduced if it contains less than 5×10^6 leukocytes while the standard in Europe is 1×10^6.

Whole-blood-derived PC

PRP–PC

At present, this is the only method used in North America for preparing whole-blood-derived PC. 450–500 ml (a unit) of whole blood is held for up to 8 hours at room temperature, and PRP is separated from red cells and buffy coat by low-speed centrifugation. The PRP is then centrifuged rapidly to produce a platelet pellet which is allowed to 'rest' for 1–2 hours before resuspension in approximately 50 ml autologous citrated plasma. Without this 'rest' period, platelets tend to clump irreversibly upon resuspension. The separated red cells are used for transfusion, while the supernatant plasma is used for transfusion or fractionation.

An average unit of PRP–PC should contain 0.8×10^{11}–0.9×10^{11}, platelets but the range around the average is high, 0.4×10^{11}–1.8×10^{11} [3,4]. One unit is adequate only for the transfusion of a small child less than 30 pounds in weight. To transfuse adults, 4 to 8 units are pooled to provide a therapeutic dose. Because of the wide range around the mean, one must pool five units to be certain that the pool will contain at least 3×10^{11} platelets[4]. Because each unit contains 0.1×10^9–0.5×10^9 leukocytes, predominantly lymphocytes, such pools contain 0.4×10^9–4.0×10^9 leukocytes, three orders of magnitude higher than a leukoreduced transfusion. There is a system which inserts a leukocyte-reduction filter between the primary blood bag and the bag that accepts the PRP[5,6]. Thus, the PRP is leukoreduced at the time of its preparation. This system was introduced in early 1998 for the preparation of all PRP–PC in Canada and is gaining acceptance in the United States.

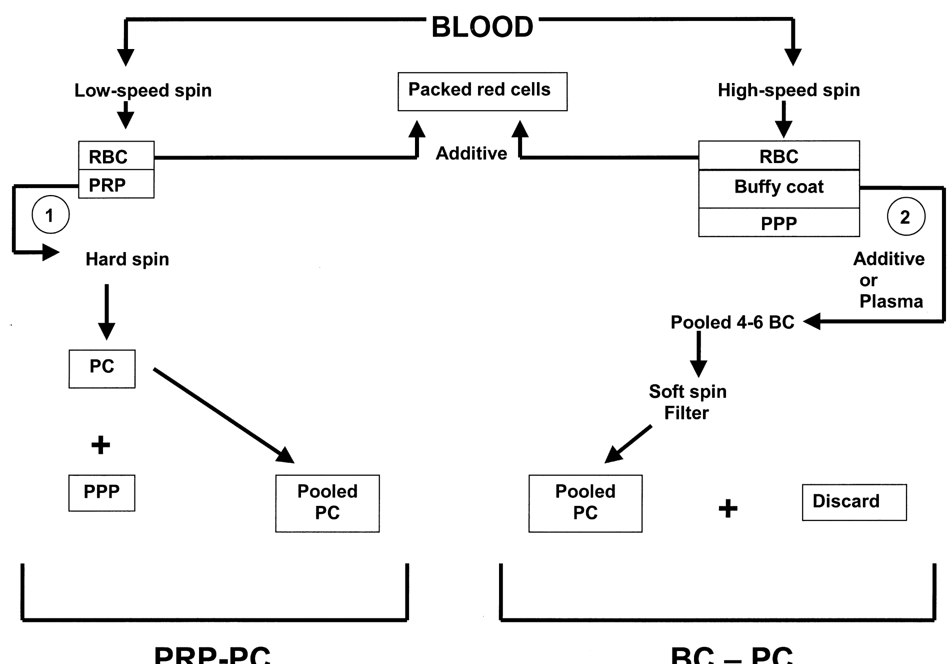

Fig. 46.1. Two ways to prepare a pool of platelet concentrates (PCs) from units of whole blood. Pathway 1 is the platelet-rich-plasma (PRP) method, the only method used in North America. Pathway 2 outlines the buffy coat (BC) method which is widely used in Europe. Both methods are described in the text. RBC, red blood cells; PPP, platelet-poor-plasma.

BC–PC

The BC method is being used with increased frequency in Europe[7]. An initial hard centrifugation sediments all blood cells so that the plasma, buffy coat, and red cells can be collected in three separate containers. The platelets at the top of the bag fall to the BC, and, remarkably, the platelets at the bottom of the bag rise to the buffy coat. Therefore, platelet yields in the buffy coat are excellent. One can pool 4–6 BCs, add twice the volume of plasma or an additive solution, centrifuge the pool at low speed to remove red cells and leukocytes, and push the supernatant through a leukoreduction filter to produce a therapeutic, leukoreduced, dose of platelets for an adult[8].

The PRP and BC methods each have their advantages and disadvantages[7,9]. Each produces platelets of high quality, and platelet yields from a unit of blood are equivalent. In the BC method, 20–25 ml of red cells are lost with the BC but an extra 70–80 ml of plasma can be collected.

Apheresis PC

One can obtain a therapeutic dose of platelets for 1–3 adults by apheresis of donors over 1–2 hours using a variety of devices[10–13] with an extraordinarily high level of safety for the donor[14]. The number of platelets obtained during the procedure varies with the platelet concentration in the blood of the donor, the volume of blood processed and the efficiency of the device. The efficiency of the newest devices is such that one should expect to obtain at least 60% of the platelets which pass through them, and most procedures are limited to 90–120 minutes. Therefore, it is the wide range of the platelet concentration in the blood of normal donors, 150000–500000 per mm^3, which accounts for the wide range in platelet yields which may be observed in practice[15]. There are also devices for obtaining an AP–PC, a unit of red cells, and a unit of plasma from the same donor at the same sitting[16].

Current standards of the Food and Drug Administration (FDA) in the United States state only that 75% of AP–PC must contain more than 3.0×10^{11} platelets. This standard probably reflected the capabilities of the apheresis devices available at the time the standard was established rather than the needs of the wide variety of patients being treated. Now, in many centres, more than 95% of collections contain 3.0×10^{11} platelets and some contain more than 10.0×10^{11} platelets. In a subsequent section, we will discuss current controversies concerning the appropriate dose for platelet transfusion. While 2.5×10^{11}–3.5×10^{11} is

Cambridge Books Online © Cambridge University Press, 2009

probably a satisfactory dose for the prophylactic transfusion of a child or small adult, it may well be insufficient for a large adult who is bleeding or has other clinical features which interfere with an optimal response to platelet transfusion. On the other hand, administration of very high yield products to small adults and children may be wasteful. Therefore, blood centres are in the process of thinking through the best way to handle the manufacturing process for apheresis platelets. Many divide high yield products (greater than 6×10^{11}–7×10^{11} platelets) to provide a therapeutic dose for two patients. Very high yield products ($>10\times10^{11}$–11×10^{11} platelets) can be divided to treat three patients. In addition, consideration is being given to the preparation of products containing two or more levels of platelet content, perhaps means of 3.2×10^{11} and 6.4×10^{11} (i.e. approximately 4 and 8 whole-blood-derived units respectively). The use of the products could be tailored to the needs of individual patients.

Platelets in PRP–PC, BC–PC, and AP–PC are probably equivalent therapeutically. However, there are two often-quoted advantages for AP–PC. First, the number of donors to whom the patient is exposed is substantially reduced thus reducing the likelihood of transmission of viral and other infectious bacterial diseases. Considering the current level of safety of the blood supply, it has been argued that choosing AP–PC for this purpose is not cost-effective[17]. Secondly, the separation technology of the various apheresis devices lends itself to the production of leukoreduced products during collection. Progressive improvements of those most recently available[10,11] has allowed the production of products with less than 1×10^6 leukocytes close to 100% of the time. However, as noted above, there are methods of leukoreduction for PRP–PC and BC–PC at the time they are manufactured. Thus, there is ongoing controversy concerning the choice between AP–PC and whole-blood-derived PC[18].

Storage of platelet concentrates

In assessing methods of platelet storage, the greatest stress has been placed on showing that the stored platelets can circulate in vivo after transfusion. The ultimate test has been the measurement of increments in platelet concentration in the blood of thrombocytopenic recipients, but reliance has also been placed on autologous, radiolabelled reinfusion studies in normal volunteers[19]. Some in vitro tests to be discussed have shown good correlation with in vivo results[20].

Liquid storage at 20–24 °C

Both whole-blood-derived and AP–PC may be stored for 5 days using the same principles: (i) The temperature must be 20–24 °C[21]; (ii) The storage container must be constructed of a plastic material that allows adequate diffusion of oxygen through its walls to meet the cells' metabolic needs[22,23]; (iii) The PC must be agitated during storage[22,23].

Using radiolabelling of stored platelets, survival after reinfusion in vivo is nearly normal if storage is carried out at 20–24 °C. However, at colder temperatures, the cells undergo irreversible disc-to-sphere transformation and survival is dramatically shortened[21]. If oxygen influx is inadequate at 20–24 °C, the cells will increase their production of lactic acid in an effort to maintain ATP levels. This leads to depletion of bicarbonate, the major buffer in plasma and fall in pH to less than 6.2[22,23]. These acid conditions lead to irreversible disc-to-sphere transformation and render the cells non-viable. A similar increase in lactic acid production and fall in pH occurs if the PC are not agitated[23]. However, agitation may be discontinued for up to 24 hours of the 5-day storage interval without harm to the platelets[24].

As already mentioned, synthetic media are now used for the storage of BC–PC[8,25,26] and they may well be used soon for apheresis PC as well[27]. Definition of the optimal solution is still in progress, but it appears that it can be relatively simple relying on 20–40% residual plasma and the presence of acetate. During storage in plasma, platelets oxidize free fatty acids in the tricarboxylic acid (TCA) cycle generating CO_2 which can leave the platelet suspension through the walls of the plastic container (Fig. 46.2). In a storage medium, acetate can enter the TCA cycle replacing the requirement for fatty acid. The oxidation of acetate utilizes a proton from the medium, thus providing an alkalinizing effect eliminating the need for bicarbonate in the medium.

Some authors have been unable to find any practical difference between fresh and stored platelets[28,29], but most find a reduction in in vivo recovery and survival of approximately 20–25% after 5 days of storage as judged by radiolabelling studies and by the increase in platelet concentration in the blood of thrombocytopenic patients[30]. Furthermore, some authors have reported an even greater defect in stored platelets relative to fresh platelets in sick patients with fever, sepsis, splenomegaly, and disseminated intravascular coagulation[31,32].

Platelet viability is no less satisfactory after 7 days of storage than after 5 days[33]. However, when storage was extended to 7 days, bacterial overgrowth and clinical sepsis in recipients of stored platelets occurred with sufficient

Cambridge Books Online © Cambridge University Press, 2009

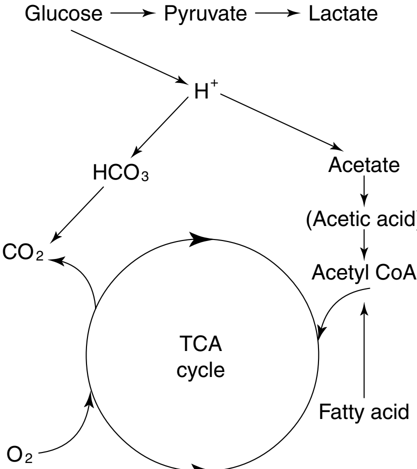

Fig. 46.2. Metabolic pathways and the control of pH during platelet storage at 20–24 °C. Almost all glucose used passes through pyruvate to form lactate and protons (H^+). Little, if any, pyruvate is decarboxylated to acetyl CoA. Rather, fatty acid provides the acetyl CoA for oxidation in the tricarboxylic acid (TCA) cycle. During storage in plasma, protons are buffered by bicarbonate. CO_2 from this source and the TCA cycle leaves the PC through the walls of the container. If there is inadequate oxygen or agitation, glycolysis accelerates overwhelming bicarbonate stores leading to fall in pH. When incorporated into a synthetic medium, acetate can bind a proton and enter the TCA cycle. This provides an alkalizing effect eliminating the need for bicarbonate in the medium.

frequency to warrant limiting liquid storage to five days[34]. If methods of bacterial decontamination[35] or bacterial detection are developed[36], it may be possible to prolong storage beyond 5 days once again.

Assuming, as most do, that platelets deteriorate to some extent during storage even under optimal circumstances, what is the nature of the platelet storage lesion? Some have proposed that it results from platelet activation[37]; others suggest that it is a form of apoptosis[38]. Either would lead to the exposure of phosphatidyl serine on the platelet surface[39]. Whatever the cause or causes of the platelet storage lesion, easily measured in vitro characteristics which correlate best with capacity to circulate in vivo are retention of disc shape and good function in the hypotonic shock response[40]. Platelets with normal discoid morphology generally circulate normally after transfusion. Platelets which are damaged by cold, acid conditions, or bacterial contamination generally lose their discoid morphology and become spheres. Normal discoid morphology is reflected by the 'swirling' or 'shimmering' appearance of well-preserved PC during gross, visual inspection[41,42]. Blood bank and clinical personnel are urged to check PC for this phenomenon prior to transfusion.

Frozen storage

The most widely studied method for frozen storage employs controlled rate freezing (1 °C per minute), 5% dimethyl sulfoxide (DMSO) as a cryoprotective agent, rapid thawing, graded reduction of the DMSO concentration, and washing prior to infusion. In vivo viability is approximately 40–50% relative to fresh platelets[43] but enhanced in vivo function has been claimed[44]. Most find that this technology is both more complex and expensive and less effective than liquid storage at 20–24 °C[45]. However, these preparations can be effective clinically and may be used for autologous transfusion of selected patients. Platelets may be obtained before myelosuppressive therapy, frozen, and then administered during subsequent periods of thrombocytopenia[46]. Newer approaches using second-messenger effectors may allow the use of lower concentrations of DMSO which would, in turn, allow the direct infusion of platelets after thawing[47].

Experimental approaches and platelet substitutes

Current methods of platelet storage are cumbersome; the duration of permissible storage is short; and 20–24 °C favours bacterial overgrowth. It would be ideal to find ways to protect platelets against the damaging effects of cold temperatures or to have a dried preparation with long shelf-life that one could simply rehydrate and infuse. A great deal of research is going on in this area examining platelets treated with paraformaldehyde and lyophilization, lyophilized platelet membrane microvesicles, fibrinogen-coated beads, albumin microspheres, and others[48]. This is an important area, but all of these ideas await validation in appropriate clinical trials.

There are also non-transfusional drugs that may help to stop thrombocytopenic bleeding. Antifibrinolytic amino acids such as aminocaproic acid and tranexamic acid would not be thought of as 'platelet substitutes'. However, they have been described as effective in controlling mucosal and dental bleeding in thrombocytopenic patients without increasing the platelet concentration in the blood[49].

Clinical response to platelet transfusion

Patients with thrombocytopenia secondary to bone marrow failure

The majority of platelet transfusions are given to patients with thrombocytopenia due to decreased platelet production secondary to bone marrow disease or myelosuppressive treatment. Normally circulating platelets are in equilibrium with a pool of platelets in the spleen with one in the spleen for every two in the circulation[50]. Therefore, one-third of infused platelets will be pooled reversibly in a spleen of normal size. The fraction may be much larger if the spleen is enlarged. Assuming that the recipient's blood volume is 2.5 litres/m^2 body surface area (BSA), the infusion of one unit of whole-blood-derived PC, containing 0.8 $\times 10^{11}$ platelets, should result in an increase in platelet concentration in the blood of 21 000 per mm^3 in a recipient with 1m^2 BSA. The response to one unit will be inversely proportional to the patient's size expressed as the BSA. Thus, one can evaluate the response to a platelet transfusion by calculating the corrected count increment or CCI[51]:

$$\frac{\text{Measured increase in platelet concentration} \times \text{BSA(m}^2\text{)}}{\text{Number of units infused (or number of platelets} \times 10^{11}\text{)}}$$

The measurement of CCI has been criticized[52], but it is the most widely used method for assessing response. In practice, it can be measured 10 minutes to a few hours after transfusion[53]. Under optimal circumstances, the response should be 21 000 per mm^3 per m^2 per unit infused or 26 000 per mm^3 per m^2 per 10^{11} platelets infused.

In practice, in patients with thrombocytopenia secondary to marrow failure, the average CCI is approximately one half of that prediction, 10 000 per mm^3 per m^2 per unit infused[51]. Many studies have attempted to identify the factors responsible for this less than optimal response in real life[32,51,54–58]. Alloimmunization has been incriminated along with a variety of non-immune factors such as platelet storage, bacterial sepsis, concomitant use of antibacterial antibiotics and Amphotericin B, graft-vs-host disease, splenomegaly, disseminated intravascular coagulation, and simply having had a recent allogeneic bone marrow transplantation. It is of interest that no one factor predominates in the majority of studies, suggesting that the crucial factors vary with the populations of patients being studied. Often, none of these factors are present but the response is mediocre. It is likely that other factors, as yet undefined, are at work as well.

After a transfusion, the time until the platelet concentration returns to baseline (time to next transfusion) also varies with the immune and nonimmune factors affecting

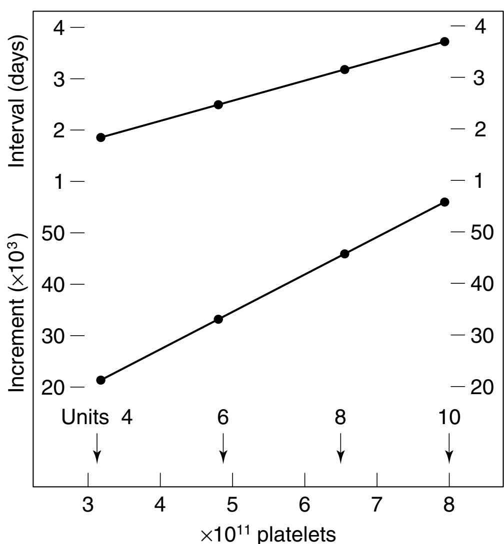

Fig. 46.3. Average response to platelet transfusion, 2 m^2 adult patient. The expected immediate increment in platelet concentration in the blood and the time for the platelet concentration to return to baseline (transfusion interval) are given relative to the platelet dose. Units, whole-blood-derived PC.

the initial CCI[59]. Furthermore, platelet survival is reduced in all patients with thrombocytopenia, regardless of the cause, with progressive reduction as the platelet concentration in the blood becomes lower[60]. Therefore, time to next transfusion varies directly with the height of the platelet concentration achieved by the transfusion and, therefore, the dose of platelets that was administered[61–63]. Everything else being equal, the larger the dose, the higher the platelet concentration achieved by transfusion, and the longer the time will be to the next transfusion (Fig. 46.3).

Platelet dose

If, as described above, the average patient has an increase in platelet concentration of 10 000 per mm^3 per m^2 per unit of platelets transfused, one can calculate the relationship between the dose administered and the average rise in the platelet concentration to be expected. Furthermore, using calculations and data[60–63], one can estimate the average time to the next transfusion. For example, for the transfusion of a myelosuppressed patient with a 2 m^2 surface area these values are given in Fig. 46.3. If the patient was not bleeding, was being transfused prophylactically, and was hospitalized so that he could be transfused again 48 hours later, five units of whole-blood-derived platelets or 4×10^{11} apheresis platelets would probably be satisfactory since raising the platelet concentration by 20 000–30 000 per

Cambridge Books Online © Cambridge University Press, 2009

mm^3 protects most thrombocytopenic patients against spontaneous, catastrophic bleeding, and there would be a 2-day transfusion interval. On the other hand, for the doses given in Fig. 46.3, the platelet concentrations achieved in a 1 m^2 patient would be twice those in Fig. 46.3 and lower doses would probably be satisfactory.

However, ten units (8.0×10^{11}) or more would be a better choice for the 2 m^2 patient if the goal was to achieve a platelet concentration over 50 000 per mm^3 because the patient was bleeding or was being prepared for an invasive procedure.[64] It is probably most critical to achieve this higher level of platelet concentration if the surgical field is highly vascular, as with inflammation or portal hypertension; if there are coexisting defects in plasma coagulation; if the procedure is 'blind' as in needle biopsy of the liver, when there is no opportunity to achieve hemostasis mechanically; or if the surgery is in an area where even a small hemorrhage could be disastrous, as in the central nervous system. A higher dose might also be chosen to facilitate transfusion in the outpatient setting where a longer transfusion interval would be preferable. However, patients vary dramatically in their responses. Therefore, the measurement of increments 1 and 24 hours after transfusion is a cost-effective way to modify the dose and frequency of transfusion based on the pathophysiology of the individual patient.

All of these considerations stress that no single dose meets the needs of all patients. On the other hand, one could argue for using the highest possible dose in all patients since increments are higher and fewer episodes of transfusion are required because of the longer interval between transfusions. However, theoretical considerations[61] and patient data[65] suggest that more platelets are utilized with such a strategy than with frequent, low-dose transfusions.

Platelet transfusion trigger

A thrombocytopenic patient who is actively bleeding requires platelet transfusion. It is more difficult to decide about transfusion if the platelet count is simply very low and the patient has no hemorrhagic signs or only minor ones such as petechiae or small ecchymoses of the skin. Clinical experience suggests that, if the platelet count is low enough, long enough, 'spontaneous', major hemorrhage, particularly into the central nervous system, may occur. Unfortunately, in an individual patient, we do not know how low and how long.

Studies of patients with acute leukemia carried out 40 years ago, prior to the availability of platelet transfusion, described the relationship between platelet concentration in the blood and clinical hemorrhage[66]. Minor and major hemorrhage began when the platelet concentration fell below 50 000 and 20 000 per mm^3, respectively. Major hemorrhage was observed in the range, 5 000–20 000 per mm^3, but on only 3% of patient days. There was no cut-off between bleeding and non-bleeding patients in that range, but there was a rapid increase in the rate of major bleeding when the platelet concentration fell below 5 000 per mm^3 reaching a frequency of 33% of patient–days as the platelet concentration approached 0 per mm^3.

Subsequently, the same group described the effect of prophylactic platelet transfusion administered whenever the platelet concentration fell below 20 000 per mm^3 [67]. There was a striking reduction in major hemorrhage when the platelet concentration (measured pretransfusion) was below 5 000 per mm^3 but no substantial change in the range, 5 000–20 000 per mm^3. Nonetheless, for many years, this experience was used to justify prophylactic platelet transfusion whenever the platelet concentration fell below 20 000 per mm^3, although the data could have been used to support 5,000 per mm^3 as an appropriate trigger.

More recently, prospective but uncontrolled studies by one group supported the safety and efficacy of a more restrictive policy using 5 000 per mm^3 as the platelet transfusion trigger[68,69]. Subsequently, three prospective studies assigned patients to one of two groups receiving prophylactic platelet transfusion at either 10 000 per mm^3 or 20 000 per mm^3 [70–72]. Uniformly, there was no increase in bleeding risk at the lower transfusion trigger which is now being adopted by many transfusion services[73].

However, it is likely that it is just as unjustified to choose a rigid, unvarying transfusion trigger as it is to choose a rigid, unvarying transfusion dose. Clinical factors may increase the risk of hemorrhage at any given platelet concentration. These include fever and sepsis, administration of drugs that interfere with platelet function, coexistent abnormalities of plasma coagulation factors, and high leukocyte concentrations in the blood. It is appropriate to raise the transfusion trigger in complicated, clinically ill patients of this type.

In addition, moderate to severe bleeding is observed in 11–23% of patients after bone marrow transplantation in spite of the aggressive use of prophylactic platelet transfusion and maintenance of morning platelet counts above 20 000 per mm^3 [74,75]. The types of bleeding are most commonly gastrointestinal and urinary and less commonly pulmonary and intracranial. Usually, there is an identifiable anatomic cause such as gastrointestinal ulceration, hemorrhagic cystitis, or diffuse alveolar hemorrhage. In effect, it is common in the myelosuppressed patient to be treating bleeding, not preventing it. Many

Cambridge Books Online © Cambridge University Press, 2009

centres increase the transfusion trigger to 30 000 or even 50 000 per mm^3 in such cases just as one would prior to a surgical procedure[74].

Thrombocytopenia due to platelet loss, sequestration, or destruction

As described in the previous section, most patients receiving platelet transfusion have a defect in platelet production. However, many patients with other types of thrombocytopenia and platelet dysfunction are transfused as well.

Massive transfusion of red cells

Dilutional thrombocytopenia will occur when massive blood loss is replaced with units of stored red cells which lack viable platelets. Following replacement of one blood volume, 35–40% of the original platelets usually remain. Even when one to two blood volumes have been replaced, abnormal bleeding usually does not develop, and routine transfusion is not indicated simply because the platelet concentration in the blood is low[76]. Platelets should be given to patients who demonstrate abnormal bleeding.

Cardiopulmonary bypass

Immediately following and for several days after cardiopulmonary bypass, the platelet concentration commonly falls to subnormal levels, occasionally as low as 50 000 per mm^3. There is an associated defect in platelet function. Prospective studies have shown no benefit from the prophylactic administration of platelet transfusions to such patients[77]. Just as in the case of massive transfusions, they should be reserved for the relatively rare patient who demonstrates clinically abnormal bleeding.

Splenomegaly

As mentioned previously, patients with massive splenomegaly have thrombocytopenia related predominantly to excessive sequestration in a splenic pool in continuous exchange with platelets in the circulation[50]. The platelet concentration rarely falls below 30 000 per mm^3 due to this mechanism alone, so that platelet transfusion is rarely considered except in anticipation of invasive procedures. Depending on the degree of splenic enlargement, one may have to administer 10 to 15 units of whole-blood-derived PC per m^2 body surface area to achieve a substantial increase in platelet concentration. In many patients with very marked splenomegaly, it may not be possible to achieve platelet concentration elevations even with very large doses of PC.

Idiopathic thrombocytopenic purpura (ITP)

In ITP, platelet transfusion is generally not used because the bleeding tendency is less severe than in thrombocytopenia due to diminished production, and the response to medical therapy is generally satisfactory and rapid (see Chapter 4). Furthermore, the survival of transfused platelets is relatively brief, similar to that of the patient's own platelets. Nonetheless, when there is critical bleeding or need for urgent surgery, platelet transfusion will generally raise the platelet count substantially for 12 to as long as 48 hours[78]. The same general principles apply to other diseases in which there is accelerated destruction of platelets, such as disseminated intravascular coagulation.

Neonatal alloimmune thrombocytopenia

In this syndrome, the mother produces an alloantibody against antigens on fetal platelets that have crossed the placenta (Chapter 6). The antibody, in turn, crosses the placenta, causing in utero thrombocytopenia, beginning as early as 20 weeks gestation. Intracerebral hemorrhage may occur in utero. The thrombocytopenia may persist for weeks after delivery. The most common antibodies is to HPA-1a (Pl^{A1}) but antibody to other platelet antigens may be involved as well.

It is common for this disease to present with the delivery of a severely thrombocytopenic newborn at the end of a first pregnancy to the surprise of the attending physicians. It is optimal to transfuse the newborn with platelets which lack the antigen to which the antibody has been formed. Since maternal platelets are compatible, platelets harvested from the mother's blood by apheresis can produce an increase in the platelet concentration of the blood of the infant (Fig. 46.4)[79]. Ideally, such platelets should be concentrated in a small volume of plasma to avoid infusing additional antibody.

Unfortunately, it is often difficult to arrange for apheresis of the mother. A randomly selected unit of platelets may raise the neonate's platelet concentration substantially[80]. If it does not, prompt serologic evaluation of the mother and father can identify the antigen to which the antibody has been formed. If the antibody is directed against HPA-1a (Pl^{A1}), platelets lacking HPA-1a (i.e. homozygous HPA-1b) can be used to support the infant[81]. One must be certain that the mother has not also formed antibody to HLA antigens which might be present on the donor's platelets[82].

Cambridge Books Online © Cambridge University Press, 2009

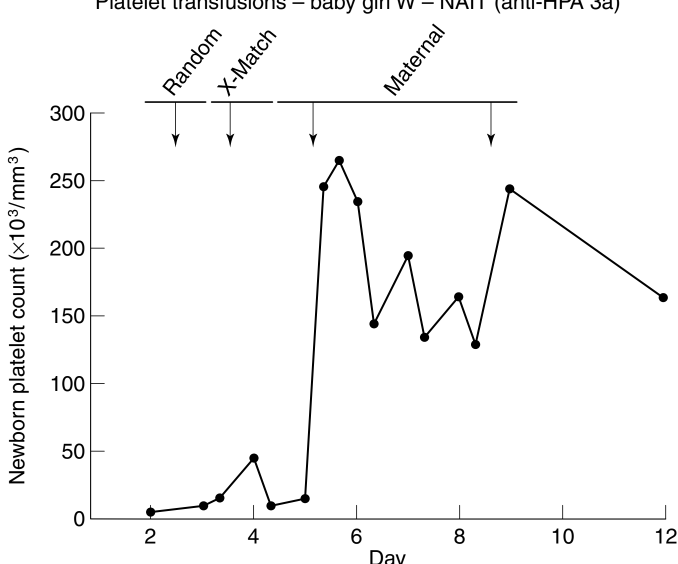

Fig. 46.4. Platelet transfusions in newborn with neonatal alloimmune thrombocytopenia secondary to anti HPA3a, BAK[a]. There was poor response to randomly selected and cross-matched platelets from unrelated donors. Platelets from the mother provided an excellent response on two occasions.

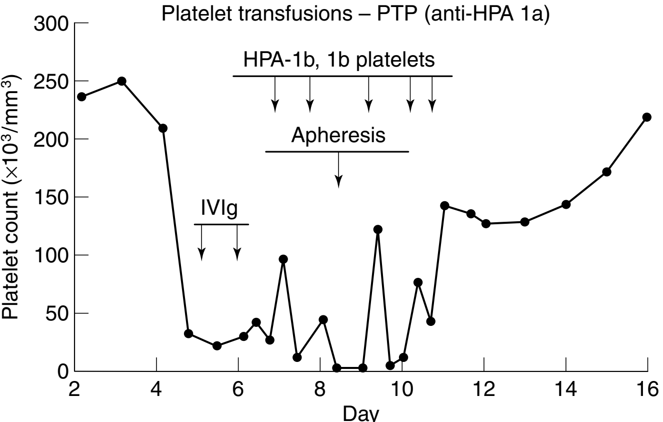

Fig. 46.5. Platelet transfusions in women with post-transfusion purpura associated with anti HPA1a, Pl[A1]. The patient developed severe thrombocytopenia and subarachnoid hemorrhage 8 days after blood transfusion during an aortic aneurysm repair. Randomly selected platelets produced severe rigors, chills, and hypertension. On five occasions, she had no adverse reactions and good increments in platelet concentration after transfusion with platelets from Pl[A1] negative (HPA-1b homozygote) donors. Data courtesty of Dr Alison Wakoff.

Should there be a subsequent pregnancy, the recurrence rate is high (>85%). Thus, there may be further requirements for platelet transfusion of the fetus in utero to prevent serious bleeding before delivery[83,84]. Some protocols call for weekly fetal blood sampling beginning at 20 weeks gestation with transfusions of platelets to the fetus each time. Variations of the normal apheresis procedures can be used to produce highly concentrated platelets from either the mother or a normal donor who lacks the antigen to which the antibody has formed[84].

Post-transfusion purpura

In this complex illness (Chapter 7), shortly after red cell transfusion, the patient develops an alloantibody to a platelet antigen (generally HPA-1a, Pl[A1]) on the platelets present in the transfused red cells. Autologous platelets lacking that platelet antigen are destroyed as well by mechanisms which are poorly understood. Random platelet transfusions are thought to be ineffective and may cause severe febrile and anaphylactoid reactions. HPA-1a-negative platelets may give some benefit[85]. Figure 46.5 provides an example of a patient where that seemed to be the case.

Hereditary thrombocytopenia

These syndromes are rare and generally not associated with severe bleeding (Chapter 2). Since the survival of allogeneic platelets is normal, platelet transfusion is quite effective and may be used for critical bleeding and surgery.

Qualitative platelet disorders

In spite of normal platelet counts, patients with qualitative platelet disorders have a clinical bleeding tendency associated with abnormal in vitro tests of platelet function and a prolonged bleeding time in vivo. The basis may be hereditary or acquired (Chapters 10–13). Platelet transfusion is generally not indicated when the cause is extrinsic to the platelet, as in uremia, von Willebrand disease, and hyperglobulinemia, since the transfused platelets will function no better than the patient's own platelets. There are exceptions in certain types of von Willebrand's disease in which normal platelets can be used to deliver their content of von Willebrand factor to a bleeding site[86]. Most inherited intrinsic disorders are mild and do not require platelet transfusions even for surgery if the procedure is carried out under direct vision, so that hemostasis may be achieved mechanically. If the bleeding tendency is more severe, as in

Cambridge Books Online © Cambridge University Press, 2009

thrombasthenia, platelet transfusions may be necessary for more severe bleeding and surgery. The acquired defects, as in the myeloproliferative and myelodysplastic syndromes, generally do not require platelet transfusion unless there is coexistent thrombocytopenia.

Possible contraindications to platelet transfusion

Concern has been voiced that platelet transfusions should not be administered to patients with forms of thrombocytopenia associated with thrombosis such as thrombotic thrombocytopenic purpura (TTP) and heparin-induced thrombocytopenia (Chapters 8, 9). It is reasoned that platelets participate in thrombus formation and that transfusions may precipitate deterioration of the disease; there are anecdotal reports of such events[87,88]. However, particularly in TTP, platelet transfusion is often requested prior to invasive procedures such as the insertion of intravenous catheters for therapy with apheresis or in response to severe clinical bleeding. The author's experience has been that platelet transfusions are safe in this setting. However, it seems prudent not to administer prophylactic platelet transfusions simply because the platelet concentration is low in these diseases.

Complications of platelet transfusion – prevention and management

There are many complications of platelet transfusion (Table 46.1). Paradoxically, the majority are not due to the platelets themselves but rather to contaminating leukocytes, red cells, plasma proteins, and microorganisms.

Complications due to contaminating leukocytes

Alloimmunization to Class I HLA antigens

Human leukocyte antigens (HLA) are expressed on integral membrane glycoproteins. Almost all cells have Class I antigens (A, B, and C subloci), whereas only a few types of circulating leukocytes (dendritic cells, monocytes, and subsets of B cells) have Class II antigens. Primary alloimmunization to Class I HLA antigens appears to require presentation of such antigens on cells that also express Class II antigens and other costimulatory molecules[89]. There is now abundant evidence that the incidence of HLA alloimmunization can be reduced by the consistent use of leukoreduced blood products[90,91].

Table 46.1. Complications of platelet transfusion

Due to contaminating leukocytes
Alloimmunization to Class I HLA antigens
Refractoriness to platelet transfusion
Febrile nonhemolytic transfusion reactions (FNHTR)
Cytokine formation
FNHTR
Transmission of cytomegalovirus (CMV)
Graft-vs.-host disease (GVHD)
Reactions associated with bedside leukoreduction filters
Due to contaminating red cells
Rh alloimmunization
Parasites – malaria, babesiosis
Due to plasma and its contents
Contaminating microorganisms
Bacteria
Viruses – HCV, HIV, HBV
Parasites – Chagas Disease
Plasma proteins
Allergic reactions
IgA in patients with IgA deficiency
? FNHTR
ABO antibodies
Transfusion-related acute lung injury (TRALI)
Due to platelets themselves
Alloantibodies to platelet-specific antibodies
? Allergic reactions to platelet products

However, it remains to be seen how completely leukoreduction can eliminate alloimmunization. In one study[92], leukoreduction had almost no effect on the development of alloimmunization in patients who had been previously exposed to foreign leukocytes either through pregnancy or transfusions that had not been leukoreduced. It may be that leukoreduction will prove to be less effective in preventing secondary as opposed to primary alloimmunization. However, another trial[90] showed efficacy of leukoreduction in such patients but failure in some patients who had not been previously exposed to foreign leukocytes.

Traditionally, platelet transfusions have been begun with PC from random donors and continued until HLA alloimmunization is suspected because there have been two or three consecutive platelet transfusions with CCI less than 3000 per mm^3 per m^2 per unit[93]. In the future, it may be wise to screen patients intermittently for HLA antibody so that HLA alloimmunization can be detected prior to refractoriness rather than vice versa. HLA alloimmunization can be confirmed in the laboratory by performing a lymphocy-

Cambridge Books Online © Cambridge University Press, 2009

totoxicity (LCT) assay for HLA antibody in the patient's serum. In this assay, leukocytes from 50–100 donors with an appropriate heterogeneity of HLA types are incubated with the patient's serum and complement. LCT is assessed microscopically. The presence of such antibody has been a good predictor of poor response to platelets from randomly selected donors[94] and improved response when platelets are HLA selected[95]. Many centres consider it inappropriate to issue platelets matched according to HLA type unless this or a similar test has demonstrated HLA antibody anticipating that matching will provide little benefit if antibody is not present[96,97]. The pattern and intensity of immunization varies greatly from patient to patient. An LCT assay can be characterized by the percentage of cells in the panel against which the patient's serum reacts, i.e. the percentage reactive antibody (PRA). Furthermore, the pattern of reactivity can be analysed to determine the antigens to which the patient has formed antibody. Patients may have PRAs at any level between 1 and 100%.

The incidence and severity of HLA alloimmunization should be gradually decreasing as the use of leukoreduced blood products becomes increasingly popular. The following discussion is based on data accumulated before widespread leukoreduction was in use. Approximately 10% of patients presenting for therapy of diseases requiring platelet transfusion will already have LCT antibodies from prior transfusions and pregnancies[98]. Another 30% become alloimmunized during therapy and 60% never do[98]. There is no known difference between those who do, and do not, become immunized. Among those who do, some will do so after only 2–4 transfusions whereas others require dozens of transfusions[99]. The majority of patients who become alloimmunized establish a level and specificity of immunization and tend to maintain that status as they continue to be transfused[100–102]. However, approximately 30% lose their antibodies over time in spite of continuing transfusion[100]. Thus, it is helpful to monitor antibody levels and specificity since such patients may regain responsiveness having been previously refractory.

The antigenic specificities of the HLA antibodies formed by these patients vary dramatically. Crossreactive groups (CREGs) of HLA antigens have been defined by serological testing. Crossreactivity among antigens in a CREG is based on the sharing of one or more public epitopes by those antigens[103]. It is common for some patients to develop antibodies to one or more public epitopes, i.e. one or more CREGs, while others develop antibodies to one or more private antigens within a CREG[104]. Furthermore, some patients demonstrate intraCREG antibodies, i.e. antibodies to antigens in the same CREGs as the patient's own antigens[105]. These facts have major implications for management.

Table 46.2. Classification of donor/recipient pairs on the basis of HLA Class I matching

A	All four antigens in donor identical to those of recipient.
B1U	Only three antigens detected in donor; all present in recipient.
B1X	Three donor antigens identical to recipient; fourth antigen cross-reactive[a] with recipient.
B2U	Only two antigens detected in donor; both present in recipient.
B2UX	Only three antigens detected in donor; 2 identical with recipient, third cross-reactive.
B2X	Two donor antigens identical to recipient; third and fourth antigens cross-reactive with recipient.
C	One antigen of donor not present in recipient and not cross-reactive with recipient.
D	Two antigens of donor not present in recipient and not cross-reactive with recipient.

Note:
[a] Antigen in a cross-reactive group (CREG) which contains one of the patient's antigens.

Management of the refractory patient

Techniques have evolved so that there are now three approaches which are useful in the management of alloimmunized patients. In 1969, it was shown that refractory patients would respond to platelets from siblings who were identical for all four Class I HLA antigens[106]. Similarly, patients could be supported by platelets from unrelated donors who were HLA-identical or closely matched. Because some patients do not make antibody to antigens within their own CREGs, it became popular to choose donors according to CREG classification, particularly BX matches, i.e. donors whose antigens are identical to or within the same CREGs as those of the patient[107]. Table 46.2 shows the categorization of such matches.

Responses were better with such matching than with random donor selection, but many BX matches failed and many C and D matches succeeded. Some patients with relatively low PRAs have antibody to only one or two CREGs so that success with some C and D matches would be expected by chance. On the other hand, failure of some BX matches would be expected in patients with intraCREG antibody. One study[108] described BX matching pairs that frequently failed and another[109] found BX matches to be no better than randomly selected platelets.

In the late 1980s and early 1990s, practical methods for platelet crossmatching became available[110]. Many centres found that they could simply crossmatch patient's serum with unselected AP-PC in inventory to find, within hours, a

Cambridge Books Online © Cambridge University Press, 2009

compatible product that would be successful in vivo[54,110]. However, it was recognized[110] that, in a highly immunized patient, one might crossmatch with dozens of donors and not find a compatible product. For many such patients, only the identification of an A or BU match (Table 46.2) will suffice.

Yet another approach has been recently proposed[101]. If the PRA in the LCT assay is less than 100%, one should be able to identify the HLA antigens to which the patient has not formed antibody. The patient can then be supported with ‘antigen-negative’ platelets, i.e. platelets which lack the antigens to which the patient has formed antibody. If the results of the LCT assay are known, one can often provide a product from inventory on an urgent basis using this approach.

There is no reason that one of these three approaches should be chosen to the exclusion of the other two[102]. If the PRA is less than 70%, successful support can usually be provided by crossmatching of random products or by ‘antigen-negative’ platelets. When the PRA is high (>80%), one can select for cross-matching the best available ‘antigen-negative’ HLA matches and/or selectively recruit A and BU matches from an HLA-typed donor file. Some patients with common HLA types, 1,2/7,8 for example, will have dozens of A and BU matches available. Unfortunately, some patients have rarer HLA types and will have no A or BU matches to recruit.

Role of ABO and platelet-specific antibodies in refractoriness to platelet transfusions

ABO determinants are carried by both glycoproteins and glycolipids of platelets, as they are on red cells[111]. Group O patients commonly have a good response to platelets from group A or B donors, but, in a subset of patients, the response can be poor[112] or very poor[113]. On the other hand, transfusing group A or B patients with platelets from group O donors exposes the recipient’s red cells to anti-A and anti-B in the donor’s plasma. Accelerated destruction of the patient’s red cells is rare[114], but frank acute hemolysis has been observed[114–116]. Furthermore, it has been proposed that formation of immune complexes between A and B substance and corresponding antibodies may have deleterious effects[117]. Thus it seems wise to observe ABO compatibility when possible.

The platelet surface carries many platelet-specific antigens which are quite capable of eliciting a strong alloantibody response as in neonatal alloimmune thrombocytopenia and post transfusion purpura. It is surprising that there are only a few case reports of such alloantibodies accounting for refractoriness to platelet transfusion[118–121]. It appears that fewer than 10% of multi-transfused patients develop platelet-specific antibody[90]; those who do also tend to form HLA antibodies.

Febrile and allergic transfusion reactions

Acute reactions to platelet transfusions are generally classified as febrile (fever, chills) or allergic (urticaria, rash, dyspnea, and bronchospasm). Prior to the availability of methods for leukoreduction, approximately 20% of platelet transfusions were accompanied by febrile reactions[122]. Some of these reactions were undoubtedly due to antibodies in the patient directed against either leukocyte-specific or HLA antigens on leukocytes contaminating the PC. Leukocyte depletion by filtration during infusion reduced the frequency of these reactions, but many continued to occur[122,123]. It is now clear that contaminating leukocytes produce inflammatory cytokines such as interleukin-1, interleukin-6, interleukin-8, and tumour necrosis factor-alpha during storage at 20–24 °C and that these compounds are responsible for many febrile reactions since they are not removed by bedside filtration[124,125]. Thus febrile reactions occur more frequently when the PC are transfused at their end of the storage interval[126,127]. These reactions provide a strong argument for routine, prestorage removal of leukocytes.

Nonetheless, febrile reactions occur in approximately 2% of platelet transfusions even with prestorage leukoreduction[128]. Furthermore, it appears that contaminating leukocytes are not involved in the production of allergic reactions[126,129]. The origins of these reactions are not known. They may be related to plasma proteins or products produced during storage by the platelets themselves. In patients who develop these difficult problems, one can wash the platelets free of plasma prior to infusion[130].

Finally, there may be complications of platelet transfusion related to the removal of leukocytes by filtration of PC at the bedside. Severe hypotension has been reported[131] predominantly when negatively charged leukocyte reduction filters are used in patients who are receiving angiotensin-converting enzyme inhibitors[132]. One proposed mechanism is that high molecular weight kininogen is converted to bradykinin, a potent vasodilator, by exposure to a negatively charged surface. Bradykinin is normally metabolized by ACE in a few seconds, but may circulate much longer in patients receiving ACE inhibitors. Although the mechanisms behind these hypotensive reactions are still hypothetical and more work needs to be done, this type of reaction provides another reason for prestorage rather than bedside leukoreduction. Prestorage leukoreduction at the blood centre offers the advantage that it is carried out under standardized conditions following good manufacturing practices (cGMP) with appropriate quality control

Cambridge Books Online © Cambridge University Press, 2009

procedures in place. Such standardization is not possible with filtration at the bedside.

Transmission of cytomegalovirus (CMV)

In asymptomatic carriers, this virus resides in the nuclei of subsets of leukocytes with little virus free in plasma. It has been shown that the use of leukoreduced blood components is essentially equivalent to the use of components from donors who have negative tests for CMV antibody in terms of risk of CMV transmission[133]. Since this infection is particularly dangerous for severely immunocompromised patients such as those who have had a recent allogeneic bone marrow transplantation, some clinicians continue to use CMV-negative blood products along with leukoreduction in this select population.

Graft-vs.-host disease (GVHD)

Immunosuppressed patients may develop graft-vs.-host disease (GVHD) from T-lymphocytes present in any transfusion, including platelet transfusion. Thus, it is standard practice to treat PC with gamma irradiation to inhibit proliferation of these T-lymphocytes when the recipient had been heavily immunosuppressed[134]. Clinicians are progressively applying this practice to all patients who have received cytotoxic chemotherapy. Exposure to 5 000 rad appears to have no deleterious effect on platelets. It is important to emphasize that current methods of leukoreduction do not remove enough T-cells to prevent GVHD.

Complications due to contaminating red cells

When transfusing PC to girls or young women who are Rh-negative, one needs to be concerned about the possibility of sensitization by Rh-positive red cells contaminating infused platelets. In practice, sensitization is rather uncommon in immunosuppressed patients[135]. However, where possible, one should administer platelets from Rh-negative donors. When this is not possible, one can administer Rh immunoglobulin (RhoGAM), about 20 microgram intramuscularly per unit of platelets, so that the infused red cells will be cleared prior to sensitization. A full dose of RhoGAM, 300 μg, is sufficient to suppress the immune response to 15 ml of Rh positive red cells.

There are enough red cells contaminating PC to transmit both malaria and babesiosis if the donor is parasitemic with these infections.

Complications due to plasma and its contents

Contaminating microorganisms

Storage of PC at 20–24 °C allows proliferation to dangerous levels of bacteria that occasionally contaminate units of whole-blood-derived or AP-PC[34]. Contamination may occur because of asymptomatic bacteremia in the donor or at the time of venipuncture because of inadequate decontamination of the skin or because of venipuncture through areas of the skin where bacterial colonization is deeper than can be reached by such decontamination. Bacterial contamination which might not be clinically significant after 2–3 days of storage may become so after 5–7 days. As previously mentioned, PC storage is limited to 5 days for this reason.

The magnitude of this problem is commonly underestimated[136]. Estimates suggest that there may be contamination of 5–10 per 10 000 whole-blood-derived PC and 150 clinical episodes associated with severe morbidity and death in the United States per year[137]. This equates to one episode of severe morbidity or mortality per 20 000 platelet transfusions which is 50- to 250-fold higher than the risk of mortality from transmission by transfusion of human immunodeficiency virus (HIV) or hepatitis B or C infection.

There are several potential approaches to this important problem. Because apheresis involves only one donor and one venipuncture, there may be less risk than for pooled whole-blood-derived PC, although this has not been conclusively demonstrated. Under investigation are methods for screening platelet products for bacteria before transfusion[36] and methods of viral inactivation which also inactivate bacteria[35]. Parenthetically, the methods of viral inactivation may inactivate T-lymphocytes and prevent GVHD as well[138].

The plasma diluent of PC can transmit viruses such as hepatitis B and C and HIV. Recently improved methods of donor screening and testing have markedly reduced but not totally eliminated this risk. Transmission of the parasite, *Trypanosoma cruzei*, which is responsible for Chagas disease has also occurred with platelet transfusion.

As with any plasma infusion, one may see urticaria, anaphylactic shock in a patient with IgA deficiency and circulating anti-IgA, and transfusion associated acute lung injury (TRALI) when a donor has leukocyte antibodies which can react with antigens on the leukocytes of the recipient[139].

During the past few years we have witnessed a remarkable advance in our understanding of the pathophysiology of coronary atherosclerosis–thrombosis. Here we focus on thrombosis with specific emphasis on the coronary arteries[1–4].

Lesion classification and progression of atherosclerosis–thrombosis

According to the criteria of the American Heart Association Committee on Vascular lesions, plaque progression can be divided into the five phases and various lesion types shown in Fig 47.1[5–7]. The so-called 'vulnerable' type IV and type Va lesions (phase 2) and the so-called 'complicated' type VI lesion (phase 4) are the most relevant to acute coronary syndromes (ACS). The acute type VI lesion that results in an ACS, rather than being characterized by a small mural thrombus, consists of an occlusive thrombus.

Type IV and type Va lesions, although not necessarily stenotic at angiography, may be prone to disruption because of their softness due to a high lipid content and macrophage-dependent chemical properties. Type IV lesions consist of confluent cellular lesions with a great deal of extracellular lipid intermixed with fibrous tissue covered by a fibrous cap, whereas type Va lesions possess a predominant extracellular lipid core also covered by a thin fibrous cap. Phase 2 can evolve into acute phase 3 or 4, and either of them can evolve into a fibrotic phase 5.

Vulnerable lipid-rich plaque and its disruption

Type IV and type Va plaques are commonly composed of an abundant crescentic mass of lipids, separated from the vessel lumen by a discrete component of extracellular matrix (Figs. 47.1, 47.2). Fairly small coronary lesions by angiography may be associated with acute progression to severe stenosis or total occlusion and may eventually account for as many as two-thirds of the patients in whom unstable angina or other ACS develop[8–10]. This unpredictable and episodic progression is most probably caused by disruption of type IV and type V plaques with subsequent thrombus formation, which changes the plaque geometry and leads to acute, or intermittent plaque growth and acute occlusive coronary syndromes. Such plaque disruption seems to depend on both passive and active phenomena.

Passive disruption of plaques

Related to physical forces, passive plaque disruption occurs most frequently where the fibrous cap is thinnest, most heavily infiltrated by foam cells, and therefore weakest. For eccentric plaques, this is often the shoulder or between the plaque and the adjacent vessel wall[11]. Pathoanatomical examination of intact and disrupted plaques and in vitro mechanical testing of isolated fibrous caps from aorta indicate that vulnerability to rupture depends on three factors: circumferential wall stress or cap 'fatigue'; location, size and consistency of the atheromatous core; and blood-flow characteristics, particularly the impact of flow on the proximal aspect of the plaque (i.e. configuration and angulations of the plaque)[5,8,11].

Active disruption plaques

The process of plaque disruption is not purely mechanical. Atherectomy specimens from patients with ACS reveal areas very rich in macrophages[12], and these cells are

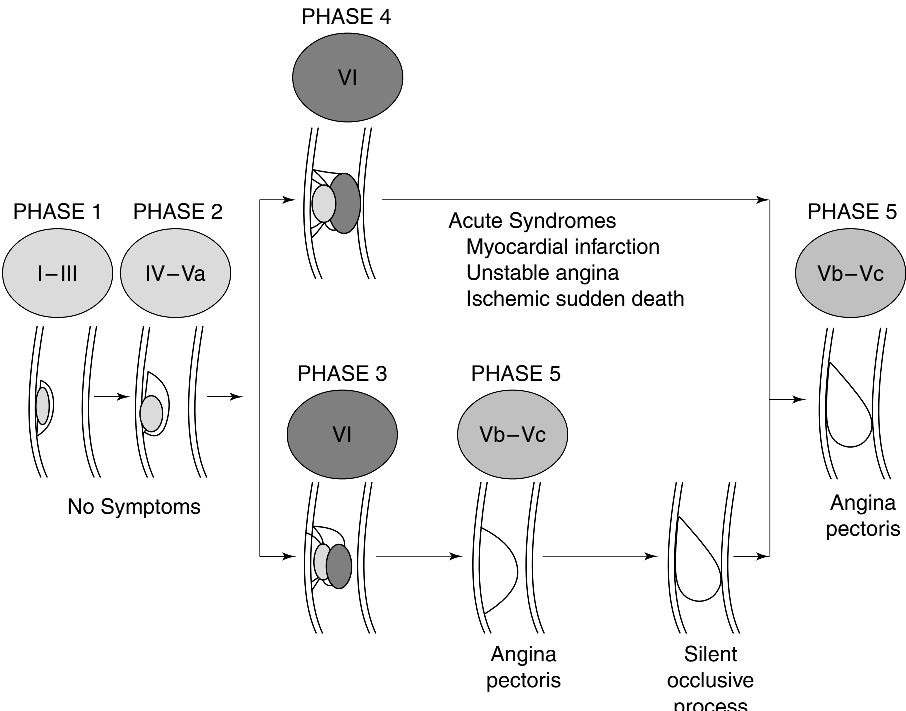

Fig. 47.1. Phases and lesion morphology of progression of coronary atherosclerosis according to gross pathological and clinical findings.

capable of degrading extracellular matrix by phagocytosis or secretion of proteolytic enzymes. Thus, enzymes such as plasminogen activators and matrix metalloproteinases (MMPs, collagenases, gelatinases, and stromelysins) may weaken the fibrous cap and predispose it to rupture[13].

Acute thrombosis

Disruption of a vulnerable or unstable plaque with a subsequent change in plaque geometry and thrombosis results in complicated lesions (Figs. 47.1 and 47.2). Such a rapid change in the geometry of atherosclerotic plaques may result in acute occlusion or subocclusion with clinical manifestations of unstable angina or other ACS. More frequently, however, the rapid changes seem to result in mural thrombus without evident clinical symptoms, which, by self-organization, may be a main contributor to the progression of atherosclerosis. More specifically, at the time of coronary plaque disruption, a number of local and systematic thrombogenic factors may influence the degree and the duration of thrombus deposition (Table 47.1). Such a thrombus may then either by partially lysed or become replaced in the process of organization by the vascular repair response.

Substrate and platelet dependent thrombosis

The platelet is a fundamental element in thrombosis[14]. In the areas with vascular lesion exposure of collagen to circulating blood and thrombin generated through the activation of the coagulation cascade, in addition to systemic agonists, can cooperate to produce a potent and rapid platelet activation process. Another pathway for platelet activation is mediated through ADP that is released by hemolysis of red blood cells in the areas of vascular lesion. ADP stimulates calcium discharge and the release of the platelet granular content. ADP produces the stimulation of neighbouring platelets, recruitment and the triggering of the full reaction for platelet aggregation and thrombus formation.

Serotonin, vasoconstrictor factor derived from the platelet can also stimulate the adrenergic nervous system in the blood vessels. Serotonin receptors are present in the coronary arteries and their stimulation produces vasoconstriction[15]. Dense granules in the platelets are also the place of storage of ADP and calcium. In addition, adhesive proteins such as fibrinogen, fibronectin, vWF, thrombospondin, and vitronectin are stored in the alpha granules of the platelets. The alpha granules contain proteins that promote growth, such as PDGF, TGFβ, and platelet factor

Cambridge Books Online © Cambridge University Press, 2009

Fig. 47.2. Plaque vulnerability, disruption and thrombosis: anatomical changes leading to ACS and subsequent plaque remodelling.

4[16–18]. The alpha granules are also the place of storage of coagulation factors such as factor V, high molecular weight kininogen (HMWK), factor XI, protein S and PAI 1. In these granules albumin and immunoglobulins are also stored. The components of alpha granules are released by the platelets at a lower concentration of agonist than those needed to release the constituents of the dense granules[19,20].

Any of the possible mechanisms of platelet activation induce the subsequent exposure of the platelet receptor glycoproteins (GP) IIb/IIIa. Adhesive molecules such as fibrinogen, vWF, and fibronectin can bind to GP IIb/IIIa and form bridges with other platelets triggering the complete process of platelet aggregation (Fig. 47.3).

In the interaction of the platelet with the vascular wall two surface glycoprotein receptors play a fundamental role. The GP Ib/IX complex is needed for the normal adhesion of the platelets to subendothelial areas, mainly at high shear rate conditions[21,22] presumably through its interaction with vWF[23]. vWF also can bind GP IIb/IIIa[24]. Several studies have suggested a double role for these glycoproteins; thus, they have a role in adhesion and also in platelet to platelet interactions that lead to thrombus formation[22–28]. We may thus conclude that in conditions of high shear rate GP Ib and GP IIb/IIIa are involved in the process of platelet adhesion while GP IIb/IIIa are involved mainly in platelet to platelet interaction. Platelet activation induces structural changes in GP IIb/IIIa that lead to the formation of a heterodimeric complex that works as the receptor for fibrinogen. ADP induces further exposition of binding sites for fibrinogen on the platelet surface. This process generates cohesive binding between platelets and

Table 47.1. Thrombotic complications of plaque disruption: local and systemic thrombogenic risk factors

Local factors
Degree of plaque disruption (i.e. erosion, ulcer)
Degree of stenosis (i.e. change in geometry)
Tissue substrate (i.e. lipid-rich plaque)
Surface of residual thrombus (i.e. recurrence)
Vasoconstriction (i.e. platelets, thrombin)

Systemic factors
Cholesterol, Lp(a)
Catecholamines (i.e. smoking, stress, cocaine)
Fibrinogen, impaired fibrinolysis (i.e. PAI-1), activated platelets and clottings (i.e. factor VII, thrombin generation, factor 112, or activity-FPA)
Infections (*Chlamydia pneumoniae*, cytomegalovirus, *Helicobacter pylori*)?

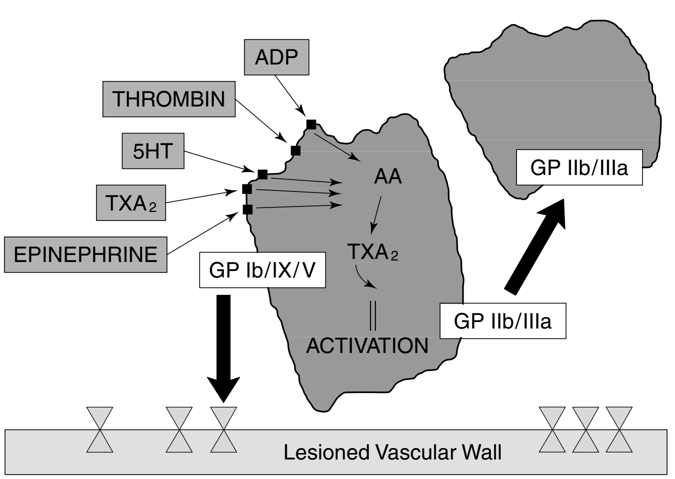

Fig. 47.3. Diagram of platelet activation, adhesion and aggregation.

therefore the growth of the thrombus. Fibrinogen molecules, with dimeric structure, form bridges between GP IIb/IIIa molecules in neighbouring platelets.

New platelet recruitment due to the platelet released products are probably the result of the action of ADP and thromboxane A_2. It is important to emphasize that recruitment produces a significant activation, potentiating aggregation and increasing the thrombotic process.

Finally the thrombotic mass will be consolidated because of the formation of thrombin that can induce the total occlusion of the vessel. The process of thrombus growth, that initially was part of a hemostatic response, will be transformed into an occlusive thrombus that will interrupt blood flow. The intact red blood cells that are reaching the area of thrombus growth respond to the released platelet secretion products increasing the production of prothrombotic substances including arachidonate and eicosanoids[29,30]. This phase of secondary consolidation of the thrombus, because of thrombin, completes the thrombotic process.

Table 47.2. Platelet receptors

Ligand	Receptor	Other names
Collagen	GPIa–IIa	VLA-2, $\alpha_2\beta_1$
	GPIIb–IIIa	$\alpha IIb\beta_3$
	GPIV	GPIIIb
Fibrinogen	GPIIb–IIIa	$aIIbb_3$

Laminin	GPIc–IIa region	VLA-6, a_6b_1

Note:
Vn-R, Vitronectin receptor; vWF, von Willebrand factor.

Glycoproteins and the platelets membrane

Platelet function depends on adhesive interactions and many of the surface glycoproteins in the platelet membrane are receptors for adhesive proteins (Table 47.2). Some of these receptors have been identified, cloned, sequenced and classified among large families of genes that mediate diverse types of cellular interactions[31]. The most abundant is the family of the integrins that includes GP IIb/IIIa, GPIa/IIa, GP Ic/IIa and the receptors of fibronectin and vitronectin in decreasing order of magnitude. The family of genes that include the leucine-rich glycoproteins is represented by the complex of GPIb, a receptor for vWF in unstimulated platelets that is involved in the binding subendothelium, and GP V. Other families of genes include the selectins (GMP 140) and PECAM-1. In addition there is a family of genes that include GP IV[31].

Cambridge Books Online © Cambridge University Press, 2009

Glycoprotein Ib (GPIb)

The GPIb complex is the glycoprotein responsible for the negative charge of the surface of the platelets, due to its high content in sialic acid and carbohydrates. It has two disulfide linked subunits, GP Ibα (143 KDa) and GP Ibβ (22KDa), that are bound not covalently to GP IX in a heterodimeric one to one complex. There are approximately 25 000 molecules of GP Ib per platelet. GP Ibβ and GP IX are transmembrane glycoproteins and they form the globular domain of larger size. The elongated part of the receptor corresponds to the GP Ibα subunit. This glycoprotein complex links immobilized vWF exposed in the vascular subendothelium and initiates platelet adhesion. GP Ib does not bind to circulating plasma vWF because it requires a conformational change that is produced when it is bound to extracellular matrix to be recognized by the receptor. The vWF binding domain is located in aa 251–279 of the GP Ibα subunit[32]. The binding domain in vWF corresponds to a trypsin fragment that extends from aa 449 to 728 and it does not contain the sequence RGD[33]. The cytoplasmic domain of the receptor has as its main function the stabilization of the plasma membrane and maintenance of the platelet shape by linking the plasma membrane to intracellular actin filaments of the cytoskeleton.

Glycoproteins IIb/IIIa (GP IIb/IIIa)

On the surface of unstimulated platelets there are around 50 000 to 80 000 molecules of GP IIb/IIIa (integrin α IIb β_3). The complex is a heterodimer consisting of two transmembrane glycoproteins GP IIb of 136 kD (α-subunit) (GP IIb-β and GP IIb-α linked by disulfide bridges) and one of GP IIIa of 92 kD (β-subunit). In the human species GP IIb and IIIa are synthesized as precursors by different genes, both of them located in the region q21–22 of the larger arm of chromosome 17[34]. The transcription of the gene is also controlled by independent factors. The receptor IIb/IIIa is a calcium-dependent heterodimer that is linked in a noncovalent fashion[35]. Calcium is fundamental for the maintenance of the complex and for the binding of adhesive glycoproteins[36,37]. In activated platelets GP IIb/IIIa is a receptor for fibrinogen, fibronectin, vWF, vitronectin and thrombospondin[38]. The sequences to which the receptor is linked correspond to small peptide sequences RGD present in the adhesive proteins[39]. Fibrinogen contains two RGD sequences in the alpha chain, one in the N-terminal region (aa 95 to 97) and the second in the C-terminal (aa 572–574)[40]. Fibrinogen has a third recognition domain that corresponds to the sequences of 12 aa localized in the C-terminal of the gamma chain of the molecule. This dodecapeptide is specific to fibrinogen and it does not contain the sequence RGD[41].

Activation and exposure of the GP IIb/IIIa receptors

In the non activated platelets the GP IIb–IIIa receptors are unable to bind plasma fibrinogen[42,43]. The receptor activity is acquired as a consequence of platelet activation because of the conformational changes in the heterodimer. Indeed, except for megakaryocytes and platelets this receptor cannot be activated when it is expressed in cell lines, indicating that the expression of this receptor is regulated by specific cell elements either in the lipidic micro-environment or by other intracellular factors[44,45]. Platelet activation signalling is transmitted by mechanisms not yet fully understood through the plasma membrane and produces changes in the relative orientation of the extracellular domain of the GP IIb/IIIa receptor[46]. The binding of plasma fibrinogen to the activated receptor produces changes in the conformation, both in the receptor and in the ligand. The link of GP IIb–IIIa/fibrinogen complexes to the platelet cytoskeleton not only facilitates the anchoring needed for clot retraction but also regulates the reorganization of the cytoskeleton and the formation of a macromolecular complex of enzymes and proteins involved in signal transduction mechanisms[46,47].

Mechanisms of signal transduction in the platelet

The binding of the agonists to the membrane receptors exposed on the platelet surface activates secondary messengers that include inositol-1,4,5-triphosphate (IP3) and diacylglycerol (DG). IP3 produces calcium release from the dense tubular system, increasing free calcium concentration in the cytosol. DG activates a serine/threonine kinase, protein kinase (PK C), inducing its translocation to the membrane and the phosphorylation of proteins in serine and threonine residues. These changes induce granular secretion and exposure of the fibrinogen receptor. Simultaneously, the increase in cytosolic free calcium facilitates the release of arachidonate by phospholipase A2 (PLA2) from the platelet membrane phospholipids. This process can occur both in the plasma membrane and in the membrane of the dense tubular system. Arachidonate is metabolized to thromboxane A2 that is released from the cell, interacts with the receptors of the platelet surface and increases the activation of the platelet (Fig. 47.4).

Cambridge Books Online © Cambridge University Press, 2009

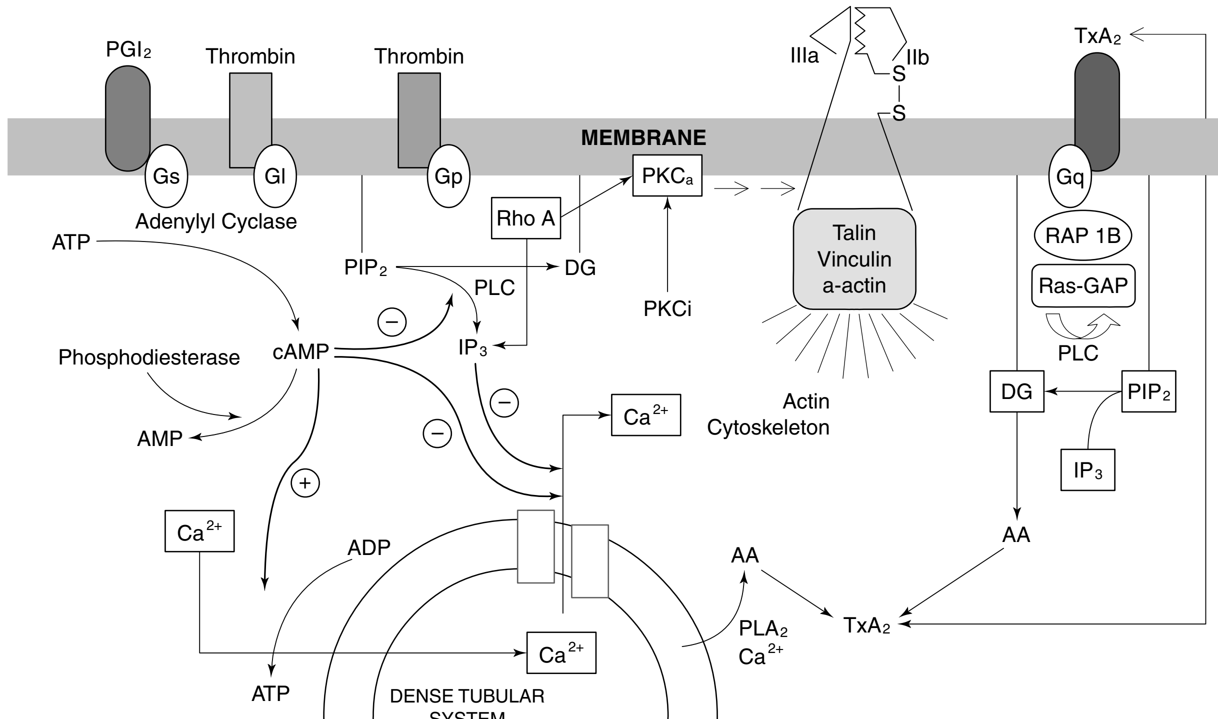

Fig. 47.4. Signal transduction mechanisms in platelet activation.

The activation of the platelet is inhibited when the levels of cyclic AMP (cAMP) are increased. This is the mechanism of action of some inhibitors of platelet function such as prostacyclin (PGI2). Similarly nitric oxide (NO) inhibits platelet function through the activation of guanil cyclase in the cytosol that increases the intracellular levels of cyclic GMP (cGMP)[48]. The elevation of cAMP levels produces the activation of cAMP-dependent protein kinases. Substrates for protein kinases are GP Ib (subunit beta), the actin binding protein, myosin light chain and Rap 1b. It is not fully known how these substrates promote the inhibition of platelet activation. In general agonists for platelet activation inhibit cAMP formation by blocking adenylate cyclase. Other compounds accelerate the metabolism of cAMP by the activation of the phosphodiesterase[49]. When cAMP levels increase in the platelet, free calcium is sequestered in the dense tubular system and PLA2 activity is inhibited[38].

Interaction between agonists and the enzymes responsible for the generation of second messengers is also mediated by G proteins. G proteins are heterotrimers formed by the subunits alpha, beta and gamma. The activation of G proteins is produced by binding to GTP (sometimes also to GDP). Platelets have at least nine types of G proteins. G proteins regulate the hydrolysis of phosphatidylcyoline and the formation of cAMP and are probably involved in the activation of PLA2 and adenylate cyclase[50,51]. Phospholipase C (PLC) is also activated by different G-proteins (Gp and Gq). Adenylate cyclase is stimulated by Gs and inhibited by Gi. We have very little information on PLA2 regulation by G-proteins. RAP1b, a G-protein of low molecular weight, has been shown to form a complex with PLC and Ras-GAP. Other low molecular weight G-proteins could be important in the regulation of vesicular transport and granular secretion in the platelet[52].

Substrate and tissue factor (TF/thrombin)

There is striking heterogeneity in the composition of human atherosclerotic plaques, even in the same individual, and the disruption of plaques exposes different vessel-wall components to blood. Data on the thrombogenicity of disrupted atherosclerotic lesions are limited. In two different experiments, human aortic plaques were exposed to flowing blood at high shear rate and their thrombogenicity was assessed. The studied material included normal intima (free of disease), fatty streaks, sclerotic plaques, fibrolipid plaques, and atheromatous lipid-rich core. The lipid core, abundant in cholesterol ester, displayed by far

Note the significant antithrombotic effect of rTFPI on deposition of platelet and fibrin(ogen) deposition.

the highest thrombogenicity and the most intense TF staining compared with other components[53,54].

TF, a small-molecular-weight glycoprotein, initiates the extrinsic clotting cascade and is believed to be a major regulator of coagulation, hemostasis, and thrombosis. TF forms a high-affinity complex that activates factors IX and X, which in turn leads to thrombin generation[55]. Colocalization analysis of coronary atherectomy specimens (culprit lesions) from patients with unstable angina showed a strong relation between TF and macrophages[56]. This relation suggests a cell-mediated thrombogenicity in patients with unstable angina and ACS. Furthermore, based on recent experimental observations, specific inhibition of vascular tissue factor by the use of r-tissue factor pathway inhibitor (rTFPi) was associated with a significant reduction of acute thrombus formation in lipid-rich plaques[57] (Fig. 47.5, see colour plate). Such observations document the role of TF activity in acute arterial thrombosis after atherosclerotic plaque disruption and open a new therapeutic strategy in the prevention of ACS.

Cambridge Books Online © Cambridge University Press, 2009

Hypercoagulable-dependent thrombosis

In regard to the thrombin generated by the primary activation of TF, the thrombin receptor has 425 aa with transmembrane domains and an NH_2-terminal extracellular domain that is cleaved by thrombin to produce a tethered ligand that binds and initiates the activation of the receptor and the signal transduction mechanisms[58]. Thrombin is a key enzyme in the formation of the thrombus, cleaving fibropeptides A and B from fibrinogen to form insoluble fibrin, which stabilizes the growing thrombus. Both free thrombin and thrombin bound to fibrin are able to transform fibrinogen into fibrin favouring the propagation of the thrombus in the area of the lesion. Simultaneously, platelet activation produces the expression of the fibrinogen receptor in the platelet membrane as discussed before. The process is perpetuated with the arrival of new platelets to the area of the lesion. There is evolving evidence that circulation monocytes and white blood cells may be involved in TF expression and thrombogenicity[59]; indeed, the predictive value for coronary events of high titres of C-reactive protein may be a manifestation of such systemic phenomena[60–63]. Hypercholesterolemia, a high catecholamine drive such as in cigarette smoking, certain chemotactic determinants, and perhaps infections may trigger such hypercoagulable phenomena (Table 47.1). Of interest, in about a third of ACS, particularly in acute sudden coronary death, there is no disruption of a fairly small lipid-rich plaque but just a superficial erosion of a markedly stenotic and fibrotic plaque[64,65]. Thus, complicated thrombi in such cases may well be dependent on a hypercoagulable state triggered by systemic factors mentioned above.

We have reported that normalization of plasma cholesterol concentrations by statins reduces the increased blood thrombogenicity observed in the same patients under hyperlipidemic conditions[66,67]. In addition, the mechanism of action was related more to the lipid-lowering activity than to the specific hypolipidaemic agent used. Systemic infections (e.g. with *Chlamydia pneumoniae*, cytomegalovirus, and *Helicobacter pylori*) have been linked to atherosclerotic disease and its thrombotic complications[68]; increased antibody titres predict future adverse events in patients with postmyocardial infarction. Infectious agents may activate circulating monocytes and white blood cells and create a hypercoagulable state (through synthesis and activation of TF and platelet interaction, as well as by raising fibrinogen concentration); however, recent antibiotic trials of the use of macrolide inhibitors have been inconclusive.

Thrombosis-related vasoconstriction

Although many episodes of unstable angina and acute myocardial infarction are caused by the disruption or erosion of a plaque with superimposed thrombosis, other mechanisms that alter myocardial oxygen supply and demand must be considered. Original studies by Maseri and colleagues[69] indicated that coronary vasoconstriction has an important role. In ACS, vasoconstriction may occur as a response to a mildly dysfunctional endothelium near the culprit lesion or, more likely, may be a response to deep arterial damage or plaque disruption of the culprit lesion itself. Thus, with regard to this second type of vasoconstriction, it seems that a predisposition exists for platelet-dependent and thrombin-dependent vasoconstriction at the site of plaque disruption and thrombosis that may be significant but transient[70]. Thus, platelet-dependent vasoconstriction, mediated by serotonin and thromboxane A_2[71] and thrombin-dependent vasoconstriction occur if the vascular wall has been damaged substantially with de-endothelialization, which suggests the direct interaction of these substances with the vascular smooth muscle cells.

Atherosclerosis-thrombosis and clinical consequences

Stable angina (usually exertional) or stable silent ischemia (exertional or not) commonly result from increases in myocardial oxygen demand that outstrip the ability of stenosed coronary arteries to increase oxygen delivery.

With regard to the pathobiology of ACS[72], in unstable angina, a fairly small fissuring of a lipid-rich plaque, and occasionally a superficial erosion of a fibrotic plaque, may lead to an acute change in plaque structure and a reduction in coronary blood flow, resulting in exacerbation of angina. Transient episodes of thrombotic-vessel occlusion at the site of plaque damage may occur, leading to angina at rest. This thrombus is usually labile and results in temporary vascular occlusion, perhaps lasting only 10–20 min. In addition, release of vasoactive substances by platelets (serotonin, thromboxane A_2), secondary to endothelial vasodilator dysfunction may alter perfusion and myocardial oxygen supply probably accounting for two-thirds of ACS, including episodes of unstable angina. The remainder one-third may be caused by transient increases in myocardial-oxygen demand.

In non-Q-wave myocardial infarction, more severe plaque damage results in more persistent thrombotic occlusion, perhaps lasting up to 1 h. Only about a fourth of patients with non-Q-wave myocardial infarction have an

Cambridge Books Online © Cambridge University Press, 2009

infarct-related vessel occluded for more than 1 h, but the distal myocardial territory is usually supplied by collaterals. Therefore, spontaneous thrombolysis, resolution of vasoconstriction, and presence of collateral circulation are important in preventing the formation of Q-wave myocardial ischemia. In Q-wave myocardial infarction, larger plaque fissures result in the formation of a fixed and persistent thrombus, which leads to an abrupt cessation of myocardial perfusion for more than 1 h, resulting in transmural necrosis of the involved myocardium. Some cases of sudden coronary death probably involve a rapidly progressive coronary lesion in which plaque disruption – commonly a superficial erosion – and resultant thrombosis lead to ischemic and fatal ventricular arrhythmias in the absence of collateral flow. Platelet microemboli may also contribute to the development of sudden ischemic death.

Platelets and atherosclerosis

Peter Verhamme and Paul Holvoet

Cardiovascular Research Unit of the Center for Experimental Surgery and Anesthesiology, University of Leuven, Belgium

Cardiovascular diseases remain the principal cause of morbidity and mortality in the Westernized world. Atherosclerosis is the common pathophysiological process underlying ischemic heart disease, cerebrovascular accidents and peripheral vascular disease. Understanding of the pathogenesis of atherosclerosis has tremendously increased in the last decade. For years, atherosclerosis had been considered as a degenerative process of the arteries. Nowadays, atherosclerosis is seen as an inflammatory disease of the artery resulting from chronic endothelial injury. Platelets have proinflammatory and growth-regulatory properties that may contribute to the progression and destabilization of atherosclerotic plaques. Platelets activate endothelium, promote lipoprotein and lipid peroxidation, mediate leukocyte–endothelial interaction and stimulate smooth muscle cell proliferation. An acute clinical syndrome usually involves thrombosis triggered by the rupture of a vulnerable atherosclerotic plaque. Incorporation of mural platelet-rich thrombi at the site of an unstable plaque contributes to the progression of atherosclerotic lesions.

Pathogenesis of atherosclerosis

Response to injury

Healthy endothelium maintains vascular integrity. It provides a non-thrombogenic inner layer of the vessel wall, and tends to dilate the vessel by releasing endothelium-derived relaxing factor (nitric oxide, NO), endothelium-derived hyperpolarizing factor (EDHF) and prostacylin (PGI2). NO and PGI2 both inhibit the adhesion and aggregation of platelets. Furthermore, healthy endothelium has fibrinolytic properties and impedes leukocyte adhesion[1].

Chronic endothelial injury is a key feature in the pathogenesis of atherosclerosis. Cardiovascular risk factors such as dyslipidemia, hypertension, smoking, diabetes, hyperhomocysteinemia and systemic infection or inflammation result in increased oxidative stress of the vascular wall, endothelial dysfunction and platelet hyperactivity (Fig. 48.1)[2]. High levels of high-density lipoproteins (HDL), moderate alcohol consumption, intake of (ω-3 fatty acids and antioxidants are associated with lower cardiovascular risk and platelet hypoactivity.

Local variations in shear stress and flow help explain the focal distribution of atherosclerosis. It occurs preferentially at lesion prone sites of large and medium-sized elastic arteries (aorta, carotid and iliac bifurcation) and some of the large and medium-sized muscular arteries (coronary arteries, circle of Willis). Lesion prone sites are characterized by decreased shear stress because of oscillatory blood flow at branching vessels or curvatures. Normal arterial shear stress induces an atheroprotective gene expression profile with high expression of NO-synthase and cyclooxygenase. Endothelium exposed to decreased shear stress expresses a more atherogenic phenotype with increased expression of intercellular adhesion molecule-1 (ICAM-1), monocyte chemotactic protein (MCP-1), vascular cell adhesion molecule-1 (VCAM-1) and platelet-derived growth factor (PDGF)[3].

One of the first hallmarks of endothelial activation is increased permeability, leading to enhanced retention of low-density lipoproteins (LDL) (Fig. 48.2). In the vessel wall LDL becomes deprived of antioxidants and undergoes minimal oxidative changes. Oxidized LDL (Ox-LDL) interferes with the NO signalling pathway through many possible mechanisms, including decreased transcription of NO-synthase and inactivation of NO[4,5]. Decreased PGI2 and NO result in decreased vasodilating and antiadhesive properties of the endothelium. Endothelial injury results in decreased anticoagulant properties by increasing Von

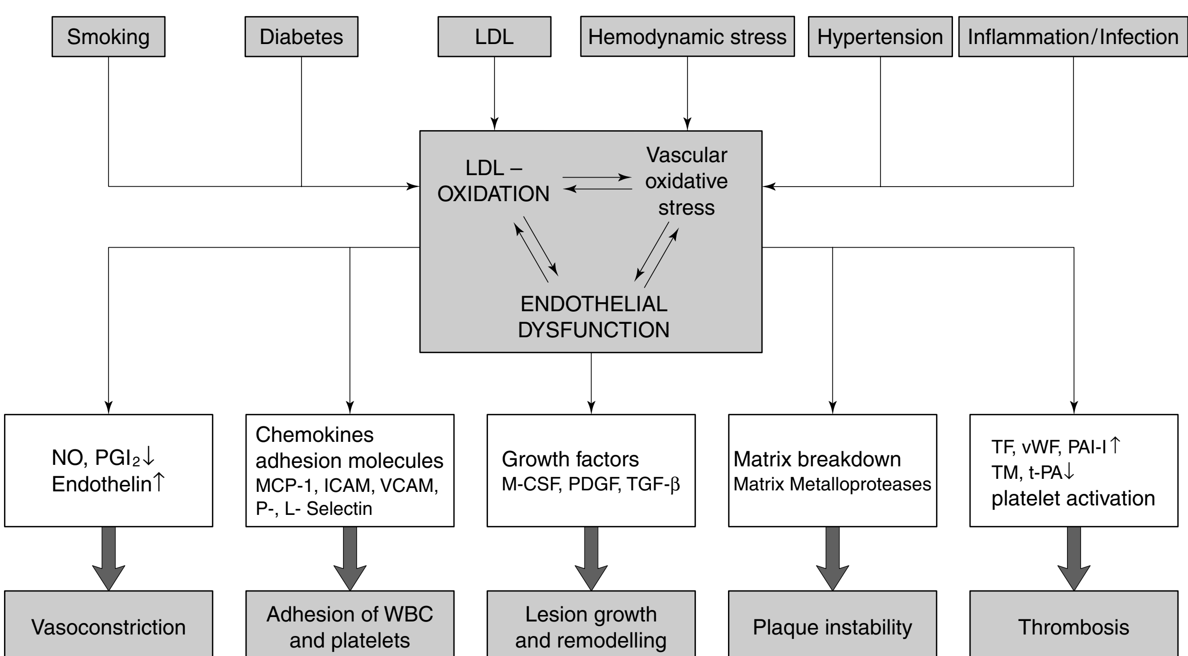

Fig. 48.1. Pathogenesis of atherothrombosis

Willebrand factor (vWF) expression and decreasing the expression of thrombomodulin. Reduced tissue-type plasminogen activator (t-PA) and increased plasminogen activator inhibitor (PAI-1) expression impair fibrinolysis. Minimally oxidized LDL contains oxidized lipids that activate the nuclear factor kappa B family (NFκB) of transcription factors. This redox-regulated transcription factor plays an important role in the chronic inflammation of the vessel wall[6]. It regulates a variety of genes encoding for cytokines (MCP-1, tumour necrosis factor-α) and adhesion molecules (ICAM-1, VCAM-1) important in macrophage adhesion and infiltration[7]. Other transcriptional factors influenced by the cellular redox state and important in the inflammatory reaction of the vessel wall are peroxisome proliferator-activated receptors (PPARs) and activator protein-1 (AP-1)[8].

Inflammatory reaction and recruitment of leukocytes

Endothelial cell activation enhances the adhesion of leukocytes to the vessel wall. MCP-1 and other chemokines such as monocyte chemotactic protein-4 (MCP-4), osteopontin and interleukin-8 are chemotactic molecules for monocytes. Studies with MCP-1 and CCR2-receptor knockout mice revealed that MCP-1 and its main chemokine receptor CCR2 play an important role in the early recruitment of monocytes into the vessel wall[9,10]. Stromal cell-derived factor-1 (SDF-1) is highly expressed in human atherosclerotic plaques. It is not only a chemotactic factor for lymphocytes and macrophages but also induces platelet activation[11].

Homing of leukocytes to the vascular endothelium involves rolling, activation and firm adhesion. Rolling of leukocytes is mediated by E- and P-selectins on endothelial cells, and L-selectins on leukocytes[12,13]. Firm adhesion involves (β_2-integrin interaction and requires activation of the leukocytes by P-selectin or platelet activating factor (PAF)[14]. Platelet endothelial cell adhesion molecule-1 (PECAM) is important in the migration of monocytes into the vessel wall[15]. Monocyte–endothelial cell interaction induces the synthesis of colony stimulating factors, which stimulate further chemotaxis, proliferation, and monocyte differentiation[16].

Resting platelets do not interact with healthy endothelium, but do adhere to activated endothelium at sites of disturbed shear stress and to apoptotic endothelial cells.

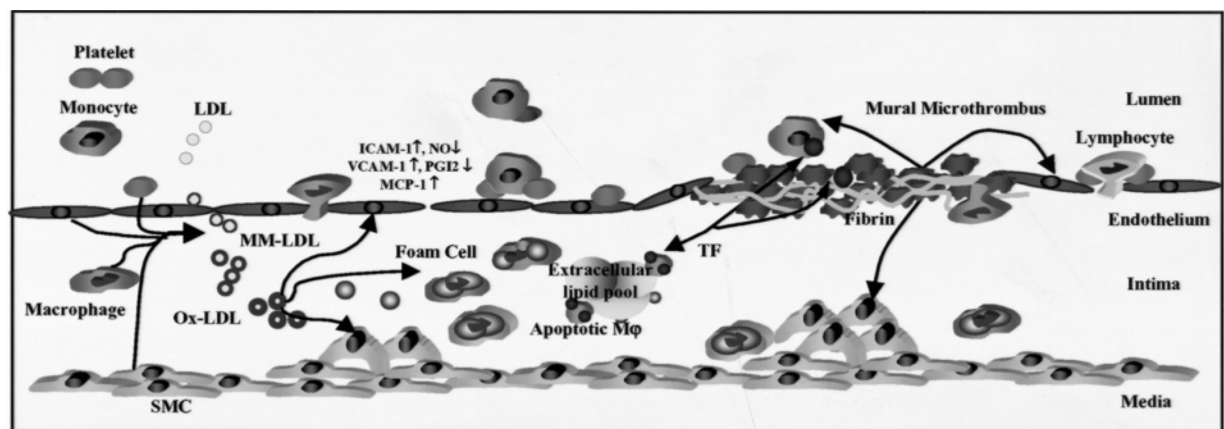

Fig. 48.2. Endothelial cells, platelets, smooth muscle cells and macrophages mediate oxidative modifications of LDL. MM-LDL activates endothelial cells and promotes smooth muscle cell migration and proliferation. Uptake of oxidized lipoproteins by macrophages and smooth muscle cells generates foam cells. Activated platelets adhere to, and activate, endothelium and facilitate monocyte adhesion. Endocytosis of platelet-derived vesicles contributes to foam cell formation. Endothelial erosion initiates platelet adhesion and aggregation and fibrin deposition on the subendothelial matrix. Tissue factor is closely associated with macrophages in the lipid core. Propagation of a thrombus may also depend on blood-borne tissue factor. Platelets release a number of growth factors propagating smooth muscle cell proliferation. Re-endothelialization and cap formation by smooth muscle cells incorporates the mural thrombus into the expanded lesion. (ICAM-1: intercellular adhesion molecule-1, Mψ: macrophage, MCP-1: monocyte chemotactic protein-1, MM-LDL: Minimally modified LDL, NO: nitric oxide, ox-LDL: oxidized LDL, PGI_2: prostacyclin, SMC: smooth muscle cell, TF: tissue factor, VCAM-1: vascular cell adhesion molecule-1.)

(*b*) Scanning electron microscopy demonstrating platelet interaction with a damaged arterial wall. Platelets adhere, get sticky and release their granules. (Illustrations kindly provided by Marc Hoylaerts and Carine Michiels.)

Activated platelets adhere to both healthy and activated endothelium (Fig. 48.3)[17]. Platelet rolling on activated endothelium is mediated by endothelial P-selectin. Firm interaction of activated platelets with endothelium involves GPIIb–IIIa-dependent bridging and ICAM-1, GPIbα and $\alpha_V\beta_3$ integrin interaction[18,19]. Activated platelets release proinflammatory cytokines, chemokines and lipid metabolites and are capable of inducing lipid peroxidation[20,21]. They express CD40 ligand, involved in inflammatory signalling, and P-selectin. CD40–CD40L signalling activates atheroma-associated cells and appears to play a key role in the progression of atherosclerotic lesions[22]. Inhibition of CD40 signalling significantly reduces atherosclerosis in mice[23]. Via CD40 ligand, activated platelets trigger an inflammatory response in endothelial cells[24]. They induce expression of adhesion molecules (ICAM-1, VCAM-1), of chemokines (IL-6, MCP-1 and IL-8) and of tissue factor (TF)[25,26].

Activated platelets also interact with leukocytes and trigger leukocyte activation, expression of NFκB regulated gene products, expression of adhesion receptors, e.g. Mac-1 and shedding of L-selectin[27,28]. P-selectin is the major surface receptor for leukocytes on activated platelets and interacts with P-selectin glycoprotein ligand that is abun-

Table 48.1. Platelet involvement in atherothrombosis

Early lesion	Activated platelets adhere to endothelium and may: • induce lipid and lipoprotein peroxidation generating a broad range of biological active lipids[21]. • trigger an inflammatory response in endothelium by CD40–CD40 ligand interaction and NFκB activation[24]. • increase expression of adhesion molecules and secretion of chemokines[26]. • facilitate adhesion of monocytes by P-selectin mediated interaction with adherent platelets[30]. Circulating monocyte–platelet conjugates may facilitate monocyte homing to the arterial wall[39]. Interaction of platelets and macrophages enhances foam cell formation.
Lesion progression	Plaque rupture or endothelial erosion triggers platelet adhesion, activation and aggregation and the formation of mural thrombi that may: • incorporate in the plaque causing rapid expansion of the lesion[63]. • release growth factors from α-granules inducing SMC proliferation, migration and differentiation[41]. • enhance adhesion and infiltration of leukocytes[74,167].
Thrombosis and clinical events	Occluding platelet-rich thrombi are formed upon rupture of a vulnerable plaque[52]. Embolization of platelet aggregates is a possible cause of ventricular fibrillation and sudden death and limb gangrene[60]. Arterial spasm can be triggered by vasoconstrictors released from activated platelets[168,169]. Activated platelets contribute to a procoagulant state[25,33].

dant on circulating monocytes and lymphocytes[29,30]. Increased soluble P-selectin among patients with atherosclerosis may reflect both platelet activation and endothelial dysfunction[31]. Furthermore, activated platelets induce TF expression in human circulating monocytes and thus contribute to a systemic procoagulant state[32,33]. Triggering of TF on circulating monocytes by activated platelets does not depend on *de novo* protein synthesis but on translocation from intracellular stores[34,35].

Adherent platelets may trap circulating lymphocytes or monocytes and propagate the adherence of leukocytes to the vessel wall even at shear stress that does not allow direct leukocyte adhesion[36–38]. Furthermore, in vitro studies suggest that rosette formation of activated platelets with monocytes or lymphocytes may facilitate adhesion of these conjugates to the vessel wall[39,40]. (see also Table 48.1 and Fig. 48.2).

Fatty streak

Recruitment of monocytes, lymphocytes and platelets to the vessel wall initiates an inflammatory response. Infiltration and proliferation of monocytes and T-lymphocytes in the subendothelial space is induced by a variety of growth-regulatory molecules released by endothelial cells, platelets, smooth muscle cells, and leukocytes[41]. Macrophages, endothelial cells, platelets and smooth muscle cells may further oxidize LDL. Oxidation of LDL may be catalysed by myeloperoxidase or lipoxygenase, or initiated by metal ions. Further oxidation of LDL results in the generation of lipid mediators such as lysophosphatidylcholine (LPC), oxysterols, and PAF-like molecules that have chemotactic properties towards macrophages and further activate endothelial cells[42]. Oxidized lipoproteins initiate an immune response. Ox-LDL activates T-lymphocytes in humans[43] and titres of plasma autoantibodies to ox-LDL are higher in patients with carotid atherosclerosis[44].

Oxidative alterations of the protein moiety of LDL result in a shift from LDL receptor binding to scavenger receptor binding. Contrary to the LDL receptor, scavenger receptors are not downregulated by intracellular cholesterol pools, resulting in an uncontrolled uptake of ox-LDL and foam cell formation[45]. Histological studies have shown platelets and foam cells in close proximity[46]. Interaction between platelets and macrophages enhances foam cell formation[47]. Activated platelets or microvesicles shed from activated platelets stimulate cholesterol esterification and cholesterol ester accumulation in macrophages. Part of the lipid content in foam cells may be derived from endocytosis of platelets or platelet-derived vesicles[48]. Accumulation of foam cells is the hallmark of the earliest recognizable lesion, the fatty streak (Fig. 48.4(*a*), see colour plate). It is very common in young children and adolescents and is still a reversible stage of atherosclerosis[49]. It consists mainly

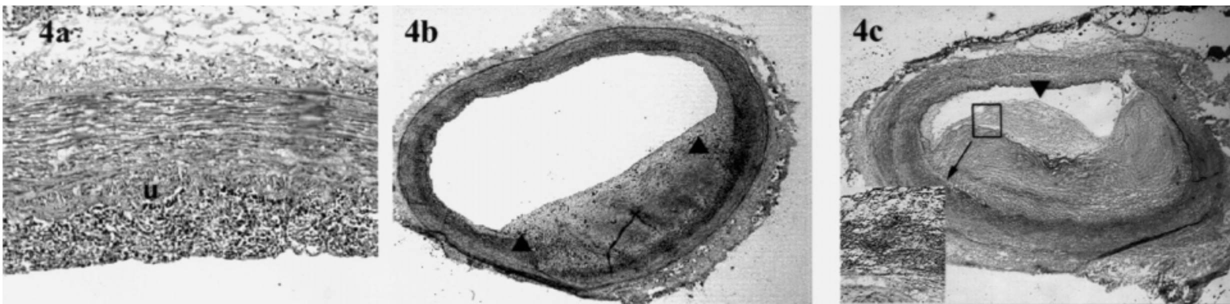

Fig. 48.4. (*a*) Oil Red O staining of a fatty streak (Stary type II lesion). The lesion is rich in foam cells. Smooth muscle cells (▶) migrate towards the intima.(*b*) Oil Red O staining of a fibroatheroma (Stary type IV–V). The eccentric lesion consists of a large lipid core with a rather thin fibrous cap. Plaque rupture occurs most frequently at the shoulder regions of the plaque (▲). (*c*) Oil Red O staining of a complicated lesion (Stary type VI). The layered aspect and the organized thrombus (▼) are hallmarks of healed disruption. Immunostaining (➔) for fibrin shows fibrin at the basis of the most recently formed cap.

of inflammatory cells, predominantly macrophages, macrophage-derived foam cells and T-cells. Uptake of ox-LDL by macrophages is initially considered to be protective, minimizing the inflammatory and cytotoxic effects of oxidized lipids on endothelial and smooth muscle cells and promoting lipid efflux out of the vessel wall.

Fibroatheroma

Ongoing endothelial injury and unregulated accumulation of oxidized lipids lead to necrosis and apoptosis of intimal macrophages and release of oxidized lipids that mitigate further inflammatory and cytotoxic effects. Confluence of extracellular lipid pools results in the formation of a lipid core. As a result of ongoing inflammation, and enhanced by oxidized lipids, macrophages, smooth muscle cells and platelets, together with the endothelium release a variety of growth-regulatory molecules. Smooth muscle cells migrate and proliferate to form a fibrous cap covering the lipid core and synthesize extracellular matrix (Fig. 48.4(*b*), see colour plate). Smooth muscle cells stimulated to express scavenger receptors become foam cells by uptake of ox-LDL. As the lesion grows, plaque vascularization is an additional source of inflammatory cells and can give rise to in-plaque hemorrhage. Calcification is a common feature of advanced atherosclerotic plaques. Calcifying vascular cells are stimulated by transforming growth factor-β (TGF-β) and oxidized lipids[50]. Plaque progression does not necessarily decrease lumen size through adaptive remodelling of the vessel. Studies with intravascular ultrasound have revealed that large atherosclerotic lesions can be present in the coronary arteries before luminal narrowing is detectable with coronary angiography. Although mechanisms for adaptive remodelling remain largely unravelled, it is generally accepted that it is shear stress and NO dependent[51].

The unstable lesion

Lesions that are prone to rupture are best characterized in the coronary arteries. A lipid-rich core underlying a thin fibrous cap is the histological hallmark of an unstable plaque. Shoulder regions are heavily infiltrated by inflammatory cells, mainly T-cells and macrophages, and are most prone to plaque rupture (Fig. 48.4(*b*), see colour plate)[52]. Matrix metalloproteases secreted and activated by macrophages and T-lymphocytes degrade the extracellular matrix[53]. Imbalance between matrix synthesis and breakdown causes weakening of the plaque. Plaque rupture exposes flowing blood to the thrombogenic core. Thrombogenicity of the lipid core is attributed to TF that is closely associated with apoptotic cells in the lipid core[54]. Oxidized LDL stimulates the expression of TF in both macrophages and endothelial cells[55,56].

Acute vascular events

Atherosclerosis is a systemic disease with a broad range of clinical manifestations. An acute coronary syndrome is triggered by an occluding platelet-rich thrombus that is formed upon a vulnerable plaque. Most frequently, an unstable plaque shows rupture into the lipid core, although coronary plaque erosion is also a common cause of coronary thrombosis and sudden death[57]. Remarkably, in about 75% of patients with acute coronary syndromes, the culprit lesion shows only mild to moderate stenosis on

Cambridge Books Online © Cambridge University Press, 2009

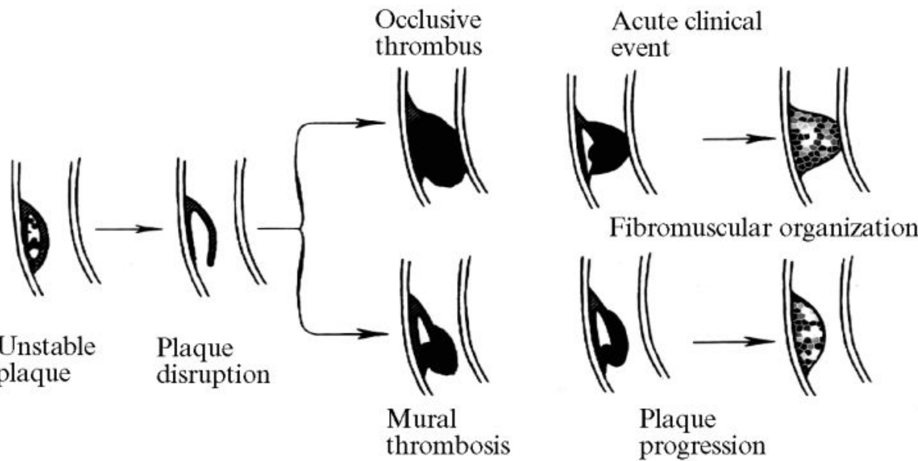

Fig. 48.5. Typical evolution of the unstable lesion. Plaque rupture triggers formation of a platelet-rich thrombus. Mural thrombi contribute to lesion progression and are far more common than occlusive thrombi that may lead to acute clinical events. (Adapted from V. Fuster[61].)

angiography. Total occlusion of a coronary artery may result in myocardial infarction. Fluctuating and recurrent thrombus formation in the coronary arteries with intermittent thrombus dissemination is the underlying mechanism for unstable angina. Markers for platelet activation are increased among patients with unstable angina, confirming ongoing thrombosis[58,59]. Adherent platelets may release vasoconstrictors mitigating coronary spasm. Distal embolization of the platelet aggregates in the myocardium is a potential cause of ventricular fibrillation and sudden death[60]. Ischemic cerebrovascular accidents are caused by occlusion or thromboembolism of vulnerable plaques in the aorta, carotid arteries or cerebral arteries. Claudication and gangrene of the lower limbs are the clinical manifestations of peripheral artery disease or thromboembolic phenomena from the aorta.

Mural thrombi

Prevalence of mural thrombi

The role of plaque vulnerability and thrombus formation in acute clinical syndromes is well recognized. Plaque instability and mural thrombosis also play a crucial role in the progression of atherosclerotic lesions (Fig. 48.5)[61]. Platelet adhesion and thrombosis are most frequently initiated by plaque disruption, but platelet-rich thrombi may also be formed at sites of activated, apoptotic or eroded endothelium. Histopathological studies have demonstrated that plaque instability and mural thrombosis are very common in coronary atherosclerosis. Postmortem studies revealed plaque disruption in 17% of patients who suddenly died because of a non-cardiac event[62]. Analysis of coronary arteries demonstrated healed disruption in 16% of atherosclerotic lesions with up to 20% stenosis, 19% of lesions with 24–50% stenosis, and 73% of lesions with more than 50%[63] stenosis. These studies stress the importance of plaque rupture and incorporation of mural thrombi with subsequent fibrotic organization in the progression of atherosclerotic plaques and help explain the episodes of rapid plaque growth and non-linear progression of atherosclerosis frequently observed among patients.

Mural versus occluding thrombi

Mural thrombosis is far more frequent than occlusive thrombosis. The extent of thrombus formation may depend on local variations in thrombogenicity of the ruptured lesion, local production of platelet activators, degree of endothelial dysfunction with impaired fibrinolysis and reduced release of platelet antagonists (NO, PGI2) and local shear stress[64]. It may also depend on systemic variations in thrombotic tendency and fibrinolytic capacity that are of environmental origin or genetically determined. Many of the proteins involved in coagulation and fibrinolysis might contribute to a thrombotic tendency. High circulating PAI-1 is an independent risk factor for recurrent myocardial infarction[65]. High factor VII, fibrinogen and vWF increase the risk of myocardial infarction[66–68]. Platelet hyperactivity also contributes to a thrombotic tendency. Well-known risk factors for atherothrombosis are associated with platelet hyperresponsiveness and will be discussed later in this chapter.

Cambridge Books Online © Cambridge University Press, 2009

Platelets of patients suffering from an acute coronary syndrome produce less NO[69]. Platelets contain both constitutive and inducible NO synthase and platelet-derived NO prevents further platelet recruitment[70,71]. Impaired platelet-derived NO production may contribute to the development of an occluding thrombus. Concurrent increase in platelet aggregability and risk of myocardial infarction early in the morning further suggests a role of platelet reactivity in the onset of myocardial infarction[72].

Incorporation of mural thrombi and plaque growth

Plaque disruption or superficial erosion initiates fibrin deposition and platelet adhesion to the sub-endothelial matrix with subsequent activation and aggregation (Fig. 48.3(*b*)). Platelet receptors involved in aggregate formation and matrix adhesion have been studied extensively[73]. vWF plays a critical role in mediating platelet adhesion to the arterial subendothelium. Initial platelet–vWF interactions are mediated primarily by GPIb and are consolidated by GPIIb/IIIa. Activated platelets and fibrin deposits may allow circulating leukocytes to adhere even at high shear rates, propagating the influx of leukocytes into the evolving thrombus and the underlying lesion[74]. P-selectin expressed on surface-bound platelets mediates leukocyte rolling. Firm adhesion requires integrin–ligand interactions. Mac-1 is the main leukocyte (β_2-integrin that binds to the platelet surface. Intercellular adhesion molecule-2 on platelets and fibrin are the main ligands for Mac-1[40,75]. Platelet–leukocyte cross-talk is important in the propagation of the thrombus. Thrombus formation may not only be dependent on vascular TF but also on the deposition of blood-borne TF shed from monocytes in microvesicles after interaction with platelets[35].

Platelet adhesion and mural thrombosis stimulate smooth muscle cell migration and proliferation. Platelets have growth regulatory properties for smooth muscle cells by the release from α-granules of platelet derived growth factor (PDFG), epidermal growth factor (EGF), insulin-like growth factor (IGF) and transforming growth factor-β (TGF-β). Serotonin released by activated platelets stimulates the expression of thrombin receptors on smooth muscle cells, thereby potentiating the mitogenic and vascoconstrictor actions of thrombin[76]. Thromboxane not only causes platelet aggregation and vasoconstriction but also induces chemotaxis of smooth muscle cells. Pigs with von Willebrand disease are resistant to atherosclerosis most likely due to reduced platelet–vessel wall interaction[77].

After re-endothelialization and cap formation by smooth muscle cells, the clot gets incorporated into the expanded lesion and undergoes further fibrotic organization (see also Fig. 48.4(*c*) and Table 48.1).

Platelets and restenosis

Angioplasty of a narrowed or occluded coronary or peripheral artery is common strategy to treat patients with coronary and peripheral artery disease. Antiplatelet and antithrombotic drugs have decreased the rate of acute occlusion of the vessel after the intervention. However, restenosis after 3 to 6 months remains a clinical problem complicating about 30% of all coronary interventions.

Rupturing the atherosclerotic vessel wall by balloon dilation promotes the adhesion and aggregation of platelets and thrombus formation (Fig. 48.3(*b*)). Activated platelets release their granules with growth factors and cytokines that promote smooth muscle cell migration and proliferation. The thrombus provides a matrix for smooth muscle cell growth[78,79]. In animal models of balloon injury, neointima formation can be retarded by anti-platelet therapy. Thrombocytopenic rabbits have reduced neointima formation after balloon injury[80]. Cyclic RGD-containing peptides and GPIIb/IIIa antagonists reduce neointima formation in animal models[81].

Antiplatelet strategies had however little effect on restenosis in humans. Constrictive remodelling of the injured vessel, rather than neointimal growth may be the major determinant of human restenosis. Stents inhibit constrictive remodelling of the vessel wall[82]. Antiplatelet therapy effectively prevents acute and subacute *in stent* thrombosis[83].

Platelet count, platelet activity and atherothrombosis

There are few arguments to consider absolute platelet count as a risk factor for atherothrombosis. In one prospective study of 487 apparently healthy men, subjects in the highest quartile of platelet count had a 2.5-fold increased risk of cardiovascular mortality within 10 years[84]. Platelet function may be more relevant than absolute number. In the *Caerphilly Collaborative Heart Disease* study, platelet aggregation was measured in 2000 men without recent history of aspirin intake. Coronary heart disease patients had significantly greater ADP-induced platelet aggregation compared with controls[85,86]. Increased platelet sensitivity to ADP in men without clinically overt ischemic heart disease was associated with increased risk of cardiovascular mortality within 13 years of follow-up[84].

Cambridge Books Online © Cambridge University Press, 2009

In the *Caerphilly Cohort* study, thrombin and ADP-induced platelet aggregation were not predictive of ischemic heart disease[87]. Among patients with myocardial infarction, spontaneous platelet aggregation was a useful predictor for survival and future coronary events within 5 years[88]. Platelet size is also shown to be a predictor of recurrent myocardial infarction and death. Men with a fatal or non-fatal myocardial infarction within two years after a first infarction had a greater mean platelet volume 6 months after the first event than men without recurrent coronary syndromes. An increased mean platelet volume is associated with increased platelet activity and may reflect an enhanced inflammatory state[89].

The most convincing evidence that platelets are involved in atherothrombosis arises from trials with antiplatelet drugs[90]. Small amounts of aspirin, sufficient to irreversibly inhibit cyclooxygenase in platelets, reduce the risk of non-fatal MI, non-fatal stroke and vascular death among patients with previous cardiovascular disease. The Physicians Health Study demonstrated a conclusive and significant reduction of a first myocardial infarction in physicians without a history of cardiovascular disease randomized to aspirin after 5 years of follow-up[91]. The strong negative relation between alcohol intake and consumption of ω-3 fatty acids and platelet aggregation may partially explain the lower incidence of ischemic heart disease in patients consuming a moderate amount of red wine or fish oil[92–95].

Platelet activity and risk factors of atherothrombosis

There is a need for a measure of platelet activity that is predictive of ischemic vascular disease and that more effectively guides antiplatelet therapy. Many assays have been proposed to determine the degree of platelet activation. Besides spontaneous platelet aggregation or aggregability using different agonists, platelet factor 4 (PF4), soluble P-selectin, β-thromboglobulin, platelet size and heterogeneity, and metabolites of thromboxane/prostacyclin synthesis are used to assess platelet activity[96]. Flow cytometry of platelets in whole blood enables investigation of functional aspects of circulating platelets by assessment of their membrane glycoproteins[97]. Other markers may indirectly reflect platelet activation. Isoprostanes are markers for lipid peroxidation in vivo. Oxidative stress results in the generation of F2-isoprostanes that are non-cyclooxygenase free radical catalysed oxidation products of arachidonic acid. They form *in situ* on esterified phospholipids of cell membranes and LDL particles and are subsequently released through phospholipases[98,99]. F2-isoprostanes are strong aggregatory and vasoconstricting agents. Their levels increase with age, in smokers, diabetics and hypercholesterolemic patients, and may contribute to persistent platelet activation in those patients[100–103].

Table 48.2. Atherogenic and atheroprotective factors associated with platelet hyper-responsiveness and platelet hyporesponsiveness

Platelet hyperactivity	Platelet hypoactivity
LDL, ox-LDL[127,133,170]	HDL[126]
Smoking[109]	Alcohol intake[172]
Diabetes[112,115]	Intake of ϖ-3 fatty acids[94]
Hypertension[104,105]	Antioxidant therapy[150]
Hyperhomocysteinemia[107]	Antiplatelet agents (e.g. aspirin)[90]
Ageing[171]	

Most of the conventional cardiovascular risk factors are associated with increased platelet responsiveness (Table 48.2). Systemic activation of circulating platelets and endothelial dysfunction may be closely interdependent and favourize thrombosis after plaque rupture.

Platelets are in an activated state in patients with hypertension, the degree of activation correlating with diastolic blood pressure[104,105]. Accelerated aggregation of platelets is demonstrated in patients with hyperhomocysteinemia[106,107]. Homocysteine enhances platelet adhesion to endothelial cells under flow conditions[108]. Smoking is associated with platelet hyperactivity[109], which is corrected after smoking cessation, but also with impaired fibrinolysis[110] and increased TF expression[111].

Coronary and peripheral artery disease is the major cause of morbidity and mortality in diabetics. Diabetes is associated with platelet hyperactivity and increased surface expression of P-selectin[112–115]. The occurrence of renal and vascular complications of diabetes mellitus correlates with the presence of advanced glycation end products (AGEs)[116]. AGEs not only enhance the aggregation of human platelets ex vivo and inhibit PGI2 synthesis[117,118], they also induce TF expression in monocytes[119] and cellular lipid peroxidation[120]. Increased plasma levels of isoprostanes[121], thiobarbituric acid reactive substances (TBARS) and lipid hydroperoxides further suggest increased oxidative stress in diabetic patients. Increased isoprostanes correlate with increased platelet activation, while improved metabolic control in diabetic patients reduces both lipid peroxidation and platelet activation[102]. Long-term administration of antiplatelet drugs to patients with type 2 diabetes attenuates the progression of carotid atherosclerosis[122].

Cambridge Books Online © Cambridge University Press, 2009

LDL is a major risk factor for cardiovascular disease. The interaction between lipoproteins and platelets is complex and incompletely understood[123]. Hypercholesterolemic patients display persistent platelet activation in vivo, increased sensitivity of platelets to aggregating agents in vitro, and increased levels of soluble P-selectin[124,125]. The platelet aggregating properties of native LDL itself are controversial. Some studies found no aggregating effect of native LDL[126,127], while others demonstrated platelet-stimulating effects of LDL[128–130]. Ex vivo LDL oxidation during LDL isolation may have troubled these findings since mild oxidation of LDL produces a wide range of biologically active lipids such as lysophosphatidylcholine, oxysterols, F_2-isoprostanes, PAF-like lipids and lysophosphatidic acid (LPA). Whereas fully oxidized LDL is abundant in atherosclerotic plaques and has important cytotoxic effects, circulating levels of ox-LDL and oxidized lipids have been demonstrated in both patients with coronary artery disease and in animal models of atherosclerosis and may directly influence platelet behavior[131,132]. Mildly oxidized LDL is more capable of activating platelets than native LDL[127,133–135]. Mildly oxidized LDL induced platelet aggregation involves phospholipase A_2 (PLA_2) and cyclooxygenase (COX) and is inhibited by aspirin[133]. Mildly oxidized LDL interacts with the lysophosphatidic acid (LPA) receptor and induces platelet shape change via the GTPase Rho and its effector molecule p160 Rho-kinase leading to phosphorylation of the myosin light chain[136,137]. Furthermore, ox-LDL decreases L-arginine uptake and NO synthase activity in platelets[138]. Endothelial dysfunction with reduced basal release of NO and PGI2 may also contribute to increased platelet activation in hypercholesterolemic patients. Platelet activation can be reversed by diet, lipid lowering[139] and administration of NO donors or L-arginine[140,141]. L-Arginine supplementation decreases platelet reactivity by directly providing the substrate for NO-synthase in platelets and by restoring endothelium derived NO activity.

Stabilization of atherosclerotic lesions

Since atherosclerosis is the result of various forms of chronic injury of the endothelium, lesions can at least partially be reversed or stabilized if the injurious agents are removed. Smoking cessation, improved metabolic control in diabetics and lipid lowering not only reduce arterial inflammation and improve endothelial function, but also influence platelet behaviour.

Lipid lowering

Lipid lowering reduces cardiovascular mortality and morbidity[142]. Lipid efflux from plaques decreases the arterial inflammation and retards matrix breakdown, improving the mechanical strength of the plaque[143]. It reduces TF expression in rabbit atherosclerotic plaque[144]. It improves endothelial antiaggregatory and fibrinolytic properties and decreases platelet reactivity. The beneficial effect of statins may partially be due to reduction of thrombotic risk and inhibition of progression of plaques by platelet-dependent processes. Both in vivo and in vitro studies have reported that most of the statins are able to reduce platelet aggregation[145–147]. Atorvastatin significantly inhibits platelet deposition on a mildly damaged vessel wall at high shear rates in hypercholesterolemic pigs[148].

Antioxidant therapy

Antioxidant therapy aiming at reducing oxidative stress and LDL oxidation in the vessel wall seems promising. In numerous animal models of atherosclerosis, therapy with α-tocopherol, β-carotene or other antioxidants retarded atherosclerosis. In humans, dietary intake of antioxidants is inversely correlated with cardiovascular risk[149]. Antioxidant supplementation reduces platelet activation[150], increases the resistance of LDL towards oxidation and improves endothelial function. However, antioxidant supplementation failed to demonstrate clinical benefit in large randomized trials[151–153]. Antioxidant therapy is still controversial[154] and warrants further investigation[153].

HDL

Epidemiological evidence has established an inverse relation between plasma HDL cholesterol levels and risk of coronary heart disease. The reverse cholesterol transport is the major proposed mechanism for the protective effect of HDL in atherothrombosis. HDL may deplete atherosclerotic plaques of cholesterol by promoting efflux of lipids. Other HDL properties may also significantly contribute to the atheroprotective effects of HDL. HDL acts as an antioxidant and inhibits oxidative modification of LDL. Two HDL-associated enzymes, paraoxonase (PON) and platelet activating factor–acetyl hydrolase (PAF–AH) prevent the oxidation of LDL. PON-deficient mice are more susceptible to atherosclerosis[155]. Overexpression of PAF–AH reduces macrophage homing in apolipoprotein E deficient mice[156]. HDL has anti-inflammatory capacities and in vitro studies show that apolipoprotein A-I, the major HDL-associated apolipoprotein, inhibits the expression of adhesion mole-

Cambridge Books Online © Cambridge University Press, 2009

cules on endothelial cells. Furthermore, HDL may play an active role in the modulation of platelet function[157]. HDL inhibits platelet aggregation in vitro[158] and apolipoprotein A-I is a prostacyclin stabilizing factor[159]. Apolipoprotein A-I Milano delayed platelet aggregation and thrombus formation after vascular injury in Sprague–Dawley rats[160].

Future developments

Genetic factors determine the susceptibility for atherothrombosis. The risk of myocardial infarction in subjects with a first-degree relative with CAD is seven times the risk of subjects without family history of cardiovascular disease[161]. Unravelling the common genetic polymorphisms involved in atherothrombosis will further improve the assessment of cardiovascular risk. Several platelet membrane proteins have two or more allelic forms. In a case-control study, the PlA2 allele of the PlA1/A2 polymorphism of the platelet glycoprotein IIIa (GPIIIa) gene was associated with the prevalence of acute vascular events before the age of 60[162]. However, these findings could not be confirmed in a larger cohort study[163].

Targeting of genes via homologous recombination in embryonic stem cells or stem cell injection has allowed the generation of knockout and transgenic mice (for review see ref.[164]). Although these genetically modified mice have already revealed important pathophysiological mechanisms of atherothrombosis, conditional or tissue-specific gene expression will further improve insight in mechanisms of atherothrombosis.

As yet patients with vulnerable plaques cannot be identified with great sensitivity. Culprit lesions often cause only mild to moderate stenosis and are not yet detectable with any current diagnostic tool. Core size and composition and cap thickness rather than the absolute plaque size determines vulnerability[165]. Better identification of patients with lesions prone to rupture will allow better prevention. Nuclear magnetic resonance seems promising for assessment of lesion distribution and composition[166].

Platelet involvement in venous thrombosis and pulmonary embolism

Andrew D. Blann and Gregory Y.H. Lip

Haemostasis, Thrombosis and Vascular Biology Unit, University Department of Medicine, City Hospital, Birmingham UK

Introduction

Since their discovery in 1842[1], platelets have commanded an increasingly prominent position in the pathophysiology of thrombosis, although this has been almost exclusively in arterial disease. However, Virchow was most likely the first to link changes in the blood (that we would today interpret as rheology, vascular function, and the soluble and cellular constituents of the blood) with venous thrombosis[2].

There are three major lines of approach that we can take in order to test the hypothesis that platelets are intimately involved in the development of DVT and PE. The pharmacological approach considers clinical trials of antiplatelet drugs (such as aspirin) in well-defined groups of high-risk patients that demonstrate a reduction in the rate and/or risk of thrombosis. The laboratory approach can be used to demonstrate changes in platelet function ex vivo or in levels of platelet-specific markers (such as beta thromboglobulin) in the plasma of those at risk of, with, or having suffered, a thrombotic event. More recently, radionucleotide and other imaging with labelled platelets, antibodies, probes or other agents provide additional evidence of the role of platelets in DVT and PE. Whilst there are considerable animal data on the subject of venous thromboembolism, this overview will be confined to human studies.

Clinical trials

The most commonly used and most successful antiplatelet drug is aspirin, which is well established as secondary prevention in vascular (arterial) disease. A recent report that aspirin inhibits smooth muscle cell proliferation may also be relevant in arterial diseases, but seems to be less important[3].

The rationale for testing the efficacy of aspirin in venous thrombosis followed directly from reports of its ability, for example, to inhibit platelet aggregatory function in vitro[4]. Perhaps the earliest clinical trial of aspirin in the prevention of postoperative DVT[5], where the frequency of the single end point of DVT, as defined by uptake of ^{125}I-fibrinogen, did not differ between those 150 subjects on placebo compared to 153 subjects who took 600 mg aspirin once before their operation and daily for the next 4 days. Lack of efficacy may have been due to the confounding inclusion of 44 subjects with a malignancy and 15 with a past history of thromboembolism, and to the short duration of treatment. Morris and Mitchell[6] were also unable to find a protective effect of aspirin, whilst Harris et al.[7] found a positive effect in men alone.

Another small study, recruiting 120 patients due for hip replacement, found that aspirin (1000 or 250 mg daily) reduced the frequency of postsurgical DVT from 30% to 3.3%[8]. Similarly, Salzman et al.[9] who defined DVT and/or PE on clinical grounds alone, found that aspirin reduced the frequency of venous thrombosis. These early studies therefore, provided conflicting results, and most were underpowered to show a clear benefit or otherwise from aspirin.

The antiplatelet Trialists Collaboration

A major landmark was the meta-analyses of the Antiplatelet Trialists Collaboration[10], which was an overview of some 9000 randomized subjects undergoing general and orthopaedic surgery, and some high-risk medical patients. This showed a clear reduction in DVT (by 39%) and PE (by 64%) that was due to an effect of aspirin (Fig. 49.1). Among the subanalyses was the finding that a combination of aspirin and dipyridamole was more

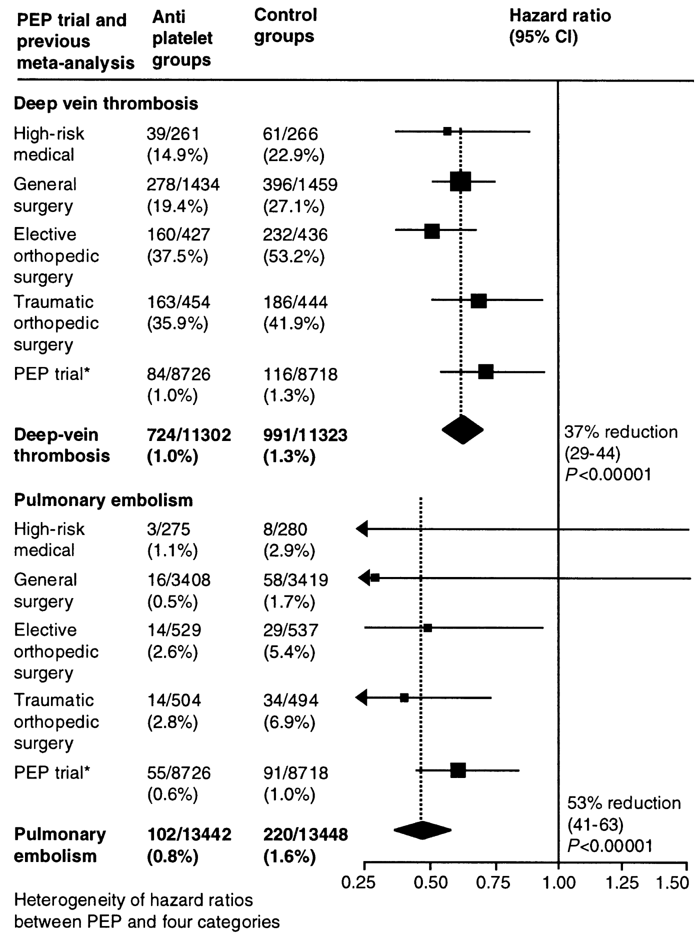

Fig. 49.1. Proportional effects of antiplatelet therapy on venous thromboembolism in previous meta-analysis and the PEP trial. (This is Fig. 5[10], with permission from Dr A. Rodgers.)

effective in reducing the risk of a DVT than the use of aspirin alone (15 events from 109 subjects vs. 33 events from 109 subjects, respectively, $2P=0.001$). Other subanalyses, in both DVT and PE, also demonstrated that the use of hydroxychloroquine was superior to placebo in reducing thrombosis. However, Ticlopidine failed to reduce the risk of either type of thrombosis.

Despite the apparent power of this analysis, some concerns about the conclusions and recommendations of this meta-analysis were raised, for example, that the absolute benefits of aspirin seem to be greater for those at higher risk – for example, those undergoing orthopedic surgery[11]. These issues were subsequently responded to[12], where the increased risk of non-fatal 'major' bleeds ($P=0.04$) and the combination of reoperation, hematoma, or infection due to bleed ($P=0.003$), apparently due to aspirin, were emphasized. However, several of these concerns have been recently answered in a further trial, the Pulmonary Embolism Prevention (PEP) Trial[13].

The Pulmonary Embolism Prevention (PEP) Trial

The Pulmonary Embolism Prevention (PEP) Trial[13] was a randomized, double blind international multicentre trial of the effects of aspirin, in 13 356 patients at risk of thrombosis by virtue of, for example, hip fracture or elective arthroplasty, who were randomized to aspirin 160 mg daily, or placebo, for 35 days: endpoints were mortality and in-hospital morbidity up to Day 35. Principal results (Fig. 49.1) demonstrated a 37% overall reduction in DVT, and a 53% reduction in PE (both $P<0.00001$), with significant reductions in both end points in various subgroups, such as 'high-risk' medical, or following elective, general or traumatic orthopedic surgery. There were no significant differences in bleeding episodes between the groups. The impressive statistical power and thorough methodology of this study provides unequivocal proof of the benefit of aspirin under these conditions.

Non-aspirin interventions

There are isolated reports of the effectiveness (or not) of other antiplatelet agents in the prevention of venous thrombosis. For example, aurin tricarboxylic acid inhibits ristocetin-induced human platelet aggregation in vitro and reduces venous thrombus formation and disseminated intravascular coagulation in in vivo animal models[14]. However, despite this promising data, this agent is rarely used in human disease.

Kakkar et al.[15] reported a synergistic effect of heparin and dihydroergotamine in reducing platelet activity, as judged by aggregation, morphology and changes in plasma levels of the platelet marker, beta thromboglobulin. These observations suggest that heparin may have some effects beyond the enhancement of the anticoagulant activity of antithrombin III. Although Alfaro et al. showed that a combination of heparin and dihydroergotamine reduced the frequency of DVT from 30% to 16.6%, this difference was not statistically significant, possibly due to the small patient numbers studied[8]. Salzman et al.[9] found that warfarin and dextran, like aspirin, also reduced the risk of venous thrombosis, but the reduced frequency of thrombosis in patients taking dipyridamole by one-third (i.e. 26% compared to a control rate of 39%) did not reach statistical significance.

Laboratory markers

Although platelet hyperaggregability following DVT has been reported[16], research in this area has focussed on three platelet-specific markers found in the plasma. Platelet factor 4 (PF4) was first described in the late 1960s, beta thromboglobulin a few years later[17–19], whilst soluble P selectin became widely reported in the 1990s[20,21].

Platelet factor 4

PF4, a heparin binding protein first described by Niewiarowski and Thomas[17], exists at a concentration of 11–12 μg per 10^9 platelets. It is a heat stable, low molecular weight (7.8 kDa) protein of 70 amino acids. However, it circulates as a tetramer, which increases the molecular weight of the molecule to about 30 kDa. These complexed tetramers are also associated with two high molecular weight proteoglycan carriers.

The presence of PF4 binding sites on the platelet surface implies that PF4 also has the ability to regulate cell–cell interactions between platelets. With heparin binding sites within a lysine-rich region, it can interact with heparin-like glycosaminoglycans on endothelial cells, thus promoting a procoagulant effect[22,23]. Consequently, the presence of this anticoagulant in the blood stream up-regulates the effective presence of PF4 by up to a factor of 20-fold[24]. This could be a major cause of measurement error as many diseases that have acute thrombotic symptoms are frequently treated in this way. Crucially, aspirin causes a reduction in the PF4 concentration[8,25,26], implying a relationship with the cyclooxygenase/prostacyclin pathways.

Beta thromboglobulin

This molecule consists of four identical subunits, each of 81 amino acid residues having a molecular weight of 8.8 kDa, and as such contributes up to 10% of the α-granules' contents, making it the most abundant platelet specific protein. It is present exclusively in megakaryocytes and in the α-granules of platelets and is present in a range of 8–24 μg per 10^9 platelets. The platelet concentration can reach 260 000 times that of the plasma concentration, making it easy to distinguish when activation has occurred. With a primary structure similar to PF4, β-thromboglobulin is released under the influence of known platelet activators such as ADP, collagen, immune complexes and thrombin, and has a plasma half-life of 100 minutes[15–17,23,26]. It is also excreted in the urine[27], and some researchers[28] advocate measurement in the latter, as it is less prone to artefactual errors, due to collection and processing of venous blood. Others advocate the use of simultaneous plasma PF4 and β-thromboglobulin measurements for a more balanced picture[29]. However, as β-thromboglobulin is cleared by the kidney, the patients' renal function needs to be taken into consideration. It has been suggested that high β-thromboglobulin levels could simply reflect renal impairment rather than the activation of platelets *per se*[30,31]. As is the case for PF4, aspirin reduces levels of this marker[8,25,26].

Soluble P selectin (CD62P)

The adhesion molecule P-selectin was first identified on the surface of activated platelets[32], and subsequently, as part of the membrane of the Weibel–Palade bodies in endothelial cells[33]. P-selectin is now known to be a component of the alpha granule membrane and, when expressed externally due to activation, extends 40 nm out from the membrane surface. Consequently, P-selectin has the capacity to mediate interactions between the endothelium, platelets and leukocytes, possibly by phosphorylation of histidine residues on the cytoplasmic tail of the molecule. The finding of a soluble form (i.e. soluble P-selectin) in the plasma implies a physiological shedding and/or a pathological cleavage of the membrane form[19,20].

Increased levels of this adhesion molecule in the plasma of patients with thrombotic disorders and atherosclerosis (i.e. soluble P-selectin) provides support for the hypothesis that such levels reflect platelet activation[19–21], a concept gaining acceptance[34–36]. In contrast to its effects on PF4 and β-thromboglobulin, aspirin appears to have no effect on levels of soluble P-selectin[35–37]. However, this has recently been challenged in a small, preliminary, cross-sectional report that also found lower membrane P-selectin (defined by flow cytometry) in subjects with an acute myocardial infarction who were already taking aspirin[38]. Unlike β-thromboglobulin, soluble P-selectin is not found in normal urine[28,37]. Although, as with PF4 and β-thromboglobulin, the literature on soluble P-selectin is dominated by data on arterial thrombosis, isolated reports in venous thrombosis exist.

Cross-sectional studies

Several simple case/control studies, often despite small numbers of patients, have reported raised levels of these markers in patients with concurrent venous disease. One of the first found raised levels of β-thromboglobulin in 24 patients presenting with a DVT compared to 16 healthy controls[39]. Cella et al.[40] and Hirose and Inada[41] confirmed this result in larger numbers, whilst Farrell et al.[42] and van

Cambridge Books Online © Cambridge University Press, 2009

Hulsteijn et al.[43] found raised levels in pulmonary embolus. The latter also reported that heparin and warfarin failed to reduce β-thromboglobulin. Sakaguchi et al. reported higher β-thromboglobulin in patients with multiple or recurrent DVT compared to those with a single episode of DVT[44]. However, others have not found significant differences in levels of β-thromboglobulin[45].

Therefore, with a single caveat[45] raised levels of β-thromboglobulin seem to be present in those with a current, acute thrombosis[39–44]. However, levels are not raised in those with a past DVT (>3 weeks)[40]. Van Hulsteijn found that increased β-thromboglobulin was still present in about 50% of patients 3 months after suffering a venous thrombosis: levels returned to normal in all patients after 1 year[46].

Smith and colleagues reported moderately increased ($P = 0.018$) levels of soluble P-selectin in patients with a current, established DVT (either spontaneous or after total hip replacement), compared to controls[47]. Our own study[48] also found moderately ($P = 0.011$) increased levels of soluble P-selectin in the plasma of 89 patients, but a median of 18 months after they had suffered a DVT, and so were considered free of active disease, compared to 126 controls. This effect was independent of smoking (Fig. 49.2). However, the wide spread of this data underlines the lack of specificity of many plasma markers, and thus, some difficulty in interpretation.

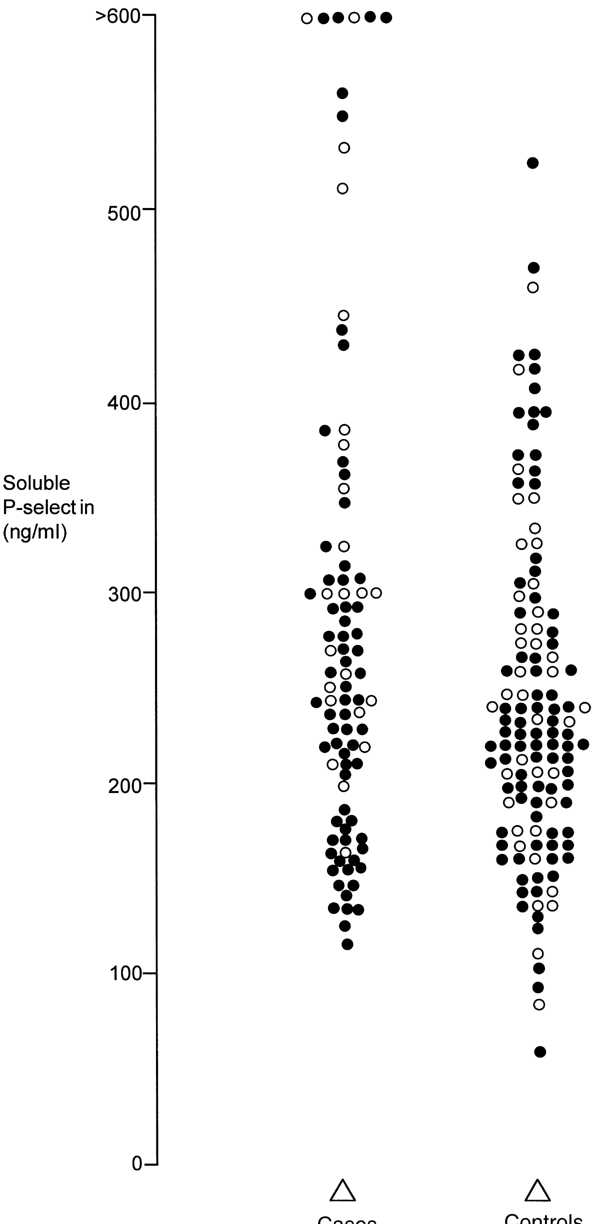

Fig. 49.2. Levels of soluble P selectin in subjects who have had a DVT compared with subjects who have not had a DVT. Open circles: smokers, closed circles: non-smokers[52].

Do platelet markers predict DVT?

The most valuable data suggesting a causal association between platelet activation and venous thromboembolism would be that which predicts the development of a DVT or a PE. As surgery is an established risk factor for thrombosis, several groups have used serial platelet markers in an attempt to do just this. Although Lane et al.[49] and Paramo and Rocha[50] both noted rising levels of β-thromboglobulin following surgery, levels failed to predict those who suffered a DVT. However, Owen et al.[51] failed to find any change in β-thromboglobulin or PF4 after craniotomy, and could also not predict those 18 from 32 developing a DVT. Despite this, it seems that urinary β-thromboglobulin may be superior, as rising levels in the postoperative period did predict those developing a DVT[52]. Similarly, Douglas et al.[53] found that plasma levels were significantly increased on the first postoperative day in 14 patients who developed a DVT after gastrointestinal surgery compared to those 18 patients who did not.

One possible reason for the failure of these studies to predict the thrombosis development is that venepuncture and/or DVT screening may have been at an inopportune window. Another may be inadequate numbers, bringing low statistical power when compared with the huge number of patients involved in the larger clinical trials[8,12]. Both platelet factor 4 and β-thromboglobulin are also prone to the artefact of ex-vivo release from the platelet α-granules once the blood has been drawn, possibly giving rise to spurious data, although this effect can be reduced

Cambridge Books Online © Cambridge University Press, 2009

with a special platelet-friendly cocktail[17,25–27,29]. This latter problem may not be relevant for non-α-granule markers such as those derived from the membrane system of the platelet. However, there are, as yet, no studies reporting the value of markers such as soluble P-selectin or soluble gpV in predicting venous thrombosis. The two studies described[47,48] cannot answer the important question of whether or not raised levels predict venous thrombosis. However, the fact that soluble P-selectin was still raised 18 months after a DVT[48], contrasts with the report of normal values of β-thromboglobulin 1 year after the DVT[46]. The clinical corollary of these differences is uncertain, and the changes may simply reflect measurement of different aspects of platelet physiology.

Platelet imaging

Among the earliest detection methods for DVT are radiolabelled fibrinogen and systematic venography[6–8,10,16,54]. However, due to advances in nuclear medicine, other techniques have become available. For example, Sundrehagen et al.[55] radiolabelled platelets with technetium-99m and used it to detect lung embolism and DVT. Morimoto et al.[56] recently used ^{111}indium to label autologous platelets, and then detected arterial and venous thrombosis. However, long before these studies, Wu et al.[16] used ^{51}chromium labelling to show a correlation between platelet hyperactivity and shortened survival in DVT patients.

Other techniques, possibly more sensitive, have been used that take advantage of various specific platelet surface molecules, as opposed to the entire cell. For example, Muto et al.[57] used a technetium-labelled synthetic peptide of 26 amino acids (P280) with affinity to gpIIb/IIIa (the platelet fibrinogen receptor) in scintigraphy to localize DVTs, and compared it with contrast venography, finding excellent sensitivity, specificity and agreement[58]. The gpIIb/IIIa complex has been the target of several other approaches using different peptides[59,60]. These studies provide further evidence (should it be needed) of the presence and importance of the platelet in thrombosis.

Conclusions and further perspectives

Without prophylaxis against venous thromboembolism, the risk of DVT after surgery to the hip usually exceeds 50%, and that of PE ranges from 4 to 25%. Moreover, the frequency of postoperative PE of perhaps 4% remains a common cause of death[61]. Furthermore, increasing evidence that thrombotic episodes may also precede the diagnosis of cancer, thus representing a potential marker for occult malignancy[62]. These and other findings add weight to the hypothesis that 'high risk' patients should be placed on antiplatelet prophylaxis. In the absence of a reliable marker of platelet activation that is of use to epidemiologists, studies of the platelet in DVT and PE fall back on the pharmacological and laboratory approaches.

Clinical trials have recently demonstrated the effectiveness of aspirin in reducing the risk of DVT and PE. Increased levels of soluble P-selectin at the time of, and post-DVT, are one of the very few instances where the laboratory may have something concrete to offer. Interestingly, increased levels of soluble P-selectin predict the development of arterial thrombosis[63,64]. Whether or not levels of this new platelet marker predict the development of venous thrombosis (whether spontaneous, postpartum or postopertive) remains to be seen. Likewise, the efficacy of GpIIb/IIIa antagonists are now established therapeutics in acute coronary syndromes: time may tell if their effectiveness extends to venous thromboembolic disease.

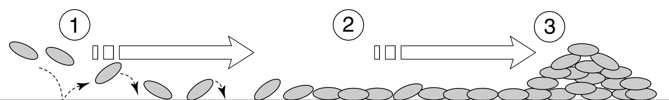
Gene regulation of platelet function

Thomas J. Kunicki

The Scripps Research Institute, La Jolla, California, USA



Stage 1. Tethering
GP Ib complex and von Willebrand factor
Stage 2. Adhesion
Integrin $\alpha_2\beta_1$ and GP VI
Stage 3. Cohesion
Integrin $a_{IIb}\beta_3$ and fibrinogen or von Willebrand factor

Fig. 50.1. Platelet thrombus formation. The process of platelet thrombus formation can arbitrarily be divided into three stages: (i) Transient adhesion (or tethering) mediated by binding of the platelet glycoprotein (GP) Ib complex to Von Willebrand Factor (VWF) adsorbed to the matrix; (ii) adhesion with synchronous platelet activation, mediated in the case of collagens by the integrin $\alpha_2\beta_1$ and platelet GPVI; and (iii) the formation of a platelet aggregate (or cohesion) mediated by the binding of either or both fibrinogen and VWF to the activated integrin $\alpha_{IIb}\beta_3$.

The process of hemostasis or thrombus formation mediated by blood platelets is complex and can involve several alternative receptor–ligand interactions. To facilitate an analysis of the mechanisms that control platelet function, we can arbitrarily divide the process of platelet hemostasis into three stages (Fig. 50.1).

The first stage is a transient tethering of platelets to the damaged subendothelium. This initial transient platelet adhesion requires the specific binding of the plasma protein Von Willebrand factor (VWF) to the membrane receptor glycoprotein Ib–IX–V complex (GP Ib complex). This association is critical to normal platelet function in preventing blood loss and is a requisite step in the adhesion of platelets to exposed thrombogenic materials in regions of atherosclerotic plaque rupture, which sets the stage for thrombus formation.

In the second stage, platelets form a more stable monolayer over the thrombogenic surface that can be mediated by a variety of receptors, depending on the nature of the extracellular matrix and the adhesive proteins that are present. In damaged areas of the blood vessel wall, where there is an abundance of collagens, this stage is frequently mediated by the interaction of collagen receptors, such as the integrin $\alpha_2\beta_1$ and the platelet-specific receptor GPVI. Integrin $\alpha_2\beta_1$ primarily supports platelet attachment to collagen, while GPVI and to a lesser extent $\alpha_2\beta_1$ work in concert to transduce signals through the membrane. The engagement of these receptors culminates in the activation of platelets and signals the onset of the next stage. This is also the stage at which the activated platelet surface catalyses the formation of thrombin serving as a nidus for the formation of a fibrin clot.

Platelet cohesion follows in a third stage resulting in the generation of platelet-rich thrombi mediated by the binding of fibrinogen or vWF to the activated platelet integrin $\alpha_{IIb}\beta_3$.

To fully appreciate the impact of genetic dimorphisms on platelet function *vis-à-vis* each of these stages, it is important to compare and contrast the regulatory properties of the several receptor genes that are restricted to, or differentially regulated within, the megakaryocyte lineage.

Gene regulation in the megakaryocyte lineage

Compared to the other hematopoietic lineages, gene expression in megakaryocytes is difficult to study, because these cells are less common, more fragile and quickly differentiate to a committed apoptotic fate. Consequently, the regulation of megakaryocyte-specific genes has been investigated predominantly in pluripotent human hematopoietic cell lines that have megakaryocyte features and express several platelet-specific genes, e.g. GPIbα, GPIbβ,

GPIX, α_{IIb}, PF-4, GPVI or GPV. The cell lines most commonly used for this purpose are erythro-megakaryocytic and include K562, HEL, Dami and CHRF-288–11.

The recent cloning of the megakaryocyte inducer thrombopoietin may now enable the development and expansion *ex vivo* of primary megakaryocytes in quantities sufficient to perform biochemical analyses and to characterize megakaryocyte developmental regulators. This will facilitate the characterization of megakaryocyte-specific transcriptional regulators, where they exist. In the interim, our current understanding is derived from the study of the aforementioned pluripotent, hematopoietic cell lines.

Megakaryocytic-specific gene promoters, including α_{IIb}, PF-4, GPVI, GPV and GPIbα, have a number of common characteristics. The core promoters are generally short (500 base pairs), lack CCAAT or TATA consensus sequences, and have functional GATA, Sp-1 and Ets *cis*-acting sites. GATA and Ets factors are not exclusive to the megakaryocyte lineage but are also critical for gene expression in erythroid cells and are important for the regulation of genes like PECAM-1and P-selectin, which are expressed in both megakaryocytes and endothelial cells.

GATA

The GATA family of transcription factors has in common a high degree of sequence homology within zinc finger DNA binding domains and specific binding to the motif (5′-GATAA/G-3′). GATA-1 is primarily expressed in erythroid, megakaryocytic, mast, and eosinophilic cells[1–4]; GATA-2 is expressed in megakaryocytes, endothelial cells and other cell types[3,5,6]; and GATA-3 is expressed in T lymphocytes, erythrocytes, and brain (during development)[7–8]. GATA-1 is only expressed early in megakaryocyte maturation while GATA-2 expression persists, and maturation-dependent differences in the utilization of GATA-1 and GATA-2 could play an important role in protein expression[9].

GATA-1 directs the differentiation of hematopoietic progenitors along either the erythroid or the megakaryocytic pathway. For example, in the primitive myeloid cell line 416B, overexpression of GATA-1 leads to megakaryocytic differentiation[10]. GATA-2 and GATA-3 transcripts in these cells remain undetectable, suggesting that GATA-2 and GATA-3 lie upstream of GATA-1. Enforced expression of GATA-2 or GATA-3 in the same cells will then also induce megakaryocytic differentiation, presumably via induction of GATA-1, a finding consistent with the conclusion that GATA-1 is a dominant regulator of megakaryocyte maturation.

Initial murine knock-out experiments did not show a direct link between GATA-1 and megakaryocytic differentiation[11,12]. GATA-1 (−/−) mice exhibited severe anemia and total arrest of erythroid differentiation at the proerythroblastic stage[13,14]. These erythroid precursors later died by apoptosis. More recently, megakaryocyte-specific GATA-1 knock-out mice have provided a more informative phenotype. These mice have decreased peripheral blood platelet counts, deregulated proliferation of megakaryocytes and a block in their terminal cytoplasmic maturation[15]. These mice, however, express normal amounts of α_{IIb} and MPL (the thrombopoietin receptor) and 50-fold higher levels of GATA-2, suggesting that GATA-2 compensates for the loss of GATA-1 and that GATA-1 negatively regulates GATA-2 during normal erythroid maturation[16].

Ets

The Ets factors are a family of transcription factors that regulate expression of many hematopoietic genes. The prototype, Ets-1, was given its name because it is expressed as part of an oncogenic protein by the E-26 virus[17]. Ets factors have in common an 82 amino acid motif (the Ets domain) that binds to DNA sequences containing a consensus 5′-GGAA/T-3′[18].

One member of the Ets family, Friend's leukemia integration-1 (Fli-1; ErgB) is over expressed in erythroleukemia cells of mice infected with Friend's leukemia virus. Recent experiments suggest that Fli-1 might play a role in the regulation of megakaryocytic genes. The human erythro-megakaryocytic cell line K562, which normally lacks Fli-1, shows an increased expression of megakaryocytic features when transfected with a vector expressing Fli-1[19]. Moreover, the α_{IIb} promoter can be transactivated by Fli-1in HeLa cells transiently cotransfected with α_{IIb} promoter constructs[19].

The Ets factor PU.1 has been identified in mature megakaryocytes, and binding sites for this factor are present in megakaryocytic genes, such as α_{IIb} and β-thromboglobulin. Overexpression of PU.1 in mice induces erythroleukemia through blockage of erythroid differentiation[20], and the overexpression of PU.1 on these murine erythroleukemia cells reduces their NF-E2 expression and the DNA-binding activity of GATA-1[21]. PU.1 can also transactivate the promoter for the megakaryocyte-specific platelet basic protein.

Fig. 50.2. The platelet GPIb complex. Four distinct gene products (GPIbα, GPIbβ, GPIX and GPV) assemble to form a functional heptamer known as the GPIb complex. Each of these polypeptides contains a transmembrane region and cytoplasmic domain. The functional keystone of the complex is GPIb, composed of the larger GPIbα (containing the VWF binding site) that is disulfide bonded to the smaller GPIbβ. Each complex is composed of: two GPIb, two GPIX and one GPV subunit. Each of the subunit genes has in common the presence of a variable number of leucine-rich motifs.

Stage 1. Transient platelet tethering mediated by the GP Ib complex

The GPIb complex (Fig. 50.2) is a heptamer composed of four distinct gene products: two molecules of GPIbα, two of GPIbβ, two of GPIX and one of GPV. VWF is directly bound by the GPIbα subunits, each of which is disulfide-linked to a GPIbβ subunit. GPIX is noncovalently associated, and GPV is loosely associated with the complex. The GPIbα, GPIX, and GPV genes are restricted in their expression to the platelet lineage and appear late in megakaryocytopoiesis.

The Bernard–Soulier syndrome is a human bleeding disorder associated with absent or significantly reduced GPIb complex on the platelet surface. Numerous genetic causes of BSS have been characterized at a molecular level, including fourteen due to mutations in GPIbα, five resulting from defects in GPIX, and four ascribed to abnormalities in GPIbβ[22–27]. There are no reports of BSS resulting from genetic differences in the GPV gene. From reconstitution studies, we now know that GPIbα, GPIbβ and GPIX are all necessary for the expression of the complex on the cell surface. GPV is not absolutely required but does promote complex stability, and the absence of GPV in transgenic mice results in an increase in GPIb complex activity. New insight in the function of GPV have been derived from murine knockout experiments, whereby it has been shown that GPV actually participates in the control of the binding activity of the GPIb complex (see below).

A common feature of the GPIb complex genes is a variable number of leucine-rich repeat motifs (LRM) in all four subunits. GPIbα (135 kd; 610 amino acids) has seven, GPIbβ (25 kd; 181 amino acids) and GPIX (22 kd; 160 amino acids) each have a single LRM, and GPV (82 kd; 544 amino acids) has 15. It is believed that the LRM play an important role in protein–protein interactions. Based on sequence comparisons, it appears that GPIX is the ancestral progenitor of the other members of this LRM family.

Comparative studies of transcriptional regulation of the four subunits has contributed to our understanding of subunit inter-relationships and the identification of those subunits which are rate limiting during complex assembly. Like the polypeptides, the genes encoding each subunit have several characteristics in common. The coding region of each gene, except GPIbβ, is contained within a single exon. In the case of GPIbβ, a small intron interrupts the signal sequence coding region[28]. In each gene, as small intron is located 5′ to the translation start site. Because of the presence of only one or two introns, the genes are relatively small. For example, the largest, GPIbα, spans only 4 kb, including the 5′ and 3′ regulatory regions[29,30]. Though they are structurally similar, however, the genes are dispersed throughout the human genome: GPIbα is located on chromosome 17 (17p12)[28]; GPIbβ is on chromosome 22 (22q11.2)[28,31]; and the genes for GPIX and GPV are located on different regions of chromosome 3 (3q29 and 3q24, respectively[32]).

GPIbα

GPIbα, the largest protein of the complex, contains, at the amino-terminus of its extracellular domain, the binding site for VWF[33] and α-thrombin[34] and has binding sites for 14.3.3ζ[35] and the actin cytoskeleton[36] in its short cytoplasmic region.

Transcription of the GPIbα gene, as well as the other members of the complex in megakaryocytes is controlled by factors of the GATA and Ets families[15], and FOG-1 (Friend of GATA-1) is a necessary cofactor controlling the lineage specificity of GPIbβ gene expression[37]. The importance of the GATA-1 site(s) is reflected by the fact that

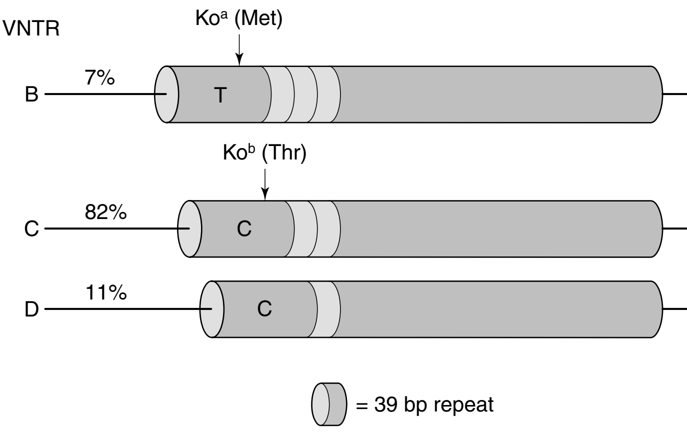
Cambridge Books Online © Cambridge University Press, 2009

mutations of the GATA-1 site in both the GPIbα and GPIX genes *in vitro* essentially eliminates transcription controlled by these promoters[9,38], and a point mutation of the GPIbβ GATA-1 site has been shown to be a cause of one case of BSS[39]. Moreover, recent murine knockout experiments have shown that mice lacking GATA-1 express platelets with a BSS phenotype[15].

At least three polymorphisms influence the function, expression and immunogenicity of the GPIb complex genes, particularly the GPIbα subunit. A variable number of tandem repeats (VNTR) polymorphism within the mucin-like macroglycopeptide region of GPIbα (Fig. 50.3, top panel) results in the duplication of a 13-amino acid sequence either once (VNTR D), twice (VNTR C), thrice (VNTR B) or four times (VNTR A), and results in a polypeptide length of 610, 623, 636 or 649 amino acids, respectively[40,41]. Because these repeats are rich in proline, serine and threonine, they can be potentially glycosylated, and each repeat could add up to 32 angstroms to the length of the GPIbα extracellular domain[40]. In a simple model, this could extend the GPIbα binding sites for VWF and thrombin further above the plane of the plasma membrane, increasing the avidity for these ligands and accounting for the observed increased risk for acute coronary artery disease associated with the longer variants, VNTR A and VNTR B[42,43].

A second clinically relevant GPIbα polymorphism is the threonine to methionine substitution at amino acid 145, within the region of the ligand-binding LRM[44,45]. This dimorphism is the basis of the HPA-2 platelet alloantigen system (Fig. 50.4), and the allele frequencies for the Thr and Met alleles in a typical Caucasian population are 90% and 10%, respectively[44,45].

A third polymorphic variation in the region surrounding the translation start site, at position −5 from the initiator ATG codon (where either T or C is present) (Fig. 50.3, bottom panel), was shown to influence the levels of the receptor expressed on the surfaces of transfected cells and platelets[46,47]. The −5C allele has a gene frequency of about 0.15 in several human ethnic populations and may be a determinant of platelet responsiveness because it influences GPIbα expression. The presence of the −5C allele increases the mean level of GPIbα on the platelet plasma membrane (roughly, a 50% increase in homozygous individuals; and a 33% increase in heterozygous individuals) presumably because it enhances the interaction of the cellular protein translation machinery with the adjacent Kozak sequence[46].



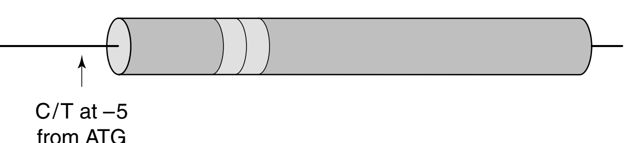


Fig. 50.3. Polymorphisms of the GPIbα subunit. Three polymorphisms are relevant to the expression and function of GPIbα. (Top panel) The variable number of tandem repeats (VNTR) polymorphism is characterized by the expression of four (VNTR A; not shown), three (VNTR B), two (VNTR C) or one (VNTR D) copy of a 39-base pair repeat sequence. In a typical Caucasian population, the gene frequencies of each allele are: A (<0.01); B (0.07); C (0.82); and D (0.11). Another dimorphism, the Met/Thr at residue 145 (nucleotide T/C substitution), gives rise to the Ko^a and Ko^b alloantigens and is linkage disequilibrium with the VNTR polymorphism. Thus, the VNTR A and B alleles express only Met-145, while the VNTR C and D alleles express only Thr-145. (Bottom panel) In GPIbα, a C/T substitution at a position five nucleotides upstream from the ATG start codon influences an adjacent Kozak sequence and thus the rate of translation of the mRNA transcript by the cell machinery. On average, the relationship of GPIb levels to genotype at this position is: T/T = 1.0; T/C = 1.3; C/C = 1.5.

GPIbβ

The functional role of GPIbβ in the complex has not been clearly defined, although in vitro evidence suggests that this protein can act as a complex-specific chaperone that protects GPIbα from lysosomal degradation while it is transported to the membrane[48].

Moran et al.[26] described recently a patient with a novel, homozygous, single-nucleotide substitution (Glycine-

159→alanine) in the coding region for GPIbβ at a tryptophan codon (TGG), which results in the premature termination of translation at amino acid 21. No sequence abnormalities were observed in either the GPIbα or the GPIX subunit of the complex. Although GPIbα, GPIX, and GPV were undetectable on the platelet surface, GPIbα was readily demonstrated in platelets. Moreover, soluble GPIbα was present in plasma. The defective GPIbβ is thus unable to support the expression of a functional complex at the platelet surface. Thus, GPIbβ affects the surface expression of the GPIb–IX complex by failing to support the insertion of GPIbα and GPIX into the platelet membrane[26].

This critical role for GPIbβ as a chaperone was confirmed by Strassel and coworkers[27] who identified a different single amino acid substitution in GPIbβ (Asparagine-63→Threonine) that also results in the inhibition of expression of cotransfected wild-type GPIbα in CHO cells.

A rare Gly→Glu substitution at residue 15 gives rise to the HPA-11bw alloantigen (ly[a])[49].

GPIX.

Like GPIbβ, GPIX is thought to act as a complex-specific chaperone that protects GPIbα from lysosomal degradation while it is transported to the membrane[48].

Bastian et al.[9] identified an Ets site (ACTTCCT) located between −35 and −49 relative to the GPIX transcriptional start site that, when disrupted, reduced promoter activity in transiently transfected HEL cells. The identity of the protein(s) that binds to this GPIX Ets site remains to be determined, however, *in vitro* binding studies had shown that Ets-1 and Ets-2 can bind to the α_{IIb} promoter sites, and there is some indication that one or both of these factors regulate GPIX promoter activity.

The oncogenic protein Fli-1 can transactivate the GPIX promoter when an intact GPIX Ets site is present. Comparative studies showed that Fli-1 was also able to transactivate the GPIbα and, to a lesser extent, the α_{IIb} promoter. Although Fli-1 protein has been identified in platelet lysates, it seems unlikely that Fli-1 is translated de novo in platelets, but more probable that the presence of Fli-1 in platelets represents residual protein synthesized in the megakaryocyte.

Negative regulation is emerging as a common theme in megakaryocyte-specific promoters. Transcriptional silencer domains have been identified upstream of the human PF-4 gene and within the rat PF-4 and human αIIb promoters. The GPIX promoter has a weak negative regulatory domain between −686 and −423 and a strong negative domain between −311 and −203. A comparison of negative regulatory domains in the megakaryocyte gene promoters led to the identification of a handful of potential regulatory motifs. Prandini *et al.*[50] identified transcriptional repression sites in the α_{IIb} promoter: 5′-TGAGT-3′ at −120 to −116 and 5′-CCCTTTGCTC-3′ −102 to −93, relative to the transcription start site (see below). An exact duplicate of the α_{IIb} 5′-TGAGT-3′ hexamer is found in the weak regulatory domain of the GPIX promoter at −455 to −451. In addition, within the strong GPIX negative repressor domain, there are two sequences (−282 to −273 and −263 to −254) that are somewhat similar (3/9 mismatches) to the α_{IIb} CCTTTGCTC sequence.

GPV

GPV is thought to play a contributory role in the high-affinity binding of thrombin to the platelet[51] but has never been considered essential for the surface expression of a functional complex[52]. The GPV gene is comprised of a short intron in the 5′ untranslated region and a coding sequence contained entirely in the second exon. The 5′-flanking region contains consensus binding sites for GATA, Ets transcription factors and Sp1. The rat and mouse genes are identical in structure and have conserved many of the putative human regulatory sequences. GPV appears late in megakaryocyte differentiation and is absent from most megakaryocytic leukemic cell lines, unlike the other platelet-specific proteins described above. HEL or K562

Cambridge Books Online © Cambridge University Press, 2009

cells are probably blocked at early stages of differentiation, because they express both erythroid and megakaryocytic markers, so that neither of these cell lines expresses GPV, even at the mRNA level. Dami cells, on the other hand, despite recent confirmation that they are subclones of HEL cells, do express GPV, accompanied by increased levels of GPIb-IX (relative to HEL cells). This implies that GPV functions in later stages of megakaryocyte maturation and would necessarily respond to late stage growth or transcription factors.

A repressor domain (-903 to -816) contains a sequence homologous to the silencer region of the α_{IIb} promoter. α_{IIb} -specific expression relies on the activity of this strong repressor, and mutation of this element leads to a ubiquitous activity of the promoter. On the other hand, deletion of this repressor region in the GPV gene does not reverse cell specificity[53]. The core promoter ($-103/+1$) contains two Ets binding sites, Ets-66 and Ets-42, and a GATA site, GATA-71. The GATA/Ets tandem of the core promoter resembles those of the other megakaryocyte-specific genes, α_{IIb}, PF4, GPIbα, β-TG, GPIX, and MPL. Mutation analysis of the GATA/Ets tandem showed that this tandem is essential for GPV transcription and that both sites are important for full transcriptional activity of the GPV promoter in the megakaryocytic lineage. The most proximal Ets site (Ets-42) is most critical for maintaining basal activity, and deletion of this site abolished transcriptional activity.

Signal transduction through the GPIb complex

GPIbα is associated through its cytoplasmic domain with actin-binding protein (ABP; filamin)[54,55] and the protein 14–3–3ζ[56].

Upon engagement of VWF, the signalling events mediated by the GPIb complex include elevation of cytoplasmic Ca^{2+} and activation of protein kinase C and tyrosine kinases[57–60]. An unidentified tyrosine kinase becomes associated with the GPIb complex as a result of VWF binding to GPIbα[61]. Two tyrosine kinase substrates (76 kd and 32 kd) become phosphorylated[57], the larger perhaps identical to syk, the smaller unidentified[58]. In addition, pleckstrin and myosin light chain are also rapidly phosphorylated by Ser/Thr protein kinases[57], both src and activated phophatidylinositol 3-kinase become associated with the cytoskeleton[60], phosphatidylinositol 4,5-biphosphate is metabolized, phosphatidic acid is synthesized, phospholipase A_2 is activated, and arachidonic acid and thromboxane A_2 (TXA_2) are synthesized[57].

Although none of the cytoplasmic sequences of the GPIb complex contain motifs known to interact with signalling proteins, these regions do interact with the cytoskeleton, and signal complexes may assemble at the junction of the GPIb complex with this scaffold. Signal transduction may be mediated, in part, by the binding of 14–3–3ζ[35]. 14–3–3ζ has been shown to bind to proteins with a conserved RSXSXP motif in which the second serine is phosphorylated[62]. It remains to be determined to what extent 14–3–3ζ is involved in the mediation of signals through the GPIb complex.

Another candidate signalling pathway would require the FcRγ chain[63] and involves Syk. Tandem Src homology 2 (SH2) domains of Syk bind to proteins containing phosphorylated ITAMs, which are not found on any of the four subunits of the GPIb complex. However, platelets do express two ITAM-containing proteins, FcγRIIA, and the FcRγ chain. It is possible that the GPIb complex can bind with either or both of these proteins, allowing the complex to couple to Syk. The contribution of FcRγ chain to signal transduction in platelets is even more extensive, since it has recently been shown to be complexed constitutively to the platelet collagen receptor GPVI (see below). From murine knockout experiments, we now know that both the FcRγ chain and Syk are essential for platelet activation by collagen. Importantly, in the absence of FcRγ chain, collagen is unable to induce Syk activation, showing the FcRγ chain is a critical upstream regulator of Syk.

These findings lead to a working model[63] in which the GPIb complex associates with FcRγ chain, either constitutively or upon receptor activation, and the Src family kinases Fyn and Lyn phosphorylate FcRγ chain resulting in the binding of Syk through its tandem SH2 domains, activation of Syk, and phosphorylation-dependent activation of PLCγ2. It remains to be proven that PLCγ2 becomes activated downstream of GPIb and, if so, whether tyrosine phosphorylation of PLCγ2 is the sole mechanism by which PLCγ2 may become activated downstream of this receptor.

Clinical relevance of GPIb complex polymorphisms

As noted above, there is ample evidence that a high degree of interdependence among the members of the GPIb complex is needed for receptor expression and efficacy. However, the bulk of clinical correlations accumulated to date involve the GPIbα subunit.

Since the GPIb complex is pivotal to the initial tethering of platelets to the extracellular matrix, it is not surprising that structural differences in the keystone subunit, GPIbα, would influence thrombosis in vivo. As summarized in Fig. 50.5, there is substantial evidence for an association between the VNTR B allele and risk of arterial thrombosis and acute adverse outcomes in coronary artery disease. On

the other hand, risk for venous thrombosis is consistently negative. Aside from two preliminary reports, the majority of studies have failed to find a correlation between the inheritance of the Kozak C genotype (high receptor density) and risk for coronary artery disease (Fig. 50.6). However, a very recent report does provide evidence that there may well be an association with the *severity* of negative outcomes following acute myocardial infarction in younger individuals (≤62 years old)[64].

Stage 2. Stable adhesion to collagens mediated by integrin $\alpha_2\beta_1$ and GPVI

Collagen receptors

Collagens will induce platelet shape change, secretion, and aggregation, accompanied by phosphoinositide hydrolysis, TXA_2 synthesis, phosphorylation of specific protein substrates, and an increase in cytoplasmic Ca^{2+}.

The human α_2 gene

The integrin α_2 subunit is a single chain transmembrane polypeptide that pairs exclusively with the β_1 subunit (Fig. 50.7, left panel). In human, a single copy of the α_2 gene is present in the haploid genome, located on chromosome 5 (5p11–12)[65]. The cDNA sequence published by Takada and Hemler[66] was nearly complete, lacking the bulk of the final exon 30 and a polyadenylation site.

Platelet $\alpha_2\beta_1$ levels among randomly selected individuals can vary up to 10-fold and correlate with differences in adhesiveness to type-I or type-III collagens. We identified linked, allelic polymorphisms within the coding sequence of the α_2 gene that correlate with platelet $\alpha_2\beta_1$ density[67,68]. These observations led to further characterization of the integrin α_2 alleles, summarized schematically in Fig. 50.7 (centre panel). Four α_2 alleles can be defined: Allele 1 (807T/1648G/2531C) is associated with increased levels of $\alpha_2\beta_1$, while Allele 2 (807C/1648G/2531C) and Allele 3

Cambridge Books Online © Cambridge University Press, 2009

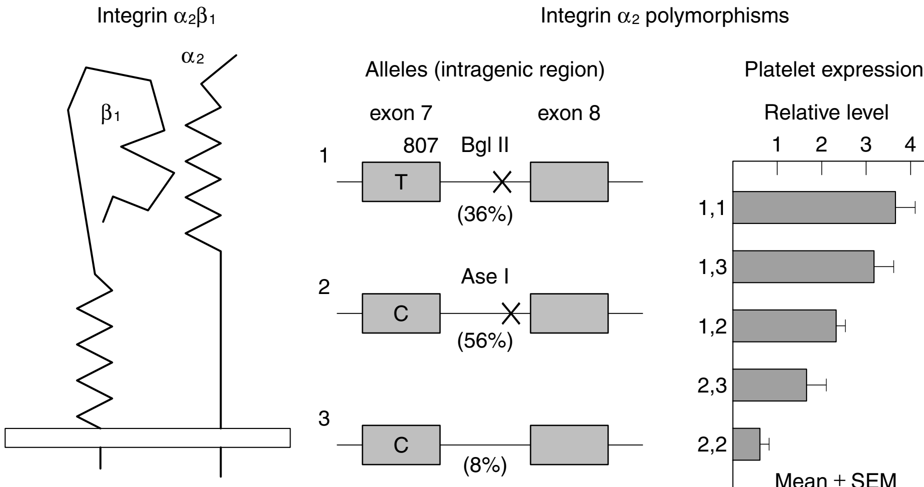

Fig. 50.7. The integrin $\alpha_2\beta_1$. (Left panel) This receptor is a heterodimer composed of non-covalently associated α_2 and β_1 subunits, both of which contain transmembrane regions and cytoplasmic domains. (Centre panel) Three common α_2 alleles can be distinguished by the silent 807 C/T dimorphism within exon 7 and the presence of unique *Bgl II* or *Ase I* restriction sites within the intron separating exons 7 and 8. The gene frequencies of each of these alleles in a typical Caucasian population are: allele 1 = 0.36; allele 2 = 0.56; and allele 3 = 0.08. (Right panel). The relative level of platelet $\alpha_2\beta_1$ is controlled by the inheritance of these three α_2 alleles. For example, individuals who are homozygous for α_2 allele 1 express, on average, fourfold the amount of this receptor that would be found on platelets of individuals who are homozygous for α_2 allele 2.

(807C/1648A/2531C) are each associated with decreased levels of this receptor. The gene frequencies of these three alleles in a typical Caucasian population are: Allele 1, 0.36; Allele 2, 0.56; and Allele 3, 0.08. Two intronic sequence differences (between exons 7 and 8) create unique *Bgl II* and *Ase I* restriction sites[69] that can be used to distinguish each allele by RFLP assay (Fig. 50.7, centre panel). The rate of platelet attachment to type I collagen in whole blood under conditions of high shear rate (1,500/s) is proportional to the density of $\alpha_2\beta_1$ receptors on the platelet surface, as determined by differential inheritance of alleles 1 or (2 + 3) (Fig. 50.7, right panel). These initial findings suggested that α_2 alleles could influence risk of thrombosis or bleeding in relevant disease states.

The very rare allele 4 (gene frequency <0.01) uniquely expresses 2531T, which defines the Sit^a alloantigen (Fig. 50.8). Within the coding sequence, two single point missense dimorphisms have been described: $A_{1648}G$ ($Lys_{505}Glu$) and $C_{2531}T$ ($Thr_{799}Met$) are responsible for the formation of the Br^a/Br^b (HPA-5) and Sit^a alloantigens (HPA-12bw), respectively[70,71] (Fig. 50.8). Neither dimorphism is causally involved in inherited expression differences.

The sequence of one human α_2 gene 5′ regulatory region has been reported by Zutter et al.[72,73]. Comparisons with our allele sequences establish that this regulatory region is that of Allele 2. The first 961 bp of the 5′ flanking region of Allele 2 isolated from the K562 cell line directs cell-type specific suppressor and enhancer activity in cells of epithelial origin[72]. This region contains critical elements that are required for efficient expression of this TATA-less promoter. The core promoter (-92/-30) contains two Sp1 elements that are necessary for full transcription activity in erythro-megakaryocytic cell line K562[74]. The distal 5′ region contains a strong megakaryocytic enhancer located at −1655/−1426 that requires two tandem AP1 binding sites[75]. Interestingly, a GATA site and AP2 elements located in this enhancer region and a GATA site within the proximal 961 bp promoter do not mediate enhancer activity in hematopoietic cells. We have recently identified two natural dimorphisms within the human α_2 promoter, $C_{-52}T$ and $C_{-92}G$, which also influence transcription rate[69] and are not linked to alleles 1 or 2. Together with the allelic differences, these promoter dimorphisms contribute to the variability in expression of human $\alpha_2\beta_1$.

Clinical relevance of α_2 polymorphisms

Platelet adhesion to collagen-coated surfaces in whole blood under flow conditions is mediated by both von Willebrand factor (VWF)-dependent recruitment of the platelet glycoprotein Ib–IX receptor complex and collagen interaction with the integrin $\alpha_2\beta_1$. In type 1 von Willebrand disease (VWD), platelet adhesive functions are impaired

Fig. 50.9. Correlation between inheritance of the integrin α_2 Allele 1 (increased $\alpha_2\beta_1$ density) and risk for adverse outcomes in various thrombotic disorders. Individual studies that confirm (YES) or refute (NO) a correlation between inheritance of α_2 allele 1 (807T genotype) and risk for thrombotic disease are indicated. The clinical syndromes include: acute myocardial infarction, cerebral vascular disease (CVD) / stroke, coronary artery disease, deep vein thrombosis (DVT), diabetic retinopathy, and venous thrombosis. Data are tabulated as of November 2000.

due to the decrease in VWF levels in plasma and platelets. Di Paola et al.[76] have demonstrated that the low-density α_2 allele 2 increases the risk factor for bleeding in type I von Willebrand Disease. They measured the frequencies of α_2 alleles in symptomatic patients with five types of VWD (type 1, $n=78$; type 2A, $n=25$, type 2B, $n=14$; type 2M, $n=10$; and type 3, $n=20$). Compared to the normal group, no significant difference in allele frequencies was observed among individuals with types 2A, 2B, 2M, or 3 VWD. However, the frequency of allele 2 among type 1 VWD patients ($=0.71$) was significantly higher than that of the normal population ($P=0.007$). Also, in patients with VWD type 1 and borderline to normal ristocetin-cofactor (VWF: RCo) activity values, collagen receptor density correlates inversely with closure time in a high shear stress system, the platelet function analyzer (PFA-100; Dade-Behring). It was proposed that low platelet $\alpha_2\beta_1$ density results in less efficient primary platelet adhesion and may result in increased tendency to bleed, as evidenced by the high frequency of this polymorphism in patients with type 1 VWD compared with normal individuals. In addition, this may account for the variability between patients with similar levels of VWF antigen, but strikingly different bleeding histories.

Santoso et al.[77] investigated the relationship of the α_2 alleles to the risk of coronary artery disease (CAD) and myocardial infarction (MI). An allele-specific polymerase chain reaction (PCR) was developed for genotyping α_2 alleles. DNA samples from 2237 male patients who underwent coronary angiography on account of coronary heart disease as verified illness or presumptive diagnosis were genotyped. They found a strong association between allele 1 and non-fatal MI among individuals younger than the mean age of 62 years ($n=1057$; odds ratio, 1.57; $P=0.004$) and an even stronger association among individuals within the youngest 10% of the study sample (<49 years; $n=223$; odds ratio, 2. 61; $P=0.009$). In contrast, no evidence of an association between α_2 alleles and CAD was found. It was concluded that inherited platelet $\alpha_2\beta_1$ variations might have an important impact on acute thrombotic disease in younger individuals. This has been confirmed by a number of other investigators (Fig. 50.9)[78,79]. In addition, a significant correlation has been found between the expression of Allele 1 and risk for adverse outcomes in younger individuals with cerebral vascular disease or stroke [80–82] and diabetic retinopathy[83].

In contrast, the density of platelet $\alpha_2\beta_1$ has not been found to be a risk factor for venous thrombosis[84–86] (Fig. 50.9). This lack of influence on thrombosis on the venous side is a typical finding for all of the platelet glycoprotein dimorphisms that are currently under study.

Hormonal regulation of $\alpha_2\beta_1$ expression

Gender differences figure prominently in risk for thromboembolic disease, leading to the suspicion that steroid hormones might influence the expression and or activity of key platelet glycoprotein receptors. It has been known for some time that hormone replacement therapy (HRT) in postmenopausal women can predispose to venous thrombosis, but it is only recently that a potential influence of HRT on platelets in the coronary circulation has been proposed[87,88]. Tarantino et al.[87] observed that, in women, platelet adhesion to type I collagen shows a biphasic periodicity in synchrony with the menstrual cycle and that human megakaryocytes express the estrogen receptor (ER). This finding implies that platelet collagen receptor function may be modulated by sex hormone levels and would be consistent with the known correlation between ER and $\alpha_2\beta_1$ expression in certain cell lineages[72,89]. Khetawat et al.[88] have subsequently observed that human megakaryocytes contain mRNA specific for the ER β and the androgen receptor (AR), and that the transcripts of both can be located in the platelet cytoplasm. Megakaryocytes are able to respond in a regulated manner to testosterone. These reports provide compelling evidence that sex hormones may be able to mediate gender differences in platelet function and antigenicity. It remains to be determined to what extent the effects of these hormones occur through genomic or non-genomic pathways.

Platelet GPVI

GPVI is a major platelet glycoprotein (60–65 kDa) (Fig. 50.10) that had been considered a putative receptor for collagen since the identification of a patient with a mild bleeding disorder whose platelets lacked GPVI and exhibited defective collagen-induced responses[90–92]. Collagen binding to GPVI induces platelet activation through a pathway that involves phosphorylation of the FcRγ chain followed by the binding of Syk and the phosphorylation-dependent activation of PLCγ2[93–96]. The sequence of collagen that is recognized by GPVI has been identified as Gly–Pro–Hyp, and a synthetic collagen-related peptide (CRP) based on the triple helical form of this tripeptide sequence is a GPVI-specific platelet agonist[97]. The GPVI–Fcγ complex will transduce outside-in signals by an immune receptor-like mechanism that involves p72^{SYK} activation, results in PLCγ2 activation, and leads to release of granule contents and platelet aggregation[98]. The C-type lectin, convulxin (CVX), from the tropical rattlesnake, *Crotalus durissus terrificus*, is a multimeric protein that binds specifically to GPVI and induces platelet activation

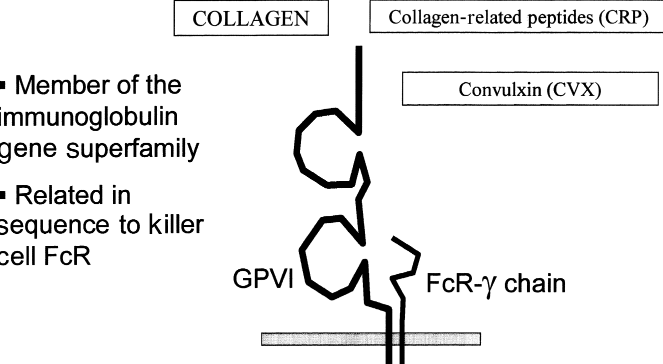

Fig. 50.10. Platelet glycoprotein VI. Platelet glycoprotein VI is a member of the immunoglobulin gene superfamily and is related in sequence to members of the killer cell FcR group. GPVI is non-covalently associated with, and requires for expression, the FcR γ chain. Both proteins contain transmembrane regions and cytoplasmic domains. GPVI binds specifically to collagens, specific sequences within type I collagen typified by the collagen-related peptide (CRP) and the snake venom protein convulxin (CVX).

through the clustering of GPVI [99,100]. CVX is a ready tool for the detection and quantitation of GPVI that also proved invaluable for the isolation and eventual sequencing of this receptor[101].

GPVI cDNA has an open reading frame of 1017 base pairs coding for a protein of 339 amino acids including a putative 23-amino acid signal sequence and a 19-amino acid transmembrane domain between residues 247 and 265. By sequence homology, GPVI is a member of the immunoglobulin superfamily, and its sequence is closely related to FcαR and the natural killer receptors. It contains two Ig-C2-like domains formed by disulfide bridges. The cytoplasmic tail, consisting of 51 amino acids, is atypical of, and shows little homology with, the C-terminal part of the other members of this protein family.

Polymorphic expression of GPVI

In the initial characterizations of platelet GPVI function, some degree of heterogeneity was noted among apparently normal subjects. For example, Jandrot-Perrus and coworkers[100] had reported that, among normal healthy volunteers, purified convulxin induced platelet aggregation at levels between 15 and 35 pM, but they noted a significant heterogeneity in platelet sensitivity to convulxin. Moreover, variability in ligand binding to GPVI was also evident in the findings of Polgar et al.[99].

Cambridge Books Online © Cambridge University Press, 2009

To specifically investigate this potential heterogeneity, we developed a semiquantitative ligand blot assay in which biotin-conjugated convulxin binds selectively to GPVI among the total content of platelet proteins separated by SDS–polyacrylamide gel electrophoresis. We found a fivefold range of platelet GPVI content among twenty-three normal healthy subjects (K. Furihata and T.J. Kunicki, unpublished observations). In addition, we found that prothrombinase activity induced by CVX- or CRP, but not ionophore A23187, is directly proportional to the platelet content of GPVI ($P<0.001$). The fivefold variation in GPVI content is strikingly similar to the previously established range in expression of platelet integrin $\alpha_2\beta_1$ (see above). Among the donors in this study, there was a direct correlation between platelet $\alpha_2\beta_1$ density and GPVI content ($P=0.004$). In view of the well-documented association of GPVI with platelet procoagulant activity, this variation in GPVI content may represent yet another genetically controlled risk factor predisposing individuals to hemorrhagic or thromboembolic disorders.

At this time, however, a genetic basis for variation in GPVI content has not been defined. The possibilities that either the two collagen receptors are physically associated or that the expression of the two receptors is coordinately regulated need to be addressed. In either case, the variation in GPVI content might be driven by the already defined genetic regulation in expression of the integrin $\alpha_2\beta_1$.

Stage 3. Platelet cohesion: thrombus formation mediated by integrin $\alpha_{IIb}\beta_3$

Platelet integrin $\alpha_{IIb}\beta_3$ (GPIIb–IIIa)

The megakaryocyte-specific integrin, α_{IIb}, is the α-subunit of the $\alpha_{IIb}\beta_3$ complex (Fig. 50.11). In the α_{IIb} gene promoter, there are two GATA-binding elements, one of which (at −454) is most critical for transcription[102–104]. A potential negative regulatory element is located within −200/−100 in both the rat and human genes[50,105]. A GA-rich region encompassing −14 appears to be a non-consensus Sp1-binding site that interacts with an Ets-consensus site at approximately −34[106]. This promoter provides another example of the cooperative effect of Ets-like proteins and Sp1 in transcriptional activation of TATA-less genes. The human α_{IIb} and β_3 genes are both physically located on chromosome 17 (17q21.32), but a detailed map of the α_{IIb} region suggests that the αIIb and β3 genes may be ≥1 mb apart, a separation that is too great to consider them located within a single tissue-specific locus[107].

FOG, the cofactor for GATA-1, plays a key role in normal erythroid and megakaryocytic differentiation[37]. FOG is a multitype zinc finger protein that binds to the amino-terminal finger of GATA-1 and modulates the transcription of GATA-1 target genes. FOG acts in concert with GATA-1 and possibly GATA-2 to stimulate α_{IIb} expression[108].

Loss of FOG in mice knockout experiments leads to the elimination of the megakaryocytic lineage at a very early stage, contrasting with the late blockage of megakaryocytic differentiation occurring with GATA-1[109]. This finding suggests that, although acting as an essential cofactor of GATA-1 in erythroid cells, FOG may act independently from GATA-1 in megakaryocytes.

The DNA *cis*-acting elements of gene promoters are also important for regulation of megakaryocyte gene expression. Transcription is regulated by the differential engagement of cis elements in patterns that are specific to each cell lineage. For example, most of the megakaryocytic gene promoters contain GATA and Ets binding sites, and the engagement of these is crucial for transcriptional control and lineage restriction of these genes[9,103,110,111].

Cumulative evidence has led to a model in which α_{IIb} gene transcription is switched off in non-megakaryocytic cells but kept active throughout megakaryocyte differentiation[50]. The α_{IIb} gene enhancer that bears GATA and Ets elements is active in both erythroid and megakaryocytic cells[50,104], and other positive *cis*-active elements that control α_{IIb} are also present in other cell lineages. Thus, the mechanism whereby α_{IIb} gene transcription is restricted to the megakaryocyte lineage must lie elsewhere. One explanation is that the positive elements are overridden by the action of a strong repressor that is lineage restricted. This repressor is even active in megakaryocytic cells, where it attenuates α_{IIb} gene transcriptional activity to a medium level. In other cell lineages, the repressor is even more active, and α_{IIb} gene transcription is essentially blocked. The expression of $\alpha_{IIb}\beta_3$ by avian multilineage hematopoietic cells suggests that, although detected in early hematopoietic progenitors, α_{IIb} expression is turned off in the course of progenitor commitment[112]. At the same time, α_{IIb} expression increases during the differentiation of megakaryocytes[113–115].

A comparison of the effect of a heterologous environment on the activity of the human and murine α_{IIb} promoter has shed some light on the transcriptional control of this gene. When transfected in a murine context, the human α_{IIb} promoter preserves its megakaryocytic specificity[116]. The murine α_{IIb} promoter is active and megakaryocyte specific in murine cell lines. However, it loses its lineage restriction when transfected into the human K562 cell line, where it exhibits an even higher expression

Cambridge Books Online © Cambridge University Press, 2009

level than in HEL cells. Conversely, the human α_{IIb} promoter is nearly inactive in K562 cells. The murine promoter was inactive in KG1 cells and in HeLa cells, indicating that the deregulation observed with this promoter only affects the erythro-megakaryocytic system[116].

The murine α_{IIb} promoter contains an enhancer element homologous to the erythro-megakaryocytic human enhancer. Recall that the activity of the human α_{IIb} promoter is dependent on two essential GATA and Ets elements. In the murine promoter, the erythro-megakaryocytic enhancer activity is dependent on the −456 GATA site but not on the −505 Ets element[116]. This result is different from the concerted engagement of both elements required for full activity of the human enhancer.

In addition to GATA-1, the murine −456 GATA formed an additional complex (termed B) of higher molecular weight[116]. The B complex was observed in all nuclear extracts tested, including HeLa cells, suggesting B complex is ubiquitously expressed. B complex did not interact with anti-GATA-1 antibodies, indicating it is different from GATA-1. Human and the murine promoters differ significantly in that they probably use different GATA-1 partners. The enhancer Ets binding site shown to be crucial for the human enhancer activity is inactive in the murine enhancer. Perhaps in the case of the mouse α_{IIb} promoter, GATA-1/B complex interactions may be an alternative to GATA-1/ETS cooperation for the human α_{IIb} promoter in human cell lines[116]. Although apparently not required for human α_{IIb} transcriptional regulation in human cell lines, B complex is present and active in these cells, suggesting that it could regulate other sets of human genes.

The integrin $\alpha_{IIb}\beta_3$

The numerically predominant platelet integrin $\alpha_{IIb}\beta_3$ (Fig. 50.11) mediates the common cohesive pathway that results from platelet activation in vivo, i.e. platelet aggregation supported by the binding of adhesive proteins, such as fibrinogen and von Willebrand factor (VWF).

Three allelic variants of the integrin subunit α_{IIb} (Fig. 50.12) have been defined which differ at either residue 837 (Val or Met)[117] or residue 843 (Ser or Ile)[118]. A very complex scenario occurs with the integrin subunit β_3. Eight different alleles of the β_3 can be distinguished (Fig. 50.13) which differ at seven positions within the coding sequence. These dimorphic residues and their serologic designations are: Leu_{33}/Pro_{33} (HPA–1a/HPA–1b)[119]; Arg_{62}/Gln_{62} (HPA–10wa/HPA–10wb)[120]; Arg_{143}/Gln_{143} (HPA–4a/HPA–4b)[121]; Pro_{407}/Ala_{407} (HPA–7a/HPA–7b)[122]; Arg_{489}/Gln_{489} (HPA–6a/HPA–6b)[123]; and Arg_{636}/Cys_{636} (HPA–8a/HPA–8b)[124]. The rare HPA–1b allele characterized by the presence of Arg_{40} does not appear to be serologically distinguishable from the HPA–1b allele bearing the more common Leu_{40}[125].

Fig. 50.11. Integrin $\alpha_{IIb}\beta_3$. (Left panel) This receptor is a heterodimer composed of noncovalently associated α_{IIb} and β_3 subunits. The α_{IIb} subunit is a two chain molecule composed of a larger chain disulfide-bonded to a smaller chain, the latter bearing a transmembrane region and cytoplasmic domain. The β_3 subunit is a single chain polypeptide with a transmembrane region and cytoplasmic domain. (Right panel) An important dimorphism of the β_3 subunit results from a leucine/proline substitution at residue 33 within a small disulfide-looped region, giving rise to the Pl^{A1} and Pl^{A2} alloantigens, respectively.

Fig. 50.12. Integrin subunit α_{IIb} alleles. Three alleles are generated by a valine/methionine substitution at residue 837 and an isoleucine/serine substitution at residue 843. These give rise to the Bak (Lek) and Max alloantigen systems, respectively. Abbreviations: a.k.a, also known as: f, gene frequency; and HPA, human platelet antigen. Gene frequencies for a typical Caucasian population are indicated.

Clinical relevance of $\alpha_{IIb}\beta_3$ polymorphisms

The first receptor to be scrutinized was $\alpha_{IIb}\beta_3$. In a pioneering study in 1996, Weiss et al.[126] reported that the gene frequency of the β_3 Pl^{A2} (Pro_{33}) allele was 3.6 times higher

among younger case patients (<60 years of age) with myocardial infarction or unstable angina as compared to age-matched controls (odds ratio = 6.2). This was the first instance of a platelet-specific risk factor in acute coronary thrombosis, and this study was rapidly followed by numerous reports that confirmed or denied this association of Pl^{A2} as a risk factor for acute coronary disease (Fig. 50.14). While many studies have confirmed the association between the Pl^{A2} allele and increased thrombotic risk in myocardial infarction or coronary artery disease, a substantial number have refuted this observation. Other clinical settings where risk might be involved are restenosis after stent[127,128] or acute renal allograft rejection (Fig. 50.15). On the other hand, as was the case with the genetic differences in integrin α_2, no correlation between integrin $\alpha_{IIb}\beta_3$ and risk for venous thrombosis has yet been observed (Fig. 50.15).

After the β_3 Pro_{33} allele had been implicated in risk for thrombosis, the search began for any indication that this allele might confer increased biological activity upon the integrin $\alpha_{IIb}\beta_3$. Although most of the identifed differences have not been obvious, they *are* statistically significant and suggest that this allele confers a lower threshold for agonist-induced platelet responses. Most recently, Vijayan et al.[130] showed, in transfected CHO or 293 cells, that the Pl^{A2} allele exhibited increased binding to immobilized fibrinogen, but not to soluble fibrinogen or immobilized fibronectin. In addition, Michelson et al.[131] found that Pl^{A2}-positive platelets displayed a lower threshold for activation and an increased sensitivity to antiplatelet drugs (e.g. aspirin and abciximab).

Platelets and bacterial infections

Mark C. Herzberg and Ke Gong

Department of Preventive Sciences, School of Dentistry, University of Minnesota, USA

Introduction

Platelet–bacterial interactions contribute to the pathogenesis of hematological infections. Interactions may occur directly with platelets, resulting in bacterial invasion or induction of platelet aggregation. Bacterial invasion of platelets is a key feature of Rickettsial and Ehrlichial infections. Induction of platelet aggregation in vivo, resulting in formation of mural thrombi on heart valves in infective endocarditis, appears to be a response to certain infecting bacteria. During bacteremia or sepsis, platelet microaggregates form and thrombocytopenia is observed. The propensity for bacterial cells to trigger platelet aggregation and thrombosis in vivo suggests concomitant procoagulant activation. Procoagulant activity can also be up-regulated by bacterial products, such as lipopolysaccharides (LPS) and expression of thrombin-like enzymes, resulting in the incorporation of platelets into aggregates or thrombi. Conversely, certain bacteria express toxins and other proteases that will inhibit platelet function or cause platelet lysis and contribute to coagulopathy. More than 30 species of bacteria show platelet activating or inhibitory functions, many of which have been documented to occur during naturally occuring infection in mammals or in experimental animal or human models. This chapter will present examples of platelet dysfunction that results from clinical infections, followed by an examination of partnered bacterial ligands and platelet receptor or targets, and will conclude with a survey of key mechanistic models of platelet–bacterial interactions.

That bacteria in the blood interact with circulating platelets has been recognized since early in the last century (see review by Clawson)[1]. Platelet–bacterial interactions were considered by many investigators to be an important feature of reticuloendothelial defense, although the supporting data were often not widely appreciated. At the turn of the last century, rabbits were shown to clear experimental bacteremias with *Vibrio cholera* by clumping with platelets and several groups reported similar observations during the next twenty years. In 1922, a report published by Bull and McKee showed that thrombocytopenic and control rabbits cleared Staphylococcal bacteremias similarly. Earlier reports notwithstanding, investigators shifted focus away from the platelet as interactive with bacteria in the blood. In 1930, interest resurfaced as Taniguchi and coworkers reported that experimental bacteremias with selected Gram-positive or Gram-negative species caused thrombocytopenia within 3 minutes, formation of platelet–bacterial aggregates, and disappearance of free bacteria by 10 minutes. The numbers of platelet-associated bacteria far exceeded those associated with leukocytes. Platelets reappeared in the circulation by 30 minutes. Direct observation of circulating platelet–bacteria aggregates in vivo waited until the 1960s, when Alfred Copley and colleagues developed a vital microscopic approach. While platelet–neutrophil interactions, described by Aaron Marcus and coworkers in the 1980s, could be modified by circulating bacteria and contribute to reticuloendothelial clearance, we are still coming to appreciate the potential for platelet–bacterial interactions to contribute to health and disease.

Platelet diseases in humans or animals caused by bacteria

Bacteria directly invading platelets – Ehrlichial and Rickettsial infections

Rickettsial and Ehrlichial infections are often associated with direct bacterial invasion of platelets. The Rickettsieae and Ehrlichieae are Gram-negative intracellular bacterial

pathogens. The human ehrlichioses and Rocky Mountain spotted fever are life-threatening yet treatable diseases. The vectors for these bacteria are hard-bodied ixodid ticks, and the reservoir hosts are probably wild rodents, deer, sheep and dogs. Prompt treatment with tetracycline or chloramphenicol markedly decreases the morbidity[2], yet the differential diagnoses may prove difficult to ascertain when treatment decisions are needed. Each presents as a non-specific febrile illness that can be followed by immunosuppression leading to secondary infection. Most patients first encounter fever, headache, chills, and myalgias and then develop anemia, elevations in serum hepatic aminotransferases, and thrombocytopenia, with or without leukopenia[2–5]. When patients are seropositive to Ehrlichiae by an indirect fluorescent antibody test (IFAT)[6,7], clusters of bacteria can frequently be found in the cytoplasm of peripheral blood neutrophils[8]. Sometimes, Ehrlichiae are not detected in peripheral blood smears, there are no antibodies to these diverse agents at the time of presentation, and isolation does not yield sensitive and timely results. For diagnosis, polymerase chain reaction (broad-range and species-specific PCR) assay promises the greatest sensitivity, specificity and timeliness[9–11].

Both diseases are tick-borne and the effects on blood cells can be similar in humans and canines[12]. The Rickettsia include the spotted fever group (Rocky Mountain or Mediterranean spotted fevers) and the bacterium primarily infects endothelial cells[13]. The Ehrlichieae species that infect humans include *E. chaffeensis, E. sennetsu, E. canis, E. ewingii, and E. platys*[10,12,14–16]. The Ehrlichieae are remarkable for tropism to neutrophils[4,14]. About 80% of serum samples from confirmed human granulocytic ehrlichiosis patients contain antiplatelet antibodies, which may contribute to profound thrombocytopenia[17]. Experimental Rickettsia and Ehrlichia infections in dogs also show elevated platelet-associated immunoglobulin[18]. Rickettsia and ehrlichia may interact with platelets through cell surface receptor(s) common also to endothelial cells and neutrophils.

The emergence of antiplatelet antibodies and activation of complement[17,18] appears to follow morphological, functional changes and destruction of platelets[19,20]. In naturally occurring and experimental canine ehrlichiosis, for example, platelets are rounded, show reduced pseudopod formation, clumping, migration and leakage, and these features are followed by pancytopenia[19]. In vitro, platelet responses to agonists are also inhibited. In response to collagen/epinephrine, thrombin and adenosine diphosphate (ADP), aggregation is attenuated with an increase in the lag time to onset, and a decrease in the maximal extent and rate[20,21]. Similarly, platelet factor 3 (PF-3) release is delayed[22]. The bleeding tendency and thrombocytopenia in acute phase ehrlichial/rickettsial infections, therefore, appear to be caused by direct effects of the bacteria on platelets, and emergence of specific autoantibodies.

Bacteria promoting platelet aggregation and coagulation: infective endocarditis

Infective endocarditis describes a family of persistent microbial infections that typically target previously damaged or diseased heart valves. Most often, infective endocarditis occurs after bacteremia containing viridans streptococci or *Staphylococcus aureus* although the specific breaching event into the blood may be uncertain[23–25]. The viridans streptococci, commensal Gram-positive bacteria, are of particular interest in infective endocarditis. They are harmless on the mucous membranes, but behave as pathogens in the blood. Oral and dental infections appear to be the most common portals of entry for infecting bacteria. For *Staphylococcus aureus*-associated endocarditis, the risk is often associated with intravenous drug abuse. The infecting microbes colonize within a thrombus-like mass of platelets and fibrin.

The platelet-fibrin 'vegetations' sequester and protect the microbial colonies from both the innate and adaptive immune systems and from therapeutic intervention with antibiotics. The ability of the bacteria to interact with platelets and promote their aggregation in vitro and in vivo appears to be linked directly to the mass of the vegetation and the severity of the clinical signs[25–27]. The ability of strains to induce platelet aggregation generally depends on their ability to adhere to platelets[28–30] and to bind to platelet receptors[31,32]. Consistent with these observations, the frequency of infection in experimental rabbit endocarditis was associated with the ability of *Staphylococcus aureus* to bind to platelets[33] and/or fibrin–platelet–endothelium matrix[34]. Potentially important virulence factors in the pathogenesis of endocarditis include lipoteichoic acid (LTA) of group A streptococci and *Staphylococcus aureus*[34–37], platelet aggregation-associated protein (PAAP) of *Streptococcus sanguis*[26], streptococcal exopolysaccharides[38] and resistance to platelet microbicidal proteins[39].

Usually infective endocarditis presents as non-specific symptoms including malaise, fever, sweats, myalgia, weight loss, and sustained elevations of C-reactive protein, erythrocyte sedimentation rate, and other inflammatory markers[40–42]. Cardiac murmur, tachycardia, vascular phenomena and a change in mental state are also commonly noted. Active disease is characterized by dynamic changes in coagulation and platelet aggregation, the increase in acute-phase reactants[43], and a tendency towards compli-

Cambridge Books Online © Cambridge University Press, 2009

cating thrombotic events[44]. Patients also show elevated antiphospholipid antibodies associated with endothelial cell activation, thrombin generation and impairment of fibrinolysis[45].

Bacterial strains that activate coagulation would be expected to trigger formation of larger vegetations, causing disease with a more complicated clinical course. Even though they are considered to be commensals with little pathogenic potential, viridans streptococci activate procoagulant and thrombotic mechanisms. The viridans streptococci express thrombin- and Hageman factor-like enzymes[46], promote expression of tissue factor by endothelial cells[47] or monocytes[48,49], and induce platelet aggregation[30,50–52]. While Bernard–Soulier platelets, lacking platelet glycoprotein Ib/V/IX, aggregate in response to *S. sanguis*, and GPIa and GPIIb/IIIa are necessary[32], the ability to engage a full coagulant response is required. For example, platelets from experimental pigs with von Willebrand disease and normal pigs aggregate in response to group C streptococci[53]. Yet the von Willebrand pigs fail to develop experimental endocarditis in response to the group C streptococci[53]. von Willebrand factor (VWF) binds platelet glycoprotein Ib/V/IX, which is not crucial to streptococcal-induced platelet aggregation. Since VWF protects cocirculating factor VIII against degradation, the data suggest that valvular thrombus formation in response to group C streptococcus infection requires activation of coagulation through factor VIII[53]. The procoagulant effect of the bacteria during infection is crucial to the development of the vegetation. Platelet aggregation at the heart valve is necessary, but not sufficient, since specific antibody blockade of the *S. sanguis* PAAP (see above) reduces, but does not eliminate the thrombotic vegetation in experimental rabbits[54].

After infection, strains releasing proteases and other tissue hydrolases can cause necrosis of the vegetations and, over time, valvular destruction and insufficiency[55]. For example, proteolytic strains of *Enterococcus faecalis* cause partial dissolution of experimental vegetations in rabbits, resulting in high levels of bacteremia, small, soft, friable vegetations, a high frequency of kidney infarcts, and shorter survival times[56]. As a result, thromboembolic events and severe complications of infective endocarditis are common. The characteristics of the embolic events are also related to the nature of the pathogen.

Antibiotic therapy is used to control the infection. Infecting microbes are more inaccessible to systemic antibiotics when embedded within the dense platelet–fibrin matrix of the vegetations than when they are colonizing the periphery of the vegetation. Platelets however express the platelet microbicial proteins (PMPs), which limit the colonization of sensitive bacteria and may act synergistically with certain antibiotics[39].

Disseminated intravascular coagulation (DIC)

DIC is an acquired syndrome characterized by intravascular fibrin formation, and depletion of platelets and coagulation factors in the course of a variety of severe diseases, most commonly infectious septicemia[57]. Intravascular fibrin contributes to thrombotic occlusion of blood vessels, compromising the blood supply to organs, while ongoing coagulation, diminished availability of platelets and depletion of coagulation factors contribute to episodes of bleeding. In DIC, platelets may be activated by direct interactions with certain bacteria[27,58]. With the generalized activation of coagulation, bacteria also activate platelets indirectly. Bacteria or their products, such as lipopolysaccharides (LPS), activate tissue factor and factor VIIa, generating thrombin. Thrombin is a potent platelet agonist and activates procoagulant activity on the platelet surface[59,60], and also promotes formation of systemic fibrin deposits. Thrombosis of mid- and small-sized vessels results in organ failure[61–63]. In DIC, suppression of anticoagulation and the delayed removal of fibrin may also contribute to the extent of coagulation.

In the presence of thrombocytopenia and depleted coagulation factors, DIC can present as a bleeding and a thrombotic disorder. In view of this seemingly contradictory presentation, DIC presents diagnostic and therapeutic challenges. DIC is diagnosed with supporting laboratory analysis of fibrinogen/fibrin degradation products (FDP; F1 + 2), D-dimer concentration, antithrombin III (AT III), thrombin–antithrombin complex (TAT), plasmin–plasmin inhibitor complex (PPIC), soluble fibrin monomer (sFM), partial thromboplastin time, prothrombin time and platelet counts[64–68]. In patients with DIC, activated platelets release thrombopoietin and the elevated concentration correlates with markers for thrombin generation, TAT complexes and F1 + 2[69]. Bacterial enzymes such as streptokinase and staphylokinase promote fibrinolysis as mimics of plasminogen activator[70]. Expression of laboratory markers of coagulation and platelet status can result from direct actions of bacteria or their products.

Bacterial enzymes can directly activate coagulation[71] and, depending on environmental conditions, also express enzymes that dissolve clots[72]. An extracellular cysteine proteinase of *Streptococcus pyogenes* can directly hydrolyse fibrinogen[73]. Two arginine-specific cysteine proteinases of *Porphyromas gingivalis* can activate and consume protein C, contributing potentially to a thrombotic tendency[74]. While bacterial products can modulate the formation and

Cambridge Books Online © Cambridge University Press, 2009

lysis of clots, direct bacterial interactions with platelets can initiate a procoagulant effect and release of thrombopoietin and other markers of DIC.

Bacteria may even more directly contribute to the consumption of coagulation factors and promote the generation of proinflammatory kinins[75]. Protein–protein interactions on the surfaces of certain Gram-negative and, perhaps, Gram-positive bacteria result in the assembly of factor XI, XII, plasma prokallikrein and high molecular weight kininogen, resulting in activation of the contact-phase system and release of bradykinin from plasma[76]. Generation of bradykinin at the bacterial surface was accompanied by prolonged clotting time, altered formation of fibrin clots, and a hypocoagulatory state in vivo. During infections, certain bacteria appear to be able to directly consume coagulation factors, independent of the activation of tissue factor. Release of kinins would contribute to the inflammatory signs of sepsis and the bleeding and epitaxis common to DIC, and by blocking the intrinsic pathway of coagulation promote hematogenous spread of the bacteria.

Hence it is not surprising that Gram-positive and Gram-negative bacteria are associated with DIC with similar frequencies[57], and clinical and laboratory presentations[77]. Diffuse coagulation is activated by the Gram-positive *Staphylococcus aureus*[78,79], *Streptococcus sanguis*[80–82], and *Streptococcus pneumoniae*[83]. The Gram-negative pathogens considered most often to be etiological are *Escherichia coli*[84] and *Neisseria meningitidis*[65,83,85]. In the United States, for example, *N. meningitidis* is the leading cause of bacterial meningitis and meningococcal sepsis in children and young adults[85]. Despite the availability of potent antibiotics, mortality in meningococcal disease remains high (about 10%), rising to 40% of patients presenting with severe shock and concurrent DIC[65]. In addition to eliciting procoagulant effects, most of these species will induce platelet aggregation in vitro in a strain-specific manner, suggesting that direct interactions with platelets can occur in vivo. In Gram-negative sepsis, endotoxin is suggested to elicit tissue factor-dependent hypercoagulation, mediated at least in part by proinflammatory upregulation of cytokines such as tumour necrosis factor-alpha and interleukin-6[86].

Thrombocytopenia frequently occurs in DIC, generally in association with hypercoagulation. Thrombocytopenia is characterized by procoagulant microparticles typically formed by aggregated, activated platelets[87,88], although reduced thrombopoiesis and immunological platelet damage may contribute[62,63]. The formation of circulating platelet microaggregates can occur in the presence of bacterial infections in the absence of sepsis and DIC. Patients with gastrointestinal *Helicobacter pylori* infections and a murine model, for example, show platelet activation and P-selectin-dependent aggregation[89]. The accompanying microvascular dysfunction and inflammatory cell infiltrate suggest that greater hematogenous spread of the *Helicobacter* or its products could cause DIC.

During DIC, tissue factor activity, which may be up-regulated directly by LPS and other bacterial products, is predominantly antagonized by plasminogen activator inhibitor-1 (PAI-1)[63,90,91]. Other natural inhibitory mechanisms of coagulation include antithrombin, the protein C system, and tissue factor pathway inhibitor. Many bacteria can enzymatically degrade selected proteins that inhibit generation of fibrin and activation of fibrinolysis. Indirectly, certain bacteria would promote decompensated DIC and thrombosis, with rapid consumption of inhibitory factors including antithrombin III (AT III) and proteins C and S[63,86]. In the clinical setting, it remains unclear if bacteria or their products actually antagonize the reversal of coagulation and thrombosis.

Bacteria may initiate or activate the coagulation cascade, and promote thrombosis by direct or indirect interactions with platelets. Circulating platelet aggregates are clinically important procoagulant particles contributing to thrombotic occlusion of microvessels and infarction and failure of major organs. Yet, when it is to their advantage, bacteria can almost paradoxically dissolve clots and consume coagulation factors, or antagonize anticoagulation mechanisms. Bacteria can promote release of kinins, activation of thrombin[92] and up-regulation of proinflammatory cytokines, creating complex molecular links between inflammation and coagulation. Confoundingly, inflammation promotes coagulation and thrombosis by promoting expression of intravascular tissue factor and leukocyte adhesion molecules, and down-regulating the fibrinolytic and protein C anticoagulant pathways. Direct and indirect bacterial interactions with platelets, therefore, may either promote or inhibit or reverse thrombosis or coagulation in DIC. Diagnostic tests must be interpreted with clear understanding of the confounding contributions of the infecting bacteria. Likewise, therapy must include antibiotic and selective anti-inflammatory treatment, but the underlying hemostatic and thrombotic disorders must be deciphered and supported with replacement therapies.

Mechanisms of bacterial–platelet interactions (in vitro evidence of biological plausibility)

Bacterial ligands

Lipoteichoic acid (LTA)

The LTA of group A streptococcal and *Staphylococcus aureus* binds to platelets in a concentration- and time-dependent manner[35–37]. By immuno-ferritin labelling of LTA, binding sites on the platelet surface show a patchy distribution. In the presence of soluble LTA, collagen- and alpha1 chain-induced platelet aggregation was inhibited, but the release reaction was apparently unaffected[35]. The LTA binds to platelets in a two-site interaction, one that interferes with collagen-induced aggregation and a second that triggers the release reaction[35]. In collagen-stimulated human platelets, the LTA of *S. aureus* causes dose-dependent reduction in membrane fluidity, inhibition of phosphoinositide hydrolysis, thromboxane A2 formation, intracellular Ca^{+2} mobilization, and phosphorylation of P47, a 47 kDa marker of protein kinase C activation[36]. These results suggest that the antiplatelet activity of LTA may involve conformational changes in the platelet membrane, leading to inhibition of phospholipase C. Downstream effects would result in inhibition of phosphoinositide metabolism and thromboxane A2 formation, intracellular Ca^{+2} mobilization and protein kinase C. LTA-mediated antagonism of platelet function may, therefore, contribute to bleeding diathesis in Gram-positive septicemic patients.

The platelet aggregation-associated protein (PAAP)

Streptococcus sanguis PAAP triggers the accumulation of platelets into the valvular vegetation in experimental endocarditis[54,93]. PAAP is synthesized as a rhamnose-rich glycoprotein of 115 kDa and contains a collagen-like platelet-interactive domain, pro–gly–glu–gln–gly–pro–lys[94–96]. This platelet-interactive protein is probably homologous to the collagen-like product of the *scl* gene in group A streptococci, which promotes adhesion to epithelial cells and contributes to soft tissue pathology in a murine model[97].

Expressed on the cell wall of platelet aggregation-inducing strains (Agg+) of *S. sanguis*, PAAP apparently interacts with a signal-transducing receptor complex on platelets, which includes CD31, CD36 and CD26 and a 65-kDa collagen-binding protein (K. Gong et al., 2000, unpublished data). In experimental endocarditis in rabbits[26], PAAP first promotes platelet accumulation into a fibrin-enmeshed thrombus (vegetation), within which *S. sanguis* colonizes. When PAAP is unexpressed or neutralized with specific antibodies, experimental endocarditis runs a milder course and vegetations are smaller. From in vitro experiments, the aggregation of platelets into the vegetative thrombus may be potentiated by an ectoATPase expressed on the surface of the *S. sanguis* and platelet alpha-adrenoreceptors that respond to endogenous catecholamines. PAAP expression may be environmentally regulated during infection in response to heat shock (fever) or collagen (exposed on damaged heart valves), enabling the bacteria to more effectively recruit platelets[98]. During infection of the heart valve, at least 13 environmentally regulated virulence genes have been identified that are unexpressed in vitro[99]. The data suggest strongly, therefore, that PAAP stimulates the development of the characteristic septic mural thrombus (vegetation) of infective endocarditis and the signs of valvular pathology.

Protein A

Expressed on the surface of *Staphylococcus aureus*, protein A is a 42 kDa protein with five homologous Ig-binding domains[100]. The designated domains bind either Fcγ or Fab portions of the antibody molecule. The domains differentially recognize membrane anchored immunoglobulins defining subsets of T and B cells[100] and platelets[101]. Strains of *S. aureus* that express protein A and purified protein A bind whole platelets through gC1qR/p33, a multifunctional, ubiquitously distributed cell surface protein. Since protein A-positive *S. aureus* induce platelet aggregation[102], binding to platelet surface gC1qR/p33 may bring other ligands on the cell wall into proximity of signal transducing receptors to trigger up-regulation of glycoprotein IIb/IIIa. While the evidence does not yet support a direct role of protein A in inducing platelet aggregation, binding to activated platelets suggests an additional mechanism to localize *S. aureus* at sites of vascular injury and thrombosis.

Phospholipase C (PLC)

Strains of *S. aureus* expressing PLC are more frequently associated with adult respiratory distress syndrome and DIC than toxic shock syndrome[103]. Purified PLC irreversibly aggregates platelets after a time lag, the length of which is inversely related to the specific activity of the enzyme[104]. A substrate for PLC, *p*-nitrophenolphosphorylcholine, inhibits PLC-induced aggregation when preincubated with platelets before addition of PLC. Conversely, PLC did not inhibit aggregation in response to ADP, epinephrine, collagen or ristocetin[105]. In ex vivo experiments, oral aspirin (500 mg) partially inhibited platelet aggregation induced by PLC[106].

An extracellular lipolytic enzyme, PLC is highly con-

Cambridge Books Online © Cambridge University Press, 2009

served in prokaryotes including *Staphylococci*, *Streptococci*, *Bacillus*, *Pseudomonas*, and *Clostridium*[107–109]. This enzyme cleaves glycosylphosphatidylinositol-anchored proteins from the plasma membranes of eukaryotic cells[110]. The N-terminal domain of PLC catalyses phospholipid hydrolysis, and its C-terminal region mediates interactions with membrane phospholipids in a calcium-dependent manner[111,112]. After incubation with PLC, human platelets lose 20–45% of total phospholipid, including 50–75% of the phosphatidylethanolamine, 20–50% of phosphatidylcholine, and 20–25% of phosphatidylserine[113]. The PLC and alpha-toxin of *S. aureus* may effect similar changes in platelets. The alpha-toxin intercalates as a pore-forming hexamer in liposomes[114] and platelet plasma membranes[108], activating endogenous PLC activity and downstream Ca^{2+}-signalling in pheochromocytoma (PC12) cells[115]. In platelets, activation of these signalling pathways may trigger secretion and aggregation.

Lipopolysaccharide (LPS)

A frequently studied prototype of macromolecules found exclusively in Gram-negative bacteria LPS of *E. coli* inhibits aggregation of collagen-stimulated human platelets[116]. Like LTA of Gram-positive bacteria, LPS causes dose-dependent inhibition of phosphoinositide hydrolysis, intracellular Ca^{2+} mobilization, membrane fluidity, and protein kinase C activation. Since LPS also increased formation of cGMP and cell-associated nitrate, the antiplatelet activity of LPS may be caused by conformational changes in the platelet membrane, leading to decreased activity of phospholipase C and formation of nitric oxide (NO)/cyclic GMP. By down-regulating platelets, LPS may contribute to bleeding diathesis in septicemic and endotoxemic patients. Lipid A is the toxic moiety of LPS, causing rapid time and concentration dependent phosphorylation of a human platelet protein of M_r 47 000, a marker of protein kinase C activation, secretion of [^{14}C]serotonin, and platelet aggregation[117]. These data suggest that lipid A may represent a significant mechanism underlying broadly the hematologic and circulatory disorders observed in endotoxic shock, since protein kinase C is expressed ubiquitously in blood cells, vascular cells and neurons.

Platelet receptors

Platelet gC1qR

A promiscuous receptor of 33 kDa on human platelets and other cells, gC1qR/p33 binds *S. aureus* protein A[101] and the globular head domains on proteins including C1q, vitronectin, and high molecular weight kininogen[118]. A similar platelet protein cC1qR is 60 kDa and binds collagen-like domains on many extracelluar matrix proteins[119]. While it is unclear if *S. aureus* mediates signal through gC1qR[101], C1q multimers promote phosphoinositide hydrolysis, upregulate glycoprotein IIb/IIIa complexes, increase binding of fibrinogen and induce platelet aggregation through cC1qR[120] and gC1qR[121]. C1q multimers also promote a procoagulant effect associated with platelets. Yet expression of gC1qR/p33 is poor on resting and activated platelets, but is up-regulated after platelets bind to immobilized fibrinogen, collagen or fibronectin[121]. gC1qR binds the D-domain of fibrinogen, impairing the polymerization to fibrin[122]. It is unclear how these several observations may mediate coagulation in sites of immune injury or inflammation, but gC1qR may function to localize *S. aureus* to activated platelets at sites of vascular injury and promote infection of thrombi.

GP IIb/IIIa

Blockade of glycoprotein IIb/IIIa protects against microvascular thrombosis in response to infusion of *Escherichia coli* in a baboon model[123]. To aggregate in response to virtually all bacteria studied, platelets must bind fibrinogen/fibrin. Fibrinogen/fibrin bridges platelets to one another to form aggregates and also bridge certain bacteria such as *S. aureus* to platelets. While it is well accepted that fibrinogen/fibrin bridges between platelets requires platelets to up-regulate glycoprotein IIb/IIIa, it is less clear that this integrin receptor serves to bridge bacteria to platelets.

For example, glycoprotein IIb/IIIa does not apparently bind *S. aureus* to platelets[102,124] favouring gC1qR[101]. Glycoprotein IIb/IIIa may be required for fibrinogen-mediated platelet–platelet aggregation triggered by *Lactobacillus* species[125] and *Streptococcus sanguis*[32,93,97]. *Lactobacillus rhamnosus* induced aggregation was inhibited by the glycoprotein antagonist peptide arginine–glycine–aspartic acid–serine (RGDS)[125]. *S. sanguis* does not induce aggregation of platelets from patients with Glanzmann's thrombasthenia, which lack glycoprotein IIb/IIIa[32] and aggregation of a type strain ATCC 7863 is inhibited by monoclonal antibody to GPIIb/IIIa, RGDS peptide, and a specific antagonist for the platelet fibrinogen receptor, GPIIb/IIIa[126]. Yet it is unclear if glycoprotein IIb/IIIa directly serves as a platelet receptor for *Staphylococcus aureus*, *Lactobacilli* or *S. sanguis*.

Glycoprotein IIb/IIIa may serve as a binding site for certain group A streptococci and *Borrelia burgdorferi*. Group A streptococci express an extracellular cysteine protease (streptococcal pyrogenic exotoxin B) that is critical for tissue invasion[127]. One variant contains an RGD

Cambridge Books Online © Cambridge University Press, 2009

sequence that confers binding to glycoprotein IIb/IIIa. This subtle molecular variation may alter virulence in group A streptococcal infections and present a clinical picture reflecting altered host–pathogen interactions. Similarly infectious strains of *Borrelia burgdorferi* bind to activated platelets, in which glycoprotein IIb/IIIa is upregulated[128]. Binding is specific for activated glycoprotein IIb/IIIa since *B. burgdorferi* bound to platelets in the presence of antibodies against other receptors but failed to bind to platelets in the presence of RGD competitors or when platelets were deficient in this integrin.

GPIb

Streptococcus sanguis strain 7863 induces aspirin-sensitive platelet aggregation suggested to require glycoprotein IIb/IIIa and also glycoprotein Ib[126,129]. When glycoprotein Ib was blocked with a monoclonal antibody, platelet aggregation was inhibited. Conversely, von Willebrand factor (vWF) binding to platelets via glycoprotein Ib was not affected, nor did *S. sanguis* prevent ristocetin-induced platelet agglutination or vWF binding. Normal subjects and patients with von Willebrand's disease showed similar platelet aggregation in response to strain 7863. Other strains of *S. sanguis* induce aggregation similarly in patients with Bernard–Soulier, which lack glycoprotein Ib, and normal platelets[32]. Collectively the evidence does not support a role of glycoprotein Ib in platelet aggregation in response to *S. sanguis*.

Glycoprotein Ib is a target for cleavage by the *o*-sialoglycoprotein endoprotease of *Pasteurella hemolytica*[130]. After hydrolysis the platelets appear to function like platelets from patients with Bernard–Soulier syndrome. The platelets respond normally to most physiological agonists, including thrombin, ADP, collagen and thromboxane A2, but fail to agglutinate in response to ristocetin/vWF.

Fc gamma receptor/glycoprotein VI

Monoclonal antibody to platelet Fc receptor (FcγRII) significantly reduced *S. aureus*–platelet binding[131]. A similar monoclonal antibody against FcγRII blocks *S. sanguis* strain 7863-induced platelet aggregation[126]. Since platelet-aggregating strains of *S. sanguis* express PAAP with its collagen-like platelet-interactive motif[95,96], interactions with FcγRII might be expected. As part of glycoprotein VI, a major receptor for collagen on platelets[132], FcγRII is crucial to signal transduction and the aggregation response[133,134].

CD26, PECAM (CD31), and glycoprotein IV (CD36)

Human platelets express binding sites for *Streptococcus sanguis* that react with murine anti-idiotype monoclonal antibodies (Mab2s) (raised against murine Mab anti-*S. sanguis* adhesins)[31]. To identify the target antigens, the Mab2.2 was used to immunoprecipitate a platelet membrane complex consisting of proteins of 70, 90, 120, and 150 kDa (K Gong, GD MacFarlane, M Costalonga, P Liu, and MC Herzberg, 2001, unpublished data). These proteins and an additional protein antigen of 195 kDa were immunoprecipitated by Mab2.1. The 90 and 195 kDa proteins were identified as CD36 (GP IV) and CD31 (PECAM-1), respectively, by Western immunoblotting. The 120 kDa protein was immunoprecipitated by several anti-CD26 Mabs, which also reacted with platelets in flow cytometry. To isolate each protein, human platelet membranes were solubilized, and fractionated by Mab2 affinity chromatography followed by preparative SDS-PAGE. Isolated CD26 and CD31 inhibited platelet adhesion to *S. sanguis* by a maximum of 40 and 61%, respectively. Mixed together, these two proteins inhibited adhesion by about 81%. Adhesion of platelets was unaffected by incubation with isolated CD36 or α-actinin (protein control). Similarly, platelet adhesion was partially inhibited by preincubation with anti-CD26 or CD31 Mabs; anti-CD36 did not affect adhesion. Preincubation of platelet-rich plasma (PRP) with anti-CD31 Mab partially inhibited *S. sanguis*-induced aggregation; collagen-induced aggregation was virtually unaffected. Anti-CD36 completely inhibited *S. sanguis*-induced aggregation and delayed collagen induced aggregation 17-fold (0.2 nmole Mab/450 μl PRP). Anti-CD26 (11.7 nmole) and a tripeptide inhibitor of CD26-associated dipeptidyl peptidase IV activity also inhibited aggregation completely. CD26 and CD36, therefore, appear to mediate platelet aggregation in response to collagen, complementing GPVI and integrin-associated signal transduction pathways. Similarly, a platelet surface complex of CD26, 31 and 36 appears to interact with *S. sanguis* 133–79. CD26 and CD31 may mediate adhesion and, with CD36, the complex promotes *S. sanguis*-induced platelet aggregation.

Anti-infective platelet responses

Release of platelet microbicidal proteins (PMPs)

Platelet microbicidal proteins (PMPs) are small, cationic peptides that possess potent microbicidal (both bactericidal and fungicidal) activities and antiadherence properties against common bloodstream pathogens. PMPs include thrombin-induced PMP-1 (tPMP-1), PMP-2, and alpha granule-derived PMP[135–137]. Recently recognized homologues, thrombocidins-1 and 2, are active antimicrobial peptides formed as post-translational, basic C-terminal

Cambridge Books Online © Cambridge University Press, 2009

truncation products of certain CXC chemokines[138]. The PMPs are released from platelets by thrombin and other agonists and act in part by permeabilizing and altering staphylococcal transmembrane potential[137,139–141]. Bacterial resistance to PMPs (thrombocidins-1 and 2) appears to be an important virulence factor in infective endocarditis and DIC, in which viable bacteria become trapped within platelet aggregates or thrombi. Specific resistance to cationic PMP-1 is encoded in the staphylococcal multidrug resistance gene *qacA*[45].

The action of the PMPs is readily shown in vitro; PMPs appear active in vivo. PMPs are released and rapidly kill *Streptococcus sanguis* M99 after inducing secretion and aggregation of rabbit platelets in vitro[38]. Furthermore, rabbits made thrombocytopenic with an antiplatelet antibody develop more highly colonized experimental vegetations in the endocarditis model in response to *S. sanguis* M99, than rabbits given a non-immune serum. Platelet release of PMPs in vivo appears, therefore, to serve an anti-infective function against sensitive strains of bacteria. Since the PMPs can also reduce *Staphylococcus aureus* adherence to platelets in vitro, other antimicrobial mechanisms may act against some sensitive strains[142,143].

A survey of bacteria and their interactions with platelets

At least 30 species of bacteria have been shown to interact directly or indirectly to modify or alter platelet function. Major mechanisms and pathological examples have been highlighted. To consider the constellation of platelet-interactive strategies intrinsic to a bacterial species, *Staphylococcus aureus* and *Porphyromonas gingivalis*, Gram-positive and negative bacteria, respectively, will be considered in greater detail. Interactions between oral streptococci and platelets, also the focus of many reports, have been discussed in recent reviews[25,26,144] and will not be detailed here.

Staphylococcus aureus

Staphylococcus aureus interactions with platelets are well studied in vitro and in experimental animals. Clinical manifestations of platelet interactions with *S. aureus* include disseminated intravascular coagulation (DIC) and infective endocarditis. In vitro protein A-positive *S. aureus* cells stimulate release of serotonin and aggregation of human platelets[145]. Platelet aggregation in response to *S. aureus* is fibrinogen dependent[146]. Interactions are mediated by the IgG Fc (gClqR) receptor on platelets[101,147], which mediates Fc fragment-sensitive binding of *S. aureus*. It is unclear if gC1qR is involved in the signal transduction to elicit a platelet response. The platelet response to *S. aureus* is biphasic. While fibrinogen is required, the secondary wave of aggregation is independent of the RGD binding site of platelet glycoprotein IIb/IIIa[102].

S. aureus expresses a surface clumping factor, ClfA, which binds fibrinogen[148,149]. Platelet aggregating strains of *S. aureus* use ClfA in vitro to present fibrinogen to an undefined platelet receptor that facilitates aggregation. The surface components on *S. aureus* that are necessary and sufficient to induce aggregation of human platelets are contained in peptidoglycan and protein A[150]. When mixed, protein A and peptidoglycan from *S. aureus* will induce platelet aggregation, but soluble lipoteichoic acid (LTA) is inhibitory. Lipoteichoic acid from *S. aureus* appears to inhibit activation of protein kinase C and mobilization of calcium from intracellular stores[36,37].

When analysed quantitatively by flow cytometry, *S. aureus* binding to platelets was found to involve a multiplicity of ligand–receptor interactions[131]. Protein A also binds Von Willebrand factor[151]. Since platelet glycoprotein Ib binds Von Willebrand factor, protein A expressing *S. aureus* may also agglutinate platelets by multiple bridging via Von Willebrand factor. *S. aureus* also binds thrombospondin through a protein A-independent mechanism[152]. Secreted and rebound by activated platelets, thrombospondin, may also serve as a binding bridge for *S. aureus*. While several bridging proteins probably participate[153], fibrinogen interactions enable *S. aureus* to bind better to activated than resting platelets[124] and appears to be a major virulence determinant in experimental endocarditis[33]. Contact-activated platelets mediate attachment of *S. epidermidis* to hydrophobic polyethylene polymer surfaces in the presence of adsorbed, antiadhesive plasma proteins[154]. As the thrombus accumulates more activated platelets and enlarges, the efficiency of staphylococcal binding increases[155]. Bacteria are found increasingly on and within the thrombus even in the presence of the antibiotic, rifampin. Bacterial viability appears inessential to drive the aggregation of platelets into the enlarging thrombus.

Important virulence factors such as protein A, fibronectin-binding proteins and α-hemolysin are environmentally regulated by SarA[156]. *SarA* is regulated and may promote adhesion of *S. aureus* to fibrin-rich matrix proteins during experimental endocarditis[34]. Consequently, expression of key virulence factors may be coregulated and change in vivo during infection.

S. aureus surface proteins, therefore, interact with platelets to promote binding and thrombotic aggregation. Potentially antagonistic to these interactions, *S. aureus*

Cambridge Books Online © Cambridge University Press, 2009

also expresses several enzymes and toxins with the potential to digest or damage platelets in the hemostatic process. *S. aureus* V8 protease cleaves a variety of the cytoplasmic platelet proteins[157,158], platelet glycoprotein IIb/IIIa[159], Von Willebrand factor[160], and IgG[161]. Furthermore, staphylokinase, a clinically important enzyme that activates plasminogen, reverses collagen-induced aggregation by promoting fibrinolysis[162,163]. The fibrinolytic effect is antagonized by α2-antiplasmin, but staphylokinase does not induce platelet aggregation itself[164]. Staphylokinase has been engineered with an RGD sequence, a segment of fibrinopeptide A and sequence from hirudin[165]. This multi-functional antithrombotic, fibrinolytic agent showed promise in preliminary testing.

Platelets express antimicrobial proteins, which are effective against many strains of *S. aureus*[166]. The ability of platelets to bind *S. aureus* is directly associated with frequency and extent of aggregation, but independent of the resistance of *S. aureus* to platelet antimicrobial mechanisms, including the PMPs[131]. Clinical isolates of *S. aureus* and viridans streptococci from patients with infective endocarditis tend to be resistant to PMPs when compared to isolates from other bacteremic subjects[167]. The PMPs appear to kill or inhibit growth of *S. aureus* in vivo and resistance is associated with enhanced virulence in experimental endocarditis[136,168].

While platelet aggregation in the presence of aspirin or quinacrine is not substantially inhibited in response to *S. aureus* in vitro[169], antiplatelet agents may reduce the mass and extent of infection of platelet vegetations in experimental endocarditis in rabbits[170,171]. When rabbits were treated with aspirin and ticlopidine, a synergistic reduction in the mass of valvular vegetations and the severity of infection was noted in *S. aureus* experimental endocarditis[172]. Furthermore, aspirin pretreatment in experimental rabbits reduced septic embolic events[173]. *S. aureus* will also cause experimental endocarditis in dogs and the experimental vegetations have been shown to contain activated platelets that can be targeted with ^{99m}technetium-GPIIb/IIIa pharmacologic antagonists[174]. In experimental endocarditis, therefore, the development of the platelet vegetation is probably triggered by direct interactions with *S. aureus* and secondarily by tissue factor-mediated coagulation. Activation of platelets in response to generalized coagulation pathways would more likely be aspirin-sensitive than the aspirin-insensitive response to *S. aureus* shown in vitro.

Staphylococcal toxins may also contribute to coagulopathies. Toxin-rich fractions have been shown to induce platelet aggregation in vitro[175–177], while α-toxins reduce myocardial contractility and increase coronary vasoconstriction in isolated rat hearts[178]. In contrast, toxic shock syndrome toxin-1 (TSST-1) inhibits aggregation of human platelets in response to epinephrine, ADP or platelet aggregating factor (PAF), but shows no effect in response to thrombin, collagen, or calcium ionophore[179]. Strain-specific expression of staphylococcal toxins may then cause diverse coagulopathies.

Porphyromonas gingivalis

P. gingivalis is of interest because it expresses several important platelet-interactive strategies and may model other Gram-negative bacteria. Through interactions with *P. gingivalis*, platelets may behave as inflammatory and procoagulant cells, reflecting its pathogenicity in local infections such as periodontitis[180]. As speculated more recently, *P. gingivalis* may promote inflammation and microthrombosis in cardiovascular disease through several mechanisms including direct interactions with platelets[180a]. *P. gingivalis* and other procoagulant and platelet-interactive microorganisms, such as *Chlamydia pneumoniae*[181] and *Helicobacter pylorii*[89], are hypothesized to promote vascular inflammation and perhaps infection, reflecting contributions to total systemic pathogen burden[182,183].

P. gingivalis expresses a PAAP-cross-reactive antigen, which contributes to its ability to induce platelet secretion and aggregation in vitro[95,180]. Platelet aggregation in vitro is also triggered by *P. gingivalis* protease activity, which cleaves platelet surface proteins but does not mimic thrombin[184]. In vivo, coagulation may be initiated and prolonged by *P. gingivalis*. Arginine-specific cysteine proteinases expressed by *P. gingivalis* activate and consume protein C in plasma, which may contibute to a thrombotic tendency[74]. These proteinases also activate factor X in plasma, triggering coagulation[71]. Furthermore, LPS from *P. gingivalis* and other black-pigmented Bacteroides promote rapid platelet secretion and microthrombosis in the lungs and other tissues of the mouse, even more effectively than from *Salmonella* and other enteric pathogens[185]. Hence, *P. gingivalis*, which is strongly associated with local contained soft and hard tissue infections originating in the gingiva, shows substantial potential to behave as a circulatory pathogen resulting in platelet dysfunction and thrombosis.

Other bacterial species

Clinical decision-making about the potential for bacteria to cause platelet pathology will require a comprehensive overview, such that virtually all known platelet-interactive species are identified and characterized. Table 51.1 presents a comprehensive summary for reference. With scientific progress, this list will grow and need modification.

Cambridge Books Online © Cambridge University Press, 2009

Table 51.1. Other bacterial species and their interactions with platelets

Species	Whole cells	Surface macromolecules	Enzymes/toxins	Indirect mechanisms	Animals/humans
Streptococci, group A	Induced secretion, aggregation, ASA-sensitive, fibrinogen-dependent[186]	Peptidoglycan causes complement-dependent thrombolysis (rabbit, not human platelets)[187,188]; LTA binds specifically, inhibits collagen-induced aggregation, not secretion[35]			Infection of neonatal mice with cells or SPE + Freund's adjuvant causes activation/aggregation in vivo, models human lymphocutaneous lymph node syndrome[189]; human bacteremia leads to thrombocytopenia/mortality[190]
Group B	Type III induced secretion, aggregation[186], cation- cyclooxygenase- fibrinogen-dependent, trypsin-sensitive[191]; trypsin-sensitive component inhibits aggregation in response to collagen, ADP, thrombin>> epinephrine, ristocetin (arachidonic acid, no effect)[192]	Antibodies against type III-specific sialic acid blocked GBS-induced secretion, aggregation[193]			Cells induce indomethecin-insensitive thrombocytopenia (rabbits)[194]
Group C	Induced aggregation, cation- cyclooxygenase- ADP-dependent, protease-sensitive[195]	*S. milleri* surface proteins bind platelet-fibrin clots[196]	*S. constellatus* expresses thrombin-like activity[196]		
S. pneumoniae	Induced aggregation, cAMP-dependent, shortened clotting time of whole blood, PRP, PPP[197]	Polysaccharide produces procoagulant effects on PRP, blood, PPP[197]; type-specific antibodies form immune complex on cell wall inducing release of serotonin[198]; peptidoglycan induces complement-dependent thrombolysis (rabbit, not human)[187]		Teichoic acid acts as phosphorylcholine PAF-like proinflammatory mediator[199]	Trypsin-resistant surface component induces complement-independent thrombocytopenia (rabbits)[200]; meningitis induces thrombocytopenia associated with mortality[201]
Enterococci	Induced secretion, aggregation, ASA-insensitive[169]				
Lactobacillus	Induced aggregation, strain-specific, pronase-sensitive, RDGS-dependent[125,202,203]; platelet interactivity restored by passage through animal[202]				
Listeria	Induces secretion, aggregation (rat), release listericidin (aggregation unaffected)[204]; complexes with actin, profilin causing rearrangement[205,206]				

Cambridge Books Online © Cambridge University Press, 2009

Salmonella	*S. minnesota* PMP-resistant, *S. typhii* PMP-sensitive[207]	*S. minnesota* lipid A induces PKC-dependent secretion, aggregation[208–210]			*S. typhimurium* infection induces thrombocytopenia, DIC in 1–2 days (rhesus monkey)[211]; *S. minnesota* LPS induces DIC, biphasic thrombocytopenia, first wave complement-dependent (rabbits)[212]
Shigella flexneri			Shiga toxin binds specific glycosphingolipids (Luke blood group antigen)[213]		Shiga toxin associated with TTP, hemolytic uremic syndrome[214]
Helicobacter pylorii					Cells extracts induce activation, aggregation in gastric microvessels (humans, mice; rats)[89,215]; PAF-release contributes to aggregation (rats)[216]
Pasturella			Leukotoxin (RTX family repeats in toxin) activates aggregates at low doses, lyses (forms pores) at high doses (ruminents)[217–219], modulates adhesion[220]; O-sialoglycoprotein endoprotease cleaves GPIb, induces unresponsiveness to low doses of thrombin[130]		Infection induces platelet activation (cows)[217]
***Chlamydia* spp.**				Upregulates TF-procoagulant activity on endothelial cells promoting platelet adhesion[181]	
Escherichia coli	Hemolysin-positive strains activate PKC, increase $[Ca_I^+]$, 12-HETE, serotonin release, induce aggregation; hemolysin-negative strains activate PKC only[221]; *E. coli* cells induce aggregation in vitro, + TXA2 antagonist inhibits[222]	LPS activates NO/cGMP pathway, inhibits aggregation[223]; inhibits PKC pathway, PLC[116]; lipid A (LPS) activates PKC, serotonin release, induces aggregation[117]; LPS-induced aggregation may require other blood cells[224]; LPS-induced aggregation inhibited by triflavin[123]		LPS activates complement alternate pathway inducing lysis (rabbit)[225]	LPS induces DIC, modest thrombocytopenia (complement-independent)[212]; LPS induces serotonin release, thrombocytopenia, pulmonary congestion (BALB/c mice)[226]; LPS + TXA2 antagonist improves survival (shock), reduces thrombocytopenia, no pulmonary congestion (rats)[222]; LPS thrombocytopenia, pulmonary/liver congestion RDGS-sensitive (baboon)[123]; LPS + NO inhibitor increases pulmonary/renal congestion, intravascular congestion (pig)[227]

Table 51.1. (*cont.*)

Species	Whole cells	Surface macromolecules	Enzymes/toxins	Indirect mechanisms	Animals/humans
Borrelia burgdorferi	Aggregation-negative[228]; bind platelets via αIIbβ3[128,229]				αIIbβ3-dependent binding associated with virulence in humans[230]
Neisseria meningitidis					Sepsis causes microvascular thrombosis; LPS induces DIC[231,232]; DIC associated with CD14, TF^{+} platelet/granulocyte microparticles (generate thrombin in vitro)[88]
Clostridium perfringens			Δ-toxin attacks GM2-like gangliosides causing lysis[233]; PLC induces aggregation[104,113], ADP- and TXA2– independent, cAMP-dependent serotonin release[234], Ca^{2+} and PI hydrolysis-dependent[235]; platelet-leukocyte aggregation mediated by GPIIb/IIIa upregulation[236]		Aggregation in mesentary (rat)[237]
C. welchii			PLC induces aggregation, phosphatidic acid production[238], TXA2-independent aggregation, phosphatidic acid mobilizes Ca^{2+}[239]		
C. botulinum			ADP-ribosyl-transferase C3 ADP-ribosylates 21–24 kDa GTP-binding proteins[240] identified as membrane and cytosol RhoA[241], which regulates actin assembly, GPIIb/IIIa avidity during aggregation[242], alters integrin ligation to actin[243], inhibits myosin light chain phosphorylation and shape change (blocks rho/rho-kinase-dependent regulation of MLC phosphorylation[244, 245]		

Cambridge Books Online © Cambridge University Press, 2009

C. difficile					Toxin A induces platelet-leukocyte aggregates in microvasculature, up-regulates P-selectin (rat)[246]
Pseudomonas aeruginosa	Induces aggregation[27]; complement-independent secretion[247]		Lipase + phospholipase C catalyses 12-HETE release[248,249]; PLC induces aggregation[105]		Disrupted cells induce aggregation, thrombocytopenia, pulmonary microthrombi in vivo (dogs)[250]
Bacillus subtillus	Rapidly killed by thrombocidin (PMP)[138,251]				PLC^{+} strain induces thrombocytopenia, intravascular coagulation, pulmonary congestion[252]
B. cereus			Exoenzyme ADP-ribosylates 20–25 kDa GTP binding membrane protein (similar to exoenzymes from *C. botulinum*, *C. limnosum*)[253]		
B. thuringiensis			PI-specific PLC induces release of glycoprotein fragment of GPIb complex[254]		
Flavobacterium ssp		13-methyl-myristate (soluble) induces lysis, perturbation[255]		Sulfobacins A and B inhibit binding of VWF to receptor, ristocetin-induced aggregation[256]	
Fusobacterium necrophorum	Virulent strains induce serotonin release, aggregation[257]; aggregation associated with hemagglutination activity[258], biovar A[259]	LPS biovar A induces aggregation (bovine)[259]			
Serratia marcesens	Inhibits aggregation of fresh, washed platelets[260,261]		Extracellular Zn^{2+}-metallo-protease cleaves GPIb, not GPV, attenuates responses to thrombin, VWF[262–264]		LPS induces DIC with biphasic thrombocytopenia, phase 1 complement-dependent (rabbits)[212]
Prevotella intermedia					LPS induces accumulation in lungs, rapid release of serotonin (mice)[185]
Klebsiella pneumoniae					LPS (low dose) induces complement-independent accumulation in lungs, complement-dependent anaphylactoid shock (mice)[273]; cells induce DIC, shock death; course improved by hirudin (rats)[265,266]

Table 51.1. (*cont.*)

Species	Whole cells	Surface macromolecules	Enzymes/toxins	Indirect mechanisms	Animals/humans
Bordetella pertussis			Adenylate cyclase toxin (RTX family) cytolytic[219]; increases cAMP inhibiting ADP-induced aggregation (rabbit)[267]		
Yersinia pestis		YopM (homology to thrombin-binding site of GPIb) inhibits thrombin-induced aggregation[268]			
Y. pseudo-tuberculosis	Induces aggregation[269]	Inv (103 kDa) interacts with GPIcIIa[269]			
Leptospira		LPS (strain variability) induces secretion, LPS (few strains) induce aggregation[270]		LPS induces PAF release from PMNs mediating aggregation[271]	Thrombocytopenia (DIC-independent) associated with activated endothelium promoting adhesion, aggregation[272]

Acknowledgements

Work in the authors' laboratory investigating platelet–bacterial interactions was conducted with the support of grants from the National Institutes of Health (DE05501, DE00224, DE00270, and DE08590). Thanks are due to many wonderful students, fellows, and technicians who asked provocative questions, to Professor Emeritus Maurice W. Meyer for establishing in vivo real-time models to study interactions, and C. C. Clawson, Professor of Pediatrics, who introduced MCH to the platelet in the context of infection.

Interactions of viruses and platelets and the inactivation of viruses in platelet concentrates prepared for transfusion

Laurence Corash

Cerus Corporation and Department of Laboratory Medicine, University of California, San Francisco, USA

Introduction

Viruses have long been causally linked, theoretically, with acquired idiopathic thrombocytopenia[1] and more recently have been associated directly with megakaryocytes and platelets during retroviral infections caused by the human immunodeficiency virus and human T-cell lymphotrophic viruses[2]. While the pathophysiology of the association of these viruses with megakaryocytes and platelets remains incompletely understood, recent investigations with molecular methods have begun to elucidate some potential mechanisms of the complex interactions between viruses and platelets. This chapter will focus on the interactions of viruses and platelets that are associated with human platelet disorders. In addition, recent technology developed to inactivate viruses in platelet concentrates prepared for transfusion is of interest. This technology appears to be an important intervention to further improve the safety of transfusion, and also may well be a significant modality for prevention of platelet transfusion associated infections due to new viruses that may enter the donor population in the future[3].

Substantial improvement in the safety of platelet transfusion has been achieved through addition of new tests, such as nucleic acid tests, yet residual risk persists in association with transfusion of platelet concentrates[4]. Transfusion of platelet concentrates has been implicated in the transmission of viruses, bacteria, and protozoa[5]. While it is commonly recognized that hepatitis B virus (HBV), hepatitis C virus (HCV), cytomegalovirus (CMV), and the retroviruses, such as human immunodeficiency virus (HIV) and the human lymphotrophic viruses (HTLV) can be transmitted through cellular components, other viruses are emerging as potentially significant transfusion-associated infectious agents[3]. More importantly, new infectious agents may periodically enter the donor population before they can be definitively identified and tested for to maintain consistent safety of the blood supply. The paradigm for this possibility is the HIV pandemic, which erupted in 1979. Another approach to improving the safety of platelet transfusion is the use of methods to inactivate potential contaminating viruses[6]. In order to develop effective viral inactivation methods, it is necessary to understand the interactions of viruses with platelets and to demonstrate that viruses can be inactivated in various platelet subcellular compartments. Since 1990 several methods to inactivate infectious pathogens in platelet concentrates have been developed and have entered the advanced clinical trial phase.

Interactions of viruses, platelets and megakaryocytes

Childhood acquired thrombocytopenia has long been associated with antecedent viral infections. Evidence based on viral isolates during the acute phase of these infections has been reported for infections due to varicella zoster virus, rubella virus, Epstein–Barr virus, influenza, and the human immunodeficiency virus type 1[1]. Several pathophysiological mechanisms have been postulated to explain the interactions of viruses with platelets in these frequently transient disorders. The most commonly asserted mechanism of action is the increased clearance of platelets by antibody directed against platelet glycoproteins and by circulating immune complexes potentially bound to platelet Fc receptors[7,8]. For example, the immunologic interactions induced by HIV-1 infection are

complex based on evidence demonstrating antibody directed against a platelet GPIIIa peptide (49–66); and purification of circulating immune complexes revealed the presence of an antiidiotype IgM which was a blocking antibody directed against the anti-GPIIIa IgG[8]. Thus, infection with HIV-1 appeared to give rise to multifactoral autoimmune responses.

More recently, evidence has been presented to suggest that certain viruses may directly infect megakaryocytes and thus interfere with thrombopoiesis by unknown mechanisms. Zucker-Franklin et al. have shown that murine and human megakaryocytes cocultured with retrovirus infected cells resulted in the presence of virus, by ultrastructural analysis, in megakaryocytes and platelets[9]. These observations are consistent with earlier reports that after experimental infection with murine retrovirus, virus was found in megakaryocytes[10,11]. At least two laboratories have reported the presence of HIV nucleic acid sequences in megakaryocytes of infected patients[12,13]. Some workers have postulated that infection of megakaryocytes, perhaps mediated by CD4 molecules expressed by megakaryocytes, results in suppressed thrombopoiesis[13]. Subsequently, Zucker-Franklin et al. suggested that the prevalence of other human retroviruses in humans may be greater than expected when sensitive molecular methods are used[2].

Additional evidence regarding the complex interactions of viruses with platelets has come from studies of HIV type 1 virus obtained from human infections. Lee and coworkers reported that platelets isolated from whole blood donations collected from HIV-1 positive asymptomatic donors contained high levels of HIV RNA after extensive washing and storage of platelets at both 4 °C and 22 °C[14]. While the washed platelets containing HIV-1 RNA did not demonstrate infectivity, platelets incubated in vitro with cell-free virus showed strong attachment and retained infectivity by in vitro assays. In combination with evidence that platelet concentrates from recognized HIV infected donors have transmitted HIV infections, and a recent report that platelets obtained from a donor prior to serologic conversion transmitted HIV infection, there is little doubt that HIV associated with platelets is infectious[15]. Moreover, the demonstration that the viral load in this implicated donor contained less than 40 copies of HIV per ml suggested that minipool nucleic acid-based detection strategies may not be sufficient to detect early stage infected blood donors[15].

In addition to HIV, other experimental evidence suggests a more generalized association of pathogenic viruses with platelets and megakaryocytes. For example, early work with murine cytomegalovirus infections (CMV) indicated that this virus exerts a direct suppressive effect on thrombopoiesis of megakaryocytes[16]. Others have shown evidence of direct infection by CMV of hematopoietic progenitor cells[17].

Hantavirus infections are associated with acute severe thrombocytopenia and hemorrhagic clinical syndromes. Based on recent studies, hantaviruses have been postulated to regulate β3-integrins which are critical adhesive and activation receptors on platelets[18]. These potential interactions may explain some of the pathophysiology due to hantavirus infection. The β3-specific integrins appear to mediate entry of hantavirus into endothelial cells leading to development of the hemorrhagic fever with renal syndrome (HFRS) and the hantavirus pulmonary syndrome (HPS). Cells lacking the β3-integrins are not permissive for hantavirus infection, and antibodies to the β3-integrins block experimental hantavirus infection. The absence or abnormality of the platelet β3 integrin complex GPIIb/IIIa is associated with a hemorrhagic syndrome, Glanzmann's thrombasthenia. The potential binding of hantaviruses to GPIIb/IIIa on platelets could interfere with platelet adhesion or potentiate platelet activation facilitating increased clearance of platelets or microvascular thrombotic events.

Bovine diarrhea virus (BVDV), a flavivirus frequently used as a model for hepatitis C virus (HCV), has been shown to be present in the platelets of experimentally infected calves[19]. This interaction of BVDV and bovine platelets may explain the hemorrhagic syndrome associated with this infection. More direct evidence of HCV interactions with platelets has come from molecular assays for detection of HCV nucleic sequences in platelets and megakaryocytes[20]. Thrombocytopenia is a frequent, although rarely severe, complication of HCV infection. Platelets from patients with HCV infection have been shown to contain HCV RNA sequences[21,22]. In further studies, Li et al. incubated serum from an HCV infected patient with a megakaryoblastic cell line derived from a patient with chronic myelogenous leukemia. The megakaryoblasts were positive for HCV RNA and minus strand HCV RNA, indicative of active infection[20]. Furthermore, HCV proteins, including core, envelope, and nonstructural proteins NS3 and NS4 were identified in cell cultures by Western blotting, and virus particles were identified by electron microscopy in megakaryoblasts. These studies clearly indicate that HCV can infect and replicate in megakaryoblast cell lines and are consistent with demonstration of HCV nucleic acid sequences in the platelets of patients infected with HCV.

Parvovirus B-19 is well recognized to be associated with pure red cell aplasia and is not commonly associated with thrombocytopenia. Patients with combined anemia and thrombocytopenia have been reported, and one patient with both HCV and parvovirus B-19 documented infection

Cambridge Books Online © Cambridge University Press, 2009

has been described with amegakaryocytosis which resolved after resolution of the parvovirus B-19 infection[23]. However, it remains unclear whether megakaryocytes or platelets were directly infected with the virus as documented for erythroblasts.

Platelet transfusion associated viral infections

Currently, prevention of transfusion-associated viral disease depends upon predonation evaluation of potential donors followed by serologic testing for infectious pathogens including: human immunodeficiency virus (HIV-1 and -2), human T-cell lymphotrophic viruses (HTLV-I), hepatitis B virus (HBV), and hepatitis C virus (HCV). Cytomegalovirus (CMV) screening is generally performed after blood collection, when CMV seronegative products are required. In addition to these agents, blood is tested for the syphilis pathogen (*Treponema pallidum*). Testing is not routinely done for parvovirus B19, hepatitis A virus (HAV), hepatitis G virus (HGV), hepatitis E virus (HEV), human herpes viruses (HHV-6 and HHV-8), Epstein–Barr virus, bacteria, or protozoa. Although continuing improvements in testing have greatly reduced the transmission of viral disease by labile blood components, viruses may still be transmitted because diagnostic tests may be insensitive during the 'window period' before sero-conversion[15]. Even direct tests for a virus, such as the hepatitis B surface antigen test, have a sensitivity threshold that allows contaminated components to escape detection. Recently, a case of HCV transfusion-associated transmission was documented despite single-sample nucleic acid testing with highly sensitive methods[24]. Similarly, a case of HIV transfusion-associated infection was reported during the window period with low virus copy numbers not detected by nucleic acid testing under conditions of minipool dilution[15].

Prior to introduction of nucleic acid testing, estimates of the frequency of viral transmission due to transfusion of blood components, per donor, were 1 in 100 000 for HCV, 1 in 63 000 for HBV, 1 in 680 000 for HIV, and 1 in 641 000 for HTLV-1[4,25]. The aggregate risk of receiving a blood component contaminated with one of the viruses for which sensitive tests are in place has been estimated to be 1 in 34 000[26]. A recent US government report estimated that the average transfusion episode results in exposure to five donors[27]. Thus, for a transfusion episode, the risk of receiving a component contaminated with virus may be as high as 1 in 6800.

Bacterial contamination of platelet concentrates is a persistent problem due to room temperature (20 °C–24 °C) storage for up to 5 days prior to use. Bacterial contamination may come directly from the donor or from an external source. Unlike viruses, a small number of contaminating bacteria can replicate to $>10^7$ per ml after 5 days of storage. A wide variety of bacteria have been cultured from patients with transfusion-transmitted septicemia[28,29]. Although the number of reported cases of serious transfusion-transmitted sepsis is small, there are no routine laboratory tests to detect bacterial contamination of platelet units. Estimates of the frequency of bacterial contamination range up to 0.4% per platelet concentrate[30]. A 1991 survey by Morrow and coworkers identified bacterial contamination culminating in a septic response from 6 of 10 219 transfusions of pooled random donor platelets, a frequency of approximately 1 in 1700[29]. A prospective study of 3584 platelet transfusions in 161 bone marrow transplant patients demonstrated the risk of symptomatic bacteremia as 1 per 16 patients, 1 per 350 transfusions, and 1 per 2100 platelet units[31]. These frequencies are significant considering that over 8 million units of platelet concentrates are transfused annually in the United States alone[32].

The logistics and costs of continued expansion of testing processes, for example nucleic acid testing, have been questioned[25]. Testing remains a reactive strategy to insure blood component safety, since new pathogens may enter the donor population before adequate tests can be implemented. Moreover, the sensitivity of all testing methods is limited inherently by the volume of blood that can be analysed. A complementary approach to improving the safety of blood component transfusion is inactivation of infectious pathogens in blood components by using a process that treats the entire blood component. For example, treatment of plasma fractions with the solvent detergent process has demonstrated the benefits of this approach[33]. A robust inactivation technology that is compatible with current blood component processing procedures offers the potential for improving transfusion safety beyond that achievable by testing. Moreover, a nucleic acid targeted technology capable of inactivating residual leukocytes may confer additional benefits due to inhibition of cytokine synthesis, lymphocyte proliferation, and antigen presentation. Donor leukocytes are associated with a variety of adverse immune events ranging in severity from febrile transfusion reactions to alloimmunization and graft versus host disease[34,35]. Although a number of measures have been implemented to reduce the likelihood of these adverse immune reactions, a robust nucleic acid targeted pathogen inactivation process offers the potential to inactivate all leukocytes, as well as infectious pathogens. Over the past decade a number of laboratories have reported investigations to apply pathogen inactivation technology

[d] Allogeneic donor platelets stored for up to 5 days before transfusion.

to platelet concentrates. These efforts have focused on several methods, one of which is now in advanced clinical trials (Table 52.1).

Systems for inactivation of viruses in platelet concentrates

Considerable effort has been devoted to investigations to develop methods for pathogen inactivation in platelet concentrates (Table 52.2, Table 52.3). The potential processes can be divided into two basic groups: psoralens and photodynamic methods. The psoralen-mediated processes generally utilize nucleic acid targeted adduct formation, while the photodynamic processes rely on the production of active oxygen species as the primary mechanism for pathogen inactivation. The photodynamic methods generally do not provide sufficient pathogen inactivation and are associated with unacceptable levels of platelet injury[36]. Psoralen methods have been more extensively investigated and more progress has been made with psoralens than with the other systems.

Early investigations with psoralen mediated pathogen inactivation were conducted with 8-methxyopsoralen (8–MOP) based on the history of prior human use to treat psoriasis and cutaneous T cell lymphoma[37,38]. These initial studies by Lin and coworkers established the principle of psoralen-mediated pathogen inactivation, but 8-MOP photochemical treatment was not a sufficiently rapid process for treatment of platelet concentrates in clinical use[39,40].

Several laboratories have investigated the use of AMT, a synthetic psoralen with enhanced nucleic acid binding

Table 52.2. Psoralen methods used to inactivate infectious pathogens and leukocytes in platelet concentrates

Photoreactive agent	Target	Reference
8-MOP	fd, R17, FeLV, E. coli *S. aureus*	40
8-MOP	MCMV, FeRTV	55
8-MOP	HIV	56
8-MOP	DHBV	50
8-MOP	12 pathogenic bacteria	57
AMT	VSV	41
AMT	HIV	42,58
AMT	VSV, Sindbis	59

[a] Studies conducted in plasma: media mixture (90 : 10) without platelets.

efficiency[41,42]. While AMT has increased nucleic acid binding affinity compared to 8–MOP, it exhibits mutagenicity in the absence of light, and thus has an unfavourable toxicology profile. Several classes of new psoralens have been synthesized which offer potential advantages over AMT and 8–MOP. The halogenated psoralens do not appear to be sufficiently effective for viral inactivation and in preliminary studies demonstrate adverse effects on platelet viability[43,44].

A new class of amino psoralens (Helinx Technology) has been synthesized and shown to be highly effective for inactivation of pathogenic viruses, bacteria and leukocytes in platelet concentrates during a 3-minute UVA illumination[45,46]. An integrated system (INTERCEPT Platelet System) using the lead compound, S-59, has been developed for large-scale production of platelet concentrates. This device consists of a series of interconnected plastic containers in a closed system for preparation of therapeutic doses of single donor and pooled platelets. The system contains an integral compound absorption device (CAD) to lower the post-treatment levels of residual S-59 and free S-59 photoproducts. In addition to inactivation of HIV and bacteria[45,47], Lin and coworkers demonstrated that human platelet concentrates (300 ml) contaminated with high titres of HCV ($10^{4.5}$) and HBV ($10^{5.5}$) treated with the S-59 process did not transmit hepatitis after transfusion into naïve chimpanzees[48]. Importantly, both cell-free and cell-associated viruses were inactivated, including duck hepatitis B virus (DHBV) which is a stringent model for human hepatitis B virus[49,50]. Importantly, the complete inactivation of bacteria, which if viable can proliferate during platelet storage, is a rigorous demonstration that the entire platelet product has been treated. Other studies confirmed that these novel psoralens inactivated high levels of T cells, inhibited leukocyte cytokine synthesis during platelet storage, and inhibited nucleic acid amplification of small nucleic acid sequences[46]. More importantly, treatment of T cells with the S-59 process prevented transfusion-associated graft versus host disease in both immune competent and immune compromised models of murine stem cell transplantation[46].

Helinx technology with the novel psoralen, S-59, has undergone extensive clinical study[51]. Phase I and II studies using Helinx-treated, 5 day-old platelets transfused in healthy subjects have shown adequate viability. In these studies, photochemically treated platelets were well tolerated during and after transfusion of full doses (300 ml, 3.0×10^{11} platelets). The therapeutic efficacy of Helinx-treated platelets was examined in a pilot study of profoundly thrombocytopenic patients. This clinical trial was designed to evaluate the hemostatic efficacy of S-59 treated platelet concentrates. In this study, transfusion of Helinx-treated platelet concentrates resulted in shortening of markedly prolonged cutaneous template bleeding times, and provided adequate platelet count increments and acceptable intervals to the next platelet transfusion[52]. The S-59 platelet concentrates were well tolerated.

Two randomized, controlled, blinded, clinical trials to determine the therapeutic efficacy of multiple transfusions of S-59 treated platelet concentrates have been completed. A European trial (*EuroSPRITE*) using pooled random donor platelets prepared by the buffy coat method enrolled 106 thrombocytopenic patients to receive up to 8 weeks of platelet transfusion support with either Helinx treated or standard platelet concentrates. One hundred and three patients were transfused during this study. The primary endpoint was the platelet count increment 1 hour after transfusion. Secondary endpoints included the platelet count increment 24 hours after transfusion, clinical hemostasis, refractoriness to transfusion, the intertransfusion interval and the frequency of acute transfusion reactions. This study demonstrated that platelet pools treated with Helinx technology and stored for up to 5 days provided count increments comparable to those of platelet pools not treated with pathogen inactivation[53]. Furthermore, Helinx treated platelets were comparable to untreated platelets with respect to transfusion intervals, refractoriness to platelet transfusion, the proportion of patients with major hemorrhage and safety.

Cambridge Books Online © Cambridge University Press, 2009

A larger US study (*SPRINT*) enrolled 671 thrombocytopenic patients to receive up to 4 weeks of platelet transfusion support with either Helinx treated platelets or standard single donor platelets. The primary endpoint in the US trial is the proportion of patients with grade 2 bleeding during the period of platelet support[54]. The secondary endpoints include the proportion of patients with high grade bleeding, platelet count increments and the same spectrum of endpoints as in the European study. This study will be unblinded later this year.

Conclusions

Viruses exhibit complex interactions with both megakaryocytes and platelets, and cause abnormalities of both platelet function and thrombopoiesis. These interactions occur by indirect immunologic mechanisms as a consequence of viral infection and via direct infection of megakaryocytes, and perhaps platelets. As a result of these interactions, these viruses give rise to hemorrhagic syndromes, and these viruses can be transmitted by transfusion of platelets. Considerable progress has been made in the development of technologies to inactivate infectious pathogens in platelet concentrates. These technologies have entered advanced clinical trials, and one platelet system has completed Phase III studies in Europe and the United States. These systems for inactivation of viruses in platelet products have the potential to markedly change the way in which platelet components are prepared and to further improve the safety of transfusion support of patients.

Platelets and parasites

Michel Joseph

INSERM IFR 17, Institut Pasteur de Lille, France

Probably due to their long common evolution with their hosts, parasites have developed an efficient strategy to escape the immune mechanisms their presence induces. Especially with helminths, these mechanisms have the advantage of limiting the infection at a level which favours the host, and therefore the parasite, survival. Three decades of research in the field of antischistosome immunity has revealed that a large panel of immune functions, involving nearly all immune cell types, several cytokines or cell mediators, and the participation of specific antibodies of various isotypes[1] are required for the rapid and effective killing of infective larvae. In this context, antibody-dependent cell cytotoxicity constitutes the mainstay of killing mechanisms against helminths, with a particular involvement of the IgE isotype. The cellular part of ADCC covers a large panel of inflammatory cells, from mononuclear phagocytes (macrophages[2] and monocytes[3]) to neutrophils[4], eosinophils[5], or blood platelets[6]. It is difficult to assign to each participant its actual importance in the defence strategy of the immune system. The in vitro and ex vivo experiments have given a biased perspective of the involvement of each cell population, artificially amplifying their individual role. However, these investigations have allowed the demonstration of new functions for several inflammatory cell types, especially in the field of IgE responses, with a particular emphasis in allergic disorders.

This is particularly true for blood platelets, once thought to be exclusively involved in hemostasis and thrombosis, but now recognized as cells demonstrating a wide reactivity to soluble mediators and a complex metabolic behaviour beyond involvement in blood clotting or thrombus formation. Furthermore, the expression of IgE receptors on platelets gives a firm background to new concepts in the field of cell activation sustaining parasite immunity as well as inflammatory mechanisms. One striking example of the improvement in our knowledge of platelet behaviour is probably the nature of the IgE receptor involved in their killing functions. For 15 years, we assigned to FcεRII/CD23, the low affinity receptor for IgE, the effector structure supporting their cytotoxic activity against schistosomes[6]. More recent experiments, linked to the availability of new immunological reagents, have evidenced that the structure accounting for that property was FcεRI, the high affinity receptor for IgE[7]. The interesting aspect of such a mistake is the crucial and fascinating information it gives to the interactions between both receptor types. This will be discussed further in the present chapter. The IgE-dependent stimulation of platelets is, however, far from being the exclusive way for platelets to fight against parasites. There are many reports in the literature displaying the participation of platelets in physiopathological manifestations of parasitic diseases. The aim of this chapter is to discuss the involvement of platelets in the immune mechanisms which deal with parasites.

Thrombocytopenia

Among the features suggesting an involvement of platelets in parasitic diseases, the fall in platelet count is one of the best documented, particularly in protozoan infections. Thrombocytopenia is classically reported in malaria[8]. After anti-malarial treatment in a case of human infection by *Plasmodium vivax*, the level of platelets returned to normal[9], and similar observations were made in mice infected with *Plasmodium berghei*, where chloroquine sulfate cured the malaria and restored the platelet count to preinfection levels after a severe thrombocytopenia during acute infection[10]. The role of platelets in infections by micro-organisms was already recognized in the 1970s when partially digested *P. vivax* material was seen in platelets[11]. Investigations in mice have also shed light on a

possible beneficial role of blood platelets in malaria as experimentally induced thrombocytopenia in chronic and acute *Plasmodium berghei* murine malaria led to a greater mortality of thrombocytopenic mice compared to the control group[12]. However, thrombocytopenia may also be the consequence of a platelet sequestration, which could contribute to pathogenesis, such as in murine malaria[13,14].

Platelet stimulation against parasites

Several triggering conditions are able to induce a platelet stimulation leading to the death of parasites. Besides IgE, other compounds have been shown to participate to platelet immune functions including PDGF, C-reactive protein, substance P, IFNγ, TNF-α and β, thrombin and platelet-activating factor, IL-6 and C3b. Some antiparasitic drugs, such as diethylcarbamazine, may use platelets to kill their targets. In some situations, human platelets induce an in vitro inhibition of the growth of *Plasmodium falciparum* into erythrocytes without the apparent participation of specific antibody or components other than the parasite itself[15].

IgE

The primary demonstration of a platelet involvement in immunity to parasites was the IgE-mediated cytotoxicity[6]. Rats infected with *S. mansoni* presented an increasing thrombocytemia during the first 6 weeks of infestation. The concentration of platelets was raised up to three times their number in uninfected animals, and simultaneously the IgE concentration was increased. In parallel with cytotoxic properties appearing progressively in platelets isolated from infected rats, with a maximum at the sixth week of infection, sera from these animals were able to induce cytotoxicity in platelets from normal rats. Similarly, in the human, platelets isolated from patients with schistosomiasis were able to kill young larvae of schistosomes in vitro, and their serum able to stimulate the same properties in platelets from healthy subjects. IgE was the active isotype in this process as shown by the adsorption of the various subtypes of immunoglobulins, leading to the inhibition of killing only after IgE depletion, or by the induction of cytotoxicity on normal platelets by IgE monoclonal antibody against *S. mansoni*[16]. Preincubation of normal human platelets with a large excess of unrelated myeloma IgE, but not with IgG, prevented the induction of effector functions by sera from infected individuals[17]. A close contact between platelets and parasites was not necessary since the killing could be obtained through a 0.2 μm porosity filter separating the effector cells from the targets. This implicated the generation of soluble cytocidal mediators induced by the cross-linking of IgE by its specific ligand (parasite antigens for IgE from patients with schistosomiasis, allergens for IgE from allergic patients, or even anti-IgE antibody with IgE of various origins including myeloma IgE)[18]. Among the cytocidal mediators, cationic proteins could be excluded, at least as essential factors, since platelets from patients with grey-platelet syndrome, which lack granules containing such proteins, killed schistosomula as effectively as did normal platelets[19]. Catalase and superoxide dismutase were good inhibitors of the platelet cytocidal activity against schistosomes, emphasizing the hypothesis of a potential generation of oxygen-dependent free radicals[20]. IgE-stimulated platelets generated chemiluminescence in vitro, a process also suppressed by free radical scavengers. Aspirin and non-steroid anti-inflammatory drugs, inhibitors of cyclo-oxygenase, inhibited the IgE-mediated stimulation (cytotoxicity and chemiluminescence) of platelets. Platelets may also have a role in the extravasation and excretion of parasite eggs in schistosomiasis[21,22]. Suppression of platelet activity in *S. mansoni*-infected mice by a treatment with rabbit antimouse platelet serum or antiplatelet drugs induced a significant reduction of the parasite egg excretion.

Similar observations were made in filarial infections where normal rat platelets could be stimulated to kill *Dipetalonema viteae* microfilariae with IgE antibody in the serum of *D. viteae*-infected rats[23]. This antifilarial killing mechanism was neither stage nor species specific among filariae, in that microfilariae (L1) of *Brugia malayi* or of *Loa loa*, and infective larvae (L3) of *D. viteae* or of *B. malayi* were all killed by platelets incubated with anti-*D. viteae* IgE. Cross-reactivity among filarial antigens was the support of this widespread effect of *D. viteae* IgE. Platelets isolated from patients infected with *B. malayi* were also able to kill *B. malayi* microfilariae in vitro. As in the case of schistosome infections, platelets from normal donors acquired cytotoxic properties against the same targets in the presence of sera from filaria-infected patients, and the specific adsorption of IgE led to the abolition of cytotoxicity, strongly supporting the role of this isotype in the stimulating process[24].

The induction of an IgE-dependent protective response in rat toxoplasmosis has also been reported[25]. During *Toxoplasma gondii* infection, developed in the nude rat model, a significant increase of serum IgE was demonstrated, correlating with an increase of IgE-positive platelets. The participation of surface IgE in this effect was emphasized by the fact that only platelets bearing surface IgE were able to express a significant cytotoxicity towards

Cambridge Books Online © Cambridge University Press, 2009

tachyzoites in vitro, and a significant increase of the survival period when the cells were transferred to immunocompromized rats. It has also been reported that platelets can exert as strong a cytotoxic activity on *T. gondii* as cytotoxic T-lymphocytes, the release of thromboxane A2 being a crucial factor in this cytotoxic process[26].

PDGF

IgE, however, is not the only potential inducer of platelet cytotoxicity. It was observed that tachyzoites of *Toxoplasma gondii* induced the activation of human platelets and that platelets mediated the inhibition of intracellular growth in a virulent strain of *T. gondii*[27]. The role of platelet-derived growth factor was demonstrated by the use of human recombinant PDGF and of antihuman PDGF antibody which partially reversed its effect. The PDGF action was only evidenced on parasite-infected fibroblasts, not on free tachyzoites.

C-reactive protein

CRP, a major acute-phase component of inflammatory reactions, was shown to stimulate the secretion of cytotoxic mediators from normal platelets[28]. Normal rat platelets, incubated in rat serum recovered 24 h after the subcutaneous injection of turpentine, a known inducer of serum CRP, were able to kill schistosome larvae, whereas the serum either alone or in association with eosinophils or macrophages, had no activity in vitro on schistosomula. Human platelets treated with homologous serum obtained during an acute phase of inflammation or with purified C-reactive protein were able to kill the immature forms of the worm in vitro, whereas CRP-depleted serum was no more effective. Platelets treated with C-reactive protein were, furthermore, capable of conferring significant protection against schistosomiasis in transfer experiments. In radiolabelling experiments, it was demonstrated that 18% of the platelets in normal rats were CRP positive. These observations are in accordance with the fact that, in rats infected with *S. mansoni*, the concentration of C-reactive protein in the serum increases after the lung stage of infection and is at its highest at the time of terminal worm rejection. It is tempting to conclude that one feature of the worm rejection after week 4 of a primary infection in this species, which is non-permissive for schistosomes, is CRP and that platelets play a part in this process. Platelets from infected rats were larvicidal as early as day 14 after infection at a time when no antibody against schistosomes could be detected in the serum.

Substance P

Sensory neuropeptides, such as substance P, appear as potent mediators of various immunological reactions, and inhibit or stimulate a wide range of functions of immune inflammatory cells[29]. Substance P (SP) and its carboxy-terminal fragment (AA 4–11) induce the cytotoxic activity of platelets towards schistosomula, by 90% and 40%, respectively, whereas the modified C-terminal SP, the acid-free SP, exhibits no effect on the platelets. The neuropeptide effect occurred at low doses (10^{-8} M), and was specific as shown by inhibition studies with a substance P antagonist, the D-SP. Binding data obtained after flow cytofluorometry with FITC-SP led to the conclusion that SP binds specifically to about 20% of the homogenous population of platelets. Moreover, IgE could modulate the SP-dependent functions of platelets since the preincubation with myeloma human IgE leads to a dramatic decrease of the SP-dependent cytotoxic activity of platelets towards the larvae. These findings identify a potent mechanism for nervous system regulation of host defence responses.

Lymphocyte mediators

If platelets appear as competent immune cells, their activity can be modulated by T lymphocyte factors. They can be activated by supernatants of antigen or concanavalin A-stimulated $CD4^+$ T lymphocytes. Two factors were identified in such supernatants: IFNγ and TNF α or β. For IFNγ, its identity was shown by the neutralization of the induction of platelet cytotoxicity by a monoclonal anti-IFNγ antibody and the direct induction of a cytotoxic effect on platelets by pure recombinant IFNγ in a dose-dependent manner[30]. The presence of high affinity receptors for IFNγ on the platelet membrane has been reported[31]. A high affinity receptor for IFNγ has also been characterized on the surface of the human megakaryocytic cell line Dami[32]. In vivo experiments showed that the passive transfer of platelets preincubated with IFNγ conferred to animals infected 24 h later a significant level of protection compared to the level obtained after the transfer of normal untreated platelets[33]. The preincubation of immune platelets recovered from infected rats with IFNγ increased the level of protection normally obtained with immune cells alone. Similarly, an additive effect on platelet cytotoxicity was observed in vitro when IFNγ and IgE were tested together on the cells. As shown by cytofluorometric analysis, this effect was due in part to the increase of the expression of IgE receptors on platelets[34].

A second stimulating factor for platelets was identified in T-lymphocyte supernatants, after isoelectric focusing. This

Cambridge Books Online © Cambridge University Press, 2009

activity was neutralized by anti-TNF monoclonal antibody[35]. Both recombinant TNF-α and TNF-β mediated platelet cytotoxicity at very low concentrations and in a dose-dependent manner. An additive effect was observed in vitro between TNF-β and IFNγ. In vivo, TNF-α-stimulated platelets, transferred passively to normal rats, induced a significant level of protection against a challenge infection, not observed with platelets treated with IL-2, a lymphokine without stimulating properties for platelets[36].

The inhibiting functions of T-lymphocytes could be shown with a platelet activity suppressive lymphokine (PASL), produced by mitogen-stimulated $CD4^-/CD8^+$ lymphocytes, which inhibited the IgE-dependent platelet cytotoxicity[24]. Furthermore, antigen-specific T lymphocytes from *S. mansoni*- or *B. malayi*-infected patients generated a factor inhibiting the cytotoxicity of platelets from the same individuals against larvae of the corresponding parasites[37,38]. This suppressive lymphokine had a molecular weight of 15 000 to 20 000, a pI of 4.6, was heat and acid stable, sensitive to trypsin and proteinase K, but was insensitive to neuraminidase. It totally abolished the protection normally conferred against a challenge infection by the passive transfer of platelets from immune animals to normal rats by a preincubation of transferred platelets with PASL[39]. In an attempt to clone the PASL, a cDNA coding for ubiquitin was isolated. Like PASL, purified ubiquitin can inhibit the cytotoxic properties of platelets and the production of oxygen metabolites by these cells[40]. PASL and ubiquitin also share similar physicochemical characteristics (acid and heat sensitivity, stability) and show an absence of species specificity: human PASL was able to inhibit the effector functions of human, and also of rat and mouse platelets and vice versa. Purified bovine ubiquitin acts similarly on human, rat or mouse platelets. A binding structure for ubiquitin exists on blood platelets. The only discrepancy observed was that a rabbit polyclonal antibody directed against ubiquitin which neutralized the inhibiting activity of ubiquitin on platelets did not do so with lymphocyte supernatants. This could be due to determinants recognized on ubiquitin possibly absent or modified on PASL. Nonetheless, provisionally, one can accept that PASL probably belongs to the family of ubiquitins.

Interleukin 6

A co-operation between monocytes and platelets for the killing of *S. mansoni* was also described[41]. Supernatants obtained after a 24 h adherence of normal human monocytes were able to induce, in a concentration dependent manner, the cytotoxicity of normal human platelets against schistosomula in vitro. The physicochemical characteristics of the factor suggested a role for IL-6, detected in such supernatants, in the activity. The hypothesis was confirmed by the neutralization of the cytotoxic effect by a polyclonal serum against IL-6, whereas polyclonal sera against IL-1β or TNF-α, also present in the medium, were inactive. Recombinant human IL-6 induced the cytotoxic functions of platelets, demonstrating a direct effect of this cytokine on blood platelets.

C3b

Investigations in mice infected with *Trypanosoma musculi* have shown an in vitro interaction between platelets and parasites, leading to the death of trypanosomes within a few minutes and their lysis[42]. The role of IgG antibody and C3b has been suggested in this mechanism[43], as well as in the clearance of promastigotes from *Trypanosoma cruzi* from the blood stream by platelets[44,45]. The group of Gresele and colleagues has brought recent support to the participation of platelets in cytocidal effects against *Trypanosoma equiperdum*, showing that this horse parasite, which can be used in experimental infections of mice, is killed in vitro by platelets, and that IgM (not C3) enhances platelet trypanocidal activity[46]. However the possibility that, in these infections, platelets could participate in pathology rather than induce protection must be kept in mind. This is true for Chagas disease[47] as well as for African trypanosomiasis[48,49].

Thrombin and platelet activating factor

We observed that, in vitro, thrombin and platelet-activating factor (PAF), two classical agonists of platelet aggregation, mediated either cytotoxicity at low concentrations or aggregation at higher concentrations, with no overlapping of the respective ranges[50]. These two effects could never be produced simultaneously. Killing functions and aggregating properties seem therefore to be two distinct mechanisms. It was also shown that triggering platelets with low concentrations of one aggregating agent, or with a cytotoxicity inducer (IgE), impaired very significantly the aggregation mediated by the other agent, ruling out receptor tachyphylaxis. These two activities appeared as distinct and antithetical. However, their induction might be the consequence of triggering the same receptors with different intensity, since PAF-induced, but not thrombin-induced, cytotoxicity could be inhibited with specific PAF-antagonists BN 52021 and BN 52024 also known to inhibit PAF-induced aggregation. The concept of a dual antinomic function of platelets is strengthened by

Cambridge Books Online © Cambridge University Press, 2009

the possibility of inducing cytotoxic expression against schistosome larvae with purified platelet membranes stimulated with IgE/anti-IgE or IgE/allergen. Aggregation inhibited almost completely the IgE-dependent cytotoxic process, even with platelet membranes from disrupted aggregates, whereas membranes from disrupted unaggregated platelets could express significant cytotoxicity. Therefore, as these effects could neither be produced successively nor simultaneously, it implies a diversion in the metabolic processes leading to one or the other function. This is the reason why we have proposed the term of platelet 'stimulation' for the induction of cytotoxicity to avoid confusion with platelet 'activation' which commonly points to aggregation.

Diethylcarbamazine

The mode of action of a 50-year-old antifilarial drug, diethylcarbamazine (DEC), has remained obscure despite widespread use and intensive investigations. The marked contrast between an extremely rapid action in vivo and the absence of any significant activity on microfilariae in vitro is unique among chemotherapeutic agents. We have reported that the effect of DEC could be mediated by blood platelets, with the additional triggering of a filarial excretory antigen (FEA)[51]. Platelets isolated from individuals treated orally with DEC were cytotoxic in vitro for microfilariae, and so were platelets from healthy donors treated in vitro with the drug. Fifteen days after oral administration, platelets were still active against microfilariae, whereas after 48 h free DEC was undetectable in sera, suggesting that the target of DEC was the platelet population and, more likely, their bone marrow precursors, as the effect of DEC outlasted the average platelet lifetime of 9–10 days. However, the observation that such platelets were inactive against schistosomula, unless microfilariae were introduced into the assay, suggested a specific signal coming from the target towards DEC-treated platelets. Support for this hypothesis came from experiments in which a filarial excretory antigen triggered the cytotoxicity against schistosomula incubated with DEC-treated platelets. Among the mediators of the killing process, oxygen free radicals have been proposed, since scavengers of activated oxygen species (sodium formiate, mannitol, uric acid, sodium salicylate and sodium azide) inhibited the platelet killing activity. Other toxic intermediates were probably involved, such as lipoperoxides, as shown by the amplification of the killing by transition metals (Fe^{2+} down to 10^{-11} M) and its abolition by iron chelators (*o*-phenanthroline).

All these stimuli probably triggered platelets by different pathways but achieved the same result: the generation of molecules expressing cytocidal properties for parasites. A common feature of these various signals was the induction of cytotoxic properties without aggregation, suggesting the stimulation of a platelet compartment different from that activated in the classical process of aggregation. This justifies the distinct denomination of stimulation and activation for these two opposite processes. We would now like to present the most surprising observation that these investigations have brought about during the last few years, in the field of the IgE-mediated stimulation of blood platelets.

Two interactive receptors for IgE

FcεRI and CD23

It is obvious today that the investigations dedicated to immune mechanisms against the helminth parasite *S. mansoni* in mammals have led to the demonstration and to original functions of IgE receptors on inflammatory cells, giving them properties other than their exclusive participation to immediate hypersensitivity reactions linked to mast cells and basophils[52]. Over two decades, we have contributed research describing, on rat peritoneal macrophages, human monocytes and alveolar macrophages, eosinophils and blood platelets in rat and man, a low affinity receptor for IgE, FcεRII, later on recognized as CD23. The binding of parasite-specific antibodies to the surface of these cells mediated cytotoxic properties for larvae of the pathogen in vitro and also in vivo as shown by the protection conferred to naïve recipients by the transfer of cells loaded with parasite-specific IgE. Very similar observations, particularly with blood platelets, were reported during that period against other metazoan[23] and protozoan parasites[25].

It is important to underline here that, if effector functions of inflammatory cells mediated by IgE are expressed through the killing of schistosomula and the larvae of *S. mansoni*, the triggering process for the cell stimulation is not necessarily provided by antiparasitic IgE. Inflammatory cells from allergic patients, bearing allergen-specific IgE, generate antischistosome cytotoxic mediators if the specific allergen is introduced into the assay. This means that, if the activating signal is specific, i.e. IgE + specific allergen, its expression is not, i.e. death of parasites unrelated to sensitizing IgE. Furthermore, cells from normal individuals may be sensitized in vitro with IgE from allergic or parasitized patients and then behave as cells isolated from individuals with the corresponding pathology.

Cambridge Books Online © Cambridge University Press, 2009

During that period, the availability of polyclonal and monoclonal antibodies limited only to the FcεRII/CD23 receptor led us to assign to that receptor the structure responsible for the binding, and therefore for the effector function of IgE on inflammatory cells. Such a conclusion was drawn from the observation that anti-CD23 antibodies inhibited both the binding of IgE on the concerned cells and the cytotoxicity they expressed in vitro against parasites. That concept now appears to be partially wrong, since in the last decade it has been demonstrated that when specific antibodies to the human high affinity receptor for IgE, FcεRI, were made available, such antibodies were also able to influence platelet function. FcεRI, and mRNA for its three different chains, were found on the same inflammatory cells: mononuclear phagocytes[53,54], eosinophils[55], blood platelets[7,56], as well as on Langerhans and dendritic cells[57,58]. Furthermore, the results obtained with eosinophils and platelets conferred to the high affinity receptor for IgE the status of the actual effector structure, until then attributed to CD23. We had therefore to understand why we misinterpreted the inhibitory effects of anti-CD23 antibodies in the killing functions of platelets, if really FcεRI was doing the job.

Recently, blood platelets led us to bring the beginning of an explanation to this apparent contradiction on the respective role of CD23 and FcεRI in the IgE-mediated cytotoxicity. As indicated above, polyclonal and monoclonal antibodies to CD23 inhibited the binding of IgE to platelets and the cytotoxicity expressed in vitro. One detail was nevertheless surprising: if the cross-linking of adjacent receptors, loaded with IgE, by specific antigens was the starting signal for the cytotoxicity, why could none of the anti-CD23 used alone mimic the process, when their divalence should have induced the killing effect. In 1994 we could use a monoclonal antibody directed towards the binding domain of IgE on the alpha chain of the FcεRI (mAb 15–1, produced by Jean-Pierre Kinet, Boston). Besides the demonstration of the presence of this receptor on platelets, this antibody inhibited the binding of IgE to platelets, its Fab monovalent fragment inhibited their IgE-induced cytotoxicity, and, above all, the antibody, either in its IgG form or in its F(ab′)2 form, triggered the effector function of platelets on parasites. We had got finally an antibody able to mimic the stimulation process of an allergen-dependent cross-linking of adjacent IgE receptors, as observed for decades in the degranulation of mast cells and basophils. Last but not least, the anti-CD23 antibody inhibited the platelet cytotoxicity induced by divalent anti-FcεRI, as efficiently as it inhibited the cytotoxicity induced by IgE. The inhibition could be obtained if anti-CD23 was added to the platelet before or at the same time as anti-FcεRI or IgE, but not after. The conclusion, for blood platelets, is that the stimulation of effector functions by IgE, generating cytocidal mediators, is linked to the high affinity receptor for IgE, FcεRI, and that the low affinity receptor, CD23, exerts a regulatory role on the effector functions of the former. Investigations carried out these last few years have brought some light on the underlying mechanism.

The regulatory role of CD23 on FcεRI signals via inhibitory phosphatases

In its intracytoplasmic N-terminus, human CD23 presents an immunoreceptor tyrosine-based inhibitory motif (ITIM), which could be involved in the inhibitory effect observed with anti-CD23. On the basis of the known amino-acid sequence of human CD23, we synthesised a trideca-peptide containing the inhibitory motif (Tyr–Ser–Leu–Leu or Y–S–L–L). Its lysine-phosphorylated form (Y–S–L–pL), which is produced during the physiological activation of CD23, is able to capture, in a human platelet lysate, a phosphatase which plays a part in the inhibition of transduction signals of activated cells. This phosphatase, called SHIP (for SH2–Inositol-5–Phosphatase) blocks calcium influx in the activation process of cells. It seems that two other inhibiting phophatases, which dephosphorylate other links of the transduction cascade, SHP-1 and SHP-2, are not captured by the phosphorylated ITIM of CD23. If these preliminary observations are confirmed, they bring a new light on the role of SHIP, the presence of which in platelets has been reported recently, but without a defined function until now in platelet stimulation or aggregation.

A second element opens interesting perspectives to the understanding of CD23–FcεRI interactions. We observed that soluble CD23 could inhibit the cytotoxic properties of platelets mediated by IgE or by anti-FcεRI. The inhibition was as strong as that obtained with anti-CD23 antibody, with very low concentrations of soluble CD23 (25 pg/ml). Soluble CD23 was unable to inhibit a non-IgE dependent pathway of platelet stimulation, also described in our laboratory, induced by thrombin. The effect of soluble CD23 seems therefore limited to IgE functions of platelets. The problem is to define the binding structure on platelet surface on which soluble CD23 exerts its inhibitory effect. Human CD23 bears, in its C-terminal part a DGR peptide (reverse of RGD) susceptible to bind lectins. We had the opportunity of getting mutant soluble CD23, devoid of DGR sequence. This RGD-free soluble CD23 lost its inhibiting activity on the cytotoxic functions of platelets induced by IgE or anti-FcεRI. This sequence is therefore potentially involved in the binding of CD23 to a platelet

Cambridge Books Online © Cambridge University Press, 2009

structure leading to inhibitory action (CD11b? CD21? Other?). It is not demonstrated that both mechanisms, that induced by anti-CD23, and that induced by soluble CD23, are based on the same patterns. One hypothesis would be that anti-CD23, by preventing IgE binding to CD23 and therefore stabilizing CD23 against autocatalysis, would increase the release of soluble CD23 or even induce it, leading to the inhibition observed. If this mechanism has some correlate in other cells implicated in immediate hypersensitivity, especially mast cells and basophils, it might open interesting new approaches in the treatment or prevention of allergic disorders.

A general feature of the platelet metabolism in IgE-dependent reactions

We would like to conclude this overview by mentioning the extensions that the anti-parasite immunity supported by platelets have gained in other fields of human and experimental pathology. The most valuable opening of our observations was that directed towards allergic diseases, with the concept of a potential direct involvement of these blood elements in either stage of the physiopathologic mechanisms of IgE-mediated allergy (especially allergic asthma to inhaled allergens or systemic anaphylactic reactions to hymenoptera venom) and drug-induced intolerance (such as aspirin-induced asthma). Another in this volume illustrates this aspect. The whole of these investigations results in the definite integration of blood platelets into the complex network of cell interactions in various immunological and inflammatory reactions or disorders. Such a benefit alone is worth the decades of research on that topic.

Platelets and tumours

Maria Benedetta Donati and Virgilio Evangelista

Department of Vascular Medicine and Pharmacology, Istituto di Ricerche Farmacologiche Mario Negri, Santa Maria Imbaro, Italy

Introduction

Despite pioneer reports in the nineteenth century[1,2] the interactions between the components of the hemostatic system and cancer have so far been studied without a really integrated approach and no true experimental–clinical cross-talk has been established.

Tumour growth and dissemination is a multistep process which goes from oncogenic transformation to progression and local growth, vascularization, detachment of tumour cells from the primary and invasion of capillary or lymphatic vessels, transport, arrest in capillary beds, adhesion to vessel wall, extravasation and growth at distant sites[3]. All these steps involve different interactions with the components of the hemostatic system, which have been clarified mainly in in vitro approaches during the past 30 years[4–7]. Tumour cells have been demonstrated as the source of procoagulant, fibrinolytic, platelet aggregation activities, adhesion processes with leukocytes and endothelial cells, and interactions with tumour-associated macrophages. In particular, clinical and experimental evidence suggests that blood platelets are involved at several steps of the tumour dissemination cascade[8,9]. In this sequence of events, the adhesion of tumour cells to the vessel wall seems to be favoured by the gathering of activated *platelets* in the surroundings. More than 40 years ago, platelet–tumour cell emboli were observed in microcinematography experiments in rabbits and human pathological specimens, suggesting the possible involvement of platelets in tumour dissemination[10]. The discovery that thrombocytopenia, induced by antiplatelet serum or neuroaminidase treatment, reduced experimental metastasis in mice, further supported this hypothesis[11,12]. Since then, various antiplatelet drugs have been used for metastasis treatment and the interactions between cancer cells and platelets have been repeatedly investigated[8,9,12,13]. However, neither the determinants of platelet involvement in metastasis nor the mechanisms underlying these interactions have been completely clarified.

It is the purpose of this chapter to revisit some of the platelet–tumour cell interactions established in the early studies with the perspective of more recent acquisitions, mainly in terms of platelet/leukocyte leukocyte/endothelial cell receptors and cross-talk, a field which has rapidly grown since the 1980s.

While 40–50 years ago platelet–tumour cell interactions were probably the first example of cell–cell interactions described in some detail, we are now in a position to follow the process of tumour cell arrest and extravasation with models taken from the sequence of events involving leukocyte recruitment, arrest and tissue penetration at an inflammatory site[14].

The study of platelet/tumour cell interactions may have a dual implication: on one hand, platelet behaviour may be modified by tumour growth, as part of the host response to the tumour, on the other, platelets may play themselves a pathogenetic role in tumour growth and dissemination.

Platelet changes associated with malignancy

The involvement of blood platelets during growth and dissemination of tumours may be mainly inferred from experimental studies; such studies have used different models and the results obtained may vary greatly, depending on the type of tumour and the route of administration of tumour cells[4,15]. Among the models of metastasis that have been developed, two have been more extensively studied in experimental animals.

(i) The intravenous (i.v.) injection of tumour cells in mice, which leads, within some weeks, to development of tumour nodules in the lung. This model is also referred

to as 'artificial' metastasis, since huge amounts of tumour cells are given to a previously healthy animal in the absence of all those metabolic and biochemical changes generally associated with the growth of a solid tumour in clinical conditions. On the other hand, this model more closely mimics metastasis formation which may occur following sudden spreading of tumour cells in the circulation of patients undergoing surgical manipulations for tumour removal.

(ii) The subcutaneous (s.c.) or intramuscular (i.m.) injection of tumour cells, which leads to the growth of a primary tumour at the site of implantation and to the subsequent dissemination to distant organs, where metastatic nodules may grow. This model is termed 'spontaneous' metastasis, since its development mimics more closely, than that of the lung colony model, the clinical evolution in patients with solid tumours from which tumour cells gradually migrate to distant organs.

The involvement of the host's hemostatic system, as well as the response to pharmacological modulation (see later), may be completely different in these two models.

We shall give some examples for this concept, taken from the experience our group has gathered mainly in murine tumours, such as the Lewis Lung Carcinoma, widely used for preclinical chemotherapy studies both in Europe and in the USA.

When tumour cells are injected i.v. in mice ('artificial model'), a marked thrombocytopenia occurs as a part of an intravascular coagulation syndrome, characterized also by low fibrinogen levels and by high levels of fibrinogen degradation products. Thrombocytopenia can be detected 2–5 minutes after tumour cell injection and is rapidly reversible. The fall in platelet count is presumably due to platelet aggregation in response to thrombin, developing from the procoagulant activities of tumour cells. Tumour cells can induce in vivo thrombocytopenia independently from their direct platelet aggregatory properties; moreover, in vivo platelet consumption can be prevented not only by antiplatelet agents, but also, and even better, by the treatment of animals with the anticoagulant warfarin[16–18]. Tumour cell-induced thrombocytopenia does not occur in mice with a congenital deficiency of platelet function due to defective content of their dense granules, the so-called 'beige' mice[8].

The above-mentioned changes are very short-lived and are reversible within 1 hour of tumour cell injection. The subsequent development of lung colonies is not accompanied by any hematological changes; normal platelet and red blood cell counts and fibrinogen levels are measured during the growth of 'artificial' metastases[15].

In contrast, several changes occurring during 'spontaneous' metastases have been described in the Lewis Lung Carcinoma, the JW sarcoma and the mFS6 fibrosarcoma in mice[16,19,20]. The platelet changes occurring during development of Lewis Lung Carcinoma implanted i.m. have been extensively studied[16]. Mild intravascular coagulation, with microangiopathic hemolytic anaemia, thrombocytopenia and raised fibrinogen levels with increased fibrinogen turnover were observed during tumour growth. Thrombocytopenia was not accompanied by increase in platelet turnover nor by changes in the splenic pool; bone marrow examination and indirect pharmacological data further confirmed that it was rather due to impaired platelet production than to enhanced intravascular consumption. Thrombocytopenia was not abolished by chronic treatment with antiplatelet or anticoagulant agents; the lack of a clear pathogenetic link with metastasis formation was suggested also by the observation that tumour-bearing animals treated with warfarin showed a marked inhibition of metastases[15,16]. In conclusion, thrombocytopenia appeared to be related to the presence of the primary tumour as also indicated by normal platelet counts in mice whose primary tumour was surgically removed when metastatic growth had already started[15]. It is thus conceivable that thrombocytopenia under these conditions could be favoured by the release of some, as yet undefined, toxic factors from the primary tumour, which would exert a myelotoxic effect.

Since the 1980s new experimental systems have been used to study the biological processes related to cancer metastasis: in particular, 'metastatic variants', i.e. sublines obtained through in vitro/in vivo passages from the same parental line, characterized by marked differences in their metastatic potential in either spontaneous or artificial models of dissemination, have been developed[3]. We studied the platelet involvement in mFS6 fibrosarcoma, a benzopyrene-induced tumour, and in several metastatic sublines derived from its lung metastasis nodules; the potential for spontaneous metastasis of the sublines ranged from 0 to 100% incidence of lung nodules. Gradual thrombocytopenia developed (until about 30% of starting levels) in all the sublines studied, whatever the occurrence of metastasis, thus reinforcing the concept that the observed platelet drop in murine tumours is not related to metastatic growth. Moreover, in the same model, platelet drop could not be ascribed to intravascular platelet consumption, since it was observed both with sublines able to induce in vitro platelet aggregation and with those devoid of such property[18,20,21].

Some interest has been devoted to the blood platelet involvement during growth of human tumours implanted

Cambridge Books Online © Cambridge University Press, 2009

in athymic 'nude' mice. We studied the occurrence of hemostatic changes in mice implanted with several lines of human melanoma or colon carcinoma, but we did not find marked signs of platelet drop, in comparison with the above-mentioned changes in murine tumours[22].

In clinical conditions there is no consistent picture of platelet involvement associated with solid tumours and/or chemotherapy; patients with metastatic cancers may exhibit increased platelet activation as also indicated by enhancement of platelet turnover and decrease in platelet survival time[9]. These platelet abnormalities may be due to greater degree of destruction of lysosomal membrane fragments and to involvement of platelets in the low-grade intravascular activation of clotting detectable in the majority of cancer patients[4,7]. Increased factor VIII antigen, ristocetin cofactor and enhanced ADP-induced platelet aggregation have all been shown in vivo and reduced sensitivity of platelets to prostacyclin has also been reported. Patients with acute malignant disease may have elevated levels of ß-thromboglobulin and platelet factor 4[23]. Circulating activated platelets have also been demonstrated in cancer patients by detection of the platelet membrane antigens CD62 and CD 63[24]. More recently, a higher platelet count within the preoperative laboratory screening of patients with colorectal cancer has been reported in association with a poor prognosis[25].

Role of platelets in cancer growth and dissemination

Platelet–tumour cell interactions: in vitro studies

As already mentioned, these represent the vast majority of data available on the subject, since platelet interaction studies have been conducted either on tumour cell lines established in culture, or freshly harvested and disgregated from experimental tumours and surgical specimens of human tumours or on extracts prepared from malignant tissues.

Tumour cell-induced platelet blood aggregation

Tumour cells can induce platelet aggregation in vitro, as first described by Gasic et al.[26] and then by several other authors[8,9,27,28]. This phenomenon may be due either to shedding of microvesicles containing lipoproteins and sialic acid from tumour cells, or to generation of thrombin via the procoagulant activity of tumour cells or to leakage of ADP from the cells. The ability of tumour cells to induce in vitro platelet aggregation has been correlated with their invasiveness in vivo: a positive relation between the aggregating capacity and the metastatic potential has been proposed by several authors[18,29,30], while others have questioned this relationship[31,32]. Grignani and Jamieson observed that tumour cell ability to release ADP was irrelevant for tumour cell dissemination[32]. In contrast, Lampugnani and Crawford[33] found that highly metastatic tumours preferentially induced platelet aggregation through thrombin generation. Moreover, the presence of membrane glycoproteins immunologically related to the platelet glycoprotein (GP)IIb–IIIa on tumour cells has been associated with the tumour cell ability to induce platelet aggregation[34]. Further data indicate that α-thrombin activates the GPIIb–IIIa or $\alpha 2b\beta 3$ receptors on tumour cells and that this process mediates tumour cell-induced platelet aggregation and increases lung colony formation in mice[35,36].

Table 54.1. Platelet-released products possibly involved in promotion of cancer growth and dissemination

Growth factors	Cytokines and chemokines	Large adhesive proteins and receptors	Protease inhibitors
PDGF	PF-4	Fibrinogen	PAI-1/PAI-2
TGFß	ßTG	von Willebrand factor	α_2-antiplasmin
EGF	PBP	Fibronectin	TAFI
ECGF	IL-1	Thrombospondin	
HGF	VPF	P-selectin	
VEGF	Cytokine RANTES		
Others	Others		

Platelet-released products

Activated platelets release the components of their alpha granules, such as growth factors, cytokines, chemoattractants, adhesive proteins and proteolytic enzymes[9,37,38]. Some of these factors are involved in the metastatic process (see Table 54.1).

Two mitogenic factors were originally discovered in platelets: platelet-derived growth factor (PDGF) and transforming growth factor beta (TGFβ). Both factors promote cell migration, stimulate cell proliferation, and induce secretion of collagenase and of extracellular matrix proteins. Epidermal growth factor (EGF), endothelial cell growth factor (ECGF) and hepatocyte growth factor (HGF) were also found in platelets[9,37,38]. The latter factors seem to have more selected targets, such as the ability to promote angiogenesis.

Cambridge Books Online © Cambridge University Press, 2009

Platelets release IL-1[39] and the cytokine RANTES[40] from their alpha granules. IL-1 and other cytokines released from platelets modulate the activation of the endothelium and take part in malignant progression[41]. A vascular permeability growth factor (VPF) was also discovered in platelets[42].

Platelet factor 4 (PF4), β-thromboglobulin (β-TG) and platelet basic protein (PBP) are specific peptides, present in platelet α granules whose biological functions have recently been re-evaluated. PF4 was known as the most potent heparin neutralizing agent and as a powerful chemoattractant for fibroblasts, neutrophils and monocytes[43]. On the other hand, recombinant PF4 devoid of anti-heparin activity showed angiostatic effects and inhibitory activity in experimental models of mestastasis in mice[44]. PF4, β-TG and PBP are members of the family of cysteine-x-cysteine (c–x–c) chemokines or intercrines that are peptides with chemotactic properties[45]. Finally, platelets release large adhesive proteins, such as fibrinogen, von Willebrand factor, fibronectin and thrombospondin, whose functions will be discussed later in this chapter; platelets also release inhibitors of the fibrinolytic system, such as plasminogen activator inhibitor-1 (PAI-1) and alpha2-antiplasmin and other protease inhibitors possibly involved in tumour invasion and metastasis[37,46,47].

Platelet-mediated tumour cell adhesion and metastasis: revisited

Tumour cells show a selective organ preference to establish metastases[48], but the mechanisms underlying this selection are largely unknown. The adhesion of tumour cells to the vessel wall is stimulated by membrane antigens present on activated platelets[49,50]. Bastida et al.[51] found that tumour cell adhesion induced by platelets was increased by high shear forces and inhibited by peptides active as competitors of cell adhesion to fibronectin.

Platelets and leukocytes can mediate the adhesion of tumour cells to the endothelium and to the extracellular matrix through the activation of specific adhesive receptors and the release of cytokines and chemokines[52]. Inflammatory cytokines would activate endothelial cells to a proinflammatory and a procoagulant state, thus facilitating tumour cell adhesion[53,54]. IL-1 seems to play a special role in this process, since it stimulates procoagulant activity, synthesis of PAI-1, release of prostacyclin and exposure of adhesive receptors on endothelial cells[53]. This cytokine, similarly to TNF, can exert a prometastatic effect in human and murine tumour models, as shown by Bani et al.[55]. Such an effect could be ascribed to IL-1-induced enhancement of adhesive interactions between tumour cells and the vascular wall[56].

Activated platelets, as mentioned, release large adhesive proteins, such as fibrinogen, von Willebrand factor, thrombospondin, fibronectin and P-selectin[38]. Fibrinogen and von Willebrand factor have a physiological role for platelet aggregation, adhesion and activation. Their involvement in the process of tumour dissemination is secondary to the interaction of tumour cells, platelets and endothelium with specific receptors, which will be discussed later on. Very recently, the role of fibrinogen as a determinant of the metastatic potential of circulating tumour cells has been re-evaluated with the help of genetically deficient models[57]. Rather than merely representing an important component of the tumour stroma, fibrinogen was found to be crucial to sustain adhesion and survival of tumour cells within the lungs with mechanisms not completely understood. Fibrinogen is known to support cell–cell adhesion through integrin and non-integrin receptors. The hypothesis that soluble fibrinogen and platelets contribute significantly to the exit of tumour cells from the vasculature is consistent with findings that fibrinogen and platelet-mediated adhesion may be important in stable leukocyte adhesion and transendothelial migration[58]. Thrombospondin (TSP), a protein originally discovered in platelets, is endowed with the ability to stimulate adhesion, migration and proliferation of normal and tumour cells[59]. This large adhesive protein seems to play a role in tumour dissemination, as suggested by the observation that TSP enhances the adhesion of human melanoma cells[60] and increases the number of pulmonary metastases, when injected together with B16 melanoma cells in mice[61]. Synthetic peptides mimicking the COOH terminal of TSP inhibit platelet aggregation, compete for tumour cell adhesion to substrates and reduce artificial metastases in experimental tumour models[62].

The requirement for platelets to adhere to tumour cells, in order to elicit a prometastatic potential was recognized several years ago[63] and the role of specific adhesive receptors as molecular bridges of this interaction has been defined.

The role of αIIbβ3

In their original report Karpatkin et al.[63] were able to reduce in vivo pulmonary metastasis of a colon carcinoma cell line and in vitro tumour cell-platelet binding by monoclonal antibody blockade of platelet αIIbβ3. In this study a polyclonal anti-von Willebrand antibody also reduced metastatization, suggesting that von Willebrand factor, binding αIIbβ3, bridges tumour cells and platelets. In agreement with this result, platelet interaction with melanoma cells was prevented by a monoclonal antibody against the platelet integrin[64]. Tumour cells may actually themselves express αIIbβ3-like complexes; αIIbβ3 receptors have been found

Cambridge Books Online © Cambridge University Press, 2009

in different types of human and animal tumours[34,65,66,67]. The presence of αIIbβ3 appeared to be positively related with the platelet aggregating ability in a series of B16 melanoma cell lines with different metastatic activity[28]. $\alpha_V\beta$3 is also present in melanoma cells where it appeared to be a marker of malignancy, since it was associated with invasive and metastatic behaviour[68]. Most notably, when the expression of the β3 subunit was examined in benign and malignant lesions of human melanocytes, it was found to be restricted to malignant lesions in vertical growth phase and in metastatic melanomas, suggesting that the presence of this integrin may be important in the development of tumour invasiveness[69]. In vitro experiments showed that $\alpha_V\beta$3 in melanoma cells mediates melanoma cell attachment to activated platelets under flow in a platelet αIIbβ3-dependent manner[70,71]. In addition to melanoma, in other malignancies, including glioma[72], and ovarian and breast cancer[73,74], expression of αVβ3 in tumour cells correlates with tumour progression.

In circulating normal cells, such as platelets and leukocytes, integrins are in an inactive state. They acquire the ability to bind the ligand and to sustain a shear resistant cell adhesion to the vascular wall as a consequence of cell activation by extracellular stimuli. As for other integrins, the adhesive function of αIIbβ3 as well as $\alpha_V\beta$3 is functionally regulated by the cell[75]. This important aspect of integrin biology may also be relevant in the process of tumour cell adhesion and invasion. Using a monoclonal antibody specifically binding an activation epitope of αIIbβ3, it was found that metastatic melanoma cells express the integrin in the high affinity state[76].

More recently Felding-Habermann et al.[77] showed that not only activated $\alpha_V\beta$3 was expressed by breast cancer cells isolated from human metastasis, but also that only cells expressing the activated state of $\alpha_V\beta$3 were able to arrest on platelets, during blood flow in vitro, and promoted metastasis in a mouse model in vivo. These observations strengthen the hypothesis that alterations in the control of integrin (particularly β3) activation within the tumour cells, may influence their metastatic potential.

The role of selectins

Studies on the mechanism of entry of circulating leukocytes into tissues during inflammation showed that this is a multistep process initiated by attachment and rolling of leukocytes on the vessel wall mediated by selectins. P-, E- and L-selectins are typical type I proteins composed of different domains. These include an amino terminal C-type lectin domain, a single epidermal growth factor (EGF)-like domain, from two to nine short consensus repeat (SCR) domains, a single membrane spanning region, and a cytoplasmic tail[78]. The selectins bind carbohydrate structures containing the sialyl-Lewis X antigen appropriately expressed by specific proteins on the cell surface[79]. Different candidate glycoprotein ligands for each of the selectins have been identified. The most extensively characterized selectin ligand is the recently cloned P-selectin glycoprotein ligand-1 (PSGL-1), a mucin-like protein with a unique structure formed by a disulfide linked homodimer of two identical 120 kD chains. The first studies showed that PSGL-1 is mainly expressed on leukocytes. Recently, analysis of murine tissues indicates that the expression of PSGL-1 is widespread. However, precisely which cells, apart from leukocytes, express PSGL-1 and what is the role of PSGL-1 is on these cells, is presently unknown in humans and is an important area of future investigations[80]. Among the carcinoma associated glycans, the expression of sialyl Lewis^X and sialyl Lewis^a correlates with tumour progression, metastatic spread, and poor prognosis[81–89]. On the other hand, treatment of tumour cells with benzyl-a GalNac to suppress the *o*-linked carbohydrate chain extension resulted in a diminished expression of sLeX and sLea on these tumour cells and reduced tumour cell adhesion to activated endothelial cells or platelets[90].

Different tumour cell lines are able to bind selectins via not yet identified receptor(s) containing the sialyl-Lewis X antigen. Colon carcinoma cell lines bind to cytokine-activated endothelial cells through E-selectin[91], and leukocytes and platelets through L- and P selectin binding mucins[92,93] distinct from PSGL-1[94]. Similarly, neuroblastoma and small cell lung cancer cells adhere to activated platelets through P-selectin[95]. Human small cell lung carcinoma cells and breast carcinoma cells are also negative for PSGL-1 and bind P-selectin through CD24, a mucin-type glycosylphosphatidylinositol-linked protein[96]. The role of platelet P-selectin in tumour metastasis is also strongly supported by the experiments of Kim and coworkers[97]. These authors showed that human colon carcinoma cells, implanted subcutaneously, grow at a lower rate and generate fewer lung metastases when injected intravenously in P-selectin deficient as compared with control mice. This effect correlated with reduced formation of tumour cell–platelet clumps in the lung vasculature of P-selectin knock-out mice[97].

More recently, CD 24 was suggested to mediate the lung metastatization by adenocarcinoma cells via a P-selectin dependent mechanism[98]. Investigating the adhesive mechanism of three human colon carcinoma cell lines on adherent platelets in flow conditions McCarty et al.[99] showed that the sequential engagement of P-selectin and aIIbβ3 is a requisite for optimal adhesion of two of them; the cells of the third cell line did not interact with P-selectin

Cambridge Books Online © Cambridge University Press, 2009

and were not recruited on platelets under flow despite the fact that they adhered on platelets under static conditions. Also in this case P-selectin ligand was distinct from PSGL-1 and CD24. Altogether, these studies indicate that during the process of metastatization tumour cells recapitulate the adhesion cascade, used by normal circulating cells, namely platelets or leukocytes, to accomplish normal functions such as hemostasis and immune responses. Figure 54.1 outlines schematically a proposed mechanism for these cellular interactions where two processes are considered: (i) the formation of platelet–tumour cell microemboli; (ii) the recruitment of tumour cells at sites of vascular damage (Fig. 54.1).

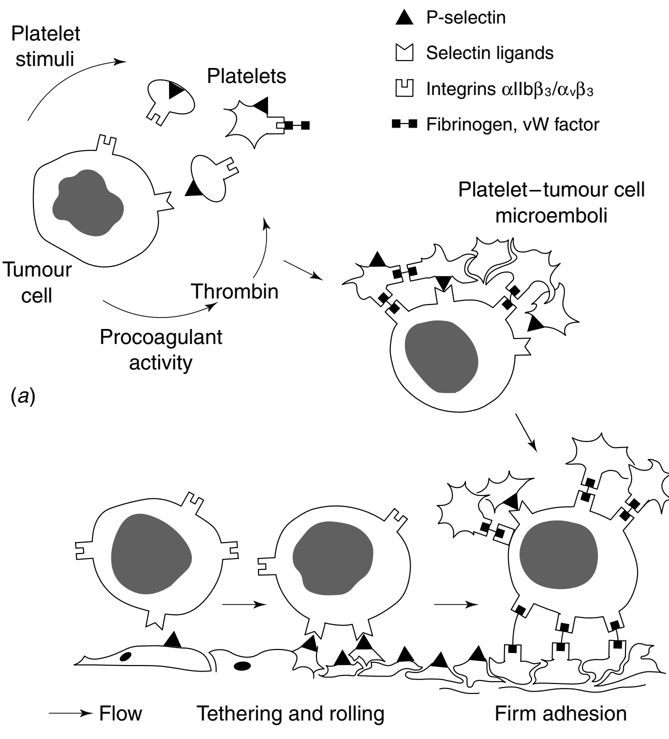

Fig. 54.1. Schematic representation of platelet–tumour cell emboli formation and of platelet-mediated tumour cell recruitment at sites of vascular damage. (*a*) Platelets activated by tumour cell-derived stimuli adhere to the tumour cell via P-selectin and β_3 integrins and forming microemboli assist tumour cell arrest and metastatization. (*b*) Platelets activated at a site of vascular damage mediate tumour cell recruitment through P-selectin-dependent tethering and rolling and β_3 integrin-dependent firm adhesion.

Platelets and angiogenesis

Although described some decades ago, the process of new vessel formation within the tumour and at the tumour host/interface, i.e. the so-called angiogenesis, has attracted increasing interest in recent years, due to the identification of some endogenous active factors (see angiostatin and endostatin) and to the preclinical and preliminary clinical tests on these agents for anticancer treatment. These agents would be active by depriving the tumour of the necessary blood supply through blockade of new vessel formation at the tumour site[100].

Among endogenous mediators known to influence the angiogenetic process, vascular endothelial growth factor (VEGF) is a potent agonist of new vessel formation. Blood platelets have been found to release VEGF upon activation and to act as major transporters of VEGF in the human circulation[101]. The hypothesis has been put forward that a specific tumour cell/ endothelium/platelet interaction can contribute to tumour-induced angiogenesis, since platelets activated f.i. by thrombin (evolved from tumour procoagulants) release VEGF. VEGF, in turn, can induce endothelial cells to release von Willebrand Factor, which may contribute to further recruitment of platelets by stimulating their adhesive properties[102].

Presumably, the increased platelet-binding capacity of the tumour vasculature and the subsequent activation of platelets are regulated by stimuli of the tumour cell and may differ for each tumour type.

Among mediators released from blood platelets during clotting, sphingosine 1-phosphate (S1P) is a potent, specific and selective endothelial cell chemoattractant that accounts for most of the strong endothelial cell chemotactic activity of blood serum. S1P would act by activating a receptor-dependent process[103]. The putative role of platelets in tumour angiogenesis is presently the topic of investigations at the clinical level in different series of patients with solid tumours.

Platelets and host's immune response to the tumour

The contribution of blood platelets to cancer metastasis depends not only on their interactions with the biological barrier represented by the leukocyte/endothelial cell system in the phase of extravasation, but may also be ascribed, at least in some tumours, to protection by platelets from tumour cell killing by natural killer (NK) cells. It has been shown that such protection occurs both in vitro and in vivo. In three different tumour cell lines from a mouse model of experimental metastasis, tumour seeding in the target organs was reduced when the host was platelet depleted, but only if the tumour cells were NK sensitive[104]. Aggregation of platelets around tumour cells also inhibited in vitro the tumourilytic activity by NK cells; besides providing a physical barrier and a steric hindrance between tumour cells and NK cells, platelets may also interfere with recognition for killing of tumour cells by NK

Cambridge Books Online © Cambridge University Press, 2009

cells. However, since platelet-caused NK inhibition was independent of the platelet donor haplotype and was equally observed with platelets from β2-microglobulin-deficient mice, a MHC class 1-dependent inhibitory mechanism is unlikely[104]. Alternatively, platelets would not only shield tumour cells but also inhibit cytolytic function of NK by some other mechanism (release of tumour cell protective factors). The presence of a platelet 'cloak' around tumour cells would also protect the latter from a closer interaction with monocytes involved physiologically in elimination of metastatic tumour cells during the early phase of metastasis. In systems of mucin-producing human tumour cells growing in athymic mice, the inhibition of platelet/tumour cell aggregation by heparin or by P selectin-deficiency leads to reduced metastasis growth; this antimetastatic effect was also concomitant with an increased association of MAC-1 positive monocytes with tumour cells[105].

Platelet–tumour cell interactions: in vivo studies

The platelet–tumour cell interactions discussed so far, mainly in in vitro systems, offer altogether biological plausibility for a role of platelets in tumour growth and dissemination, but only from in vivo studies can direct proof be obtained on the platelet involvement in tumours. For several years, experimental models where the host's hemostatic system had been pharmacologically modified, have been followed for tumour and metastasis growth[18]. This approach has been more recently integrated with the use of genetically modified animals, selectively lacking one or more factors of the hemostatic system[6].

Pharmacological implications

We shall now discuss some of the pharmacological approaches used with the general 'caveat' that none of these has so far found a well-established clinical counterpart. At the moment there are few studies of anticoagulants/antiplatelet drugs which really fulfil modern criteria of controlled randomized trials to evaluate drug efficacy.

The published studies have different designs (case reports, phase I, II and III studies, and largely retrospective epidemiological reviews) and most studies have tested anticoagulants in combination with cytotoxic drugs which makes evaluation of the results more difficult. From the data obtained so far, the following conclusions can be drawn for clinical studies:

- for small cell lung carcinoma, therapy with warfarin may lead to a longer period of disease-free survival and overall survival;
- therapy with RA-233, a dipyridamole analogue, leads to an increased overall survival in patients with localized non-small cell lung carcinoma;
- the efficacy of low-dose acetylsalicylic acid in colorectal cancer is still the subject of controversy. Treatment with sulindac, another non-steroidal anti-inflammatory drug, leads to a statistically significant reduction in amount and size of colon polyps in adenomatosis coli. It is noteworthy that not only the efficacy but also the mechanism of action of these anti-inflammatory agents in colorectal cancer is still debated and the role of platelets uncertain.

In experimental models the pioneering studies of Gasic and Gasic[11], and Gasic et al.[12] showed that induction of thrombocytopenia by antiplatelet serum or by treatment with neuraminidase inhibited metastases in experimental animal models. The effect of platelet antiserum was confirmed by Pearlstein et al.[106] and also by our group[9]. The intravenous injection of B16BL6 melanoma in mice, pretreated with antiplatelet serum, causes a 70% reduction in lung colony formation after 15 days. It is likely that the antimetastatic effect exerted by the antiplatelet serum may be the consequence of concomitant alterations of the endothelium, due to the removal of the sialic acid coating, which seems to be important for tumour dissemination, at least in conditions of high shear stress[90].

Various antiplatelet drugs have been used in the attempt to inhibit metastases[8,28,107]. The antimetastatic effect of aspirin was observed by Gasic et al.[13] but not confirmed by other investigators[108]. Ticlopidine, another potent platelet aggregation inhibitor, was unable to reduce metastasis in a model of spontaneous dissemination[63]. The effects of prostacyclin[109,110], prostacyclin analogues[111] and thromboxane synthetase inhibitors[112,113] were rather controversial. Calcium channel blockers have successfully been used as antimetastatic agents[111]. Dipyridamole and the pyrimido-pyrimidine derivative RA233 were active in some experimental models.

Thus, the effect of antiplatelet agents on metastasis was often controversial[28]. This may be the consequence of heterogeneity of tumours and administration schedules or may reflect the fact that antiplatelet drugs have multiple effects on different cell targets (anti-inflammatory, antiadhesive, immunomodulatory, besides platelet inhibition). As a general comment, antiplatelet agents have been found to be much more active in preventing lung colony formation ('artificial metastasis') than the 'spontaneous' dissemination process. This is a type of behaviour shared by virtually all anticoagulant, antiplatelet and defibrinating agents used so far; it suggests that, in the artificial model, whatever is pharmacologically operated prior to tumour cell injection in order to reduce blood coagulability and/or

Cambridge Books Online © Cambridge University Press, 2009

blood cell stickiness between them and to the vascular wall, the result will be a longer circulation time of tumour cells in the host and a higher rate of their destruction by the reticuloendothelial system: as a result, metastatic growth will be reduced.

In the last 10–15 years some platelet–tumour cell interactions have been more deeply studied in their multicellular scenario (see the section on cell adhesion).

The in vitro studies have also provided new candidates for in vivo testing against cancer metastasis; more selective agents, whose effects are directed towards specific cell functions, have recently been developed.

Monoclonal antibodies to αIIbβ3

The monoclonal antibody (mAb) 7E3, a specific inhibitor of the platelet αIIbβ3 receptor, was rather active as an inhibitor of human platelet aggregation[116]. This antibody reduced lung colony formation after intravenous injection of tumour cells in mice[63]. Monoclonal antibodies to αIIbβ3 also inhibited the adhesion of human tumour cells to fibronectin[117] and tumour cell induced platelet aggregation[34]. In addition, Boukerche et al.[64] observed a reduction of the growth of human melanoma cells in nude mice after treatment with LYP18, another mAb to αIIbβ3.

RGD peptides

Renewed interest in selective inhibition of platelet–tumour cell interaction was given by synthetic peptides with RGD sequence[118]. The intravenous injection of B16 melanoma cells together with peptide gly–arg–gly–asp–ser (GRGDS), significantly inhibited lung colony formation in mice[119]. This effect was attributed to accelerated disappearance of tumour cells from the lungs of treated mice. Modified peptides, lacking the RGD sequence, such as gly–arg–gly–glu–ser (GRGES) were not active[120]. Several RGD-containing peptides have been used successfully in experimental models of tumour dissemination[121–123]. However, the short half-life and the reversibility of the effect of these agents on platelets have limited their use as antimetastatic agents. The effect of RGD-containing peptides on metastasis may be due to the blockade of platelet–tumour cell interactions or to the inhibition of tumour cell adhesion to fibronectin. To clarify this problem, we studied arg–gly–asp–trp (RGDW),a tetrapeptide with a potent inhibitory effect on platelet aggregation and a more limited effect on cell adhesion, in the B16BL6 lung colony assay.RGDW was about ten times more active in inhibiting ADP-induced platelet aggregation and ^{125}I-fibrinogen binding to platelets, as compared to arg–gly–asp–ser[124]. RGDW was also more potent than RGDS in inhibiting B16BL6 lung colony formation[125]. Arg–gly–gly–trp(RGGW),a tetrapeptide devoid of antiplatelet activity, was also inactive on metastases, suggesting that inhibition of platelet functions was crucial, at least in our model.

Disintegrins

Disintegrins are a class of snake venom-derived peptides, characterized by the presence of the RGD sequence and a cysteine-rich region. Disintegrins are several orders of magnitude more potent than small RGD peptides as inhibitors of platelet aggregation and cell adhesion[126,127]. Trigramin, a peptide purified from the venom of *Trimeresurus gramineus*, showed a potent inhibitory effect on the adhesion of human melanoma cells to fibronectin and fibrinogen[128]. Batroxostatin also caused a potent inhibition of the adhesion of human and murine melanoma cells to fibronectin[129] and triflavin inhibited the adhesion of B16 melanoma cells to various substrates[130]. We found that albolabrin, a disintegrin derived from the venom of *Trimeresurus albolabris*, was about 2000-fold more active than RGDS at inhibiting mouse platelet aggregation (IC_{50}: 166 nM and 50 μM, respectively) and was also more active than RGDS at protecting mice from pulmonary thromboembolism[131]. Similarly, albolabrin was more active than RGDS at inhibiting B16BL6 melanoma lung colony formation in mice[132]. Since albolabrin prevented the accumulation of ^{51}Cr-labelled platelets in the lungs of treated mice, it is possible that its antimetastatic effect may be due to the diversion of platelet–tumour cell emboli from the lungs of treated mice. Eristostatin, a disintegrin with a more selective inhibitory effect on platelet aggregation, was also found to have more potent inhibitory effects on lung colony formation than albolabrin (IC_{50}: 0.05 μM and 1.0 μM, respectively)[133]. Analysis of disintegrin structure revealed that disintegrins with the RGDW sequence, such as eristostatin, have a higher affinity for αIIbβ3 receptors than other RGDX sequence, thus explaining their increased activity on platelet functions[134]. The design of even more selective inhibitors of cell functions, such as platelet aggregation or cell adhesion, may improve the effectiveness of these agents on metastases.

Conclusions

Platelet interactions with tumour cells have been described both in vitro and in vivo. Platelet activation can stimulate tumour cell adhesion to the vessel wall, with a mechanism involving selectins, integrins, IgG-like molecules and other adhesive receptors. Similar receptors present on neutrophils, monocytes and endothelial cells take part in this process, with a concerted action. Growth

Cambridge Books Online © Cambridge University Press, 2009

factors, cytokines, chemokines and other products released after platelet aggregation and activation may further stimulate the adhesion of tumour cells to activated endothelium. More experimental work is needed to translate knowledge on this fascinating machinery into new pharmacological tools for cancer and mestastasis control; new approaches aimed at inhibiting receptor-mediated platelet adhesion and activation may be promising for the prevention and cure of metastasis.

Platelets in uremia

Morgagni in 1764 in his *Opera Omnia*[1] was the first to recognize the remarkable association between bleeding and renal dysfunction. Bleeding may be a serious complication of acute and chronic renal failure[2,3], and since the first review in 1907 on the association between uremia and abnormal bleeding, the clinical manifestations of uremic bleeding have been well described[4–7]. Hemorrhagic complications varying from ecchymoses, epistaxis, bleeding from gums and venipuncture sites, and overt gastrointestinal bleeding have been observed in up to one-third of uremic patients[5,8,9], however, low-grade gastrointestinal bleeding may be even more common[10].

Bleeding became a clinical problem at the beginning of the dialysis era, when patients sometimes died from excessive bleeding from the gastrointestinal tract or abdominal organs[8,11].

With the advent of modern dialysis techniques and the use of erythropoietin to correct anemia[12] the frequency of severe hemorrhage has decreased; however, this complication still limits surgery and invasive procedures in these patients.

The cause of uremic bleeding has been the subject of a major debate since the 1970s. The pathogenesis is considered multifactorial (Table 55.1); however, platelet–platelet and platelet–vessel wall interactions appear to be of crucial importance. Abnormalities of blood coagulation and fibrinolysis partially corrected by dialysis predispose the uremic patients to thrombosis rather than bleeding. Chronic renal failure also seems to be associated with an increased incidence of arterial and venous thromboembolic complications and this chapter will review the platelet and vascular defects in uremia.

Table 55.1. Factors involved in the pathogenesis of bleeding associated with chronic renal failure

Platelet abnormalities
Subnormal dense granule content
Reduction in intracellular ADP and serotonin
Impaired release of the platelet α-granule protein and β-thromboglobulin
Enhanced intracellular c-AMP
Abnormal mobilization of platelet Ca^{2+}
Abnormal platelet arachidonic acid metabolism
Abnormal ex vivo platelet aggregation in response to different stimuli
Defective cyclooxygenase activity
Abnormality of the activation-dependent binding activity of GP IIb–IIIa
Uremic toxins, especially parathyroid hormone
Abnormal platelet–vessel wall interactions
Abnormal platelet adhesion
Increased formation of vascular PGI_2
Altered von Willebrand factor
Anemia
Altered blood rheology
Erythropoietin deficiency
Abnormal production of nitric oxide
Drug treatment
β-Lactam antibiotics
Third-generation cephalosporins
Non-steroidal anti-inflammatory drugs

Thrombocytopenia

Thrombocytopenia is found in 16–55% of uremic patients[6,8,9,13–19], suggesting platelet overconsumption or inadequate production[20]. However, platelet number is rarely less than 80 000/μl[5,6,8,9,14,21–23], a concentration generally considered adequate for normal hemostasis.

The interaction of blood with biocompatible (e.g. cuprophane) hemodialysis membranes leads to complement activation, transient neutropenia, and significant thrombocytopenia during dialysis[24,25]. This phenomenon does not occur when biocompatible membranes, which do not activate complement, are used[24,25]. Heparin therapy, used to inhibit clotting in the extracorporeal circuit, can activate platelets and can occasionally induce thrombocytopenia by an immunologic mechanism[26,27].

A major decrease in platelet count is present in patients with renal failure associated with lupus vasculitis, hemolytic uremic syndrome/thrombotic thrombocytopenic purpura, disseminated intravascular coagulation, eclampsia, and renal allograft rejection.

The mean platelet volume may also be decreased in uremia. This decrease in the circulating platelet mass is inversely related to the bleeding time in uremic individuals[28].

Platelet abnormalities

Dense granule content is subnormal in uremic platelets[29,30]; the storage pool defect is denoted by the reduction in platelet ADP and serotonin and by the increase in the ratio of ATP to ADP. Cyclic AMP (cAMP) is elevated in patients with terminal renal insufficiency and hemodialysis partially corrects this abnormality[31]. Since ADP and serotonin are platelet agonists and cyclic AMP is an inhibitor of platelet function, this imbalance could contribute to an activation defect. The release of ATP in response to thrombin is also reduced in uremia[29] suggesting a defective secretory mechanism. Calcium content is increased in uremic platelets[32], which also mobilize calcium abnormally in response to stimulation[33]. Elevation in platelet cAMP and abnormal calcium mobilisation drew attention to the possibility that parathyroid hormone (PTH) may play a role in uremic platelet dysfunction. This speculation was supported by the observation that PTH inhibits platelet aggregation in vitro[34,35]. However, the bleeding time does not correlate with serum concentrations of intact PTH or PTH fragments[36], suggesting that elevated PTH in renal failure patients is not likely to play a major role in the uremic platelet defect. An impairment in the release of the platelet α-granule proteins and β-thromboglobulin was demonstrated in hemodialysis patients[37].

Defective platelet aggregation in response to various stimuli such as ADP, epinephrine, collagen, and thrombin is documented in a great number of studies[11,20,22,29,38–44], although the degree of impairment of platelet aggregation in uremia varies considerably, and in several reports platelet aggregation was found to be normal or increased[45–48].

Impaired synthesis by uremic platelets of thromboxane A_2 (TxA_2), a potent enhancer of both platelet release and aggregation, has been documented, but the nature of this abnormality remains controversial[29,30,49–54]. A decreased platelet aggregation and TxA_2 formation in response to ADP, collagen, and thrombin as well as to arachidonic acid, consistent with a defect in platelet prostaglandin synthesis at or beyond the cyclooxygenase level was observed by some investigators[51,52]. Others found normal TxA_2 formation by uremic platelets in response to arachidonic acid as well as to the TxA_2 analogue, U-46619, while TxA_2 synthesis in response to ADP, collagen, or the combination of collagen with ADP or epinephrine was impaired[29,50,53]. These findings would be consistent with a defect in the stimulated release of arachidonic acid from platelets. The observation that these defects are corrected by dialysis, indicates that they are probably due to a factor present in uremic plasma[29,52,53].

Platelet–vessel wall interaction

Normal platelet adhesion requires initial platelet contact followed by platelet spreading on the subendothelial matrix. Two adhesive proteins, fibrinogen and von Willebrand factor (vWF), and two platelet adhesion receptors, glycoprotein (GP) Ib and the $\alpha_{IIb}\beta_3$ complex play a vital role in the formation of platelet thrombi at sites of injury. At high shear rates, such as those found in the capillary circulation, contact is dependent on the binding of vWF to the platelet GP Ib[55,56]. This interaction is also necessary for ristocetin-induced platelet aggregation in vitro. Binding of GP Ib to vWF is normal in uremic patients[57], as is the surface expression of the receptor[57,58]. In patients with chronic renal failure, a decrease in the total content of platelet GP Ib has been documented[58,59], accompanied by an increase in soluble glycocalicin (a soluble proteolytic fragment of GP Ib), and is probably due to proteolytic damage to membrane GP Ib. The normal surface expression of this receptor and the total decrease in content account for a redistribution from the intraplatelet pool to the surface pool[57,58]. The activation-dependent receptor function of the $\alpha_{IIb}\beta_3$ complex is defective in uremia, as

Cambridge Books Online © Cambridge University Press, 2009

shown by decreased binding of both vWF and fibrinogen to stimulated platelets[57]. The number of $\alpha_{IIb}\beta_3$ receptors expressed on the platelet membrane is normal. Removal of substances present in uremic plasma markedly improved the $\alpha_{IIb}\beta_3$ defect. Thus, a reversible abnormality of the activation dependent binding activity of $\alpha_{IIb}\beta_3$ caused by a dialysable toxic substance or substances[57,60], or due to receptor occupancy by fibrinogen fragments present in uremic plasma[61], is probably a major component of the altered platelet function in uremia. The impaired $\alpha_{IIb}\beta_3$ activation in uremia may explain aggregation defects as well as reduced vWF-dependent adhesion and thrombus formation[62–64].

vWF levels in plasma, measured either by immunologic methods or functionally by ristocetin cofactor activity, are normal or elevated in renal failure[65], and qualitative abnormalities of vWF have not been uniformly observed[43,59,63,66].

The observation that cryoprecipitate[67] – a plasma derivative rich in vWF – and desmopressin[68] – a synthetic derivative of antidiuretic hormone that releases autologous vWF from storage sites – significantly shorten the bleeding time of uremic patients suggests that a functional defect in the vWF–platelet interaction may indeed play a role in the abnormal hemostasis of these patients.

Molecules such as PGI_2 and nitric oxide (NO) may affect platelet–vessel wall interaction thus amplifying the platelet defects observed in uremia.

An increased synthesis by vascular endothelium formation of prostacyclin (PGI_2), a potent vasodilator and inhibitor of platelet function, was documented in uremic patients[37,69] and blood vessels from rats with experimentally induced uremia[70,71]. Furthermore, plasma from uremic patients stimulates PGI_2 generation by cultured endothelial cells more than normal plasma[72].

NO is a potent modulator of vascular tone that limits platelet adhesion to endothelium[73] and platelet–platelet interaction increasing the formation of cell cyclic GMP[74–76]. Data are available showing that platelets from uremic patients on hemodialysis generate more NO than healthy subjects[77,78]. Uremics have higher levels of NO in exhaled air[79] and higher plasma levels of NO metabolites[80–83] than normal humans. In addition, plasma from chronic hemodialysed patients potently induces NO synthesis from human umbilical vein endothelial cells (HUVEC)[78] and cultured human microvascular endothelial cells[84]. The stimulatory activity found in uremic plasma is attributed to cytokines such as TNFα and IL-1β that are potent inducers of the inducible isoform of NO synthase and circulate in increased amounts in the plasma of patients with chronic renal failure who either are, or are not, on maintenance hemodialysis[77,85–88].

Dialysis

Several dialysable uremic toxins, e.g. urea, creatinine, phenol, phenolic acids, or guanidinosuccinic acid (GSA) may possibly be involved in the genesis of the uremic platelet dysfunction[89–91]. GSA, which accumulates in uremic plasma, inhibits the second wave of platelet aggregation to ADP when added to normal platelet-rich plasma[90], and as recently demonstrated GSA is involved in the generation of NO[78]. The effect of GSA of stimulating NO release provides a biological explanation of the old data of early 1970 showing that, among uremic toxins, GSA was the only one that consistently inhibited platelet function to such a degree that it was defined the 'x' factor in uremic bleeding[92,93].

Phenolic acid, at the concentrations found in uremic plasma, also impairs primary aggregation to ADP[89].

All these observations suggest that reducing the blood levels of these compounds may correct the abnormal hemostasis of patients with renal failure. However, no correlation has been found between bleeding time or platelet adhesion and serum levels of the dialysable metabolites mainly accumulating in uremia[91].

Dialysis improves platelet functional abnormalities and reduces, but does not eliminate the risk of hemorrhage[49]. Hemodialysis can even contribute to the bleeding. The continuous platelet activation induced by the interaction between blood and artificial surfaces, and the release of platelet-derived proteins, can induce platelet 'exhaustion' and consequently favour bleeding in uremic patients. Peritoneal dialysis has been suggested to be more effective than hemodialysis in removing uremic toxins that adversely affect platelet function, however this procedure may cause platelet hyper-reactivity, which in some cases may be related to hypoalbuminemia[94].

Role of anemia

Platelet adhesion and aggregation in flowing systems[56,95] are markedly potentiated by red blood cells. Erythrocytes enhance platelet function by releasing ADP[96], by inactivating PGI_2[97], and by increasing platelet–vessel wall contact by displacing platelets away from the axial flow and toward the vessel wall[95]. The independent role of anemia in the bleeding tendency of uremia has been extensively investigated. A significant negative correlation was found between bleeding time and packed cell volume (PCV)[98]. In fact, despite a shorter bleeding time, a significant negative correlation between hematocrit and bleeding time was also demonstrable in 15 non-uremic anemic patients.

Cambridge Books Online © Cambridge University Press, 2009

These results were subsequently confirmed by other studies[99,100] that found that anemia was the main determinant of the prolonged bleeding time in uremic patients.

The cloning of the human erythropoietin gene and the production of the human recombinant erythropoietin (rhEPO) have provided clinicians with a powerful tool to correct the anemia associated with the renal failure. Clinical trials have provided evidence that rhEPO reverses the anemia of renal failure and eliminates any dependency upon transfusion[101]. Increasing doses of rhEPO, when given to hemodialysis patients with a history of bleeding, severe anemia (hematocrit less than 23%), and the long basal bleeding time (more than 19 minutes), induced a progressive increase in hematocrit accompanied by significant shortening of the bleeding time[12]. Although improvement in platelet adhesion to subendothelium was observed in some studies, no consistent changes in platelet number, platelet aggregability, markers of platelet activation in plasma, platelet TxA_2 formation, platelet adenine nucleotide content, global coagulation test results, antithrombin III, or cross-linked fibrin derivatives were reported[12,102,103].

The efficacy of erythropoietin is indisputable with improvement in the quality of life, cardiac function, physical work capacity, cognitive function and sexual function with hematocrit of 36% to 39%[104]; however the benefits and risks of complete correction of anemia (hematocrit 38% to 42%) and the optimal target concentration have not yet been established. Recently, the safety of the long-term maintenance of a normal hematocrit has been questioned, as a consequence, in part, of the early termination of the Normal Hematocrit Cardiac Trial[105], in which the patients randomly assigned to the normal hematocrit group presented with a higher mortality and a higher incidence of non-fatal myocardial infarction[106].

Effect of drugs

Uremic patients may be at an increased risk of bleeding complications caused by drug treatment. The risk of bleeding associated with the accumulation of β-lactam antibiotics in uremia has been highlighted[107]. β-lactam antibiotics apparently act by perturbing platelet membrane function and by interfering with ADP receptors[108,109]. The prolonged bleeding time and the abnormal platelet aggregation are related to the dose and duration of treatment and are promptly reversible after discontinuation. Third-generation cephalosporins may also inhibit platelet function and may lead to marked disturbances of blood coagulation[110,111].

Risk of bleeding in uremic patients is also associated with aspirin given to prevent vascular access thrombosis[112] or platelet activation on dialysis membranes[113]. The beneficial effect of aspirin on vascular access thrombosis can be achieved with a moderate dose of 160 mg/d, which inhibits platelet TxA_2 generation without affecting vascular PGI_2 formation[112]. However, a moderate dose of aspirin may prolong the bleeding time to a greater extent in uremic than in control subjects[114,115]. This difference appears not to be related to increased susceptibility of cyclooxygenase in uremic platelets. Furthermore, a temporal dissociation was found in uremic patients between the prolongation of bleeding time and inhibition of serum TxA_2 generation after aspirin. Indeed aspirin seems to have two distinct inhibitory effects on platelet function in uremia: a transient effect which interferes with one of the determinants of bleeding time, and the lasting effect due to the irreversible blocking of platelet cyclooxygenase[115]. However, the prolongation of bleeding caused by aspirin may explain the frequency of gastrointestinal bleeding in uremic patients[116,117]. Thus the use of aspirin for uremic patients treated with rhEPO to prevent thrombotic complications associated with an increased hematocrit is highly questionable.

Nonsteroidal anti-inflammatory drugs such as indomethacin, ibuprofen, naproxen, phenylbutazone, and sulfinpyrazone also inhibit platelet cyclooxygenase[118] and disturb platelet function[119]. However, in contrast to aspirin, the inhibitory effect of these compounds on platelet cyclooxygenase is readily reversible as the blood concentration of the drugs falls upon cessation of administration[119].

Therapeutic strategies to correct uremic bleeding

Guidelines for the management of hemorrhagic complications of uremia are summarized in Table 55.2.

Thrombotic complications

Paradoxically, hemodialysis exposes uremic patients to the thrombotic complications of vascular access. Percutaneous cannulation, arteriovenous shunt, and native vein or prosthetic arteriovenous fistula, and fistulas made of artificial polymers used for chronic hemodialysis are particularly prone to thrombotic occlusion, which accounts for a substantial percentage of hospital admission of dialysis patients[120]. It has been estimated that more than half of all grafts develop thrombosis within 2 years[121]. To prevent

Cambridge Books Online © Cambridge University Press, 2009

Table 55.2. Guidelines for the management of hemorrhagic complications of uremia

For all patients with hemorrhagic complications or undergoing major surgery, the adequacy of dialysis should be appropriately checked. It is also advisable to change the dialysis schedule for 1 to 2 mo in patients who have experienced severe hemorrhages (such as major gastrointestinal bleeding, hemorrhagic pericarditis, subdural hematomas) or who have undergone recent cardiovascular surgery, so that heparin can be avoided.
Acute bleeding episodes may be treated with desmopressin at a dose of 0.3 μg/kg intravenously (added to 50 ml of saline over 30 min) or subcutaneously. Intranasal administration of this drug at a dose of 3 mg/kg is also effective and is well tolerated. The effect of desmopressin lasts only a few hours, a major limitation to its use in treating severe hemorrhage, and desmopressin appears to lose efficacy when repeatedly administered. Because the favourable effect of cryoprecipitate on bleeding time has not been uniformely observed, we do not recommend its use.
The ideal treatment of persistent chronic bleeding should have a long-lasting effect. Conjugated estrogen treatment given by intravenous infusion in a cumulative dose of 3 μg/kg as daily divided dose (i.e. 0.6 mg/kg for 5 consecutive days) is the most appropriate way of achieving long-lasting hemostatic competence.
Severely anemic patients should receive blood or red blood cell transfusions to improve hematocrit values. Red blood cell transfusion is hemostatically effective only when the hematocrit rises above 30%. As an alternative, bleeding in patients with renal failure and hematocrit less than 30% can be treated successfully with erythropoietin, according to the following indications. Before therapy, iron stores should be assessed by determination of serum ferritin, serum iron, and total iron-binding capacity (TIBC). Patients with microcytic anemia and normal iron stores should be evaluated for aluminium toxicity and thalassemia. Uncontrolled hypertension is a contraindication to the initiation of rhEPO therapy. Patients must be urged to adhere to pre-hEPO dietary restriction. The hemoglobin level or hematocrit should be measured each week during induction of therapy and every 2 wk thereafter. Serum iron, TIBC and serum ferritin should be measured monthly for 3 mo and every 2 to 3 mo thereafter.

vascular access thrombosis, antiplatelet agents such as low-dose aspirin[112,113], sulfinpyrazone[122,123] or ticlopidine[124–126] have been used, with encouraging results, but concerns about the possibility of increases in bleeding complications have limited the routine use of these agents in dialysis centres.

Cardiovascular events related to thrombosis are a predominant cause of death and account also for an important morbidity in uremic patients both on conservative treatments, or on replacement of renal function by dialysis or transplantation. It is evident that the vast majority of patients with chronic uremia has several risks for developing cardiovascular disease, either pre-existing or caused or aggravated by chronic renal failure, such as hyperlipidemia, hypertension, glucose intolerance and hyperparathyroidism. In addition, hemodialysis itself may contribute to lipid abnormalities that are present in every type of chronic renal disease[120,127]. Hemostatic abnormalities consistent with a hypercoagulable state have been widely described in patients with end-stage renal failure on hemodialysis. Risk factors include enhanced platelet aggregability, increased plasma fibrinogen, Factor VIII: C and vWF, decreased protein C anticoagulant activity and protein S, impaired fibrinolytic system activity, raised plasma lipoprotein(a), increased plasmatic concentration of homocysteine, and the presence of lupus anticoagulant (for review see Joist et al.[128]).

The association between renal vein thrombosis (RVT) and the nephrotic syndrome (NS) has been long recognized[129,130]. The incidence of RVT appears to be substantially higher in NS caused by membranous glomerulonephritis than with membranoproliferative glomerulonephritis or other forms of renal disease[129–133]. A variety of hemostatic alterations, consistent with a hypercoagulable state, have been reported in NS[130,134]. Increased platelet aggregability to ADP and collagen was found in nephrotic children[135]. Platelet defects[128] vary from spontaneous platelet aggregation, enhanced response to arachidonic acid, increased production and release of arachidonic acid, and shortened platelet survival. Platelet hyperaggregability in NS has generally been attributed to hypoalbuminemia because albumin inhibits arachidonic acid-induced platelet aggregation and arachidonic acid conversion from platelet phospholipids to endoperoxide intermediates and TxA_2. However, no apparent relationship between hyperaggregability and hypoalbuminemia has been found in some studies[129,136–139]. Hypocalcemia and hypercholesterolemia may be involved as well in platelet hyperaggregability in NS[127,137,140–142]. The complex interaction between the effects on platelet function in uremia, the underlying glomerulonephritis, hemodialysis, and medications may account for the lack of a statistically significant relationship between platelet hyperaggregability, hypoalbuminemia, and/or hypercholesterolemia in patients with NS. In these patients,

platelet abnormalities in association with the common modest thrombocytosis, with increased levels of coagulation factors, and with reduced levels of antithrombin III may play an important role in the development of RVT and other venous and arterial thromboembolic complications[128].

Platelets in glomerular diseases

Platelets are involved in the pathogenesis of glomerular diseases through a variety of mechanisms[143,144]. The release of platelet activating factor (PAF) and other platelet secretory products (Table 55.3) may alter glomerular permeability to proteins and enhance immune-mediated glomerular injury. In addition platelet-derived growth factors may account for the renal disease progression via their chemotactic activity for infiltrating leukocytes and their effect of promoting extracellular matrix synthesis by resident renal cells. Evidence of platelet activation in renal diseases has been demonstrated by the clinical observation of shortened platelet survival or intrarenal platelet sequestration in patients with membranoproliferative, membranous or lupus glomerulonephritis, focal segmental glomerulosclerosis and diabetic nephropathy[145–147]. In diffuse proliferative glomerulonephritis accelerated platelet destruction has been found to be prominent and correlations between platelet destruction and intraglomerular cellular proliferation were reported[146–148]. In patients with lupus nephritis thrombocytopenia and glomerular thrombosis, factors important in determining the subsequent development of glomerulosclerosis, are common findings[148,149]. Platelet and fibrin thrombi in lumens of small arteries and glomerular capillaries are also common renal pathologic features in hemolytic uremic syndrome/thrombotic thrombocytopenic purpura, systemic sclerosis, acute and chronic transplant rejection, and nephropathy associated with essential hypertension[150–153]. Intraglomerular platelet aggregates were found also in patients with mesangiocapillary glomerulonephritis and IgA nephropathy[154–158].

Platelet secretory products as a cause of glomerular permeability alteration and glomerular injury amplification

There is evidence that during glomerulonephritis platelets are activated and their secretory products localise in glomerular structures, however little is known about the effects of these platelet constituents and nearly all of our understanding derives from animal experiments.

The initiation of immune vascular injury involves a complex array of inflammatory mediators, including PAF, which may play a central role. PAF is a potent phospholipid autacoid, initially isolated from stimulated basophils, that is synthesized by different cell types, including neutrophils, monocytes, endothelial cells and glomerular mesangial cells[159,160]. PAF is also secreted by platelets and, in turn, triggers platelet aggregation, activation and degranulation[161]. Biological effects of PAF that may determine glomerular injury include chemotaxis and activation of leukocytes, complement activation, contraction and stimulation of mesangial cells to produce eicosanoids and radical oxygen species. Evidence that PAF is involved in glomerular injury derives from studies in different experimental models of glomerulonephritis: increased glomerular production of PAF and improvement of the glomerular disease by a specific PAF receptor antagonist was observed in nephrotoxic nephritis (NTN)[162–164], acute serum sickness[165], anti-Thy-1 glomerulonephritis[166] and murine lupus nephritis[167,168]. Increased plasma and urinary levels of PAF correlated with proteinuria and renal histological abnormalities in murine lupus nephritis[169] and, in this model, reduced proteinuria and improved survival were observed after the chronic administration of a PAF receptor antagonist[168].

Other platelet secretory products that are implicated in proteinuria and immune complex localization by virtue of their ability to alter glomerular permeability are endogenous polycationic macromolecules, platelet factor 4 (PF4) and β-thromboglobulin. They may bind to glomerular polyanions, neutralizing the electrostatic barrier to circulating macromolecules[170,171]. In experimental animal models such as rabbits with acute serum sickness and

Cambridge Books Online © Cambridge University Press, 2009

after infusion of bovine serum albumin in pre-immunized animals, the loss of glomerular polyanions together with glomerular localization of platelet cationic proteins and immune complexes has been documented[172,173]. Loss of polyanions has also been reported in several human glomerular diseases[171,174,175]. The causes of the loss of glomerular polyanions in glomerulonephritis have not been fully elucidated. However platelet products could interfere with glomerular polyanions by different processes, including neutralization of fixed negative charges by polycations, enzymatic degradation of polyanions and reduction in glomerular cell synthesis or quality of basement membrane constituents such as type IV collagen, fibronectin and heparan sulfate. The latter molecules are sensitive to the action of elastase, collagenase and heparatinase, which are released by platelets upon stimulation[176]. Infusion of collagenase, heparatinase, elastase or cathepsin G into the renal vasculature resulted in increased glomerular permeability to tracer molecules or development of proteinuria.

Platelet-derived growth factors as mediators of renal disease progression in experimental and human glomerulopathies

A variety of cytokines and growth factors that are secreted by platelets directly influence glomerular mesangial cell functions, including proliferation, migration, contraction and extracellular matrix protein synthesis[177].

Platelet-derived growth factor (PDGF) is a 30-kilodalton glycoprotein that appears to mediate mesangial cell proliferation in glomerulonephritis[177,178]. In response to activation by numerous substances, including PAF, thrombin, collagen and immune complexes[179], platelets release PDGF – stored in the α-granules – into the extracellular environment. PDGF is a potent mitogen for mesangial cells[180] and may have an additional role as an intermediary in the effects of other growth factors. Epidermal growth factor and basic fibroblast growth factor induce the PDGF gene in mesangial cells and exert their mitogenic effect at least partly through the PDGF loop[181]. Binding of PDGF to its receptor on mesangial cells activates phospholipase C with generation of inositol triphosphate, enhancement of intracellular calcium and diacylglycerol and protein kinase C activation[182]. PDGF together with other platelet secretory products such as fibronectin[183] and thrombospondin[184] act as chemoattractants for mesangial cells and this process appears important in conditions of mesangial cells interposition as in membranoproliferative glomerulonephritis. PDGF also regulates matrix production directly or by additional growth factor pathways, such as stimulating the release from mesangial cells of transforming growth factor beta (TGFβ) which, in turn, controls the synthesis of a variety of mesangial matrix proteins. Administration of an antibody to PDGF inhibited mesangial cell proliferation in the anti-Thy-1 model[185] suggesting that PDGF plays an important role in the progression of proliferative diseases. In rats with proliferative glomerulonephritis induced by anti-Thy-1 antibody[186], renal ablation[187] and streptozotocin-induced diabetes[188] it has been demonstrated that increased mesangial expression of PDGF and/or PDGF-β receptor as well as their respective mRNAs in glomeruli is a consequence of platelet activation.

Autocrine pathways involving peptide growth factors exist also in human glomerular disease. This evidence derives from findings that expression of PDGF and PDGFβ receptor is enhanced in vascular structures and glomeruli in diverse proliferative diseases such as IgA, crescentic glomerulonephritis, focal segmental glomerulosclerosis, chronic transplant rejection and lupus nephritis[189–192].

TGFβ is released from platelets locally at the site of injury and has a variety of biological actions[193–195], including induction of its own production by local cells. TGFβ is also a strong chemoattractant of inflammatory cells that generate TGFβ by themselves as part of the cytokine network. In its defensive role, TGFβ mediates the recruitment of leukocytes, stimulates extracellular matrix deposition promoting tissue repair and the resolution of inflammation. In this context TGFβ induces the production of fibronectin, collagens, proteoglycans and tenascin and, in the mean time, blocks matrix degradation by increasing the levels of protease inhibitors, such as plasminogen activator inhibitor-1, and by reducing the secretion of proteases[196]. On mesangial cell proliferation TGFβ displays a dual mode of action: it inhibits the proliferation of cells actively proliferating in low density, but is a potent mitogen for confluent cells[197,198]. Evidence that TGFβ has a role in inflammatory renal diseases rests on the fact that TGFβ is stored in high concentration in platelets[199] and is expressed in activated monocytes and macrophages infiltrating the glomerulus. In glomerulonephritis and glomerulosclerosis TGFβ is supposed to be the principal mediator of increased extracellular matrix synthesis[195,200]. A role for TGFβ in mediating tubulo-interstitial and glomerular damage in progressive nephropathies is supported by the following observations. Glomerular expression of TGFβ is increased together with matrix deposition in experimental and human diabetic nephropathy[201]. In the experimental adriamycin-induced chronic model of progressive renal disease, the development of glomerulosclerosis parallels the increase in mRNA TGFβ and TGFβ receptor expression and the

Cambridge Books Online © Cambridge University Press, 2009

enhanced secretion of TGFβ and is associated with raised mRNA levels of fibronectin in both cortex and glomeruli[202].

Thus, platelets appear to play a central role in the early events in glomerular disease, however perpetuation of the proliferation of resident cells in clinical disease may also involve other autocrine pathways.

Effect of antiplatelet agents on glomerular diseases

Depleting circulating platelets has been very effective in prevention of immune complex nephritis[162,176,203–205] and in inhibiting mesangial cell proliferation in several models of proliferative glomerular nephritis[206–208] and diabetic nephropathy[188]. In experimental and clinical glomerulonephritis the use of drugs against specific pathways of platelet activation and secretion ameliorates the progression of renal failure. These successful therapeutic results provide further evidence for the role of platelets as mediators of the progression of glomerular disease.

In 1972, treatment with cyclophosphamide, the anticoagulant warfarin and the platelet-inhibiting drug dipyridamole improved the prognosis in patients with membranoproliferative glomerulonephritis[209]. However, a multicentre prospective randomized Canadian study found no beneficial effect of this triple therapy[210].

The effects of drugs such as warfarin, dipyridamole, aspirin and their association derive from reports involving a small number of patients. A prospective trial of warfarin and dipyridamole was performed in 18 patients with membranoproliferative glomerulonephritis[211]. The unpaired analysis compared ten patients followed for an initial year with eight patients receiving treatment first. Renal function remained stable and proteinuria decreased in the treated group. Favourable effects of the treatment were observed only in 6 out of 13 patients who completed both the control and treatment year. Association with dipyridamole and aspirin was studied in 40 patients with type I membranoproliferative glomerulonephritis[212]. In treated patients glomerular filtration rate (GFR) was better maintained, platelet half-life was increased and progression to end-stage renal disease occurred less often and over a longer period with respect to the placebo group. The interpretation of these results is difficult because this finding could derive from reduction in platelet/vascular wall interaction or in platelet consumption or, alternatively, might have been related to inhibition of both the platelet and the renal production of TXA_2 and prostaglandins. However, even if inhibition of TXA_2 synthesis may have a beneficial effect, the simultaneous inhibition of vasodilatory prostaglandins should theoretically be deleterious to renal function.

Ticlopidine is a potent inhibitor of platelet function, with a broad spectrum of pharmacological actions on platelet and platelet/cell interactions[213,214]. This drug differs significantly from aspirin in its mechanism of antiplatelet action and in its toxicity profile. Ex vivo studies have shown that ticlopidine impairs fibrinogen binding to its platelet receptor $\alpha_{IIb}\beta_3$ complex, and inhibits platelet aggregation in response to many agonists, particularly ADP[213,214]. In vivo ticlopidine prolongs bleeding time in man and laboratory animals, causes red cell deformability and reduces blood viscosity. Ticlopidine has been used clinically to examine long-term drug effects in patients with chronic glomerular disease including focal glomerulosclerosis, membranous nephropathy and membranoproliferative and diffuse proliferative nephritis[215]. In such patients, proteinuria was reduced, platelet count improved and circulatory levels of β-thromboglobulin and PF4 decreased.

Although the findings in experimental animals provide a rationale for the use of ticlopidine in progressive glomerular diseases, the lack of controlled clinical trials makes it impossible to draw any conclusion about its efficacy. Moreover, caution in the use of this drug should be exercised because of the possibility of the induction of hemolytic uremic syndrome/thrombotic thrombocytopenic purpura, as a rare collateral effect[216–220].

The effect of certain foods, such as fish oil, on platelet function must be considered. Fish oil contains omega-3 fatty acids that act by reducing the platelet content of arachidonic acid and by competing with arachidonic acid for cyclooxygenase[221,222]. Since the first report of beneficial effects of fish oil therapy on IgA nephropathy[223] several controlled trials have been reported with rather inconsistent findings[223–228]. However, the largest prospective controlled study reported to date, from the Mayo Clinic, did demonstrate a positive effect of fish oil therapy[227]. By the end of treatment, 5% of treated patients versus 33% of the placebo group reached an increase of serum creatinine of at least 50%. There was no beneficial effect observed in urinary protein excretion. Because of its safety, fish oil therapy is an attractive approach for combination with other regimens.

A variety of therapies that inhibit platelet function have been shown to be effective in glomerular diseases despite the non-specific nature of their actions. Identification of specific platelet inhibitors or target interventions to specific platelet pathways, will be crucial for understanding the exact role of platelets and their products in glomerular diseases.
