Platelets and allergic diseases

Simon Pitchford and Clive P. Page

Sackler Institute of Pulmonary Pharmacology, GKT School of Biomedical Sciences, Guy's Campus, King's College London, UK

Introduction

Irrefutable clinical evidence exists demonstrating the involvement of platelets in allergic diseases, including asthma, allergic rhinitis and eczema. Experimental models of allergic disease suggest that platelets may play a fundamental role in the pathogenesis of the inflammatory response that follows exposure to allergens. Of importance are the observations that, despite being anucleate, platelets share many characteristics of inflammatory cells and, of particular interest in allergy, undergo chemotaxis, express adhesion molecules, release a wide variety of proinflammatory mediators, enzymes, cationic proteins, and themselves become activated by mediators released by other cell types involved in inflammation.

Clinical evidence of platelet involvement in allergic diseases

Numerous studies have revealed an alteration in the character and function of platelets from patients with allergic diseases, and these alterations may be dissociated from the well-characterized involvement of platelets in thrombosis and hemostasis[1–7], illustrating a dichotomy in platelet fu[illegible]

platelet activation in vivo, whilst platelets from the same allergic patients are found to be refractory to a variety of stimuli ex vivo, a phenomenon possibly resulting from platelet 'exhaustion', where platelets are over stimulated in vivo and subsequently respond poorly to stimuli in vitro[8,9]. In support of this concept, platelet aggregation has been observed to be abnormal in asthmatic patients. The ability of proaggregatory mediators such as noradrenaline and adenosine diphosphate (ADP) to induce aggregation is seen to be impaired, with no second phase aggregation, an occurrence that has also been correlated with increased serum immunoglobulin E (IgE) in asthmatic patients[10,11]. It is also accompanied by a defective release of 5-hydroxytryptamine (5-HT) and platelet factor-4 (PF4)[10]. In vitro data investigating platelet function from atopic patients suffering from allergy to food, eczema, asthma or allergic rhinitis showed 5-HT uptake into platelets was slower compared to non-atopics. The release of 5-HT from washed platelets after stimulation with aggregated IgG was also significantly lower in the atopic groups[12], even though serum from asthmatic patients has been found to contain higher levels of 5-HT and its metabolites[13], thus raising the possibility of platelet desensitization due to chronic in vivo activation. The antidepressant drug tianeptine, a drug capable of reducing the levels of free 5-HT in plasma, via the enhancement of 5-HT uptake by platelets, resulted in a reduction in clinical severity of asthmatic indices in asthmatic patients, accompanied by an improvement in pulmonary function[14]. Other abnormalities of platelet function observed in vitro include a decrease in arachidonic acid metabolism in washed platelets from atopic subjects, although an increase in lipoxygenase products has been observed[15,16]. Platelet-activating factor (PAF) levels have been observed to rise during periods of acute asthma attacks. However, platelets from these patients [illegible] vitro[17]. Other investigations have suggested that intracellular second messenger systems are altered in platelets from atopic patients. Phosphatidyl inositol (PI) turnover and the formation of inositol triphosphate (IP_{145}) and intracellular Ca^{2+} $[Ca^{2+}]_i$ are found to be greater than basal levels, and are also heightened after in vitro exposure to PAF[18], providing evidence of increased in vivo stimulation.

These traits are accompanied by a prolonged bleeding time, increased platelet mass, an altered sensitivity to PAF of platelets isolated from patients with asthma and hay

Cambridge Books Online © Cambridge University Press, 2009

fever, and an increase in platelet volume[16,19]. Observations have also been made of decreased platelet survival time in stable atopic asthmatics, perhaps as a result of chronic platelet activation[20]. These phenomena can be corrected by treatment of patients with glucocorticoids[21] or with platelets treated with disodium chromoglycate in vitro before reinfusion[22]. Large numbers of pulmonary megakaryocytes (precursors to platelets) have been noted in the lungs obtained at autopsy from patients who have died from *status asthmaticus*[23,24], an occurrence that is accompanied with bone marrow karyopoiesis and thrombopoiesis[23]. This is perhaps the result of localized platelet recruitment and activation within lungs[25], since circulating venous platelet numbers have been shown to drop during an early phase response to allergen[26,27]. Circulating platelet aggregates have also been detected in patients with spontaneous asthma attacks[1,3]. Platelets have been observed to accumulate in the microvasculature of lungs from atopic asthmatics[28], and platelets[29,30] and platelet products[31], have been detected in the bronchoalveolar lavage (BAL) fluid, and attached to the lumenal side of the epithelium in patients with late onset airways obstruction. Platelets have also been observed to undergo diapedesis in sections of lung from asthmatic patients[32]. The close association of platelets with eosinophils in BAL fluid[29] has led to the hypothesis that activated platelets may enhance leukocyte migration across endothelium (see below), since it is apparent that platelets carry glycohydrolases in their liposomes, capable of degrading glycoproteins, glycolipids and glycosaminoglycans on cell membranes[33], and thus may facilitate transmigration. Altered platelet function has been shown to be associated with bronchial hyper-responsiveness occurring in nocturnal asthma, where a reduction in the aggregatory response to collagen and PAF was accompanied by lower levels of intraplatelet β-thromboglobulin (β-TG), a platelet specific protein, in a time-dependent phenomenon that occurred concomitantly with a corresponding maximal reduction in peak expiratory flow and a maximal increase in bronchial hyper-responsiveness to methacholine[34].

Raised levels of mediators peculiar to platelets are observed in atopic individuals compared to normal individuals during allergen exposure. The release of platelet specific granular products such as β-TG, and platelet factor 4 (PF4) are increased during symptomatic periods of asthma[35], and are observed in plasma and BAL fluid of atopic subjects[31,36], and platelets become activated after allergen provocation, as measured by thromboxane (TXA_2) production[37]. Other mediators common to platelets have been observed in atopic patients: PAF levels, as measured by the precursor and metabolite lyso-PAF, are significantly increased in patients suffering a late asthmatic response, when compared to the immediate response[38,39]. Nedocromil sodium, a drug used in the treatment of asthma, has been shown to inhibit platelet activation induced by PAF in ex vivo studies[40]. This rise in PAF levels may be related to a deficiency in PAF acetylhydrolase, an enzyme that inactivates PAF, in children studied with moderate or severe asthma[41]. The increased release of 'regulated upon activation, normally T-cell expressed and secreted' (RANTES), CD62P (P-selectin) expression and an increase in intracellular free calcium concentration $[Ca^{2+}]_i$ is observed in platelets from asthmatics after thromboxane stimulation[42,43], and the release of these products has been correlated to a rise in β-TG levels in vivo[43]. The increased presence of these mediators has been shown to be suppressed by oral administration of theophylline[42], which may contribute to the efficacy of theophylline in the treatment of asthmatics.

The role of IgE on platelet function in allergies

Production of antigen-specific IgE in response to allergen provocation is a fundamental hallmark of atopic diseases[44,45]. The cross-linking of IgE by antigen is believed to provide the stimulus for mast cell degranulation in early phase reactions, an event that precipitates a cascade of inflammatory events in response to allergen[24,46,47]. Compelling evidence reveals that platelets are also activated via IgE, perhaps initiating an important pathway to platelet activation, independent of mediator release from other inflammatory cells. Patients allergic to *Dermatophagoides pteronyssinus* have been exposed to synthetic peptides derived from the allergen Der p1, and were shown to have specifically activated platelets. This was a process mediated by IgE, that did not stimulate platelets from healthy subjects or non-Der p1 allergic patients, illustrating the selectivity of how platelets respond to a specific allergen stimulus[48]. Similarly, platelets bearing IgE were found to be activated only via specific antigens in IgE dependent killing of *Schistosoma mansoni*[49]. The involvement of platelets in IgE-mediated responses may well represent inappropriate actions of platelets commonly displayed in IgE-mediated immunity against helminth and protozoan parasitic infections[50,51], processes that can be inhibited by T-cell products[49].

Between 20 and 30% of platelets from normal individuals bind IgE, this binding affinity rising up to 50% from patients with allergies[10,52]. Platelets from atopic individuals are characterized by a much greater IgE content compared to non-atopics, and this correlates to the levels of IgE in serum from atopic patients, the stimulation of whose platelets resulted

Cambridge Books Online © Cambridge University Press, 2009

in the release of 65% of stored IgE by PAF stimulation but not by platelet mediators, thrombin and ADP[53]. IgE appears to be stored in platelet α-granules[53]. This is through a specific directional uptake mechanism under the control of intracellular IgE receptors[54,55]. Platelets contain both the high (10^{-9}M) and low affinity (10^{-7}M) receptors for IgE (FcεRI and FcεRII/CD23, respectively) on the surface membrane[50,52,56,57]. However, it is apparent that only low proportions of platelets express both FcεRI and FcεRII simultaneously[58]. The activation of the high affinity receptor on human platelets with monoclonal IgE resulted in the activation of platelets, as demonstrated by platelet cytotoxicity to *Schistomonia mansoni* larvae[58] and the stimulation of platelets via FcεRI has been shown to induce the release of 5-HT and RANTES, demonstrating that platelets may play an important role in the progression of allergic inflammation via IgE-dependent mechanisms[53,57]. Platelets from allergic patients produce free-radical oxygen species in response to IgE stimulation via specific allergens or antibodies[52]. This process of platelet activation could be inhibited by antibodies specific for the low affinity receptor for IgE (fcεRII/CD23)[58], and thus reveals a negative feedback response of platelets to IgE stimulation, governed by the differential up-regulation of IgE receptors. Platelets from asthmatic patients have also been observed to undergo chemotaxis in response to allergen exposure, perhaps via platelet bound, antigen specific IgE[59]. The process of platelet activation by IgE has been demonstrated to be inhibited by drugs used for the treatment of atopic asthma, such as nedocromil sodium and disodium cromoglycate[60,61], resulting in a decrease in the generation of cytotoxic mediators and the inhibition of oxidative metabolism[60], as well as increasing the survival time of platelets from asthmatic patients and increasing monoamine uptake, a process inhibited by IgE[22,62], whilst the inhibition of eosinophil chemotaxis by cetirizine (an H_1 receptor antagonist used in the treatment of allergies) may be linked to the inhibition of IgE dependent platelet activation[63]. Recent evidence has highlighted the possible stimulation of the collagen receptor (GPVI), via mechanisms similar to IgE receptor activation[56], since it is also a member of the Ig superfamily of proteins being associated with the Fc receptor γ chain which can be activated upon cross-linking of antibodies[64,65]. However, observed aggregation of platelets via IgE cross-linking may be the result of platelets self-adhering to each other via P-selectin, since stimulation up-regulates expression in asthmatic individuals[42], and platelets also contain the counter ligand (see below), because it is known that aggregation, as observed in thrombotic events, occurs via different mechanisms to that which stimulates platelet activation in asthmatic patients[11].

Experimental evidence for the role of platelets in animal models of allergy

Experimental animal models have been utilized to better understand the role played by platelets in allergic inflammation. Research in vivo has emphasized the intimate nature in which platelets cooperate with other inflammatory cells, due to the perception that the pathogenesis of atopic asthma is driven by an acquired inflammatory response to allergen via IgE dependent processes, resulting in eosinophil infiltration to the lung and damaged epithelium. Asthma is characterized clinically by hyper-responsiveness of airway smooth muscle in vivo to various spasmogens and, chronically, an accelerated decline in lung function, accompanied by airway wall obstruction and tissue remodelling, which may be the consequence of a cycle of damage and inappropriate repair mechanisms. Evidence now suggests that platelets are recruited to the lung after exposure to allergen and may therefore participate in these various processes, as well as interacting with other effector cells driving the pathogenesis of asthma.

Platelets were first observed to undergo diapedesis into the extravascular tissue of guinea pig lungs following antigen sensitisation, an effect that could be mimicked by exposure to PAF[66]. In particular, platelets were found in close proximity to areas of bronchial smooth muscle and eosinophil infiltration. The actions of PAF were found to be selective since other platelet agonists such as ADP that are capable of inducing platelet activation within the pulmonary vasculature did not induce the diapedesis of eosinophils, suggesting a cohesive link between the two cell types, which is unrelated to stimuli that cause aggregation[66]. Platelets have also been reported in the BAL fluid of allergic rabbits undergoing late onset airways obstruction following antigen challenge[29]. Recent evidence has suggested that platelets may be selectively recruited to sites of inflammation, being targets for certain chemokines, after reports that the chemokine, stromal cell-derived factor-1 (SDF-1), and macrophage-derived chemokine (MDC) activate platelets[67,68] via their receptors CXCR4 and CCR4 respectively. Intravenous administration of PAF and other platelet agonists into guinea pigs also induced bronchospasm, and was associated with an accumulation of platelets in the lung[69–74]. The depletion of platelets in similar models resulted in the abolition of the acute bronchoconstriction to inhaled allergen[75], and has been shown to protect against anaphylaxis in allergic rabbits[71]. The inhibition of bronchoactive agents released by platelets has also been reported to abrogate the resulting bronchospasm in such models[76–78]. Platelets therefore have the

Cambridge Books Online © Cambridge University Press, 2009

capacity, either solely or by interacting with other cell types, to critically affect certain parameters of asthma (see Fig. 56.2).

Platelet derived mediators involved in asthma

Platelets contain a plethora of inflammatory mediators released during allergic responses: preformed mediators, either stored in dense (ADP, ATP, 5-HT, Ca^{2+}) and α granules, containing mediators synthesized by megakaryocytes (e.g. PF4, PDGF) or sequestered in the circulation (e.g. IgE) or lysosomes, which contain matrix metalloproteinases capable of degrading structural tissue, and also the *de novo* production of arachidonic acid metabolites. 5-HT is a vasoconstrictor and increases vascular permeability during inflammatory events[79]. 5-HT has also been shown to induce fibroblast proliferation and thus may contribute to the phenomenon of airway remodelling[80], since drug induced 5-HT uptake by platelets has been shown to reduce the clinical severity in asthmatic patients[14]. Adenosine, also released from dense granules, has been shown to act as a bronchoconstrictor[81]. Platelets are capable of synthesizing and releasing histamine[82,83], which enhances platelet aggregation[84], and is also released during aggregation in vivo[83]. Human platelets may also induce the release of histamine from mast cells and basophils through IgE dependent mechanisms, as well as through thrombin, PAF, and collagen activation, resulting in bronchoconstriction[85,86]. This process is via the release of platelet derived histamine releasing factor (PDHRF), which is also a powerful eosinophil chemoattractant, causing early and late phase airway obstruction and the induction of airways hyper-responsiveness in an allergic rabbit model[87]. Free radical production by platelets may contribute to tissue damage directly[88]. Platelets that release free radicals do not aggregate, and platelet aggregation itself inhibits free radical production[88]. Platelets contain cationic proteins, which enhance vascular permeability to leukocytes[89]. Cationic proteins are also capable of cleaving the fifth component of complement to produce C5a, a chemoattractant to leukocytes[90]. Cationic proteins have also been observed to contribute to tissue damage directly[91]. Of particular interest is the platelet-specific cationic protein PF4, a mediator shown to induce the upregulation of IgG and IgE receptors on eosinophils[92], and stimulates basophils to release histamine[93]. PF4 also acts as a chemokine towards neutrophils, monocytes, fibroblasts, and eosinophils[94] and can activate eosinophils, thus indirectly contributing to the induction of tissue damage and ensuing hyper-responsiveness associated with eosinophil activation[91,95–100]. PF4 has been shown to augment eosinophil adhesion to plates coated with plasma or recombinant soluble intracellular adhesion molecule-1 (rsICAM-1)[101], perhaps via the up-regulation of adhesion molecule expression (leukocyte functional antigen: LFA-1α and LFA-1β) on eosinophils[101], and thus, may be an important mechanism by which PF4 induces hyper-responsiveness to inhaled methacholine in rats, via eosinophil chemoattraction[102]. PF4 is able to reverse immunosuppression by lymphoma cells in mice[103–105]. This was independent of the ability of PF4 to bind to heparin[106], an agent known for its antiproliferative actions[107,108], raising the possibility that platelets are capable of stimulating T-helper 2 lymphocyte proliferation, a T-cell subset believed to orchestrate the inflammatory reaction to allergens.

Other mediators released from the α-granules of platelets have also been shown to induce leukocyte chemotaxis. The stimulation of human platelets with thrombin or via IgE results in the release of RANTES[53,109,110], a mediator that has been shown to be released in asthma[43]. RANTES was demonstrated to act as a chemoattractant towards monocytes and T-lymphocytes[111], and is a potent chemokine for eosinophils[109,112]. RANTES opens Ca^{2+} activated K^{+} channels in eosinophils[113], and may be a mechanism by which eosinophils become activated via chemokine activation, the outcome of which may include the augmentation of eosinophil oxygen free radical production[114].

Other substances released by platelets in allergic reactions are those of arachidonic acid and phospholipid metabolism, produced *de novo* upon activation by a wide variety of inflammatory stimuli[115], the importance of which is illustrated in aspirin sensitive asthma (see below). TXA_2 is a potent vasoconstrictor and smooth muscle spasmogen[116], and platelets interact with macrophages and eosinophils in a co-operative manner, enhancing TXA_2 synthesis[117]. Other arachidonic acid metabolites include the prostaglandins. $PGF_{2\alpha}$ induces platelet aggregation, and has vasoconstrictor properties, whilst PGE_2 acts as a vasodilator and can induce pain[116]. PGE_2 has recently been shown to act as an immunomodulator, with the ability to prime naïve T-cells into producing high levels of T-helper (Th) 2 cytokine expression, cytokines believed to be important in inducing eosinophil recruitment to allergic airways[118]. This action of PGE_2 may be through the inhibition of IL-12 responses (a cytokine that is pivotal in driving the immune system to a Th1 response)[119]. Hydroxyeicosatetraenoic acid (12-HETE) is produced by a platelet specific enzyme (12-lipoxygenase) and has chemotactic activity for eosinophils[120,121]. 12-HETE is also taken up by neutrophils to produce 12, 20-diHETE, a

Cambridge Books Online © Cambridge University Press, 2009

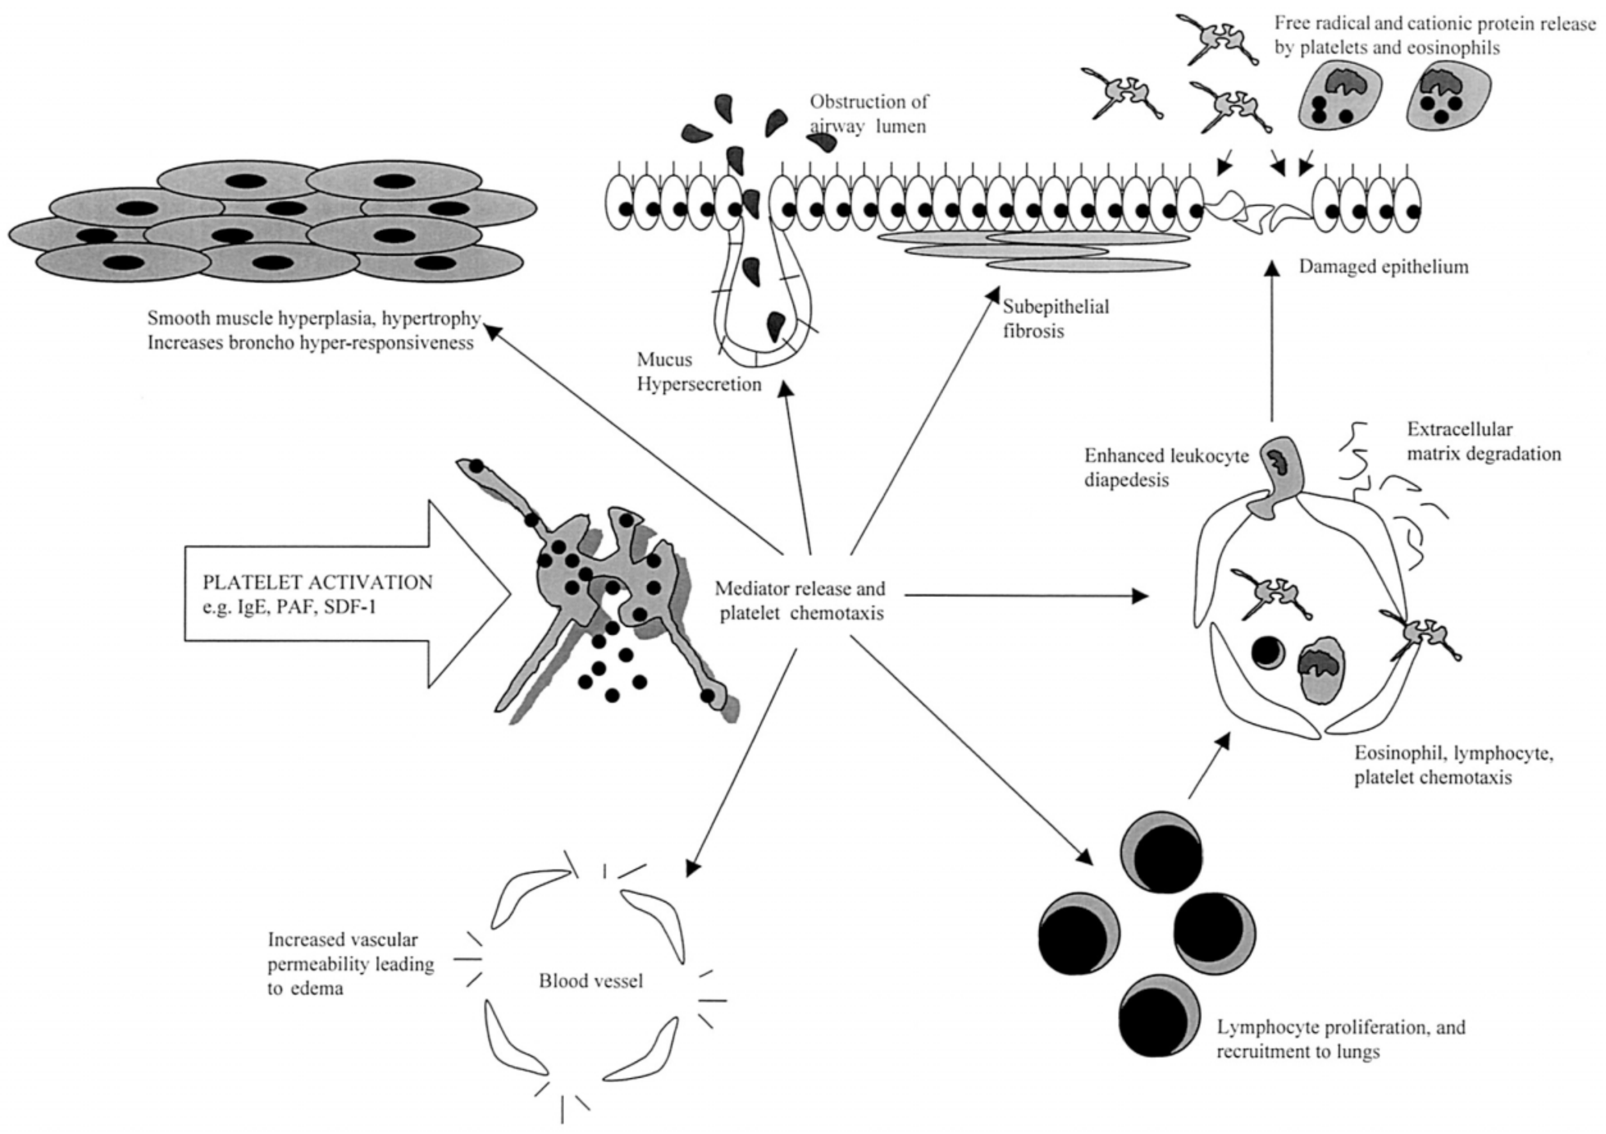

Fig. 56.2. Effects of platelets on cell activation in asthma.

Cambridge Books Online © Cambridge University Press, 2009

chemoattractant that neutrophils are unable to produce in isolation and require activated platelets[121–123]. 12-HETE also stimulates leukocyte 5-lipoxygenase and thus increases leukotriene production[124]. The leukotrienes comprise of cysteinyl leukotrienes (LTC_4, LTD_4, and LTE_4) and LTB_4. Cysteinyl leukotrienes are potent inflammatory mediators, inducing bronchospasm, mucus hypersecretion, and increased vascular permeability[125–127], and also increase hyper-responsiveness in asthmatics[128]. LTC_4 and LTD_4 induce eosinophil infiltration into the lungs of guinea-pigs and humans[129,130], whilst LTB_4 acts as a non-specific chemoattractant[131]. Platelets and neutrophils have been shown to cooperate in a synergistic manner with regards to arachidonic acid metabolism. Arachidonic acid from platelets is sequestered by neutrophils with the resulting synthesis of 5-HETE and leukotriene B_4 (LTB_4)[132]. PAF may also enhance LTB_4 production by neutrophils[133]. LTA_4 produced by leukocytes may be converted to LTC_4 by platelets via glutathione-s-transferase via intimate contact between the two cell types[126]. This phenomenon may occur by PMN cells activating platelets via cathepsin-G release, resulting in the expression of P-selectin on platelets[134].

PAF, another phospholipid derived mediator often generated along with arachidonic acid metabolites, is now known to be produced *de novo* by a number of inflammatory cells including platelets via the activation of phospholipase A_2[135]. Many actions of PAF have since been uncovered which are of relevance to allergic inflammation. Guinea pig trachea from animals exposed to aerosolised PAF have been shown to depolarize to a greater extent to histamine than controls, and animals receiving PAF also had eosinophil infiltration into the submucosa[136]. PAF administration has also been shown to induce platelet accumulation into the lungs of baboons and guinea pigs[66,137,138], culminating in the extravasation of platelets into close proximity to areas rich in airway smooth muscle[66], and platelet depletion inhibited PAF induced hyper-responsiveness in rabbits[139]. This phenomenon has been associated with an increase in lung resistance and therefore the changes in lung mechanics may be attributable to platelet activation alone[74], since animals depleted of platelets have a reduction in hyper-responsiveness and eosinophilia[75,140]. The release of substances such as platelet-derived hyper-responsiveness factor (PDHF), after stimulation by PAF may contribute to these effects[141]. PAF is also capable of inducing leukocyte recruitment, perhaps via the ability to induce surface expression of adhesion molecules on eosinophils[101], and the transmigration of eosinophils through artificial membranes has uncovered an important synergistic relationship of PAF and eosinophil stimulating cytokines such as interleukin-5 (IL-5)[142]. Several studies have highlighted the effects of PAF on inflammatory cell product release. The generation of superoxide anion products by formylmethionylleucylphenylalanine (fMLP) stimulated eosinophils is enhanced by preincubation with low concentrations of PAF[143].

Early studies with PAF antagonists in human asthmatics were shown to have no effect on the early or late response to inhaled allergen, or subsequently on airway hyper-responsiveness[144,145]. However, recent evidence suggests other PAF antagonists have activity in asthmatics[146,147], raising the possibility that PAF does play a role in asthma under some circumstances.

Effects of platelets on airway remodelling in asthma

Airway wall thickening, brought about by smooth muscle hypertrophy/hyperplasia, along with subepithelial fibrosis is a common feature in the asthmatic lung, contributing to decline in lung function and increased hyper-responsiveness. Platelets release a number of mitogens that may contribute to bronchial smooth muscle growth and myofibroblast proliferation after continuous platelet activation, since it has been shown that platelets control smooth muscle proliferation in atherosclerosis and restenosis[148]. This is perhaps through the release of chemotactic factors for structural cells, since a platelet-derived factor was found to be chemotactic for rabbit arterial smooth muscle cells in culture[149,150]. Intimal proliferation of smooth muscle, occurring after endothelial injury, has been shown to be preceded by platelet adhesion to the subendothelium[151]. Platelet-derived growth factor (PDGF) has since been shown to affect human, rat, and rabbit tracheal smooth muscle mitogenesis, acting as a potent mitogen for airway smooth muscle cells in culture[152,153], and acts as a potent chemoattractant for fibroblasts[154], as well as monocytes and neutrophils[155]. Recently, PGDF overexpression was observed, along with airway smooth muscle thickening in mice repeatedly exposed to allergen[156]. Transforming growth factor-β (TGFβ), also released by platelets has also been shown to increase smooth muscle cell mitogenesis in culture[157,158], and may contribute to subepithelial fibrosis[159] via its chemotactic properties for fibroblasts and neutrophils[160]. These findings support the hypothesis that platelets are crucial in the induction of chronic airway remodelling in asthmatics due to the granular storage of PDGF and other growth factors released during inflammation.

Cambridge Books Online © Cambridge University Press, 2009

Platelet involvement in leukocyte adherence to endothelium

Platelets, along with eosinophils and monocytes, have been observed attached to the vascular endothelium of asthmatics, an event that was accompanied by extensive inflammatory changes to the airways[28]. A more intimate association between platelets and other inflammatory cells has since been demonstrated by an increase in the number of platelet–leukocyte aggregates during the late asthmatic response[161], an event that correlates with increased platelet activation (see Fig. 56.3). The adhesive events between platelets and leukocytes may be induced by the up-regulation of the adhesion molecule: platelet-selectin (P-selectin), a sialyl Lewis^x tetrasaccharide found on myeloid cells, thus making it possible that leukocytes could adhere to platelets (and endothelium) which carry the P-selectin ligand[162]. P-selectin is stored in the α-granules of platelets and is released to the surface upon activation[163]. Activated platelets have been demonstrated to bind monocytes, PMN cells, eosinophils, basophils and a subpopulation of CD4$^+$ and CD8$^+$ T cells[164,165]. This interaction is dependent on divalent cations, and is completely inhibited by monoclonal antibodies to P-selectin. It has subsequently been shown that circulating activated platelets are capable of reconstituting lymphocyte homing on endothelium in L-selectin deficient mice[166]. P-selectin is also critical in eosinophil recruitment, because it has been demonstrated as the common factor in several selectin combinations for eosinophil attachment to the endothelium[167]. P-selectin deficient mice had no obvious defects in hemostasis, suggesting that P-selectin is only expressed on platelets during inflammatory events[168]. However, in an allergic model of inflammation, mice deficient in P-selectin were shown to have a reduction in eosinophil and lymphocyte accumulation to the lungs, accompanied by a reduction in airways hyper-responsiveness and IL-4 and EPO levels[169]. Furthermore, activated platelets, through P-selectin/sialyl Lewis^x interactions, were shown to be able to induce superoxide anion production in monocytes and neutrophils[170]. Activated platelets are also able to adhere to unstimulated PMN leukocytes, a process involving a P-selectin dependent recognition step and a functional signal that did not require PMN cell activation, thus platelets might directly induce a change in leukocyte activation status[171], via a process dependent on platelet P-selectin recognizing the counter ligand PSGL-1 on PMN cells[172]. Platelet PMN leukocyte interaction in dynamic conditions has also been shown to be dependent on P-selectin interactions with PMN cells resulting in the up-regulation of β_2 integrin CD11b/CD18 on leukocytes[171]. The expression of CD11b/CD18 has subsequently been shown to be most marked in neutrophil populations complexed to platelets[173]. These leukocyte–platelet complexes are found to be the most adhesive cells (respective to their type) in the circulation[174]. P-selectin bound to antigen primed CD4$^+$ T-cells was able to differentially modulate the production of proinflammatory cytokines[175], and thus may facilitate T-cell activation via an interaction with activated platelets. Activated platelets have since been shown to bind to circulating lymphocytes and mediate rolling in high endothelial venules through this interaction with P-selectin and peripheral node addressin, and P-selectin expression on platelets but not endothelial cells was responsible for leukocyte rolling along endothelium[176]. Platelets have also been observed to roll on stimulated endothelium in vivo in a manner similar to leukocyte rolling, being dependent on endothelial, but not on platelet P-selectin[177]. However, mice deficient in P-selectin exhibited virtually no leukocyte rolling in mesenteric venules[168]. Subsequent findings have shown that both human and murine platelets also express PSGL-1, the counter ligand for P-selectin[178], the blocking of which with anti-PSGL-1 antibodies reduced platelet rolling in mesenteric venules[178]. Thus, leukocyte rolling may be enhanced through platelet rosetting around the leukocyte, with subsequent platelet tethering to the endothelial surface, resulting in leukocyte attachment via platelet rosettes. Direct observation of membrane tethering between neutrophils and platelets has been shown under physiological flow conditions[179]. The tethering between spread platelets and free flowing neutrophils was abolished by antibodies to P-selectin and PSGL-1[179]. Platelet rosetting around leukocytes with subsequent attachment and transmigration across endothelium may be a critical process that is further enhanced by the release of platelet lysosomal enzymes degrading glycolipids attached to cell membranes[33], facilitating the movement of leukocytes across the tissue.

Within lysosomes, platelets contain a number of enzymes, termed matrix metalloproteinases[180,181] which are released when platelets become activated[33], and increased levels of which have been observed in the BAL fluid of allergen-challenged subjects[182], and ozone-challenged guinea pigs[183]. These are believed to disrupt the composition and integrity of cell membranes by degrading glycoproteins, glycolipids and glycosaminoglycans. The outcome of this is thought to induce the diapedesis and extravasation of leukocytes, as well as to release membrane-bound growth factors for wound repair[184]. Platelets contain a number of β-hexosaminidases[33], which have been shown to have a mitogenic effect on airway smooth muscle proliferation[185,186]. The implications of

Cambridge Books Online © Cambridge University Press, 2009

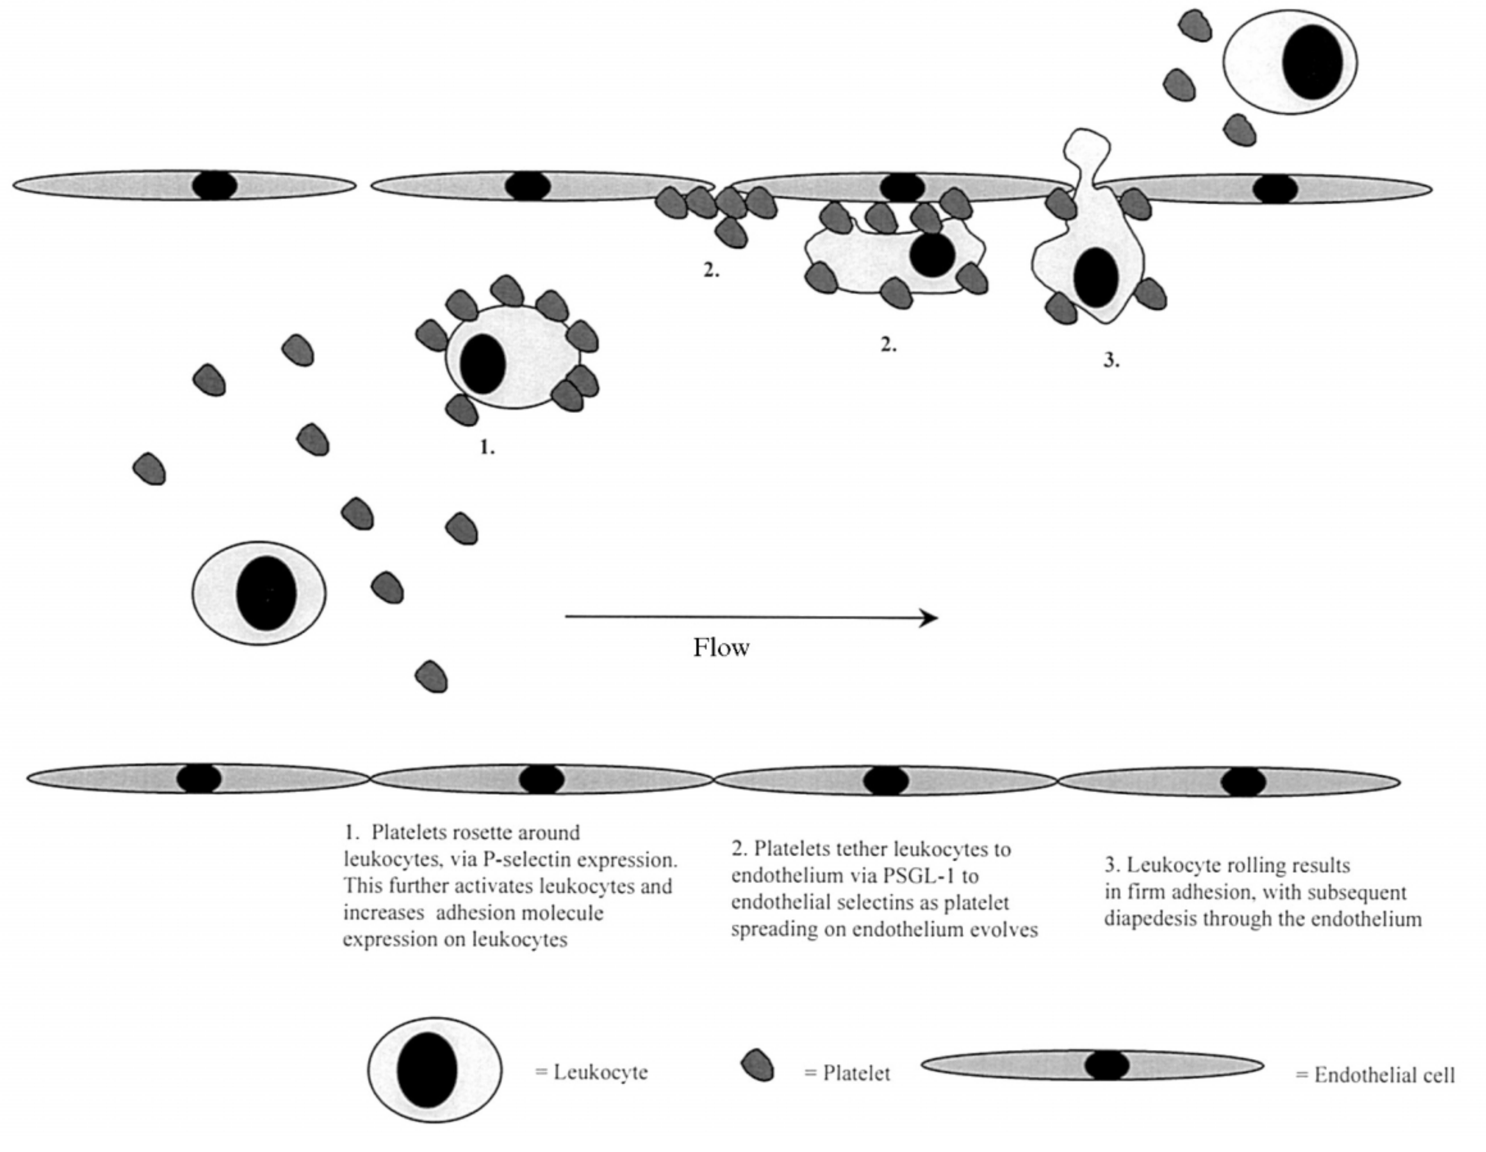

Fig. 56.3. Enhanced leukocyte recruitment via platelet tethering.

these actions are profound in the progression of asthma as they may facilitate inflammatory cell extravasation and stimulate tissue remodelling.

The role of platelets in aspirin and NSAID sensitive asthma

Further evidence of platelet involvement in asthma is provided by the growing body of evidence demonstrating that platelets are critically involved in the condition of aspirin induced asthma. Aspirin-induced asthma affects about 10% of adult asthmatics, and is based upon an individual's intolerance to aspirin and other related non-steroidal anti-inflammatory drugs (NSAIDs), due to the pharmacological action of the drug rather than the NSAID inducing an antigen–antibody reaction *per se*. This is demonstrated by the serum of aspirin-sensitive atopic patients being unable to passively sensitise platelets from healthy controls to NSAIDs[187], and the fact that no antibody for NSAIDs has ever been detected.

The phenomenon of aspirin-induced asthma is now thought, in part, to be related to an abnormal response of platelets from such individuals to NSAIDs. Heightened platelet responsiveness to aspirin is recorded in these individuals, this being reduced dramatically after the inhalation of nedocromil sodium[188], a drug that is of clinical benefit in the treatment of aspirin-sensitive asthmatic patients. It has been suggested that the irreversible inhibition of cyclooxygenase (COX) leads to the shunting of arachidonic acid metabolism via the lipooxygenase pathways to increase the production of leukotrienes by platelets[189], especially since leukotriene levels may be enhanced by overproduction of 12-HPETE[124], and the consequences of removing the inhibitory effects of prostaglandins[190]. A decrease in PGE_1, PGE_2, $PGF_{2\alpha}$, and TXB_2 is noted in asthma-sensitive patients[191], whilst higher levels of LTC_4 in nasal secretions and altered levels of LTE_4 have been observed[192]. Lipooxygenase inhibitors are able to prevent the abnormal response of platelets to NSAIDs in vitro[193], and recent clinical studies suggest that such patients respond well clinically to treatment with leukotriene receptor antagonists[194]. However, it is not clear why only a proportion of asthmatic subjects exhibit such an abnormal sensitivity to NSAIDs, and some investigators have reported that aspirin can increase the levels of $PGF_{2\alpha}$, (a bronchoconstrictor) from platelet suspensions obtained from subjects with aspirin-induced asthma, possibly via the displacement of protein-bound $PGF_{2\alpha}$[195], although no changes in β-TG and PGE_2 levels had been observed in this study.

Aspirin-induced asthma has also been linked to the actions of platelet specific glutathione peroxidase activity in such individuals[196]. Glutathione is a tripeptide, playing a key role in detoxification, by reacting with reactive oxygen species, through glutathione peroxidase, an enzyme that has a covalently linked selenium atom at the active site[197]. Serum selenium levels are lower in aspirin-tolerant asthmatics compared to aspirin intolerant asthmatics, and is believed to alter the activity of glutathione peroxidase in this group[196]. Aspirin induces an increase in oxygen-free radical production in aspirin-intolerant asthmatic platelets, although no differences in glutathione peroxidase levels were found between patient groups[198]. The increased production of reactive oxygen species may contribute to the pathogenesis of asthma by causing epithelial damage, leading to an increase in bronchial hyper-responsiveness; since glutathione acts as an antioxidant, and has been recognized as being important in preventing oxidative damage in mice and rats[199,200], and recent evidence has suggested that paracetamol, a drug known to deplete glutathione levels in the lung, increased the clinical severity of asthma, with the incidence of asthma attacks correlating with the frequency of paracetamol usage[201].

Conclusion

A clear dichotomy exists in platelet function, with an inflammatory activity clearly distinguishable from the processes observed during thrombosis and hemostasis. It is now very clear that platelets possess a formidable array of machinery that allows them to play an active role in primary defence mechanisms involving IgE-dependent cytotoxicity to parasites. Allergic insults appear to inappropriately activate these mechanisms by which platelets subsequently contribute to leukocyte infiltration and destruction of the airway architecture leading to a decline in lung function and heightened bronchial responsiveness observed in asthma. There are thus novel possibilities by which the pathogenesis of allergic inflammation can be better understood and perhaps influenced to a greater and better degree than current therapies allow.

Platelet interactions with other cells related to inflammatory diseases

Patrice E. Poubelle and Pierre Borgeat

From the Centre de Recherche en Rhumatologie et Immunologie, Centre de Recherche du CHUQ and Faculté de Médecine, Université Laval, Quebec, Canada

Introduction

Many inflammatory disorders are clinically associated with high blood platelet counts[1–5]. Unlike in primary thrombocytosis where both arterial and venous complications are present[6,7], these reactive or secondary thrombocytoses are mainly asymptomatic. However, when a secondary thrombocytosis is associated with other risk factors, thromboembolic events can occur in the venous system[7]. Interestingly, thrombocytosis observed in inflammatory diseases is associated with elevated serum levels of inflammatory mediators such as interleukin-6[8,9] or P-selectin[10] as opposed to increased blood thrombopoietin in primary thrombocytosis[11]; in addition, platelets from patients with primary thrombocytosis exhibit a decreased 12-lipoxygenase activity[12]. The clinical impact and the significance of such reactive thrombocytosis, most of the time neglected because it is asymptomatic, remain hypothetical. During chronic inflammatory disorders such as rheumatoid arthritis, thrombocytosis is a hallmark of disease activity[13]. Thrombocytosis has also been associated with a poor prognosis of cervical cancer; this was, however, considered as an indirect indicator and no correlation between platelets and tumour growth was noted[14]. On the other hand, thrombocytosis has been reported in progressive systemic sclerosis[1,15], during which Raynaud's phenomenon is an interesting example of a symptom where platelets are implicated through their activation and interaction with other cells such as endothelial cells. Besides the structural narrowing of digital arteries seen in systemic sclerosis[16], the pathogenesis of Raynaud's phenomenon is, at least in part, related to endothelial injury causing platelet activation (release of vasoconstrictive mediators such as thromboxane A_2, serotonin, ADP) and platelet adhesion to the endothelium[15]. Interactions between platelets and endothelial cells have also been implicated in the pathogenesis of hypertrophic osteoarthropathy where the digital clubbing may be due to the release of fibroblast growth factors by large platelets in distal sites[17–19]. Although platelets and their interactions with other cells are mainly reported to enhance the inflammatory process, one has to keep in mind that platelets are also involved in homeostasis of the vasculature and possibly in the down-regulation of tissue inflammation. Hence, secondary thrombocytosis may be contributing to this control. Indirect evidence of such a role has been reported in in vitro experiments with platelets from healthy subjects which exhibited decreased in vitro production of superoxide anion[20] or LTB_4[21] by ionophore A23187-stimulated neutrophils from uremic or allergic patients, respectively. In the same experiments, platelets from uremic or allergic patients did not show a similar inhibitory activity[20,21]. In vitro experiments also demonstrated that interactions between platelets and endothelial cells, neutrophils or erythrocytes resulted in an active transcellular metabolism of eicosanoids leading to the formation of new bioactive compounds[22–24]. On the other hand, circulating platelets bind to neutrophils and platelet–neutrophil complexes have been found in blood[25]. Unactivated platelets preferentially bind to resting monocytes as compared to neutrophils, at a ratio of three platelets per monocyte[26]. Such cellular complexes may have pathophysiological relevance since, for example, at rest, 25 to 34% of normal blood neutrophils bind platelets and the percentage reaches 70 to 82% after platelet activation[25,27]. Neutrophils and platelets of such cell complexes constitute a subpopulation of activated cells; neutrophils with rosetted platelets have been shown to express higher levels of CD11b (a marker of cell activation) and lower levels of CD62L (L-selectin), have greater capacity to ingest bacteria, and show higher production of superoxide anion than free neutrophils[28]. Cardiopulmonary bypasses, unstable

angina and acute myocardial infarction are clinical conditions where adhesion of platelets to leukocytes is reportedly increased in blood[29–31]. Moreover, low circulating platelet–neutrophil complexes observed in multiorgan failure is associated with a poor prognosis[32]. Depending on the pathophysiological conditions, platelets may regulate inflammation by inducing or by reducing phlogogenic events of the inflammatory reaction. Although in vitro experiments and animal models allow us to explore the regulatory role of platelets in inflammation and the mechanisms involved in such platelet functions, our knowledge of these potentially important homeostatic mechanisms remains fragmentary. The consequence of platelet interactions with other cells in the initiation of an inflammatory (and thrombogenic) process (see below) and the numerous possibilities of promising therapeutic approaches through the pharmacological control of these cell–cell interactions justify the past and present research efforts in this area. We will attempt here to summarize the present knowledge and concepts on the consequences of such interactions between platelets and other cells implicated in inflammation.

Phlogogenic functions of platelets

To date, inflammation, thrombosis and hemostasis are recognized as complex situations with overlapping steps and connecting pathways. Interactions between platelets and inflammatory cells take place at various stages of the inflammatory process; they occur in the circulation and are also observed at extravascular inflammatory sites. The presence of such granulocytes in close contact with platelets at inflammatory sites has been reported as early as 1967[33,34] and has been confirmed later in various conditions such as in adult respiratory distress syndrome[35], in immune complex disease in rabbits[36] and in atherosclerosis. Activated platelets undergo homologous aggregation and adhere to endothelial cells, leukocytes and erythrocytes. Platelets can interact with other cells directly by adhesion to cells or indirectly by releasing endogenous factors. The understanding of such interactions is complicated by the fragmentation of platelets following their activation and the generation of platelet microparticles possessing biological activities such as the acceleration of blood coagulation[37], and the binding to, and activation of, neutrophils[38]. Blood platelet microparticles are increased in pathological conditions such as immune-mediated thrombocytopenia and cardiopulmonary bypass[39–41]. In adult respiratory distress syndrome platelets are activated in vivo and express GMP-140 (P-selectin) and thrombospondin on their surface, while no platelet microparticles are present in blood[42]. Activated as well as non-activated platelets may bind to monocytes, neutrophils, eosinophils and basophils[26,43,44]. Thrombin-activated platelets also bind subpopulations of T-lymphocytes, such as natural killer cells (50% are rosetted with platelets), $CD4^+$ (20%) and $CD8^+$ (30%) lymphocytes [44]. Note that platelets can roll on the endothelium and are actively involved in lymphocyte homing in immune responses in vivo[45–47]. Thus, intact platelets and platelet microparticles bound to leukocytes may actively participate in the inflammatory process from blood to tissues. During the early events of an inflammatory response, activated platelets as well as platelet microparticles exhibit catalytic phospholipid surfaces, which facilitate the prothrombinase reaction[48,49]. The subsequent local formation of thrombin leads to activation not only of platelets but also of endothelial cells, leukocytes and mesenchymal cells[50]. Thrombin is chemotactic for neutrophils and directly stimulates them to release tissue kallikrein[51]; this procoagulant factor activates the expression of IL-8 and IL-6 by mononuclear cells[52], and IL-8 and E-selectin by HUVECs[53]. Thus, experiments addressing the impact of thrombin in platelet interactions with other cells have to be cautiously interpreted. It is also important to stress that the presence of thrombin during inflammation in vivo has been reported to influence local and systemic reactions. For instance, thrombin or activated protein C infusion protects the experimental animals from the lethal effects of LPS[54,55]. Activation of protein C in vivo by thrombin during inflammation leads, in the presence of protein S[56], to the formation of a natural anticoagulant which is further involved in host defense against infection[55]. These observations again point to the complexity of the inflammatory process implicating a highly sophisticated network of mediators and cells interacting to initially promote the development of inflammation, then to control the local response and finally to restore homeostasis.

Interactions of platelets with cells involved in inflammation

Proinflammatory or phlogogenic activities of platelets are efficient when these anuclear blood cells are activated and/or interact with endothelial cells, leukocytes such as neutrophils or monocytes and erythrocytes. The physiologic goal of an inflammatory response is to remove the foreign agent(s) or substance(s) from injured tissue or organ, to promote repair and to restore local equilibrium. The sustained presence of injurious agents in tissues leads to a chronic inflammatory response with decreased func-

Cambridge Books Online © Cambridge University Press, 2009

tions of the targeted tissue(s) or organ(s). The process of removal of injurious agents during inflammation implicates non-resident cells arising locally from blood. Specialized blood cells exit the microvascular compartment through complex events during which cells are activated and undergo cell–cell interactions. Platelets are among these cells and cross-talks between platelets and other cells, in particular endothelial cells, are a very early event in the inflammatory process.

Platelet interactions with endothelial cells during inflammation

Platelet activation is a prerequisite to their interaction with endothelium. Platelet activation can be achieved in vivo as well as in vitro with various agonists which will induce different levels of platelet reactivity. For instance, thrombin or collagen are potent activators of platelets and cause the release of agents contained in various types of granules[57]. Other agonists such as adenosine diphosphate (ADP) or platelet activation following cardiopulmonary bypasses cause the release of α-granule only[58,59]. α-granules contain, among other substances, fibrinogen (further cleaved to fibrin by thrombin), platelet factor 4 (PF4), β-thromboglobulin, transforming growth factor-β (TGF-β), platelet-derived growth factor (PDGF), and thrombospondin, all mediators of inflammation[60]. These α-granules also contain important adhesion receptors, such as P-selectin (or GMP-40, PADGEM, CD-62) and the glycoprotein IIb/IIIa (GP IIb/IIIa is the receptor for fibrinogen) which, upon platelet activation, are expressed at the level of the plasma membrane, allowing cellular interactions (see below). Platelets certainly have not yet revealed all of their secrets and it must be kept in mind that they remain very unstable anucleate cytoplasmic fragments with vestigial *de novo* protein biosynthesis[61]. Platelets activated by ADP, collagen or thrombin express an IL-1 cell-associated material[62], which causes the expression of ICAM-1 (intercellular adhesion molecule-1), IL-6 and GM-CSF by human endothelial cells[63]. Activated platelets are also able to induce the production of IL-8 by endothelial cells via their membrane-associated IL-1 activity[64]. Subsequent to an injury to the endothelium during inflammation, platelets adhere to components of the subendothelium such as collagen or osteopontin and are thereby activated[65,66]. Such activated platelets have been shown to increase the adherence of granulocytes to endothelial cells in vitro and subsequently to amplify granulocyte-mediated ^{51}Cr release from prelabelled endothelial cells in a mechanism implicating serotonin or its derivatives[67]. Moreover, platelets and neutrophils synergize in enhancing the adherence of neutrophils to endothelial cells in models of myocardial reperfusion injury, an effect involving the expression of platelet P-selectin with subsequent neutrophil activation[68,69]. Platelets directly adhere to the endothelium stimulated by lipopolysaccharides (LPS), TNF-α or IL-1[70] through CD11a-CD54 interactions[71]. Platelet depletion efficiently protects mice against systemic and local reactions induced by injection of LPS, indicating that platelets are directly involved in the vascular lesions and tissue damage. In this model, platelets also actively participate in tissue damage through a concomitant activation of neutrophils[71]. Platelet–endothelial cell interactions in vivo were also characterized in rat mesenteric venules by using intravital microscopy; it was shown that the endotoxin-induced rolling of platelets on endothelium was reduced after GP Ibα immunoneutralization[72]. Platelets are also involved in the initiation of inflammatory responses through the local generation of high concentrations of PF-4. This chemokine, which neither induces chemotaxis of neutrophils nor their random migration[73], has been shown to stimulate neutrophil adhesion to unactivated endothelial cells in vitro and secondary granule exocytosis[74]. Another important interaction of platelets on endothelial cells has been recently underlined by using human platelets activated by thrombin, collagen or ADP plus adrenaline and cultured endothelial cells. Preformed CD40 ligand (CD40L, CD154) in platelets is translocated to the cell surface following platelet activation; moreover, activated platelets directly attached to the endothelium in vivo express CD40L[75], and human endothelial cells express CD40 and are activated upon CD40L–CD40 interactions[76]. Coincubation of activated platelets with endothelial cells leads to the endothelial production of IL-8 and MCP-1, as well as the up-regulation of adhesion molecules (E-selectin, VCAM-1, ICAM-1), and these effects are abrogated by an anti-CD40L antibody[75].

Thus, platelet interactions with endothelial cells in inflammation may occur early in the initiation of the inflammatory process, and could lead to the local formation of proinflammatory cytokines and expression of adhesion molecules. These early events triggered by the adhesion of activated platelets to endothelial cells are likely to contribute to the development of inflammation in its initial phase.

Platelet interactions with neutrophils during inflammation

The inflammatory peptide n-formyl-methionyl-leucyl-phenylalanine (fMLP) triggers the accumulation of neutrophils and platelets at the injection site in rabbits. Neutrophil depletion in this model is associated with

Cambridge Books Online © Cambridge University Press, 2009

reduced accumulation of platelets in the inflammatory sites, indicating that neutrophils are required for local platelet accumulation[77]. Similar platelet–neutrophil interactions resulting in platelet extravasation have also been demonstrated in other in vivo inflammatory conditions such as in immune complex nephritis in rats[78–80], myocardial infarction[31,81,82], cardiopulmonary bypass[29,59], and LPS-associated lesions[71,83]. Numerous in vitro studies have attempted to dissect and characterize platelet–neutrophil interactions in experimental conditions mimicking pathophysiological conditions. The stimulatory activity of platelets on neutrophils was suspected as early as 1972 by Nachman et al., who found that platelets promote the migration of leukocytes into thrombi[84]. This chemotactic activity of platelets towards leukocytes was confirmed by Weksler et al.[85] and the chemoattractant was initially identified as platelet factor 4[86], a finding to be taken cautiously in view of recent reports on the properties of highly purified PF4[73,74]. Platelets have also been shown to increase neutrophil aggregation induced by fMLP[87]. Shear-induced microaggregates of neutrophils, which have been demonstrated in whole blood[88], are due to cooperation between platelets and neutrophils[89]. Leukocytes have been shown to respond to conditioned media of activated platelets and migrate to infectious sites formed of invading bacteria and platelet aggregates[90]. Activated human platelets can also stimulate neutrophil phagocytosis[91,92], and enhance the neutrophil production of superoxide anion in response to fMLP, phorbol esters or zymosan[93,94]. Platelet factors responsible, at least in part, for the stimulatory effects were found to be adenine nucleotides such as ATP/ADP[93,95]. However, it has recently been reported that platelets also release macromolecular activators of phagocytosis by neutrophils. Such factors may include among other possible agents transferrin molecules acting by increasing the binding capacity of neutrophil FcγRII[96,97]. Depending on the agonist used to activate neutrophils, platelet products were shown to exhibit divergent effects. Hence, ATP, ADP, AMP and adenosine stimulated O_2^- responses of human neutrophils activated by immune complexes; in contrast, when neutrophils were challenged with fMLP, ATP and ADP increased the responses, whereas AMP and adenosine inhibited the fMLP-induced superoxide anion production[98]. The increase of superoxide anion production induced by platelets during neutrophil–platelet coincubation with ionophore A23187 was also linked to the release of the purine nucleotide ATP by platelets[99]. Neutrophil cytotoxicity and the release of neutrophil lysosome contents are also increased by coincubation with platelets[67,100,101]. Among neutrophil factors affecting platelets, cathepsin G has been shown to be strongly involved in platelet activation[102,103]. This serine protease stored in azurophil granules and released from fMLP-, C5a- or LTB_4-stimulated neutrophils[104–106] can cause, in addition to matrix damage, recruitment and activation of platelets at inflammatory sites through a specific receptor on platelets[107]. NAP-2 (neutrophil-activating peptide-2), a chemotactic activator of neutrophils present in platelet α-granules[108], is formed from the cleavage of NAP-2 precursors, such as CTAP-III (connective tissue-activating peptide III) and β-thromboglobulin, by cathepsin G[109]. Moreover, neutrophil–platelet interactions create a local protected microenvironment favouring the maintenance of an active cathepsin G[110]. Thus, adhesive interactions between platelets and neutrophils generate microenvironments which are likely to favour high local concentrations of mediators protected from neutralizing plasma inhibitors. The inflammatory and thrombotic processes are tightly linked at the very onset of the inflammatory reaction, and factors locally released in association with cell–cell binding through adhesion receptors cooperatively act to transduce regulatory signals. To date, there is convergent evidence that such in vivo platelet–neutrophil interactions are not only relevant to pathophysiological conditions, but are also occurring at rest, participating in the homeostatic equilibrium of tissues and organs.

Platelet interactions with monocytes during inflammation

Interactions between platelets and monocytes, although often similar to those between platelets and neutrophils, present several interesting differences potentially relevant to the regulation of the inflammatory process. Platelets can adhere to monocytes and monocytoid cells such as U937 or THP-1 cells[43,111,112]. Incubation of monocytes with unactivated and thrombin-activated platelets resulted in the rosetting of 87% and 93% of monocytes, respectively[26]. The kinetics of platelet binding to monocytes and neutrophils were different, with a slow binding of unactivated or activated platelets to monocytes over 30–60 minutes compared to a rapid binding of platelets to neutrophils, a process dependent on divalent cations in monocytes, but not in neutrophils[26]. The binding of platelets to monocytes has been demonstrated to implicate thrombospondin and a membrane receptor named glycoprotein IV[111,113]. Activated platelets stimulate monocytes to phagocytoze solid particles[91], to produce superoxide anion[114], to express cytokines such as IL-1β, IL-8 or MCP-1 (monocyte chemotactic protein-1)[31,115]. RANTES ('regulated upon activation normal T cells expressed presumed secreted') is a CC chemokine stored and released by platelets[115]. The RANTES-mediated platelet expression of IL-8 and MCP-1

Cambridge Books Online © Cambridge University Press, 2009

by monocytes during platelet–monocyte interactions requires P-selectin. Direct interactions between platelets and monocytes were shown to be required for the release of MCP-1 and the translocation of NF-κB in monocytes, insofar as supernatants from activated platelets were not able to induce such translocation[115]. Another issue related to platelet and monocyte interactions and the inflammatory process is the expression of tissue factor activity on monocytes[116], a critical event promoting thrombosis during inflammation[117,118]. Blood clotting is initiated by the action of tissue factor, a transmembrane protein of 47 kD acting as a cofactor and produced by endothelial cells, vascular smooth muscle cells and monocytes. Tissue factor binds factors VII and VIIa leading to a molecular complex acting on factors IX and X. Agonists such as LPS, cytokines and immune complexes stimulate the expression of tissue factor by endothelial cells and monocytes; interactions between endothelial cells and lymphocytes[119,120], and between platelets and monocytes[116,121] also induce the generation of tissue factor. Platelet–neutrophil interactions are involved in the enhancement of tissue factor activity in monocytes exposed to LPS[122]. Although in vitro experiments on the effects of platelets on tissue factor expression by monocytes sometimes provided paradoxical results, platelet interactions with monocytes in vivo have been shown to promote tissue factor formation[115,116,123,124]. The stimulatory activity of platelets on monocyte expression of tissue factor is mediated by P-selectin[116]. Moreover, the presence of a circulating pool of tissue factor has recently been shown[125]; in a process that promotes thrombogenesis, this tissue factor is transfered from monocytes to platelets through direct interactions involving CD15 (a leukocyte membrane-bound carbohydrate or sialyl Lewis^x) and tissue factor itself with platelets[126].

Thus, specific events implicating interactions of platelets with monocytes occur during the local thrombogenic process of inflammation.

Platelet interactions with erythrocytes during inflammation

Erythrocytes can also interact with platelets and enhance their ability to produce arachidonic acid and eicosanoids, to release ADP and serotonin and to increase platelet recruitment and aggregation[127,128]. The influence of erythrocytes on platelet reactivity was observed even when using platelet preparations where thromboxane formation was abrogated by aspirin, ADP removed by apyrase or creatine phosphokinase, and protease activity inhibited by a mixture of antiproteases. These data indicate the putative importance of such interactions during the evolution of an inflammatory reaction.

Transcellular metabolism during platelet interactions with other cells

Interactions of platelets with other inflammatory cells have also been suspected at the level of arachidonic acid metabolism since the pioneer studies of Marcus et al[22]. When coincubated, endothelial cells and platelets released greater quantities of prostacyclin (PGI_2) than endothelial cells alone in similar in vitro conditions[22]. Thus, it was concluded that endothelial cells use platelet-derived endoperoxides to generate more PGI_2[129], a phenomenon also observed in vivo at the site of a bleeding time wound[130]. It has also been shown that endothelial cells, through compartmentalized cyclooxygenases, can generate PGH_2 for intracellular production of PGI_2 and transcellular formation of TxB_2 by aspirin-treated platelets[131]. Platelet microparticles have been shown to activate platelets themselves and endothelial cells through transcellular delivery of arachidonic acid leading to TxB_2 and PGI_2 biosynthesis in platelets and endothelial cells, respectively[132]. Such transfer of arachidonic acid during cellular interactions has also been shown to occur from neutrophils to platelets leading to increased formation of TxB_2[133,134]. An increased formation of TxB_2 by platelets was also recorded during interactions between smooth muscle cells and platelets in vitro[135]. Further studies on metabolic interactions resulting in the generation of products not synthesized by single cell types have indicated the pathophysiological relevance of such a transcellular metabolism in different experimental conditions in vitro as well as in vivo. Thus, 12S-hydroperoxy-5,8,10,14(Z,Z,E,Z)-eicosatetraenoic acid (12-HPETE) generated by platelets has been reported to stimulate the production of LTB_4 by human blood neutrophils[136], a phenomenon also observed in pathophysiological states in studies demonstrating the decreased LTB_4 synthesis by neutrophils in the presence of lipoxygenase-deficient platelets from patients with myeloproliferative disorders[137]. It was also demonstrated that neutrophils coincubated with platelets in the presence of ionophore A23187 can transform the platelet product 12S-hydroxy-5,8,10,14(Z,Z,E,Z)-eicosatetraenoic acid (12-HETE) into 5S,12S-dihydroxy-6,8,10,14(E,Z,E,Z)-eicosatetraenoic acid (5S,12S-diHETE)[23,138]. In addition, 12-HETE produced by platelets is metabolized to 12S,20-dihydroxy-5,8,10,14(Z,Z,E,Z)-eicosatetraenoic acid (12,20-diHETE) by unstimulated neutrophils[139]. Amplification of LTB_4 biosynthesis in neutrophils by thrombin-activated platelets was observed using the ionophore but also physiological agonists such as zymosan, fMLP, C5a, or platelet-activating factor (PAF) as stimuli for LTB_4 biosynthesis[140,141]. The mechanisms of the stimulatory effect of

Cambridge Books Online © Cambridge University Press, 2009

platelets on neutrophils implicate the release of arachidonic acid (AA) from platelets[23,141]; however, the platelet-derived AA was shown to be mainly converted by human neutrophils into 5-HETE and Δ6-*trans*-LTB_4 isomers and only marginally transformed into LTB_4[142]. Coincubated platelets and monocytes were also shown to be involved in an active transcellular metabolism of eicosanoids different, however, from that reported during platelet–neutrophil interactions. Monocytes were found to provide unesterified AA, 5-HETE and LTA_4 to platelets. No stimulatory effect of platelet 12-HPETE on 5-lipoxygenase of human blood monocytes was reported, and monocytes did not utilize lipoxygenase products released by platelets[143]. LTA_4 from monocytes was converted by platelets to LTC_4[143], a transcellular metabolism previously reported with neutrophil-derived LTA_4[144]. It is also important to point out that, during platelet–neutrophil interactions, the formation of LTC_4 (and TxB_2) is dependent on the expression of P-selectin by platelets activated by the release of cathepsin G from fMLP-stimulated neutrophils[145]. Moreover, by using reverse transcription PCR techniques it was recently confirmed that platelets contain a LTC_4 synthase[146]. Note that platelet–neutrophil cooperation can lead to increased formation of PAF largely originating from neutrophils, an effect only found after stimulation of platelets[147]. To confirm the in vivo functional significance of platelet interactions with neutrophils during inflammation, Evangelista et al. studied rabbits receiving an intravenous infusion of fMLP[148]. This treatment induced an immediate neutropenia and thrombocytopenia with a concomitant increase of TxB_2, LTB_4 and LTE_4 levels in blood. The chemotactic peptide fMLP is known to activate leukocytes, in particular neutrophils, but not platelets. In fMLP-treated animals, platelets were found aggregated on vessel walls and neutrophils were shown to be activated, especially in capillary lumen of lungs. When rabbits were pretreated with an antiplatelet antiserum, circulating LTB_4 and LTE_4 in fMLP-treated animals were lower than in control rabbits, unlike fMLP-treated rabbits rendered leukopenic where LTB_4 and LTE_4 levels were similar to controls. This interesting report brings invaluable insights into the importance of in vivo interactions of platelets with other cells in the generation of arachidonic acid-derived metabolites involved in acute inflammation.

The transcellular metabolism occurring in platelet-neutrophil interactions also gives rise to other lipoxygenase-derived compounds, the lipoxins. These eicosanoids are generated by the sequential action of two lipoxygenases (LO), either 5–LO and 15–LO or 5–LO and 12–LO on AA[149,150]. Thus, platelets were reported to convert neutrophil-derived (or exogenous) LTA_4 to lipoxins, including the bioactive lipoxin A_4 (LXA_4, 5S,6R,15S-trihydroxy-7E,9E,11Z,13E-eicosatetraenoic acid)[151]; lipoxin formation was also shown in ligand-activated platelet and neutrophil coincubations in vitro[152]. Neutrophil–platelet interactions have been shown to occur in inflamed glomeruli during immune complex-mediated glomerulonephritis in rats and mice with subsequent transcellular formation of LXA_4, as assessed by a specific ELISA[80,153].

Mechanisms of interactions between platelets and inflammatory cells

As discussed in the preceding paragraphs, interactions between platelets and other inflammatory cells involve complex mechanisms implicating direct cellular contact and multiple soluble mediators. Cells express on their surface adhesion molecules with binding activity to cognate ligands, also named counter-receptors, which are either expressed on other cells allowing intercellular adhesion, or are soluble. Activated platelets express on their surface several adhesion molecules, which can also participate in the subsequent activation of adherent cells through activation of signalling pathways, such as the P-selectin (or GMP140, PAGDEM, CD62)[154] undergoing phosphorylation under activation[155,156], GP IIb/IIIa (or integrin αIIbβ3)[157], ICAM-2 (intercellular adhesion molecule-2, an Ig-like protein acting as a ligand of β2 integrin)[158], and GPIbα (belonging to the GPIb–IX–V complex)[159], which has recently been implicated in LPS-stimulated interactions of platelets with endothelium[72]. It is important to point out that in the initiation of the inflammatory process, P-selectin is also expressed by endothelial cells implicated in the capture of blood leukocytes. P-selectin has been shown to play a necessary role in platelet interactions with other cells. Platelet adhesion to leukocytes implicates a calcium-dependent mechanism completely abrogated by an anti-P-selectin antibody indicating the importance of P-selectin in such interactions[44,160,161]. The process of rolling and firm adhesion of leukocytes on activated platelets precluding inflammation also involves P-selectin[162–164]. The LPS-induced neutropenia in vivo has been shown to be inhibited by anti-P-selectin antibodies, suggesting that P-selectin is implicated in the early entrapment of leukocytes in tissues such as lungs, kidneys and liver[165]. Using mutant mice lacking P-selectin, Hartwell et al. recently demonstrated the contribution of this receptor in the development of a delayed-type hypersensitivity reaction and a surprising antiinflammatory effect of P-selectin in the immunologically induced glomerulonephritis[47]. Neutrophils and monocytes show increased production of superoxide

Cambridge Books Online © Cambridge University Press, 2009

anion in the presence of activated platelets, a phenomenon inhibited by antibodies to P-selectin[94,114]. P-selectin is also involved in the platelet–leukocyte interaction-dependent formation of TxB_2, LTC_4, and cytokines[145,166]. The counter-receptor for P-selectin has also been the focus of great attention[167]. This ligand, a mucin-like protein named PSGL-1 (P-selectin glycoprotein ligand-1), contains oligosaccharide sequences of the sialyl Lewis^X antigen and fucosylated lactosamine[168–170] providing high selectivity but low affinity for P-selectin. In addition, PSGL-1 binding to P-selectin is dependent on tyrosine sulfation[171]. Blood myeloid cells including polymorpho and mononuclear phagocytes, lymphocytes and dendritic cells express PSGL-1[167]. Binding of P-selectin to PSGL-1 is required in various models of inflammation in animals, i.e. cytokine-induced meningitis[172] and immune complexes-induced lung injury[173]. PSGL-1 has also been shown to be implicated in inflammatory conditions by using PSGL-1 antibodies or soluble PSGL-1 blocking neutrophil infiltration towards inflammatory sites[174,175]. Importantly, PSGL-1 could also be implicated in malignancy since P-selectin was shown to be required in platelet adhesion to neuroblastoma, lung cancer and melanoma[176,177]. Thus, the broad implication of this ligand in pathophysiology supports the intense pharmacological research on P-selectin and its ligand.

The other major mechanism in platelet adhesion and interactions with other cells relies on the integrin system, i.e. the platelet integrin GPIIb/IIIa, and the leukocyte β_2 (CD18) integrins combined with the three different α subunits CD11a (LFA-1), CD11b (Mac-1) or CD11c (GP 150,95). Both platelet GPIIa/IIIb and leukocyte CD11b/CD18 bind fibrinogen through different sequences on fibrinogen chains. Antifibrinogen antibodies decrease the interaction of platelets with leukocytes[178]. Thus, elevated levels of fibrinogen during inflammation contribute to the down-regulation of leukocyte migration at inflammatory sites, insofar as chemoattractants such as PAF (more than LTB_4) promote neutrophil accumulation and adhesion on activated platelets in flow conditions[178]. Endogenous PAF from platelets has also been implicated as a juxtacrine mediator of P-selectin-dependent neutrophil rolling spontaneously leading to a CD18-dependent adhesion[179]. The role of neutrophil-derived PAF has already been demonstrated in neutrophil–platelet interactions triggered by fMLP or LTB_4, a phenomenon blocked by a peptidomimetic of the fibrinogen binding sequence Arg–Gly–Asp–Phe[180]. Moreover, human neutrophils activated in vitro by adhesion to adsorbed fibrinogen undergo induction of IL-1, -8, -6 and TNF-α (as evaluated by RT-PCR, Northern blotting and ELISA techniques); these data were confirmed in vitro using neutrophils from CD18-deficient mice and in vivo in a murine model of peritonitis[181]. Using anti-CD18 antibodies, it has been demonstrated that, during C5a-induced myocardial ischemia, the formation of TxB_2 and sequestration of neutrophils were related to CD18-dependent mechanisms[82], and that in dynamic conditions, such as under high-speed rotatory motion, platelet–neutrophil interactions required β_2 integrins[182]. Platelet aggregation induced by various agonists can be blocked by preincubation with an antibody against the integrin GPIIb/IIIa[183]. This platelet integrin is also involved in platelet–neutrophil interactions since tirofiban, an inhibitor of GPIIb/IIIa given to patients with unstable angina, reduced the number of platelets in blood platelet–neutrophil aggregates[184]. Activated platelets can also bind to the endothelium through interactions of their GPIIb/IIIa with the endothelial cell ICAM-1, $\alpha_v\beta_3$ and GPIbα[185]. Another integrin implicated in platelet interactions with other cells is the integrin $\alpha_v\beta_3$ with a β_3 subunit identical to GPIIIa and an α_v subunit homologous to GPIIb. Although $\alpha_v\beta_3$ is not highly expressed by platelets, it could be involved in platelet adhesion since $\alpha_v\beta_3$ binds fibrinogen, and this binding is inhibited by RGD-containing peptides and an antibody raised against GPIIb/IIIa[186]. Elements other than fibrinogen such as thrombospondin, tenascin, osteopontin and collagens can serve as substrates for the attachment of inflammatory cells. From that point of view, monosodium urate crystals, the causal agent of gouty inflammation, can also act as extracellular substrates for cell attachment, insofar as they have been shown to directly activate platelets through GPIIb/IIIa[187] and neutrophils through CD11b/CD18[188]. This could suggest an amplification process for the local capture of inflammatory cells during gouty inflammation.

It is also important to stress that adhesion molecules are involved not only in cell adhesion but also in intracellular signalling. For example, P-selectin stimulates a very early adhesion of monocytes to activated platelets and endothelial cells while inducing the monocytic generation of inflammatory cytokines such as MCP-1 and TNF-α through enhanced nuclear translocation of NF-κB[166]. Fibrinogen binding to CD11b/CD18 in the monocytoid U937 cells activates the transcription factors NFk-B and AP-1[189]. Studies with human neutrophils incubated on fibrinogen-coated surfaces demonstrated that, under TNF-α stimulation, the adhesion-stimulated neutrophils degranulate through a mechanism implicating Src family kinases[190]. Moreover, platelets adhering to neutrophils stimulate protein–tyrosine phosphorylation in neutrophils through P-selectin/PSGL-1 inducing the activation of CD11b/CD18[191].

Inhibitory effects of inflammatory cells on phlogogenic reactivity of platelets

While interactions of platelets with other inflammatory cells result in the activation of the latter, it has also been shown that in contrast inflammatory cells down-regulate platelet reactivity. Thus, human neutrophils have been reported to inhibit platelet aggregation and β-thromboglobulin release in whole blood. The effects of neutrophils were shown to depend, at least in part, on ADPase activity, nitric oxide production and antiaggregatory AA-derived metabolites of neutrophils[192]. Neutrophils have been reported to modulate platelet functions through different mechanisms such as the release of hydrogen peroxide[193], nitric oxide[194] or elastase [195]. As another example, unstimulated neutrophils have been shown to inhibit the release of serotonin from platelets activated by collagen or thrombin, an effect which was amplified by addition of antibodies to P-selectin or by preincubation with lipoxygenase inhibitors. The role of neutrophil ecto-nucleotidase or nitric oxide in these inhibitory effects was ruled out[196]. Endothelial cells can also modulate platelet reactivity through prostacyclin and the subsequent activation of platelet adenylate cyclase, through the generation of nitric oxide or through endothelial ectonucleotidase which rapidly metabolizes platelet-derived ADP[197]. Neutrophils also reduce the formation of TxB_2 by activated platelets in vitro[134]. It has also been reported that activation of neutrophils, but not monocytes, was associated with a decreased expression of PSGL-1 and to an inhibition of neutrophil–platelet adhesion as well as dissociation of pre-existing aggregates[198]. Lymphocytes also appear to have the capacity to inhibit platelet aggregation by a mechanism independent of prostaglandins, nitric oxide or adenosine[199].

Such down-modulation of platelet functions by other inflammatory cells may play an important role in the limitation of the inflammatory process and the restoration of homeostasis.

Antiphlogogenic functions of platelets

If platelets exhibit multiple proinflammatory activities, in particular at the onset of the inflammatory reaction, they have also been reported to down-regulate phlogogenic functions of adjacent cells involved in the process. Ginsburg et al. reported that platelet-conditioned media significantly inhibited the chemotaxis of neutrophils[200]. The production of superoxide anion by neutrophils, a basic function in the control of invading microorganisms, has been shown to be down-modulated by platelets[20,201] or platelet-derived products such as PDGF (platelet-derived growth factor), or P-selectin[20,202–204]. Platelets have also been found to inhibit other functions of human neutrophils such as degranulation and chemotaxis[205], synthesis of LTB_4 and PAF[21,134,206], and apoptosis[207]. The inhibitory effect of platelets on neutrophil apoptosis depends on TGF-β_1 acting through the p38 MAPK pathway[208]. Resting platelets have also been found to decrease the adhesion of neutrophils to endothelial cells, an effect independent of adenosine or P-selectin[209]. Angiogenesis is a critical process for tumour growth and tissue proliferation during the chronic inflammatory reaction; the platelet-derived product PF4 has been shown to inhibit angiogenesis and proliferation of hematopoietic progenitor cells[210,211], an effect related to a decreased cdk2 (cyclin E-cyclin-dependent kinase 2) activity[212].

During experimental glomerulonephritis, the presence of recruited neutrophils and platelets at inflammatory foci is associated with enhanced glomerular arachidonic acid metabolism and increased generation of LTB_4 and TxB_2[79]. However, interactions between platelets and neutrophils in this model lead to the local formation of lipoxin A_4 through transcellular metabolism, a compound with inhibitory effects on neutrophil chemotaxis and neutrophil interactions with endothelial, mesangial and epithelial cells[80]. Experimental glomerulonephritis in P-selectin-deficient mice is associated with increased glomerular neutrophils and more severe proteinuria[153]. The inhibitory roles of LXA_4 generated through platelet–neutrophil interactions was confirmed in these P-selectin deficient mice; the infusion of normal platelets restored the generation of LXA_4 as well as the neutrophil influx to the levels seen in wild-type mice with glomerulonephritis[153,213].

Conclusions

Interactions of platelets or platelet microparticles with other cells involved in the inflammatory process appear to be critical to the initiation and normal course of an acute inflammatory reaction. These complex interactions arise very early in the process through the expression of selectins and integrins by activated platelets allowing interactions with other cell types closely implicated in inflammation and with malignant cells. The data already accumulated on these interactions demonstrated numerous proinflammatory functions of platelets, mainly during the very early phase of the inflammatory process, as well as anti-inflammatory properties later in the course of this

Cambridge Books Online © Cambridge University Press, 2009

inflammatory reaction. Many questions remain, however, unanswered about their impact in host defence and various disease states. Additional studies with either selective antibodies to adhesion molecules, soluble adhesion molecules or synthetic antagonists or with gene (adhesion molecules or their counter-receptors) knockout animals will be necessary to further characterize platelet interactions with other cells, their role in modulating inflammatory cell activity and their pathophysiological significance in acute or chronic inflammatory diseases as well as in infectious disorders. Such studies might provide the necessary proof of concept in support of the development of therapeutic approaches to inflammatory diseases based on the modulation of platelet activity, more specifically of their stimulatory interactions with other inflammatory cells.

Platelets and the preimplantation stage of embryo development

Christopher O'Neill

Human Reproduction Unit, Department of Physiology, University of Sydney, Royal North Shore Hospital, St Leonards NSW, Australia

Introduction

The preimplantation phase of pregnancy occurs from the time of fertilization until the embryo implants into the endometrium of the uterus. Implantation occurs on days 5–6 of pregnancy in humans. Implantation triggers differentiation of the embryo's trophoblast layer, leading to a sequence of developmental changes that produce the placenta. Prior to implantation, the embryo exists in a free-living state, initially within the oviduct (fallopian tube) and then in the lumen of the uterus. It has generally been considered that the embryo is passive during this time, relying upon the reproductive tract for the provision of its nutrients and a benevolent environment. However, it is now becoming clear that the local environment of the reproductive tract is conditioned and modified by the early embryo and these modifications are important for normal embryo development. These modifications include the activation of blood platelets within the reproductive tract and are elicited by the production of soluble and diffusible factors by the early embryo. The best characterized of these is platelet-activating factor (PAF).

Embryo-derived platelet-activating factor

The well-known ether phospholipid 1-*o*-alkyl-2-acetyl-*sn*-glyceryl-3-phosphocholine (PAF) is a potent pleiotrophic mediator (Fig. 58.1). It is produced by the preimplantation embryo of many species soon after fertilization (mouse[1,2]; human[3,4]; rabbit[5]; and sheep[6]). It accumulates to significant concentrations within the embryo and is also released into the embryo's surrounding fluid. The production of embryo-derived PAF seems to be largely *de novo* occurring from simple substrates[7,8]. The rate-limiting enzyme for the synthesis of embryo-derived PAF is

$n = 15, 17$

Fig. 58.1. The structure of platelet-activating factor.

lysoPAF: acetyltransferase[8] (EC 2.3.1.67). This calcium-dependent enzyme is present within the preimplantation embryo. Its activity is at a low level in the unfertilized oocyte but increases soon after fertilization. This is the time when PAF release from the zygote is first detected[9]. This temporal correlation between the activity of lysoPAF: acetyltransferase and PAF release suggests that activation of this rate-limiting enzyme is the regulatory event following fertilization that initiates PAF production and release by the early embryo. The activation of lysoPAF: acetyltransferase activity and PAF release occur prior to the onset of new transcription of mRNA from the zygotic genome[10]. Thus, the production of PAF is not dependent upon transcription but on the post-transcriptional activation of the biosynthetic pathway.

The release of PAF by the preimplantation embryo was first detected by the observation that a mild but consistent thrombocytopenia occurred in mice within a short time of fertilization and persisted throughout the preimplantation phase of pregnancy[11]. The thrombocytopenia was unequivocally a consequence of the presence of the preimplantation embryo[11,12]. It has been subsequently shown that spermatozoa[13], the luteal phase uterus[14,15] and follicular fluid[16] also produce PAF, yet these sources of PAF are without detectable effect on blood platelets and do not induce thrombocytopenia.

Early pregnancy-induced thrombocytopenia

The release of PAF from the embryo induces localized platelet activation within the vasculature of the reproductive tract[17]. It is assumed that these activated platelets are trapped by the reticuloendothelial system and removed from the circulation, resulting in thrombocytopenia[11]. In the mouse, this platelet activation is accompanied by the contraction of the spleen[11] and preferential loss of platelets from the spleen into circulation. This is a well-characterized response to increased platelet activation – with the spleen acting as a reservoir of blood platelets that can be called upon during acute periods of platelet consumption[18,19]. This homeostatic mechanism normally acts to stabilize the number of platelets in the circulation; only prolonged or profound loss of platelets results in detectable peripheral thrombocytopenia. The size of the spleen's platelet reservoir varies greatly between species[18]. The consistent detection of thrombocytopenia in mice is testament to the extent that PAF released by the embryo causes platelet activation. The mouse, however, may be a special case – thrombocytopenia may not be a general characteristic of early pregnancy in all mammalian species.

Thrombocytopenia was observed in the preimplantation phase of some human pregnancies[20], but in others there was a trend to thrombocytosis[21]. The variable response may reflect the ability of the spleen to compensate for platelet loss from the circulation in the human, or it may be a consequence of increased thrombopoiesis compensating for platelet loss in early human pregnancy. An association was discovered between the thrombocrit prior to pregnancy and the change in platelet count during early pregnancy. Those women with a high thrombocrit prior to pregnancy showed a subsequent thrombocytopenia. By contrast, those with a low thrombocrit generally did not display thrombocytopenia. A possible interpretation of this result is that release of the splenic platelet pool or activation of thrombopoiesis occurred more readily and rapidly where the thrombocrit, prior to pregnancy, was low[21]. Early pregnancy was also associated with variable thrombocytopenia in cows following embryo transfer[22]. It is noteworthy that, in the intact female rabbit, thrombocytopenia in early pregnancy is not readily detected[23]. However, in splenectomized females, early pregnancy associated thrombocytopenia was detected[23]. This observation supports the role of the spleen in the homeostatic maintenance of the circulating platelet concentration following the localized platelet activation that occurs during early pregnancy. A further consideration is that the mouse is a polytocous species, therefore many embryos are present in a small reproductive tract. This contrasts with the human, where generally only one embryo is present in a large reproductive tract (with a correspondingly large blood supply). Thus in large mono-ovulatory species, even extensive early pregnancy-associated platelet activation may be less likely to be detected as peripheral thrombocytopenia. It seems that monitoring platelet numbers during early pregnancy cannot be used in a reliable manner to detect or monitor pregnancy in most species[21]. Should reliable, sensitive and accurate measures of platelet turnover become widely available, these may prove useful for monitoring early pregnancy.

Metabolism of PAF and platelet activation in the reproductive tract

PAF is present in many reproductive tissues (sperm[13], ovary[16], uterus[14]), yet PAF-induced platelet activation and transient thrombocytopenia is only associated with early pregnancy[11,12]. The current assay methods do not allow reliable measurement of the rate of PAF release but only the amount that accumulates in medium over time. The zygote releases 1.3–6.7 ng PAF/embryo (mouse) and 0–80 ng PAF/embryo (human)[24,25] over a 12 h period. It is not known if this is released at a consistent rate over this period, or whether its release is episodic.

There exists in most tissues and fluids studied to date a high capacity enzyme PAF: acetylhydrolase, that degrades PAF to its inactive metabolite, lysoPAF. It was anticipated that, within the reproductive tract, there would be sufficient PAF: acetylhydrolase activity to degrade all the embryo-derived PAF released prior to it being able to cause significant platelet activation. The fact that extensive platelet activation was observed to occur suggested that there was some interesting PAF biology occurring within the reproductive tract. Acute administration of synthetic PAF at a concentration at least an order of magnitude higher than is produced by the embryo was required to induce detectable thrombocytopenia in the mouse, and this thrombocytopenia was only transient despite the high doses[12].

Since embryo-derived PAF was unequivocally demonstrated to be structurally homologous with synthetic-PAF[2], studies were performed to determine whether the uterine environment resulted in reduced metabolism of PAF[26]. The activity of PAF: acetylhydrolase was measured in uterine tissue and in uterine lumen fluid throughout the reproductive cycle and in early pregnancy. A precipitous decline in enzyme activity in these preparations occurred after ovulation. This resulted in both uterine tissue and lumenal

Cambridge Books Online © Cambridge University Press, 2009

fluid having low enzyme activity during the preimplantation phase[26]. PAF: acetylhydrolase activity in the uterus increased substantially after implantation. These changes in the enzyme activity occurred without detectable alterations to plasma enzyme activity. Thus, during the period that the preimplantation embryo released PAF the catalytic activity directed against PAF in the uterus declined to a low level. The change in enzyme activity would be expected to result in a prolonged half-life of embryo-derived PAF. The decline in PAF: acetylhydrolase activity was steroid hormone dependent, with progesterone dominance over estradiol being required[26]. This is the pattern of hormone production during the preimplantation (early luteal) phase of pregnancy.

Investigations show that the plasma form of PAF: acetylhydrolase is responsible for the activity in the uterus (O. Chami & C. O'Neill, unpublished data). It seems that hormone-dependent alterations in blood flow and vasopermability in the uterus allow dynamic and rapid alterations in the PAF: acetylhydrolase activity within the uterus independently of a change in enzyme activity within the blood plasma. The results suggest that a reduction in PAF metabolism within the uterus during the preimplantation phase may contribute to the ability of the small amounts of PAF released by the embryo to induce platelet activation.

Another mechanism favouring a prolonged half-life for embryo-derived PAF also exists in the uterus. Recent results show that PAF released by the embryo is released in a unique binding configuration with albumin that prevents or dramatically reduces its metabolism by PAF: acetylhydrolase[27,28]. A preliminary observation in support of this hypothesis was that PAF released from human embryos in medium containing high concentrations of human serum ($<$10% v/v) was stable[29], yet the culture medium contained a high concentration of PAF: acetylhydrolase from the serum[30]. When an equivalent concentration of synthetic PAF was added to the same embryo culture medium, it was degraded within minutes by the PAF: acetylhydrolase present in the serum[30].

The possibility that, upon its release from cells, PAF was bound to a special protein that protected it from metabolism was tested. However, PAF released from embryos was all bound to albumin[27,28]. Albumin in medium was required for PAF release by embryos and PAF co-migrated with albumin upon various forms of chromatography. An alternative hypothesis was tested: the nature of albumin's binding of embryo-derived PAF conferred protection from metabolism by PAF: acetylhydrolase. When embryo-conditioned medium was subjected to organic extraction and the resulting purified PAF was then added back to medium containing albumin, the PAF became readily susceptible to the action of PAF: acetylhydrolase[27,28]. In this regard its behaviour was equivalent to synthetic-PAF added to medium. Extracted embryo-derived PAF and synthetic-PAF added to medium bound preferentially to hydrophobic surfaces, being lost from the albumin. By contrast, unextracted embryo-derived PAF remained bound to albumin in the presence of hydrophobic surfaces. Both synthetic PAF and extracted embryo-derived PAF, when added to embryo culture medium, could be recognized by a PAF-specific antibody and could thus be measured by a direct immunoassay. This was not the case for PAF in embryo-conditioned medium from which PAF could only be assayed after its organic extraction. The results suggest that upon the release of PAF from embryos (but not following its addition to medium) PAF binds to albumin in a manner that protects it from metabolism by PAF: acetylhydrolase. The fact that this type of binding to albumin also prevented a PAF antibody binding to embryo-derived PAF suggests that it may involve a steric modification of the albumin molecule[27,28].

Limited proteolytic analysis of albumin showed that PAF released from cells bound only to a site within domain II of the albumin molecule (total of 583 amino acids), between amino acids 240 and 386[27,28]. By contrast, when PAF was added to medium it bound to albumin at sites other than domain II. Albumin forms a heart-shaped molecule of three domains. Domain II (amino acid 208–398) is composed of two similar subdomains, *a* and *b*, each being composed of a cluster of four α-helices[31]. The interface between subdomains II*a* and II*b* form a hydrophobic cleft that may serves as a binding site for lipids[31].

The observation that PAF binding within domain II only occurred upon release of PAF from cells but not upon addition of PAF to albumin-containing medium, infers that an interaction between the cell and albumin is required before PAF can be loaded onto domain II of albumin. Covalent modification of albumin involving cysteine–cysteine disulfide bonds seemed to be required for PAF to be loaded onto domain II from cells. For instance, after exposure to cells there was an increased molar concentration of solvent exposed thiol groups; albumin was more susceptible to denaturation following exposure to dithiothreitol; and following such denaturation, the albumin-associated PAF became susceptible to degradation by PAF: acetylhydrolase[27,28]. Notwithstanding the high affinity nature of this binding, the PAF released was clearly still active as assessed by the platelet activation and thrombocytopenia induced in early pregnancy and the thrombocytopenia induced in mice upon injection of embryo-conditioned culture medium[12].

While this special form of cell-dependent release of PAF

Cambridge Books Online © Cambridge University Press, 2009

within domain II of albumin was first observed with preimplantation stage embryos, it was not restricted to this type of cell. The same biochemical behaviour was observed for PAF released by endothelial cells[28]. Thus PAF may be released from cells in at least two forms. It can be released and bound in a superficial manner with albumin. In this configuration it can be rapidly degraded by PAF: acetylhydrolase. It consequently has a short half-life and can act only as a local mediator. PAF released from inflammatory cells probably exists primarily in this configuration. For other cells in non-inflammatory states that release PAF, such as the embryo and endothelial cells, PAF can be released in a stable configuration in association with albumin. It can accumulate due to its prolonged half-life and can therefore enter the circulation. It may therefore have roles as a conventional circulating hormone, as well as a local mediator. These important implications arising from studies of embryo-derived PAF warrant further investigation.

Physiological actions of embryo-derived PAF

A range of PAF antagonists can inhibit the thrombocytopenia induced by embryo-derived PAF[32]. When administered throughout the preimplantation phase of pregnancy, PAF antagonists also blocked the successful implantation of embryos in rats and mice[32–35]. The pharmacology of these antagonists was curious, however. The dose–response showed a characteristic quadratic effect, with inhibition of pregnancy at relatively low doses but loss of the inhibition at higher doses of antagonist[36].

This characteristic quadratic dose–response occurred for a range of antagonists with varying structures, and was independent of its mode or route of administration[36]. The nature of the dose–response suggests that the antagonists act as partial agonists rather than as true antagonists. This mode of action has not been widely reported or observed in other PAF mediated processes, although WEB 2086 and WEB 2170[37] are reported to exert partial agonistic actions on the perfused heart. PAF antagonists can also act as inhibitors of PAF metabolism[38], thus the complex pharmacological response observed at high drug concentrations in early pregnancy may result from the dual interactions of the drugs with the PAF-receptor and PAF: acetylhydrolase. It is therefore of interest to note that the genetic knockout of the β-subunit of intracellular PAF: acetylhydrolase 1b also results in implantation failure and early embryonic demise[39]. The observation that PAF antagonists act as true antagonists in many models but partial agonists in others suggests that they may be acting against different receptor types. Another possibility may be that the binding of PAF within domain II of albumin alters the nature of its interaction with the PAF-receptor and hence alters the pharmacology of the PAF antagonists. Currently, there is insufficient experimental data to distinguish between these alternative hypotheses.

Using the antagonists in a dose range where pregnancy was inhibited, embryo transfer experiments established that the actions of embryo-derived PAF are required for the normal development of the embryo[40]. There was no support for a role of embryo-derived PAF in the preparation of the maternal reproductive tract to be receptive to the embryo. These embryo transfer experiments with PAF antagonist treated mice did not, however, establish whether this action of PAF was a direct autocrine effect or whether it was indirect – for instance, secondary to the activation of platelets. There is experimental data to support a role for both mechanisms.

Roles for platelet activation during early pregnancy

A factor of maternal origin that is expressed with a similar temporal profile to PAF is a protein known as early pregnancy factor (EPF)[41]. For many years this factor was known by its actions in modifying T-lymphocyte function. Its secretion during early pregnancy was reasoned to provide an immunosuppressive action that allowed the embryonic 'allograft' to survive the maternal immune system. It was recently shown that PAF induces the expression of EPF[42], while EPF has been shown to be a secreted form of chaperonin 10[43]. It is released from blood platelets following their activation[43]. Chaperonin 10 is normally considered an intracellular protein that has important functions in protein folding and conformation. It acts in concert with chaperonin 60[44] to allow importation of proteins into cellular organelles, particularly mitochondria, and is therefore essential for normal organellogenesis.

The discovery of chaperonin 10 as a PAF-induced secretory product of platelets, that is present in the blood of pregnant animals, was an unexpected observation. A full description of chaperonin 10's actions in early pregnancy is awaited. However, it may exert actions in modifying the conformation of some extracellular proteins or perhaps has a role in protein import into cells. The observation that immunization of mice against EPF resulted in failed embryo development and pregnancy loss[45] demonstrates the important role of the factor in normal pregnancy.

A confounding observation was that, while synthetic-PAF induced chaperonin 10 release from platelets in vitro,

Cambridge Books Online © Cambridge University Press, 2009

embryo-derived PAF apparently did not[46]. This conflicting result raised questions about the role of embryo-derived PAF in chaperonin 10 release from platelets. The experimental design and conclusion, however, did not take into account the evidence that embryo-derived PAF is not active in defined medium in vitro because of it binding within domain II of albumin. It is also not capable of inducing blood platelet activation in vitro[27,28] yet upon injection into mice it does induce platelet activation and thrombocytopenia[1]. This difference between its actions in vitro and in vivo suggests that an auxiliary activity may also be required to allow embryo-derived PAF accessible to its receptor when it is bound to domain II of albumin. Since binding in this configuration involves modifications to cysteine–cysteine disulfide bonds[27,28], it seems likely that a protein disulfide isomerase or thioredoxin-like activity may be required.

The expression of EPF activity requires the action of a circulating thioredoxin[47]. Indeed, it was shown that pregnancy is associated with the expression of a novel secreted form of thioredoxin[48]. The target of action of this thioredoxin is yet to be defined. We speculate that the secreted thioredoxin may change the conformation of albumin that contains embryo-derived PAF within domain II. Following this conformational change to albumin, PAF can access its receptor allowing it to activate maternal blood platelets and other target cells. The platelets release their contents, including chaperonin 10.

A full description of the actions and interactions of these four players – PAF, albumin, secreted thioredoxin and secreted chaperonin 10 – will provide a new model for intercellular communication. The observation that a similar form of secreted chaperonin 10 is also active in neoplastic tissue and in rapidly proliferating and regenerating tissues suggest a fundamental role for this novel peptide[44]. The platelet, as a rich source of secreted chaperonin 10, may have a hitherto unexpected role in intracellular communication and regulation.

The actions of PAF on the oviduct

As well as acting on platelets, embryo-derived PAF may act directly on the oviduct. The gene coding for a G-protein linked receptor for PAF is expressed on the epithelial and subepithelial cells of the hamster oviduct. Oviductal cells (cow) in primary culture responded to PAF with a characteristic calcium transient that required extracellular calcium and was receptor dependent[49]. The responsiveness of the cells varied with the stage of the estrous cycle. Treatment with PAF could also induce proliferation in these cells[49]. In the human, PAF induced an increase in the transepithelial potential difference across a polarized primary culture layer of oviductal epithelial cells and also increased the shortcircuit current activity. The results were interpreted to indicate an effect of PAF on the transepithelial Cl^- current and hence regulate oviductal fluid production[50].

It has been also shown that embryo-derived PAF provides a message that allows the reproductive tract to distinguish between fertilized and unfertilized oocytes, providing a means of differential transport[51] (fertilized oocytes are transported down the oviduct towards the uterus, while unfertilized oocytes remain trapped within the upper oviduct where they degenerate). It has been suggested that PAF's ability to regulate fluid fluxes across the epithelium may be a mechanism for its role in embryo migration[50]. Embryo-derived PAF also induces a reduction of blood flow to the oviduct due to a decrease in the median cross-sectional area of blood vessels (indicating vasoconstriction) and the collapse of subepithelial capillaries[17]. Embryo-derived PAF also induces a reduction in the incidence of fenestrated capillaries in the oviduct (that are common in pseudopregnant animals)[17]. This alteration in the pattern of fenestrations may act together with PAF's transepithelial fluid flow to regulate oviduct fluid dynamics. It has not yet been defined whether these actions of embryo-derived PAF on vascular dynamics are direct or indirect effects, for instance as a consequence of localized platelet activation. Fig. 58.2 shows the possible interrelationships of these actions.

Action of PAF released by the uterus in early pregnancy

During early pregnancy, PAF is produced by the uterus as well as the embryo. The steroid hormones of the luteal phase cause a significant increase in the synthesis of PAF by the uterus[14,15,52,53]. Although endometrial PAF is released, and can be detected within the uterine lumen[53], it does not appear to result in detectable platelet activation[11]. The PAF that is released is not bound to domain II of albumin and is readily degraded by PAF: acetylhydrolase[53]. Therefore, unlike embryo-derived PAF, it is unlikely to accumulate to sufficient concentrations to enter the blood vessels to induce platelet activation. Within the uterus, the main role of PAF seems to be to modify the production and release of prostaglandins[54,55]. In sheep, a good case has been made for PAF produced by the uterus to act as an autocrine pulse-generator of luteolytic $PGF_{2\alpha}$[53]. The pulsatile release of $PGF_{2\alpha}$ acts on the corpus luteum of the ovary

to prevent the secretion of progesterone. During pregnancy, embryonic factors (interferon tau in the sheep) act to block this pulse-generation by the embryo (Fig. 58.3). It is yet to be determined whether these actions occur via PAF's action on platelets or by direct action on the cells of the endometrium.

Autocrine actions of embryo-derived PAF

As well as the actions of embryo-derived PAF on the reproductive tract, it also has an important role as an autocrine mediator of embryo development. PAF can act directly upon the embryo to enhance its rate of oxidative metabolism[56] and survival[57,58]. Embryos cultured in defined medium containing PAF grow to the blastocyst stage with greater cell numbers[59–61]. The transfer of embryos treated in this way resulted in increased implantation and birth rates[57,62]. The production of zygotes by the method of in vitro fertilization reduces the ability of embryos to release PAF[60]. This is correlated with reduced growth and viability of the IVF embryos. Supplementation of medium with PAF improves the survival and viability of the resulting embryos without having specific growth factor effects[61], while an antibody to PAF blocked embryo development[63].

PAF acts on the zygote and two-cell stage embryo by specifically inducing intracellular calcium transients[64,65]. These transients can be induced by both embryo-derived and exogenous PAF[65]. The calcium transients occur as single global waves with a periodicity of approximately 60–90 minutes[65]. The transients result from an interdependent combination of the release of intracellular stores of calcium and the influx of external calcium. Blocking the calcium transients blocked normal embryo development, showing that this is the important mechanism of signal transduction for PAF in the preimplantation embryo. Extracellular albumin is required for PAF release and the actions of PAF can be prevented by pretreatment of embryos with high concentrations of PAF: acetylhydrolase. The results to date show embryo-derived PAF acts as an autocrine trophic mediator but do not provide support for its actions as an intracellular message or as a juxtacrine mediator in the early embryo[65].

Conclusions

Platelet-activating factor coordinates a range of important physiological processes during early pregnancy. Its release occurs in a novel manner, being bound to serum albumin in a 'caged' form. This form of binding is associated with conformational alteration of the albumin molecule involving cysteine–cysteine disulfide bonds. In this configuration PAF is resistant to metabolism by PAF: acetylhydrolase, shifting its mode of action from a labile local mediator to a stable mediator acting on various tissues. An important target is the embryo itself, with released PAF acting in an autocrine loop. It exerts paracrine effects, inducing extensive blood platelet activation and altered vascular dynamics within the reproductive tract. Embryo-derived PAF also signals to the oviduct to induce embryo transport down the fallopian tube to the uterus, perhaps via modification of oviductal fluid formation. This provides a means of differential migration for fertilized and unfertilized eggs. Platelet activation results in the release of a novel secreted form of chaperonin 10. This protein probably has a role in modifying protein conformation within the embryo's vicinity, including those associated with T-lymphocyte function. Although its precise function in early pregnancy is yet to be defined, its role in embryo development is established by the pregnancy failure that occurs following immunisation against it. The release and action of chaperonin 10 from platelets adds a further interesting candidate in the long list of potent cellular mediators released by platelets.

Platelets in psychiatric and neurological disorders

Brian E Leonard

Pharmacology Department, National University of Ireland, Galway, Ireland

Introduction

The difficulty in studying neurotransmitter function in psychiatric patients is legion, despite the initial optimism that surrounded the studies of amine metabolites and neurotransmitter receptors in the brains of suicide victims. It is now generally accepted that factors such as the contribution of amine metabolites from the spinal cord, and the lack of diagnostic certainty in the case of suicide victims, raises serious difficulties when attempting to define the relationship between changes in neurotransmitter function and the symptoms of a psychiatric or neurological disease.

It is against this background that pharmacologists have become interested in the blood platelet as a peripheral model of the nerve terminal. The platelet has many important features in common with the nerve terminal[1]. Thus (a) both the neuron and the platelet contain mitochondria and dense core vesicles in which transmitters are stored. (b) In both cases, the mitochondria provide energy for intracellular functions and also contain monoamine oxidase that catabolizes any free monoamines. (c) The vesicle acts as a storage site for serotonin in the platelet, and most transmitters in addition to serotonin in the neuron, and the release of the amines following activation of the platelet or neuronal membrane is facilitated by a calcium dependent excitation-excretion coupling mechanism. (d) Both platelets and neurons are of the same ectodermal origin and contain neuron specific enolases that, apart from platelets, are only found in nervous tissue. (e) Both platelets and neurons contain functional neurotransmitter and neuromodulator receptor sites on their outer membranes. (f) Both platelets and neurons contain energy-dependent amine transporter sites on their outer membranes. There are also major differences between the platelet and the neuron. Thus the neuron functions as part of a complex nervous network and is not directly influenced by changes in the blood whereas the platelet has no direct connection with the nervous system, has a relatively short half-life (about 10 days) and is directly influenced by changes in the composition of the blood. In addition, whereas the synthesis and metabolism of the neurotransmitters takes place within the neuron, the platelet does not synthesize serotonin, the only major amine transmitter that is of importance for platelet function. In the platelet, the synthesis of serotonin occurs within the amine precursor, uptake and decarboxylation system (APUD cell) which contains all the relevant enzymes necessary for the synthesis for serotonin from its tryptophan precursor. The APUD cells are of the same embryonic origin as the neurons and platelets and may therefore be considered to form part of the paraneuronal system[1]. Thus, while the platelet may be considered to be a useful peripheral model of the serotonergic neuron, it would be incautious to consider it as a relevant model of all types of neuron in the brain. However, a major advantage in studying the platelet lies in its ease of access in patients.

The purpose of this chapter is to critically consider the value of studies of platelet function in some major psychiatric diseases in particular and to demonstrate how such studies may help to understand their pathological bases and response to treatment. It must be emphasized that a disproportionately large amount of data comes from studies of platelet function in depression.

Physiological changes in platelet function of relevance to neurotransmission in the brain

Platelet aggregation is a crucial step in normal hemostasis. Following stimulation by a variety of physiological stimuli such as adenosine diphosphate, adrenaline, serotonin,

thrombin and collagen, platelets undergo a shape change associated with pseudopodia formation and the initiation of the primary reversible phase of aggregation. After a strong physiological stimulus, secretion of the platelet contents takes place with the release of granule proteins and serotonin and the recruitment of additional platelets. This gives rise to the secondary irreversible phase of aggregation. Studies of the two phases of platelet aggregation under controlled conditions in vitro have been valuable in elucidating the complex mechanisms involved in aggregation. These mechanisms have been reviewed by Kroll and Schafer[2] and Leung and Nachman[3] and will not be considered further here.

Activation of platelet aggregation by biogenic amines occurs following the action of the agonists on alpha adrenoceptors and serotonin type 2 receptors[4]. As a consequence of such changes, it has been possible to apply amine-induced platelet aggregation to assess adrenoceptor and serotonin receptor function. For example, nearly two decades ago, Healy et al.[5] showed that a reduction in serotonin-induced aggregation occurred in a group of untreated endogenously depressed patients, an effect which was absent following effective treatment with either amitriptyline or trazodone. Qualitatively, similar changes were reported in a group of depressed patients treated with the selective serotonin reuptake inhibitor (SSRI) antidepressants sertraline and fluoxetine, and the tetracyclic antidepressant mianserin[6,7]. As the normalization of the serotonin-induced aggregatory response did not occur in those patients who failed to respond to antidepressant treatment, it is concluded that the serotonin-induced aggregatory response is a state marker of depression.

Another approach has been to determine serotonin-induced platelet shape change in the presence and absence of the serotonin 2 receptor antagonist ketanserin[8]. While no differences in the platelet shape change occurred between the depressed patients and their controls, it was found that effective treatment with nortriptyline increased platelet aggregation, while those who failed to respond showed no such change. Thus it may be concluded that antidepressants, irrespective of their presumed mechanisms of action, enhance 5-HT 2 receptor function on the platelet membrane. Brusov and coworkers[9] approached the problem of platelet aggregation in a slightly different way. These investigators determined the EC50 values of serotonin-induced aggregation in a small group of depressed women relative to their untreated controls, both before the start of drug treatment and up to 3 months after the commencement of treatment. They found that serotonin-induced platelet aggregation was reduced in the untreated patients but returned to control values in those who responded to treatment lending further support to the view that in depression the platelet 5 HT2 receptor is subfunctional, but returns to normal after effective treatment.

McAdams and Leonard[10] extended the studies of platelet aggregation by comparing a group of patients with major depression with a small group of patients with schizophrenia and with mania before and following effective therapy. They confirmed that effective treatment reverses the reduction in serotonin-induced platelet aggregation in depressed patients, but also showed that a similar reduction in serotonin responsiveness occurred in both schizophrenia and mania. In addition, it was also shown that the aggregatory response to collagen was significantly reduced in both schizophrenic and manic patients, but not in those who were depressed, and remained reduced even following clinical recovery. Thus, a decrease in collagen-induced platelet aggregation appears to be a trait marker of schizophrenia and mania. The action of collagen in inducing platelet aggregation would appear to involve changes in the polyunsaturated fatty acid composition of the membrane[11], which may suggest that the platelet membrane, and possibly the neuronal membrane, are functionally more rigid to physiological stimuli than is normal.

It may be argued that these changes in the aggregatory response to different stimuli are a result of the direct actions of the drugs used to treat the patients and/or due to the effects of the elevated cortisol concentrations which commonly occur in these conditions. This seems unlikely as unpublished evidence by McAdams and Leonard has shown that neither cortisol nor any of the antidepressants, when incubated with platelets and the aggregating agents in vitro had any influence on the aggregatory response.

From these studies, it may be concluded that studies of the aggregating responses of platelets to serotonin and collagen are of some value in identifying changes which are causally related to the pathology of the affective disorders and schizophrenia. However, the question arises regarding the cause of platelet malfunction. This has been the subject of several investigations beginning with those of McAdams et al.[12], who showed that there was a plasma factor which decreased the aggregatory response to serotonin in depressed patients and that its activity was significantly decreased in those patients following recovery. Other investigators had also implicated a plasma factor(s) as responsible for changes in the transport of ^{3}H-serotonin into platelets from depressed patients[9]. Nugent and colleagues[13] extended the studies on the plasma factor(s) by showing that it was stable to freezing, is present in both male and female depressed patients and is equally effective in inhibiting both the primary and secondary aggregatory response. In addition, the plasma factor was

Cambridge Books Online © Cambridge University Press, 2009

found to inhibit the aggregatory response to ADP, noradrenaline, adrenaline, thrombin, collagen and ristocetin. As all these agonists produce their effects by activating specific membrane associated receptors, it would appear that the plasma factor(s) acts on secondary or tertiary messengers within the platelet. Evidence in support of this hypothesis was provided by studies showing that high concentrations of the aggregating agents failed to reverse the inhibitory effects of the plasma factor[13]. It was also shown that the plasma factor(s) inhibited the aggegatory response to sodium fluoride (which activates the guanine nucleotide binding protein system within the platelet[14]), the calcium ionophore A[15] (which stimulates aggregation by increasing the influx of calcium into the platelet[16]) and the phorbol ester PMA (which mediates aggregation by activating protein kinase C[17]).

The identity of the plasma factor(s) is presently unknown, but all the experimental evidence suggests that its action may be at, or beyond, protein kinase C and within the platelet. Furthermore, preliminary studies suggest that the factor is absent from patients with obsessive compulsive disorder, panic disorder, schizophrenia or manic depression[18].

Role of calcium in platelet aggregation

A number of studies have shown that the 5-HT 2A receptor is dysfunctional in mood disorders. For example, the density of these receptors is increased in postmortem brain from depressed patients and suicide victims (for review, see Kusumi and Koyama[19]). In addition, there is evidence that platelets from depressed patients have an increased density of 5-HT 2A receptors which normalize when the patients respond to treatment[6,7,20]. Measurement of serotonin-induced intraplatelet calcium mobilization has also indicated that the 5-HT 2A receptor function is enhanced in unmedicated patients with bipolar disorder or in those with major depression[19,21]. However, unlike the changes in 5-HT 2A density, it appears that the altered calcium response in the affective disorders is a trait-dependent phenomenon. This has been confirmed by Yamawaki et al.[22] and by Berk et al.[23].

In a recent study of bipolar patients and those with major depression, Kusumi et al.[24] showed that those bipolar patients in the depressed phase of their illness who exhibited an enhanced platelet calcium response to serotonin also demonstrated a good clinical response to mood-stabilizing drugs.

The results of this series of clinical studies suggest that serotonin-induced calcium mobilization in the platelet is defective in patients with affective disorders and that, if this is also reflected in the neuron, may help to explain the changes in central serotonin function in these patients. The changes induced by the activation of the 5-HT 2A receptors on the platelet membrane would not appear to be due to those in the basal calcium concentration or in the calcium availability. Thus Dubovsky et al.[15,25] found no difference in either the baseline platelet calcium concentration or in the platelet-activating factor and thrombin-induced calcium response in a group of patients with major depression.

Changes in platelet ^{3}H-serotonin reuptake

Properties of the serotonin transporter on the platelet membrane

The serotonin transporter on both the platelet and the neuronal membrane show absolute dependence on extracellular sodium, a feature known to be characteristic of the Na^+/K^+ cotransport properties where energy, from mitochondrial ATP, for the inward solute transfer is coupled to the energetically favourable influx of Na^+ down its concentration gradient. It is also evident that extracellular Cl^- is absolutely necessary for the normal functioning of the serotonin transporter in the brain. As the platelet and the neuron are similar both in function and in response to physiological stimuli with respect to the serotonin transporter, studies of the transporter on the platelet membrane have some validity. It should be noted, however, that although the structure of the serotonin transporter on the platelet and neuronal membrane of the rat are identical, there appears to be at least three different variants of the transporter in human tissue[26]. Which of these variants is common to the neuron and platelet in human is uncertain, so caution must be expressed in making assumptions about the relevance of changes in the platelet serotonin transporter to those occurring in the brain until this is clarified.

The transport of serotonin into platelets has similar kinetic characteristics to those reported to occur in neurons[27] and therefore it should be possible to use the information obtained from studies of the ^{3}H-serotonin transport into platelets not only to investigate possible changes in serotonergic function in psychiatric and neurological diseases but also to assess how psychotropic drugs may modulate serotonin transport. The most extensive literature on serotonin reuptake into platelets relates to patients with major depression. The first report, by Tuomisto and Tukiainen[28], showed that the serotonin

Table 59.1. Effect of antidepressant treatments on the V_{max} of ^{3}H-serotonin reuptake into platelets from depressed patients

Drug	Effect	Reference
Tricyclic antidepressants	Non-reversal of reduced V_{max}	30
Mianserin	Reversed reduced V_{max}	118
Imipramine	Reversed reduced V_{max}	33
Amoxepine	Non-reversal of reduced V_{max}	33
Nortriptyline	Reversed reduced V_{max}	120
Amitriptyline and Trazodone	Reversed reduced V_{max}	5
Lithium	Reversed reduced V_{max}	118
Dothiepin,mianserin and ECT	Reversed reduced V_{max}	74,75
Nomifensin	Reversed reduced V_{max}	34
Sertraline	Reversed reduced V_{max}	6
Peptide analogue with antidepressant effects (INN 00835)	Reversed reduced V_{max}	119

reuptake was decreased in depressed patients. This was confirmed by many other investigators[5,6,29–34]. However, some studies have failed to report an abnormality in platelet serotonin reuptake in depressed patients[35–38] and therefore it has been claimed that a reduced serotonin transport into platelets from depressed patients could be a valuable biological marker of depression[39]. Table 59.1 summarizes the effects of antidepressant treatments on 3H-serotonin reuptake in depressed patients. The majority of these studies indicate that effective drug treatment results in the normalization of serotonin transport suggesting that this is a state marker of depression.

Despite the largely confirmatory evidence that the V_{max} for ^{3}H-serotonin reuptake is a state marker of depression, there is also some preliminary evidence that a similar change occurs in some patients suffering from migraine, hypertension, asthma and myeloproliferative disorders[40]. Patients with panic disorder have also been reported to have a reduced platelet serotonin reuptake, at least in some studies[6,41] but not in others[17,42]. There is also experimental evidence that chronic alcohol administration results in a decreased V_{max} for serotonin reuptake into platelets from rats[43], an effect that was reversed by the chronic administration of omega 6 fatty acids.

The cause of the decreased V_{max} values for serotonin reuptake in untreated depressed patients is difficult to explain. There is evidence that the frequency of the serotonin transporter gene long allele is significantly increased in severely depressed patients[44], which suggests that a functional polymorphism in the serotonin transporter may be associated with severe depression and suicide. In addition, there is evidence that the number of serotonin transport sites on platelet membranes from depressed patients is decreased, and the platelet inositol triphosphate concentration increased[45]; the latter returned to control values following the successful treatment of the patients with a SSRI antidepressant.

One plausible possibility is that hypercortisolemia, a frequent occurrence in depression, is primarily responsible for the change in platelet serotonin dynamics[46]. However, more recently Owens and coworkers[47] examined the changes in serotonin dynamics in rats following the induction of a chronic hyperglucocorticoid state. The results of this study showed that a raised plasma glucocorticoid concentration did not directly affect either the reuptake of platelet serotonin or the affinity of ^{3}H-citalopram for transporter on platelets or synaptosomes. It would therefore appear that changes in the concentration of the glucocorticoids is unlikely to play a role in causing the abnormal serotonin transport associated with depression and other disorders. The possibility remains that the factor(s) that inhibit the serotonin induced aggregatory response of platelets might also inhibit serotonin transport. There is preliminary evidence for such an effect[12] but whether this is the same or a different factor(s) is unknown.

Finally, it is possible that the availability of tryptophan for the APUD cells is abnormal in depression[48], which would adversely impact on the vesicular pool of serotonin in the platelets. However, any change in the availability of the serotonin precursor would not appear to be reflected in the platelet serotonin concentration as there is little evidence of any change in the basal concentration in depressed patients[49,50], even though different types of antidepressants, on chronic treatment, were found to significantly decrease platelet serotonin.

^{3}H-imipramine and ^{3}H-paroxetine binding sites on the platelet serotonin transporter

The description of high affinity binding sites for ^{3}H-imipramine in rat and human brain[51,52], as well as on platelets[53,54] has helped to focus attention on the role of modulatory sites in the transport of serotonin. In spite of the methodological differences, many studies have reported a low density (B_{max} values) for ^{3}H-imipramine binding on the platelet membrane from drug-free depressed patients[53–57]. Ellis and Salmond[58] performed a meta-analysis of 76 studies in which platelet ^{3}H-imipramine binding was measured in depressed patients and healthy controls. The result of this analysis showed a highly significant decrease in the B_{max} in the depressed patients. More recent studies have also shown that the B_{max} of the imipramine binding returns to control values after the symptoms of depression have remitted[59–62]. However, the influence of medication on imipramine binding sites is less clear, even though some investigators have shown that antidepressant treatment and concomitant recovery is associated with the increase in the B_{max} values[57]. The reason for the lack of consensus may be related to the heterogenous populations of depressed patients studied, differing methodology for determining platelet ^{3}H-imipramine binding, seasonal factors and the duration of the drug free status of the patients. Another factor that could influence the B_{max} value relates to the plasma cortisol concentration. Unlike ^{3}H-serotonin reuptake or aggregation, a reduction in the B_{max} of platelet imipramine binding correlates well with the cortisol concentration[63], is low in patients with Cushing's disease[64] and in depressed patients who are dexamethasone non-suppressors of cortisol[65]. Thus studies of the ^{3}H-imipramine binding sites on the platelet serotonin transporter may act as a useful marker of depression, but it is uncertain whether this is a state or trait marker of the condition.

Paroxetine is a more specific ligand for labelling a single class of binding sites on the serotonin transporter than imipramine[60] and therefore it would be anticipated that studies in which this ligand, rather than imipramine, is used would give clearer evidence of any abnormality in the serotonin transporter. However, in the few studies in which ^{3}H-paroxetine has been used, no differences have been found between depressed patients and their controls[66–68]. More recently, Nelson and coworkers[69] found no difference between patients with major depression and comorbid obsessive compulsive disorders and their controls.

The assumption has been made that the changes in paroxetine, and possibly also imipramine, binding to the serotonin transporter on the platelet membrane reflect similar changes to those occurring on the neuronal membrane. There is experimental evidence to suggest that this may not be the case. Thus Moret and Briley[70] demonstrated that, while central lesions of the serotonergic system markedly reduced the ^{3}H-paroxetine binding to neuronal membranes, the binding to platelet membranes remained unchanged. It would therefore appear that studies of the imipramine and paroxetine binding sites on the platelet membrane are of only very limited value as markers of the disease state.

The role of platelet adrenoceptors in depression

It is well established that platelets are involved in the pathogenesis of vascular damage in atherosclerosis and arterial hypertension. The reactivity of platelets in vivo is influenced by the activity of the sympathoadrenal system, plasma concentrations of atherogenic lipids and changes in the fluid dynamics of the blood[71]. There is evidence that the human platelet membrane contains both alpha 2A adrenoceptors and dopamine receptors; the alpha 2A are the most prominent and probably responsible for the physiological and pathological changes in platelet function associated with the cardiovascular system. Increases in circulating catecholamines, (for example, caused by physical or mental exercise) initiates responses which include platelet aggregation, secretion of serotonin from the storage granules and activation of the arachidonate pathway[71]. There is evidence that genetic polymorphism of the alpha 2A adrenoceptor encoded by chromosome 10 is associated with hypertension and increased adrenaline mediated platelet aggregation in human[72]. Furthermore, in hypertensive patients, it was shown that subthreshold concentrations of adrenaline potentiated thrombin-induced platelet aggregation.

Epidemiological studies indicate that patients with major depression are predisposed to heart disease. Whether such a predisposition is linked to a polymorphism of the alpha 2 adrenoceptor, as in some types of hypertension, is unknown. However, there are numerous studies showing that the density (B_{max}) of alpha 2 receptors on the platelet membrane of depressed patients is increased. Some of the first studies were published by Garcia Seville et al.[73] and by Healy et al.[73–75] and showed that an increase in the density of alpha 2 receptors on the platelet membranes of drug-free depressed patients returned to control values in those patients who recovered following treatment. Similar increases in the alpha 2 receptor density were sub-

Cambridge Books Online © Cambridge University Press, 2009

sequently reported by Takeda et al.[76], Garcia-Sevilla et al.[77], by Werstiuk et al.[78] and by Gurguis et al.[79] However, there are also studies in which the density of these adrenoceptors in depressed patients was either unchanged or even decreased[80–85]. Possible reasons for these differences may lay in the criteria used for the patient selection, differences in the methods used to prepare the platelet membranes and the differences in the specificities of the ligands used to determine the receptor density. For example, partial agonists, such as ^{3}H-clonidine, indicate an increased density of the alpha 2 receptors[73], while no differences were found when alpha 2 antagonists such as ^{3}H-yohimbine or dihydroergocriptine were used[80].

Determination of the density of a receptor on the platelet membrane does not tell the investigator anything about the functional activity of the receptors. It is therefore essential to determine the activity of the second messenger systems that are activated by the adrenoceptors in order to assess possible changes in functional activity. Newman and coworkers[86] determined both the basal adenylate cyclase activity and also the activities of the second messenger systems that were triggered by sodium fluoride, prostaglandin E1 and forskolin in a group of patients with major depression. These investigators reported no differences in either the basal or stimulated activity of adenylate cyclase in those patients treated with clomipramine together with lithium. Similar results were reported by Garcia-Seville et al.[77], who incidentally also reported such changes in the brains of suicide victims[87]. While such studies suggest that the activity of adenylate cyclase is unchanged in depression, it is known that the alpha 2 receptor exists in different conformational states and therefore any functional change in depression may specifically reflect one of these states which differs from that occurring in the non-depressed state. For example, Gurguis and coworkers[79] showed that the alpha 2A receptor can exist in a low and a high conformational state that is regulated by the Gi protein. In a group of patients with major depression, these investigators showed that the effects of imipramine treatment on the clinical response depended on the conformational state of the receptor. Those patients with a high density of alpha 2 receptors in the higher state had a more positive response to the antidepressant treatment.

Another method for assessing the functional activity of alpha 2 adrenoceptors is to determine platelet aggregation in response to specific alpha 2 agonists. Garcia-Seville et al.[77] demonstrated that the aggregatory response to agonists such as UK-14304 was potentiated in depressed patients, indicating a receptor supersensitivity, but normalised after effective treatment with tricyclic antidepressants. It may be speculated that, although adenylate cyclase is unchanged in depression, it is possible that the activity of protein kinase C is defective, or that the alpha 2 receptor-mediated inositol triphosphate is activated[88].

In addition to the alpha 2 adrenoceptor located on the platelet membrane, there is also evidence that beta adrenoceptors play a role in platelet adhesion and aggregation following prothrombin stimulation. Thus platelet beta 2 receptors mediate inhibition of aggregation and adhesion by stimulation of nitric oxide synthase activity, changes which follow the receptor mediated increase in adenylate cyclase activity[89]. It is not known how the density of platelet beta receptors changes in response to treatment, even though there is considerable evidence to show that the density of beta 2 receptors on lymphocyte membranes is increased in the untreated depressed patient and return to control values following effective treatment[5,6,20]. However, there is some preliminary evidence to indicate that the aggregation response to adrenaline of platelets from normal subjects is reduced when incubated with plasma from depressed patients[18,90], suggesting that an inhibitory plasma factor(s) present in untreated depressed patients affect(s) the functioning of beta adrenoceptors on the platelet membrane.

Because of their lack of specificity for the alpha 2 receptor, attention has recently been focused on the imidazoline receptors, which are also located on platelet membranes and to which many of the alpha 2 receptor ligands are now known to bind. Piletz and coworkers[91] studied changes in the I1 imidazoline receptors and alpha 2 adrenoceptors on platelets from depressed patients. Like the alpha 2 receptors, the platelet I1 receptors were increased in untreated depressed patients, but returned to control values following effective treatment. However, whereas there was a correlation between the plasma adrenaline concentration and the platelet alpha 2 receptor density, there was no correlation between the I1 receptor density and the plasma catecholamine concentration. Differences were also found in the responsiveness of these different receptors and their changes in response to antidepressant treatments. Thus the I1 receptors were decreased in response to both serotonin and noradrenaline reuptake inhibitors, whereas the alpha 2 receptors were primarily responsive to noradrenaline reuptake inhibitors. The results of this study stress the importance in independently assessing both the alpha 2 and imidazoline receptors on platelet membranes before drawing conclusions regarding the possible significance of platelet alpha 2 receptor changes in psychiatric states.

Changes in platelet function in headache

A change in the blood serotonin concentration is believed to be a major factor in the initiation of headache particularly in patients with migraine. There is evidence that there is an increase in the basal nitric oxide synthase activity in the platelets from migraine sufferers, which is independent of an acute migraine attack. Sarchielli and coworkers[92] therefore investigated the variation in the nitric oxide synthase and cyclic guanosine monophosphate (cGMP) levels in a group of patients subject to a daily migraine headache by assessing the effect of collagen-induced platelet aggregation on these parameters. The results showed that there was a reduction in the collagen aggregatory response, which was coupled to an increase in both nitric oxide and cGMP synthesis, a significant increase in intracytosolic calcium and a reduction in the platelet serotonin, content. These results therefore suggest that migraine headache, which follows the depletion of platelet serotonin is a reflection of the increased platelet nitric oxide synthesis and increased intracytosolic calcium that follows an abnormal platelet response to collagen stimulation. However, other investigators have cast doubt on the relationship between the free blood serotonin concentration and the pain experienced in a migraine attack. Thus Panconesi et al.[93] reported no correlation between the mechanical overdistension of the hand–forearm veins and the whole blood serotonin concentration. It is therefore possible that other platelet factors, such as nitric oxide, may be the primary cause of the pain associated with the venous distension that occurs in migraine. For example, adenosine, which acts as a potent vasodilator and participates in the control of cerebral and meningial blood flow, is a major factor in migraine headache. For this reason, Guien and colleagues[94] assessed the interaction between adenosine and its antagonists on the release of platelet serotonin. They showed that, during a migraine attack, there was a marked increase in the circulating concentration of adenosine which was associated with the pain. Furthermore, activation of the adenosine A2 receptor on the platelet membrane was found to inhibit serotonin reuptake into platelets, an effect which could result in the rapid elimination of platelet serotonin in migraine sufferers. These results raise the possibility that both adenosine and serotonin play crucial roles in migraine and that adenosine antagonists may be an effective complementary treatment of the condition.

Headache may also be associated with allergic factors and therefore the increase in blood histamine, which may rise in allergic and inflammatory conditions, could play a role. There is evidence, for example, that platelets can store and take up histamine from the blood by an energy dependent process, the uptake being blocked by H1 histamine receptor antagonists[95]. Thrombin is known to release histamine from platelet stores and extracellular histamine causes platelet aggregation and serotonin release. This raises the possibility that headache associated with allergies and inflammatory processes may cause pain not only due to its vasoconstrictor action but also by increasing the release of platelet serotonin.

Changes in platelet function in autism, aggression and impulsivity

Although the literature linking an abnormality in platelet serotonin function with these disorders is limited, there are preliminary indications that there may be a link between changes in serotonin transport into platelets which may reflect the symptoms of these disorders. For example, Cook and Leventhal[96] have shown that the platelet serotonin uptake is increased in patients with autism, which may support the finding that SSRI antidepressants are effective in reducing the ritualistic behaviour and aggression in autistic patients. However, in a group of aggressive patients who were not autistic, Maguire et al.[97] reported no correlation between the psychopathology ratings, aggression and hostility scores and the ^{3}H-paroxetine binding sites on the platelet membrane. Similar results have been obtained in studies of aggressive behaviour in schizophrenic patients[97]. Other studies, however, showed that delinquent boys had a significantly reduced B_{max} for serotonin 2A receptors on platelet membranes that appear to correlate with the degree of antisocial behaviour[98]. The results of the latter two studies emphasize the importance in studying several parameters of platelet serotonin function and that ^{3}H-paroxetine binding studies are of little value in attempting to assess peripheral serotonin function in patients with psychiatric or neurological disorders.

Changes in platelet function in bipolar disorder and schizophrenia

While there has been considerable attention paid to changes in platelet function in patients with major depression, few studies to date have attempted to assess such changes in those with mania or schizophrenia. The comparison between mania and schizophrenia is particularly important not only because the acute symptoms of these disorders frequently overlap[99], but also because such patients are commonly treated with neuroleptics, which

Cambridge Books Online © Cambridge University Press, 2009

may indicate that these conditions share a common biochemical pathology.

Meagher and Leonard[100] studied the changes in platelet aggregation in a small group of patients with acute mania and schizophrenia and compared the aggregation responses to serotonin, noradrenaline and adrenaline with appropriate controls. In an attempt to determine whether the changes in platelet aggregation were correlated with the response to treatment, changes in the aggregatory response to serotonin were also studied during the first 15 days of treatment. The results of this investigation indicated that the serotonin-elicited response was significantly enhanced during the acute phase of the illness, but returned to control values following several weeks of treatment. No changes were found in the adrenaline or noradrenaline-induced platelet aggregatory responses nor was there a correlation between the symptoms of mania, as assessed by the Young Mania Scale, and the serotonin-induced aggregation response. However, unlike the results of the study by McAdams and Leonard[12], no change was found in the serotonin-induced aggregation response in schizophrenic patients. One possible explanation for these differences may lie in the fact that, in the latter study, the patients were unmedicated whereas they were on neuroleptics in the study by Meagher and Leonard[100].

Several studies have been made of changes in platelet serotonin transport in patients with mania. Patients with mania have a higher serotonin content and a higher serotonin reuptake rate than control subjects[39,101–104]. Thus it may be concluded that patients with mania may have an increased presynaptic serotonin concentration. In support of this view, Southam and coworkers[105] have shown that the mood-stabilizing agent lamotrigine dose dependently inhibits the serotonin reuptake into platelets and synaptosomes.

Changes in platelet function in patients with anxiety disorders and fibromyalgia

Both clinical and experimental evidence suggests that an abnormality in noradrenergic and serotonergic function play a crucial role in anxiety disorders. Clinically, it has been shown that the SSRI antidepressants, such as clomipramine and fluvoxamine, reduce the incidence of panic attack. The infusion of lactate into susceptible patients consistently initiates a panic attack. Lingjaerde[106] reported that lactate facilitates the transport of serotonin into platelets which suggest that, if this also occurs in the brain, the intersynaptic concentration of serotonin will be lowered, which could lead to a reduction in the inhibitory effect of serotonin on the firing of the locus coeruleus, the main noradrenergic centre in the brain. Such a mechanism may account for the observed changes in both the serotonergic and noradrenergic systems in patients with panic attack. In support of the imbalance between the noradrenergic and serotonergic systems in panic attack, a detailed study of a group of panic disorder patients before and during treatment with tricyclic antidepressants showed that platelet aggregation to noradrenaline was increased, while that of serotonin was decreased, before treatment and remained largely unchanged following effective treatment[41]. The rate of serotonin transport (V_{max}) was also shown to be decreased, while the density of the serotonin 2A receptors on the platelet membranes was increased in the panic disorder patients irrespective of the response to drug treatment. In a follow-up study of some of the patients conducted some 5 to 6 years later, it was found that the platelet serotonin reuptake was still significantly reduced despite the apparent recovery of the patients[107]. Platelet responses to a number of different aggregatory agents was unchanged relative to the controls. There are qualitatively significant differences between patients with panic disorder and those with depression in that most of the abnormal parameters of platelet function return to control values in those with depression (i.e. act as state markers) whereas many remain abnormal in those with panic disorder (i.e. act as trait markers). However, it should be added that not all investigators have found these changes in patients with panic disorder. Thus some[108] have found no change in ^{3}H-serotonin reuptake into platelets, while others have reported an increase in the serotonin uptake[109]. Similarly, some investigators have shown an increase in the density of alpha-2 adrenoceptors on platelet membranes[6] while others[110] reported no change.

Of the other anxiety disorders in which platelet function has been investigated, there is evidence that the ^{3}H-imipramine binding sites on the serotonin transporter are decreased in patients with obsessive compulsive disorder, the decrease correlating with the severity of the clinical symptoms[111]. Effective treatment of these patients with a SSRI antidepressant largely reversed this abnormality.

Although fibromyalgia cannot be classified as either an anxiety or as an affective disorder, some of the symptoms of the condition do overlap with these disorders. It is therefore of interest to find that the density of the alpha 2 adrenoceptor ligand ^{3}H-rauwulscine on platelet membranes was significantly higher in fibromyalgia than in the control subjects and that the administration of the SSRI sertraline did not reverse these changes. If the results of these platelet studies can be extrapolated to the brain of the fibromyalgia patient, they do suggest that there is a

Cambridge Books Online © Cambridge University Press, 2009

supersensitivity of the inhibitory presynaptic adrenoceptors that may contribute to the general malaise and dysphoria which characterize these patients.

Changes in platelet serotonin transport have also been investigated in women with premenstrual syndrome by Steege and colleagues[112]. It was reported that reduced ^{3}H-imipramine binding occurred in these patients; the decrease in the binding did not correlate with the Beck Depression Inventory Scores, however. Thus changes in serotonergic function may contribute to premenstrual dysphoric symptoms.

Platelet changes in alcoholism

There is experimental evidence to show that the reuptake of ^{3}H-serotonin into platelets is significantly reduced when rats are fed an alcohol rich diet for a period of 21 days[43]. This adverse effect of alcohol on the platelet membrane is reversed by the concurrent administration of a polyunsaturated fatty acid-rich diet, which counteracted the depletion of these fatty acids in the platelet membranes. By contrast, several clinical studies have reported that the platelet ^{3}H-serotonin uptake in alcoholics was higher in alcoholics than in their controls[113], a result which was supported by the later findings of Ernouf et al.[114] and Faraj et al.[115] More recently, Javours and coworkers[116] studied changes in ^{3}H-serotonin reuptake in a group of alcohol-dependent male subjects in which those patients in the early onset category (i.e. they began heavy drinking under the age of 25) were compared with those in the late onset category (i.e. who began heavy drinking after the age of 25). The results indicated that the ^{3}H-serotonin reuptake was higher in the early onset alcoholics than in the late category group, or in the respective controls. Thus, there is a disparity between the experimental and clinical findings with regard to the effects of chronic alcohol consumption on the platelet serotonin transporter. With regard to the other platelet parameters of serotonin function, no change has been reported in the serotonin 2A receptor-stimulated calcium response in platelets in alcoholic men[117].

Conclusions

Much of our understanding of the role of serotonin in psychiatric and neurological disorders is based on peripheral marker studies of serotonin function. As illustrated in this chapter, most of these studies have utilized the platelet as a model of the serotonergic neuron and have concentrated on determining changes in activity of the serotonin transporter, changes in the density and responsiveness of the serotonin 2A receptor and the alpha 2 adrenoceptor on the platelet membrane, changes in the ^{3}H-imipramine binding sites on the serotonin transporter and, finally, changes in the intracellular calcium response of the platelet to serotonin.

This chapter has summarized the results mainly of clinical studies illustrating the importance of the platelet in obtaining an insight into the changes in serotonergic, and to some extent noradrenergic, function in major depression, schizophrenia, mania, the anxiety disorders and also preliminary evidence citing disorders of platelet function in patients with headache, alcoholism and autism. Evidence was also presented that some of these changes in platelet function could be due to plasma factor(s) that, in the case of patients with major depression, appear to be state markers of the condition.

Thus studies of platelet function have been invaluable in enabling an insight to be gained into the role of serotonin in a number of psychiatric and neurological disorders.

Introduction

The term inflammatory bowel disease (IBD) encompasses two chronic inflammatory disorders of the gastrointestinal tract, ulcerative colitis and Crohn's disease[1]. The aim of this chapter is to review the abnormalities of platelet number, morphology and function which occur in IBD, the possible role of platelets in its pathogenesis, and the relevance which pharmacological modification of platelet function may have to its treatment.

Inflammatory bowel disease

Ulcerative colitis affects only the colon, while Crohn's may involve any part of the bowel from mouth to anus. The incidence of ulcerative colitis is about 10/100 000/year, and of Crohn's disease about half that figure: their combined prevalence approximates 200/100 000 of the population. Both diseases are commonest in the Western world, and their most frequent age of onset is 20–35 years.

Clinical features

Ulcerative colitis and Crohn's disease of the colon most commonly present with bloody diarrhea, while Crohn's disease of the small intestine tends to cause not only diarrhea but also abdominal pain, weight loss, malaise and fever. Both diseases are characterized by a waxing and waning natural history, and may be complicated, in patients with chronic extensive colitis, by the development of colorectal cancer. Ulcerative colitis and Crohn's disease may be associated with extraintestinal manifestations including iriitis, erythema nodosum, pyoderma gangrenosum, joint disease, a spectrum of hepatobiliary disorders and systemic thromboembolic events.

Thromboembolic disease

Since the 1930s, clinical series have reported that the incidence of arterial and venous thromboembolic disease is increased in patients with IBD, lying between 1 and 8% (Table 60.1). Autopsy studies indicate that underdiagnosis in life is common, and that the true incidence of thromboembolic diseases may be higher (7–41%).

Many of the patients described in the various series have more than one risk factor for thromboembolic events: these include recent abdominal surgery, fluid depletion and bed rest. However, several studies have indicated that thromboembolism in IBD is also common in fully ambulant patients whose disease is in clinical remission[7,12–15].

Treatment

Corticosteroids are the most effective medical treatment of active IBD. Aminosalicylates such as sulfasalazine and mesalazine are useful in the maintenance of remission in ulcerative colitis and are moderately useful in active IBD.

Table 60.1. Increased incidence of thromboembolic disease in inflammatory bowel disease

Clinical studies	Number of cases examined	Incidence of thromboembolic disease (%)
Bargen and Barker (1936)[2]	1500	1.2
Jankelson et al. (1942)[3]	145	3.6
Ricketts and Palmer (1946)[4]	206	1.9
Dennis and Karlson (1952)[5]	261	7.5
Edwards and Truelove (1964)[6]	647	6.4
Talbot et al. (1986)[7]	7199	1.3
Webberley et al (1993)[8]	104	7.8
Postmortem Studies		
Bargen and Barker (1936)[2]	43	31
Warren and Sommers (1949)[9]	180	7
Sloan et al. (1950)[10]	99	41
Graef et al. (1966)[11]	100	39

Patients with refractory disease benefit from immunomodulatory agents such as azathioprine, 6-mercaptopurine, cyclosporin and methotrexate. In Crohn's disease antibiotics, a liquid formula diet and anti-TNF alpha antibody (infliximab) may also be useful. Despite these medical measures, surgery to remove the inflamed bowel is required in up to 20% of patients with ulcerative colitis and in 70% of those with Crohn's disease.

Etiopathogenesis

The Etiopathogenesis of both types of IBD is gradually being unravelled. There is a genetic predisposition to both ulcerative colitis and Crohn's disease, while environmental factors proposed in the pathogenesis include changes in gut microflora, smoking, various drugs and stress. In IBD there is an inappropriately excessive and prolonged mucosal inflammatory response. This response is amplified and perpetuated by recruitment of neutrophils, mononuclear cells and other leukocytes from the intestinal vasculature, with consequent release locally of a variety of proinflammatory cytokines (particularly TNF-alpha and interleukin-1 (IL-1)) and mediators (eicosanoids, platelet activating factor (PAF), reactive oxygen metabolites, proteases).

Multifocal mesenteric microinfarction in Crohn's disease

Evidence, mainly from the Royal Free Medical School in London, suggests that mesenteric vascular injury may be an early pathogenic event in Crohn's disease. This group have proposed a pathogenic sequence, perhaps induced by a persisting virus infection, which comprises focal granulomatous arteritis, fibrin deposition and arterial occlusion at the level of the muscularis mucosa, followed by tissue infarction and mucosal ulceration[16–18] (Fig. 60.1).

Platelets in IBD

Evidence suggesting that platelet activity may have a pathogenic role in IBD includes the increased incidence of thromboembolic disease in affected patients (Table 60.1) and the proposal that microvascular intestinal mucosal thrombosis may be an early event in Crohn's disease[16,17].

What are the abnormalities of platelet number, morphology and function reported in IBD?

Platelet number

Active IBD is associated with thrombocytosis, as first reported in 1968[19]. So high were the platelet counts in this initial study that three of the six ulcerative colitis patients described were given busulfan with reduction of platelet counts to normal in two and prolonged thrombocytopenia in the third. Further reports in larger groups of patients showed a close correlation with other markers of IBD activity, such as hypoalbuminemia, and raised ESR[20] and serum orosomucoid concentration[21]. These findings indicated that platelet counts provide a useful indicator of IBD activity.

Acute diarrhea due to IBD may be difficult to distinguish from infective diarrhea using clinical indicators. Platelet count may be a valuable discriminatory tool: 60% of patients with IBD but only 2% of those with infective diarrhea had a platelet count greater than 450×10^9/l in one study[22].

Platelet size and survival

Studies of mean platelet volume assessed by various methods have shown platelets to be smaller in patients with ulcerative colitis and Crohn's disease compared with controls[8,23,24], consistent with the increased platelet count. Decreased survival half time has been reported[8,20]: since the platelet count is raised in IBD, this observation indicates a greatly increased rate of platelet destruction.

Platelet aggregation

The first report of platelet aggregation, using Born's method, indicated an impaired response to adenosine

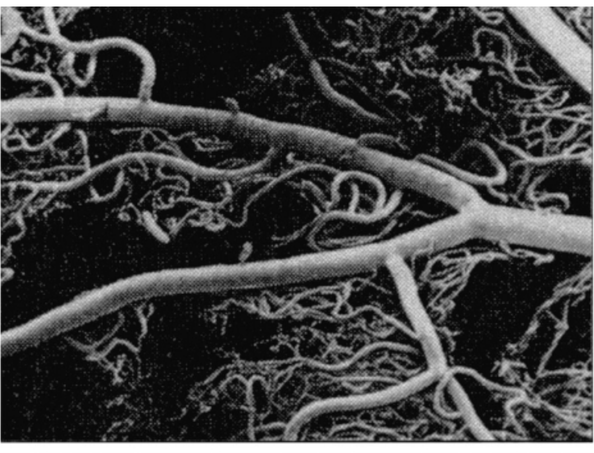

Fig. 60.1. Scanning electron microscopy of resin casts of normal intestine and vascular changes in Crohn's disease. (*a*) Subserosal vessels overlying submucous plexus in normal bowel. (*b*) Crohn's disease showing pronounced stenosis of all vessels subjacent to area of vascular proliferation. (Reproduced with kind permission of *The Lancet* and the author[16].)

diphosphate (ADP), adrenaline and collagen during active IBD which returned to normal with effective treatment[25]. The authors concluded that platelets in active IBD might be 'refractory' due to prolonged low-grade stimulation by ADP released from hemolysed erythrocytes or partially activated platelets; they postulated that their results, paradoxically, provided evidence for increased platelet activation in active IBD.

Subsequent studies have shown that platelet aggregation is enhanced in active IBD, with increased responses occurring to arachidonic acid, ADP, collagen and ristocetin[8,26–28]. Conflicting laboratory results are likely to be explained by differences in methods used for preparing platelet-rich plasma, the most aggregable platelets having been removed from platelet-rich plasma during its preparation from whole blood in the first study[25].

In quiescent IBD, no significant increase in response to ADP was seen in a group of 40 patients[29]. However, in six of these patients, and in none of the healthy controls, spontaneous platelet aggregation in vitro was noted. A later detailed study of platelet-rich plasma taken from 104 patients with active and quiescent disease also reported spontaneous aggregation in vitro in some of the samples[8]. Platelets from these patients, when resuspended in control plasma, continued to exhibit spontaneous aggregation; in contrast, plasma from IBD patients added to control platelets did not induce spontaneous aggregation. Increased aggregation in IBD appeared therefore, to be due to intrinsic platelet abnormalities rather than to the presence of stable proaggregatory compounds in the circulation.

Increased numbers of circulating platelet aggregates in vivo have been detected in patients with active IBD compared to healthy controls and patients with active rheumatoid arthritis not taking NSAIDs[28]. Furthermore, in patients with Crohn's disease undergoing surgery, increased numbers of circulating platelet aggregates were found in mesenteric venous blood in comparison with paired arterial and control mesenteric venous samples[30]: these results suggested that platelet activity was stimulated in the mesenteric microcirculation in Crohn's disease.

Very recent work has shown increased numbers of platelet–leukocyte aggregates in the peripheral blood of patients with IBD, a finding compatible with the hypothesis that platelet activation can influence leukocyte function in this disease[31].

Histological studies demonstrate platelet aggregation in the mesenteric microcirculation in IBD, rectal biopsies from patients with ulcerative colitis showing aggregates plugging mucosal capillaries[32].

Serum proteins and platelet surface markers

Increased plasma platelet factor 4 and beta thromboglobulin have been reported in IBD and, in contrast to results of platelet aggregation studies, did not appear to correlate with disease activity[8,28,33]. More recently, however, positive correlations have been found between these variables and

indices of activity of Crohn's disease and ulcerative colitis[34]. Differences in results are likely to reflect, primarily, the difficulty of assessing disease activity accurately in IBD with clinical and/or laboratory scoring systems.

Enhanced platelet activation, as indicated by expression of platelet surface P-selectin and GP53, is seen in peripheral blood samples in Crohn's disease and ulcerative colitis independent of disease activity[28,35,36] (Fig. 60.2).

P-selectin expression is greater in finger tip capillary blood than in venous samples in normal individuals. This gradient is exaggerated in patients with Crohn's disease, suggesting that their platelets may be more susceptible to activation in the microcirculation[37].

Possible explanations for abnormal platelet number, morphology and function in IBD

It is not easy to account for the abnormalities of platelet count, size and survival which occur in IBD.

Platelet count is the net result of the balance between production and destruction. IL-3 and IL-6, and thrombopoeitin stimulate thrombopoeisis[38]: plasma IL-6 at least is raised in active Crohn's disease[39].

The data suggesting that, despite being activated, platelets in IBD are small[8,23,24] presents a paradox, since in other disease settings reactivity of platelets correlates with their volume[40–42]. One possible explanation for a reduced platelet volume in the peripheral circulation in IBD could be sequestration or consumption of large activated platelets in the intestinal vasculature. Although such a phenomenon could contribute to reduced platelet survival, attempts to image sequestration in the mesenteric circulation in IBD using radiolabelled platelets have proved inconclusive to date[8].

Release of PAF[43] and thromboxane A_2 (TXA_2)[8] from neutrophils into the mesenteric circulation at the site of mucosal disease could precipitate or amplify platelet activation. A similar effect could be induced by monocytes or neutrophils activated by endotoxin[44], absorption of which is increased in IBD[45].

Basement membrane collagen exposed by endothelial cell damage in the mesenteric circulation is a further possible trigger for increased platelet activation[46]. Increased circulating levels of von Willebrand factor are found in patients with both active and quiescent Crohn's disease demonstrating that endothelial cell damage occurs in this condition[47]. Changes in the endothelium, such as that induced by persistent virus infection, could promote platelet adherence and activation prior to any structural endothelial cell damage[48]. Lastly, exposure of endothelial cells to endotoxin acts as a potent stimulus for platelet aggregation[49].

Pathogenic implications of abnormal platelet function in IBD

Enhanced platelet aggregation and activation may contribute to the pathogenesis of IBD not only through increased release of inflammatory mediators such as PAF, TXA_2, serotonin and reactive oxygen metabolites from

Cambridge Books Online © Cambridge University Press, 2009

platelets themselves, but also through the recruitment, chemotaxis and modulation of the activity of neutrophils, monocytes and other inflammatory cells[50].

Platelet phospholipid membrane provides the template for assembly of the coagulation factors (platelet factor 3) essential for the generation of thrombin and thereby fibrin. If mesenteric microinfarction followed by intravascular fibrin deposition is an important pathogenic mechanism in Crohn's disease[16,17], then platelets, whether activated, aggregated or both, are involved. Their effects in this context are likely to include not only fibrin generation, but also induction of neutrophil accumulation and vasoconstriction as a result of local release of TXA_2 and other soluble mediators.

Platelet aggregates are a potent source of platelet-derived growth factor (PDGF). The mitogenic properties of this factor have been implicated in the pathogenesis of clubbing in cyanotic heart disease[51]. It has been proposed that platelet 'clumps' which, in health, are fragmented in the pulmonary circulation, bypass the pulmonary circulation in cyanotic heart disease and become impacted in the digital circulation. Release of PDGF may stimulate smooth and fibroblast proliferation and thereby account for finger clubbing. The same argument could be applicable in active Crohn's disease[52].

Increased platelet numbers and activation may contribute not only to the pathogenesis of the intestinal lesion in IBD, as indicated above, but also to the increased risk of systemic thromboembolic disease in patients with IBD (Table 60.1).

Therapeutic implications of platelet dysfunction in inflammatory bowel disease

The observations described above provide the rationale for a possible place for antiplatelet agents as a therapeutic strategy in IBD[50].

5-Aminosalicylates

Drugs containing 5-aminosalicylic acid (5ASA) are used in the conventional treatment of IBD and have antiplatelet activity. Sulfasalazine inhibits platelet aggregation in vitro although only at high concentrations (IC_{50} 2 mM)[53]. 5-aminosalicylic acid (1 μM or more) in vitro inhibits platelet activation, while in patients with IBD, taking standard doses of 5-aminosalicylic acid orally inhibits platelet activation in vitro[36] (Fig. 60.3). In patients with IBD, blood and mucosal levels of 5–ASA are 1–10 μM and 1–1000 μM respectively after standard oral dosing[54,55]; thus the inhibition of platelet activation observed in vitro occurs at therapeutically relevant concentrations. However, aminosalicylates have many other pharmacological actions which could explain their efficacy in patients with IBD.

Aspirin and NSAIDS

Aspirin permanently inactivates platelet cyclooxygenase by acetylation and other non-steroidal anti-inflammatory drugs (NSAIDs) reversibly block cyclooxygenase; thus both exert an antiplatelet effect by inhibiting the formation of TXA_2. Not only do these agents have harmful effects on gastrointestinal mucosa[56,57] but NSAIDs have also been associated with reactivation of quiescent IBD[58–60]. It has been suggested that the deleterious effects of NSAIDs in patients with IBD may be due to inhibition of protective prostaglandin production with diversion of arachidonic acid metabolism towards increased synthesis of harmful leukotrienes[57,61]; other proinflammatory mechanisms could also be involved[57]. The possibility that NSAIDs may have a therapeutic role in the prevention of colon cancer suggests that, in the future, these drugs might be used as cancer prevention agents in patients with IBD; careful assessment of their toxicity/benefit ratio would be needed.

Thromboxane synthesis inhibitors

Specific thromboxane synthase inhibitors reduce the formation of TXA_2 in platelets and other cells. They ameliorate colonic inflammation in an animal model of IBD, are anti-inflammatory in studies with inflamed colonic biopsies in vitro, and have shown some benefit in preliminary trials in patients with ulcerative colitis[62–66]. However, a randomized, double-blind, placebo-controlled trial has shown no benefit for the thromboxane synthase inhibitor and receptor blocker, ridogrel, 5 mg daily in patients with active CD[67]. Although it therefore seems unlikely that specifically targeting thromboxanes will be a therapeutically useful approach in IBD, final rejection of the hypothesis that thromboxanes play a pivotal role in its pathogenesis requires a clinical trial using an antithromboxane agent more potent than ridogrel.

Heparin

Heparin has anticoagulant as well as other biological actions, including reduction of leukocyte recruitment[68]. Heparin also inhibits platelet function by antagonizing activation by cathepsin G and inhibiting collagen-induced aggregation[69,70]. While uncontrolled studies have suggested benefits of heparin therapy in patients with active

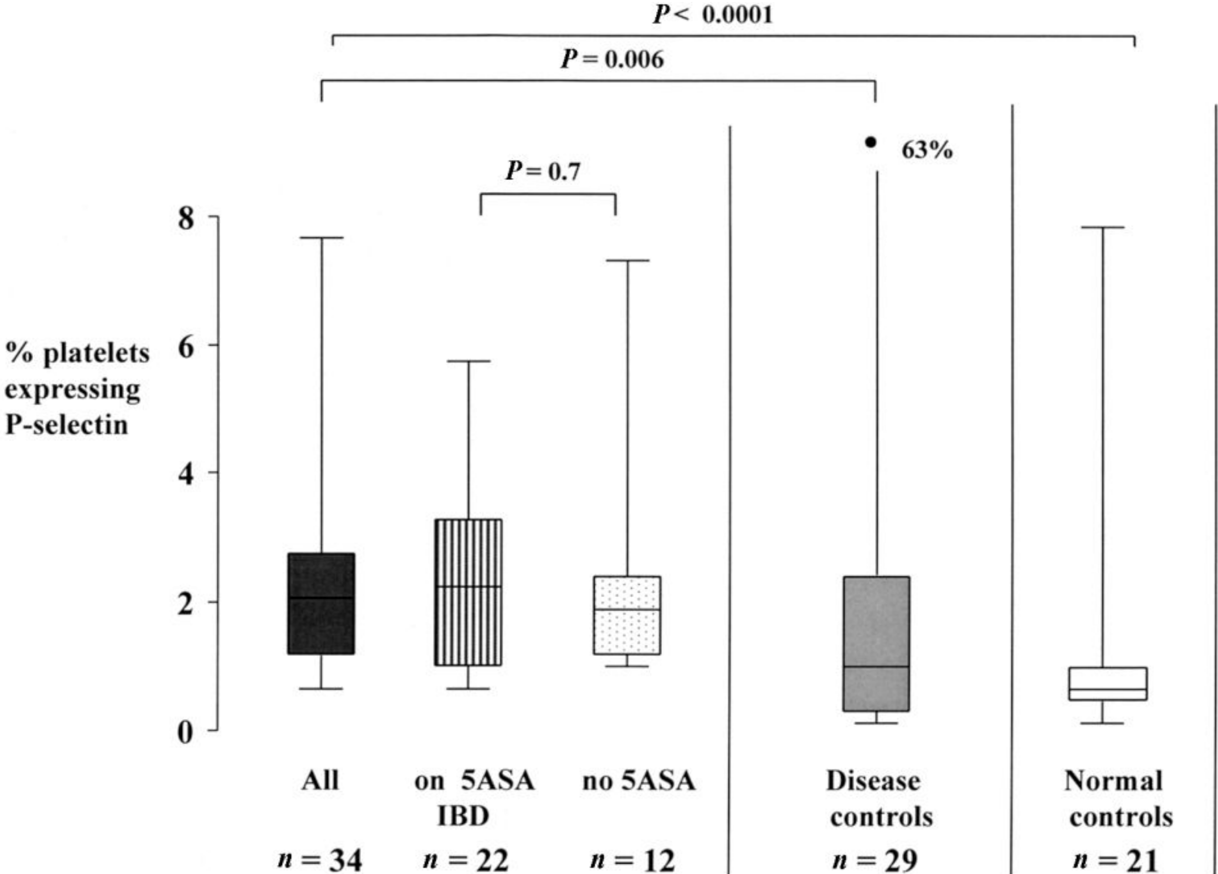

Fig. 60.3. Percentage of platelets expressing P-selectin immediately after venepuncture in patients with IBD, (on and not on 5ASA), disease controls and normal controls. Box and whisker plots are shown, where the box is the interquartile range, the horizontal line the median, and the whiskers show the highest and lowest values. Numbers of patients studied are shown below the *x*-axis. (Reproduced with permission from *Alimentary Pharmacology and Therapeutics*[36].)

UC and CD[71–73], a single controlled trial of heparin monotherapy in UC has had negative results[74]. To date, serious bleeding has been reported only rarely, but results of large-scale randomized controlled trials of heparin therapy in IBD are still awaited.

Antitumour necrosis factor-alpha (TNFα) antibodies

Monoclonal antibodies to TNFα are of proven benefit in patients with otherwise refractory Crohn's disease[75,76] and offer a new therapeutic approach to the treatment of IBD. Studies on markers of coagulation and fibrinolysis in patients with steroid-resistant Crohn's disease given monoclonal TNFα antibodies have shown decreased thrombin generation and endothelial activation markers in association with disease remission.[77] These findings suggest that this therapy could act, in part, by blocking intravascular fibrin deposition in the inflamed gut and thereby reducing any secondary ischemic damage and accelerating healing. However, the place of TNFα at the head of the proinflammatory cascade makes it unlikely that this is its only important mechanism of action in Crohn's disease.

Ticlopidine and clopidogrel

Ticlopidine and its analogue clopidogrel are antagonists of the platelet ADP receptor and are effective in patients with clinical manifestations of atherosclerosis in the coronary and cerebral circulations[78–80]. However, 20% of patients taking ticlopidine develop diarrhea: proposed mechanisms include lymphocytic colitis, small bowel dysmotility and altered prostaglandin production[81,82]. Diarrhea, as well as other serious side effects including thrombotic

Cambridge Books Online © Cambridge University Press, 2009

thrombocytopenic purpura, neutropenia and hepatic dysfunction, make a therapeutic role for this antiplatelet agent in patients with IBD unlikely. Clopidogrel appears to be better tolerated than ticoplidine. However, case reports of thrombotic thrombocytopenic purpura[83] and haemolytic uremic syndrome[84] associated with its use probably preclude assessment of clopidogrel in IBD.

GP IIb/IIIa antibodies

Monoclonal antibodies to the platelet fibrinogen receptor, GPIIb/IIIa, which reduce platelet–platelet and platelet–fibrinogen interactions, are used in patients undergoing coronary artery angioplasty[85]. However, these agents would be unsuitable for evaluation in IBD because of the risk of bleeding associated with their use.

Conclusion

Platelets appear to contribute to the pathogenesis of IBD, and conventional therapy with aminosalicylates inhibits platelet function. However, more specific antiplatelet therapy has not yet been shown to be efficacious in this setting, and it is possible that any benefits of agents potently interfering with platelet function would be outweighed by an increased risk of intestinal mucosal bleeding.

Aspirin

Carlo Patrono

Department of Pharmacology, University of Rome 'La Sapienza', Rome, Italy

Acetylsalicylic acid was first marketed as aspirin in 1899 and used extensively over the next decades as a prototypic non-steroidal anti-inflammatory drug (NSAID). Following the seminal discoveries made by John Vane and Bengt Samuelsson in the early 1970s on the biochemistry and pharmacology of arachidonic acid metabolism, the molecular mechanism of action of aspirin in inhibiting platelet function was elucidated by the elegant studies of Philip Majerus[1]. The development of whole blood thromboxane (TX)B_2 production as a biochemical endpoint for human studies allowed the characterization of the dose- and time-dependence of the antiplatelet effect of aspirin in the early 1980s. This, in turn, provided the rationale for a new wave of randomized clinical trials employing daily doses 10– to 50-fold lower than used empirically in the past[2]. A large database consisting of over 100 clinical trials of aspirin prophylaxis in a wide range of vascular disorders now provides solid grounds for assessing the balance between benefits and risks in the whole spectrum of atherothrombosis[3,4].

Mechanism of action of aspirin

The best characterized mechanism of action of the drug is related to its capacity to inactivate permanently the cyclooxygenase (COX) activity of prostaglandin H-synthase (PGHS)-1 and -2 (also referred to as COX-1 and COX-2)[5]. These isozymes catalyse the first committed step in prostanoid biosynthesis, i.e., the conversion of arachidonic acid to PGH_2. PGH_2 is the immediate precursor of PGD_2, PGE_2, $PGF_{2\alpha}$, PGI_2 and TXA_2. COX-1 and COX-2 are homodimers of a ~72 kDa monomeric unit. Within the enzymatic domain, there is a peroxidase catalytic site and a separate, but adjacent, site for COX activity at the apex of a long, hydrophobic channel. There are a number of important differences between COX-1 and COX-2, some of which may contribute to variable inhibitor selectivity[5].

The molecular mechanism of permanent inactivation of COX activity by aspirin is related to blockade of the COX channel as a consequence of acetylation of a strategically located serine residue (Ser529 in the human COX-1, Ser516 in the human COX-2), that prevents access of the substrate to the catalytic site of the enzyme[6]. Because aspirin has a short half-life (15–20 min) in the human circulation and is approximately 50– to 100-fold more potent in inhibiting platelet COX-1 than monocyte COX-2[7], it is ideally suited to act on anucleate platelets, inducing a permanent defect in TXA_2-dependent platelet function. Moreover, since aspirin probably also inactivates COX-1 in relatively mature megakaryocytes, and since only 10% of the platelet pool is replenished each day, once-a-day dosing of aspirin is able to maintain virtually complete inhibition of platelet TXA_2 production[8]. In contrast, inhibition of COX-2-dependent pathophysiologic processes (e.g. hyperalgesia and inflammation) requires larger doses of aspirin (because of lower sensitivity of COX-2 to aspirin) and a much shorter dosing interval (because nucleated cells rapidly resynthesize the enzyme). This results in markedly different benefit/risk profiles of the drug, depending on the clinical indication and its variable dose requirements[2,3].

Pharmacokinetics

Aspirin is rapidly absorbed in the stomach and upper intestine. Peak plasma levels occur 30 to 40 min after aspirin ingestion, and inhibition of platelet function is evident by 1 h. In contrast, it can take up to 3 to 4 h to reach peak plasma levels after administration of enteric-coated aspirin. If only enteric-coated tablets are available, and a rapid effect is required, the tablets should be chewed. The

oral bioavailability of regular aspirin tablets is approximately 40 to 50% over a wide range of doses[9]. A considerably lower bioavailability has been reported for enteric-coated tablets and sustained-release, microencapsulated preparations. Because platelet COX-1 is acetylated in the presystemic circulation, the antiplatelet effect of aspirin is largely independent of systemic bioavailability[9]. Both a controlled-release formulation[10] and a transdermal patch[11] with negligible systemic bioavailability have been developed in an attempt to achieve selective inhibition of platelet TXA_2 production without suppressing systemic PGI_2 synthesis. However, the clinical relevance of preparations relatively selective for the presystemic circulation remains to be established (see below).

The plasma concentration of aspirin decays with a half-life of 15 to 20 min. Despite the rapid clearance of aspirin from the circulation, the platelet-inhibitory effect lasts for the lifespan of the platelet because aspirin irreversibly inactivates platelet COX-1[1]. Aspirin also acetylates the enzyme in megakaryocytes before new platelets are released into the circulation. The mean lifespan of human platelets is approximately 10 days. Therefore, about 10% of circulating platelets are replaced every 24 h, and 5 to 6 days following aspirin ingestion, approximately 50% of the platelets function normally[1,8].

Pharmacodynamics

Effects on TXA_2 and PGI_2

Human platelets and vascular endothelial cells process PGH_2 to produce TXA_2 and prostacyclin (PGI_2), respectively[1]. TXA_2 induces platelet aggregation and vasoconstriction, while PGI_2 inhibits platelet aggregation and induces vasodilation. Aspirin is antithrombotic in a wide range of doses inhibiting TXA_2 and PGI_2[2]. While TXA_2 is largely a COX-1-derived product (mostly from platelets) and thus highly sensitive to aspirin inhibition, vascular PGI_2 can derive from both COX-1 (short-term changes in response to agonist stimulation, e.g. bradykinin; sensitive to transient aspirin inhibition) and COX-2 (long-term changes in response to laminar shear stress and inflammatory cytokines; largely insensitive to aspirin inhibition at conventional antiplatelet doses)[5,12,13]. This may account for the substantial residual COX-2-dependent PGI_2 biosynthesis in vivo at daily doses of aspirin in the range of 30 to 100 mg, despite transient suppression of COX-1-dependent PGI_2 release[10,14]. It is not established that more profound suppression of PGI_2 formation by higher doses of aspirin is sufficient to initiate or predispose to thrombosis. However, studies with mice deficient in the gene encoding the PGI_2 receptor support the importance of this prostanoid in the prevention of arterial thrombosis[15].

Effects of aspirin not related to TXA_2

Aspirin has been reported to have effects on hemostasis that are unrelated to its ability to inactivate platelet COX-1. These include dose-dependent inhibition of platelet function, enhancement of fibrinolysis, and suppression of plasma coagulation. In contrast to the saturable and well-characterized (nanomolar aspirin concentration, rapid time course, physiological conditions, single serine modification) inhibition of COX-1 by aspirin, the putative mechanisms underpinning the 'non-prostaglandin' effects of aspirin on hemostasis are dose dependent and less clearly defined[3].

A subgroup analysis of the Physicians' Health Study, based on *post-hoc* measurements of baseline plasma C-reactive protein (CRP: the prototypic acute phase protein, whose serum levels can increase in response to tissue damage, infection or inflammation) performed in 543 apparently healthy men who subsequently developed MI, stroke or venous thrombosis, and in 543 study participants who did not report vascular complications, has found that the reduction in the risk of a first MI associated with the use of aspirin (325 mg on alternate days) appears to be directly related to the level of CRP, raising the possibility of anti-inflammatory as well as antiplatelet effects of the drug in cardiovascular prophylaxis[16]. As noted above, the anti-inflammatory effects of aspirin and other NSAIDs are largely related to their capacity to inhibit COX-2 activity induced in response to inflammatory cytokines, as these clinical effects can be fully reproduced by highly selective COX-2 inhibitors (coxibs) in patients with rheumatoid arthritis[17]. The dose- and time dependence of the effects of aspirin on nucleated inflammatory cells expressing COX-2 vs anucleated platelets expressing COX-1 are markedly different, thus making an anti-inflammatory effect of the drug at 325 mg every other day pharmacologically implausible, given its very short half-life in the human circulation[3].

Finally, aspirin has been reported to modify the way in which neutrophils and platelets or erythrocytes and platelets interact, to protect endothelial cells from oxidative stress and to improve endothelial dysfunction in atherosclerotic patients. However, neither the molecular mechanism(s) nor the dose dependence of these effects have been clearly established.

Cambridge Books Online © Cambridge University Press, 2009

Aspirin 'Resistance'

Aspirin 'resistance' has been used to describe a number of different phenomena, including the inability of aspirin to: (i) protect individuals from thrombotic complications, (ii) cause a prolongation of the bleeding time, or (iii) produce an anticipated effect on one or more in vitro tests of platelet function[3]. A variable proportion (up to 1/4) of patients with cerebrovascular disease only achieve partial inhibition of platelet aggregation at initial testing, and some (up to 1/3) seem to develop 'resistance' to aspirin over time, even with increasing doses. The results of these long-term studies carried out by Helgason et al.[18–20] are at variance with those of a short-term study of Weksler et al. showing that 40 mg aspirin daily inhibited platelet aggregation and TXA_2 formation as effectively as higher doses of aspirin in patients who had recent cerebral ischemia[21]. Variable platelet responses to aspirin have also been described in patients with peripheral arterial disease and with ischemic heart disease. In the study of Buchanan and Brister, aspirin 'non-responders' were identified on the basis of bleeding time measurements[22]. Approximately 40% of patients undergoing elective coronary artery bypass grafting showed no prolongation of bleeding time in response to aspirin. This was associated with increased platelet adhesion and 12–HETE synthesis[22]. In contrast, repeated measurements of platelet aggregation carried out over 24 months of placebo-controlled treatment by Berglund and Wallentin demonstrated that 100 patients with unstable coronary artery disease randomized to receive 75 mg aspirin daily in the RISC study had consistently reduced platelet aggregation without attenuation during long-term treatment[23].

Several relatively small studies in stroke patients have suggested that aspirin 'resistance' may contribute to treatment 'failure', i.e., recurrent ischemic events while on antiplatelet therapy, and that doses higher than 500 mg may be more effective than lower doses in limiting this phenomenon. The uncontrolled nature and small sample size of these studies makes it difficult to interpret the results. As discussed below, a much larger database failed to substantiate a dose-dependent effect of aspirin in stroke prevention, an effect that one would theoretically expect if aspirin 'resistance' could be overcome, at least in part, by increasing the daily dose of the drug. The apparent discrepancy between the theoretical predictions originating from studies of aspirin 'resistance' and the actual findings of approximately 100 randomized clinical trials of aspirin prophylaxis in high-risk patients[4] can be reconciled by acknowledging the limitations of platelet function studies. Thus, platelet aggregation as measured by conventional methods ex vivo has less than ideal intra- and intersubject variability and displays limited sensitivity to the effect of aspirin, often considered a 'weak' antiplatelet agent based on such measurements. Moreover, the relevance of changes in this index of capacity to the actual occurrence of platelet activation and inhibition in vivo is largely unknown. Similarly, the bleeding time has serious problems of methodologic standardization and is of limited value in predicting hemostatic competence.

In a recent study, Weber et al. reported that circulating platelets from healthy subjects express COX-2 protein and mRNA, and suggested that this may represent a factor in aspirin 'resistance'[24]. This finding has been disputed by several groups. On the other hand, incomplete suppression of 11-dehydro-TXB_2 excretion – a non-invasive index of in vivo TXA_2 biosynthesis – has been observed episodically in some patients with unstable angina treated with i.v. low-dose aspirin, despite greater than 95% suppression of platelet COX-1 activity[25]. COX-2 induction in plaque monocytes/macrophages or activated endothelial cells may contribute to aspirin-insensitive TXA_2 biosynthesis in unstable angina by generating PGH_2 as a substrate for the TX-synthase of the same cell ('constitutive' biosynthesis) or by providing PGH_2 to the TX-synthase of aspirinated platelets ('transcellular' metabolism)[26]. The clinical importance of this phenomenon remains to be established.

The coadministration of aspirin and other NSAIDs can lead to pharmacodynamic interactions between the two, leading to attenuation of the antiplatelet effect of aspirin. Because aspirin's ability to acetylate a critical serine residue at the apex of the cyclooxygenase channel is dependent upon its initial binding to arginine-120, a common docking site for all NSAIDs, the stronger binding affinity of non-aspirin NSAIDs may preclude aspirin from permanently modifying platelet COX-1[6]. A highly selective COX-2 inhibitor, such as rofecoxib, is less likely to interfere with the antiplatelet effect of aspirin than conventional NSAIDs because of its limited interaction with platelet COX-1[17]. Finally, it is theoretically possible that polymorphisms and/or mutations in the COX-1 gene affecting Ser529 may represent the structural basis for aspirin 'resistance' in some patients, although this hypothesis remains to be tested.

Thus, in summary, both the mechanism(s) and clinical relevance of aspirin 'resistance' remain to be established. Until its true nature and prevalence are better defined, no test of platelet function is recommended to assess the antiplatelet effect of aspirin in the individual patient[3].

The antithrombotic effects of aspirin

Well-designed randomized trials have shown that aspirin is an effective antithrombotic agent when used in doses ranging between 50 and 100 mg/d and there is a suggestion that it is effective in doses as low as 30 mg/d[2–4]. Aspirin in a dose of 75 mg/d was shown to be effective in reducing the risk of acute myocardial infarction (MI) or death in patients with unstable angina[27] and chronic stable angina[28] as well as in reducing stroke or death in patients with transient cerebral ischemia[29] and the number of postoperative strokes after carotid endarterectomy[30]. In the European Stroke Prevention Study II[31], aspirin, 25 mg bid, was effective in reducing the risks of stroke and stroke or death in patients with prior stroke or transient ischemic attack (TIA). Finally, in a study of 3131 patients after a TIA or minor ischemic stroke, aspirin in a dose of 30 mg/d was compared with a dose of 283 mg/d, and no statistically significant difference was found in the incidence of the combined outcome of vascular death, stroke, or myocardial infarction between the two aspirin regimens[32]. The lowest effective dose of aspirin for these various indications is shown in Table 61.1.

Table 61.1. Vascular disorders for which aspirin has been shown to be effective and minimum effective dose

Disorder	Minimum effective daily dose (mg)
Men at high cardiovascular risk	75
Hypertension	75
Stable angina	75
Unstable angina[a]	75
Acute myocardial infarction	160
Transient ischemic attack and ischemic stroke[a]	50
Severe carotid artery stenosis[a]	75
Acute ischemic stroke[a]	160

Note:
[a] Higher doses have been tested in other trials and not found to confer any greater risk reduction.
Source: Reproduced with permission[3].

The clinical effectiveness of different doses of aspirin has been compared directly in a small number of randomized trials. In the United Kingdom–TIA (UK–TIA) study, no difference in efficacy was found between 300 and 1200 mg/d of aspirin[33]. The Dutch TIA study failed to show a difference between 30 and 283 mg/d of aspirin. The Aspirin and Carotid Endarterectomy trial[34] has recently reported that the risk of stroke, MI or death within 3 months of carotid endarterectomy is significantly lower for patients taking 81 mg or 325 mg aspirin daily than for those taking 650 mg or 1300 mg (6.2% vs. 8.4%; $P = 0.03$). Thus, there is no convincing evidence from randomized studies that have compared different doses of aspirin for a dose dependence of the antithrombotic effect[3,4].

The antithrombotic effects of a range of doses of aspirin have also been compared with an untreated control group in a number of thrombotic vascular disorders. The doses have varied between 50 and 1500 mg/d. Aspirin has been shown to be effective in the following conditions[2–4]: unstable angina in which the incidence of acute MI or death was significantly reduced to a similar degree in four separate studies using daily doses of 75 mg, 325 mg, 650 mg, and 1300 mg; stable angina in which a dose of 75 mg daily reduced the incidence of acute MI or sudden death; aorto-coronary bypass surgery in which the incidence of early occlusion was similarly reduced with daily doses of 100 mg, 325 mg, 975 mg, and 1200 mg; thromboprophylaxis of patients with prosthetic heart valves who also received warfarin in whom the incidence of systemic embolism was reduced with daily doses of 100 mg, 500 mg, and 1500 mg; thromboprophylaxis of patients with arterial venous shunts undergoing long-term hemodialysis in whom a dose of 160 mg/d was shown to be effective; acute MI in which a dose of 162.5 mg/d reduced early (35 day) mortality as well as non-fatal reinfarction and stroke; transient cerebral ischemia in which doses between 50 and 1200 mg/d were effective; and acute ischemic stroke in which doses of 160 to 300 mg/d were effective in reducing early mortality and stroke recurrence.

Although the proportional effects of aspirin therapy on major vascular events (non-fatal MI, non-fatal stroke or vascular death) in these high-risk settings have been characterized as relatively homogeneous ($23 \pm 2\%$ odds reduction) based on a recent overview of all secondary prevention studies[4], individual trial data show substantial heterogeneity ranging from no apparent benefits in patients with peripheral arterial disease to ≥50% risk reductions in patients with unstable coronary syndromes. These findings may reflect the variable importance of TXA_2 as a mechanism amplifying the hemostatic response to plaque destabilization in different clinical settings[3].

Finally, the variable underlying risk of developing a major vascular event if untreated appears to represent the major determinant of the absolute benefit of aspirin prophylaxis in different patient groups, as depicted in Fig. 61.1[3].

HOT[34]	Hypertensive pts (18 790)	3.8	1.1	0.85
SAPAT[36]	Stable angina pts (2035)	4.2	3.7	0.71

Note:
RR = relative risk of non-fatal MI, non-fatal stroke or vascular death.
Source: Reproduced in updated form[3].

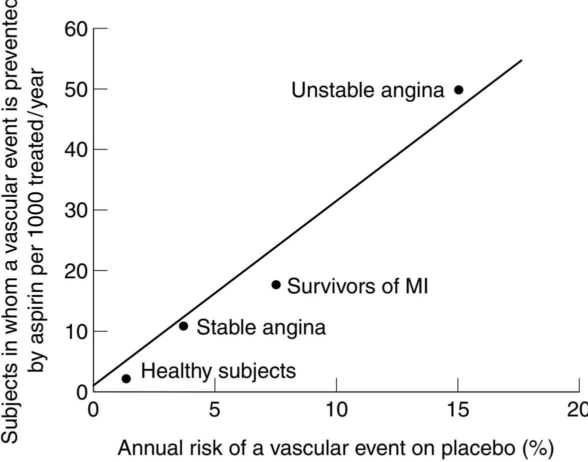

Fig. 61.1. The absolute risk of vascular complications is the major determinant of the absolute benefit of antiplatelet prophylaxis. Data are plotted from placebo-controlled aspirin trials in different clinical settings. For each category of patients, the abscissa denotes the absolute risk of experiencing a major vascular event as recorded in the placebo arm of the trial(s). The absolute benefit of antiplatelet treatment is reported on the ordinate as the number of subjects in whom an important vascular event (non-fatal MI, non-fatal stroke, or vascular death) is actually prevented by treating 1000 subjects with aspirin for 1 year. (Reproduced with permission[3].)

Aspirin and primary prevention

Aspirin has been evaluated in six 'primary' prevention trials in approximately 58 000 persons at variable cardiovascular risk (Table 61.2)[35–40]. In the US Physicians' Health Study (PHS), among 22 071 healthy physicians, an alternate-day regimen of 325 mg of aspirin conferred a statistically significant 44% reduction in risk of first MI[35]. Neither the overall cardiovascular mortality, which was the primary end point of the study, nor the total number of strokes was reduced by long-term aspirin prophylaxis, but there was evidence of a possible increase in hemorrhagic strokes. The British Doctors' trial[36] found no statistically significant effects of aspirin, 500 mg daily, but it had a much smaller sample size than the US trial. An overview of both trials suggested a highly significant 32% reduction in risk of first MI, but the data for stroke and cardiovascular mortality were inconclusive[40]. In terms of absolute benefit, the protective effect of aspirin translated into a major vascular event being avoided in four healthy physicians per 1000 men treated for 5 years. It should be emphasized that this self-selected group of health-conscious male physicians had an absolute risk of developing a major vascular event, if untreated, of <1.0% per year, much lower than the expected rate in the general population.

In the Thrombosis Prevention Trial (TPT)[37], 5499 men aged between 45 and 69 years were recruited from >100 general practices in the United Kingdom because they were considered to be at high risk of ischemic heart disease (in the top 20 to 25% of the risk score distribution). Low-dose aspirin therapy, 75 mg/d, in a controlled-release formulation discussed above, produced a statistically significant 20% relative reduction in the risk of the primary end point of all ischemic heart disease (i.e., coronary death, fatal or non-fatal MI), which was almost entirely due to a 32% reduction in nonfatal events[37]. As in the two previous 'primary' prevention trials, neither the total number of strokes nor the overall cardiovascular mortality was modified by aspirin prophylaxis in TPT. Although the men recruited in TPT were selected for being at high risk of ischemic heart disease, their actual risk of developing a major vascular complication, as assessed in the control group, was considerably lower than expected and only a little more than the rate found in the British Doctors' Trial,

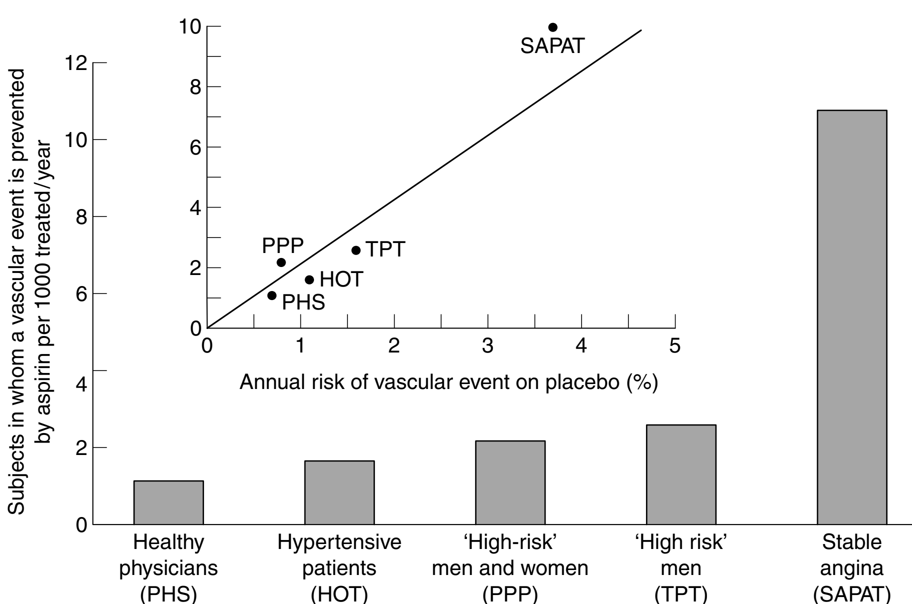

Fig. 61.2. Absolute benefit of aspirin in 'primary' prevention. Data were calculated from placebo-controlled aspirin trials in different settings characterized by variable cardiovascular risk, as noted on the abscissa. The absolute benefit of aspirin prophylaxis is reported on the ordinate as the number of subjects in whom an important vascular event (non-fatal MI, non-fatal stroke, or vascular death) is prevented by treating 1000 subjects with low-dose aspirin for 1 year.

i.e., approximately 1.5% per year. In this setting, an ischemic cardiac event would be avoided in two high-risk subjects by treating 1000 such men with aspirin for a year (Fig. 61.2). The recently reported Primary Prevention Project (PPP) has extended these findings to a group of 4495 men and women older than 50 years and with one or more cardiovascular risk factors recruited by 315 general practitioners in Italy[38]. After a mean follow-up of 3.6 years, the trial was prematurely stopped on ethical grounds and failed to demonstrate a statistically significant reduction in the primary endpoint (RR, 0.71; 95% CI, 0.48–1.04).

Quite similar results were obtained in the Hypertension Optimal Treatment study[39], in which 18 790 male and female patients with intensively treated hypertension were randomly allocated to aspirin, 75 mg daily, or placebo. Aspirin reduced major vascular events by 15% ($P = 0.03$) and all MI by 36% ($P = 0.002$), with no effects on stroke or cardiovascular mortality. Because of the low vascular risk of these well-treated hypertensive patients (only about 1.0% per year), a major cardiovascular event would be avoided in one to two patients by treating 1000 hypertensive men and women with low-dose aspirin therapy for a year (Fig. 61.2). If one compares these absolute benefits of aspirin prophylaxis with those achieved in the 'primary' prevention of MI in patients with stable chronic angina[28], it becomes apparent that the level of cardiovascular risk in the control population (i.e., those on placebo) represents a major determinant of the absolute benefit of antiplatelet therapy (Fig. 61.2).

These results do not support the widespread use of aspirin for 'primary' cardiovascular prophylaxis, because they clearly demonstrate that proper management of modifiable risk factors by current multifactorial strategies can reduce the actual risk of experiencing a major vascular event to a level where the additional benefit of aspirin does not clearly outweigh the risk of major bleeding complications (see below).

Adverse effects of aspirin

Aspirin does not cause a generalized bleeding abnormality unless it is given to patients with an underlying hemostatic defect, such as hemophilia, uremia, or that induced by anticoagulant therapy. Aspirin-induced impairment of primary hemostasis cannot be separated from its antithrombotic effect and is similarly independent of the dose[2,3].

The balance between preventing vascular occlusion and causing excess bleeding with aspirin depends critically on the absolute thrombotic vs. hemorrhagic risk of the patient. Thus, in individuals at very low risk for vascular occlusion (e.g., 1% per year), a very small absolute benefit is offset by exposure of a large number of healthy subjects

Table 61.3. Benefit/risk ratio of antiplatelet prophylaxis with aspirin in different settings

Clinical setting	Benefit[a] (Number of patients in whom a major vascular event is avoided per 1000/year)	Risk[b] (Number of patients in whom a major GI bleeding event is caused per 1000/year)
Men at low to high cardiovascular risk	1–2	1–2
Essential hypertension	1–2	1–2
Chronic stable angina	10	1–2
Prior myocardial infarction	20	1–2
Unstable angina	50	1–2

Notes:
[a] Benefits are calculated from randomized trial data reviewed in this chapter and depicted in Figs. 61.1 and 61.2.
[b] Risks of upper GI bleeding are estimated from a background rate of 1 event per 1000 per year in the general population of non-users and a relative risk of 2.0 to 3.0 associated with aspirin prophylaxis[42]. Such an estimate assumes comparability of other risk factors for upper GI bleeding, such as age and concomitant use of NSAIDs, and may actually underestimate the absolute risk in an elderly population exposed to 'primary' prevention. The absolute excess of major bleeding complications in the 'primary' prevention trials reviewed in Table 61.2 ranged between 0.3 and 2.2 per 1000 patient–years.
Source: Reproduced with permission[3].

to undue bleeding complications. In contrast, in patients at high risk of cardiovascular or cerebrovascular complications (e.g., >5% per year), the substantial absolute benefit of aspirin prophylaxis clearly outweighs the risk (Table 61.3)[3]. For example, the absolute excess of major bleeds (i.e., those requiring transfusion) in acute MI is approximately 1/100th the absolute number of major vascular events avoided by aspirin therapy[4].

Hypertension has often been considered a contraindication to aspirin because of the concern that possible benefits in the prevention of cardiovascular events may be counterbalanced by an increased risk of cerebral bleeding. The results of the aspirin component of the Hypertension Optimal Treatment study are reassuring in this regard, since hypertensive patients whose BP was well controlled were protected from MI by aspirin without an increase in cerebral bleeds or strokes[39].

The overall risk of major extracranial and intracranial bleeds associated with antiplatelet drugs is difficult to assess in individual trials because their incidence is low, i.e., <1% per year, making detection of even a 50 to 60% relative increase in risk unrealistic in most trials of a few thousand patients.

Aspirin-induced GI toxicity, as detected in randomized clinical trials, appears to be dose related in the range of 30 to 1300 mg daily[41]. This is based largely on indirect comparisons of different trials and on a limited number of randomized, direct comparisons of different aspirin doses, as reviewed above. Such a dose–response relationship is thought to reflect at least two COX-1-dependent components, i.e., dose-dependent inhibition of COX-1 in the GI mucosa and dose-independent (within the range of examined doses) inhibition of COX-1 in platelets[3]. Thus, it is not surprising that the antithrombotic effect of aspirin can be dissociated, at least in part, from its most common side effect. However, even when administered at low doses, aspirin can cause serious GI bleeding, as reported in studies using 30 to 50 mg daily[31,32]. Because of the underlying prevalence of gastric mucosal erosions related to concurrent use of other NSAIDs and/or *Helicobacter pylori* infection in the general population, it should be expected that any antiplatelet dose of aspirin will cause more bleeding from pre-existing lesions than a placebo. Consistent with this mechanistic interpretation, the relative risk of hospitalization due to upper GI bleeding and/or perforation associated with low-dose aspirin therapy (mostly, 100 to 300 mg daily) is comparable to that of other antiplatelet agents and anticoagulants, i.e., 2.3 (95% confidence interval [CI], 1.7 to 3.2), 2.0 (95% CI, 1.4 to 2.7), and 2.2 (95% CI, 1.4 to 3.4), respectively, in a large population-based observational study[42]. A case-control study with hospital and community controls has examined the risks of hospitalization for bleeding peptic ulcer associated with three different regimens of aspirin prophylaxis. Odds ratios were raised for all doses of aspirin taken: 75 mg, 2.3 (95%CI, 1.2 to 4.4); 150 mg, 3.2 (1.7 to 6.5); 300 mg, 3.9 (2.5 to 6.3). It has been calculated that approximately 900 of the 10 000 episodes of ulcer bleeding occurring in people aged over 60 each year in England and Wales could be associated with, and ascribed to, prophylactic aspirin use[43]. A general change to lower doses (75 mg) of aspirin would not eliminate risks but, if these figures are soundly based, would reduce risk by about 40% compared with 300 mg and by 30% compared with 150 mg doses. Given that the mortality rate among patients who are hospitalized for NSAID-induced upper GI bleeding is about 5 to 10%[44], such a strategy could save a significant number of lives.

The widely held belief that enteric-coated and buffered varieties of aspirin are less likely to occasion major upper GI bleeding than plain tablets was tested in data from a multicentre case-control study[45]. The relative risks of

Cambridge Books Online © Cambridge University Press, 2009

upper GI bleeding for plain, enteric-coated, and buffered aspirin at average daily doses of ≤325 mg was 2.6, 2.7, and 3.1, respectively. At doses >325 mg, the relative risk was 5.8 for plain and 7.0 for buffered aspirin; there were insufficient data to evaluate enteric-coated aspirin at this dose level[45]. Thus, physicians who recommend aspirin in an enteric-coated or buffered form should not assume that these formulations are less likely to cause GI tract bleeding than plain aspirin.

Suppressing acid secretion is thought to reduce the risk of ulcers associated with regular use of NSAIDs. In patients who required continuous treatment with NSAIDs and who had ulcers or >10 erosions in either the stomach or duodenum, omeprazole healed and prevented ulcers more effectively than did ranitidine. In these patients, maintenance therapy with omeprazole was associated with a lower rate of relapse and was better tolerated than misoprostol. However, whether suppressing acid secretion might reduce GI toxicity associated with low-dose aspirin remains to be established.

Substantially less information is available concerning the risk of intracranial hemorrhage associated with aspirin use. In the Nurses' Health Study cohort of approximately 79 000 women aged 34 to 59 yr, infrequent use of aspirin (1 to 6 tablets per week) was associated with reduced risk of ischemic stroke, while high frequency of use (15 or more aspirin per week) was associated with increased risk of subarachnoid hemorrhage, particularly among older or hypertensive women[46]. In the overview of the Antithrombotic Trialists' Collaboration, the absolute excess of intracranial hemorrhage due to aspirin therapy is less than 1 per 1 000 patients per year in high-risk trials, with somewhat higher risks in patients with cerebrovascular disease[4].

Low-dose aspirin therapy has not been reported to affect renal function or blood pressure control, consistent with its lack of effect on renal prostaglandin synthesis. Moreover, aspirin 75 mg daily did not affect BP nor the need for antihypertensive therapy in intensively treated hypertensive patients[39]. The suggestion that the use of aspirin and other antiplatelet agents is associated with reduced benefit from enalapril in patients with left ventricular systolic dysfunction is not supported by the results of a large meta-analysis of MI trials[47].

Conclusions

Thus, in summary, inhibition of TXA_2-dependent platelet function by aspirin may lead to prevention of thrombosis as well as to excess bleeding. Assessing the net effect requires an estimation of the absolute thrombotic vs. hemorrhagic risk of the individual patient. In individuals at very low risk for vascular occlusion, a very small absolute benefit may be offset by exposure of very large numbers of healthy subjects to undue bleeding complications. As the risk of experiencing a major vascular event increases, so does the absolute benefit of antiplatelet prophylaxis with aspirin, as shown in Fig. 61.1, for a number of clinical settings in which the efficacy of the drug has been tested in randomized clinical trials[3]. Based on the results of >100 such trials, the antithrombotic effect of aspirin does not appear to be dose related, over a wide range of daily doses (30 to 1300 mg), an observation consistent with saturability of platelet COX inhibition at very low doses. In contrast, GI toxicity of the drug does appear to be dose related, consistent with dose- and dosing interval-dependent inhibition of COX activity in the nucleated lining cells of the GI mucosa. Thus, aspirin once daily is recommended in all clinical conditions in which antiplatelet prophylaxis has a favourable benefit/risk profile. Because of GI toxicity and its potential impact on compliance, physicians are encouraged to use the lowest dose of aspirin shown effective in each clinical setting[3].

Pharmacology of ticlopidine and clopidogrel

Jean-Pierre Cazenave and Christian Gachet

Institut National de la Santé et de la Recherche Médicale U.311, Établissement Français du Sang-Alsace, Strasbourg, France

Introduction

The thienopyridines ticlopidine and clopidogrel have a closely related chemical structure and similar pharmacological activity[1–3]. In vivo, an active metabolite of these drugs is generated which selectively inhibits adenosine-5′diphosphate (ADP)-induced platelet aggregation and the ADP-mediated amplification of platelet responses to other agonists[4]. This selective effect is due to irreversible covalent modification by the active metabolite of the recently cloned purinergic P2 receptor of platelets, $P2Y_{12}$[5]. As a result, ticlopidine and clopidogrel were the first $P2Y_{12}$ inhibitors to be used clinically as antithrombotic drugs. These compounds have proved to be safe and highly efficacious in preventing the thrombotic complications of atherosclerotic vascular disease in the brain, heart and peripheral arteries. In addition, they are useful molecular probes of the $P2Y_{12}$ receptor and have permitted progress in our understanding of the role of ADP in platelet activation and vascular thrombosis[6].

ADP was identified in the early 1960s as a factor released from erythrocytes which influenced platelet adhesiveness to glass[7,8] and induced platelet aggregation[9,10]. The crucial role of ADP as a mediator of platelet activation was rapidly recognized in relation to both the physiological process of hemostasis and the development and extension of arterial thrombosis[11,12]. ADP is present at very high concentrations in platelet dense granules and is released when platelets are exposed to thrombin, collagen or thromboxane A_2 (TXA_2), thus reinforcing their aggregation[13–15]. Inhibitors of ADP-induced platelet aggregation have proved to be effective antithrombotic drugs in animal models and clinical trials[3,16,17]. ADP removing enzymes are also antithrombotic in experimental models[18,19], while patients with defects of ADP receptors or lacking ADP in their platelet dense granules experience bleeding[20]. Hence considerable evidence has accumulated to support the important role of platelets in atherosclerosis and its thrombotic complications (atherothrombosis) and has provided a rationale for the development of drugs which inhibit platelet functions.

The first thienopyridines were developed as antiphlogistic agents in 1972. Ticlopidine was found later in 1975 to be an inhibitor of platelet aggregation in man[21] and in 1980 was introduced to prevent platelet aggregation and thrombosis during extracorporeal circulation[22]. Since then several clinical trials have shown its beneficial effects in the secondary prevention of major vascular events in patients with a history of cerebrovascular disease and of major cardiac events after coronary artery stent insertion, as likewise in peripheral vascular disease. The further development of new thienopyridines led to the discovery in 1986 of the successor of ticlopidine, clopidogrel[23]. Clopidogrel was approved for clinical use in 1997 after a large phase III clinical trial (CAPRIE) involving 19 185 patients with a history of symptomatic atherosclerotic disease. The CAPRIE trial demonstrated an overall superiority of clopidogrel over aspirin in the prevention of vascular ischemic events, stroke, myocardial infarction and vascular death[24].

Activation of platelets by ADP (Gachet, C. and Cazenave, J.P. Chapter 9)

Addition of exogenous ADP to washed human platelets results in shape change, reversible aggregation in the presence of physiological concentrations of external ionized calcium and finally desensitization[6,25–27]. This primary aggregation is not associated with TXA_2 formation or secretion of granule contents[15,28]. Although itself a weak aggregating agent, ADP is a necessary cofactor for normal activation of platelets by other agonists such as thrombin or collagen which induce secretion of ADP from the dense

granules[13]. This might explain the well-known stabilization by ADP of platelet aggregates induced by thrombin[29,30]. In addition, low concentrations of ADP potentiate or amplify the effects of all agonists including weak agonists like serotonin[25], adrenaline[31] or chemokines[32,33].

Activation of platelets by ADP leads to extremely rapid Ca^{2+} entry and mobilization of intracellular Ca^{2+} stores and simultaneously to inhibition of adenylyl cyclase[6,26]. The molecular identity of the platelet receptors through which extracellular ADP elicits these physiological responses is known. The $P2Y_1$ metabotropic receptor, coupled to Gq protein/phospholipase C activation, is responsible for the mobilization of Ca^{2+} from internal stores and initiates aggregation[34–36], while the $P2Y_{12}$ metabotropic receptor is coupled to Gi_2 protein/adenylyl cyclase inhibition and is essential for full aggregation in response to ADP[5]. Coactivation of $P2Y_1$ and $P2Y_{12}$ is necessary for normal ADP-induced platelet aggregation[37–41], since inhibition of either receptor with selective antagonists[6] or by gene targeting is sufficient to block it[42–44].

Selective antagonists allow one to discriminate between the $P2Y_1$ and $P2Y_{12}$ receptors[6]. Adenosine-2′, 5′ bisphosphate (A2P5P), adenosine-3′, 5′ bisphosphate (A3P5P) and the structurally modified more potent compound MRS 2179 are selective antagonists of the $P2Y_1$ receptor[45–48]. The antiplatelet thienopyridine compounds ticlopidine, clopidogrel and its active metabolite[3,4], and CS-747[49] and its active metabolite R-99224[50] are specific inhibitors of the $P2Y_{12}$ receptor. The ATP analogues AR-C 66096 MX, AR-C67085 MX and AR-C 69931 MX are also selective $P2Y_{12}$ antagonists[17].

Pharmacology of thienopyridines

Ticlopidine and clopidogrel are structurally related thienopyridines which have similar pharmacological effects following oral or intravenous administration to animals or humans[2,3,51]. These drugs selectively inhibit the ex vivo platelet aggregation induced by ADP, collagen or low concentrations of thrombin[52,53]. The molecular target of ticlopidine and clopidogrel is the ADP receptor $P2Y_{12}$, as has been demonstrated experimentally by biochemistry, molecular biology and pharmacology[6].

Metabolism and pharmacokinetics

Ticlopidine's chemical name is 5-(2-chlorobenzyl)-4,5,6,7-tetrahydrothieno-[3,2-c] pyridine hydrochloride and its structure is shown in Fig. 62.1. It is administered orally to humans as a coated tablet containing 125 or 250 mg ticlopidine hydrochloride (Ticlid®). Ticlopidine is readily absorbed (90%) following a single oral dose of 250 mg and the peak plasma concentration is attained after 1 to 3 hours. Plasma levels of ticlopidine increase about threefold to reach a plateau when the drug is administered twice daily over a period of 2 to 3 weeks, due to drug accumulation. Most of the compound (>98%) is reversibly bound to plasma proteins, primarily albumin. Ticlopidine is a prodrug, which requires in vivo metabolism by the hepatic cytochrome P-450 enzymatic pathway to acquire pharmacological activity[1]. In rats, its metabolism is extensive and rapid, and, among the 13 metabolites identified, the 2-keto derivative found in bile is a more potent inhibitor, after further biotransformation, of ADP-induced platelet aggregation than ticlopidine itself[54]. The apparent elimination half-life of ticlopidine is 24 to 36 h after a single oral dose and up to 96 h after 14 days of repeated administration (250 mg twice daily). Thus the onset of the antiplatelet effect of ticlopidine is not immediate[2,55].

Clopidogrel hydrogen sulfate, methyl (+)-(S)-a-(2-chlorophenyl)-6,7-dihydrothieno [3,2-c] pyridin-5 (4 H)-acetate hydrogen sulfate, is a thienopyridine derivative chemically related to ticlopidine (Fig. 62.1). The presence of a carboxymethyl side group in the benzylic position gives the clopidogrel molecule increased pharmacological activity and a better safety profile than ticlopidine. Clopidogrel is a chiral drug with S-configuration[56]. The S-enantiomer is inactive in vitro[57] but is rapidly absorbed and undergoes extensive metabolism and metabolic activation in animals and humans. The R-enantiomer (SR 25989) (Fig. 62.1) does not inhibit ADP-induced platelet aggregation ex vivo and is devoid of antithrombotic activity[56]. The pharmacokinetics of clopidogrel are different from those of ticlopidine and its antiplatelet effect is more rapid, particularly when a loading dose is administered. An inhibition of ADP-induced platelet aggregation is detectable 2 h after oral administration of 400 mg clopidogrel and remains stable for up to 48 h. Repeated daily administration of 75 mg clopidogrel in human volunteers or atherothrombotic patients results in a steady-state maximal inhibition (40 to 60%), comparable to that afforded by 500 mg ticlopidine daily[23,55].

Clopidogrel hydrogen sulfate (Plavix®, Iscover®) is administered orally to humans as a coated tablet containing 75 mg clopidogrel base. After a single oral dose (up to 200 mg) or repeated doses (up to 100 mg), the unchanged molecule is not detected in peripheral blood. Clopidogrel is rapidly absorbed and undergoes extensive hepatic metabolization in experimental animals[58,59]. Its main systemic metabolite (85%), the carboxylic acid derivative SR 26334, is devoid of pharmacological activity and has a plasma elimination half-

Clopidogrel active metabolite

Fig. 62.1. Molecular structures of the thienopyridines ticlopidine and clopidogrel. The S-enantiomer of clopidogrel is metabolized in the liver to an active metabolite, while its R-enantiomer (SR 25989) is metabolized to an inactive compound. PCR 4099 (not shown) is a racemic mixture of the two enantiomers of clopidogrel.

life of about 8 h. Clopidogrel and its major circulating inactive metabolite are reversibly bound (98% and 94% respectively) to plasma proteins. The metabolic pathway leading to formation of the active metabolite of clopidogrel and its mechanism of action have recently been elucidated using hepatocytes in culture. The prodrug clopidogrel is converted in the liver into 2-oxo-clopidogrel through a cytochrome P450–1A mono-oxygenase-dependent pathway. Hydrolysis of this 2-oxo-clopidogrel intermediate generates the active metabolite (Fig. 62.1), which has been identified as 2-{1-[(1S)-1(2-chlorophenyl)-2-methoxy-2-oxoethyl]-4-sulfanyl-3-piperidinyli-diene} acetic acid[4]. This highly labile active metabolite reacts irreversibly as a thiol reagent with the thiol of an amino acid, putatively one of the extracellular cysteines, of the $P2Y_{12}$ purinoceptor when platelets pass through the liver. Such a local, irreversible effect accounts for the irreversible tagging of the platelet $P2Y_{12}$ receptor, the duration of the specific inhibition for the life span of the platelet and the lack of antiaggregatory activity of the drug in plasma[4]. Since the corresponding metabolite of the R-enantiomer of clopidogrel (SR 25989) is inactive, this interaction with the $P2Y_{12}$ receptor is clearly highly dependent on its stereoisomery[56]. The active metabolite of clopidogrel is also highly labile in vitro. In contrast to the parent molecule, it acts on platelets and specifically inhibits all the effects induced by ADP through its binding to the

Cambridge Books Online © Cambridge University Press, 2009

$P2Y_{12}$ receptor. Finally, although ticlopidine and clopidogrel inhibit ADP-induced platelet aggregation by a similar mechanism, they must do so by generating two different active metabolites, as that of clopidogrel could not be derived from ticlopidine[4].

Mode of action on platelets

The pharmacological effects of ticlopidine and clopidogrel on platelet functions are identical and have been extensively studied in animals and humans[3]. It was reported from early work that administration of ticlopidine reduced platelet aggregation in response to many agonists[23]. This led to proposals that inhibition of the generation of prostanoids[60], activation of adenylyl cyclase and inhibition of phosphodiesterases[61] and/or inhibition of the fibrinogen receptor GPIIb–IIIa were the mechanisms responsible for the inhibition of platelet aggregation by thienopyridines. A so-called 'thrombasthenic state' of ticlopidine treated platelets was also suggested[62]. However, although ticlopidine inhibits the binding of fibrinogen to GPIIb–IIIa, this is not the consequence of a direct modification of the integrin[63]. It is now clear that ticlopidine and clopidogrel selectively block ADP-induced platelet aggregation and the ADP-mediated amplification of platelet responses to other agonists such as collagen or low concentrations of thrombin through specific and covalent modification of the $P2Y_{12}$ receptor[6,52,53,64,65]. The thienopyridine compounds have been used as molecular tools to probe the ADP-induced platelet activation/aggregation pathway and the elucidation of their mechanism of action on platelets is closely linked to the discovery of the ADP receptors and their signal transduction pathways.

Oral administration of the thienopyridines ticlopidine, clopidogrel or PCR 4099 (the racemic form of clopidogrel) to rats, rabbits or humans demonstrated that these compounds irreversibly inhibited the effects of ADP on platelets and prolonged the bleeding time. One important finding was that ticlopidine and clopidogrel selectively prevented the reduction by ADP but not by adrenaline of cAMP levels raised by stimulation of platelet adenylyl cyclase with PGE_1[64,65]. This suggested that the ADP receptor, at the time a pharmacological concept termed $P2_T$[66], could be coupled to a seven transmembrane domain G-protein. It was then shown that ADP stimulates the binding of GTPγS to G proteins and in particular to Gi_2, coupled to adenylyl cyclase, in human platelet membranes and that this effect was blocked by clopidogrel[67–69].

The thienopyridine compounds antagonize ADP-induced tyrosine phosphorylation of several platelet proteins[70] and dephosphorylation of the vasodilator-stimulated phosphoprotein VASP[39,71]. In contrast, they do not modify other specific receptor-mediated effects of ADP on platelets like shape change, intracellular calcium movements or the phosphorylation of proteins involved in these processes[6,35,72]. Ticlopidine and clopidogrel induce a dose-dependent reduction in the number of 2-methylthio-ADP binding sites on rodent or human platelets[73–76]. Binding studies using the poorly hydrolysable analogue [^{33}P]-2MeS–ADP have shown that human platelets have about 600 high-affinity binding sites for 2MeS–ADP (K_d ~5 nM)[76]. Clopidogrel treatment reduces the number of sites by 70% on rat platelets (from 1200 to 450) and leaves binding sites resistant to clopidogrel[74]. In these cells, whereas ADP-induced inhibition of adenylyl cyclase is completely blocked, this agonist can still elicit platelet shape change, a rise in intracellular calcium and at high concentrations transient residual aggregation[35]. Moreover, in patients with a congenital impairment of ADP-induced platelet aggregation but normal shape change, the platelets display very low levels of [^{33}P]-2MeS–ADP binding sites[76–78].

These pharmacological and clinical data fit the current model whereby ADP activates platelets through two G-protein coupled receptors, the $P2Y_1$ receptor which is responsible for initiation of aggregation and transient platelet aggregation and is insensitive to thienopyridine compounds, and the $P2Y_{12}$ receptor which is responsible for completion and amplification of the platelet responses to ADP and other agonists. The latter receptor is the molecular target of clopidogrel and has been shown to be defective in the patients cited above[5,6].

Antithrombotic activity in experimental thrombosis

The antithrombotic activity of ticlopidine and clopidogrel has been demonstrated in several animal species using models of arterial thrombosis where platelet aggregation plays a major part. As specific inhibitors of ADP-induced aggregation, the thienopyridines have thus contributed to recognition of the important role of ADP in arterial thrombosis. In various arterial models, clopidogrel exhibited a dose-dependent antithrombotic activity and was about 50 times more potent than ticlopidine. These compounds both strongly inhibited thrombosis induced by different methods in rats[12,79]. Experimental thrombosis on a collagen-coated arterioarterial shunt in rats was reduced by clopidogrel under conditions where aspirin was inefficient but hirudin more potent, thus demonstrating that thrombin generation contributed significantly to platelet activation[80]. Clopidogrel also inhibited thrombus formation when the shunt was coated with tissue factor and thrombin generation was important[81]. In rats, rabbits, dogs, pigs

Cambridge Books Online © Cambridge University Press, 2009

or non human primates, clopidogrel was able to reduce thrombosis and cyclic flow variation in stenosed and endothelium-injured arteries, to inhibit stent thrombosis induced by high shear stress and to prevent the thrombotic occlusion of vascular grafts or vessels with deep medial injury[79,82–87]. A number of these studies showed that clopidogrel was superior to aspirin, particularly as an adjuvant to prevent reocclusion after thrombolysis induced by streptokinase[88] or tissue-type plasminogen activator[89]. The antiaggregatory and antithrombotic properties of clopidogrel were, however, potentiated by aspirin in several experimental models of arterial injury (silk thread or stent in an arteriovenous shunt, electrical stimulation) and in models of myointimal proliferation leading to restenosis in normal and atherosclerotic rabbits[90].

Thrombin is the most potent platelet activating agent and its effects are not inhibited by antiplatelet drugs. Clopidogrel nevertheless diminished stasis-induced venous thrombosis in rats and rabbits, demonstrating that under low thrombogenic experimental conditions ADP-induced platelet activation plays a role in thrombin formation[91,92]. In similar low thrombogenic conditions, clopidogrel was able to reduce thrombin generation in platelet-rich plasma from rats[93], an effect comparable to the inhibition of tissue factor-induced coagulation of human blood by platelet GPIIb–IIIa inhibitors but not by aspirin[94].

Other pharmacological effects of thienopyridines

Antiplatelet effects of clopidogrel have been reported in vitro using high concentrations and long incubation times[95], but this action of the drug is not specific as it is not due to inhibition of the $P2Y_{12}$ receptor[57]. However, although the antithrombotic activity of thienopyridines has been essentially attributed to inhibition of ADP-induced platelet aggregation, other pharmacological effects have been described which may contribute to their antithrombotic properties. These include a direct inhibitory effect on megakaryocytes[96], a decrease in levels of circulating fibrinogen[97], a reduction of erythrocyte aggregability[98], stimulation of nitric oxide generation[99], relaxation of the thoracic aorta in rats[100] and inhibition of platelet-dependent tissue factor expression on endothelial cells[101].

Ticlopidine has been shown to inhibit the synthesis of fibronectin by human endothelial cells in culture[102], to slow the progression of non proliferative diabetic retinopathy[103,104] and to inhibit pulmonary metastases in mice[105,106]. It was recently demonstrated that SR 25989, the R-enantiomer of clopidogrel which lacks antiaggregatory and antithrombotic activity, inhibited endothelial cell proliferation and migration in a wound healing model, while ticlopidine was two times less active[107]. This effect of SR 25989 was attributed to an up-regulation of thrombospondin-1 expression[108]. The antiangiogenic properties of SR 25989 have been further demonstrated by its inhibition of spontaneous microvessel formation from rat aorta embedded in a fibrin gel and in vivo inhibition of pulmonary metastatic dissemination in mice[109].

Clinical pharmacology

Platelets contribute to the arterial thrombotic complications of atherosclerosis (atherothrombosis) through multiple mechanisms promoting platelet activation, thrombin generation, vasoconstriction, the procoagulant activity of endothelium and inflammation. These platelet effects increase when the arteries are stenosed and the blood flow is turbulent. It is now known that platelet activation involves different agonists and receptor pathways, alone or in combination, and hence it is important to select and use the appropriate antiplatelet drug to inhibit a specific pathway in this complex process of thrombosis.

Aspirin and other drugs acting on platelets have proved beneficial in the treatment and prevention of atherothrombosis[55]. In a meta-analysis of more than 50 secondary prevention trials in various groups of patients[110], aspirin was found to reduce vascular death by about 15% and non fatal vascular events by about 30%. It could be concluded from these results that aspirin, which specifically inhibits COX-1 and the thromboxane A_2 pathway, has important but limited antithrombotic properties and that antiplatelet drugs targeting other activation pathways such as ADP, thrombin or GPIIb–IIIa should be compared to it in clinical trials. A number of such trials have been reviewed recently[2,51,55,111–115] and have shown ticlopidine and clopidogrel to be at least equally as efficacious as aspirin in specific clinical conditions. Thus, clinical trials have confirmed the pathophysiological importance of ADP-induced platelet aggregation in thrombosis complicating human vascular disease involving the brain, heart and peripheral arteries.

Long term treatment with ticlopidine in patients with a history of a neurologic ischemic event has consistently demonstrated a significant benefit over placebo or aspirin[116,117]. Ticlopidine was also efficacious in the secondary prevention of adverse events in unstable angina[118], myocardial infarction[119], percutaneous coronary intervention[120] and intermittent claudication[119]. The drug did not however gain wide acceptance on account of its association with side effects like hypercholesterolemia, neutropenia

Cambridge Books Online © Cambridge University Press, 2009

and thrombocytopenia[121], aplastic anemia[122] or thrombotic thrombocytopenic purpura[123] and it was usually prescribed as an alternative to aspirin in most situations. Since the antiplatelet and antithrombotic effects of ticlopidine were potentiated by aspirin in animals[124] and human volunteers[125], ticlopidine was nevertheless used in combination with aspirin in high risk situations. A combination of ticlopidine and aspirin has been routinely employed to prevent thrombosis after coronary stent insertion and has proved to be superior to aspirin alone[126] or aspirin with warfarin anticoagulation[127]. As the risk of serious side effects still persists with use of ticlopidine, clinicians have tended to replace it by clopidogrel following publication of the results of a large phase III clinical trial (CAPRIE, clopidogrel vs. aspirin in patients at risk of ischemic events).

CAPRIE[24] enrolled 19 185 patients in three groups, all with an increased risk of recurrent ischemic events: individuals who had experienced a recent stroke or recent myocardial infarction or had symptomatic peripheral arterial disease. This was the first study to test the efficacity and safety of clopidogrel (75 mg/day) as compared to aspirin (325 mg/day) after a mean follow-up of 1.9 years. Clopidogrel was significantly more effective than aspirin. The annual event rates for aspirin and clopidogrel were 5.83% and 5.32%, respectively, giving a risk reduction of 8.7%. When the three groups of patients were analysed separately, the risk reduction was much greater (23.8%) in those with symptomatic peripheral arterial disease, suggesting that the benefit of clopidogrel may not be identical in different clinical situations. It might be that ADP is more important in platelet activation through contact with diseased peripheral arteries, whereas ADP and TXA_2 are equally involved in platelet activation when a plaque ruptures in a coronary artery.

The CAPRIE study provided important safety data for clopidogrel, which appeared to be equally as well tolerated as aspirin. There was notably no excess neutropenia in the clopidogrel group and although the frequencies of severe rash and diarrhea were higher in these patients, gastrointestinal discomfort and hemorrhage were more frequent in the aspirin group. Thrombotic thrombocytopenic purpura could occur within the first 2 weeks after initiation of clopidogrel, but to a lesser extent than with ticlopidine[128]. Thus, as clopidogrel is safer than ticlopidine and has a much more rapid onset of action, new strategies are being tested which include its association with other antiplatelet drugs to inhibit different pathways of platelet activation. Administration of a front-loaded dose of clopidogrel (300 mg) to atherosclerotic patients on aspirin achieved an antithrombotic effect within 2 hours during acute coronary syndromes and after coronary stenting[129,130]. Although combined treatment with clopidogrel and aspirin has significantly reduced early ischemic events following coronary stenting, thrombosis of the stent still occurs in up to 1% of patients. A recent study[131] showed that treatment with clopidogrel and aspirin at a higher continuous dose (150 mg/day) and loading dose (600 mg) was superior to the combination of standard clopidogrel (75 mg/day) and aspirin at a lower loading dose (300 mg)[129]. This regimen inhibited ADP-induced platelet aggregation and secretion but had no effect on the aggregation and degranulation induced by activation of the platelet thrombin receptor, PAR-1. The latter observation is highly relevant to the thrombotic complications occurring during acute coronary syndromes, after stent replacement or following fibrinolytic treatment, where thrombin generation is important and aspirin and thienopyridines are not efficacious. Other recent studies have explored the possibility of blocking platelet functions by combining ticlopidine with further antiplatelet drugs, including GPIIb–IIIa blockers such as abciximab, in order to improve the clinical outcome in patients undergoing coronary angioplasty[132] or experiencing acute myocardial infarction during fibrinolysis[133].

Conclusions

The thienopyridines ticlopidine and clopidogrel are the first antithrombotic drugs specific for the ADP purinoceptor $P2Y_{12}$ and are used in humans to prevent the thrombotic complications of vascular atherosclerosis. Clinical trials have demonstrated the safety of clopidogrel and its superiority over aspirin in preventing ischemic events, while association of clopidogrel with aspirin and other antiplatelet drugs inhibiting different platelet activation receptors can further reduce the incidence of thrombosis. The recent cloning of the $P2Y_{12}$ receptor offers the possibility of designing new $P2Y_{12}$ antagonists with improved specificity and efficacy. Finally, as ADP is a key mediator of platelet activation, the development of inhibitors targeting its second receptor on platelets, the $P2Y_1$ receptor, may provide other important antithrombotic agents for use alone or in combination with $P2Y_{12}$ antagonists.

Platelet membrane glycoprotein (GP) IIb–IIIa antagonists and acute arterial thrombosis

David R. Phillips and Lisa Nannizzi-Alaimo

COR Therapeutics, Inc., San Francisco, CA, USA

Introduction

GP IIb–IIIa (αIIbβ3 in integrin nomenclature[1]), the most abundant protein on the platelet surface, is the primary receptor mediating platelet aggregation, a process central to acute arterial thrombosis and to hemostasis. Indeed, its central role in aggregation positions GP IIb–IIIa at the heart of thrombosis and has directed aggressive strategies into developing a new class of drugs, termed GP IIb–IIIa antagonists, which block the binding of adhesive proteins to GP IIb–IIIa thus preventing platelet aggregation. GP IIb–IIIa antagonists have been shown to efficiently regulate platelet function, and to have a therapeutic benefit in reducing the acute thrombotic complications associated with coronary artery disease[2–5]. The pivotal role that GP IIb–IIIa serves in platelet aggregation arises due to the dynamic nature of this receptor which displays several functional activities that are important not only in understanding how this receptor is involved in platelet aggregation and thrombosis, but also, ultimately, for understanding how GP IIb–IIIa antagonists can be more effectively utilized to optimize their antithrombotic activities.

This chapter summarizes the role of GP IIb–IIIa in platelet function and the use of GP IIb–IIIa antagonists for the regulation of platelet functions involved in acute arterial thrombosis. The themes to be developed are threefold. First, GP IIb–IIIa is involved in a wide spectrum of reactions affecting platelet function and vascular biology. For example, while the central role of GP IIb–IIIa in platelet aggregation and thrombosis is well known, its central role in platelet function also involves it in clot formation, fibrinolysis, vascular remodelling and inflammation. Many of these functions occur because GP IIb–IIIa is not a static receptor, but dynamic, mediating signal transduction processes within the platelet that can affect, for example, the procoagulant activity of platelet, the secretion of granule proteins and the release of inflammatory activities. Second, nuances involved in the activities of GP IIb–IIIa antagonists have been identified which has facilitated the therapeutic use of this class of drug. Third, because GP IIb–IIIa ligand binding and signalling affects several platelet functions, it can be anticipated that use of GP IIb–IIIa antagonists will have clinical benefits in addition to the prevention of occlusive thrombosis, for example in anticoagulation, the enhancement of fibrinolysis and the reduction of inflammation. Several reviews of GP IIb–IIIa antagonists have been published[6]: the emphasis here will be on concepts relevant to the affects of these antagonists on platelet physiology, concepts relevant to the clinical use of these antagonists and on recent advances.

GP IIb–IIIa in platelet aggregation

‘Inside-out’ GP IIb–IIIa signalling

GP IIb–IIIa is a member of the integrin family of adhesion receptors[1]. Integrins are widely distributed, found on almost all cells at least in some stage of development, and mediate a broad spectrum of cell–cell and cell–substratum interactions. Both subunits, GP IIb and GP IIIa, have large extracellular domains, single transmembrane domains, and relatively short cytoplasmic domains. The distribution of GP IIb–IIIa is restricted to platelets and cells of the megakaryocytic lineage. On unstimulated, discoid platelets as normally exist in circulation, GP IIb–IIIa is distributed between the plasma membrane (~80 000 copies per platelet), the alpha granule membrane (~40 000 copies per platelet) and the dense body membrane (trace amounts)[7,8]. Although GP IIb–IIIa on unstimulated platelets has low affinity for plasma proteins, platelet stimula-

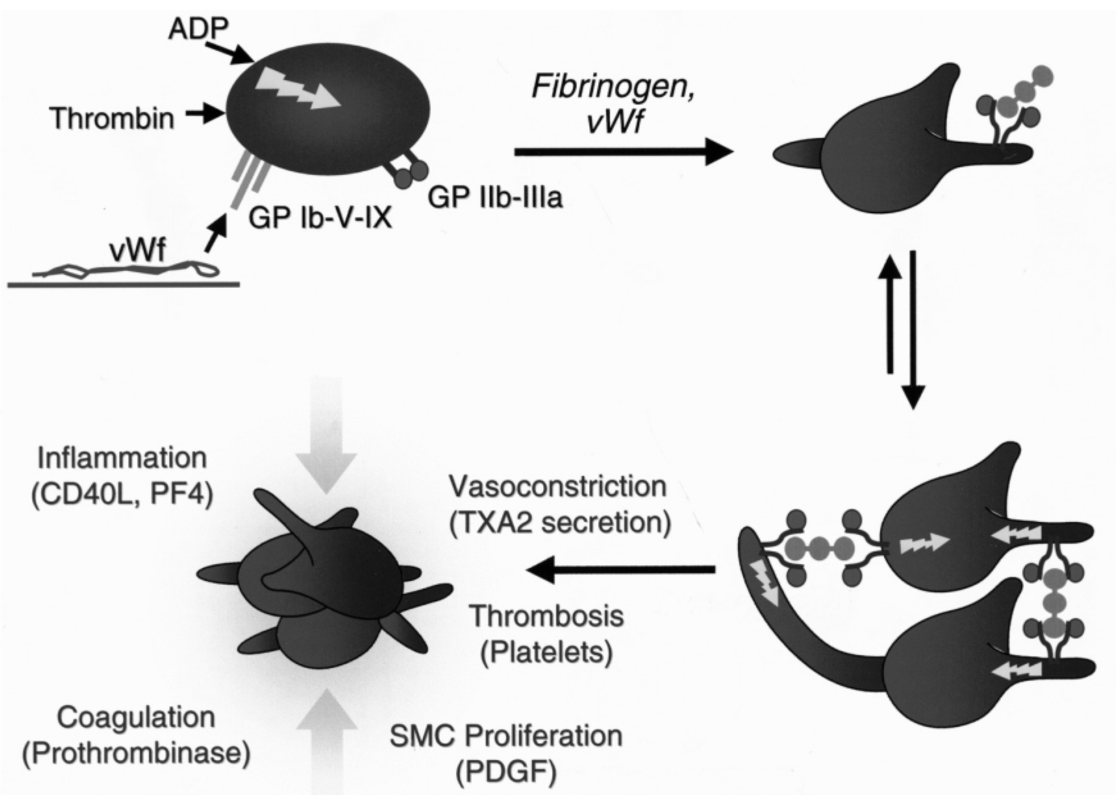

Fig. 63.1 (see also colour plate). Schematic illustrating the role of GP IIb–IIIa in platelet aggregation. On resting, discoid platelets the GP IIb–IIIa is present in an 'inactive' conformation and is unable to bind soluble fibrinogen. Upon activation by classical agonists such as collagen, thrombin or adenosine diphosphate (ADP) the platelet undergoes a shape change and the GP IIb–IIIa is activated such that it can now bind its soluble ligands, fibrinogen and von Willebrand factor (vWf). Platelet aggregation is mediated by the bivalent fibrinogen forming bridges between GP IIb–IIIa molecules on the surfaces of neighbouring, activated platelets.

tion, through a process known as 'inside-out' GP IIb–IIIa signalling, causes an upregulation of the affinity of GP IIb–IIIa for the soluble forms of several adhesive proteins, including fibrinogen, von Willebrand factor (vWf), vitronectin and fibronectin. Although the mechanism(s) responsible for inside-out GP IIb–IIIa signalling are not known, proteins that bind to the cytoplasmic domains of GP IIb and GP IIIa have been identified as have determinants of GP IIb and GP IIIa that maintain GP IIb–IIIa in the low affinity state[9]. Investigations into understanding how these factors regulate the affinity of GP IIb–IIIa for plasma proteins is being actively pursued. As shown in Fig. 63.1, see colour plate, platelet stimulation can be induced by a variety of stimuli, more commonly by thrombin generated in response to vascular injury, but ADP released from platelets or other cells in addition to vWf or collagen exposed in subendothelium, also play major roles in this process. Platelet stimulation, particularly when thrombin is the agonist, may also involve alpha granule secretion, causing up to a 50% increase in the exposure of GP IIb–IIIa. GP IIb–IIIa also shuttles between the plasma membrane and the alpha granule membrane, which is independent of platelet stimulation[10]. This shuttling allows for the packaging of fibrinogen in alpha granules during megakaryocytopoiesis[11] and for the uptake of GP IIb–IIIa ligands in mature platelets[12]. Nurden and coworkers[13] have shown the uptake of abciximab, a GP IIb–IIIa antagonist, which most likely occurred by this mechanism.

'Outside-in' GP IIb–IIIa signalling

The binding of fibrinogen and von Willebrand factor to GP IIb–IIIa on stimulated platelets is the primary driving force for the formation of initial platelet–platelet contacts to initiate aggregation. Both of these proteins are polyvalent, abundant, with high affinity for GP IIb–IIIa on stimulated platelets making them ideally suited to cross-link the

Cambridge Books Online © Cambridge University Press, 2009

membrane surfaces of interacting platelets. Recent data suggest that additional proteins are also involved in mediating platelet aggregation and thrombosis as these processes have been documented in a mouse strain lacking fibrinogen and vWf[14]. Platelet–platelet contacts during normal aggregation are initially reversible, but these contacts induce subsequent 'outside-in' GP IIb–IIIa signalling, which consolidates and stabilizes the platelet aggregate. Outside-in GP IIb–IIIa signalling can also be induced by the adhesion of unstimulated platelets to immobilized fibrinogen, a reaction that is mediated by fibrinogen binding to GP IIb–IIIa and facilitated by the structural change of fibrinogen that occurs because of its immobilization[15,16]. Outside-in GP IIb–IIIa signalling induces diverse functions that are critical to platelet physiology, since they are important not only to platelet aggregation, but also to responses of the vessel wall. Examples are numerous. Thromboxane A2 is generated which functions in an autocrine loop to stimulate platelets, but also has vasoconstrictive activity[17]. Metabolic events are induced, e.g. increased cytoplasmic Ca^{2+}, calpain activation, phosphorylation of platelet proteins and phospholipid metabolism, including the expression of phosphatidylinositol metabolites, which function during the platelet stimulatory process[9]. Alpha-granule proteins are secreted or expressed, many of which have been shown to have effects on the vasculature, e.g. P-selectin, PDGF, TGFβ and PF4. Dense body constituents are secreted, e.g. serotonin, ADP, which also appear to function in autocrine loops to induce further platelet stimulation and recruitment. New actin filaments form and cytoskeletal structures rearrange, events required for stable platelet adhesion, spreading and aggregation. A membrane 'PL scramblase' becomes activated resulting in the increased exposure of phosphatidyl serine and the increased expression of tenase and prothrombinase, enzyme complexes that are active in clot formation[18,19]. Membrane vesicles rich in these procoagulant activities bud off into microvesicles which are released from the platelet surface[20]. Translation of Bcl-3 and other proteins within the stimulated platelets is induced[21]. These secondary, outside-in platelet responses are important to consider in the present context as they predict, as discuss below, that GP IIb–IIIa antagonists will provide additional effects beyond simple inhibition of platelet aggregation and vessel occlusion. Recent work from our laboratory has established that GP IIIa becomes tyrosine phosphorylated during outside-in GP IIb–IIIa signalling, providing one mechanism by which GP IIb–IIIa transmits outside-in signals[22–24]. Inhibition of this pathway has been shown to prevent the formation of stable platelet aggregates[25].

Platelet agonist receptors

Platelet stimulation including inside out GP IIb–IIIa signalling occurs in response to a wide spectrum of physiological and pathophysiological conditions, e.g. vascular trauma to initiate normal hemostasis; atherosclerotic plaque rupture or percutaneous intervention to initiate thrombosis. Given the fundamental role of hemostasis for survival, it is not surprising that the pathways leading to GP IIb–IIIa activation are redundant. Redundancy is found on at least three levels. First, multiple agonists acting on distinct receptors are capable of initiating and augmenting the signal transduction pathways to induce the activation of the receptor function of GP IIb–IIIa and include soluble agonists, e.g. thrombin, ADP, epinephrine, serotonin and thromboxane A2, several adhesive proteins in the extracellular matrix, e.g. collagen, vWf and fibrinogen, high shear and a host of additional factors. This multiplicity of agonists broadens the physiological conditions capable of initiating platelet aggregation to cause thrombosis and hemostasis. It also means that therapeutic targeting of only one agonist, for example thrombin with heparin, or ADP with CD39, will only partially inhibit platelet stimulation, and may not have any inhibitory effect when high concentrations of other agonists are present. The second level of redundancy is that many of the primary agonists, e.g. thrombin, collagen and ADP, act on multiple receptors. In one example, ADP acts on at least three receptors on platelets: P2X1, a ligand-gated ion channel that allows for rapid Ca^{2+} influx; P2Y1, a Gq-coupled receptor that is linked to phospholipase C and mediates mobilization of Ca^{2+} from intracellular stores and platelet shape change, and the recently cloned P2Y12, a Gi-coupled receptor that inhibits adenylylcyclase and induces platelet aggregation[26]. In another example, collagen is known to bind to at least two receptors, the integrin $\alpha2\beta1$, and another membrane glycoprotein, GP VI[27,28]. A third example is thrombin, which stimulates platelets both through the PAR family of G-protein coupled receptors and through GP Ib–IX-V. The PAR receptors are cleaved by thrombin to initiate signal transduction reactions within platelets and GP IIb–IIIa activation and PAR-1 is recognized as the primary platelet receptor for thrombin in human platelets[29]. The GPIb–IX–V complex also appears to be involved in thrombin signalling, most likely because it contains a thrombin cleavage site (in GPV) and a high affinity thrombin binding site (in GP Ibα)[30,31]. The presence of multiple agonist receptors means that therapeutic targeting of only one of them, for example the P2Y12 with the thienopyridines, will only partially inhibit platelet stimulation. The third level of redundancy is the signal transduction pathway from agonist

Table 63.1. Structures and uses for the three approved GP IIb–IIIa antagonists

Generic name	Eptifibatide	Tirofiban	Abciximab
Brand name	INTEGRILIN®	AGGRASTAT®	ReoPro®
Structure			Fab fragment of the chimeric human–murine monoclonal antibody 7E3
Affinity (K_D) for GP IIb–IIIa	120 nmol/l	15 nmol/l	5 nmol/l
Approved for use	PCI and unstable angina/ non Q-wave MI	unstable angina/non Q-wave MI	PCI

receptor stimulation through GP IIb–IIIa activation. Several pathways have been described, including pathway utilizing PKC and others involving phospholipase A2 (PLA2), which act in parallel to buttress inside-out signalling of GP IIb–IIIa to activate its receptor function. The presence of these multiple pathways means that therapeutic targeting of only one of them, for example, by targeting of cyclooxygenase with aspirin to inhibit the metabolism of arachidonate released by PLA2, or by targeting P2Y12 with one of the thienopyridines to block ADP-induced platelet stimulation, or by targeting thrombin with heparin or Factor Xa with low molecular weight heparin, will only partially inhibit platelet aggregation.

Clinical GP IIb–IIIa antagonists

Since GP IIb–IIIa is on the 'Final Common Pathway' leading to platelet aggregation, a term and concept first presented by Coller[32], antagonism of GP IIb–IIIa inhibits platelet aggregation irrespective of the agonist that stimulates platelets, irrespective of the agonist receptor, and irrespective of the stimulus–response coupling pathway used to activate the receptor function of GP IIb–IIIa. Table 63.1 lists the three approved GP IIb–IIIa antagonists. Abciximab (ReoPro®) is a Fab fragment of humanized 7E3, a GP IIb–IIIa monoclonal antibody[33]. Tirofiban (AGGRASTAT®) is a synthetic small molecule GP IIb–IIIa antagonist[34]. Eptifibatide (INTEGRILIN®) is a synthetic heptapeptide modelled on the active site of barbourin, a disintegrin found in the venom of the southeastern pigmy rattlesnake[35]. All are used by an i.v. mode of administration and bind directly to GP IIb–IIIa, both on stimulated or unstimulated platelets. While these agents do not affect agonist-induced platelet shape change, they function as antagonists of adhesive protein binding to GP IIb–IIIa, and therefore negate any upregulation of the receptor function of GP IIb–IIIa during platelet stimulation and block platelet aggregation induced by any of the platelet agonists. All are infused for short intervals (12–72 hours), but achieve a clinical benefit that persists months to years following therapy. Abciximab has been studied in the EPIC, EPILOG and CAPTURE trials and is approved for percutaneous revascularization; tirofiban was studied in the PRISM, PRISM Plus, and RESTORE trials and is approved for unstable angina/nonQ wave myocardial infarction; eptifibatide (INTEGRILIN®) was studied in the IMPACT II, PURSUIT and ESPRIT trials and is approved for both indications. The data supporting these approvals have been the subject of several reviews[5,36,37].

While the three parenterally available GP IIb–IIIa antagonists have many properties in common, important differences have been observed, many of which occur because these drugs have different affinities for GP IIb–IIIa (K_D = 5 nmol/l for abciximab; 15 nmol/l for tirofiban; and 120 nmol/l for eptifibatide[38]). The effect of affinity becomes important both during the infusion and in the recovery phase after infusion has been terminated. The three drugs are each infused at rates that yield plasma concentrations to achieve 70–90% occupancy of GP IIb–IIIa at steady state (less than 100% receptor occupancy is targeted to allow for sufficient hemostasis to prevent bleeding). During infusion, GP IIb–IIIa antagonists are in equilibrium between the plasma phase and GP IIb–IIIa on platelets. Accordingly, the highest affinity drug, abciximab, has the lowest unbound

Cambridge Books Online © Cambridge University Press, 2009

pool during infusion. The low unbound pool abciximab becomes important in individuals with high platelet count and may account for the variable inhibition of platelet aggregation observed with this drug[39,40]. The lower affinities of eptifibatide and tirofiban suggest that they have a faster off-rate from GP IIb–IIIa, and indeed, platelet function recovers faster when infusion of these drugs is discontinued compared to that which occurs with abciximab (2–4 hours for tirofiban and eptifibatide vs. 12–24 hours for abciximab). The unbound pools of all drugs are rapidly cleared. Even with abciximab, in the absence of the unbound pool, normal platelet aggregation can be observed, even with the persistent occupancy of the majority of the platelet surface GP IIb–IIIa 48 hours following the infusion of this drug[41]. Since it has not been shown that any GP IIb–IIIa antagonist provides any clinical benefit in the absence of an unbound pool, i.e. after infusion has been discontinued, it is not known whether the difference in rates of drug clearance have any effect on therapeutic efficacy or safety.

Effect of GP IIb–IIIa antagonists on platelet aggregation

The relative effects of GP IIb–IIIa antagonists on platelet aggregation has been the subject of extensive experimentation and of correspondingly much debate. The question is usually to determine the relative activities of the various antagonists in blocking platelet aggregation. All antagonists, added in sufficient quantity, are capable of totally blocking platelet function. The question, therefore, can be restated to ask 'how much is platelet aggregation inhibited when these drugs are administered to patients?' Studies that attempt to address this question by adding GP IIb–IIIa antagonists in vitro[42] are difficult to interpret as it is almost impossible to arrive at the concentration of drug that is achieved, in patients, during the bolus and steady-state phases of drug therapy. Because all antagonists are in equilibrium during the infusion phase of drug administration, dilution of samples prior to analysis characteristically cannot be done as this shifts the equilibrium and alters apparent inhibitory activities.

Three factors affect the apparent aggregation inhibitory activity of GP IIb–IIIa antagonists: the anticoagulant used for blood collection; the agonist used for platelet stimulation; and, the device used to measure platelet aggregation.

Anticoagulant effect on platelet aggregation

GP IIb–IIIa contains five divalent cation binding sites and the affinities of these sites for Ca^{2+} predict that all are occupied by this divalent cation when platelets are suspended in plasma[43]. Divalent cation binding is reversible and chelation of extracellular divalent cations removes Ca^{2+} from GP IIb–IIIa, dramatically affecting its structure, its binding of adhesive proteins and its binding of antagonists. For example, suspension of platelets in solutions containing ionized calcium concentrations of 40 to 50 μmol/l, as achieved in citrate-anticoagulated blood, causes partial removal of Ca^{2+} from GP IIb–IIIa. These effects of citrate not only cause a loss of fibrinogen-binding activity[44] but also increases the activity of GP IIb–IIIa antagonists in blocking platelet aggregation[45]. Because of these effects, platelet assays relying on GP IIb–IIIa function may not be valid when performed in buffers containing less than the 1.1 mmol/l Ca^{2+} normally found in plasma. One illustration of this effect was seen in the pharmacodynamic analysis of eptifibatide. The reduced Ca^{2+} caused by citrate anticoagulation not only increased the binding of eptifibatide, but also decreased the binding of fibrinogen. Since citrate anticoagulation was used for the ex vivo analysis of platelet aggregation by eptifibatide in the IMPACT II trial[46], the apparent inhibitory activity of eptifibatide was markedly overestimated. This analysis led to a dose that gave 40–50% inhibition of platelet aggregation at steady state, vs. the 80% inhibition that had been targeted in the IMPACT II trial[45]. When PPACK-anticoagulated blood was used to analyse the inhibitory activity of eptifibatide as was done in the subsequent PURSUIT[47] and ESPRIT[48] trials, markedly improved therapeutic efficacy was observed. Recent studies have shown that the apparent inhibitory activities of abciximab, tirofiban and other GP IIb–IIIa antagonists are also overestimated, although less so, in blood anticoagulated with citrate[49]. Thus, when inhibitory activities are compared between trials, or even within the same trial, the data can only be compared in blood anticoagulated by a mechanism which maintains the Ca^{2+} ion concentration that exists in blood. PPACK is preferable to heparin for this purpose, as heparin can induce platelet stimulation in some samples. Maintenance of plasma levels of Ca^{2+} during analysis also provides the most accurate estimate of in vivo platelet aggregation inhibitory activity.

Agonist effect on platelet aggregation

The 'strength' of the platelet agonist affects the amount of receptor competent GP IIb–IIIa recruited to the platelet surface and therefore the apparent inhibitory activity of any GP IIb–IIIa antagonist. Potent agonists like thrombin cause most of the alpha granule GP IIb–IIIa to be recruited with prebound fibrinogen to the platelet surface, while

Cambridge Books Online © Cambridge University Press, 2009

weak agonists like ADP only marginally increase the platelet surface GP IIb–IIIa[50,51]. This alpha granule pool of GP IIb–IIIa is functionally important as thrombin-stimulation of platelets in which the plasma membrane GP IIb–IIIa has been rendered inactive[52] or have been blocked with abciximab in the absence of the unbound pool[41] can still induce sufficient functional GP IIb–IIIa to the platelet surface to support platelet aggregation[53,54]. Alpha-granule secretion also induces the expression of P-selectin, a protein with a proven role in platelet function, to the platelet surface[55]. Pharmacodynamic studies consistently show that increased amounts of all three GP IIb–IIIa antagonists are required to block platelet aggregation by thrombin, the more potent platelet agonist, than by ADP[56]. For example, a lower amount of eptifibatide is required to inhibit aggregation induced by ADP (IC50 = 570 nM in PPACK anticoagulated PRP) than by thrombin (IC50 = 1190 nM), illustrating that increased amounts of GP IIb–IIIa antagonism is required to block platelet aggregation by the more potent platelet agonist[57]. Yet other studies show that the amount of antagonist required to inhibit platelet aggregation is proportional to the concentration of agonist used for platelet stimulation[49]. Since both thrombin and ADP (as well as collagen) are known to induce thrombosis in vivo, all are relevant to therapy. It is not known, however, which is more relevant, or is it known whether the importance of any agonist differs with different thrombotic conditions. These considerations illustrate that GP IIb–IIIa antagonists can only be compared when they are also measured using the same concentrations of the same agonists.

The recovery of platelet function following cessation of antagonist infusion is also differentially affected by agonists. Clinical studies have shown that thrombin-induced, but not ADP-induced platelet aggregation, is rapidly restored following discontinuation of infusion of high affinity GP IIb–IIIa antagonists like abciximab, or the synthetic GP IIb–IIIa antagonist L-738,167[55,58]. The unbound pools of these antagonists, but not the platelet bound pools, are rapidly cleared. Since thrombin, but not ADP, induces maximal surface expression of the alpha granule pool of GP IIb–IIIa, thrombin-induced aggregation is more rapidly restored.

Monitoring the effects of GP IIb–IIIa antagonists

Platelet aggregation has traditionally been measured by the rate of increased light transmittance through a stirred suspension of platelets (LTA). This method has been the most widely used for monitoring the aggregation inhibitory activities of GP IIb–IIIa antagonists and has been correlated to antithrombotic activities in animal models and in clinical studies. Using LTA, the targeted receptor occupancies of 70–90% nearly completely inhibit platelet aggregation induced by ADP but have less effect on platelet aggregation induced by TRAP, a synthetic peptide that activates platelets through the thrombin receptor. Because of this consideration, TRAP is preferred over ADP as the platelet agonist when the upper end of the dose–response curve for GP IIb–IIIa antagonists is being examined.

Because LTA is cumbersome and may not measure platelet aggregation under conditions that have in vivo relevancy such as high shear, attempts have been made to develop additional devices for this purpose[59]. One is the Cone and Platelet Analyser (CPA) which relies on flow-dependent platelet deposition onto a collagen-coated orifice. Another is the rapid platelet function Analyser (RPFA), which characteristically measures the ability of TRAP-activated platelets to aggregate with fibrinogen-coated beads in citrate anticoagulated PRP. The differences in anticoagulant, agonist and shear undoubtedly contribute to the differences observed in the analyses obtained with these devices[60]. Although the CPA and RPFA devices have the advantage of simplicity of use and point of care application, these methods have not yet been validated with respect to antithrombotic activities and clinical outcomes. Accordingly, it is not yet clear how the differences observed with these three methodologies will be used to optimize the extent of platelet aggregation inhibition required to optimize antithrombotic activity and minimize bleeding using GP IIb–IIIa antagonists.

Integrin cross-reactivity of GP IIb–IIIa antagonists

Tirofiban and eptifibatide were designed to specifically inhibit GP IIb–IIIa. In contrast, abciximab has been reported to also bind to and antagonize the receptor functions of two other integrins, $\alpha_v\beta3$ and Mac-1 (αMβ2, CD11b/CD18). It has been speculated that these integrin cross-reactivities of abciximab might provide a clinical advantage as $\alpha_v\beta3$ has been implicated in smooth muscle cell proliferation and vascular remodelling following percutaneous intervention and Mac-1 has been shown to be involved in the acute responses of leukocytes within the vasculature[61]. However, rigorous analysis of the binding properties of abciximab for these other integrins and close inspection of the clinical data suggests otherwise. αvβ3 is upregulated on smooth muscle cells and may modulate smooth muscle cell and endothelial cell replication[62].

Cambridge Books Online © Cambridge University Press, 2009

Because experimental vascular injury-induced intimal hyperplasia models show that inhibition of $\alpha v\beta 3$ reduces smooth muscle cell proliferation[63,64], abciximab was analysed for its ability to reduce the incidence of restenosis. While EPIC, the initial Phase III trial of abciximab showed that there was a reduction in the need for revascularization procedures due to the administration of abciximab, subsequent clinical trials[65] and studies of nonhuman primates[66] specifically designed to examine the antirestenotic activity of abciximab failed to demonstrate that this drug affected late loss following percutaneous intervention. Recent studies demonstrated antagonism of yet another integrin, $\alpha 5\beta 1$, in addition to $\alpha v\beta 3$ is required to block migration of smooth muscle cells on fibrin matrices[67], suggesting a reason for these results. Yet another reason is that the short interval of abciximab administration, 12 hours, and the rapid clearance of the unbound pool after infusion is terminated, does not coincide with the up-regulation of $\alpha v\beta 3$. Because experimental models showed that gene targeting of Mac-1 inhibited restenosis in mice[68] and that Mac-1 is required for leukocyte adhesive reactions[69], it has also been suggested that the Mac-1 binding property of abciximab may provide an anti-inflammatory benefit[61]. However, in order for abciximab to bind Mac-1, this integrin must first be activated[70]. Most leukocytes circulate with Mac-1 in an inactive state: no abciximab can be detected on circulating leukocytes during abciximab therapy[71]. Since abciximab binds to GP IIb–IIIa on unstimulated platelets with 40-fold higher affinity than to stimulated Mac-1, and since fibrinogen, present at approximately 1000 fold greater concentration than the unbound pool of abciximab, also binds to Mac-1 once it is stimulated, it is unlikely that effective antagonism of Mac-1 can be achieved under the clinical administration of this drug. Thus, while a clinical benefit may result by targeting of integrins such as $\alpha v\beta 3$ and Mac-1 in acute vascular conditions, possibly by the development of specific antagonists that can be used at concentrations that saturate receptors for prolonged periods of time, the existing data do not support the notion that any of the three approved parenteral GP IIb–IIIa antagonists provide a clinical benefit by any mechanism other than those resulting from the antagonism of GP IIb–IIIa.

GP IIb–IIIa antagonists and LIBS epitope expression

All GP IIb–IIIa ligands (adhesive proteins such as fibrinogen, GP IIb–IIIa antagonists such as tirofiban and eptifibatide, including selected antibodies such as abciximab) induce a conformational change in GP IIb–IIIa that can be detected by the expression of LIBS (ligand-induced binding site) antibodies. The repertoire of LIBS epitopes expressed by these ligands, however, differs, and LIBS antibodies have been identified that identify these changes in GP IIb–IIIa. For example, while eptifibatide and tirofiban but not lamifiban[72,73] induce the binding of the LIBS antibody termed D3, all these GP IIb–IIIa antagonists induce the binding of mAb15–758[74]. Abciximab binding to GP IIb–IIIa induces the expression of additional LIBS epitopes[75]. Presumably, additional changes in GP IIb–IIIa occur that have not yet been detected by any of the known LIBS antibodies.

LIBS epitope expression is increasingly recognized for its potential impact in limiting the use of GP IIb–IIIa antagonists particularly in long-term, oral administration. Reports have appeared indicating thrombocytopenia in a few individuals as a complication of exposure to GP IIb–IIIa antagonists[76–78]. Hypotheses for this phenomenon are that the LIBS epitopes expressed either cause platelet clearance directly or induce the production of antibodies to the LIBS epitopes which secondarily cause platelet clearance by an immune mechanism. Evidence for this comes from animal studies where thrombocytopenia was observed in both chimpanzee and Rhesus monkeys and this condition corresponded to the presence of drug-dependent antibodies against GP IIb–IIIa[79]. Accumulation of information on this point for different GP IIb–IIIa antagonists could identify LIBS epitopes critical for this response. Thrombocytopenia induced by the three parenteral GP IIb–IIIa antagonists is infrequent, and not routinely associated with severe bleeding complications[80,81].

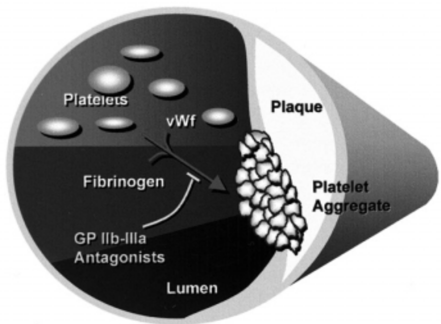
GP IIb–IIIa in coagulation, inflammation and vascular cell proliferation

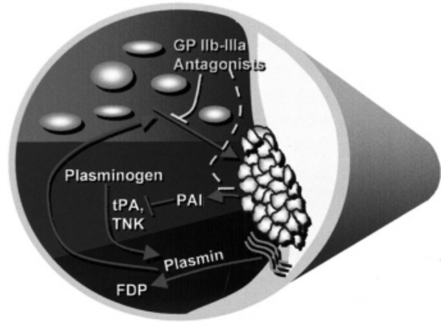
Recent data suggest that GP IIb–IIIa antagonists may have activities in addition to inhibition of platelet aggregation. The data summarized below, and in Fig. 63.2, see colour plate, suggest that these additional activities include anticoagulant, fibrinolytic, and anti-inflammation.

Coagulation

It is well known that the presence of platelets in blood shortens the time required for clot formation as platelets provide a surface for the assembly of the tenase complex which activates Factor X to Factor Xa, and the prothrombinase complex which converts prothrombin to thrombin.

Cambridge Books Online © Cambridge University Press, 2009





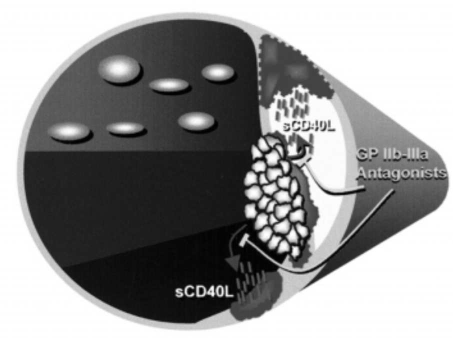


Fig. 63.2 (see also colour plate). Diagrams depict the multiple benefits of GP IIb–IIIa antagonists. (*a*) GP IIb–IIIa antagonists block platelet aggregation and recruitment to prevent thrombosis. (*b*) The prothrombinase complex (FVa, FXa) is predominantly formed on the surface of aggregated platelets. The anticoagulant activity of GP IIb–IIIa antagonists can be attributed to their antiaggregatory activity. (*c*) GP IIb–IIIa antagonists inhibit platelet aggregation induced by plasmin and thrombin which are generated during thrombolysis. These antagonists also inhibit the aggregation-induced release of PAI-1, an inhibitor of fibrinolysis. The apparent 'fibrinolytic' activities of GP IIb–IIIa antagonists can be attributed to these synergistic activities with fibrinolytic agents. (*d*) Platelet aggregation induces the expression and release of the potent proinflammatory protein CD40L. Inhibition of platelet adhesion to vascular cells and sCD40L release from platelets by GP IIb–IIIa antagonists may allow this class of drugs to be anti-inflammatory.

It has been shown that GP IIb–IIIa antagonists reduced tissue factor induced thrombin formation indicating that clot formation and GP IIb–IIIa may be linked[82–85]. These findings raise the interesting possibility that GP IIb–IIIa antagonists may decrease thrombin formation at sites of vascular injury. In support of this suggestion, ex vivo samples have prolonged clot formation time when obtained from patients receiving GP IIb–IIIa antagonists[86]. Although unstimulated platelets have poor clot promoting activity, activated, adherent platelets assemble prothrombinase and Factor Xase on their surface to greatly enhance the rate of thrombin generation[87]. As shown in Fig. 63.2(*b*), see colour plate, GP IIb–IIIa antagonists actually inhibit thrombin generation[84]. Since aggregation induces platelet activation through outside-in GP IIb–IIIa signalling, this may account for the ability of the three GP IIb–IIIa antagonists to reduce thrombin formation[88]. An alternative hypothesis is derived from the experiments of Byzova and Plow[89], who showed that prothrombin binds to GP IIb–IIIa on unstimulated platelets. These authors speculate that prothrombin binding occurs via the RGD sequence in this proenzyme and found that RGD-containing peptides blocked this interaction. Since GP IIb–IIIa binding enhanced the rate of prothrombin activation, a reaction that was blocked by GP IIb–IIIa antagonists, these data suggest that GP IIb–IIIa antagonists may also inhibit clot formation because they displace prothrombin binding to the platelet surface. Either explanation could account for

Cambridge Books Online © Cambridge University Press, 2009

the long clotting times in the platelet rich plasma (PRP) from patients with Glanzmann's thrombasthenia[90].

Fibrinolysis

Recent studies suggest that GP IIb–IIIa antagonists may augment the ability of fibrinolytics to achieve patency in occluded arteries[91,92]. As shown in Fig. 63.2(*c*), there are two primary mechanistic reasons why GP IIb–IIIa antagonists have this activity. First, platelet stimuli are generated by thrombolysis. This can occur by plasmin, known to have a platelet stimulatory activity[93–95], thrombin released from clots during lysis[96] or the adhesive proteins on the vessel wall re-expressed during thrombolysis. GP IIb–IIIa antagonists prevent platelet recruitment by these stimuli. Secondly, platelet alpha granules contain PAI-1 (plasminogen activator inhibitor) which is secreted during platelet thrombosis. GP IIb–IIIa antagonists block platelet recruitment and the secretion of this negative modulator of fibrinolysis. Ongoing clinical trials are designed to establish conditions and protocols for the efficacious combination of GP IIb–IIIa antagonists with thrombolytics[97].

Inflammation

Atherosclerotic cardiovascular disease is the consequence of vascular inflammation[98]. The fibrinogen binding activity of GP IIb–IIIa may contribute to this process in four ways. First, fibrinogen bound to GP IIb–IIIa can bind to Mac-1, a $\beta 2$ integrin, and recruit neutrophils into a growing thrombus[99]. Second, bound fibrinogen, together with aggregation, induces outside-in GP IIb–IIIa signalling and alpha granule secretion resulting in the release of inflammatory mediators such as TGFβ, PF4, RANTES and other chemokines[100,101]. Third, outside-in GP IIb–IIIa signalling also enhances the production of inflammatory mediators from the coagulation cascade such as Factor Xa[102]. Perhaps most importantly, fibrinogen bound to GP IIb–IIIa also mediates the binding of platelets to endothelial cells and leukocytes so that the CD40 ligand (CD40L) expressed on the platelet surface can induce an inflammatory response through these cells[103]. CD40L (CD154, gp 39), is a membrane protein in the TNF family and is a potent proinflammatory factor originally identified in $CD4^+$ T lymphocytes. The platelet location was established in a pioneering study by Henn et al.[103], who showed that while CD40L was not exposed on the surface of unstimulated, discoid platelets, it rapidly became exposed on platelets during thrombin-induced platelet activation. CD40L is a ligand for CD40, an inflammation receptor found on many vascular cells and, indeed, incubation of aggregated platelets that bear exposed CD40L with vascular cells induced an inflammatory response as detected by the release of inflammatory cytokines and the expression of adhesion receptors, e.g. ICAM-1, VCAM-1, and tissue factor[104]. A critical role for CD40L in atherosclerosis has been established by studies showing that CD40L antibodies[105] or CD40L gene targeting[106] reduce atherosclerotic lesion development in mice prone to atherosclerosis. Aukrust et al.[107], showed that a soluble form of CD40L was generated in patients with acute coronary thrombotic syndromes, e.g. unstable angina and with complications of PCI and that the soluble CD40L was inflammatory to peripheral blood mononuclear cells. Since aggregated platelets are associated with atherosclerosis throughout lesion progression and since the adhesion of platelets to the CD40L-responsive cells within the vasculature is mediated by GP IIb–IIIa, it follows that GP IIb–IIIa antagonism may inhibit the CD40L inflammatory activity. An untested hypothesis is that GP IIb–IIIa antagonists may reduce the pathological consequences of inflammation and atherosclerotic lesion progression in acute coronary syndromes.

Orally available GP IIb–IIIa antagonists

Because of the clinical benefits demonstrated by the three parenterally available GP IIb–IIIa antagonists and the hope of extending the clinical benefits by GP IIb–IIIa antagonism beyond the in-hospital administration of therapy, extensive effort has been directed towards the development of orally available GP IIb–IIIa antagonists. Most of these antagonists are mono- or double-prodrugs that are rapidly converted to their active forms in circulation. Although these antagonists are of diverse chemical structures, the active forms of each have a common structural feature, positive and negative charges separated by a distance of 10–20 angstroms[108], a distance is similar to that between the positive charge of arginine and the negative charge of aspartic acid on the Arg–Gly–Asp (RGD) sequence, and a sequence responsible for the GP IIb–IIIa binding activities of several adhesive proteins including vWf, vitronectin and fibronectin[109].

As of writing, five placebo controlled phase III clinical trials have been performed using the orally available GP IIb–IIIa antagonists. None have shown a clinical benefit. The clinical conditions evaluated are diverse and include unstable coronary syndrome, percutaneous revascularization and peripheral vascular disease. Because of the lack of clinical success, the development of the drugs has either been terminated, or is on hold. Several authors have discussed possible reasons why the orally available GP

Cambridge Books Online © Cambridge University Press, 2009

IIb–IIIa antagonists have not yet shown clinical benefit. Adderley and Fitzgerald[110] found in in vitro studies that orbofiban and xemilofiban induced dose-dependent apoptosis and procaspase-3 activation in cardiomyocytes, suggesting that failure of these drugs in the clinic could have been due to their induction of cell death. However, since these studies were performed with the proforms of the antagonists, forms that have low concentrations in circulation, the apoptotic hypothesis needs to be supported by additional studies using the active forms of these drugs, at concentrations closer to that used in the clinic, which also induce an apoptotic response. Another possibility is that the pharmacokinetic profiles of the tested drugs, which permits wide variations in the extent of platelet coverage during the 8-to-12 hours between dosing[111], allows for extended periods where insufficient GP IIb–IIIa antagonism is achieved[112]. This undoubtedly occurred. Presumably, orally available antagonists with improved pharmacokinetic profiles, possibly achieved by once a day formulations with little change in plasma levels during this time interval, may solve this problem. A third possibility is the lack of aspirin in the treatment arm (e.g. Symphony I using sibrafiban[113]) or non-compliance of aspirin use during other trials. Aspirin has been found to synergize with GP IIb–IIIa antagonists in blocking aggregation to collagen[114]. Since collagen is an integral component in atheromas and would be expected to be involved in platelet stimulation following plaque rupture[115], less than optimal inhibition of platelet aggregation to this agonist, as would be provided by the noninclusion of aspirin, may have contributed to a less than optimal therapeutic outcome. A fourth possibility is that the suboptimal doses used chronically, i.e. 10–60% inhibition of platelet aggregation, may provide negative consequences such as the enhancement of inflammation or thrombosis. One example is CD40L, an inflammatory protein that is known to be involved in the progression of atherosclerosis. GP IIb–IIIa antagonists both positively and negatively regulate the release CD40L in vitro: optimal concentrations inhibit, e.g. doses that achieve >60% inhibition of platelet aggregation; surprisingly, suboptimal concentrations potentiate release, e.g. doses that achieve 20–50% inhibition of platelet aggregation (L. Nannizzi-Alaimo, S. Prasad and D. Phillips, unpublished observations). These findings predict that suboptimal doses of the orally available GP IIb–IIIa antagonists may have caused an enhancement of inflammation. Although experiments have been performed which suggest that selected orally available GP IIb–IIIa antagonists may potentiate platelet stimulation, indicating that they may also paradoxically potentiate thrombosis[116], it remains to be determined whether this occurs during the clinical use of these agents. These considerations predict that an orally available GP IIb–IIIa antagonist with an improved pharmacokinetic profile such as demonstrated by Roxifiban[117], or other GP IIb–IIIa under development, may have a therapeutic benefit not achieved in previous clinical trials of this class of drugs.

Conclusions

The combined study of Glanzmann's thrombasthenia, of GP IIb–IIIa, and of GP IIb–IIIa antagonists in arterial thrombotic disease have now clearly established the pivotal roles of GP IIb–IIIa in platelet aggregation and of platelet aggregation in arterial thrombosis. Use of GP IIb–IIIa antagonists is now a proven strategy for the reduction of arterial thrombosis to reduce morbidity and mortality in human disease. It is now established that aggregation is only part of GP IIb–IIIa function in that its signalling in platelets facilitates a wide range of reactions such as platelet shape change, secretion of alpha granule and dense body constituents, consolidation of aggregates and clot retraction. These functions of GP IIb–IIIa indicate that it is not only involved in thrombosis and hemostasis but also links platelets and platelet aggregates to coagulation, inflammation, thrombolysis, atherosclerosis and the proliferation of cells in the vessel wall in a dynamic way, more than would result from simple vessel occlusion. Thus, it is predicted that GP IIb–IIIa antagonists may provide additional benefits beyond simple prevention of vessel occlusion. Data are also accumulating that GP IIb–IIIa antagonists also provide added benefit in combination with other antithrombotics and with fibrinolytics. All initial trials were performed in combination with aspirin and heparin: data are emerging on combinations with clopidigrel (Plavix®) and low molecular weight heparins. Data are also available suggesting that GP IIb–IIIa antagonists act synergistically with fibrinolytics in the setting of acute myocardial infarction, suggesting that such combinations may be a preferred therapy. Future clinical trials are required to evaluate these possibilities.

Given the pivotal role of GP IIb–IIIa in platelet function, it has been disappointing that orally available GP IIb–IIIa antagonists have not yet provided a therapeutic benefit. However, newer orally available GP IIb–IIIa antagonists are now available with improved pharmacokinetic and pharmacodynamic profiles, and it may well be of great interest to understand how these agents perform in large-scale clinical trials. It is also possible that alternative strategies might be developed to regulate GP IIb–IIIa function. For example, future directions on GP IIb–IIIa research can be

Cambridge Books Online © Cambridge University Press, 2009

expected to continue to focus on extracellular and intracellular domains, providing new insights into the molecular description of how GP IIb–IIIa interacts with its ligands and into how GP IIb–IIIa is involved in the various signal transduction pathways. Evidence, both from naturally occurring and experimentally induced mutations of GP IIb–IIIa, clearly indicate a role for the cytoplasmic domains of GP IIb and GP IIIa in the function of GP IIb–IIIa, both in linking the integrin to the platelet cytoskeleton and in associations with signalling proteins. These proximal events in GP IIb–IIIa signalling may offer new targets for pharmacological intervention of GP IIb–IIIa which may provide for inhibition of platelet aggregation and arterial thrombosis with minimal effects on hemostasis.

Reversible COX-1 inhibitors

While aspirin induces irreversible acetylation of the cyclooxygenase moiety of the PGG/H synthase enzyme, other non-steroidal anti-inflammatory drugs (NSAIDs) bind reversibly at, or close to, the active site.

Several NSAIDs have been tested as inhibitors of platelet function. Their effects are reversible within several hours, necessitating multiple daily doses to produce important inhibition of thromboxane A_2[1]. The use of NSAID is also limited by the high rate of gastrointestinal side effects. During naproxen therapy, 400 mg twice a day, increasing the bleeding time, the rate of endoscopically determined gastroduodenal ulcers was 26%, significantly greater than with placebo[2]. The prevalence of gastroduodenal ulcers is from 15% to 30% among users of other NSAIDs[3–5].

Sulfinpyrazone is one of the most studied platelet COX inhibitors. The inhibitory effects of sulfinpyrazone on platelets are more marked ex vivo than in vitro. This behaviour is shared with other antiplatelet drugs including ticlopidine and is dependent on active metabolites formed in vivo. The thioether metabolite of sulfinpyrazone is between 8 and 13 times more potent than the parent compound as an inhibitor of platelet aggregation induced by arachidonic acid[6]. Platelet inhibition is transient with sulfinpyrazone and, after several daily regimens of 200 mg four times a day, inhibition of platelet aggregation no longer is evident 24 hours after the final dose[7]. Initial results from clinical trials using sulfinpyrazone in the secondary prevention of myocardial infarction (MI) were encouraging[8]. In the Anturan Reinfarction Italian Study, patients with MI randomized to sulfinpyrazone (400 mg twice a day) were at lesser risk of suffering from reinfarction compared to the placebo group[8]. However, these results were disproved by a subsequent large trial in unstable angina[9] and the drug was never developed further for this indication.

Indobufene, 2–[*p*-(1-oxo-2-isoindolinyl)phenyl]butyric acid, is a competitive inhibitor of the cyclooxygenase moiety of the PGG/H synthase enzyme[10,11] and dose-dependently inhibits platelet aggregation in vitro and in vivo[12–15] and prolongs the bleeding time[16]. After a single oral dose of 200 mg indobufen, peak inhibition of TXB_2 production, using whole blood clotting, is at 2 h following administration[11]. After repeated administration, platelet inhibition lasts 12 hours after discontinuation of the drug[17]. Indobufen was shown to inhibit thrombosis in experimental animal models in vivo[18].

Indobufen has been investigated in clinical trials for preventing thromboembolism and graft closure. Indobufen, 100 mg b.i.d., was proven to reduce cardiovascular events, in particular stroke, in patients with heart disease associated with an increased risk of cardiogenic embolism[19]. The effect of indobufen on graft patency was investigated in patients with coronary artery disease and peripheral artery disease. In patients with coronary artery bypass grafting, indobufen at a daily dosage of 400 mg was as effective as aspirin plus dipyridamole in reducing graft closure[20]. Similar effects were observed in patients undergoing femoro-popliteal bypass[21]. In a pilot study, indobufen has been shown effective in the secondary prevention of major vascular events in non-rheumatic atrial fibrillation[22]. Further study is in progress to test the clinical efficacy of indobufen in this setting. Gastrointestinal drug-related adverse effects range from 3.9% to 23% in clinical trials[23].

Trifusal is a salicylic acid derivative that blocks COX-1 after transformation in vivo to the metabolite 2-hydroxy-4-trifluoromethyl-benzoate[24]. The use of trifusal in several clinical settings has given no convincing data for its use as an antiplatelet agent in human.

Serotonin antagonists

Serotonin (5-HT) acts on different cells by binding to specific receptors. Several 5-HT receptors have been identified and cloned, and the family of 5-HT receptors is the largest family of neurotransmitter receptors. Serotonin, accumulated in platelet dense granules by an active transport system, is liberated during the secretion reaction and acts as a positive feedback signal in the platelet activation process. The 5-HT_2 receptor, a G-protein coupled receptor, mediates amplification of platelet activation reactions induced by serotonin, and the prototype 5-HT_2 antagonist is ketanserin[25].

Ergoline derivatives LY53857, LY237733, sergolexole[26], and AT-1015[27] are as potent as ketanserin in inhibiting platelet aggregation. SR46349 and DV-7028 are highly potent 5-HT_2 receptor antagonists and exhibit antithrombotic action in animal models in vivo[28,29].

The effect of ketanserin (40 mg three times daily) on morbidity and mortality in patients with intermittent claudication was assessed by the PACK (Prevention of Atherosclerotic Complication with Ketanserin) study. Ketanserin was associated with an increased number of deaths in patients taking ketanserin and potassium-losing diuretics[30]. A secondary analysis, which excluded patients taking ketanserin and diuretics, showed a 23% reduction in major and minor cardiovascular events in patients taking ketanserin. Compared to placebo, ketanserin did not improve pain-free treadmill walking distance, but increased the ankle to arm systolic pressure ratio by decreasing the brachial systolic pressure[31].

Serious side effects, such as prolongation of QT and risk of torsade the pointes in patients receiving diuretics[32,33], potentially limit the use of ketanserin and other 5-HT_2 receptor blockers.

Thromboxane synthase inhibitors and TxA_2/PGH_2 receptor (TP) antagonists

For a long time, inhibition of thromboxane has been an attractive target for developing new antiplatelet drugs. TxA_2 synthesized in platelets by TxA_2 synthase, which uses PGH_2 as substrate, is a potent platelet activator and vasoconstrictor (Fig. 64.1). In addition, TxA_2 exerts additional vascular effects relevant to thrombosis and atherosclerosis, including proliferative effects[34] and stimulation of expression of adhesion molecules[35]. TxA_2 effects are mediated by a G protein-coupled receptor (TP). Thus, pharmacological blockade of TxA_2 can be achieved at two levels, the TxA_2 synthase and the TP (Fig. 64.1). Development of thromboxane synthase inhibitors was clinically relevant because these inhibitors could have overcome the unwanted effect of aspirin, i.e the broad suppression of eicosanoid synthesis both in platelets and endothelial cells. Dazoxiben is the prototype drug of TxA_2 synthase inhibitors[36], but the short half-life raised some concerns about the drug's capability to induce a constant suppression of TxA_2 synthesis in vivo[1]; the drug was evaluated in clinical trials with negative results and the development of the drug was abandoned. Other TxA_2 synthase inhibitors have been reported, including the imidazolyl derivatives Y-20811[37], CS-518[38] and OKY-046[39], and pyrazolotriazinyl alkanoic acids[40]. The development of specific TxA_2 synthase inhibitors was subsequently limited by the observation that both TxA_2 and its precursor PGH_2, which accumulates after TxA_2 synthase inhibition, act at the same receptor site. The blockade of TxA_2 synthase obstructs the arachidonic acid cascade with consequent accumulation of precursor substrates. Accumulated PGH_2 binds to TP as an agonist and potentially activates platelets (Fig. 65.1). In addition, the TP receptor is used by F_2-isoprostanes, potent platelet activators whose production is not affected by TxA_2 synthase inhibitors[41]. Experimental support to that concept has been given by in vitro and in vivo studies[42–44]. TxA_2 synthase inhibitors do not completely inhibit platelet aggregation, and have little effect on bleeding time and experimental thrombosis[42–44]. Dual inhibition of TxA_2 synthase and TP has resulted in a strong inhibition of platelet aggregation and prolongation of bleeding time, much greater than either drug alone[43]. In this context, the additional contribution to the impairment of hemostasis is given by PGI_2 formed by reorientation of the metabolism of the cyclic endoperoxides. Accumulated PGH_2 in platelets, as a result of TxA_2 synthase block, translocate to endothelial cells where they are transformed to PGI_2. Elegant demonstration of this concept was given by Gresele et al.[43], who showed that the effects of dual inhibition were reversed by blocking PGH synthase with aspirin. Thus, the development of new drugs has focused on dual inhibitors, enzyme plus receptor, and TP blockers (Fig. 64.1). The prototype drug of dual inhibitors is Ridogrel[45]. A series of new dual inhibitors is under investigation, including cinnaminophilin, a lignan isolated from *Cinnamonum philippinense*[46], and the non-carboxylic derivative BM-531[47]. The dual inhibitor picotamide, N,N′-bis[3-picolyl]-4-methoxy-isophthalamide, inhibits platelet aggregation induced by different agonists in vitro and ex vivo[48,49]. The drug is an inhibitor of thromboxane synthase[49], and competitive binding studies have shown that picotamide acts also as a TP antagonist[50].

Picotamide was tested on the clinical progression of

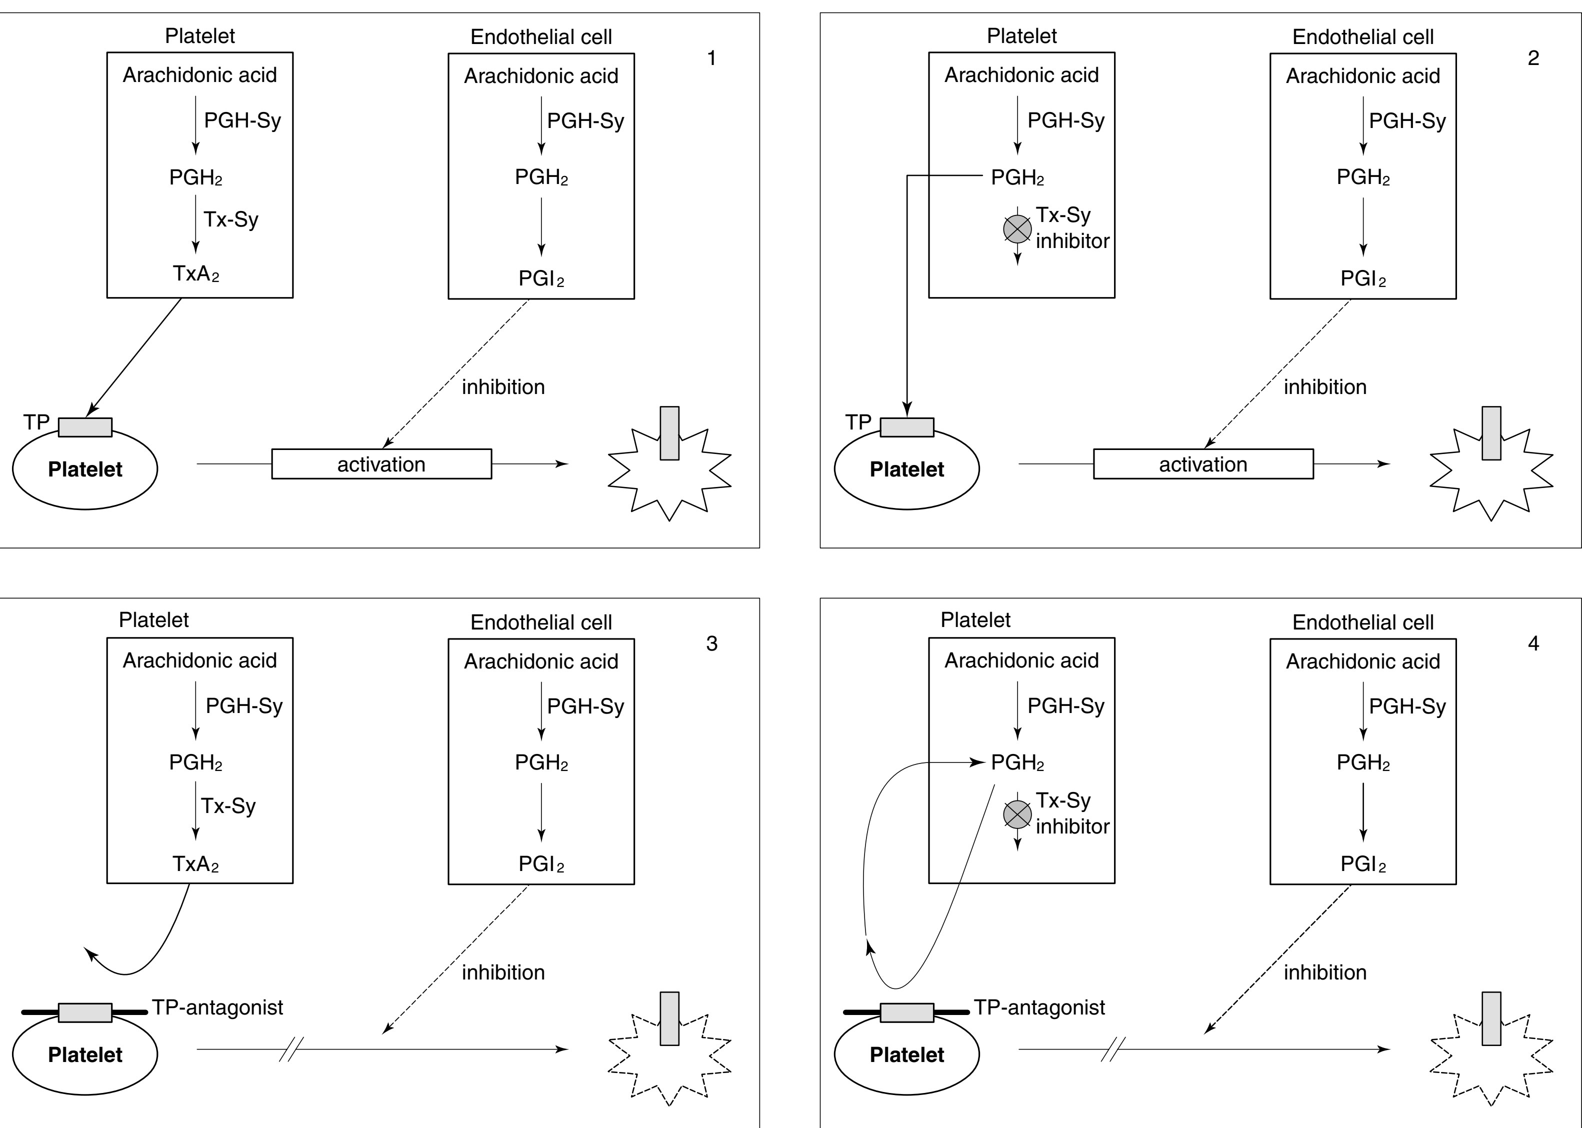

Fig. 64.1. Beyond aspirin-mediated inhibition of the arachidonic acid cascade: potential pharmacological interventions for blocking TxA_2-mediated platelet activation. Synthesis of TxA_2 is dependent on availability of free arachidonic acid, which is liberated from membrane phospholipids by phospholipases (not shown in the scheme), and on the activity of PGH_2- synthase (PG–Sy) and TxA_2-synthase (Tx–Sy); TxA_2 binds to a specific G protein-coupled receptor (TP) and initiates a series of intracellular events that leads to platelet activation (scheme 1). Specific TxA_2-synthase inhibitors block the production of TxA_2 with potential accumulation of its precursor PGH_2, which in turn may activate platelets by mimicking TxA_2 at the TP level (scheme 2). The combination of Tx–Sy inhibitors and TP inhibitors results in a marked inhibition of arachidonate-induced platelet aggregation and prolongation of bleeding time much greater than either drug alone (scheme 4). Contribution to this effect is given by metabolic reorientation of cyclic endoperoxide towards antiaggregatory prostaglandins, such as PGI_2 (scheme 4)[43].

Cambridge Books Online © Cambridge University Press, 2009

peripheral vascular disease in patients with intermittent claudication[51]. After 18 months follow-up there was no difference in terms of major and minor events in patients assigned to placebo or picotamide (intention to treat analysis)[51].

Several pharmacological TP inhibitors have been reported, including BM13.177, SQ-29,548, and GR32191[52–54], and the novel non-carboxylic derivatives BM-144 and BM-500 that are under investigation[55]. Two clinical trials were performed to test the effectiveness of TP inhibitors in reducing restenosis after PTCA. Both GR32191 and sulotroban, evaluated in the CARPORT (coronary artery restenosis prevention on repeated thromboxane A_2 antagonism) study[56] and in the M-HERT-II (multi-Hospital Eastern Atlantic restenosis trial) study, respectively[57], failed to prevent restenosis after PTCA. However, sulotroban was as effective as aspirin in preventing the occurrence of myocardial infarction[57].

Antithrombins and thrombin receptor antagonists

Thrombin is a serine protease that catalyses the cleavage of fibrinogen and of the platelet thrombin receptor. As a result thrombin activates both the coagulation pathway and platelets. As such, thrombin plays a central role in the mechanism of thrombosis. Antithrombins include the protease inhibitors r-hirudin and D-Phe–Pro–Arg–chloromethylketone that block the thrombin catalytic activity and are antithrombotic agents in vivo. These inhibitors are able to inactivate thrombus-bound thrombin and interrupt radiolabelled-platelet and radiolabelled-fibrinogen deposition in the vascular graft model[58]. In contrast, the heparin–ATIII complex is not able to affect thrombus formation in this model[58]. The clinical relevance of these findings has been supported by clinical trials with r-hirudin. In a randomized placebo-controlled study assessing subcutaneous hirudin vs. standard heparin or LMWH, hirudin reduced more effectively than heparin the rate of deep vein thrombosis and pulmonary embolism, without significant increase in bleeding[59]. Controlled clinical trials of bivalirudin[60–62] or hirudin[63,64] vs. standard heparin have also shown that antithrombins are effective in reducing reocclusion after thrombolysis, without producing significant bleeding. Randomized studies in patients undergoing PTCA have shown that hirudin or bivalirudin are comparable to heparin in protecting from angioplasty-related complications and are similar in frequency of bleeding[65–68]. In contrast, randomized placebo-controlled clinical trials in acute coronary syndromes have demonstrated that hirudin and bivalirudin do not cause significant clinical improvement compared to heparin, but increase intracranial bleeding[69–72].

This last evidence is in agreement with studies of experimental antithrombogenesis in baboons[58]. In this model the hirudin dose required to block platelet recruitment is at least one order of magnitude higher than the dose needed for inhibiting fibrin formation, and as a consequence a marked prolongation of clotting time, template bleeding, and surgical bleeding are observed[73]. Thus, some authors believe that antithrombin concentrations necessary to interrupt platelet activation in arterial thrombosis may never be achievable by systemic infusion without undesirable bleeding[73].

Thrombin receptors are G protein-coupled receptors activated by proteolytic cleavage (PAR receptors)[74]. Two main PAR receptors are specific for thrombin, PAR-1 and PAR-3[75]. PARs-targeted monoclonal antibodies are attractive candidates for receptor blockade. Strategies for developing antibodies against thrombin receptor are likely to require agents that inhibit both PAR-1 and PAR-3. Anti-PAR-1 monoclonal antibodies failed to fully prevent thrombin-induced platelet activation[76]. In contrast, anti-PAR-1 polyclonal antibodies, which probably cross-react with PAR-3, have provided protection from thrombosis in non human primates in vivo[77].

Cleavage of the receptor between Arg^{41} and Ser^{42} unmasks a new NH_2-terminal sequence that functions as a tethered ligand for the receptor. Peptides based on the new exposed sequence, from 5 (SFLLR) to 14 (SFLLRRNPNDKYEPF) amino acids, are potent thrombin receptor agonists[78]. Based on these sequences, receptor antagonist peptides have been constructed[79,80]. The undecapeptide C186–65 is a specific inhibitor of thrombin-mediated platelet activation[79]. Thus, thrombin receptor antagonists act differently from specific thrombin protease inhibitors and their effect is limited to platelet inhibition without affecting the clotting system. FR171113 is a selective non-peptide thrombin receptor antagonist, that is 50 times more potent than C186–65 in inhibiting thrombin-induced platelet aggregation (IC(50) 0.29 μM)[80]. FR171113 does not inhibit platelet aggregation induced by other agonists (ADP, collagen, arachidonic acid, U46619, PAF, adrenaline and calcium ionophore), and does not prolong the thrombin time, activated partial thromboplastin time, or prothrombin time[80].

Phosphodiesterase inhibitors

Cyclic AMP and GMP are intracellular second messengers that regulate physiological responses triggered by extracel-

Cambridge Books Online © Cambridge University Press, 2009

lular stimuli. Intracellular levels of cAMP and cGMP are regulated by the rate of synthesis and degradation operated by specific cyclases and phosphodiesterases (PDE), respectively. Most cells express one or more PDE isoenzymes that regulate intracellular cAMP or cGMP. At least nine different gene families of PDEs have been identified in mammalian tissues[81,82]. Platelets express PDE2, PDE3, and PDE5 isoenzymes. Specific inhibitors of PDEs inhibit platelet function in vitro and in vivo[83,84]. The antiplatelet drug cilostazol[85] is a selective inhibitor of PDE3 with IC(50) of 0.19 μM[86]. Cilostazol also has vasodilating activity due to inhibition of PDE3 in vascular smooth muscle cells, which also express PDE1, PDE4, and PDE5.

Cilostazol has been used for a decade in several countries for the treatment of peripheral arterial disease, and in 1999 was approved in the United States for intermittent claudication. In a recent study, 81 patients with intermittent claudication were randomly treated with cilostazol (200 mg/day for 12 weeks) or placebo. Patients receiving cilostazol showed a statistically significant increase in walking distance compared to placebo[87]. The efficacy of cilostazol combined with aspirin was also assessed in coronary stenting in comparison with ticlopidine plus aspirin[88]. The two treatment regimens were randomly assigned to 300 patients starting 2 days before stent implantation. Primary end point at 30 days was a composite of angiographic stent thrombosis and major cardiac events (death, myocardial infarction, bypass surgery, repeat intervention). The combination of cilostazol plus aspirin was as effective as aspirin plus ticlopidine.

Novel potent PDEs inhibitors have been synthesized. The cyclooctylurea derivative OPC-33540 inhibits recombinant PDE3 with IC^{50} of 0.32 nM[89]. The cyclohexenyl derivative NSP-513 is an orally active inhibitor of PDE3 with IC^{50} of 39 nM[90]. Aggregation of dog platelets induced by collagen and ADP is inhibited by NSP-513 with IC^{50} of 0.15 and 12 μM, respectively. NSP-513 administered to dogs inhibits ex vivo platelet aggregation and exhibits an antithrombotic activity in experimental femoral arterial thrombosis[90].

Dipyridamole (2,6-bis-diethanolamino-4,8-dipiperidino-pyrimido-(5,4-D)-pyrimidine), is an antithrombotic agent in experimental models and in several animal models acts as platelet inhibitor in vivo[91]. Dipyridamole has three main pharmacological activities relevant to platelet inhibition. First, dipyridamole is a potent inhibitor of phosphodiesterases[82,84], which control the intracellular levels of cAMP and cGMP, pivotal regulators of a wide variety of signal transduction pathways[83,84]. Secondly, dipyridamole is an inhibitor of adenosine reuptake by erythrocytes and endothelial cells[92,93]. Adenosine, which derives from ADP released during platelet aggregation, inhibits platelet function[94]. Thus, dipyridamole has been suggested to inhibit platelet function by locally increasing adenosine concentration during thrombus formation[94,95]. Third, dipyridamole is a potent chain breaking antioxidant[96,97]. Scavenging of free radicals, which inactivate the cyclooxygenase enzyme[98], could account for the delay in the exhaustion of platelet-inhibiting PGI_2[98–100]. In analogy with other antioxidants, dipyridamole could also affect free-radical mediated amplification of platelet activation[101].

Despite its pharmacological activities, the antiplatelet effect of dipyridamole is difficult to demonstrate in vitro. This is partly caused by a strong binding activity of dipyridamole to alpha-1-acid glycoprotein and consequent low free drug concentration in the platelet environment in vitro[102]. Thus, there is no clear-cut evidence of a specific platelet target for dipyridamole, and the mechanism of its antiplatelet activity is mainly speculative.

In the European Stroke Prevention Study 2 (ESPS-2), dipyridamole (200 mg twice a day) reduced the risk of stroke by 36.8% and the cumulative risk of stroke and death by 24.2% when compared with placebo[103]. Dipyridamole combined with 50 mg aspirin was also significantly more effective than either drug alone. This combination, approved by the FDA[104], is currently recommended as one of the first-line treatments for stroke prevention after a first transient ischemic attack or stroke[105].

Dipyridamole is FDA approved as an adjunct to warfarin for the prevention of postoperative thromboembolic complications of cardiac valve replacement with a mechanical prosthesis[106].

Pharmacogenetics as a new antiplatelet strategy

Giovanni de Gaetano*, Chiara Cerletti and Licia Iacoviello

Department of Vascular Medicine and Pharmacology, Istituto di Ricerche Farmacologiche Mario Negri, Consorzio Mario Negri Sud, Santa Maria Imbaro, Italy and Centro di Ricerca e Formazione ad Alta Tecnologia nelle Scienze Biomediche, Università Cattolica, Campobasso, Italy

"At that time two men will be working in a field:
one will be taken away, the other will be left behind.
Two women will be at a mill grinding meal:
one will be taken away, the other will be left behind."
Mt. 24, 40–41

Antiplatelet strategy: a brief historical review

The first three drugs tested in clinical trials for their potential antiplatelet effects were all already used in current practice for different reasons, unrelated to thrombosis and ischemic artery disease[1].

Aspirin was known as an anti-inflammatory compound, sulfinpyrazone was used for its uricosuric properties and dipyridamole was endowed with vasodilatory (coronarodilatory) effect. Their mechanism of action, as antiplatelet agents, was largely unknown, but the possibility of replacing oral anticoagulants with relatively safer substances, not requiring any laboratory control, convinced many clinicians to adapt an antiplatelet strategy, even before the results of well-planned and conducted clinical trials were made available.

The discovery of the crucial role of prostaglandins and thromboxane A2 (TxA2) in platelet function and of their possibly unselective pharmacological control by aspirin, stimulated for the first time the search for a more rational antiplatelet strategy.

However, the development of selective TxA2-synthase inhibitors, TxA2-receptor antagonists and of compounds endowed with both properties was not followed by the expected clinical results. This was due to several reasons, including the complex re-orientation of platelet arachidonate metabolism following pharmacological suppression of TxA2 synthesis or of its receptor function[2–4].

In the meantime, ticlopidine, a new compound, whose mechanism of action was unrelated to arachidonate metabolism was made available: this drug inhibited platelet function, particularly ADP-induced platelet aggregation[1]. Some workers suggested a parallel between the effect of ticlopidine and the congenital platelet defect observed in a rare hemorrhagic disorder, Glanzmann's thrombasthenia[5]. The assumption was incomplete, but had the great merit to orient new antiplatelet strategy towards mimicking naturally occurring platelet disorders. The role of ADP as the princeps of platelet function agonists was discovered in 1960, but the molecular basis of its effects is just beginning to be understood. A model of three purinergic receptors, each contributing separately to ADP-induced mechanisms has recently been proposed[6].

Following the results of clinical trials suggesting that ticlopidine, an inhibitor of ADP-induced platelet aggregation, might be at least as effective as aspirin, the search for other anti-ADP selective agents led to the development of clopidogrel[7]. The antiaggregating activity of this compound has been attributed to an active metabolite, which irreversibly affects the ADP receptor P2Y12[8]. More recently selective, specific and competitive P2Y12 antagonists have been identified. Experience gained with intravenous administration of these compounds has encouraged the development of orally active P2Y12 receptor antagonists with the expectation that these compounds will have significant advantages over other existing or emerging oral antiplatelet agents[9].

The concomitant progress in biochemical and molecular mechanisms regulating platelet function made it possible to develop RGD peptides, and to identify some snake venoms containing RGD proteins. RGD is a triplet of amino acids (Arg–Gly–Asp) which allow fibrinogen binding to the

platelet glycoprotein GPIIb–IIIa. The latter is lacking or dysfunctional in Glanzmann's thrombasthenia[10].

Another obvious approach to control platelet function was to develop monoclonal antibodies against the GPIIb–IIIa (the first humanized antibody, currently used with success in some clinical conditions was abciximab or c7E3 or ReoPro)[11]. More recently, GPIIb–IIIa antagonists have been developed, based on the RGD sequence (or on a KGD sequence where Arg is substituted by Lys). Orally active inhibitors of the GPIIb–IIIa receptor have been developed as well. They are inherently active or are metabolized to the active form after ingestion[12]. The hypothesis that blockade of the GPIIb–IIIa function would be translated into a reduction in short-term ischemic complications and improvement in long-term clinical outcomes has only been partially met. The recent publication of the results of clinical trials with different oral GPIIb–IIIa inhibitory drugs has generated a serious disappointment on the true clinical benefit of this antiplatelet strategy[13].

From a conceptual point of view an antiplatelet strategy similar to that mentioned above can be considered in relation to the glycoprotein GPIb and its major binding protein, namely von Willebrand factor[14].

In conclusion, since the 1970s a great effort was made to improve the efficacy of the antiplatelet strategy by developing new drugs based on the discovery of new biochemical mechanisms underlying platelet function. Such an effort has been paralleled by the performance of dozens of clinical trials on old and new antiplatelet drugs. Both individual trials[7,15–17] and accurate metanalysis of hundreds of trials of different size[18] have provided fundamental indications for therapy and prevention of major vascular events such as myocardial infarction, stroke and vascular mortality.

Populations rather than individuals as traditional targets of antiplatelet strategy

The indications obtained by traditional trials are well adapted to wide populations, but not as well to individual patients. The transferability of clinical data to the greatest number of patients is an important result of clinical trials such as ISIS-2[15]: one of the most useful advancements in the cardiovascular therapy during the past decades has been the demonstration of the efficacy to take an aspirin as soon as possible when myocardial infarction has only been suspected on the basis of a clinical judgement, without waiting for laboratory enzyme measurements or ECG confirmation. However, clinicians would like to have clearer indications, if not for any single patient, at least for less heterogeneous groups than those identified by epidemiologists.

Table 65.1. Results of a current hypothetical trial with an antiplatelet drug

Patients	Control treatment	Antiplatelet drug
Treated	100	100
No event	90	93
With events	10	7
Benefit from the drug	0	3

Note:
The beneficial effect of the antiplatelet drug is 30%, but only three out of 100 treated patients will be 'saved' by the treatment. At the moment, there is little chance to identify *a priori* the 90 patients who will have no benefit from the drug, the ten patients who will suffer an event despite the treatment and the three patients who will gain the maximum benefit from the drug (based on ref.[19]).

If, in a simplified hypothetical trial, one treats for 1 year 100 heart attack patients with the best available therapy plus an antiplatelet drug, seven out of the ten patients who would have died without that drug will die anyway, three will be saved by the antiplatelet treatment and the other 90 will only be exposed to the risks of treatment without having any benefits. The problem is that we are presently unable to identify *a priori* the three patients who would gain their maximum benefits from an antiplatelet drug or even the patients who most likely will suffer a new vascular event or will die[19] (Table 65.1).

In the last few years, some possibilities have been proposed to select *a priori* groups of subjects who could benefit from aspirin or other antiplatelet therapy, with results which could be more targeted to them.

An observation derived from the Physicians' Health Study[20] has shown that individuals who had lower C reactive protein, a marker of inflammation and a prognostic parameter in severe unstable angina[21], had little or no protection from aspirin against cardiovascular events, whereas aspirin was particularly active in those with higher levels of this protein[22].

The significant association between C reactive protein and the clinical effectiveness of aspirin might be related to reduction by this drug of the inflammatory components that might play a pathogenetic role in acute coronary syndromes[23]. Although this interpretation can be challenged on the basis of the relatively low, apparently non-anti-inflammatory dose of aspirin used in the Physicians' Health Study, the possibility to include in future primary prevention studies only those subjects with high levels of C

Cambridge Books Online © Cambridge University Press, 2009

reactive protein (or some other easily measurable parameter) is attracting attention. One can argue that C reactive protein does not directly distinguish 'responders' and 'non-responders' to aspirin, but identifies higher risk subjects for whom it will be easier to highlight the evidence of aspirin efficacy[19].

This concept is in apparent contrast with the conclusions of a recent study[24] suggesting that the lower the blood pressure, the greater the effectiveness of aspirin. Moreover, subjects with higher blood pressure (systolic values above 145 mmHg) not only did not benefit from aspirin but were exposed to a serious risk of hemorrhage. Thus, whatever the relationship between aspirin effect and laboratory (C reactive protein) or clinical (hypertension) parameters, it is ethical to reduce the number of subjects and patients exposed to the side effects of aspirin (or other antiplatelet drug) without any clinical benefits.

The use of aspirin and other antiplatelet drugs prescribed today or presently in the development phase is thus limited by suboptimal efficacy that results largely from our inability to account for interindividual differences in disease etiology and drug response[19,23].

The development of pharmacogenetics and individualized medicine

These interindividual differences are determined, to a large extent, by inherited predispositions and susceptibilities. Knowledge of the genetic differences that explain these individual characteristics, and, based upon it, the development of specific diagnostics and therapeutics, will therefore be critical for the successful transition to a future progress in health care.

Today, a typical drug development programme usually proceeds on the broad assumption that subjects (or patients) are homogeneous groups with little interindividual variability. However, the efficacy of a drug may display differences between patients, some of whom may suffer adverse drug reactions that do not occur in others taking the same drug at the same dose.

It is the impact of these individual genetic differences on the risk/benefit ratio and on improved therapeutic use of drugs that the science of pharmacogenetics aims to unravel. This subject has been recently reviewed by several authors[25–38].

While mutation is a rare variation in DNA sequence, which is found in less than 1% of the population, polymorphism indicates a difference in DNA sequence among individuals that occurs in 1% or more of the population. Sometimes up to 50% of a population is carrying a given polymorphism. Each individual is characterized by a sequence of three billion base pairs. One out of 300 base pairs varies from person to person, which means that any individual can be distinguished from his neighbour by about 10 million base pairs. As only 1% of the base pairs appears to be functional, about 100 000 base pairs account for changes in protein structure and function. This common variation is called polymorphism and single nucleotide polymorphism (SNP) is the most common form, where the DNA varies by only a single base or nucleotide. Identification and mapping of SNP will provide new markers across the genome that will help identify regions of the genome itself associated with therapeutic response or adverse effects. Presently, pharmacogenetic studies are mainly based on correlating individual response with variations in 'candidate' genes involved in the drug's mode of action or metabolic pathways[38].

Pharmacogenetics may be defined as the variability in drug response due to genetic factors. Response is used here in the broadest sense: absorption, distribution, metabolism, excretion pathways, target receptors, drug's mechanism of action, efficacy, side effects.

From an experimental point of view, having a certain result in a pharmacogenetic test would become part of the inclusion criteria for enrolling patients in clinical trials.

This new scientific approach would have the potential to enable physicians to identify susceptible patients and enhance the risk/benefit ratio for a given drug. One could envision a day when physicians will use pharmacogenetic rather than population data to make more informed decisions about therapy, especially in those multifactorial conditions such as cardiovascular disease.

It is important, however, to have realistic expectations about pharmacogenetics, at least in the next few years. The analysis of a broad set of genetic markers may only show that a genotypically defined subgroup of patients with a certain disease may have a higher probability of responding in a certain way to a certain drug. In this respect pharmacogenetic analysis has been compared to the assessment of blood pressure or cholesterol levels: when raised, these parameters are accepted risk factors for cardiovascular disease, but they do not necessarily imply that the patient will definitely suffer from a specific cardiovascular disease.

Moreover, cardiovascular disease, like other chronic diseases, is multifactorial and is caused by a combination of several genes and environment or non-genetic factors such as diet and physical excercise. These diseases are therefore difficult to dissect and the degree of correlation between genotypes and disease or drug response may be quite low. These days, genetic epidemiology is focusing

Cambridge Books Online © Cambridge University Press, 2009

increasing effort on controlling for potential environmental confounders.

Adverse events associated with drugs remain a significant problem[32]. Despite the large numbers typically enrolled in clinical trials to evaluate efficacy and safety of new drugs, rare adverse reactions (less than 1 in 1000) tend to be identified only when the drug has been used in much broader patient populations, i.e. during the initial marketing phase.

Pharmacogenetics could overcome this difficulty by targeting drugs to patients likely to benefit and unlikely to experience adverse events.

If a new molecule is developed for the treatment of acute myocardial infarction and, in phase II trials definite measures of efficacy are demonstrated in only 30% of patients, a phase III placebo-controlled trial would need to be very large, because 70% of patients would be predicted not to respond to the drug[34]. As no one would know which 70% would be 'non-responders', these patients would, in effect, participate in the trial solely for the purpose of revealing adverse reactions. Using a SNP profile one could identify in the phase II trial, the 30% of patients likely to respond. A phase III trial could then recruit only those patients with that pharmacogenetic profile, and trials could be smaller, faster and less expensive. Inclusion of patients whose pharmacogenetic profiles indicate a low chance of efficacy would expose them to potential adverse reactions and would be ethically questionable.

A 'single nucleotide polymorphisms' (SNP) Consortium has been recently formed to advance the development of genetic-based diagnostics and therapeutics, through the creation of a high quality, high density SNP map of the human genome, which will be made available to all parties at no cost. The SNP Consortium is a public initiative funded by the Wellcome Trust and 11 major pharmaceutical companies and contracts SNP research to leading academic centres. The creation of this genome-wide map of SNP, together with the recent completion of the human genome sequence, is expected to greatly expedite genetic research in the next few years[38].

Finally, race or ethnic specificity must be considered in relation to the population frequency of polymorphic genes of pharmacogenetic interest, as recently reviewed by Weber[39]. Association of these genes with person-to-person differences in drug effectiveness and toxicity may also depend on the racial or ethnic characteristics of a population. Information about ethnic specificity is an integral part of pharmacogenetics. For example, primaquine sensitivity, a sex-linked trait attributed to glucose-6-phosphate dehydrogenase deficiency, mainly affects males among African, Mediterranean and Oriental people. Other examples include the remarkable sensitivity of Japanese to alcohol (ethanol) compared with whites and the ethnic specificity of the cytochrome P-450 enzyme CYP2D6* polymorphism, that results in poor, extensive and ultrarapid metabolizers of at least 30 drugs, including warfarin. CYP2C19* polymorphism, which accounts for variable metabolism of proguanyl, omeprazole and certain barbiturates, is present in 3–6% of whites, but in 8–23% of Asians. The polymorphic (*N*-acyl-transferase2, NAT2*) acetylation of hydrazine and aromatic amine drugs, such as isoniazid, has been found in 40–70% of whites, in 50–60% of black Africans, but only in 10–20% of Asians[39,32].

Some examples of possible variability in antiplatelet and other antithrombotic drug response due to genetic factors

Data is still lacking on the genetic control of antiplatelet drugs' pharmacokinetics, but an instructive example of the importance of pharmacogenetics in drug metabolism and pharmacological response is given by a common and quite old antithrombotic compound such as warfarin.

Polymorphisms and the efficacy and safety of the oral anticoagulant warfarin

Warfarin is the oral anticoagulant drug most widely used in patients with venous and arterial thromboembolism. To keep the WHO international normalized ratio (INR) values between 2.0 and 3.0, doses of warfarin may widely fluctuate, from 1 to 20 mg or more daily. Standardized induction schemes with monitoring of INR over the first 4 days have only a 69% success rate. Such interindividual variations are partly due to the presence of polymorphism of the CYP2C9 gene[40]. CYP2C9 is a cytochrome P450 enzyme responsible for the metabolism of S-warfarin. S-warfarin, the more potent isoform of warfarin, is converted by CYP2C9 into inactive 6-hydroxy and 7-hydroxy metabolites.

CYP2C9*2 and CYP2C9*3 polymorphisms are both point mutations of the wild-type gene CYP2C9. In vitro data show that the CYP2C9*3 variant is less than 5% and the CYP2C9*2 about 12% as efficient as the wild-type enzyme. In vivo data show that the presence of the mutant polymorphism is responsible for impaired metabolism of warfarin, as carriers of either mutant allelic form behave as 'poor' warfarin metabolizers. Up to 20% of the general population could be carrier of at least one of these variations.

To verify the impact of the CYP2C9 gene polymorphism on the warfarin dose requirements, a study has been

Cambridge Books Online © Cambridge University Press, 2009

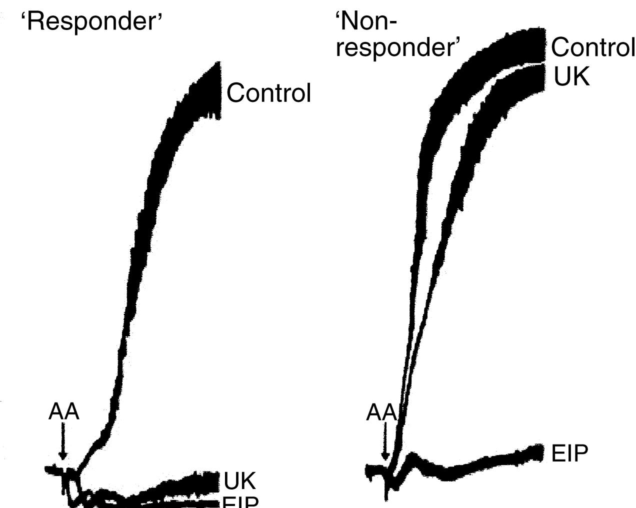

Fig. 65.1. Effect of dazoxiben (UK), a thromboxane A2-synthase inhibitor, and of 9,11-epoxyiminoprosta-5,13-dienoic acid (EIP), a thromboxane A2 receptor antagonist on platelet aggregation induced by arachidonic acid (AA, 0.4 mM) in platelet-rich plasma from a responder and a non-responder subject. In both specimens dazoxiben inhibited immunoreactive thromboxane B2 generation by more than 95%. The comparable inhibitory effect of EIP on platelet aggregation suggested a normal thromboxane A2 receptor function in both the responder and the non-responder subject. (From ref.[46], with permission.)

conducted on patients requiring low daily doses of warfarin[40]. The frequency of the two allelic variants of CYP2C9 polymorphism in this population has been compared to that of a control group of patients with a wide range of dose requirements attending an anticoagulation clinic and to a control group of healthy volunteers. A strong association has been found between the need for a low dose of warfarin and the presence of at least one mutant allele of the CYP2D9 gene. Moreover, in these patients the induction of anticoagulation was more difficult than in controls, as indicated by longer hospitalization or repeated visits to the outpatient clinic. The lower metabolism of warfarin also makes carriers several times more susceptible to bleeding complications in spite of low dose administration. The concern for this complication is justified by the high mortality risk, especially in the aged population. Therefore, identification of these polymorphisms before starting the therapy might help prevent complications.

The recent discovery of different mutations in coagulation Factor IX has revealed a new type of genetic predisposition to bleeding complications during oral anticoagulant therapy. When receiving warfarin or other coumarins, patients with these variants show a very marked decrease in Factor IX activity approaching that of severe hemophilia B. As a consequence these patients may suffer from bleeding at the beginning of therapy, even before the therapeutic range has been reached[41].

The cost of large-scale genetic screening for different responsiveness to warfarin might be quite high (at least in the forthcoming years), but it should be verified and weighed against prolonged hospitalization, emergency admission for bleeding complications and mortality risk[42].

Responders and non responders to Tx-synthase inhibitors: an *antelitteram* example of pharmacogenetics

As already mentioned, the fascinating concept that selective Tx-synthase inhibition might suppress platelet function while leaving intact vascular prostacyclin generation was developed in the early 1980s[43,44].

However, several studies showed that, when preincubated with a Tx-synthase inhibitor, only the platelets from some subjects (so-called responders) were inhibited, i.e. they did not aggregate after arachidonic acid stimulation, whereas platelets from other subjects (non responders) continued to aggregate despite a similar degree of suppression of TxA2 formation[2,45–50] (Fig. 65.1). It was suggested that in some particular individuals the complex balance between aggregatory (PG endoperoxides, PGE2) and inhibitory (PGD2) prostaglandins and their interactions with specific receptors might result in prevention or stimulation of platelet aggregation associated with TxA2 synthesis inhibition[2].

The unequal functional response of platelets from different subjects to Tx-synthase inhibition was shown to depend on adenylate cyclase function[49,50], that modulates the inhibitory activity of PGD2[51].

Some authors found it not easy to identify characteristics that clearly distinguished platelets from responders and non-responders to Tx-synthase inhibition. Platelets from responders and non responders appeared equally sensitive to the aggregating effect of U46619, an endoperoxide analogue and a TxA2 mimic; the amount of PGE2 generated in the presence of a Tx-synthase inhibitor was very similar in responder and non-responder platelets and they showed the same sensitivity to inhibition of platelet aggregation by PGD2[2,45,48].

Gresele et al.[50], however, found that higher amounts of PGD2, prostacyclin and adenosine were required to suppress arachidonic acid-induced aggregation of platelets from non-responders, while they observed no difference between responders and non-responders concerning platelet sensitivity to forskolin or dibutyryl cyclic AMP. The

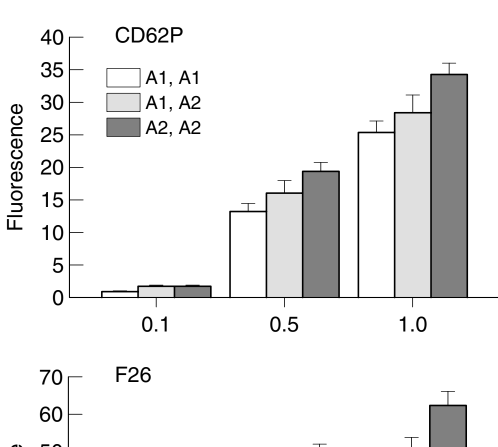

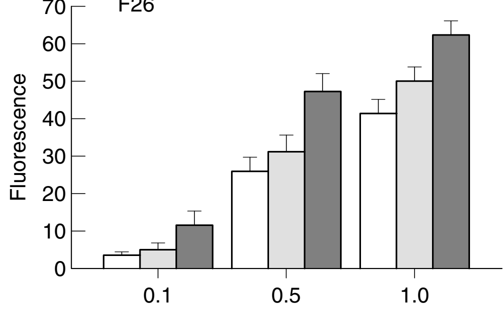

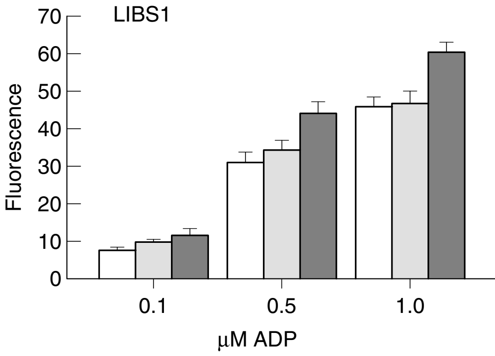

Fig. 65.2. Platelet activation state in whole blood from normal donors, carriers of Pl^{A1} and Pl^{A2} genotypes, stimulated with low-dose ADP. Flow cytometric analysis of surface expression of P-selectin (CD62P), GPIIb–IIIa-bound fibrinogen (F26) and activated GPIIb–IIIa (LIBS1). (From ref.[57], with permission.)

cyclic AMP rise induced by prostacyclin was lower in platelets from non-responders; exogenous PGE2 exerted a pro-aggregatory effect on platelets from all non-responders, but not in platelets from most of the responders. These authors suggested the reason for the relative insensitivity of non-responder platelets to adenylate cyclase stimulators might be an intrinsic hereditary defect of the enzyme[50].

Whether the observation of the existence of responders and non-responders to Tx-synthase inhibitors might be considered as an early unrecognized example of platelet pharmacogenetics is a stimulating possibility, which, however, lacks any direct proof.

Polymorphisms of platelet glycoprotein IIIa and the efficacy of abciximab and aspirin

The glycoprotein IIb–IIIa complex acts as a receptor for fibrinogen and other adhesive molecules on the surface of platelets and is required for their aggregation[10,11]. Polymorphism PI^{A2} is a variant of the gene encoding for glycoprotein IIIa and is present in about 25% of the white population[52]. This polymorphism has been associated with an overall moderate, but significant increased risk of coronary heart disease, especially at young age and in patients undergoing coronary bypass[52–54]. It has recently been shown that PI^{A2} allele is associated with an increased reactivity of platelets to aggregation and with an altered integrin-mediated function of adhesion, spreading and clot retraction[55]. Within the large Framingham Offspring Study, GPIIIa genotype and platelet reactivity phenotype was determined in 1,422 subjects. Allele frequencies of Pl^{A1} and Pl^{A2} were 0.84 and 0.16, respectively. The presence of one or both Pl^{A2} alleles was associated with increased platelet aggregability by adrenaline and, to a lesser extent, by ADP (Table 65.2)[56].

Michelson et al.[57] studied 56 normal donors and compared platelet function in Pl^{A1} and Pl^{A2} genotype carriers: compared with homozygous Pl^{A1} platelets, Pl^{A2} positive platelets showed a significantly higher surface-expressed P-selectin, GPIIb–IIIa-bound fibrinogen and activated GPIIb–IIIa in response to low concentrations of ADP (Fig. 65.2). Surface expression of GPIIb–IIIa was similar in resting platelets of all three genotypes but was significantly greater on $Pl^{A2/A2}$ platelets after ADP stimulation.

While the observations mentioned above offer a biological plausibility to the thrombogenic effect of the Pl^{A2} polymorphism[54], other studies seem to exclude its relation

Cambridge Books Online © Cambridge University Press, 2009

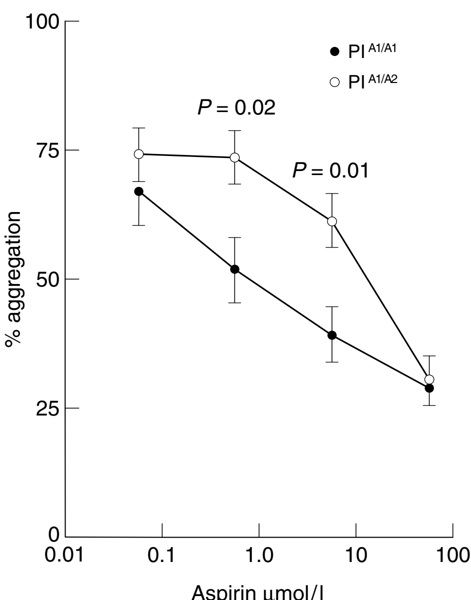

Fig. 65.3. Inhibition of aggregation of $Pl^{A1/A1}$ and $Pl^{A1/A2}$ platelets by aspirin. (From ref.[60], with permission.)

to platelet hyper-reactivity: indeed hyporeactivity of platelets from carriers of Pl^{A2} polymorphism was reported when thrombin or ADP[58], and arachidonic acid or a TxA2 analogue[59] were used as agonists.

In a way unrelated to its possible effect on platelet reactivity to aggregating stimuli, the presence of PI^{A2} polymorphism might influence the antiaggregatory effect of platelet inhibitory drugs[57,60]. In particular, abciximab (ReoPro), a monovalent chimeric Fab fragment of the 7E3 antibody that blocks ligand binding to GPIIb–IIIa and is reportedly beneficial in coronary ischemic syndromes[11], caused small but significant differences among genotypes in inhibiting aggregation. The IC50 (μg/ml) for abciximab was 1.90 ± 0.21 in platelets with the $Pl^{A1/A1}$ genotype but 2.27 ± 0.19 in platelets with $Pl^{A1/A2}$ genotype and 2.13 ± 0.14 in those with $Pl^{A2/A2}$ genotype. Similarly, there were significant differences among these genotypes in the aspirin IC50 (μM): (7.4 ± 2.5 vs. 13.1 ± 3.7 and 14.0 ± 2.1, respectively)[57].

In an earlier study by the same group[60], the inhibitory efficacy of aspirin had been tested in vitro against adrenaline-induced platelet aggregation. The IC50 (μM) of aspirin was 22.8 ± 5.8 in $Pl^{A1/A1}$ platelets but only 2.3 ± 1.2 (a tenfold difference) in $Pl^{A1/A2}$ platelets (Fig. 65.3).

An increased sensitivity to the inhibitory effect of aspirin was also observed in platelets challenged with arachidonic acid from subjects with the Pl^{A2} allele[59].

These in vitro data are to be interpreted in relation to in vivo experiments. Undas et al.[61], measuring the amount of thrombin generated in blood samples collected from bleeding time wounds, found that aspirin (75 mg/daily for 7 days) was inhibitory in 23 out of 25 $Pl^{A1/A1}$ but only in 9 out of 15 $Pl^{A1/A2}$ carriers ($P = 0.02$). Average thrombin generation decreased in A1 homozygous by 63% but in A2 carriers by only 28%. The same group[62] has lately reported that bleeding time was significantly shorter in carriers of the Pl^{A2} allele than in Pl^{A1} homozygous. Four hours after ingestion of 300 mg aspirin, the difference between the two groups was increased: in $Pl^{A1/A1}$ the average bleeding time was prolonged from 372 s to 485 s (Δ 113 s), while in the $Pl^{A1/A2}/Pl^{A2/A2}$ group it was only prolonged from 302 s to 349 s (Δ 47 s). In the latter group, bleeding time after aspirin was still shorter than bleeding time before aspirin in the former group (349 s vs. 372 s).

Altogether, these data support the hypothesis that differential platelet sensitivity to commonly used agents could influence the response of patients to these drugs. However, which aspect of in vitro and/or in vivo platelet function would better reflect the genetic control of the antithrombotic action of antiplatelet drugs remains to be established.

It has been suggested that receptor clustering, a phenomenon that increases GPIIb–IIIa signalling[63], might be inhibited in carriers of a given polymorphism but not of another, so that platelets become more or less susceptible to inhibition by antiplatelet drugs. The significant differences in inhibition may affect either beneficial (antithrombotic) or adverse (hemorrhagic) effects. The GPIIb–IIIa is the most abundant receptor on human blood platelets (about 80000 copies per platelet or 12×10^{16} copies in our body), so that even a subtle functional alteration could have profound effects over the lifetime of a patient[57].

Pharmacogenetics: a new key of interpretation of the Thrombosis Prevention Trial

Analyzing the results of the Thrombosis Prevention Trial[16] in the light of a genetic approach to pharmacology, new interpretations for drug efficacy and new clinical trial designs have been proposed[64]. This trial was performed by general practitioners in the United Kingdom and aimed at finding differences in a primary prevention approach of high risk individuals for cardiovascular disease, by treating them at random with low dose warfarin and/or low dose aspirin against placebo. The prospective follow-up revealed that the group receiving warfarin had the same quantitative reduction in all ischemic events as did the group receiving aspirin. The beneficial effect was greater

Cambridge Books Online © Cambridge University Press, 2009

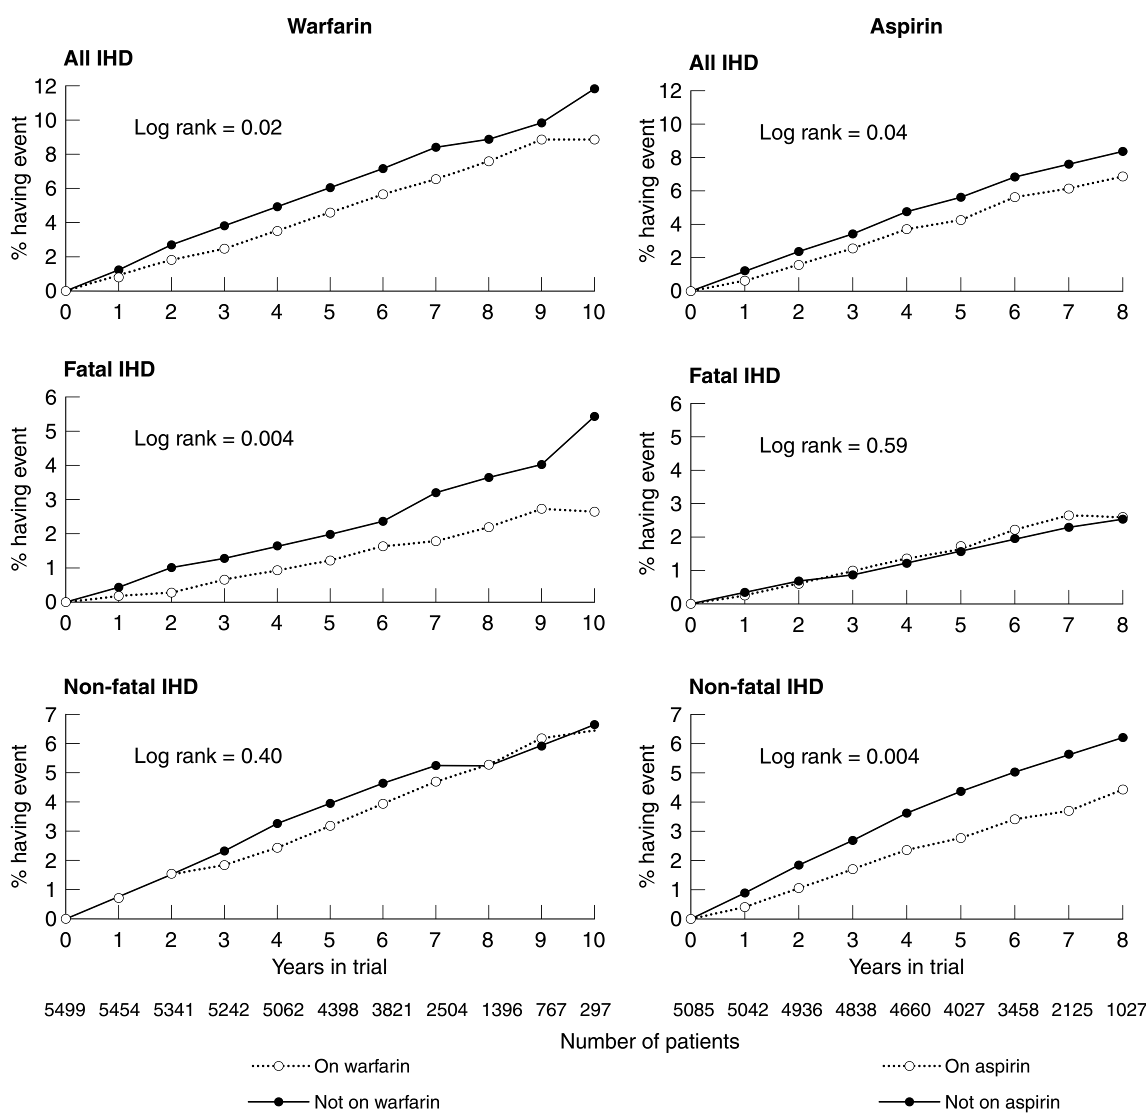

Fig. 65.4. Cumulative proportion (percent) of men with ischemic heart disease (IHD), main effects. *n*, number of patients still on trial for specified duration of follow-up. (From ref.[16], with permission.)

for the group receiving the combined therapy (Fig. 65.4). Bleeding being still a problem of anticoagulant and antiplatelet therapy, subjects receiving the combination also showed an increased hemorrhagic risk as compared to placebo and individual therapies. Future trials might consider genetic categories related to platelet function and coagulation factor activity as a model to predict drug efficacy and risk of bleeding of patients, ultimately providing the choice of the best antithrombotic drug for each patient or subject. In this context, we have already mentioned the Pl^A polymorphisms which may render platelets more or less sensitive to aspirin[57–62]. Polymorphisms in coagulation factor VII and their effect in reducing factor VII levels and the risk of myocardial infarction have also been described[65,66].

On the basis of these considerations, the population included in the Thrombosis Prevention Trial might be theoretically divided into four groups according to the polymorphisms $Pl^{A1/A2}$ of platelet GPIIIa and R356Q of factor VII gene (Table 65.3). The first group includes subjects carrying the alleles Pl^{A2} and 353Q. The second one carries the allele 353R combined with Pl^{A1}. The third group includes carriers of factor VII allele 353R but combined with Pl^{A2}. Finally, the fourth group consists of factor VII allele 353Q carriers

combined with Pl^{A1} allele of GPIIIa. According to the associations genotype/phenotype described in the literature, these groups might have: increased platelet aggregability, high sensitivity to aspirin and low factor VII levels (first group); decreased platelet function, low sensitivity to aspirin and high factor VII levels (second group); increased platelet function, high sensitivity to aspirin and high factor VII levels (third group); and finally decreased platelet function, low sensitivity to aspirin and low factor VII levels (fourth group). We could expect that the first group would benefit from aspirin. It would be useful to reduce high platelet reactivity with a drug to which platelets are genetically sensitive; moreover further reduction by warfarin of already genetically low levels of factor VII could only expose patients to hemorrhagic side effects. In a similar way, the second group should benefit from warfarin, the third group from the combination of aspirin and warfarin, and finally the fourth group should not benefit either from aspirin or from warfarin. The latter could be an ideal group for testing new antithrombotic drugs.

We have also mentioned the CYP2C9 gene polymorphism which can distinguish 'poor' and 'high' metabolizers of warfarin[40]: the former patients should be identified and monitored with particular care as they would be preferential candidates to hemorrhagic side effects.

Metabolism of thienopyridine prodrugs to exhibit antiaggregating activity and/or side effects

Ticlopidine and clopidogrel need to be administered in vivo to exhibit antiaggregating activity. Although some direct effects of thienopyridines in vitro have been reported, most of them are observed at non-relevant doses and do not seem to account for the antiaggregatory activity of these drugs, responsible for their antithrombotic properties[9]. The achievement of an antiaggregating effect only after in vivo administration suggests that the thienopyridines do not act directly on platelets, and shows that active antiaggregating substance(s) must be produced through a metabolic process[9]. A study performed on clopidogrel showed the liver was the metabolic site from which the antiaggregant activity of this drug originates. The hepatic bioactivation of clopidogrel required a cytochrome P450–1A (CYP-1A)-dependent metabolism[8].

A study of the metabolism of ticlopidine resulted in the identification of about 20 separate metabolites, eight representing approximately 30% of the initial compound, but none of them had in vitro activity. The other metabolites representing approximately 70% of the initial compound have not yet been identified, but no study has been able to demonstrate an antiaggregant activity in the plasma of treated subjects[67,68]. This suggests that the active metabolite(s) circulate at very low concentrations and/or may have a very short half-life/lives. Furthermore, the platelets of clopidogrel-treated subjects remain resistant to ADP even after washing, in vitro[67,68] or after the end of treatment, and the rate at which aggregation is restored correlates closely with platelet production[69]. These observations suggest the presence of an active metabolite of clopidogrel, produced by the liver, acting in an irreversible manner on platelets. This compound has recently been purified and its chemical structure determined[8,9]. It is a thiol reactive of clopidogrel which directly targets the ADP- receptor binding on platelets. This interaction is highly specific and irreversible, two features which correspond to the antiaggregating activity observed after clopidogrel treatment. Similarly to what has already been shown for CYP2C9-dependent metabolism of warfarin[40], it is likely that the metabolism of ticlopidine and clopidogrel[70] is also genetically modulated, f.i. by polymorphisms of the P-450–1A cytochrome in the liver (Fig. 65.5).

Not only the efficacy of these drugs but also their safety could be better monitored by a pharmacogenetic approach. Although no cases of thrombotic thrombocytopenic purpura (TTP) were reported among the 20 000 patients who received clopidogrel in clinical trials[7], 11 cases of this serious hematologic adverse effect have been recently described that occurred in patients during or shortly after they received the drug[71]. Nine additional cases of clopidogrel-associated TTP were identified in the weeks following Bennett et al.'s paper[72]. The disorder began within 14 days after the initiation of clopidogrel therapy in all but one patient.

Cambridge Books Online © Cambridge University Press, 2009

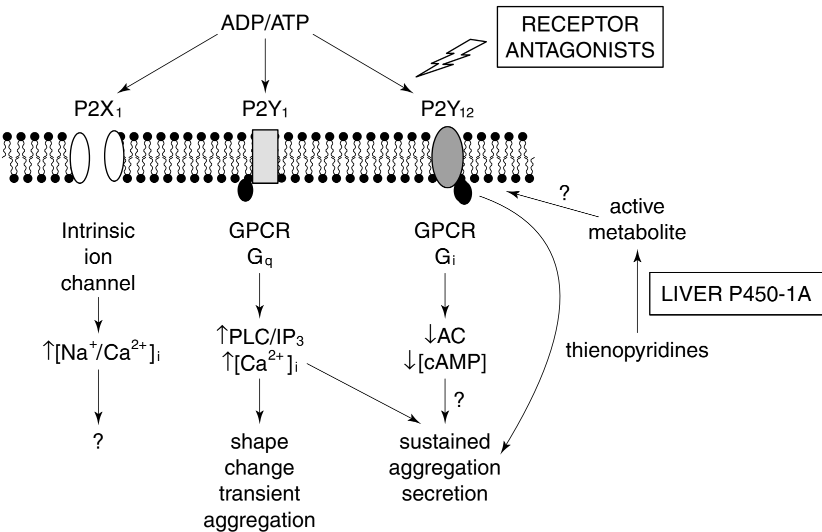

Fig. 65.5. The three-receptor model of ADP-induced platelet activation indicating the sites of action of receptor antagonists and of thienopyridines and their liver metabolite(s). (Modified from ref.[70], with permission.)

In several countries the occurrence of side effects after a drug is marketed is monitored by voluntary reporting systems. However, it has been calculated that only 1% to 10% of all side effects is reported to a reporting body such as the Food and Drug Administration (FDA)-controlled system MedWatch[73]. The need for new, non-traditional approaches to drug safety has been underlined in the Editorial accompanying the report of TTP-clopidogrel association[73], but no mention is made of the possibility that people could be genetically predisposed to develop a side effect while using ticlopidine or clopidogrel. An immune-mediated deficiency of von Willebrand factor-cleaving metalloproteinase activity has been reported in some patients with thienopiridine-related TTP[71,74], thus a mutation or a polymorphism of this protease might contribute to the development of the clinical syndrome.

A novel platelet ADP receptor and its polymorphisms

Hollopeter et al.[75] have recently described a novel ADP receptor expressed in platelets that mediates platelet aggregation via inhibition of adenylyl cyclase. They identified and cloned the P2Y12 receptor, and showed that it is abundantly expressed on the surface of human platelets, and to a smaller extent in the brain. The predominant transcript of P2Y12 was absent from all other tissues examined. The gene for P2Y12 is located on chromosome 3, in a region that contains genes encoding at least three receptors, two of which mediate ADP-dependent platelet aggregation. Analysis of platelets from a patient previously diagnosed with a mild bleeding disorder revealed the presence of a mutant allele at the locus corresponding with the P2Y12 gene[76]. Although only one allele was affected by a frame-shift mutation, this patient did not produce any wild-type P2Y12 protein, suggesting that expression of the normal allele is repressed. As already mentioned, ticlopidine and clopidogrel block the P2Y12 receptor, but have therapeutic limitations. These include their slow onset of action, irreversible blockade of the receptor and undesirable side effects in some patients. Now that the receptor has been cloned, the development of more highly targeted drugs should be accelerated. Some groups are also developing a P2Y12-deficient mouse to further evaluate the role of this receptor in normal platelet function and in thrombotic models of vascular injury. The more we know about this receptor, the more opportunities there will be for rational drug design. Future work to identify further mutations and polymorphisms in the receptor gene will be another important step. If abnormalities in P2Y12 are common, this could be a modulating factor in the population that can decrease risk for thrombotic disease[77–79].

A hypothetical case in 2010

General visions of gene-based medicine in the future are useful, and may allow to anticipate some future scenarios of the daily practice of medicine in a primary care setting. A hypothetical clinical encounter in 2010 has been recently

Cambridge Books Online © Cambridge University Press, 2009

described[80] and will be reported here with some modifications.

John, a 23-year-old college graduate, is referred to his physician because a serum cholesterol level of 255 mg per decilitre was detected in the course of a medical examination required for employment. He is in good health but has smoked one pack of cigarettes per day for 6 years. Aided by an interactive computer program that takes John's family history, his physician notes that there is a strong paternal history of myocardial infarction and that John's father died at the age of 48 years.

To obtain more precise information about his risks of contracting coronary artery disease and other illnesses in the future, John agrees to consider a battery of genetic tests. After working through an interactive computer program that explains the benefits and risks of such tests, John agrees (and signs informed consent) to undergo 15 genetic tests that provide risk information for illnesses for which preventive strategies are available. He decides against an additional ten tests involving disorders for which no clinically validated preventive interventions are yet available.

A cheek-swab DNA specimen is sent off for testing, and the results are returned in one week. John's subsequent counselling session with the physician and a genetic nurse specialist focuses on the conditions for which his risk differs substantially (by a factor of more than two) from that of the general population.

John is pleased to learn that genetic testing does not always give bad news. His risks of contracting prostate cancer and Alzheimer's disease are reduced, because he carries low-risk variants of the several genes known (in 2010) to contribute to these illnesses. But, John is sobered by the evidence of his increased risks of contracting coronary artery disease, colon cancer and lung cancer. Confronted with the reality of his own genetic data, he decides to introduce some change in health-related behaviour, focused on reducing specific risks. By 2010, the field of pharmacogenetics has blossomed, and a prophylactic drug regimen based on the knowledge of John's personal genetic data can be precisely prescribed to reduce not only his cholesterol level but his global risk of coronary artery disease to normal levels. In particular, as he carries the platelet glycoprotein IIIa Pl^{A2} variant gene, that makes platelets more sensitive to aspirin inhibition[57,59] a low-dose, slow release, bone marrow targeted aspirin is prescribed (to be taken twice a week). On the other hand, considering that John carries the B2B2 polymorphism of the cholesterol ester transfer protein (CETP), that is present in about 16% of the population and makes its carriers quite resistant to cholesterol lowering drugs[81] no prevention with a statin is planned. John also carries the ApoEe4 form of the ApoE polymorphism, that shows a high response to probucol, another cholesterol lowering drug[82]; thus he is given dietary advice and a probucol course. John is also informed to be a genetically 'slow' ethanol oxidizer as he is homozygous for the alcohol dehydrogenase type 3 $\gamma 2$ allele: in moderate wine drinkers (one or two drinks per day) this allele is associated not only with a reduced rate of ethanol oxidation, but also with high plasma levels of HDL and a substantially decreased risk of myocardial infarction (relative risk: 0.14, 95% confidence limits from 0.04 to 0.45, in respect to carriers of $\gamma 1$ $\gamma 1$ alleles who consume less than one drink per week)[83]. Although individuals with a slow rate of metabolism of ethanol may be at higher risk for alcohol-associated diseases, John, who is already a usual moderate wine consumer, is encouraged to continue this dietary habit and to drink with meals[84]. His risk of colon cancer will be addressed by beginning a programme of annual colonoscopy at the age of 45, which in his situation is a very cost-effective way to avoid colon cancer. His substantial risk of contracting lung cancer provides the key motivation for him to join a support group of persons at genetically high risk for serious complications of smoking, and he successfully kicks the habit.

Next stop: proteomics

The simplified, though useful, idea of one gene to one protein to one function is no more acceptable, as cells and organisms are far more complex than is indicated by analysis of the genetic material alone. The concept of a human protein index was put forward in the 1980s[85]: proteins are the functional output of the cell and might therefore be expected to provide the most relevant information in specific biological contexts[86]. Proteomics thus complements the genomics, as the genetic code cannot always indicate which proteins are expressed, if they are glycosylated or phosphorylated, which is their three-dimensional structure, and finally, what is (are) their function(s). Moreover, the influence of environmental factors such as dietary habits or drug administration or of multifactorial processes such as ageing, cardiovascular disease or cancer cannot be fully evaluated by the simple analysis of the genome. Therefore, new perspectives and new biomedical opportunities are emerging by proteomics-based approaches[86]). Preliminary studies suggest an average number of three to more than six protein forms per each gene, in human beings[87]. This means that the human body may contain more than 200 000 modified proteins. Most drugs, including antiplatelet agents, exert their effects on

Cambridge Books Online © Cambridge University Press, 2009

proteins. It is thus conceivable that in the postgenome era a concerted strategy with proteomics approaches will allow pharmacogenetics to achieve its potential in biomedical research and clinical practice.

Cardiovascular gene therapy: implications for platelet vessel wall interactions

Pierre Zoldhelyi, Harold Eichstaedt, Thomas Jax, Janice M. McNatt, Zhi Qiang Chen, Harnath S. Shelat, Harris Rose and James T. Willerson

Wafic Said Molecular Cardiology and Gene Therapy Research Laboratory and Cullen Research Laboratory, Texas Heart Institute, and Department of Medicine (Divisions of Cardiology and of Clinical Pharmacology), The University of Texas Medical School at Houston, USA

Introduction

Evidence for the occurrence of coronary thrombosis early after percutaneous coronary interventions in humans was provided by serial angioscopic studies that demonstrated the development of varying degrees of thrombosis in over 90% of cases within 60 min after successful coronary balloon angioplasty[1]. Furthermore, studies on the effectiveness of acute PTCA during unstable angina have indicated not only an increased number of periprocedural complications but a relatively high incidence of restenosis[2,3]. Based on experimental and clinical evidence, it has been suggested that arterial thrombosis promotes the fibroproliferative response during later restenosis and progression of atherosclerosis[4–6]. The platelet IIb/IIIa and α_v/β_3 integrin receptor blocker, abciximab (ReoPro), reduced the need for recurrent clinical revascularization only in the EPIC trial[7], which enrolled patients with unstable angina (due, in general, to coronary thrombosis). In contrast, the later EPILOG trial in patients without acute coronary thrombosis failed to show a reduction in the need for recurrent revascularization[8], consistent with a role of early acute thrombosis in the pathogenesis of clinical restenosis. The incidence of periprocedural complications and 'clinically apparent' thrombosis after PTCA and stenting is sharply decreased by the administration of antiplatelet regimens, including the platelet IIb/IIIa receptor blockers and aspirin/ticlopidine or plavix. The efficacy of such interventions for the long-term prevention of 'subclinical' thrombosis and platelet deposition is uncertain, especially after these agents are withdrawn. Nevertheless, platelet thrombi are a rich source of vasoconstriction, mitogens, and chemotactic agents (Table 66.1 and Fig. 66.1).

Table 66.1. Selected thrombus-related mediators of neointimal VSMC accumulation

Agent	Action
Serotonin	Vasoconstrictor[a], VSMC mitogen
Thromboxane A_2	Vasoconstrictor, VSMC mitogen
PDGF	Vasoconstrictor, VSMC mitogen, VSMC chemotaxis
Thrombin	Vasoconstrictor[a], VSMC mitogen monocyte chemotaxis, activates MMP-1,2
Factor Xa	SMC mitogen
TGF-β	Stimulates ECM production

Note:
[a] In atherosclerotic arteries.

Experimental antithrombotic gene therapy

Compared to the large number of gene transfer approaches aimed at inhibiting VSMC proliferation, experimental gene therapy approaches for the prevention of arterial thrombosis have been limited. In part, this may reflect the greater technical challenge posed by developing thrombosis models for gene therapy. Since there is usually a delay between gene transfer and gene expression, the therapeutic test (i.e. the thrombotic challenge) requires at least one additional experiment, usually several days after the gene vector is delivered to the artery. Thrombosis is

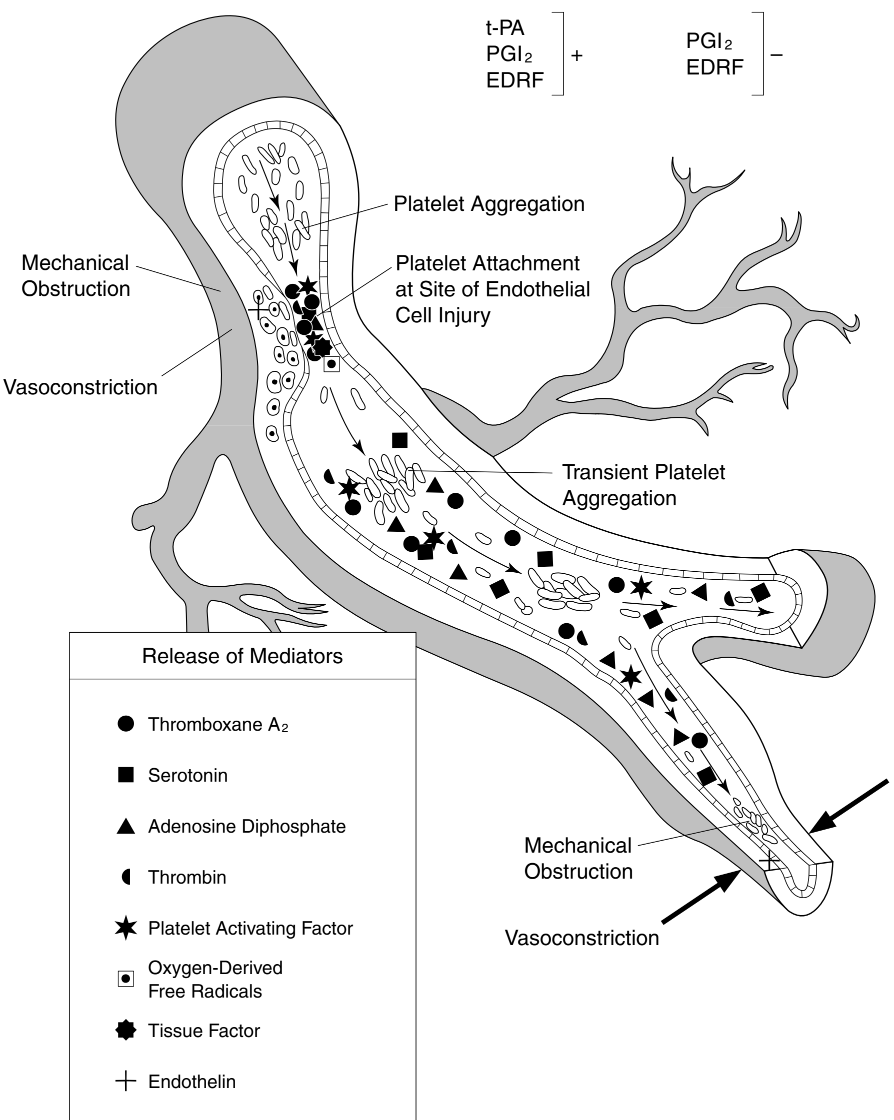

Fig. 66.1. Schematic diagram suggests probable mechanisms responsible for the conversion from chronic coronary heart disease to acute coronary artery disease syndromes. In this scheme, endothelial injury, generally at sites of atherosclerotic plaques and usually plaque ulceration or fissuring, is associated with platelet adhesion and aggregation and the release and activation of selected mediators, including thromboxane A_2, serotonin, adenosine diphosphate, platelet-activating factor, thrombin, oxygen-derived free radicals, and endothelin. Local accumulation of thromboxane A_2, serotonin, platelet-activating factor, thrombin, adenosine diphosphate, and tissue factor promotes platelet aggregation. Thromboxane A_2, serotonin, thrombin, and platelet activating factor are vasoconstrictors at sites of endothelial injury. Therefore, the conversion from chronic stable to acute unstable coronary heart disease syndromes is usually associated with endothelial injury, platelet aggregation, accumulation of platelet and other cell-derived mediators, further platelet aggregation, and vasoconstriction, with consequent dynamic narrowing of the coronary artery lumen. In addition to atherosclerotic plaque fissuring or ulceration, other reasons for endothelial injury include flow shear stress, hypertension, immune complex deposition and complement activation, infection, and mechanical injury to the endothelium as it occurs with coronary artery angioplasty and after heart transplantation. EDRF, endothelium-derived relaxing factor, PGI_2, prostaglandin I_2; t-PA, tissue-type plasminogen activator. (From Willerson JT: *Treatment of heart disease*. New York: Gower Medical, 1992; modified from Willerson JT, Golino P, Eidt JF et al. Specific platelet mediators and unstable coronary artery lesions. Experimental evidence and potential clinical implications. *Circulation* 1989; 80:198.

Cambridge Books Online © Cambridge University Press, 2009

often provoked by endothelial injury and increasing shear stress and thrombus formation is monitored in vivo by measurement of blood flow (or a surrogate such as flow velocity) or assessed after death by histomorphometry of the thrombosis-covered luminal area. Another issue, when the thrombotic test is delayed several days after the administration of the gene, is the clinical relevance of providing antithrombotic protection beginning 1 or more days after the insult. Thrombosis in patients with atherosclerotic disorders is a dynamic process, posing a lifelong risk. Chronically recurrent cycles of thrombosis, thrombolysis, thrombus organization, and rethrombosis encroach on the vascular lumen over the course of months and years and provide a myriad of stimuli for VSMC and ECM accumulation. In addition, whether involving heart, brain, or other structures, the final trigger of tissue death caused by the atherosclerotic process is formation of an occlusive thrombus. Thus, we believe that more durable and continuous antithrombotic protection may exert benefits beyond those provided by antithrombotic drug therapy during the first 24 h after the iatrogenic insult. Vectors that can express foreign genes within hours of their delivery have been described, but presently often have the trade-off of very short-lived expression[9].

Gene transfer techniques

Endothelial injury and dysfunction result in local deficiency of vasoprotective molecules, including prostacyclin (PGI_2), NO, tissue-type plasminogen activator (tPA), thrombomodulin, and tissue factor pathway inhibitor (TFPI), with an attendant risk of thrombosis. Endothelial proteins synthesizing vasoprotective molecules, such as cyclooxygenase-1 (COX-1) and endothelial nitric oxide synthase (eNOS), are membrane-bound and synthesize autacoids with short half-lives. Thus, restoration and augmentation of these autacoids by local gene transfer of crucial enzymes to sites of endothelial injury appears to be a physiologically sound strategy. In contrast to pharmacological approaches, local gene transfer techniques restrict the presence of a potentially therapeutic protein to the vascular site at risk, while extending in time the effect of a single administration of the therapeutic precursor, the DNA encoding a potentially beneficial protein. Genes transferred to the arterial wall to restore or augment the endogenous antithrombotic defence include COX-1 (catalysing PGI_2 synthesis), thrombomodulin (enhancing protein C activation), tPA (generating plasmin), and most recently TFPI, which inhibits factor Xa and the tissue factor/factor VIIa complex.

Gene transfer of thrombomodulin

Thrombomodulin, an endothelial transmembrane protein containing six tandemly repeated EGF domains, binds thrombin and its active precursors, meizothrombin and desmeizothrombin. After binding to thrombomodulin, thrombin loses its affinity for fibrinogen and, concurrently, becomes a potent activator of circulating protein C, which inactivates factors Va and VIIIa. Compared to thrombin alone, protein C activation is accelerated 20 000-fold by the endothelial thrombomodulin–thrombin complex[10]. Luminal surface expression of thrombomodulin decreases after perturbation of endothelial cells, after removal of endothelial cells (during angioplasty), and in saphenous veins after harvesting the vein[11]. Systemic infusion of recombinant thrombomodulin and of recombinant activated protein C prevents thrombosis and accelerated thrombolysis in animal models of arterial injury[12].

Shenaq's group has described a rabbit arterial stasis/minimal injury model designed to study prevention of small vessel thrombosis at sites of anastomoses[13]. In its adaptation to gene therapy studies, division of the common femoral artery was followed by microsurgical reanastomosis of the segments and adenovirally mediated gene delivery to the reanastomosed vessel. Three days later, two perpendicular sutures loops were loosely placed through the lumen distal to the anastomosis and animals were allowed to survive for an additional 3 days. At death, the thrombus area was assessed by quantitative histomorphometry. In this model of 'microvascular thrombosis', the common femoral artery was targeted by adenoviral vector injection through the inferior epigastric artery. Trauma to the endothelium was deliberately avoided. Local endothelial gene transfer of thrombomodulin in this anastomosis model reduced arterial thrombosis formation compared to viral and nonviral controls[14]. By histological analysis, delivery of the viral suspension buffer alone and of a viral control vector was associated with thrombi occluding $71 \pm 4\%$ and $87 \pm 3\%$ of the lumen, respectively. In contrast, adenoviral delivery of the thrombomodulin gene (titre of 3 $\times$109 pfu/ml) reduced the thrombus area to $29 \pm 3\%$ and significantly decreased local infiltration of granulocytes and macrophages compared to nonviral and viral control. Thrombus was exclusively assessed postmortem[14]. No information was provided about dynamic changes in thrombus formation over time or under the influence of added prothrombotic stimuli, such as systemically administered epinephrine (see below).

Gene restoration of tPA

Some of the first reports of gene transfer of plasminogen activators against arterial thrombosis were made by Dicheck et al.[15]. Using recombinant retroviral vectors, these co-worker transduced cultured baboon endothelial cells ex vivo with tPA and a urokinase-type plasminogen activator variant (a-UPA). The transduced endothelial cells were instilled into exteriorized arteriovenous femoral shunts grafted with collagen. The authors were able to show a reduction in ^{111}In-labelled platelet deposition in areas covered by 'sparsely attached' endothelial cells over-expressing tPA. However, in a follow-up paper, the authors reported that the transduced endothelial cells were rapidly lost from the luminal surface. Plasmin, generated under influence of the transgene product itself (tPA, a-UPA), severely comprised the anchorage of the endothelial producer cells[16].

Gerard et al. reported in a mouse model that intravenous injection of an adenovirus encoding wild-type and a plasminogen activator inhibitor-1 (PAI-1)-resistant variant of tPA human to mice with inactivated tPA gene achieved restoration of circulating tPA[17]. Typically, systemically injected adenovirus localizes to $>$95% in the liver from which the secreted transgene product enters the blood stream[18]. In the mice injected with the viral construct, plasma levels of tPA antigen and activity were increased approximately 1000-fold above normal levels. The lysis of 1251-fibrin-labelled pulmonary emboli closely correlated with plasma tPA activity and clot lysis was obtained after injection of adenoviral constructs encoding wild-type and inhibitor-resistant tPA. Adenovirus-mediated tPA gene transfer was found to augment clot lysis as early as 4 h after infection, but expression was lost within 7 days. The authors concluded that adenovirus-mediated transfer of a tPA gene can effectively increase plasma fibrinolytic activity and either restore (in t-PA-deficient mice) or augment (in PAI-1-overexpressing mice) the thrombolytic capacity in this animal model[17].

While these mice experiments serve as a corollary to the physiological importance of circulating tPA, they do not enhance our understanding of the potential of local tPA gene therapy for the prevention of arterial thrombosis. This issue was directly addressed in recent study by Waugh et al. in the rabbit stasis-minimal injury model[19]. An adenoviral construct encoding human wild-type tPA was delivered to the minimally injured common femoral artery of New Zealand White rabbits. Three days later, thrombus formation was initiated by transection of the artery, immediate re-anastomosis and placement through the lumen of two perpendicular 8.0 silk loops distal to the anastomosis. After death on day 6 (3 days after placement of the anastomosis), the cross-sectional area of thrombotic obstruction was found to be 68 ± 8, 80 ± 6, $61 + 6$ and 19 ± 2% for rabbits treated locally with, respectively, buffer, control virus, a systemic rtPA infusion, and Ad-tPA (5×10^9 pfu/ml). Systemic hemostatic variables and plasma fibrin split products were unchanged from baseline. In this study, local expression of tPA was more effective than a systemic tPA infusion and completely spared the systemic hemostatic system[19].

Gene transfer of cyclooxygenase-1 to sites of severe arterial injury

Like tPA and NO, prostacyclin (PGI_2) is a vasoprotective molecule constitutively expressed by the healthy endothelium. PGI_2 is a potent platelet inhibitor and vasorelaxant molecule that acts on platelets on the luminal side and on VSMC underneath the endothelium. It inhibits platelet secretion and aggregation, relieves vascular contraction, suppresses VSMC proliferation, reduces lipid accumulation in mononuclear and VSMC, and is reported to block the interaction between monocytes and endothelium[20,21]. Its actions involve receptor-mediated activation of adenylyl cyclase, leading to increased intracellular cAMP levels. Attempts to prevent thrombosis by systemic infusion of prostacyclin or its stable analogues have been unsatisfactory because of unacceptable side effects.

COX-1 is considered to be the key rate-limiting step in endothelial PGI_2 synthesis[22]. Maintenance of physiological levels of PGI_2 requires continuous synthesis of this autacoid by COX-1 and other enzymes. Like its product, however, COX-1 has a relatively short half-life (about 7 min) due to autoinactivation, i.e. accelerated degradation during catalysis of PGI_2. Thus, maintenance of physiological PGI_2 levels requires continuous synthesis of COX-1 and is exquisitely vulnerable to endothelial insults[22].

In order to overcome the limitations of PGI_2 synthesis, we constructed an adenovirus encoding COX-1 (Ad-COX-1). Compared to a control vector and buffer only, gene transfer of COX-1 enhanced PGI_2 synthesis in cultured VSMC and in balloon injured porcine carotid arteries about fivefold. When porcine carotid arteries were treated for 30 min with Ad-COX-1 at a relatively high titre (6×10^{10} pfu/ml) immediately after balloon injury (5 inflations at 7 atm), cyclic flow variations (CFVs), caused by recurrent embolizing thrombi, were completely prevented for 10 days after surgery (as observed on continuous blood flow velocity recordings) and no thrombi were seen at death, suggesting that local enhancement of PGI_2 synthesis is

Cambridge Books Online © Cambridge University Press, 2009

highly effective against platelet-rich thrombosis at sites of severe arterial injury[23].

Gene restoration of tissue factor pathway inhibitor

Recently, we[24] and others[25] have begun to study the antithrombotic efficacy of gene transfer of tissue factor pathway inhibitor (TFPI). TFPI is an endogenous inhibitor of factor Xa and of tissue factor (TF), the cellular initiator of thrombin generation and blood coagulation in hemostasis and thrombosis[26]. TF-driven thrombin generation plays a pivotal role in arterial and venous thrombosis, leads to activation of enzymes involved in neointima formation[27], and is a potent VSMC mitogen[28]. Factor Xa is a VSMC mitogen as well[29]. Up-regulation of TF contributes importantly to the thrombogenicity of the atherosclerotic plaque[30]. Although systemic administration of TFPI has been studied as a new approach to the prevention of thrombosis, and restenosis[31–33], it is uncertain whether short-term administration of recombinant TFPI will achieve lasting vasoprotection, particularly at sites of increased tissue factor burden. In addition, while continuous administration of antithrombin agents, including desirudin, may promote long-term patency of injured vessel[34], hemorrhagic risks are inevitable and the systemic doses of recombinant human TFPI capable of preventing arterial thrombosis and, potentially, restenosis are substantial (100 (g/kg/min in[32]), raising further questions on the practicality of a systemic dosing approach. The need for such a high dosage has substantially tempered the enthusiasm for the development of recombinant TFPI for the treatment of arterial thrombotic disorders.

In order to study the effects of TFPI gene transfer on thrombus formation at sites of severe arterial injury, porcine carotid arteries were balloon-injured and locally treated with an adenovirus encoding human wild-type TFPI (Ad-TFPI) or a control virus. Gene transfer of TFPI was confirmed by detection of human TFPI in the conditioned medium of porcine carotid arteries kept in culture after in vivo vector delivery. When carotid flow was measured by Doppler probes 5 days after surgery, cyclic flow variations (CFVs) developed in seven of eight control pigs after constriction of the injured carotid artery by 40%, and all control treated arteries occluded after 70% constriction. In contrast, CFVs were observed in only one of eight Ad-TFPI treated pigs after 40% constriction, and only three of eight occluded after constriction by 70% ($P = 0.0027$ and $P = 0.007$, respectively). None of the five TFPI-transduced arteries open after 70% constriction developed CFVs during an incremental epinephrine infusion. A detailed analysis of coagulation variables and BT on the day of the thrombosis challenge (day 0) illustrates the potential of local arterial gene therapy to exert vasoprotection in the complete absence of systemic effects. Indeed, neither coagulation variables nor BT were significantly different between the Ad-TFPI and the control group and between baseline (day 0) and day 5. Platelet aggregation was completely conserved after local treatment with Ad-TFPI. Whether overexpression of TFPI and COX-1 at sites of increased thrombogenicity will provide lasting protection against thrombus formation and reduce the degree of neointima formation needs to be determined in future experiments.

Gene therapy to prevent fibroproliferative lesions

Local cell proliferation and migration, apoptosis, vascular remodelling, ECM deposition, and episodes of recurrent clinical and subclinical platelet deposition and thrombosis determine the magnitude of neointima formation and restenosis after percutaneous revascularization[6]. Vascular injury during PTCA/stenting stimulates proliferation and migration of vascular smooth muscle cells (VSMC) and the deposition of ECM by the 'activated' VSMC[35,36]. This role of VSMC in the restenotic process was first recognized in a rat carotid injury model. In this model, VSMC begin to proliferate within days after injury and soon migrate to the intima, helped by their production of hyaluronidase, urokinase, matrix metalloproteinases (MMP) and perhaps tPA[37,38]. There, the VSMC proliferate further and synthesize ECM and other paracrine and autocrine growth factors and cytokines, amplifying the cellular and non-cellular responses to injury. After 3–6 months, 90% of the neointimal cell population are VSMC. However, the bulk of VSMC constitutes only 20% of the neointimal mass, with most of the rest being ECM[37,39,40].

The growth of VSMC and extracellular matrix deposition are driven by a variety of growth factors, including bFGF[41], PDGF[42–44], TGF-β[45], IGF-1[46] and angiotensin II[47]. Loss of endothelial inhibitors of VSMC proliferation and inhibitors of collagen and proteoglycan synthesis, like NO, shift the balance further towards proliferation and migration of VSMC and the accumulation of ECM[48,49].

The main cellular target of antiproliferative gene therapy to date has been VSMC. The proteins encoded by the gene vector include cell cycle-regulatory proteins that inhibit entry or progression of the cell cycle ('cytostatic gene products'), or cause cell cycle exit by programmed cell death

Cambridge Books Online © Cambridge University Press, 2009

and elimination of the VSMC ('cytotoxic or apoptotic gene products'). Other transferred genes encode endothelial proteins with diverse functions, some of which affect the cell cycle machinery. Others suppress VSMC proliferation by accelerating endothelial healing of the injured vascular site, making available to the injured site the broad range of endothelial VSMC growth inhibitors. Using gene transfer techniques, the cell cycle inhibitory proteins can be overexpressed at the site of injury (e.g. adenovirus-mediated overexpression of p21 or Rb). Alternatively, the expression of cell cycle-promoting proteins can be blocked by the delivery of specific, short DNA sequences. These specific, short DNA sequences function by either decoy or antisense mechanism (see below). Both are intended to inhibit the translation of specific mRNA sequences and, thus, the synthesis of cell cycle regulatory proteins. While this latter strategy is attractive in principle, there is some concern about the specificity of the target(s) sequence inhibited by decoy and especially antisense oligodeoxynucleotides ('ODN'). On the other hand, this approach may avoid potential side effects related to the overexpression of cell cycle proteins with, as yet, unknown functions and risks.

Inhibiting cell cycle

In order to block the entry into the cell cycle and replication of the cell, a variety of gene transfer approaches are under investigation. Chang et al.[50] showed in a rat and porcine balloon injury model that adenovirus mediated transfer of a mutant gene encoding a hypophosphorylated retinoblastoma significantly reduced the intima–media ratio compared to non-treated or control-treated animals. This mutant is constitutively active and binds to and blocks E2F, a family of transcription factors that plays a major role in S-phase entry of the cell. An alternative approach uses the overexpression of the endogenous cell-cycle-dependent kinase inhibitors protein, p21[51,52], p16[52,53], and p27[54]. These proteins act upstream of Rb and function by maintaining Rb in a hypophosphorylated (inactive) state[55].

Gax is a homeobox gene normally expressed by vascular smooth cells that is down-regulated following vascular injury[56]. Overexpression by gene transfer of this gene prevents neointimal hyperplasia, but does not affect re-endothelialization and vasomotion[57]. Inhibition of cellular *ras* has also been reported to reduce neointimal thickening in a rat carotid injury model[58,59].

Promoting apoptosis

The Herpes simplex virus thymidine kinase (Hstk) is toxic when combined with ganciclovir administration. Transduced cells, expressing the thymidine kinase, phosphorylate inactive ganciclovir into the active compound, ganciclovir phosphate, which inhibits DNA polymerase (thereby blocking DNA synthesis) and results in apoptosis of the transduced cells. Using the adenovirally mediated HStk gene transfer strategy, originally developed as an approach to cancer treatment, neointimal proliferation was reduced by 50% in rat and porcine arterial injury models[60,61]. Importantly, adenovirus-mediated transfer of the HStk gene inhibited neointima formation in hyperlipidemic rabbit iliac injury model, suggesting that approach may be effective in truly atherosclerotic arteries[62]. Adenovirus-mediated gene transfer of cytosine deaminase and co-administration of 5-fluorocytosine showed similar results but may be associated with more toxicity[63].

An innovative approach is inhibition of neointima formation by transfer of proapoptotic genes. Gene transfer of the Fas ligand (activating FAS-dependent apoptosis) was shown to markedly suppress growth of cultured rat VSMC and neointima formation in a rat carotid balloon injury model at unusually low adenoviral doses (8×10^{10} pfu/ml)[64]. Coadministration of Ad-FasL with an adenoviral vector transferring an *E. coli* LacZ 'reporter' gene (encoding the enzyme, betagalactosidase, which is easily visualized by a histochemical reaction) results in markedly prolonged expression of the transferred beta-galactosidase, suggesting a role for the FasL-triggered death pathway in suppressing the immune response elicited by adenovirus-mediated gene transfer. Taking another approach, we recently reported that gene transfer of the transcription factor, E2F-1, induced S-phase entry in serum deprived human coronary VSMC, followed by rapid development of apoptosis and marked growth suppression of the VSMC. In vitro, we found that human umbilical venous endothelial cells also underwent apoptosis after transfer of E2F-1[65]. Losardo et al. reported that adenovirus-mediated gene transfer of E2F-1 protected cultured bovine endothelial cells from TNF-induced apoptosis and, at sites of balloon injury in rat carotid arteries, promoted endothelial regrowth and reduced neointima formation[66]. These apparently contradictory in vitro findings warrant clarification. Nonetheless, we have also observed marked suppression of neointima formation (in the absence of pseudoaneurysm formation) in balloon injured carotid arteries of hyperlipidemic rabbits at 28 days after the intervention[67]. Thus, gene transfer of E2F-1 may deserve further study as an approach to the prevention of neointima formation after vascular injury.

Antisense oligodeoxynucleotides and decoy sequences

Expression of genes involved in cell cycle initiation and progression can be inhibited by introduction into the host nucleus of DNA sequences that contain short 'consensus' sequences, i.e. sequences that bind and inhibit several (or all) members of a family of transcription factors. An example for this strategy is the transfection into cells of double-stranded E2F decoy sequence that inhibits expression of transcription factors of the E2F family. Transfection of an E2F decoy sequence into balloon-injured rat carotid arteries markedly suppressed neointima formation[68].

Antisense oligonucleotides

Antisense oligonucleotides are short DNA sequences designed to bind and render silent specific mRNA sequences. The synthetic antisense oligonucleotides are complementary to the mRNA encoded by the gene and their mechanism of action is complex involving hybridization of mRNA and the synthetic oligonucleotide, activation of ribonucleases H and L and elimination of the mRNA[69]. Oligonucleotides against transcriptional or regulatory proteins have been designed, including those binding to the mRNA of c-myb, Cdk2, NFkB and others. Local administration of antisense oligonucleotides directed against cell cycle-promoting factors, including proliferating cell nuclear antigen (PCNA, an essential cofactor for the principle DNA polymerase, pol-δ), the cell cycle-dependent kinase 2 (Cdk2), and other cell cycle promoting factors were reported to inhibit the proliferation of VSMC in vitro and formation of intimal hyperplasia in vivo[70–80]. In a rabbit vein graft model, a combined administration of antisense ODN against PCNA and Cdk2 inhibited neointimal formation and atherosclerosis hyperplasia[81]. This latter strategy has been tested in the first human trial of gene therapy against vein graft deterioration (see below). Problems with the transfection of antisense ODN include their stability within the cell, their specificity and mechanism of action, and possible effects related to the liposomal transfection method itself[69,82]. A somewhat related approach (aiming at silencing the mRNA of target proteins) is delivery of ribozymes (especially of the hammerhead type) to the arterial wall. This approach has been studied in the vasculature only preliminarily[83–85].

Gene therapy inhibiting migration of VSMC

Another approach to the prevention of neointima formation involves the blockade of signals promoting VSMC migration. Like hyaluronidase, plasmin facilitates migration of VSMC through the ECM. Plasminogen activator-inhibitor-1 (PAI-1) is the endogenous inhibitor of the plasminogen activators, urokinase (UPA) and tPA. Carmeliet et al. demonstrated that systemic adenovirus mediated gene transfer of PAI-1 to mice with inactivated PAI-1 gene reduced neointima formation in injured carotid arteries from a cross-sectional luminal reduction ('restenosis') of 35% in the control vector treated animals to 5% in the Ad-PAI-1-treated animals[86]. On the other hand, the same vector (Ad-PAI-1) did not inhibit neointima formation after coronary balloon injury in normal pigs[87].

An essential component in the pathogenesis of the neointima in injured arteries and vein grafts is migration of cells, especially VSMC, through the ECM towards the vascular lumen. This process is markedly facilitated by the enhanced synthesis matrix metalloproteinases (gelatinases, MMP), especially MMP-2 and MMP-9[88–93]. Several groups have reported that gene transfer of TIMP-1 and -2 to injured rat balloon arteries and saphenous veins kept in organ culture markedly inhibited neointima formation[89,94,95].

Promoting nitric oxide synthase (NOS) and vascular endothelial growth factor (VEGF)

Nitric oxide (NO) is a regulator of vasomotion, platelet aggregation, VSMC proliferation and migration, adhesion of monocytes, and promotes the synthesis of vascular endothelial growth factor (VEGF). At high concentrations (such as those produced by the inducible form of NOS, iNOS), NO impairs the function of many proteins by nitration of tyrosine residues and it induces p53 and apoptosis in VSMC and other cells[96,97]. NO (like PGI_2) is reduced after vascular injury and can be restored by local gene transfer of eNOS. eNOS produces NO in a non-toxic, picomolar concentration, whereas iNOS produces NO in the nanomolar range. Gene transfer of eNOS has been conclusively shown to reduce neointimal formation in balloon-injured and stented rat carotid arteries and in balloon-injured porcine coronary arteries[98–100]. Endovascular and adventitial delivery of the NOS genes has been shown to restore vasorelaxation in carotid arteries of cholesterol-fed and Watanabe rabbits (the rabbit model of human familial hypercholesterolemia) and cerebral arteries in rats[101–103]. The potential of eNOS gene therapy (which was more

Cambridge Books Online © Cambridge University Press, 2009

efficacious than ganciclovir) plus gene transfer of HStk in a head-to-head comparison of gene therapy for the prevention of neointima formation in balloon injured porcine coronary arteries[87], is substantial and clinical trials are imminent. Gene transfer of *iNOS* was found to prevent restenosis after balloon injury, transplant arteriopathy, and may find other potential application[104,105].

Gene transfer of VEGF and more recently, hepatic growth factor (hGF, scatter factor[106]) has been under intense investigation. VEGF not only promotes growth of new microvasculature, but also accelerates re-endothelialization of injured, denuded muscular and conductive arteries, thereby reducing restenosis[107] and, potentially, thrombosis (a hypothesis yet to be tested in appropriate animal experiments).

Gene therapy and vein grafts

Veins are the most frequently used conduits to bypass stenotic arteries in the coronary or peripheral circulation.

With approximately 400 000 coronary bypass procedures (CABG) performed annually, CABG is the most commonly performed major operation in the USA. Although arterial conduits, such as the internal mammary artery, have a longer patency rate compared to grafted veins, saphenous vein grafts represent over 70% of grafts because of their plentiful availability, easy accessibility, and the simplicity of the harvesting procedure. Due to the higher pressures and pulsatility of the arterial circulation, and factors related to the surgical procedure (focal endothelial loss, ischemia of the graft), the grafted vein undergoes a characteristic sequence of adaptive changes after its insertion into the arterial circulation. In the presence of often persistent coronary risk factors, these 'adaptive' responses set the stage for the early and late graft failure. The suboptimal patency of vein grafts begins with a thrombotic occlusion rate of 8–18% within the first month. One year after surgery, 15–30% of vein grafts are stenosed and 50% of vein grafts are occluded at 10 years[108–110]. Repeated CABG procedures are associated with increased surgical risk and higher occlusion rates compared to the initial graft and now account for 10–20% of CABG surgery performed in the USA. Although relatively small trials have shown that aggressive lipid-lowering strategy, smoking cessation and control of hyperglycemia may have beneficial influences on late graft patency[108,111,112], no pharmacological approach has reduced the incidence of vein graft failure to the single digit range.

Implications for gene delivery

Some special considerations apply to transduction of vein grafts. Native veins are thin and weak. A single layer of endothelial cells is separated from the media by a rudimentary internal elastic membrane. The media consists of several layers of VSMC, which in general are circular oriented. However, longitudinally oriented VSMC are often found in the innermost layers. The adventitial tissue is composed of collagen, scattered VSMC, many elastic fibres and vasa vasorum. In contrast, the artery is constructed much more compactly. The thick media consists of VSMC and elastic fibres that enable the artery to resist high blood pressure and other forms of stress.

Three major mechanisms involved in the development of early and late vein graft failure are: thrombosis, fibrointimal hyperplasia, and graft atherosclerosis[108].

Recurrent thrombosis plays a role in early (within 1 month) graft failure and the chronic progression of vein graft disease and is, in general, the immediate cause of vein graft-related myocardial infarction and ischemic death. Tissue factor has been shown, at least experimentally, to accumulate early in vein grafts[113], and may play a role in all stages of vein graft deterioration. Endothelial cell loss and vessel injury also impair the availability of cell-based antithrombotic molecules, including thrombomodulin, PGI_2 and NO. Recurrent mural platelet thrombus formation contributes to narrowing and, often occlusion of the graft at all stages[108].

Beyond the first month after surgery, intimal 'hyperplasia' becomes a prominent determinant of vein graft deterioration.

After the first year, the vein graft undergoes atherosclerotic changes very similar to those observed in native arteries, although the atherosclerotic process in vein grafts appears to be more diffuse and concentric. Atherosclerotic plaques developing in vein grafts seem to be weaker and thinner than in native arteries. Therefore, the risk of plaque rupture might be greater in vein grafts compared to arteries of comparable size and, in concert with the accumulation of TF in the vein grafts, may play a role in the higher thrombus burden observed in vein grafts compared to arterial conduits.

Gene therapy to prevent vein graft deterioration

Treatment of vein grafts with gene vectors represents an opportunity to incubate the vessel for relatively long time periods (20–40 min) with the viral solution before

Cambridge Books Online © Cambridge University Press, 2009

interpositioning the vein into the artery[114]. By limiting gene transfer to an ex vivo procedure, the risk of systemic virus distribution is probably very limited. However, the optimal vector for vein graft transduction is uncertain. Adenoviral vectors, currently the most efficient vectors for direct vascular gene transfer, circumvent the need for autologous cell preparation. However, at concentrations of 5×10^9 pfu/ml, they elicit a marked inflammatory response, which may lead to cell death, tissue destruction, and accelerated neointima formation and in general limits foreign gene expression to 7–10 days. Thus, Channon et al. detected Ad-LacZ transduced endothelial cells and infrequently transduced medial VSMC in rabbit jugular vein grafts 3 days after intrasurgical gene delivery, but reported that transgene expression was markedly decreased by day 7[115]. Consequently, for the use of adenoviral vectors, the therapeutic 'window of opportunity' may involve a narrow dose range. In contrast 'recombinant adeno-associated virus-based vectors' (rAAV) are small (20 nm), appear to transduce all layers of the artery even in the absence of vascular injury[116,117], elicit little, if any, inflammation, and can drive transgene expression for more than 18 months[118,119]. Like adenovirus-mediated gene transfer, rAAV-based gene transfer does not require dividing target cells. However, gene expression after rAAV is relatively slow in onset and no reports of rAAV-mediated LacZ expression within the first 6 days after vascular gene transfer are available.

Chen et al. were the first to report on adenovirus-mediated gene expression in a (porcine) vein graft in vivo[114]. Gene transfer involves in general ex vivo incubation of the rabbit jugular vein with the gene vector, division of the carotid artery, and insertion of the transduced vein in reversed fashion into the divided carotid artery with creation of end-to-end or end-to-side anastomoses to restore carotid flow. After surgery, rabbits are generally fed with 0.75–1% cholesterol-enriched food to allow the development of 'atherosclerotic' (lipid-infiltrated) neointimal lesion in the grafted jugular veins.

Mann et al. pioneered the use of antisense ODN targeting genes encoding cell-cycle proteins in the rabbit jugular vein graft model. Cdk2 and PCNA expression in grafted vein was found to be increased, respectively, ten and fivefold after surgery. Using liposomes complexed with proteins from the hemagglutinating virus of Japan (HVJ), a single ex vivo treatment of the grafts with the antisense ODN reduced expression of Cdk2 and PCNA by 90% compared to control treated animals and markedly suppressed formation of lipid-rich ('atherosclerotic') neointimal lesion formation[81]. Other approaches shown to be effective in inhibiting atherosclerosis/neointima formation in rabbit carotid grafts were ex vivo adenovirus-mediated gene transfer of a specific inhibitor of G-β,γ[120] and a hypophosphorylated, constitutively active form of the retinoblastoma protein[121].

Conclusion

We predict that improved gene transfer vectors and simplified vector delivery systems should allow the clinician in the not too distant future to use gene therapy to prevent thrombosis and restenosis after (and potentially before) vascular injury.

Pharmacological modulation of the inflammatory actions of platelets

Carla Cicala and Giuseppe Cirino

Department of Experimental Pharmacology, University of Naples 'Federico II', Naples, Italy

Cross-talk between inflammation and coagulation pathways

Blood clotting is a host defence mechanism that, together with inflammatory and repair processes, provides to preserve the integrity of the vascular system. There is much evidence for a cross-talk between inflammation and coagulation coming from both experimental and clinical evidence. In this respect, there is now a tendency to consider an inflammatory event as a prethrombotic status and to look for therapeutic agents that modulate both processes. The endothelium is the first site where the coagulation and inflammatory cascades interact. Under physiological conditions, vascular endothelium prevents coagulation and thrombosis by releasing inhibitors of platelet activation and potent vasodilators, such as prostacyclin (PGI_2) and nitric oxide, counteracting the effect of procoagulant factors. Endothelial cells also synthesize a number of negatively charged molecules, such as glycoproteins, glycosaminoglycans, chondroitin sulfate and heparan sulfate, which contribute to a non-thrombogenic surface. On the endothelial surface, thrombomodulin (TM), a high affinity receptor for thrombin is also expressed. The complex thrombin–TM activates protein C (PC), a vitamin K dependent glycoprotein that circulates in plasma as zymogen. Once PC is activated, it forms a complex with a vitamin K-dependent cofactor, Protein S (PS) on endothelium. Activated Protein C (APC) plays a major role in regulating the coagulation and fibrinolysis by inactivating factor Va and VIIIa and by inactivating tissue-plasminogen activator inhibitor (t-PAI). Thus, APC inhibits coagulation and stimulates the fibrinolytic pathway[1–4].

An endothelial protein C receptor (EPCR) has been identified and it seems to participate in the regulation of APC by binding to an exosite of APC and blocking the ability of APC to inhibit the factor Va[5,6]. In the plasma, APC is slowly inhibited by complex formation with PC inhibitor or alpha 1 antitrypsin; on the other hand, thrombin by activating the protein C pathway, acts as a feedback inhibitor of its own production[7]. It is clear that the presence of TM on endothelial surface and the integrity of the PC pathway are critical for the correct balance between coagulation and fibrinolysis. However, when the endothelium is damaged, this balance is lost, precipitating a procoagulant state[2,7,8].

In the complex events involved in inflammation, early produced cytokines strongly impair the balance between pro- and anti-coagulant factors. The major cytokines responsible for this impairment are TNFα and IL-1β which, by eliciting tissue factor (TF) production on endothelium and monocytes, provide an intravascular source of TF, causing activation of the extrinsic pathway of coagulation. At the same time, activation of Hageman factor by kallikrein leads to activation of the intrinsic coagulation pathway. Intrinsic and extrinsic pathways merge at a common point, e.g. the activation of factor X, and finally lead to fibrin formation. Fibrin clots, formed following activation of the coagulation system, has a temporary function; once damage has been repaired and blood loss arrested, the fibrin clot is removed and blood flow restored by activation of the fibrinolytic system. This latter phenomenon, known as fibrinolysis, also involves the release of substances from endothelial cells. In this case, the endothelium releases tissue plasminogen activator (t-PA), whose function is to convert plasminogen to plasmin; t-PA activity is modulated by tissue plasminogen activator inhibitor (t-PAI), also released by endothelial cells. The balance between t-PA and t-PAI is critical for the modulation of the fibrinolytic pathway[1,9,10].

All the effects so far discussed are up-regulated by cytokines; however, cytokines are also responsible for the

down-regulation of TM and PC expression. Once TM is down-regulated, thrombin does not bind to it and the PC pathway is not activated thereby the balance is shifted towards a procoagulant state which may lead to critical thrombosis[7].

Although it is not easy to dissect these two pathways that are so intimately related, the role of the coagulation system in several inflammatory disorders has been evaluated. There is much evidence that naturally occurring anticoagulants, such as APC, antithrombin III (AT III), TM and inhibitors of coagulation factors can improve symptoms of local and systemic inflammation. In particular, experimental sepsis has been considered as a paradigm to study the interplay between these two systems. PC activation plays a critical role in the host response to bacterial endotoxins and several studies have reported on the beneficial effect of low doses of APC on thrombosis or on disseminated intravascular coagulation (DIC) during endotoxemia. On the other hand, inhibition of PC by specific antibodies, before challenging animals with *E.coli* lipopolysaccharide, causes a more severe DIC[11,12]. Experimental evidence in animals has been confirmed by clinical studies demonstrating that APC supplementation has a beneficial role in human sepsis[4]. Furthermore, there are also data reporting a beneficial effect of ATIII supplementation in sepsis, based upon the observation that reduced ATIII levels in DIC are associated with increased mortality[13].

Another interaction between the inflammation and coagulation pathways is represented by proteases involved in coagulation, such as factor Xa and thrombin, that mediate several biological effects through activation of specific receptors, termed protease activated receptors (PARs). In particular, thrombin has been shown to play a role in several inflammatory events, to stimulate cell proliferation and cytokine production. Similarly, factor Xa has been shown to have a proinflammatory effect through activation of its receptor EPR-1 (effector cell protease receptor-1)[14,15].

In the light of this finding, which assigns a role to proteases beyond their 'procoagulant' effects, it is easy to understand why these molecules could represent a target for new anti-inflammatory drugs.

Platelets in inflammation

Early evidence for the involvement of platelets in inflammation was already given in 1961 by Jancsò, who showed by microscopy that inflammation induced in rat paw by local injection of thrombin was accompanied by clumping of platelets together and to damaged endothelium, polymerization of fibrinogen into fibrin strands and localization of microthrombi in capillaries and lymphatics[16]. In 1968, Wiseman and colleagues demonstrated that carrageenin-induced edema in the rat paw was characterized by fibrin deposition, inhibited by anticoagulant agents and increased by systemic administration of thrombin[17]. It is known that fibrin activates platelets through binding with specific receptors on the platelet surface. Since fibrin formation is strictly linked to platelet activation, inflammatory reactions that involve fibrin polymerization are also characterized by clumping of platelets in damaged organs.

Normally, platelets circulate freely in the blood, by mechanisms involving non-adhesive properties of endothelial cells[18,19]. However, when endothelium is damaged, such as during inflammation, the exposure of collagen fibres of the subendothelium, together with the loss of antihemostatic properties of endothelium at the site of injury, promotes platelet adhesion on to endothelium with subsequent activation. Platelet adhesion to endothelium is mediated by adhesion molecules expressed on both endothelial cells and platelets following stimulation by cytokines. P-selectin receptors expressed on the surface of both activated platelets and endothelial cells, as well as the presence of a receptor protein for P-selectin on monocytes and neutrophils promotes interactions among these cells. The protein P-selectin is normally present on the external membrane of platelet α-granules and of Weibel–Palade bodies of endothelial cells, and translocates to the cell membrane soon after cell activation by thrombin or other platelet agonists[20,21]. Hence, P-selectin plays a pivotal role in regulating interactions among platelets, endothelial cells, monocytes and neutrophils. Indeed, appearance of P-selectin on platelets and endothelial cells precedes other adhesion molecule expression, and it is feasible that interactions among platelets, endothelial cells and neutrophils contributes to platelet translocation at the site of injury and to the release of proinflammatory mediators in the early phase of inflammation. Moreover, P-selectin can induce the expression of tissue factor on monocytes participating, in this way, to amplify activation of the coagulation cascade[22]. In this context, P-selectin plays an important role in the orchestration of the inflammatory response[23].

Platelets have been shown to contain a number of cytokines that contribute to modifying endothelial function and participating in the spreading of an inflammatory lesion. Stimulated platelets express IL-1β on their surface, providing an early source of this cytokine at the site of injured endothelium. Through IL-1β, activated platelets induce the expression of intercellular adhesion molecule 1 (ICAM-1), IL-6, IL-8 and granulocyte monocyte-colony

Cambridge Books Online © Cambridge University Press, 2009

stimulating factor (GM-CSF) in endothelial cells. These cytokines all contribute to leukocyte attraction and adhesion to endothelium[24,25]. While IL-1 remains associated to platelet membrane, other cytokines are stored in α-granules and released upon platelet activation. Transforming growth factor beta (TGF-β) is an α-granule product that promotes chemotaxis, inhibits endothelial cell proliferation, enhances synthesis of PAI-1 and increases the production of endothelin–1[26–28]. There is evidence that injection of TGFβ subcutaneously to experimental animals leads to granuloma formation suggesting a role for TGFβ in wound healing and tissue proliferation[29]. Alpha granules also contain PDGF that is the major mitogen associated with platelets and it plays a role in pathogenesis of atherosclerosis, by stimulating proliferation of arterial smooth muscle cells[30,31]. Moreover, PDGF plays an important role in the generation of granulation tissue during wound repairing, in inflammatory reactions and proliferative responses[32,33]. Another cytokine contained in α-granules is the platelet factor 4 (PF4). PF-4 can neutralize the anticoagulant activity of heparin or compete for the binding to AT III[34,35] and stimulates histamine release from basophils[36]. Platelet α-granules are also a source of the secreted form of phospholipase A_2 (PLA_2; 14 kDa), an enzyme that has been found in several inflammatory exudates[37] and shown to be proinflammatory[38] or to exacerbate an ongoing inflammation[39,40].

As well as being factors secreted by α-granules, platelets also release the source of other substances, mostly amines released following degranulation of dense granules. In this respect, platelets, as inflammatory cells, have been compared to mast cells. Like mast cells, upon activation they degranulate and release a wide array of inflammatory mediators that can cause flogosis when injected locally in experimental animals[41,42].

Platelets also synthesize lipid mediators *ex novo*, such as eicosanoids and platelet activating factor (PAF). Among eicosanoids, thromboxane A_2 (TXA_2) is the major product of the metabolism of arachidonic acid in platelets, and is synthesized following platelet activation and causes platelet aggregation and degranulation. At the site of injury, TXA_2 formed by activated platelets contributes to stabilizing platelet aggregates. TXA_2 has been also shown to cause smooth muscle contraction and thus it provides local vasoconstriction[43].

PAF is a lipid mediator produced by platelets and a wide array of inflammatory cells, and it is one of the most potent inflammatory mediators of lipid origin. Injection of PAF into experimental animals causes a variety of responses, some of them involve platelet activation, while others are independent of platelets. PAF has been shown to be a potent bronchoconstrictor agent; given intravenously to experimental animals, PAF-induced bronchoconstriction is dependent upon platelet activation, indeed in animals depleted of platelets, or in animal species whose platelets are unresponsive to PAF, this reaction is prevented. However, PAF also causes airway hyper-responsiveness when given by aerosol[44,45] and it increases vascular permeability in the acute inflammatory reaction[46,47], in sepsis[48] and in gastrointestinal inflammation[49,50]. PAF is also an eosinophil chemoattractant[42].

Cooperation between platelets and polymorphonuclear leukocytes for production of proinflammatory mediators[51–53] and between platelets and monocytes for protection against parasites[54,55] has also been shown. However, platelets contribute to inflammation not only via the release of a wide range of mediators, but also via the ability to kill mycobacteria and bacterial endotoxins, providing protection against invading organisms[56,57].

Direct evidence for the involvement of platelets in inflammation comes from studies performed using labelled platelets that have shown platelet accumulation in the inflamed area after local administration of an irritant[58]. An increased platelet response to aggregating agent has also been shown for platelets obtained from rats injected in the paw with carrageenin[59] or from humans affected by asthma[60], psoriasis[61] or intestinal tubercolosis[62].

There is much evidence for an involvement of platelets in sepsis. In particular, a decrease in platelet count has been shown several hours after endotoxin administration, and thrombocytopenia has been shown to be correlated to clumping of platelets in liver and spleen[63,64]; platelet responsiveness following endotoxin administration to rats is reduced[65]. Anticoagulant agents have been shown to ameliorate shock symptoms as well as to prevent thrombocytopenia, outlining the importance of platelets in the organ damage associated with bacterial endotoxemia[11,66].

Furthermore, platelet depletion has been shown to protect animals from both allergic and non-allergic inflammation[41]. Moreover, it has been demonstrated that paw edema development in mice is inhibited after splenectomy[67].

Platelets also represent a surface for clotting factor activation and they are required for optimal expression of clotting activity. Factor V released from α-granules binds to platelet surface and, together with anionic phospholipids exposed, functions as a binding site for factor Xa. An analogous system involves the binding of factor IX and factor VIII that in presence of membrane phospholipids converts factor X to Xa on platelet surface. Thus, platelets are involved in inflammation either as a source of inflammatory mediators and as a surface for coagulation. Moreover, by interacting with other cells platelets contribute to amplifying proinflammatory signals[2,8].

Cambridge Books Online © Cambridge University Press, 2009

In the light of this knowledge, the mechanism by which several agents are beneficial in inflammation has been revised and it has been now recognized that inhibition of platelet activation or the neutralization of platelet derived mediators might be useful in preventing tissue damage during an inflammatory state.

Platelet thrombin receptor(s)

Thrombin signalling to cells is mediated through a family of G-protein coupled receptors, designated as PARs (*protease activated receptors*). The first identified was the thrombin receptor PAR-1 that presents, together with other PARs, a peculiar mechanism of autoactivation. Following proteolytic cleavage by thrombin, between a residue of Arg-41 and Ser-42, a new N-terminus peptide is unmasked which acts as a tethered ligand. Synthetic peptides containing a minimum of five residues (SFLLR) of the tethered ligand can activate the receptor, even in the absence of proteolysis. The mechanism of PAR-1 activation is irreversible and the tethered ligand generated cannot diffuse away from the receptor. Up to now, four PARs have been identified: PAR-1, PAR-3 and PAR-4 can be activated by thrombin, while PAR-2 is activated by trypsin, tryptase and factor Xa[68].

Thrombin receptors on platelets and the requirement of receptor activation to trigger platelet responses vary among species. Evidence that PAR-1 blocking antibodies inhibited human platelet activation induced by low, but not by high, thrombin concentrations, and that PAR-1 deficient mice responded like wild type mice to thrombin, has led to the discovery of PAR-3 and PAR-4[69,70]. Human platelets have both PAR-1 and PAR-4[71]; in contrast, mouse platelets express PAR-3 and PAR-4, but not PAR-1[72–74]. In human PAR-1 and in mouse PAR-3 are high affinity thrombin receptors, while in both species PAR-4 is a low affinity thrombin receptor. Recent evidence suggests that either in humans or in mice activation of both receptors is necessary to trigger a full platelet response[71]. PAR-1 activation causes an early, transient response, while PAR-4 activation is responsible for a late, prolonged signal[75]. The existence of two different thrombin receptors on human platelets might explain why synthetic peptides activating PAR-1 or PAR-4 are not able to trigger the same platelet response caused by thrombin. Evidence that peptides activating PAR-1 inhibit thrombin-mediated rat platelet aggregation suggests the presence of a modified PAR-1 in rats rather than a total absence of this type of receptor[76].

Platelet activation by thrombin has been extensively studied and it includes aggregation, degranulation and stimulation of platelet procoagulant activity. Besides thrombin, other platelet agonists, such as collagen and calcium ionophore, A23187, stimulate platelet procoagulant activity, measured as an increase of platelet phosphatidylserine and posphatidylethanolamine exposure[77].

On human platelets, PAR-1 and PAR-4 contribute differently to mediate thrombin effects; PAR-1 activation by thrombin is mainly responsible for platelet activation, calcium flux and clotting system activation, while PAR-4 activation leads to a less potent platelet response[78]. In this respect, since activation of the coagulation cascade is an important event in the development of inflammation, it is feasible that PAR-1 more than PAR-4 plays a major role in inflammation. This hypothesis is consistent with experimental evidence demonstrating a role for PAR-1 in the inflammatory response triggered by thrombin[15].

The knowledge on the proinflammatory effect of thrombin has been greatly improved only following identification and cloning of the thrombin receptor and its activation by small synthetic peptides mimicking the sequence of the tethered ligand. In 1996, it was possible to demonstrate that thrombin acts as a mediator of inflammation, through activation of PAR-1[79]. Further studies have shown the involvement of PAR-1 even in other proinflammatory responses to thrombin. Indeed, PAR-1 mediates thrombin-induced bronchoconstriction in guinea-pig but not in rats, whose platelets lack PAR-1[80].

In 1990 Ferrer-Lopez et al. demonstrated that cathepsin G released by activated neutrophils stimulates human platelets and reduces platelet response to thrombin[81]. The mechanism at the basis of the cathepsin G effect seems to be due to its ability to cleave PAR-1, creating a ‘disarmed’ receptor unable to be activated by thrombin[82]. Recently, it has been shown that PAR-4 is involved in the cathepsin G effect; PAR-4 activated by cathepsin G released by neutrophils, mediates human platelet secretion and aggregation[83]. This finding suggests a role for PAR-4 in inflammation, by mediating neutrophil–platelet interaction at the site of injury.

An interaction between PAR-1 and aprotinin has been recently demonstrated[84]. It has been shown that aprotinin inhibits thrombin-induced platelet activation by preventing PAR-1 cleavage by thrombin. There is much literature on the protective role of aprotinin in diseases such as sepsis. Thus, in the light of these new findings, it is feasible that the mechanism involving PAR-1 inhibition is at the basis of the aprotinin protective effect.

Drugs affecting inflammatory functions of platelets

Evidence that platelets are involved in inflammation has led to platelets being considered as targets for anti-inflammatory agents.

Antiserototinergic and antihistaminergic drugs

Biogenic amines, histamine and serotonin, participate in the vascular events characteristic of the early phase of an immune or non-immune inflammatory reaction, both in humans and in experimental animals[85–87].

Although mast cells have been implicated as the main source, there is much evidence that also platelets are source of biogenic amines at the site of injury. Platelet accumulation at the site of injury has been demonstrated either in carrageenin-induced edema, or in zymosan-induced pleurisy. Platelet derived serotonin has been implicated not only in acute but also in chronic inflammation, both in humans and in experimental animals[85,86], as well as in pain associated with inflammation[88,89].

Among different species, release of histamine by platelets has been demonstrated in pig, rabbit and humans[90,91]. Platelet histamine content has been shown to be increased in humans affected by peripheral vascular disorders[92].

Antiserotinergic and antihistaminergic drugs are effective in the early phase of inflammation either in carrageenin-induced rat paw edema or in zymosan-induced rat pleurisy, at a time when indomethacin is not effective[87,93] and when platelet accumulation occurs at sites of inflammation. Thus, it is feasible that in the early stage of an inflammatory event, platelets are the main source of histamine and serotonin.

There are several lines of evidence that platelet functions are altered in asthmatics and in patients suffering from atopic diseases. Platelet activation occurs during asthma and platelet hyper-responsiveness is a common feature of asthmatic subjects[60,94]. Experimental evidence has shown that disodium cromoglycate is able to inhibit PAF-induced airway hyper-reactivity in asthmatic subjects and also to inhibit human platelet aggregation induced by ADP and collagen[95]. This effect has been suggested to be involved in its beneficial role in the treatment of asthma. Further studies have shown that ketotifen, whose mechanism is similar to that of sodium cromoglycate, inhibits both rabbit and human platelet activation[96]. Nedocromil sodium reduces platelet hyper-reactivity from ASA-induced asthmatic subjects[94].

Hirudin and Hirulog

The prototype of a direct thrombin inhibitor is hirudin, first isolated from saliva of the leech *Hirudo medicinalis* [98]. Hirudin inhibits thrombin by binding to both anionic and catalytic sites, that recognise fibrinogen and the platelet surface. Several hirudin-like peptides have been synthesized, among these hirulog has been extensively described as a thrombin inhibitor[99,100]. Hirudin and hirulog have been shown to be beneficial in several inflammatory disorders[101] and to inhibit inflammatory effects of thrombin on endothelial cells[102]. More recently, it has been shown that PEG-hirudin inhibits collagen-induced arthritis in mouse, demonstrating a role for thrombin also in an inflammatory reaction with an immunologic basis.[103]

In rat experimental endotoxin shock, hirulog inhibits thrombocytopenia induced by bacterial endotoxin, suggesting that inhibition of platelet activation might partially contribute to its beneficial effect.[66]

Heparin

Heparin and other anticoagulants were firstly described to be beneficial as anti-inflammatory agents in 1968 by Wiseman and Chang[17], who demonstrated that several anticoagulant agents can inhibit carrageenin induced rat paw edema, while thrombin had a potentiating effect. Subsequently, anticoagulant agents have been extensively used as anti-inflammatory agents, even though the mechanism at the basis of this effect is unclear. There is fairly recent evidence for inhibition of thrombin platelet stimulation by high and low molecular weight heparins and this mechanism might be involved in the anti-inflammatory effect exerted by these molecules[104].

NSAIDs

The most used anti-inflammatory drugs all over the world are non-steroid anti-inflammatory drugs (NSAIDs). Among them, aspirin is widely used for its analgesic, anti-inflammatory and antithrombotic properties. Compared to other drugs, aspirin has the ability to irreversibly inhibit platelet COX-1 through the acetylation of the enzyme.

Non-selective COX-1 and COX-2 inhibitors are the most widely used anti-inflammatory drugs. Although the research in the field has developed COX-2 selective inhibitors that have been shown to be devoid of gastrotoxicity, there is evidence that in some models of inflammation, COX-1 inhibitors appear to be more effective than selective COX-2 inhibitors. A study performed by testing the anti-inflammatory effect of different COX-1 and COX-2

Cambridge Books Online © Cambridge University Press, 2009

inhibitors on rat experimental pleurisy showed that the most effective in reducing cell influx and exudation were aspirin and piroxicam, but not the more COX-2 selective inhibitors, NS398 and nimesulide[105]. Since platelets possess only COX-1, it is likely that platelet COX-1 inhibition is essential for some of the anti-inflammatory effects displayed by NSAIDs.

Concluding remarks

Inflammation is undoubtedly linked to coagulation and recent work suggests that drugs targeting the coagulation pathway may provide novel therapeutic approaches for inflammatory conditions.

Introduction

Recognition of the central role of platelets in the pathophysiology of cardiovascular disease has led to intensified efforts to develop more effective and safer antiplatelet strategies. Randomized trials and meta-analyses of those trials are currently our most powerful tools for evaluating the effects of these newer antiplatelet strategies[1–3]. However, careful consideration of key issues in design, conduct and interpretation of randomized controlled trials is essential in order that moderate but clinically worthwhile treatment differences are reliably detected[4–6].

This chapter will describe the key underlying principles of randomized trials, with particular emphasis on clinical trials of antiplatelet therapy.

Fundamental principles of randomized controlled trials (Table 68.1)

The question

The criteria for a good clinical trial are straightforward. Ask an important question and answer it reliably. Even the most meticulously designed randomized trial will be of little use and, perhaps wasteful, if the study question is not of major clinical or biological relevance. A good study question is one which has not yet been answered, is based on a strong biologic rationale, and is relevant to individual patient care or public health.

Table 68.1. Key aspects of sound randomized control trial design

Design feature	Potential benefits
Proper randomization	Ensures that both known and unknown potential confounders are balanced between the treatment groups
Unbiased ascertainment of outcomes	
Blinding of patient	Avoids loss of the placebo effect which may otherwise inflate the observed treatment effect
Blinding of caregiver	Avoids differences between treatment groups in administration of effective cointerventions, compliance, or reporting of symptoms
Unbiased analyses of results	
Minimizing loss to follow-up	Avoids bias due to differential loss to follow-up among the treatment groups
Intention to treat analysis	Minimizes biases due to imbalance between patients who receive and those who do not receive study treatment/intervention
Avoidance of data-derived subgroups	Avoids focusing on underpowered analyses which may be potentially biased and misleading
Complete reporting of results according to prespecified plan	Avoids selective emphasis on particular subgroups and investigator driven biases based on knowledge of trial results

Minimizing bias: the principles of sound clinical trial design

If randomized trials are to provide unbiased and reliable estimates of treatment effect, they must avoid systematic biases and minimize random error. The potential for systematic bias can be minimized through (i) proper generation of the randomization sequence and concealment of treatment allocation; (ii) unbiased ascertainment of outcomes; (iii) unbiased analysis of results; and (iv) basing decisions on the totality of information (all related data from all relevant properly randomized trials).

Proper randomization

Randomization is the most important method of minimizing moderate biases in a clinical trial. The purpose of randomization is to allocate patients so as to balance treatment groups with respect to both known and unknown prognostic variables, which makes it more likely that the observed differences in outcome between the groups are due to the intervention or treatment. Secondly, randomization ensures the validity of statistical tests which enables one to ascribe, under the null hypothesis, a probability distribution for the differences in study outcomes, and therefore allows one to calculate the significance level (*P*-value) of the observed outcome of the trial in question. Thirdly, properly concealed randomization eliminates selection bias since this ensures that patients and clinicians remain unaware of treatment allocation prior to registration or randomization[7]. Many forms of randomization (such as randomizing patients according to day of the week) are inadequate because they allow both patients and clinicians to predict to which treatment the patient will be allocated. Inadequate concealment of treatment allocation can lead to systematic exaggeration of estimates of treatment effect[8]. Secure methods involving use of prepackaged blinded treatment or central telephone or computer-based randomization are now widely used in major cardiovascular trials.

Unbiased ascertainment of outcomes

Objective and unbiased ascertainment of study outcomes is critically important to the validity of a clinical trial. Ascertainment of outcomes may be biased if the patient or those responsible for treatment and evaluation know which treatment is being used. This problem may well be avoided if both patients and clinicians (or outcome evaluator) are blinded to the randomised treatment allocation, i.e. the trial is double-blind. Uncertainty remains regarding the importance of blinding with conflicting empirical evidence from recent studies addressing this issue[9,10]. However, most would agree that blinding is important, particularly when there are subjective outcomes in a trial (i.e. refractory angina, clinical DVT and recurrence of unstable angina) or when there is a potential for differential use of cointerventions that may be influenced by knowledge of the randomized treatment allocation or imbalances in other therapies that might affect outcome. By contrast, in clinical trials with objective and irreversible outcomes (i.e. mortality, myocardial infarction), blinding may be less important. For example, several major thrombolytic trials (including ISIS-3, GISSI-2 or GUSTO-1) were unblinded but used mortality as their primary outcome. However, in these trials, knowledge of the randomised treatment allocation may still have resulted in differences in the use of cointervention (e.g. use of percutaneous coronary intervention or coronary artery bypass graft surgery), which, in turn, could theoretically affect mortality. However, comparisons of ancillary treatments in open vs. blind trials of the same question have not shown systematic differences. Meanwhile, blinding may be of particular importance when outcome events are subjective in nature since knowledge of the randomized treatment allocation in this setting could influence both outcome ascertainment and use of cointerventions.

In some clinical trials, it may not be feasible to blind patients (for example, in trials of surgery vs. medicine). In this setting, blinded assessment of outcomes by a central committee of adjudicators may reduce the likelihood of bias.

Unbiased analysis of results

There are four principles that guide the approach to the analysis of clinical trial in order to minimize bias and increase validity. First, the number of patients lost to follow-up must be minimized (ideally, there should be no patients lost to follow-up); secondly, an intention-to-treat analysis should ideally be utilized; thirdly, an overemphasis on data-derived subgroup analyses should be avoided; and finally, complete reporting of the results of the trial according to a prespecified statistical analysis plan should be employed.

Patients who are lost to follow-up may differ from those who are not lost to follow-up in terms of their response to treatment and prognosis. If the proportion of patients lost to follow-up was randomly distributed among different treatment allocation groups, no bias would be expected. However, loss to follow-up is unlikely to be a random event. Therefore, complete follow-up (or near complete follow-up) is critical to ensure the validity of the results of a study. A similar rationale underlies the principle of analysis by intention-to-treat[6]. Patients who do not receive the allo-

Cambridge Books Online © Cambridge University Press, 2009

cated treatment (for whatever reason) may differ systematically from patients who receive the allocated treatment, and these selection processes may differ between treatment groups. Any potential biases resulting from this imbalance can only be mitigated by analysing results according to the groups into which the patients were randomized. Therefore, although the intention to treat approach may 'dilute' the result of a trial by including patients who did not actually receive active treatment, this approach ensures that the internal validity of any observed treatment difference is preserved.

Use of a prespecified analysis plan can prevent bias in the reporting of results of a clinical trial by avoiding undue emphasis of a data-derived subgroup[32]. Investigators often analyse data from clinical trials by subgroups within which the responses to treatment are expected to be fairly similar, but between which the responses are expected to differ. However this approach is seriously flawed. A key principle for interpretation of subgroup results is that quantitative interactions (differences in degree) are much more likely than qualitative interactions (differences in kind). Quantitative interactions are likely to be truly present whether or not they are apparent, whereas apparent qualitative interactions should generally be disbelieved as they have usually not been replicated consistently. Therefore, the overall trial result is usually a better guide to the direction of effect in subgroups than the apparent effect observed within a subgroup. Failure to specify prior hypotheses, to account for multiple comparisons, or to correct P values for multiple comparisons increases the chance of finding spurious subgroup effects. Conversely, inadequate sample size, classification of patients into the wrong subgroup, and low power of tests of interaction limit the power of a study to detect true subgroup effects. To avoid these potential pitfalls, the architecture of the entire set of subgroups within a trial should be carefully examined, similar subgroups should be analysed across independent trials, and results of subgroup analyses should be interpreted in the context of known biologic mechanisms and patient prognosis[32].

Decisions regarding therapies should be based on the totality of information (from all randomized trials)

In order to avoid selective biases and to minimize random errors, inference about the effects of treatment should not be based on a selective subset of the available trial results, but on a systematic overview of the totality of the evidence from all the relevant unconfounded randomized trials[2]. This fundamental principle is often overlooked, especially by clinical trialists who want to believe that their trial results warrant emphasis over and above other trials in area, and can result in bias[2,14,11]. The play of chance is more likely to influence the results of individual trials which can, in turn, determine which trials are emphasized and which trials are ignored. Therefore, proper assessment of a therapeutic issue must involve a compilation of all the available evidence, rather than a potentially biased subset of trials.

What are the expected findings in a trial of a new antiplatelet agent in a patient with vascular disease and what are their implications for the design of new trials?

In designing a clinical trial of an antiplatelet agent in patients with vascular disease, there are several key expectations that can guide the approach to the sound design of clinical trials.

Moderate (not large) treatment effects are likely to be observed

Moderate treatment benefits

A fundamental feature of a randomized trial addressing an important question in a common disease is that moderate treatment benefits (i.e. risk reductions of 15–30%) rather than large treatment effects (i.e. greater than 50%) are likely to be observed and that such moderate differences are clinically worthwhile[1]. Overwhelming treatment effects (e.g. defibrillation for ventricular fibrillation) may be apparent even in the absence of randomized trials, although, even in such cases, the magnitude of benefit may be more reliably and persuasively established by a randomized controlled trial. However, the impact of the vast majority of new treatments is 'reasonably uncertain', and the effects of these new treatments are likely to be small, moderate or neutral, rather than large. Nevertheless, small or moderate risk reductions may be worth detecting, particularly if the disease entity is common and if the outcome measures are clinically important such as mortality or major morbidity (such as myocardial infarction or stroke). For example, the use of aspirin in patients with acute myocardial infarction reduced the risk of vascular death by 23% in the ISIS-2 trial, a treatment effect which is 'only moderate'. This 23% reduction in mortality represents the avoidance of about 25 deaths per 1000 patients treated with aspirin for 1 month. Since aspirin is a simple, inexpensive and relatively non-toxic treatment, this moderate treatment effect translates in to tens of thousands of lives potentially saved per year, if aspirin is used widely. Tangible gains from small or moderate treatment effects of important outcomes in common

Cambridge Books Online © Cambridge University Press, 2009

disorders have had, and will continue to have, profound effects on global health and the modern practice of medicine. These treatments may exceed the numbers of lives that could hypothetically be saved by a simple cure for all patients with a rare disease, such as acute myeloid leukemia[1].

Minimizing random error and ensuring study power

Having established that biases should be avoided and that moderate treatment effects are generally worth detecting, the next step is to ensure that these effects can be detected reliably. The reliable detection of moderate treatment effects in randomized trials requires maintenance of statistical power by ensuring that a sufficient number of primary outcome events are collected. In general, this requires a study of sufficient size to accrue between 1000 and 2000 primary outcome events. Achieving this number of outcome events should be the starting point in the design of any major phase-3 randomized trial (this does not apply to phase-2 trials) of antiplatelet therapy in cardiovascular disease, because it has important implications on not only sample size but also inclusion criteria (and hence baseline event rate) and choice of primary outcome (single vs. composite). It is important that Steering Committees monitor the overall event rates during the course of a trial (remaining blinded to treatment allocation) to ensure that the projected event rates are actually being attained. If not, then it may be reasonable to either increase the sample size, to alter the entry criteria to focus on higher risk patients or increase the duration of treatment to ensure that a minimum number of events accrue during treatment (Table 68.2).

Two other pitfalls which may lead to an underpowered trial are the overestimation of the expected treatment effect of a particular agent or overestimation of the control event rate. In some instances, it may not be possible for a clinical trial to enroll sufficient numbers of patients to maintain adequate power to detect a given outcome, either for practical or economic reasons. Two commonly adopted methods of dealing with this problem are to use composite outcomes or to amend the inclusion criteria to focus on higher risk patients. The basic tenet of both these manoeuvres is to ensure that a minimum number of outcome events occur to maintain study power (Table 68.3).

Active vs. control randomized trials and trials comparing various active treatments (Table 68.4)

Treatment effects in clinical trials will vary, depending on whether the experimental agent is compared with control

Table 68.2. Key issues (based upon previous clinical trial results) which should affect the design of trial of antiplatelet agents in vascular disease

Key issue	Aspects of the clinical trial which will be affected
Expect moderate (not large) treatment effects	Ensure study power is maintained by recruiting large numbers of patients
Minimizing competing risks	Choice of endpoints, disease-specific vs. all-cause mortality
True unanticipated qualitative treatment effects are extremely rare	Use broad inclusion criteria ('uncertainty principle'); minimize exclusions
Treatment benefit will be greatest during treatment	Measure outcomes at or soon after end of treatment
Benefits will be clearer if treatment modifiable endpoints are chosen	Avoid including outcomes that are unlikely to be affected by treatment

Table 68.3. Potential strategies to maintain study power. In general, a phase III antiplatelet trial should record at least 1000 to 2000 primary outcome events in order to be adequately powered

Increase sample size
Alter entry criteria to focus on higher risk patients
Choose responsive and valid composite outcomes
Implement strategies to ensure optimal compliance of study medication

Table 68.4. Common pitfalls in the design of randomized trials

1	Overestimation of control event rates or treatment effects resulting in an underpowered trial
2	Failure to appreciate the difference in treatment effects between trials of active treatment vs. placebo and trials of active treatment vs active treatment
3	Entry criteria are too narrow, resulting in difficult recruitment and poor generalizabilty
4	Incomplete follow-up
5	Timing of primary outcome too long after end of active treatment

Cambridge Books Online © Cambridge University Press, 2009

(or placebo) or whether it is compared to another active agent. While moderate treatment effects (e.g. up to 20–30% relative risk reduction) may be seen when an effective agent is compared to placebo, the difference between two effective agents is likely to be much smaller (i.e. about half, which translates into relative risk reductions of 10 to 15%). Therefore, trials comparing active drugs may need to be substantially larger than placebo-controlled trials and may require a three- to fourfold greater number of events. This issue is of particular relevance to trials of antiplatelet therapy, where at least in the case of atherosclerotic disease, new agents must be compared to aspirin, which is a well-established and effective therapy, rather than placebo. Sometimes, a new agent may be compared in addition to aspirin vs. aspirin alone (plus placebo). Larger treatment benefits might be expected in this type of trial compared with a trial of the new agent alone vs. aspirin, assuming there is a sound rationale for dual antiplatelet therapy. For example, the CURE trial compared clopidogrel plus aspirin to placebo plus aspirin[15]. In this trial, the combination of aspirin plus clopidogrel compared with aspirin alone might be expected to yield greater treatment effects than simply comparing clopidogrel to aspirin, as in the CAPRIE study[16]. In the CAPRIE study the comparison of clopidogrel to aspirin resulted in a very modest 9% reduction in vascular events. By contrast, in a meta-analysis of the trials of clopidogrel vs. placebo in addition to aspirin (in patients receiving an intracoronary stent), risk reductions of 26–48% were observed[15]. Similarly in the CURE trial there was a 20% risk reduction in CV death, MI and stroke in favour of clopidogrel compared with placebo in patients receiving aspirin[37].

Adherence to randomized treatments

Lack of adherence to study treatments is one of the most important threats to maintaining power in a randomized trial. Adherence may include both those patients who temporarily or permanently discontinue study medication ('drop-outs'); those patients who take the study medication, but incorrectly; and those patients who take open-label study drug ('drop-ins'). The effect of non-adherence is likely to be greater than loss of study power resulting from low event rates because the statistical power of a study is proportional to the square of the proportion of non-adherent patients, but only directly proportional to the event rate. For example, in a study originally designed to have 90% power under a given set of assumptions, a change in adherence to 70% would decrease power to approximately 50%. Thus the issue of non-adherence requires close monitoring during the course of a trial to ensure that statistical power is maintained.

Use of composite outcomes

The selection of appropriate measures to assess the effect of therapy is critically important in a randomized trial. In general, outcome measures should be objective, valid, reliable, sensitive to change and clinically relevant. Mortality fulfils most of these criteria and is commonly used as a primary outcome in major cardiovascular and cancer trials. However, in many other disease states, use of mortality as a primary outcome would require an impractical number of patients, because of its low incidence. Therefore, composite outcomes that include mortality as one component are often employed to ensure accrual of sufficient primary outcome events. Death or myocardial infarction is a commonly used composite primary outcome in cardiovascular trials because myocardial infarction fulfills almost all of the criteria mentioned above, although it does, under some circumstances, require clinical judgement to make the diagnosis. Stroke may also be a suitable component of a primary composite outcome in trials of antiplatelet therapy in cardiovascular medicine because patients with coronary artery disease also have cerebrovascular disease, and the antiplatelet agent may prevent cerebrovascular atherothrombotic events or cardioembolic events resulting in stroke as well. For example, in both the CURE[15,37] and the BRAVO[17] trials, in which an oral antiplatelet was given for a few months in aspirin-treated patients (clopidogrel in CURE and lotrifiban in BRAVO), the primary outcomes were death, MI or stroke (cardiovascular death in CURE and all-cause death in BRAVO).

Refractory angina is a significantly more subjective endpoint than either death or myocardial infarction, but is increasingly being used in clinical trials of antiplatelet or antithrombotic therapies in an attempt to reduce sample size and study costs. However, a review of several trials in this area demonstrates that there are widely differing definitions of refractory angina among the various trials. Generally, a definition of refractory angina consists of three essential components: (i) signs or symptoms of recurrent ischemia (or manifestations such as pulmonary edema) for a specified duration of time; (ii) electrocardiographic changes and (iii) the performance of an intervention prompted by this episode (such as cardiac catheterization, a revascularization procedure, thrombolytic therapy, etc.). Most trials require two of three criteria, although some trials require only one out of three criteria and others require all three. The objectivity of this endpoint will depend on how the individual components of the outcome are defined (i.e. duration of chest pain, degree of ECG change required, etc.) and the number of criteria in the

Cambridge Books Online © Cambridge University Press, 2009

definition. As is often the case, the primary endpoint, consisting of death, MI or refractory ischemia is almost invariably driven by the latter, most subjective component. Readers are therefore cautioned when interpreting the results of clinical trials which have refractory ischemia as a primary endpoint, especially when the trial therapies demonstrate no impact on death or myocardial infarction.

Unanticipated qualitative treatment effects are rare

A qualitative interaction is one in which the direction of treatment within subgroups of patients within a trial is in different directions. As alluded to previously, true qualitative interactions are exceedingly rare, a fact that has important implications for the selection of patients in a clinical trial[18]. First, it implies that entering a wide group of patients with the same disease would be an asset because direct evidence for benefit can be sought in such a heterogeneous population. This makes the study results more relevant to clinical practice. Secondly, selection of wide categories of patients with the same disease is unlikely to reduce the observed treatment effect to such a significant extent that it outweighs the benefits of greater recruitment and broader clinical relevance. Thirdly, since even apparently similar patients are likely to differ quantitatively in their response to treatment, precise characterization of patients is usually not worthwhile. This, in turn, implies that patients entering a trial need only be broadly characterized using those few baseline variables that are known to provide powerful prognostic information, those that might modify the effects of a particular treatment or those that may be part of the endpoint in some surrogate endpoint trials.

This has led to what has been termed as the 'uncertainty principle', which states that the sole eligibility criterion is that both patient and doctor should be substantially uncertain about the appropriateness for this particular patient for each of the trial treatments[19]. This principle has been used successfully to simplify and therefore facilitate recruitment into many trials, such as the ISIS studies.

A common pitfall in the design of clinical trials of antiplatelet therapy is that a homogeneous patient population should be studied in order for the trial to be valid[18]. Thus it is often the case in trials of antiplatelet therapy that the criteria for recruitment is exceedingly narrow, thus severely limiting the generalizability of the study's findings and posing unnecessary hurdles to smooth and prompt patient recruitment. For example, there is good evidence that abciximab reduces major cardiovascular events in a wide variety of patients undergoing PCI, an effect which is sustained long term. The initial trial which established the benefits of abciximab in the context of PCI was the EPIC trial, which was performed only in patients undergoing PTCA at high risk of abrupt closure, a fraction of the total number of patients undergoing PTCA[20]. It was only subsequently in the EPILOG trial where the inclusion criteria broadened to include almost any patient undergoing PTCA (both elective and urgent), that it became apparent that the treatment benefit was present in all patients undergoing PTCA, not only high-risk patients[21]. These broad inclusion criteria were also adopted in the EPISTENT trial, which was consistent in demonstrating a benefit of abciximab in both elective and urgent PTCA in patients undergoing stenting[22].

CAPRIE is another example of a randomized trial of antiplatelet therapy with wide inclusion criteria[16]. This trial included patients with coronary artery disease, cerebrovascular disease and peripheral vascular disease because all these entities are due to a common pathophysiological mechanism. Similarly, the BRAVO trial of lotrafiban versus aspirin included patients with cardiovascular, cerebrovascular and peripheral vascular disease[17]. Meanwhile, results of the Antiplatelet Trialists' Collaboration meta-analysis clearly demonstrated consistent treatment effects across all these disease entities[23]. This is not surprising considering that occlusive vascular disease (atherothrombosis) is the common underlying pathophysiological mechanism for all these disease entities.

Treatment effect will be greatest during the treatment period

One basic principle of clinical trials of antiplatelet therapy is that the greatest treatment benefit will be observed during active treatment. Therefore, the optimum time to assess both efficacy and safety is either at the end of treatment or shortly thereafter. Following treatment cessation, loss of benefit may occur in the setting of clinical rebound, but there is unlikely to be any added benefit. Consequently, the time-to-event curves are likely to be parallel, reflecting maintenance of the absolute treatment benefit and apparent diminution of the relative treatment benefit. Lack of statistically significant treatment effect during long-term follow-up may be mistakenly interpreted as a 'loss of benefit'. However, careful analysis of the data will often reveal that no loss of benefit occurs, but rather, no added benefit occurs once treatment is stopped. Table 68.5 illustrates this pattern in five large randomized trials of antithrombotic therapy.

Cambridge Books Online © Cambridge University Press, 2009

Table 68.5. Efficacy results of five clinical trials during or just after the end of treatment and at 30 days. The lower treatment effect at 30 days does not represent a 'loss of benefit', but rather that no added benefit accrues once treatment is stopped

			Event rates and relative risk reduction (Death or myocardial infarction)	
	Antiplatelet/Anticoagulant	Duration of treatment	During or just after treatment (%)	30 days (%)
PRISM PLUS[27]	Tirofiban vs. placebo[a,b]	72 hours	0.6 vs. 2.0; RRR 70	6.8 vs. 11.7; RRR 42
PURSUIT[30]	Eptifibatide vs. placebo[a]	72 hours	7.6 vs. 9.1; RRR 16.4	14.2 vs. 15.7; RRR 9.6
FRISC[35]	Dalteparin vs. placebo	6 days acute phase	1.8 vs. 4.8; RRR 67	14.0 vs. 15.5; RRR 10
PRISM[28]	Tirofiban vs. UFH	48 hours	1.2 vs. 1.6; RRR24	5.8 vs. 7.1; RRR 20
GUSTO IIb[36]	Desirudin vs. UFH	72 hours	2.3 vs. 3.1; RRR 17	8.9 vs. 9.8; RRR 11
OASIS-2[26]	Lepirudin vs. UFH	72 hours	2.0 vs. 2.6; RRR 24	6.8 vs. 7.7; RRR 13

Notes:
[a] Both groups received unfractionated heparin. [b] Only non-discontinued arms.

The 'durability of effect' is also relevant and, for that reason, a 30-day endpoint is often chosen for treatment durations which are substantially shorter. However, it is less important if the results are statistically significant at this late time point. What matters more is whether the original difference (in absolute terms) is maintained during longer-term follow-up.

Confirming the maintenance of early benefit during longer-term follow-up is a complex issue. If, truly, there is no loss or gain of the original benefit during treatment, the risk reduction will appear to be maintained only some of the time but the absolute risk reduction will be constant. In other situations, the play of chance may exaggerate or reduce the observed treatment effect over time. For example, in the EPIC trial, the absolute treatment benefit of abciximab appeared to increase between 30 days and 6 months[20], but the reverse was observed in the CAPTURE trial[24]. Meanwhile, in the EPILOG study a consistent treatment benefit was maintained[34]. The most likely explanation for these apparently disparate results is the play of chance; in all likelihood, the true treatment benefit was maintained in all three cases.

The effect of cardiac interventions (when performed during study drug administration) in a trial of antiplatelet therapy will increase the event rate and the treatment effect

There are two main effects of cardiac interventions on the results of randomized trials of antiplatelet therapy[25]. First, interventions increase both the control and the treatment event rates. Secondly, interventions tend to exaggerate the treatment effect of the antiplatelet agent. These phenomena are demonstrated in Fig. 68.1 and Table 68.6. Therefore, in a clinical trial of a new antiplatelet agent in acute coronary syndrome, the performance of interventions as per usual clinical practice, will usually generate treatment-modifiable events. Suppressing interventions early on in these trials, may result in a reduced event rate. For example, in the OASIS-2 study[26], investigators were requested to delay interventions until after the 72-hour treatment period. However, among the small number of patients who underwent early intervention, the treatment effect was large. Had more interventions been performed early in this trial, the event rate would likely have been higher and the treatment effect of hirudin increased.

Several unique issues relate to the use of invasive procedures in trials of antiplatelet therapy in cardiovascular medicine. For example, in the PRISM PLUS trial[27], over 80% of patients received an intervention raising the possibility that the study drug (tirofiban) is only useful in the setting when an ACS patient can be taken to the catheterization lab early. By contrast, the difference observed in the PRISM study[28] was modest and no differences were observed in the GUSTO IV study[29] – both studied patients in centres without immediate access to PTCA. In the PCI CURE Study[38], there was a 31% reduction in CV death or MI ($P = 0.002$) in the large number of patients undergoing PCI ($N = 2658$); however, there was also a clear benefit of clopidogrel in those patients not undergoing PCI (relative risk 0.83; $P = 0.004$).

Table 68.6. Impact of interventions on relative risk reduction in trials of antiplatelet agents

	Relative risk reduction	
Trial	Patients undergoing PCI(%)	Patients not undergoing PCI(%)
PURSUIT[30]	31	6
PARAGON B[31]	35	7
PRISM PLUS[27]	42	12
OASIS-2[26]	75	7
CURE[37,38]	31	17

In long-term trials, competing risks are important

Patients with cardiovascular disease are often an elderly cohort of patients who may have multiple overt or occult comorbidities. They are therefore prone to dying not only from cardiovascular disease, but also from other causes, such as malignancy. These other reasons for mortality are known as 'competing risks'. Because an antiplatelet agent would not be able to modify a non-cardiovascular death, these non-cardiovascular deaths would be expected to be balanced between treatment and control. This serves only to dilute out the treatment effect of the antiplatelet agent. It has been argued that distinguishing between cardiovascular and non-cardiovascular causes of death may be difficult and therefore this subjectivity diminishes the objectivity of mortality as an outcome. However, this is not true if, in a cardiovascular trial, one defines all deaths as cardiovascular, unless proven otherwise. Thus, the onus is upon the investigator to 'prove' that the death was not cardiovascular in nature. For example, a CT scan demonstrating a herniating brain tumour in a patient who died of coma might be ruled as non-cardiovascular, or a patient who develops acute leukemia, which is substantiated by pathological specimens or autopsy, might be ruled as non-cardiovascular. Deaths due to unknown causes, motor vehicle accidents, bleeding, etc. are all considered cardiovascular. When a cause of death is unknown in a trial of a patient who already has cardiovascular disease, 80–90% of the time, the death is due to cardiovascular causes. This minimizes any impact due to the subjectivity in classifying the cause of death. Others have argued that cardiovascular death fails to include those patients who may have a side effect from treatment, for example bleeding or severe bone marrow suppression. However, bleeding would be considered a cardiovascular death, as would any complication of a cardiovascular procedure, such as wound infection following CABG surgery. For example, there was a consistent reduction in CV death with clopidogrel (318 clopidogrel vs. 345 with placebo), with similar numbers of non-CV death (41 clopidogrel vs. 45 placebo)[37]. As for the rare instances where the drug of interest may have a deleterious effect on another system, separating deaths between cardiovascular and non-cardiovascular actually allows the investigator to study and report on these findings, which may otherwise have been overlooked if all deaths were grouped together.

Antiplatelet therapy in cardiology

Herbert D. Aronow and Eric J. Topol

Department of Cardiovascular Medicine, The Cleveland Clinic, Ohio, USA

Introduction

Antiplatelet therapy has revolutionized the care of patients with cardiovascular disease. It is frequently utilized in patients with heart failure[1,2], valvular heart disease[3–8] and rhythm disturbances[9,10]. However, its greatest impact has been in the prevention and treatment of coronary artery disease (CAD). CAD is presently the leading cause of death[11], and fifth leading cause of disability[12] worldwide and is projected to be the number one cause of death and disability in the world by the year 2020[13]. Given its considerable contribution to the global burden of disease, and the substantial reductions antiplatelet therapy has made on its attendant morbidity and mortality, this chapter will focus on the role of antiplatelet therapy in CAD.

The platelet plays a pivotal role in the development and progression of stable CAD as well as in the pathogenesis of its unstable clinical presentations (i.e. unstable angina, non-ST elevation myocardial infarction (MI) and ST elevation MI)[14,15]. While the pathways of platelet activation are manifold[16], relatively few have been successfully exploited for the prevention and treatment of CAD (Fig. 69.1). This chapter will review the current evidence base for three types of antiplatelet agents: aspirin, adenosine diphosphate (ADP) receptor antagonists and platelet glycoprotein (GP) IIb/IIIa inhibitors. As detailed elsewhere in this book, aspirin inhibits platelet aggregation by interfering with the formation of cyclic prostanoids (thromboxane A_2, prostacyclin and other prostaglandins)[17], ticlopidine and clopidogrel do so by irreversible antagonism of ADP P2Y receptors[18], and GP IIb/IIIa inhibitors accomplish this via blockade of the integrin receptor $\alpha_{IIb}\beta_3$, the final common pathway of platelet aggregation[19].

Primary prevention

Aspirin

Four randomized trials, the British Doctors' Trial (BDT)[20], Physicians' Health Study (PHS)[21], Thrombosis Prevention Trial (TPT)[22] and Hypertension Optimal Treatment study (HOT)[23], have examined long-term aspirin therapy for the primary prevention of cardiovascular events (Table 69.1). Individually, three of these have demonstrated significant reductions in the incidence of MI and composite vascular events (coronary death or non-fatal MI in TPT; coronary death, non-fatal MI or non-fatal stroke in PHS and HOT)[21–23], while in the fourth[20], these reductions were non-significant.

In a meta-analysis of these four trials, aspirin's effect on vascular death was null (RR 1.01, 95% CI 0.88–1.16). However, aspirin therapy was associated with a significant reduction in vascular events (defined as cardiac death, non-fatal MI, or fatal or non-fatal stroke) (RR 0.87, 95% CI 0.81–0.95), a difference largely driven by reductions in non-fatal MI (RR 0.68, 95% CI 0.59–0.79). Nevertheless, its clinical benefits were offset by a significant increase in the risk of hemorrhagic stroke (RR 1.69, 95% CI 1.06–2.69). On balance, treating 10 000 patients with aspirin therapy for the primary prevention of cardiovascular events would prevent 67 MIs while causing an excess of 11 hemorrhagic strokes[24].

ADP receptor antagonists and GP IIb/IIIa inhibitors

To date, there have been no published studies of ADP or GP IIb/IIIa receptor antagonists for the primary prevention of cardiovascular disease.

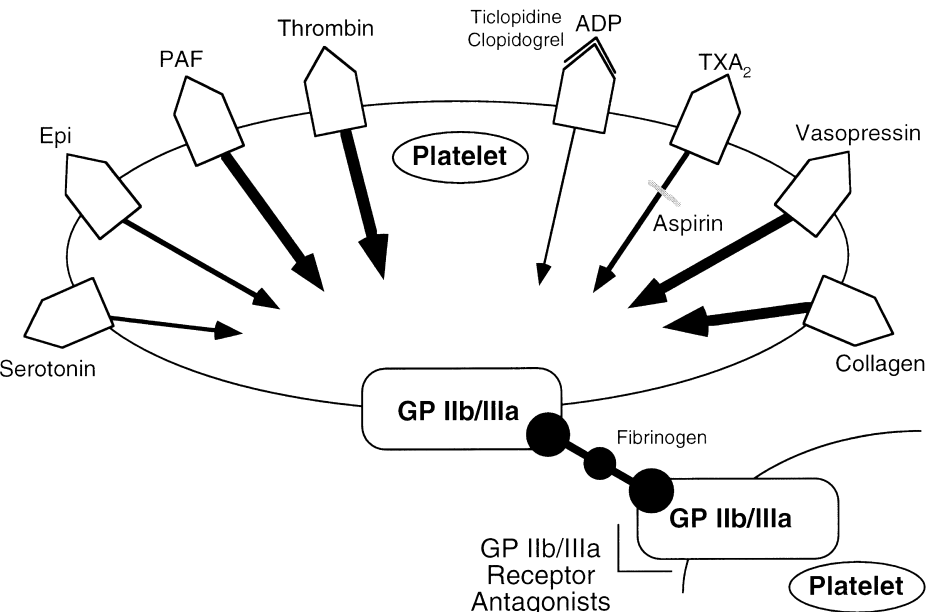

Fig. 69.1. Pathways of platelet activation and their pharmacologic inhibition. Epi = epinephrine; PAF = platelet activating factor; ADP = adenosine diphosphate; TXA2 = thromboxane; GP IIb/IIIa = platelet glycoprotein IIb/IIIa receptor. From[16]. Pending author's permission.

Secondary prevention

Aspirin

Six large randomized trials of aspirin alone for secondary prevention after acute MI have been published[25–30]. Aspirin was associated with a non-significant trend toward reduced total mortality excepting one[25], in which it was non-significantly increased. Significant benefits associated with aspirin therapy in individual trials include, decreased total mortality in patients enrolled within 6 months of an MI[28], decreased coronary mortality among men[30], and significantly reduced reinfarction or readmission for MI[25,29]. The results from these six trials were combined with those from 40 other smaller trials of aspirin monotherapy in a meta-analysis of more than 45 000 patients at high risk for suffering recurrent vascular events (defined as vascular death, non-fatal MI or non-fatal stroke). The pooled risk reduction afforded by aspirin monotherapy was highly significant (OR 0.75, 95% CI 0.70–0.79)[31].

ADP receptor antagonists

Two trials have assessed the efficacy of ADP receptor antagonism for the secondary prevention of cardiovascular disease, the Swedish Ticlopidine Multicentre Study (STIMS) and the Clopidogrel vs. Aspirin in Patients at Risk for Ischemic Events (CAPRIE) trial.

Ticlopidine

STIMS randomized 687 patients with a history of peripheral vascular disease (PVD), to ticlopidine or placebo and followed them for a mean of 5.9 years[32]. Ticlopidine was associated with a non-significant reduction in the primary composite endpoint of MI, stroke or TIA, (25.7% vs. 29.0%, $P = 0.24$), and a significant reduction in mortality (18.5% vs. 26.1%, $P = 0.015$), a difference primarily explained by reduced death from CAD.

Clopidogrel

CAPRIE randomized 19 185 patients with a recent acute MI, recent stroke or PVD to daily clopidogrel or aspirin for a mean of 1.9 years. The average yearly rate of ischemic stroke, MI or vascular death, the study's primary composite endpoint, was significantly reduced among patients in the clopidogrel group (5.32% vs. 5.83%, $P = 0.043$)[33]. A posthoc analysis revealed that clopidogrel was also associated with a significant reduction in MI (RR 0.81, 95% CI 0.69–0.95)[34]. The ongoing Clopidogrel for Reduction of Events During extended Observation (**CREDO**) trial, a study of patients with CAD undergoing percutaneous coronary interventions (PCI), is assessing whether clopidogrel

[c] Includes fatal and non-fatal events (separate data on non-fatal events not published).

and aspirin in combination are superior to aspirin alone for preventing late ischemic events.

GP IIb/IIIa inhibitors

Intravenous GP IIb/IIIa inhibitors reduce ischemic complications in patients undergoing PCI and in those with acute coronary syndromes (ACS) (see below). Given that increased levels of platelet activation persist for some time after an ACS[35], a number of studies have examined whether prolonged treatment with oral GP IIb/IIIa inhibitors might offer additional protection after such an event (Table 69.2). Despite promising results in Phase II studies of sibrafiban[36] orbofiban[37], and xemilofiban[38], four Phase III clinical trials evaluating these three agents have failed to demonstrate clinical benefits (Table 69.2). Mortality was increased significantly in the second Sibrafiban vs. aspirin to Yield Maximum Protection from ischemic Heart events post-acute cOroNary sYndromes (2nd SYMPHONY)[39], Orbofiban in Patients with Unstable coronary Syndromes (OPUS-TIMI 16)[37] and Evaluation of oral Xemilofiban in ControllIng Thrombotic Events (EXCITE)[40] trials, and non-significantly increased in the SYMPHONY[41,42] trial. Significant increases in the composite endpoint of death or non-fatal MI were also noted in the second SYMPHONY trial, while non-significant increases in this endpoint were observed in the remaining three. Bleeding was significantly increased in all four of these studies. When the results of these four trials were meta-analysed, the increase in mortality associated with use of an oral GP IIb/IIIa inhibitor was highly significant (OR 1.37, 95% CI 1.13–1.66, P= 0.002)[43].

Despite these discouraging results, clinical outcomes from one Phase II study appear promising. The Fibrinogen Receptor Occupancy Study Trial (FROST) randomized 513 patients with unstable angina to low, intermediate or high doses of the oral GP IIb/IIIa receptor blocker lefradafiban. The incidence of the composite endpoint, death, MI, PCI or coronary artery bypass grafting (CABG) was lower in the intermediate-dose than placebo arm at 30 days[44], and this benefit persisted at 6 months (38.5% vs. 56.9%)[45]; the high-dose arm was terminated early due to unacceptably high

bleeding rates. Further analysis revealed an inverse relationship between fibrinogen receptor occupancy and the clinical event rate[46]. Whether more individualized dosing of existing agents based on fibrinogen receptor occupancy will lead to improved clinical outcomes remains to be seen. Regardless, a number of promising new agents are under development or being assessed in ongoing or recently completed clinical trials, including fradafiban/lefradafiban[47–49], roxifiban[50,51], lotrafiban[52,53] and chromofiban.

Non-ST elevation acute coronary syndromes

Aspirin

The efficacy of aspirin for treating unstable angina and non-ST elevation MI (i.e. non-ST ACS) is well established. Four trials have demonstrated that aspirin reduces ischemic events in patients with non-ST elevation ACS (Table 69.3). In the Veterans Administration (VA) Cooperative Study[54], a trial by Theroux et al.[55], the Research Group on Instability in Coronary artery disease (RISC) study[56,57], and the Canadian Multicenter Trial[58], aspirin significantly reduced rates of the composite endpoint, death or non-fatal MI (in the latter trial, this association was only significant in the on-treatment analysis). In two of these, the VA Cooperative Study and Canadian Multicenter Trial, aspirin significantly reduced mortality rates at 1–2 years of follow-up, whereas in RISC and the study by Theroux et al., there were non-significant reductions in this endpoint among aspirin-treated patients. Finally, in the study by Theroux et al., the composite endpoint, death, non-fatal MI or refractory ischemia was significantly reduced with aspirin therapy. Importantly, bleeding occurred no more frequently in aspirin- than placebo-treated patients in any of these trials. In sum, these studies demonstrate that aspirin offers significant protection against death, MI and refractory ischemia without an attendant increase in hemorrhagic risk when used for non-ST elevation ACS.

ADP receptor antagonists

Ticlopidine

Only one trial has examined the effect of ADP receptor antagonism for non-ST elevation ACS. Studio della Ticlopidine nell' Angina Instabile (STAI) randomized 652 patients with unstable angina to 6 months of conventional therapy (i.e. beta blockers, calcium channel blockers or nitrates, but not aspirin) alone or in combination with ticlopidine 250 mg twice daily. The addition of ticlopidine significantly reduced the incidence of vascular death or MI (7.3% vs. 13.6%, OR 0.50, 95% CI 0.30–0.84; $P=0.009$)[59,60].

Clopidogrel

While the efficacy of aspirin and ticlopidine for the treatment of non-ST elevation ACS has been clearly demonstrated, these agents have not been compared in a head-to-head fashion, nor have they been evaluated in combination in this setting. The ongoing Clopidogrel in Unstable angina to prevent Recurrent ischemic Events (CURE) trial is randomizing 12 500 patients with unstable angina to aspirin plus placebo or aspirin plus clopidogrel to assess the incremental effect of ADP receptor antagonism on vascular death and non-fatal MI[61].

GP IIb/IIIa inhibitors

After preliminary clinical data suggested that the intravenous GP IIb/IIIa inhibitors tirofiban[62], lamifiban[63], eptifibatide[64] and abciximab[65–67] reduce the incidence of ischemic events in patients with non-ST elevation ACS, six phase III trials evaluating these agents were performed (Table 69.4).

Tirofiban

In the Platelet Receptor Inhibition in Ischemic Syndrome Management (PRISM) trial, tirofiban treatment was associated with a reduction in death, non-fatal MI or refractory ischemia at 48 hours, the study's primary endpoint[68]. This benefit attenuated thereafter, such that it was no longer statistically significant at 7 or 30 days. Nevertheless, when compared with heparin at 30 days, tirofiban reduced the incidence of death in the entire cohort. Furthermore, it reduced the composite of death, non-fatal MI or refractory ischemia among patients who underwent early PCI (21.6% vs. 27.3%, $P<0.05$) and reduced the risk of death (1.6% vs. 6.2%, $P=0.004$) and MI (2.7% vs. 6.8%, $P=0.01$) at 30 days among patients with an elevated baseline troponin level[69]. These benefits did not occur at the expense of increased bleeding risk. The Platelet Receptor Inhibition in Ischemic Syndrome Management in Patients Limited by Unstable Signs and Symptoms (PRISM–PLUS) study, randomized patients to one of three regimens: standard-dose tirofiban (as in PRISM), low-dose tirofiban with heparin or heparin alone[70]. The tirofiban-only arm was stopped prematurely given its higher incidence of death at seven days. Nevertheless, when compared with heparin alone, the tirofiban-heparin combination clearly reduced the composite primary endpoint of death, non-fatal MI, refractory

ischemia or rehospitalization at both 30 days and 6 months and these benefits were only offset by a small increase in bleeding risk. Based on these results, heparin is now routinely administered with tirofiban in non-ST elevation ACS.

Lamifiban

The PARAGON-A trial randomized patients to either placebo with heparin, low-dose lamifiban with or without heparin or high-dose lamifiban with or without heparin[71]. At 30 days, the incidence of death or non-fatal MI, the study's primary endpoint, was not significantly different between groups. However, by six months, there was a statistically significant reduction in death or non-fatal MI among all patients treated with low-dose lamifiban when compared with placebo, irrespective of concomitant heparin administration. As expected, major or intermediate bleeding occurred more frequently in high- and low-dose groups than in placebo. In subsequent posthoc analyses of these data, those with intermediate serum lamifiban concentrations (i.e. 18–42 ng/ml) witnessed the greatest event reductions at 30 days and 6 months when compared with placebo and these reductions persisted at six months[72]. Accordingly, the PARAGON-B[73] trial evaluated the effect of treatment to intermediate serum lamifiban levels. This trial randomized patients to placebo or renal-dosed lamifiban. The primary efficacy endpoint, a composite of death, non-fatal MI or severe recurrent ischemia at 30 days was non-significantly reduced while bleeding complications were more frequent among lamifiban-treated patients. However, lamifiban significantly reduced the incidence of the primary endpoint at 30 days among patients who underwent early PCI (11.6% vs. 18.5%, $P<0.05$) and in those with a positive troponin level on admission (11.0% vs. 19.4%, $P=0.01$)[74], a finding similar to that seen in other trials of IIb/IIIa inhibitors for non-ST elevation ACS.

Eptifibatide

In the Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy (PURSUIT) trial, patients were randomized to eptifibatide or placebo for 72 hours or until hospital discharge, whichever occurred sooner. The primary endpoint, death or non-fatal MI, was significantly reduced in the eptifibatide group at 30 days and this benefit persisted at 6 months. Not surprisingly, bleeding was significantly more frequent among those treated with eptifibatide. In a substudy that included only US patients, eptifibatide significantly reduced the composite endpoint, death or non-fatal MI, at 30 days and 6 months, reductions that were greater in magnitude than those observed in non-US patients[75]. In contrast to patients who underwent early PCI in trials of tirofiban and lamifiban, the risk reduction attributable to eptifibatide was similar in patients who underwent early PCI and in those who were managed more conservatively[76].

Abciximab

Finally, the Global Use of Streptokinase or t-PA for Occluded Coronary Arteries–Acute Coronary Syndromes (GUSTO IV–ACS) trial randomized patients to abciximab for 24 or 48 hours, or to placebo. This trial revealed a trend toward increased ischemic events and significantly increased rates of bleeding among patients assigned to the 24– and 48-hour abciximab arms. Furthermore, no benefits were observed with abciximab in patients with positive troponin levels or with ST-depression on baseline ECG.

The trend towards harm associated with abciximab in GUSTO IV-ACS, especially during study drug administration, occurred despite the apparent benefits observed in patients with ACS who underwent PCI in earlier trials of abciximab[65–67] and in contrast to accumulating trial evidence supporting the use of tirofiban, eptifibatide and possibly lamifiban for ACS. Whether this lack of benefit was due to the selection of patients with a lower risk profile, the use of a suboptimal dosing strategy, the administration of abciximab in a non-PCI setting or to some other property of the agent itself will require further study. Recent data suggesting pro-inflammatory effects, such as the shedding of CD40 ligand receptors due to suboptimal GP IIb/IIIa receptor blockade, have also been cited as an explanation. Nevertheless, the ability of GP IIb/IIIa inhibitors to reduce ischemic events after a non-ST elevation ACS remains well established. In a meta-analysis of the PRISM, PRISM-PLUS, PARAGON A and B, PURSUIT and GUSTO IV–ACS trials, GP IIb/IIIa receptor blockade significantly reduced 30-day death or non-fatal MI (pooled OR 0.92, 95% CI 0.86–0.995, $P=0.037$; Breslow–Day test for heterogeneity: $P=0.34$)[77].

ST elevation acute coronary syndromes

Aspirin

Although one earlier randomized trial of 1682 patients had suggested that early aspirin therapy after an acute MI could reduce mortality[29], aspirin's overwhelming and unquestionable benefit in this setting was demonstrated in the landmark International Study of Infarct Survival (ISIS) – 2[78]. In that trial, 17 187 patients within 24 hours of a suspected acute MI were randomized to aspirin 162.5 mg daily

for one month, streptokinase 150 million units intravenously over one hour, both or neither. Compared with placebo, aspirin significantly reduced the incidence of in-hospital non-fatal reinfarction (1.0% vs. 2.0%, $P<0.0000001$) and the incidence of the study's primary endpoint, vascular death at five weeks (9.4% vs. 11.8%; OR = 0.77 [95% CI 0.70–0.85], $P<0.00001$). Streptokinase also significantly reduced the incidence of the primary endpoint, but the combination of aspirin and streptokinase was not only superior to that of its placebo (8.0% vs. 13.2%; OR = 0.58 [95% CI 0.50–0.66], $P<0.00001$), but yielded significantly greater benefits than either agent alone. The mortality benefit in both aspirin groups persisted at 10 years of follow-up[79].

ADP receptor antagonists

To date, there have been no studies evaluating ADP receptor antagonists as monotherapy in the setting of ST elevation MI. However, when stenting is used as reperfusion therapy in this setting (i.e. primary stenting), these agents are routinely co-administered with aspirin (see below). In patients who receive either fibrinolysis or no reperfusion therapy and who do not undergo percutaneous revascularization, the relative benefits and risks of ADP receptor antagonism have not been explored. Given the benefits attributable to these agents in lower risk patients with CAD[33], such studies would be worthwhile.

GP IIb/IIIa inhibitors

Primary PCI with or without adjunctive abciximab

After encouraging preliminary observational data from the EPIC trial[66], the ReoPro and Primary PTCA Organization and Randomized Trial (RAPPORT) prospectively evaluated abciximab in the setting of primary PTCA (Table 69.5)[80]. At 6 months, the study's primary endpoint, death, MI or any target vessel revascularization (TVR) was not significantly different between abciximab and placebo groups. However, there was less death, MI or urgent TVR in the abciximab group. As expected, the incidence of major bleeding was greater among abciximab-treated patients.

In a small trial ($n = 200$), Neumann et al. demonstrated that the use of abciximab in primary stenting improved coronary microvascular function and left ventricular wall motion. Furthermore, it significantly reduced the incidence of the secondary endpoint, death, non-fatal MI or TVR at 30 days[81]. In the Abciximab before Direct Angioplasty and Stenting in Myocardial Infarction Regarding Acute and Long-term Follow-up (ADMIRAL) study, abciximab reduced the incidence of the study's primary endpoint, death, MI or urgent TVR at 30 days, a benefit that was preserved at 6 months (Table 69.5)[82]. Minor bleeding was more frequent among abciximab-treated patients as well.

In contrast, the Controlled Abciximab and Device Investigation to Lower Late Angioplasty Complications (CADILLAC) trial randomized patients to PTCA alone, PTCA + abciximab, stent alone or stent + abciximab and found that the study's primary endpoint, death, MI, disabling stroke or urgent TVR at six months, was significantly reduced by stenting but not by abciximab (Table 69.5)[83]. Bleeding rates were not different between any of the four treatment strategies. While the addition of abciximab appeared to decrease the incidence of major adverse cardiac events among patients treated with primary PTCA, it conferred no additional benefit in the setting of primary stenting. Of concern, the study endpoints were not consistent in direction among patients in the stent arms; while abciximab was associated with increased death and MI in these patients (a finding inconsistent with the weight of previous trial evidence), it substantially reduced ischemic TVR. In the end, these opposing benefits nullified one another and the overall incidence of major adverse cardiac events appeared equal in both stent groups. It is also noteworthy that the incidence of reinfarction was much lower than expected in the placebo arms; as a result, the overall number of cardiac events upon which the analysis was performed and from which the study conclusions were drawn was relatively small.

Primary stenting with adjunctive abciximab vs. full-dose thrombolysis

The Stent versus Thrombolysis for Occluded coronary arteries in Patients with Acute Myocardial Infarction (STOP–AMI) study randomized 140 patients to either primary stenting with adjunctive abciximab or thrombolysis using accelerated alteplase[84]. Primary stenting with abciximab was associated with greater myocardial salvage and a reduced incidence of the secondary endpoint, death, MI or stroke at 6 months (8.5% vs. 23.2%; RR 0.34, 95% CI 0.13–0.88, $P = 0.02$).

Full-dose thrombolysis with or without adjunctive abciximab, eptifibatide or lamifiban

Three phase II studies of full-dose thrombolysis with or without adjunctive GP IIb/IIIa inhibition for ST elevation MI have been conducted. The Thrombolysis and Angioplasty in Myocardial Infarction (TAMI) 8 Pilot[85], Integrilin to Minimize Platelet Aggregation and Coronary Thrombosis (IMPACT)-AMI[86] and Platelet Aggregation

Receptor Antagonist Dose Investigation and Reperfusion Gain in Myocardial Infarction (PARADIGM)[87] trials assessed abciximab, eptifibatide and lamifiban for this purpose, respectively. Two of these studies demonstrated that adjunctive GP IIb/IIIa inhibition improved coronary macrovascular flow (as measured by Thrombolysis In Myocardial Infarction (TIMI) flow grade[88])[85,86], two revealed enhanced coronary microvascular flow (as measured by time to ECG ST segment recovery/stabilization)[86,87], but only one found that adverse clinical event rates were lower with the addition of these agents[85]. Not surprisingly, bleeding rates were greater among those patients treated with GP IIb/IIIa inhibitors in the TAMI-8 and PARADIGM trials.

Reduced-dose thrombolysis with adjunctive abciximab vs. full-dose thrombolysis

In the Phase II study, Thrombolysis In Myocardial Infarction (TIMI)-14, greater rates of 90-minute IRA patency (the study's primary endpoint) and more complete resolution of ECG ST segment elevation at 90 minutes were observed with reduced-dose alteplase and abciximab than with full-dose alteplase alone[89]. The Phase II Strategies for Patency Enhancement in the Emergency Department (SPEED) trial assessed whether the combination of reduced-dose reteplase with abciximab could safely provide superior reperfusion than full-dose reteplase alone. Reteplase was employed for thrombolysis as earlier data had demonstrated higher rates of reperfusion with this agent than alteplase[90]. Reduced-dose reteplase with abciximab yielded significantly greater 60–90 minute TIMI 3 grade flow than full-dose reteplase alone. Interestingly, TIMI 3 flow was achieved less often if low-dose rather than standard-dose heparin (40 vs. 60 U/kg intravenous bolus) was administered with the reduced-dose reteplase and abciximab regimen. Based on these findings, the GUSTO V-trial, is randomizing 16600 patients to full-dose reteplase vs. reduced-dose reteplase + abciximab with standard-dose heparin.

In summary, the evidence to date suggests that GP IIb/IIIa inhibitors improve angiographic and clinical outcomes when combined with thrombolysis and likely with primary PCI. Furthermore, primary stenting with adjunctive abciximab may be superior to full dose thrombolysis. Whether primary PCI with adjunctive GP IIb/IIIa receptor blockade is superior to reduced-dose thrombolysis with adjunctive GP IIb/IIIa inhibition remains to be seen.

Percutaneous coronary intervention

Aspirin with or without ADP receptor antagonists

Percutaneous transluminal coronary angioplasty

Adjunctive aspirin has been administered with percutaneous transluminal coronary angioplasty (PTCA) since this procedure was first performed in 1977. However, the first trial to demonstrate aspirin's clinical benefit in this setting did not appear until 1988[91]. In this study, aspirin given in combination with dipyridamole was associated with a significant reduction in the incidence of acute closure as manifest by lower rates of periprocedural Q-wave MI when compared with placebo (1.6% vs. 6.9%, $P = 0.011$).

Coronary stenting

Aspirin has been an integral component of the adjunctive pharmacologic regimen employed for coronary stenting as well[92,93]. Early pharmacologic regimens employed aspirin in combination with aggressive anticoagulation but were associated with poorer clinical outcomes and more procedural complications. At the other extreme, aspirin monotherapy is inadequate at preventing adverse clinical outcomes after coronary stenting. Although one small randomized trial suggested that aspirin in combination with ticlopidine was equivalent to aspirin monotherapy in preventing death, MI, revascularization or stent thrombosis, this study was underpowered[94]. The much larger Stent Anticoagulation Restenosis Study subsequently established the superiority of the aspirin–ticlopidine combination over aspirin alone. In that study, aspirin with ticlopidine significantly reduced the primary endpoint, death, TVR, target vessel thrombosis or recurrent MI when compared with aspirin monotherapy[95]. In addition, each of the individual component endpoints barring death were significantly reduced with aspirin–ticlopidine as compared with aspirin alone.

ADP receptor antagonists

Percutaneous transluminal coronary angioplasty with adjunctive ticlopidine

Few data are available on the use of ADP receptor antagonists in the setting of stand-alone PTCA. One small study by Bertrand et al. randomized 266 patients to ticlopidine 250 mg twice daily or placebo beginning 2 days prior to and continuing for 6 months following PTCA in order to assess the effect of ticlopidine on acute closure and angiographic restenosis[96]. While no significant differences were noted in the rate of restenosis between groups, those in the ticlopi-

Cambridge Books Online © Cambridge University Press, 2009

dine group had significantly fewer episodes of acute closure (5.1% vs. 16.2%, $P<0.01$).

Coronary stenting with adjunctive ticlopidine

The ADP receptor antagonists have played a much more integral role in the adjunctive pharmacotherapy for coronary stenting than stand-alone PTCA. Four randomized controlled trials comparing anticoagulation to antiplatelet therapy with ADP receptor antagonists have been published (Table 69.6). The Intracoronary Stenting and Antithrombotic Regimen (ISAR) trial[97] and Stent Anticoagulation Restenosis Study (STARS)[95] both demonstrated significant reductions in composite major adverse cardiac events, while in the Full ANTicoagulation vs. ASpirin and TIClopidine (FANTASTIC) trial[98] and Multicenter Aspirin and Ticlopidine Trial after Intracoronary Stenting (MATTIS)[99] non-significant reductions in these events were observed with antiplatelet therapy. Treatment with an ADP receptor antagonist reduced the incidence of MI, target lesion revascularization (TLR) and stent thrombosis by varying degrees in each of these trials, and significantly reduced the incidence of bleeding complications in all four. Finally, hospital length of stay (LOS) was significantly shortened by ADP receptor antagonism in FANTASTIC and MATTIS, the two trials in which this endpoint was measured.

Pre- vs. postprocedure ADP receptor antagonism

The duration of pretreatment with ADP receptor antagonists before coronary stenting also appears to influence the degree of protection from ischemic events conferred by these agents. In a Cleveland Clinic registry study of 175 patients who underwent coronary stenting, Steinhubl et al. observed that the rate of procedure-related non-Q MI varied with the duration of ticlopidine pretreatment[100]. Among those who began taking ticlopidine on the day of procedure, 1 to 2 days preprocedure and greater than 3 days before the procedure, the respective rates of post-procedure non-Q MI were 29%, 14% and 5% (chi-square for trend $=9.6$, $P=0.002$). A TARGET trial (see below) substudy, examining the effect of clopidogrel pretreatment is under way.

Coronary stenting with adjunctive ticlopidine vs. clopidogrel

Despite the significant reductions in thrombotic and hemorrhagic complications following coronary stenting afforded by combination antiplatelet therapy compared to oral anticoagulation, ticlopidine use is limited by significant hematological and gastrointestinal side effects[18]. As a result, clopidogrel, a newer ADP receptor antagonist with a more rapid onset of action, greater inhibition of platelet aggregation and more tolerable side effect profile[18] has also been tested in this setting. Ten studies have compared the combination of ASA and ticlopidine with ASA and clopidogrel in patients undergoing coronary stenting. Considered individually, data from these three randomized trials[101–103] and seven registries[104–110] have demonstrated that the combination of clopidogrel and ASA is safer and at least as efficacious in preventing major adverse cardiac events following coronary stenting than combined ticlopidine and ASA. When these studies were meta-analysed, clopidogrel was associated with significant reductions in the incidence of major adverse cardiac events (OR 0.50, 95% CI 0.41–0.62, $P=0.001$), including mortality (OR 0.43, 95% CI 0.28–0.66, $P=0.001$) as compared with ticlopidine[111]. Consequently, most interventional cardiologists have now switched from ticlopidine to clopidogrel for patients undergoing coronary stenting.

GP IIb/IIIa receptor blockade for percutaneous coronary intervention

Platelets play a central role in the development of ischemic complications following percutaneous interventions[112,113], and therapeutic intravenous GP IIb/IIIa receptor blockade was first explored in this setting (Table 69.7).

Abciximab

The first clinical trial demonstrating the benefit of GP IIb/IIIa receptor blockade in any patient population was the Evaluation of c7E3 for the Prevention of Ischemic Complications (EPIC). EPIC randomly assigned patients undergoing PTCA or DCA who were at high-risk for abrupt closure to an abciximab (C7E3) bolus and infusion, abciximab bolus with placebo infusion, or placebo bolus and infusion[114]. Compared with the placebo bolus and infusion, the abciximab bolus and infusion was associated with a significant reduction in major ischemic events by 30 days, a difference largely due to reductions in non-fatal MI and emergent PTCA. Nevertheless, major bleeding was twice as common with abciximab than placebo. The clinical benefits were durable at 6 months[115] and 3 years[116]. Notably, among those enrolled with unstable angina or evolving MI, the highest risk patient subgroup in that trial, abciximab treatment was associated with a substantial reduction in 3-year mortality (5.1% vs. 12.7%, $P=0.01$).

The Evaluation of PTCA to Improve Long-Term Outcome with Abciximab GP IIb/IIIa Blockade (EPILOG) trial was conducted to discern whether GP IIb/IIIa receptor blockade would benefit a broad range of patients undergoing PCI, and whether using less heparin could reduce

hemorrhagic complications without attenuating the clinical benefit. EPILOG randomly assigned patients to a bolus and infusion of placebo with standard-dose heparin, abciximab with standard-dose heparin or abciximab with low-dose heparin. By 30 days, abciximab treatment had significantly reduced the incidence of ischemic events by more than half, regardless of the heparin dosing strategy. Although major bleeding did not vary by treatment assignment, significantly more minor bleeding was observed in the abciximab + standard-dose heparin than control group (7.4% vs. 3.7%, $P < 0.001$). Between 30 days and six months, some attenuation in benefit occurred due to abciximab's lack of effect on non-urgent TVR (a finding in direct contrast with the EPIC trial). Nevertheless, the incidence of the composite, death, MI or repeat revascularization at 6 months was reduced from 25.8% in the placebo group, to 22.3% in the abciximab + standard-dose heparin group ($P = 0.04$) and 22.8% in the abciximab + low-dose heparin group ($P = 0.07$).

While the EPIC and EPILOG studies examined the effect of abciximab during and following a PCI, the C7E3 Fab AntiPlatelet Therapy in Unstable REfractory angina (CAPTURE) trial[67] assessed the effect of prolonged preprocedural abciximab in medically refractory unstable angina. The trial was terminated early due to the significant reduction in the 30-day ischemic endpoint afforded by abciximab. However, by 6 months, there was no longer a significant difference in the incidence of ischemic events between abciximab and placebo arms. Abciximab pretreatment reduced the incidence of MI before the index PCI, a finding that suggested abciximab might be of benefit for unstable coronary syndromes regardless of the ultimate treatment strategy. As noted above, this hypothesis was not borne out in the subsequent GUSTO IV-ACS trial.

Very few patients in the EPIC, EPILOG and CAPTURE trials underwent coronary stenting. Given the superiority of stenting over PTCA for preventing repeat revascularization[92,93], the Evaluation of Platelet IIb/IIIa Inhibitor for STENTing (EPISTENT) trial randomized patients to stent + abciximab, PTCA + abciximab or stent + placebo[65]. The incidence of death, non-fatal MI or urgent revascularization was significantly reduced in the stent + abciximab group and in the PTCA + abciximab group when compared with the stent + placebo group. These results were durable at six months[117] and 1 year, and were largely the result of reductions in death and MI afforded by abciximab[118]. Perhaps, most notably, the death rate at 1 year was significantly lower in the stent + abciximab group than the stent + placebo group (2.4% vs. 1.0%, $P = 0.037$), additional data suggesting that GP IIb/IIIa blockade might confer a survival advantage in the setting of PCI.

Despite the suggestion that GP IIb/IIIa inhibition with abciximab might reduce the incidence of clinical restenosis in the EPIC trial[115], these findings were not borne out in the subsequent EPILOG[119] or EPISTENT[117] studies, excepting diabetics, who witnessed a significant reduction in TVR at 6 months in the latter trial (22.4% vs. 13.7%, $P = 0.035$)[120]. The Evaluation of ReoPro And Stenting to Eliminate Restenosis (ERASER) trial randomized approximately 200 patients to a bolus and infusion of abciximab or placebo at the time of coronary stenting and found no difference in the primary endpoint, restenotic tissue volume by intravascular ultrasound (there was a non-significant trend toward reduced volume of restenotic tissue among abciximab-treated diabetics, however)[121]. Similarly, the Intracoronary Stenting and Antithrombotic Regimen-2 (ISAR-2) trial randomized patients undergoing coronary stenting within 48 hours of an acute ST elevation MI to abciximab or placebo bolus and infusion and found no difference in the primary endpoint, angiographic restenosis at 6 months among 366 patients[122]. Thus, to date, the only data supporting the role of GP IIb/IIIa receptor blockade for inhibiting restenosis are in diabetics.

Eptifibatide

After promising pilot data on eptifibatide in the setting of PCI[123,124], patients undergoing elective, urgent or emergent intervention in the Integrilin to Minimize Platelet Aggregation and Coronary Thrombosis (IMPACT)-II study were randomized to an eptifibatide bolus with moderate-dose infusion, eptifibatide bolus with low-dose infusion or a placebo bolus and infusion[125]. At 30 days, there was a gradient of benefit, albeit non-significant, with increasing eptifibatide dose and no statistically significant difference in the rates of bleeding complications. In an on-treatment analysis, the composite endpoint, death, MI, urgent revascularization or placement of a stent for abrupt or threatened closure was significantly reduced in the low-dose eptifibatide group when compared with placebo.

The Enhanced Suppression of the Platelet Receptor glycoprotein IIb/IIIa using Integrilin Therapy (ESPRIT) trial sought to determine whether eptifibatide would confer benefit in patients undergoing elective coronary stenting. Utilizing a novel dosing strategy aimed at attaining greater platelet inhibition, this trial randomized patients to a double bolus and infusion of eptifibatide or placebo. At 48 hours, the study's primary endpoint, death, MI, urgent TVR or bailout GP IIb/IIIa inhibitor use, was significantly reduced. By 30 days, the composite secondary endpoint, death, MI or urgent TVR was significantly reduced by eptifibatide (6.8% vs. 10.5%, $P = 0.003$), a difference largely driven by reductions in death and MI. Finally, a posthoc analysis of the angiographic data from 43 patients in this

Cambridge Books Online © Cambridge University Press, 2009

trial revealed that eptifibatide also significantly improved coronary flow reserve when compared with placebo (1.78 ± 0.95 vs. 1.28 ± 0.40, $P = 0.02$)[126]. Six-month trial results are not yet available. While it appears that eptifibatide reduces major adverse cardiac events following PCI, its efficacy relative to other GP IIb/IIIa inhibitors in this setting has not yet been studied.

Tirofiban

The Randomized Efficacy Study of Tirofiban for Outcomes and Restenosis (RESTORE) was designed to assess the effect of tirofiban in PCI. RESTORE enrolled patients undergoing PTCA or DCA within 72 hours of USA or an MI and randomized them to tirofiban or placebo bolus and infusion[127]. The incidence of death, MI, stent for threatened/abrupt closure or any revascularization at 30 days was non-significantly reduced in the tirofiban-treated group and bleeding complications were similar in the two treatment groups. When the composite endpoint, death, non-fatal MI or urgent/emergent revascularization was examined to allow for comparison with trials of other GP IIb/IIIa inhibitors in this setting, the event rate in the tirofiban group was reduced by 24%, although this result was of only marginal statistical significance. At 6 months, the incidence of the primary endpoint remained lower in the tirofiban group (24.1% vs. 27.1%, $P = 0.11$)[128].

Head-to-head comparison of GP IIb/IIIa inhibition in PCI

The role of tirofiban in PCI was further examined in the equivalency trial, do Tirofiban and Abciximab for Revascularization Give Equivalent outcomes? (TARGET)[129]. This study randomized patients undergoing coronary stenting to either abciximab or tirofiban and found that abciximab was superior to tirofiban in preventing the composite endpoint, death, MI or urgent revascularization at 30 days. No trials of abciximab or tirofiban vs. eptifibatide for PCI are currently under way.

Note added in proof

A number of noteworthy developments in the antiplatelet therapy arena occurred following submission of this chapter. Important trials in primary and secondary prevention, non-ST and ST elevation ACS and PCI have subsequently been published or presented and are reviewed below:

Primary prevention

The Primary Prevention Project (**PPP**) randomized 4495 people who had at least one cardiovascular disease risk factor but no known coronary heart disease to either aspirin 100 mg daily or placebo.[130] It was stopped prematurely after a mean of 3.6 years after the TPT[22] and HOT[23] trials revealed that aspirin therapy was of unequivocal benefit in the primary prevention of cardiovascular disease. In the PPP, aspirin therapy significantly lowered the risk of cardiovascular death compared with placebo (0.8% vs. 1.4%, RR 0.56 [95% CI 0.31–0.99], $P = 0.049$). In addition, the composite cardiovascular death, non-fatal MI, angina, non-fatal stroke, transient ischemic attack, peripheral arterial disease or revascularization procedures was also significantly lowered among patients assigned to aspirin treatment (6.3% vs. 8.2%, RR 0.77 [95% CI 0.62–0.95], $P = 0.014$). Importantly, while bleeding complications were more frequent among aspirin-treated patients (1.1 vs. 0.3%, $P = 0.0008$), aspirin's observed benefit did not occur at the expense more hemorrhagic cerebrovascular events.

Secondary prevention

After enrolling 9200 patients, the Blockade of the IIb/IIIa Receptor to Avoid Vascular Occlusion (**BRAVO**) trial was prematurely terminated per the recommendation of the independent Data and Safety Monitoring Board. Compared with placebo, lotrafiban was associated with a significant increase in mortality (2.7% vs. 2.0%, $P = 0.022$), serious thrombocytopenia (2.2% vs. 0.5%) and major bleeding (4.2% vs. 1.3%, $P < 0.0001$). Given similar findings in studies of sibrafiban, orbofiban and zemilofiban, trials of chromofiban and roxifiban been terminated and there are currently no ongoing phase III trials of any oral glycoprotein IIb/IIIa inhibitor.

In the Clopidogrel in Unstable Angina to Prevent Recurrent Events (**CURE**) trial, clopidogrel treatment was added to background aspirin therapy for 3–12 months following a non-ST elevation ACS.[131] At 12 months, clopidogrel significantly reduced the primary composite endpoint, cardiovascular death, non-fatal MI or stroke (9.3% vs. 11.4%, RR 0.80 [0.72–0.90], $P < 0.001$). The occurrence of any composite endpoint component or refractory ischemia was also significantly reduced (16.5% vs. 18.8%, RR 0.86 [0.79–0.94], $P < 0.001$). Nevertheless, minor (5.1% vs. 2.4%, RR 2.12 [1.75–2.56], $P < 0.001$) and major (3.7% vs. 2.7%, RR 1.38 [1.13–1.67], $P = 0.001$) bleeding, and the need to transfuse two or more units of blood (2.8% vs. 2.2%, RR 1.30 [1.04–1.62], $P = 0.02$) occurred more frequently among patients randomized to clopidogrel therapy.

Non-ST elevation ACS

The **TACTICS** Thrombolysis In Myocardial Infarction (**TIMI**)**-18** trial randomized 2220 patients with a non-ST elevation ACS to an early invasive or conservative

Cambridge Books Online © Cambridge University Press, 2009

approach.[132] All patients were treated with aspirin, heparin and tirofiban (the latter for 48 hours or until revascularization and then for 12 hours following PCI). The early invasive strategy was associated with a significantly lower incidence of the primary composite endpoint, death, non-fatal MI or rehospitalization for an ACS within six months when compared with the conservative strategy (15.9% vs. 19.4%, OR 0.97 [0.62–0.97], *P* = 0.025). While the trial did not specifically assess the efficacy of tirofiban, it was remarkable in that an early invasive strategy with background tirofiban was associated with a 4.7% incidence of death or non-fatal MI at 30 days, a rate lower than in prior trials of patients with non-ST elevation ACS.

ST elevation ACS

The Global Use of Strategies To Open occluded coronary arteries (**GUSTO**) **V** trial randomized 16,588 patients who presented within six hours of an ST elevation MI to either standard-dose reteplase or half-dose reteplase with full-dose abciximab.[133] Although the incidence of the trial's primary endpoint, all-cause mortality at 30-days, was lower among patients treated with combination therapy, this difference was not statistically significant (5.6% vs. 5.9%, RR 0.95 [95% CI 0.84–1.08], *P* = 0.43). Nevertheless, the rates of the composite endpoint death or non-fatal MI (7.4% vs. 8.8%, RR 0.83 [0.74–0.93], *P* = 0.0011) were significantly reduced by combination therapy. Although the incidence of intracranial bleeding was similar in each group, mild, moderate and severe bleeding complications were nearly twice as common, and the development of thrombocytopenia and need for blood transfusion were also significantly increased among patients treated with combination therapy.

The Assessment of the Safety and Efficacy of a New Thrombolytic (**ASSENT**)**-3** study randomized 6,095 patients with an ST elevation MI to one of three treatment strategies: full-dose tenecteplase plus *enoxaparin*; half-dose tenecteplase plus weight-adjusted low-dose unfractionated heparin and *abciximab*; or, full-dose tenecteplase plus weight-adjusted *unfractionated heparin*.[134] As in GUSTO V, 30-day mortality did not vary by treatment group. However, after adjusting for multiple statistical comparisons, the composite primary efficacy endpoint 30-day death, in-hospital non-fatal MI or in-hospital refractory ischemia was significantly reduced in both the enoxaparin and abciximab groups compared to the unfractionated heparin group (11.4% enoxaparin vs. 15.4% unfractionated heparin, RR 0.74 [95% CI 0.63–0.87], *P* = 0.0002; 11.1% abciximab vs. 15.4% unfractionated heparin, RR 0.72 [0.61–0.84], *P* = 0.0009). After similar adjustments, the composite efficacy and safety endpoint (primary efficacy endpoint plus intracranial bleeding or major in-hospital bleeding complications) was significantly reduced in the enoxaparin but only marginally reduced in the abciximab group compared with the unfractionated heparin group (13.7% enoxaparin vs. 17.0% unfractionated heparin, RR 0.81 [95% CI 0.70–0.93], *P* = 0.0146; 14.2% abciximab vs. 17.0% unfractionated heparin, RR 0.84 [95% CI 0.72–0.96], *P* = 0.057).

Thus, the addition of glycoprotein IIb/IIIa inhibitor therapy to thrombolysis not only improves patency in the infarct-related epicardial vessel and enhances tissue-level perfusion in the downstream myocardium, but appears to reduce combined morbidity and mortality as well. Nevertheless, these benefits occurred at the cost of more frequent thrombocytopenia, bleeding complications and need for blood transfusion.

PCI

In the **TARGET** trial, while abciximab was superior to tirofiban in preventing the composite endpoint death, non-fatal MI or urgent target vessel revascularization at 30 days,[135] these treatments appeared to be equally efficacious at six months (14.3% abciximab vs. 14.8% tirofiban, RR 1.04 [95%CI 0.90–1.21], *P* = 0.591).

In the **CURE** trial **PCI** substudy, 1313 patients were randomized to clopidogrel and 1345 to placebo.[136] In addition to aspirin, patients were pretreated with study drug for a median of six days prior to their PCI and the majority given an open-label thienopyridine for four weeks afterward. Study drug was subsequently reinitiated for an additional eight months on average. Clopidogrel treatment significantly reduced the incidence of the primary composite endpoint, death, non-fatal MI or urgent target vessel revascularization at 30 days compared with placebo (4.5% vs. 6.4%, RR 0.70 [95% CI 0.50–0.97], *P* = 0.03). The incidence of MI prior to the PCI was also significantly reduced by clopidogrel treatment (3.6% vs. 5.1%, RR 0.68 [0.47–0.99], *P* = 0.04). While minor bleeding complications were more frequent among clopidogrel-treated patients (3.5% vs. 2.1%, RR 1.68 [1.06–2.68], *P* = 0.03), the incidence of major bleeding and the need for blood transfusion were no different between groups.

Antiplatelet therapies in neurology

Graeme J. Hankey

Royal Perth Hospital, Western Australia and Department of Medicine, University of Western Australia

The major role of antiplatelet therapy in neurology is in the acute treatment and secondary prevention of ischemic stroke caused by arterial thromboembolism and, in some patients, atrial fibrillation. Because ischemic stroke is one of the most common neurological conditions[1], antiplatelet agents are used widely by neurologists and their patients.

Stroke

Definition

Stroke is characterized by rapidly developing clinical symptoms and signs of focal, and at times global, loss of cerebral function lasting more than 24 hours or leading to death, with no apparent cause other than that of vascular origin[2,3].

Incidence/prevalence

Stroke is a worldwide problem with an incidence of about 2 per 1000 per year[1,4,5]. The prevalence is about 9–12 per 1000[1,6]. Stroke can occur at any age, but half of all strokes occur in people over 70–75 years of age.

Etiology

About 80% of all strokes are ischemic in nature and are due to cerebral infarction, usually resulting from thrombotic or embolic occlusion of a cerebral artery; the remainder are caused by either intracerebral hemorrhage (15%) or subarachnoid hemorrhage (5%)[7]. The causes of ischemic stroke include embolism via, or from, the heart (20%), large artery atherothromboembolism (45–50%), small artery microatheroma/lipohyalinosis (25%), other arteriopathies such as dissection and arteritis (5%), and hematological disorders causing a prothrombotic state (<5%)[3].

Prognosis

Stroke kills 4.5 million people each year throughout the world, making it the third most common cause of death in most developed countries[8]. About 10% of individuals with acute ischemic stroke die within 30 days of stroke onset, and 30% by 1 year[7]. Among those who survive the acute event, about half will experience some level of disability at 6 months after the stroke, making stroke one of the major causes of physical disability[9,10]. Despite best medical and surgical strategies of secondary stroke prevention, recurrent stroke occurs in about 10% of cases within the first year after stroke[11].

Pathogenesis of ischemic stroke

Acute cerebral ischemia begins with the occlusion of a cerebral blood vessel, usually by *in situ* thrombus or embolism of thrombus (or other material) from a more proximal source[12]. Modern ideas about the pathogenesis of vessel thrombosis began with Rudolph Virchow's dissertation in 1845 in which he enunciated his famous triad that thrombosis was due to changes in the vessel wall, changes in the pattern of blood flow and changes in the constituents of the blood. Indeed, this concept had been already hinted at by John Hunter nearly 100 years earlier[13]. However, it has since been established that the most critical event in the formation of an arterial thrombus is injury to the vascular endothelium[14,15].

Normal endothelium

Under resting physiological conditions, the endothelium prevents thrombus formation. It acts as a physical barrier separating hemostatic from reactive subendothelial components and its negative surface charge may help to repel platelets. It possesses anticoagulant properties attributable to constitutional expression of thrombomodulin and

heparan sulfate, endogenous synthesis of ectoenzymes which degrade platelet agonists such as ADP, and endogenous synthesis of high local concentrations of the vasodilators prostacyclin (PGI_2) and nitric oxide (NO) which inhibit platelet aggregation.

Atherosclerosis

The most common cause of injury to the vascular endothelium is atherosclerosis, but there are other causes such as arterial dissection and trauma. Atherosclerosis is a disseminated pathological process which affects large- and medium-sized arteries, particularly at branching points. The most commonly affected sites in the cerebral circulation are the aortic arch, the origin of the internal carotid artery (ICA) in Caucasians, the siphon of the intracranial ICA, the origin of the middle cerebral artery and the vertebral and basilar arteries.

Acute coronary syndromes, and presumably many acute ischemic stroke syndromes caused by arterial disease, are precipitated by thrombus which develops on an atherosclerotic plaque in which the overlying endothelium is eroded or, perhaps more commonly, the atherosclerotic plaque has ruptured[16–18].

The initiation, progression and maturation of atherosclerotic plaque have been well documented[15,19]. Furthermore, it is now realized that inflammation in the vessel wall plays an essential part in the initiation and progression of atherosclerosis as well as in the erosion or fissure of plaques and, eventually, in the rupture of plaques[15]. However, it remains uncertain exactly what triggers a 'dormant' atherosclerotic plaque to become active and symptomatic.

The vulnerable, unstable plaque

Ruptured plaques contain a large core of eccentrically located lipid-laden macrophages (foam cells) engorged with oxidized low density lipoprotein (LDL) cholesterol, and a thin friable overlying fibrous cap devoid of smooth muscle cells[16,18,20]. The oxidized LDL within the lipid core stimulates plaque inflammation, which undermines the structural integrity of the plaque and activates the endothelium to a proinflammatory and procoagulant state[21–23]. The oxidized LDL and other inflammatory stimuli initiate recruitment of inflammatory cells into the lesion, and serve as a second messenger to enhance the synthesis of other vascular inflammatory products such as adhesion molecules and cytokines. Cytokines and metalloproteinases weaken the fibrous cap. The plaque is believed to rupture because the large lipid core redistributes the shear stress on the thin fibrous cap and very high loads are imparted upon localized areas of the weakened cap[24].

Triggers of plaque rupture

Recent epidemiological studies suggest that plaque inflammation (and rupture) may be triggered by exposure (acute or chronic) to an exogenous infectious antigen. There is a consistent significant relationship between symptomatic coronary artery disease and moderately elevated markers of inflammation that are unrelated to chronic infection (e.g. fibrinogen, C-reactive protein, albumin, serum amyloid A, and leukocyte count), particularly C-reactive protein[25,26]. Some studies have identified a higher than expected incidence of chronic infections of the teeth, gums and lungs, and with *Chlamydia pneumoniae*, *Helicobacter pylori*, and cytomegalovirus[15,27–29]. Although there is emerging evidence that these associations with chronic infections may be coincidental rather than causal[30–32], a similar, yet less robust, body of evidence is also mounting for the role of a systemic, low grade, inflammatory response being an integral part of the pathogenesis of acute ischemic stroke due to atherosclerosis[33–40].

Sequelae of plaque rupture: atherothrombosis

Following plaque rupture or endothelial erosion, blood is exposed to the endothelial basement membrane and extracellular matrix. Von Willebrand factor (vWF), which is a large, multimeric protein synthesized by the endothelium and secreted into the subendothelium, binds to extracellular collagen, primarily through its A3 domain. Platelets adhere to the subendothelial collagen (particularly types I and III), von Willebrand factor and fibronectin by means of platelet–membrane glycoprotein receptors, which are receptors for adhesive proteins. The largest glycoprotein (Gp) is designated I, the smallest IX. Letters a and b were added when better techniques allowed resolution of single protein bands on electrophoresis into two separate bands (e.g. glycoprotein I became Ia and Ib)[41]. The most abundant receptor is the integrin family which are heterodimic molecules composed of α and β subunits[42].

Under conditions of low shear stress, platelets adhere to subendothelial collagen and fibronectin through the binding of platelet glycoprotein Ia–IIa receptors[41,43]. Under conditions of high shear stress, platelets adhere to subendothelial vWF by means of platelet glycoprotein Ib–V–IX (Ib/IX)[43].

Platelets become activated when specific platelet receptors bind to various agonists such as collagen, thrombin, thromboxane A2, adenosine diphosphate (ADP), adrenaline and arachidonic acid. A series of intracellular reactions takes place. The final common pathway of platelet activation is the assembly of the glycoprotein IIb/IIIa receptor on the surface of activated platelets. Under resting conditions,

Cambridge Books Online © Cambridge University Press, 2009

the surface of a platelet contains 50 000 to 80 000 copies of the Gp IIb–IIIa ($\alpha_{IIb}\beta_3$) receptor. Upon platelet activation, the platelet GPIIb–IIIa receptor undergoes a conformational change, enabling it to bind both vWF and fibrinogen, resulting in irreversible platelet adhesion and aggregation, respectively. The dimeric nature of the fibrinogen molecule allows it to bind to Gp IIb–IIIa receptors on two separate platelets, resulting in interplatelet bridging, platelet aggregation, and growth of the primary platelet clot[44,45].

Platelet recruitment into the thrombus

Adherent, activated platelets recruit additional platelets into the growing thrombus by three mechanisms which are coordinated around the central role of thrombin[43].

First, activated platelets release ADP from storage granules, and the ADP binds to the ADP receptor of adjacent platelets, which activates them.

Secondly, activated platelets generate and release arachidonic acid, which is metabolized by the enzyme cyclo-oxygenase to prostaglandin endoperoxide, which in turn is converted by thromboxane synthetase to thromboxane A_2, a potent vasoconstrictor and platelet agonist. The platelets also release other eicosanoids, such as prostaglandin F_{2alpha} and serotonin, which induce further vasoconstriction and platelet aggregation[46–49].

Third, the modified membrane of activated platelets promotes assembly of clotting factors on the platelet surface (V,X, VIII), thereby amplifying thrombin generation (see below)[50]. Thrombin is central to platelet aggregation.

Coagulation

Coagulation is initiated by exposure of blood to tissue factors located in the necrotic core of ruptured atherosclerotic plaques, in the subendothelium of injured vessels, and on the surface of activated leukocytes attracted to the damaged vessel. The original cascade/waterfall hypothesis of blood coagulation is that there are two activating pathways: (i) the tissue factor or extrinsic pathway; and (ii) the contact or intrinsic pathway. A revised hypothesis of blood coagulation maintains that there is a single coagulation pathway, triggered by vessel injury and tissue factor (TF) (the factor VIIa/TF complex)[51]. Tissue factor binds factor VIIa and the resulting factor VIIa tissue factor complex activates both factors IX and X (i.e. the intrinsic and extrinsic pathways are intergrated in vivo). Factor IXa assembles on the surface of activated platelets as part of the intrinsic tenase complex which comprises factor IXa, factor VIIIa and calcium. Factor Xa, generated through the extrinsic (factor VIIa/tissue factor) and the intrinsic tenase complex, assembles on the surface of activated platelets as part of the prothrombin-activating (prothrombinase) complex, which consists of factor Xa, factor Va and calcium. When assembled in this way, the prothrombinase complex generates a burst of thrombin activity[43]. Thrombin (IIa) activates platelets and factors V and VIII and also converts fibrinogen to fibrin; thrombin then binds to fibrin where it remains active.

As blood clot forms at the site of vessel injury, plasminogen, an inert circulating protein closely bound to the deposited fibrin, is slowly activated (by tissue plasminogen activator which has been activated by kallikrein) to form plasmin, which digests the fibrin clot to give fibrin degradation products. The net result is that platelets and later fibrin accumulate at, and are limited to, the site of vascular injury. The rest of the vasculature remains free of platelet and fibrin deposits because, in circulating blood, the tendency of the coagulation mechanism to be activated is counterbalanced by inhibitory factors in the blood such as antithrombin III (which inactivates factors IX, X, XI and XII). However, at the point of vessel injury, the activation of the coagulation mechanism is so powerful that the inhibitors are overwhelmed.

The three major inhibitory systems which modulate the coagulation pathway are the protein C anticoagulant pathway, tissue factor pathway inhibitor (TFPI), and antithrombin. Protein C is activated by the thrombin/thrombomodulin complex on the endothelial cell surface. When thrombin binds to thrombomodulin (an endothelial membrane protein) it undergoes a conformational change at its active site that converts it from a procoagulant enzyme to a potent activator of protein C. Activated protein C acts as an anticoagulant in the presence of protein S by proteolytic degradation and inactivation of factors Va and VIIIa[50,52]. TFPI binds and inactivates factors Xa and the TFPI/factor Xa complex and then inactivates factor VIIa within the factor VIIa/tissue factor complex. Antithrombin inactivates free thrombin and factor Xa, but these clotting enzymes are protected from inactivation by antithrombin when they are bound to fibrin and activated platelets, respectively[43].

Antiplatelet therapy to prevent atherothrombosis

The preceding section highlights the pivotal role of platelets in atherothrombosis. It also underpins the rationale for, and biological plausibility of, antiplatelet therapy as an effective therapeutic strategy to prevent atherothrombosis and its sequelae (e.g. ischemic stroke).

The most reliable evidence for the effectiveness and safety of antiplatelet therapy in the acute treatment and

Cambridge Books Online © Cambridge University Press, 2009

secondary prevention of stroke are systematic reviews of all published and unpublished randomized controlled trials (RCTs)[53,54].

Antiplatelet therapy in acute ischemic stroke

There have been nine randomized trials of antiplatelet therapy in a total of 41 848 patients with acute ischemic stroke[53,55–61]. The antiplatelet regimens that have been compared with control are: aspirin 300 mg daily by mouth (or per rectum if unable to swallow)[55,56], aspirin 160 mg daily by mouth or nasogastric tube[57,58], ticlopidine[59], aspirin plus dipyridamole, OKY 046 (thromboxane synthase inhibitor)[60], and Abciximab[61]. Three of the trials, comprising a total of 162 patients, remain unpublished[53]. Two of the published studies, the International Stroke Trial (IST)[56] and the Chinese Acute Stroke Trial (CAST)[57], contribute 98% of all the data and both examined aspirin in acute ischemic stroke.

Aspirin in acute ischemic stroke

The IST and CAST randomized 40 090 patients within 48 hours of symptom onset to receive either aspirin (300 mg daily in IST, 160 mg daily in CAST) or no aspirin for the first 2 to 4 weeks following an acute ischemic stroke[56,57,62].

Early outcomes

A combined analysis of the patients randomized in CAST and IST found that early aspirin use within the first two to four weeks of acute ischemic stroke was associated with a highly significant reduction of 7 (SD 1) per 1000 in the risk of recurrent ischemic stroke in hospital (320 [1.6%] aspirin vs. 457 [2.3%] control, $2P<0.000001$) and a less clearly significant reduction of 4 (SD 2) per 1000 in death without further stroke (5.0% vs. 5.4%, $2P=0.05$)[62].

Against these early benefits, early aspirin use was associated with an increase of 2 (SD 1) per 1000 in hemorrhagic stroke or hemorrhagic transformation of the original infarct (1.0% vs. 0.8%, $2P=0.07$) and no apparent effect on further stroke of unknown cause (0.9% vs. 0.9%). Aspirin also increased the risk of major extracranial hemorrhage during the treatment period by four events per 1000 patients treated (0.97% vs. 0.57%, odds ratio [OR]: 1.7, 95% confidence interval [CI]: 1.3 to 2.1). However, for patients not also receiving anticoagulants, the excess was only two hemorrhages per 1000 patients treated (i.e. 0.2% excess). The total short-term net effect of early aspirin use was a reduction of 9 (SD 3) per 1000 in the overall risk of further stroke or death in hospital (8.2% vs. 9.1%, $2P=0.001$)[62].

The proportional and absolute benefits of aspirin in acute ischemic stroke were similar in a wide range of patients irrespective of age, gender, delay between symptom onset and randomization, presence or absence of atrial fibrillation, conscious level, systolic blood pressure, stroke subtype, CT brain scan findings, or concomitant heparin use[62]. Among the 9000 patients (22%) randomized without a prior CT brain scan, aspirin appeared to be of net benefit with no unusual excess of hemorrhagic stroke; moreover, even among the 800 (2%) who had inadvertently been randomized after a hemorrhagic stroke, there was no evidence of net hazard (further stroke or death, 63 aspirin vs. 67 control)[62].

Later outcomes

Early aspirin therapy was associated with a 5% (95% CI 2% to 9%) reduction in the odds of death or dependency at the end of follow-up at 1 to 6 months after stroke, corresponding to an absolute reduction of 13 per 1000 patients treated[53].

Other antiplatelet agents in acute ischemic stroke

Limited, current data indicate that other antiplatelet agents (e.g. ADP receptor antagonists (ticlopidine), platelet glycoprotein IIb/IIIa receptor antagonists (e.g. abciximab), thromboxane synthase inhibitors (e.g. OKY 046), and combination therapies (e.g. aspirin combined with dipyridamole)) are safe in acute ischemic stroke[59–61], but further trials are needed to establish their safety and efficacy.

Antiplatelet therapy for the secondary prevention of stroke and other serious vascular events

The most recent systematic review of the evidence from RCTs of all antiplatelet therapies in secondary prevention of stroke and other vascular events to have been published was undertaken by the Antiplatelet Trialists' Collaboration (APT) and published in 1994[54]. An updated review was undertaken by the Antithrombotic Trialists' (ATT) Collaboration in September 1997, but the results await publication[63]. In this section I will present the results of all relevant clinical trials published since 1994 and incorporate them into previous data published by the APT. Hopefully, this will provide an updated systematic review which will be consistent with the results of the anticipated forthcoming publication by the ATT in 2001 or 2002.

The APT (and ATT) analysed the individual patient data

Cambridge Books Online © Cambridge University Press, 2009

from each trial according to the qualifying medical condition of the patient, the type of antiplatelet regimen and the type of outcome events recorded.

The qualifying medical condition of the patient was categorised as symptomatic vascular disease of the brain, heart of limbs (i.e. previous TIA or stroke, previous MI, previous PAD).

The primary outcome event was the composite of non-fatal stroke, non-fatal myocardial infarction (MI) and death from vascular causes. This was chosen because these events generally share the same underlying pathophysiology, pathogenesis and response to antiplatelet therapy. Moreover, they are all important to avoid from the patient's perspective and, by combining them as a composite outcome, the total number of outcome events and hence statistical power, is maximized.

Because the analysis showed that the effects of antiplatelet agents were qualitatively the same in each subgroup of patients with symptomatic vascular disease of the brain, heart and limbs (i.e. antiplatelet therapy was effective for all qualifying conditions), and differed only quantitatively (i.e. the magnitude of the favourable effect varied), this group of patients at high risk of future vascular events were analysed together in order to further maximize statistical power. This concept of 'lumping' different qualifying conditions and vascular outcomes together is valid, and more precise, if the underlying cause of the conditions and response to the therapy is similar, as it is in this case. I have therefore presented the results of the APT and subsequent published trials in all high-risk patients (e.g. angina, MI, stroke, TIA, peripheral vascular disease, recent vascular surgery), because the effects are qualitatively the same and the precision of the estimates (i.e. statistical power) is maximized. However, in recognition of the pathophysiological heterogeneity of stroke (i.e. perhaps only a small majority of all strokes are due to atherothromboembolism), I have also presented the results for TIA and stroke patients, which are compromised a little by smaller sample sizes, and hence the estimates have wider confidence intervals and less precision.

All antiplatelet agents

Benefits

Antiplatelet therapy, given to around 70 000 patients at high risk of vascular disease (i.e. symptomatic vascular disease of the brain, heart and limbs) for a month or more, is associated with a reduction in odds of a subsequent serious vascular event (stroke, MI or vascular death) by about a quarter (odds reduction 27%; 95% CI 24% to 31%; $2P < 0.00001$)[54].

The proportional effects are similar in the various categories of patients, including more than 11 700 with a prior (presumed ischemic) stroke or transient ischemic attack (TIA), amongst whom the odds reduction is about 21 + 3%. The absolute risk reduction is about 3.7% over about 3 years, which means that 37 vascular events (20 non-fatal strokes, nine non-fatal myocardial infarctions, and 11 vascular deaths) are prevented per 1000 patients treated with antiplatelet therapy for about 2–3 years, or 15 events prevented per year. The number of patients needed to treat (NNT) with antiplatelet therapy to prevent one serious vascular event each year is therefore about 83 (i.e. 1000/12). Antiplatelet therapy is also associated with a 16% (SD 6) reduction in the odds of all-cause mortality among patients with prior TIA or stroke.

Risks

The most important adverse effect of antiplatelet therapy is bleeding, particularly intracranial hemorrhage because it is frequently fatal or disabling. However, the risk of intracranial hemorrhage associated with antiplatelet therapy is small, and at most one or two per 1000 patients treated per year[54]. This excess risk is included in the overall estimate above of the effect of antiplatelet therapy on serious vascular events (i.e. stroke, MI or vascular death).

Antiplatelet therapy is also associated with a small but significant excess of non-fatal extracranial hemorrhage (mainly from the gastrointestinal tract) of one to two per 1000 patients treated per year but there is no clear excess of fatal extracranial hemorrhage.

Thus, the relatively large absolute reduction in serious vascular events (15 events per 1000 patients treated per year) clearly outweighs the smaller hazards (1–2 non-fatal extracranial hemorrhages per 1000 patients treated per year)[54].

Aspirin

Benefit

Aspirin, the most widely studied antiplatelet drug, reduces the odds of a serious vascular event by about one quarter among high risk patients (odds reduction 25% (SD 2); 95% CI 21% to 30%; $2P < 0.00001$)[54].

In 11 placebo-controlled RCTs of aspirin in more than 10 000 patients with prior TIA or ischemic stroke, aspirin reduced the odds of a serious vascular event by 17% + 4.4 ($2P = 0.00009$). This is a relative risk reduction (RRR) of 13% (95%CI 6% to 19%) and an absolute risk reduction (ARR) of 3% over about 3 years, or about 1% per year (Fig. 70.1)[64]. The number of patients with previous TIA or ischemic

Cambridge Books Online © Cambridge University Press, 2009

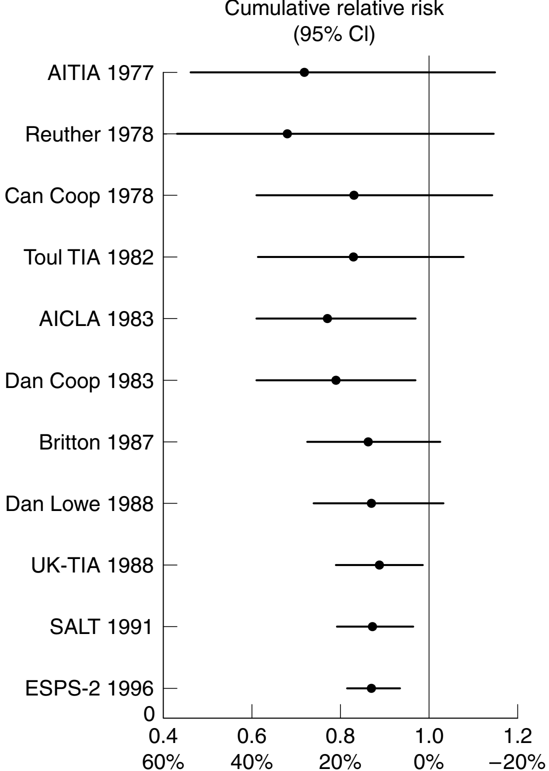

Fig. 70.1. Cumulative meta-analysis of 11 randomized controlled trials of aspirin vs. control in patients with previous TIA or ischemic stroke in chronological order (1977 to 1996), showing relative risks and corresponding relative risk reductions with 95% confidence intervals (CI). Each line represents the relative risk and 95% CI of that study combined with all previous studies[64].

stroke needed to treat with aspirin to prevent one serious vascular event each year (NNT) is therefore about 100.

Safety

Aspirin is associated with a dose-dependent increase in symptoms of upper gastrointestinal upset (nausea, heartburn and epigastric pain), upper GI bleeding, and intracranial hemorrhage, and a non-dose-dependent increase in constipation.

Observational studies reveal symptoms of upper gastrointestinal upset (nausea, heartburn, and epigastric pain) in about 15–32% of people taking placebo, about 30% of people taking aspirin 300 mg/day, and 24–44% of people taking 900–1300 mg aspirin per day[65]. Randomized trials involving direct comparisons of different doses of aspirin indicate that high dose (500–1500 mg daily) aspirin significantly increases the odds of upper gastrointestinal symptoms compared with medium dose (75–325 mg daily) aspirin (high dose 26.2%, medium dose 21.9%, OR 1.3, 95% CI 1.1 to 1.5)[66,67], and that medium dose (283 mg) aspirin is associated with a trend towards an increase in odds of upper gastrointestinal upset compared with low dose (30 mg) aspirin (medium dose 11.4%, low dose 10.5%, OR 1.1, 95% CI: 0.9 to 1.4)[68].

Observational and case-control studies reveal an increased rate of upper gastrointestinal (GI) and other extracranial hemorrhage in people taking aspirin, and probably also a dose–response[66–68]. The risk of hematemesis attributable to aspirin has been estimated to be 0.2 to 1.0 per 1000 person–years of exposure[69]. The odds ratio of GI bleeding is 2.3, 3.2 and 3.9 for 75 mg, 150 mg and 300 mg, respectively, on at least 5 days a week[70]. Direct comparisons of different doses of aspirin in randomized trials also indicate that high dose (500–1500 mg daily) aspirin is associated with a trend towards an increase in odds of upper GI hemorrhage compared with medium dose (75–325 mg daily) aspirin (high dose 2.6%, medium dose 1.9%, OR 1.4, 95% CI 0.9 to 2.1)[66,67], but there is no apparent increase in odds of upper GI hemorrhage between medium dose (283 mg) aspirin and low dose (30 mg) aspirin from the limited trial data available (medium dose 1.9%, low dose 1.8%, OR 1.2, 95% CI 0.7 to 2.0)[68]. The type of aspirin may also be important (as well as dose). At average daily doses of aspirin of 325 mg or less, the relative risks of upper GI hemorrhage for plain, enteric-coated, and buffered aspirin are about 2.6, 2.7, and 3.1, respectively[71]. At doses greater than 325 mg, the relative risk is about 5.8 for plain and 7.0 for buffered aspirin[71]. Indirect evidence suggests that enteric-coated aspirin is associated with less upper GI bleeding at doses above 325 mg/day[71].

Intracranial hemorrhage is also increased in people taking aspirin by about one per 1000, and there appears to be a dose–response[72].

Costs

Plain aspirin costs about Aus$ 20 per patient per year (Aus $1 = US$ 0.55 = Euro 0.6)[73], or about Aus $2000 to treat 100 TIA/stroke patients for one year to prevent one serious vascular event. The cost of 75 mg enteric-coated aspirin is more than 20 times that of 75 mg plain aspirin.

Different doses of aspirin

Controversy has surrounded the most appropriate dose of aspirin for the long-term secondary prevention of serious vascular events, particularly stroke, with arguments for the use of daily doses as low as 30 mg to as high as 1500 mg[74–77]. The rationale for the lower doses has been evidence from laboratory studies showing that single oral doses of 5 to 200 mg of aspirin result in dose-dependent inhibition of platelet cyclooxygenase activity, with 100 mg almost completely

Cambridge Books Online © Cambridge University Press, 2009

suppressing the biosynthesis of thromboxane A2[65]. Because the effect is permanent, lasting for the life of the platelet (8–10 days), the inhibitory effect of repeated daily doses below 100 mg is cumulative. Thus the daily administration of 30 to 50 mg aspirin results in complete suppression of platelet thromboxane biosynthesis after 7 to 10 days[78].

Benefit

The most reliable evidence of the relative effect of different doses of aspirin comes from direct comparisons in randomized trials. Direct comparisons of the effect of daily doses of 75–325 mg and 500–1500 mg among 2425 high-risk patients, two-thirds of whom had a history of ischemic stroke or TIA, showed that daily doses of 75–325 mg and 500–1500 mg were similarly effective[54,66]. A recent randomized trial comparing the effects of lower doses of aspirin (81 mg or 325 mg daily) and higher doses (650 mg or 1300 mg daily) among 2849 patients undergoing carotid endarterectomy found that the combined rate of stroke, myocardial infarction or death was lower in the low-dose groups than in the high-dose groups at 30 days (5.4 vs. 7.0%, $P=0.07$) and at 3 months follow-up (6.2% vs. 8.4%, $P=0.03$)[67]. In an efficacy analysis, which included patients taking 650 mg or more acetylsalicylic acid before randomization, and patients randomized within 1 day of carotid surgery, combined rates were 3.7% (low-dose) and 8.2% (high dose), respectively, at 30 days ($P=0.002$) and 4.2% (low dose) and 10.0% (high dose) at 3 months ($P=0.002$)[67]. The authors concluded that the risk of stroke, MI and death within 30 days and 3 months of carotid endarterectomy is lower for patients taking 81mg or 325 mg acetylsalicylic acid daily than for those taking 650 mg or 1300 mg daily[67].

A direct randomized comparison of the effects of daily doses of very low dose aspirin (30 mg) and medium dose aspirin (283 mg) among about 3000 patients with a recent TIA or minor ischemic stroke, found no significant difference in subsequent serious vascular events but the possibility of a small (yet clinically important) difference could not be excluded[68].

Indirect comparisons of the effect of different doses, as compared with placebo, are less reliable, in the same way that it is unreliable to compare different teams, athletes, or horses by their respective performances against an opponent in common; it is more reliable to have them oppose each other directly. Nevertheless, indirect comparisons of trials comparing daily doses of <160 mg (mostly 75–150 mg), 160–325 mg, and 500–1500 mg against placebo reveals similar proportional reductions in serious vascular events among those allocated low, medium and high-dose aspirin[54,79]. The inclusion of data from two large trials among high-risk patients (one of them including almost 1400 patients with a prior ischemic stroke or TIA) assessing a daily dose of 75 mg vs. control[80,81], showed that low-dose aspirin (75 mg daily) was associated with a clear reduction in vascular events (odds reduction 29%, 95% CI 17% to 39%), similar to the proportional effects of higher doses[54].

The effects of doses lower than 75 mg daily have been less extensively studied in randomized trials. In the second European Stroke Prevention Study (ESPS-2), around 6000 people with a prior stroke or TIA were randomized, in a factorial design, to receive aspirin 50 mg daily, modified release dipyridamole 400 mg daily, both or neither[82]. Compared with no antiplatelet therapy, aspirin 50 mg daily produced a reduction of 16% (95% CI 1% to 29%; $2P=0.02$) in the odds of stroke or death[82]. Since most non-fatal vascular outcomes in this group of patients were strokes, and most deaths were vascular, this outcome closely approximates vascular events.

The available evidence from randomized trials therefore suggests that aspirin at a dose of 75 mg daily is as effective as higher doses, but there is insufficient evidence to be certain that doses below 75 mg daily are as effective.

Alternative antiplatelet regimens to aspirin

In the last APT overview, neither direct nor indirect comparisons between different antiplatelet regimens provided clear evidence that any regimen was more effective than aspirin in the prevention of vascular events[54]. Direct comparisons of alternative antiplatelet regimens revealed that the most promising single agent was the thienopyridine derivative, ticlopidine; the three trials in which ticlopidine was compared directly with aspirin showed that ticlopidine was associated with a non-significant reduction in the odds of a vascular event of 10% (95% CI −1% to 24%) when compared directly with aspirin[54]. However, in comparison with aspirin, ticlopidine was associated with a threefold excess of neutropenia ($<1.2\times10^9$/litre) (2.3% ticlopidine vs. 0.8% aspirin; OR 2.7; 95% CI 1.5 to 4.8), and a twofold increase in the odds of skin rash (11.8% ticlopidine vs. 5.5% aspirin; OR 2.2; 95% CI 1.7 to 2.9) and of diarrhea (20.4% vs. 9.9%; OR 2.3; 95% CI 1.9 to 2.8)[54].

Two recent large trials have since provided further information about a new thienopyridine agent, clopidogrel[83], and the combination of aspirin and dipyridamole in patients with previous TIA or ischemic stroke[82].

The CAPRIE (Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events) trial was designed to determine whether clopidogrel (a thienopyridine like ticlopidine) was as safe as aspirin and, like ticlopidine, also about 10% more effective than aspirin in preventing vascular events among patients with symptomatic atherothrombosis of the cere-

Cambridge Books Online © Cambridge University Press, 2009

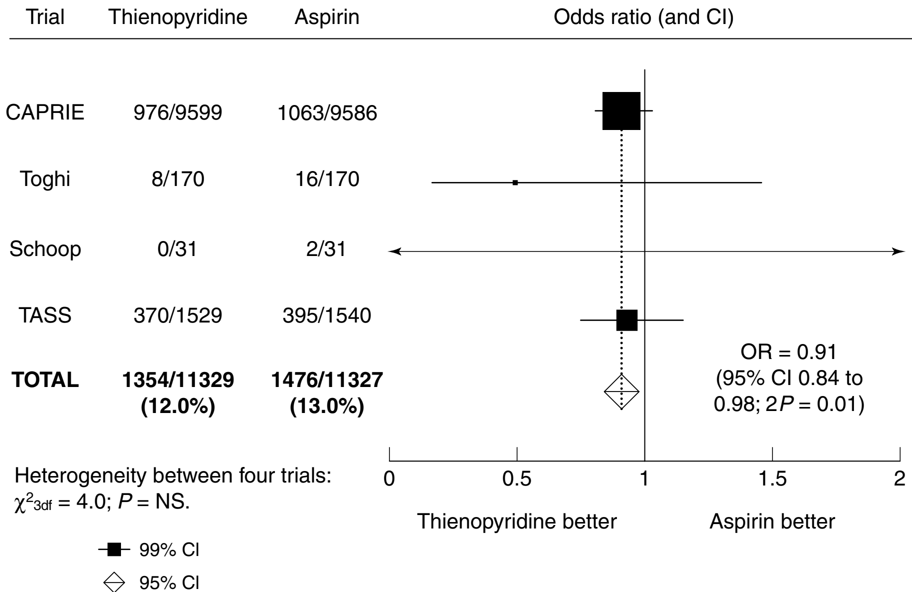

Fig. 70.2. Direct comparisons of the proportional effects of the thienopyridines vs. aspirin on vascular events (stroke, myocardial infarction, or vascular death) in patients at high risk of vascular disease. TASS: Ticlopidine Aspirin Stroke Study. CAPRIE: Clopidogrel vs. Aspirin in Patients at Risk of Ischemic Events[84].

bral, coronary and peripheral arteries[83]. The study was powered to detect a realistic (i.e. 10%) treatment effect in the whole cohort and not in the three clinical subgroups. Ultimately, 19 185 patients with recent ischemic stroke (6431), MI (6302), and PAD (6452) were randomized to 'gold standard' treatment with aspirin 325 mg daily or to clopidogrel 75 mg daily, over three years (mean 1.9 years)[83]. In CAPRIE, the annual risk of subsequent ischemic stroke, MI or vascular death (the primary outcome event) was 5.8% among patients allocated aspirin and 5.3% among patients allocated clopidogrel[83]. This is a relative risk reduction of 8.7% (95% CI 0.3% to 16.5%; $P=0.043$), and an absolute risk reduction of 0.51% per year. In CAPRIE, both drugs (aspirin and clopidogrel) had a low incidence and similar profile of adverse events; the only significant differences being a higher proportion of severe gastrointestinal (GI) hemorrhage in the aspirin group (0.49% vs. 0.71%) and skin rash in the clopidogrel group (0.26% vs. 0.10%). There was no significant difference in the occurrence of severe thrombocytopenia and neutropenia.

Thienopyridines (ticlopidine and clopidogrel)

A systematic review of the four randomized trials comparing the thienopyridines (either ticlopidine or clopidogrel) with aspirin among over 20 000 patients at high risk of vascular disease (including almost 10 000 presenting with a TIA or ischemic stroke) has since been undertaken[84].

Benefit

Compared with aspirin, allocation to a thienopyridine was associated with a modest, yet statistically significant, reduction in the odds of a serious vascular event (12.0% thienopyridine vs. 13.0% aspirin; OR 0.91; 95% CI 0.84 to 0.98; $2P=0.01$), corresponding to the prevention or delay of 11 (95% CI 2 to 19) vascular events per 1 000 patients treated for about 2 years (Fig. 70.2)[84].

The patients in the thienopyridine group also experienced a significant reduction in the odds of any stroke (5.7% thienopyridine vs. 6.4% aspirin; OR 0.88; 95% CI 0.79 to 0.98), corresponding to the prevention or delay of 7 (95% CI 1 to 13) strokes per 1000 patients treated for two years. There was also a non-significant trend towards a reduction in ischemic stroke (OR 0.90; 95% CI 0.81 to 1.01), myocardial infarction (OR 0.88; 95% CI 0.76 to 1.01), vascular or unknown cause of death (OR 0.93; 95% CI 0.82 to 1.06), and death from any cause (OR 0.95; 95% CI 0.85 to 1.05)[84].

Patients with stroke or TIA

Among the 9840 patients with TIA/ischemic stroke, the thienopyridines produced similar proportional benefits to those found overall, both in terms of vascular events (16.8% thienopyridine vs. 18.3% aspirin; OR 0.90; 95% CI 0.81 to 1.00) and in terms of any stroke (10.4% vs. 12.0%; OR 0.86; 95% CI 0.75 to 0.97). The absolute reduction of 14 (95% CI −1 to 29) vascular events per 1000 patients treated for about 2 years was similar to that observed among all

Cambridge Books Online © Cambridge University Press, 2009

high-risk patients. However, the risk of stroke among patients with a previous TIA or ischemic stroke in the aspirin group (12.0%) was almost twice as high as that for all high-risk patients (6.4%). The absolute reduction of 16 strokes (95% CI: 3 to 28) per 1000 patients over about 2 years was therefore about twice as large as that for all high-risk patients combined[84].

If the risk of stroke and other serious vascular events is about 6.0% per year with aspirin therapy, then clopidogrel could reduce it by 10%, to 5.4% per year, which is an ARR of 0.6% per year. The NNT is 166 (100/0.6) compared with aspirin.

Safety

There was no clear difference between the thienopyridines and aspirin in the odds of experiencing an intracranial hemorrhage (0.3% thienopyridine vs. 0.4% aspirin; OR 0.82; 95% CI 0.53 to 1.27) or an extracranial hemorrhage (8.8% thienopyridine vs. 8.9% aspirin; OR 1.00; 95% CI 0.91 to 1.09)[84].

The thienopyridines were, however, associated with a significant reduction in the odds of both gastrointestinal hemorrhage (1.8% thienopyridine vs. 2.5% aspirin; OR 0.71; 95% CI 0.59 to 0.86) and indigestion/nausea/vomiting (14.8% vs 17.1%; OR 0.84; 95% CI 0.78 to 0.90), and with an increased odds of diarrhea, and of skin rash (Fig. 70.3). There was substantial heterogeneity between the results for ticlopidine and clopidogrel both for diarrhea (χ^2_{1df}= 13.4; 2P=0.0003) and for skin rash (χ^2_{1df}=17.9; 2P= 0.00002) (Fig. 70.3). Hence, in comparison with aspirin, ticlopidine produced about a twofold increase in the odds of skin rash (11.8% ticlopidine vs. 5.5% aspirin; OR 2.2; 95% CI 1.7 to 2.9) and of diarrhea (20.4% vs. 9.9%; OR 2.3; 95% CI 1.9 to 2.8), whilst clopidogrel produced a smaller increase of about one-third in the odds of skin rash (6.0% clopidogrel vs. 4.6% aspirin; OR 1.3; 95% CI 1.2 to 1.5) and of diarrhea (4.5% vs. 3.4%; OR 1.3; 95% CI 1.2 to 1.6) (Fig. 70.3).

Ticlopidine was associated with an excess of neutropenia (<1.2×10^9/litre) (2.3% ticlopidine vs. 0.8% aspirin; OR 2.7; 95% CI 1.5 to 4.8), but clopidogrel was not (0.1% clopidogrel vs. 0.2% aspirin; OR 0.63; 95% CI 0.29 to 1.36; test for heterogeneity between results for ticlopidine and clopidogrel: χ^2_{1df}=8.9; 2P=0.003) (Fig. 70.3).

There were no published trial data available for the frequency of thrombocytopenia associated with ticlopidine compared with aspirin, but observational data from 43 332 patients undergoing ticlopidine therapy in association with coronary artery stenting indicate that ticlopidine is associated with a significant excess incidence of thrombotic thrombocytopenic purpura (TTP) of 0.02% (95% CI 0.009% to 0.04%)[85], compared with the estimated incidence of 0.00037% (standardized morbidity ratio 56 95% CI 26 to 107)[86].

Clopidogrel was not associated with any excess of thrombocytopenia (<100×10^9 platelets per litre) compared with aspirin (0.26% vs. 0.26%; OR 1.00; 95% CI 0.57 to 1.74) among the 9553 patients who were screened before being allocated clopidogrel in CAPRIE, and of whom 99.8% were followed up carefully for an average of about 1.9 years[83]. However, recent reports of 20 cases of TTP associated with clopidogrel use has raised concerns about the safety of clopidogrel[87,88], particularly because clopidogrel and ticlopidine are thienopyridine derivatives which share a similar chemical structure, mechanism of antiplatelet action (ADP receptor blockade) and therapeutic efficacy; and because a causal association between ticlopidine and TTP was not established until several years after ticlopidine was introduced into clinical practice. However, it remains uncertain whether the reported association between clopidogrel and TTP is coincidental or causal[89]. Follow-up studies are in progress.

The results for adverse effects among patients with TIA/ischemic stroke were similar to those for all patients combined.

Cost

The cost of clopidogrel is Aus$ 1200 per patient per annum[73], or about Aus$ 200 000 to treat 166 TIA/stroke patients for 1 year to prevent one more serious vascular event than if they had been treated with aspirin.

Aspirin and dipyridamole

Benefit

In the APT overview, the addition of dipyridamole to aspirin among around 5000 high-risk patients was not associated with any significant reduction in vascular events, but the possibility of a small additional benefit was not excluded[54]. When data from a further 3000 patients in the second European Stroke Prevention Study (ESPS-2) study were included, the addition of dipyridamole to aspirin produced a non-significant reduction of 10% (95% CI 0% to 20%) in the odds of a vascular event (Fig. 70.4)[82,90]. Most of this reduction appeared to be attributable to a 23% reduction in non-fatal strokes, suggesting that the addition of dipyridamole to aspirin may be appropriate for patients at particularly high risk of stroke (Fig. 70.4)[90]. A detailed overview of all trials that have assessed the addition of dipyridamole to aspirin is currently being prepared by the Antithrombotic Trialists' Collaboration[63].

No heterogeneity between trials
Heterogeneity between odds ratios for ticlopidine and clopidogrel: $\chi^2_{1df} = 17.9$; $2P = 0.00002$
* Heterogeneity between odds ratios for ticlopidine and clopidogrel: $\chi^2_{1df} = 13.4$; $2P = 0.0003$
** Heterogeneity between odds ratios for ticlopidine and clopidogrel: $\chi^2_{1df} = 8.9$; $2P = 0.003$

Diamonds representing the odds ration and 95% CI for the top (intracranial haemorrhage, etc) are for any thienopyridine (i.e. ticlopidine or clopidogrel.

Fig. 70.3. Direct comparisons of the proportional effects of the thienopyridines vs. aspirin on adverse events in patients at high risk of vascular disease[84].

Cambridge Books Online © Cambridge University Press, 2009

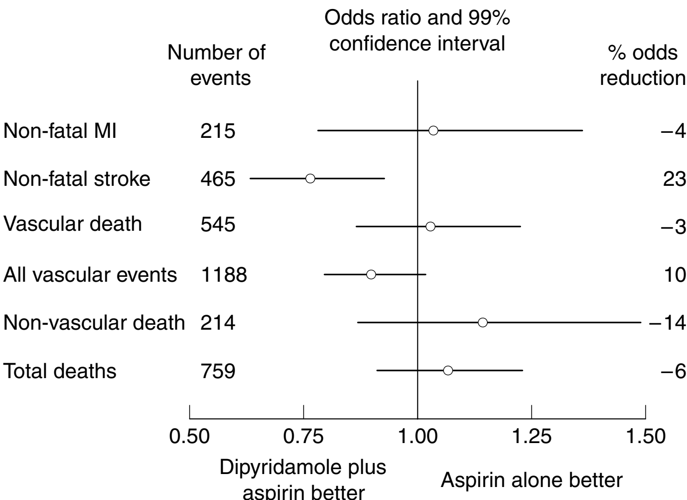

Fig. 70.4. Direct comparisons of the proportional effects of the combination of aspirin and dipyridamole vs. aspirin on vascular events and non-vascular deaths, derived from a total of 8616 patients study in the Antiplatelet Trialists' Collaboration and the second European Stroke Prevention Study[89].

For patients with prior stroke or TIA, four trials involving a total of 2473 patients indicate that the combination of aspirin and dipyridamole is associated with about a 16% (5 to 26%, $P = 0.012$) reduction in the relative risk of serious vascular events[91]. If the risk of stroke and other serious vascular events is about 6.0% per year with aspirin therapy, the combination of aspirin and dipyridamole could reduce it by 16%, to 5.1% per year, which is an ARR of 0.9% per year. The NNT is 111 (100/0.9) compared with aspirin.

The magnitude of this treatment effect continues to be studied in the ongoing European and Australian Stroke Prevention in Reversible Ischaemia (ESPRIT) trial, in which more than 1000 patients (target 4500 patients) with a prior TIA or minor ischemic stroke are being randomized between oral anticoagulation, the combination of aspirin (in any dose between 30 and 325 mg daily) plus dipyridamole (400 mg daily), and aspirin alone[92].

Safety

Headache and gastrointestinal events (e.g. nausea, diarrhea) are the main reasons that patients receiving dipyridamole-containing antiplatelet regimens discontinue treatment prematurely. In the ESPS-2 study, 8.1% of the 1628 patients allocated dipyridamole and 7.1% of the 1631 patients given the combination of aspirin and dipyridamole prematurely ceased their study medication due to headache, compared with 1.9% of the 1631 allocated aspirin and 2.4% if the 1622 given placebo ($P < 0.001$)[82]. Similarly, GI events led to premature discontinuation of study drug in 6.2% of those allocated dipyridamole, and 7.1% of those given the combination of aspirin and dipyridamole compared with 3.7% of each of those allocated aspirin and placebo ($P < 0.001$)[82]. The addition of dipyridamole to aspirin does not appear to exaggerate the excess risk of hemorrhage associated with aspirin.

Cost

The cost of aspirin combined with dipyridamole is Aus$ 350 per patient per year[73]; or about Aus$ 38 850 to treat 111 TIA/stroke patients with aspirin and dipyridamole for 1 year to prevent one more stroke or other serious vascular event than if they were treated with aspirin.

Aspirin and platelet glycoprotein IIb/IIIa receptor antagonists

The combination of aspirin and a parenteral platelet glycoprotein IIb/IIIa blocker given immediately to patients with unstable angina or non-Q-wave MI, or undergoing percutaneous coronary interventions, is significantly more effective than aspirin alone in reducing the 30-day rate of death or non-fatal MI (OR 0.81, 95% CI 0.75 to 0.88)[93]. However, the combination of long-term aspirin and an oral platelet GP IIb/IIIa blocker has, to date, been shown to be no more effective than aspirin alone[94]. The possible reasons for this include an unanticipated thrombotic effect of long-term glycoprotein IIb/IIIa receptor blockade; s excessive drug dose, platelet inhibition and therefore bleeding complication (particularly for patients with creatinine clearance of less than 90 ml/min); inadequate monitoring of platelet inhibition, inadequate duration of treatment and follow-up and the random play of chance (i.e. bad luck). The results from the Blockage of the GP IIb/IIIa Receptor to Avoid Vascular Occlusion (BRAVO) trial are awaited. The primary objective of BRAVO is to compare the incidence of the composite outcome comprising stroke, MI, death from any cause, recurrent ischemia requiring hospitalization, and urgent ischemic-driven revascularizations in patients with TIA, ischemic stroke, acute myocardial infarction, unstable angina, or double bed vascular disease (i.e. peripheral vascular disease combined with cardiovascular or cerebrovascular disease) who are randomized to receive either lotrafiban 30–50 mg b.i.d (depending on age and renal function) or placebo, which is added to their usual prescribed aspirin 75–325 mg daily, for about 2 years. More than 9000 patients will be enrolled from 700 centres in 30 countries thoughout the world.

Aspirin and clopidogrel

The combination of aspirin and clopidogrel is the short-term treatment of choice for coronary artery stenting[95,96], and the safety and efficacy of long-term treatment with clopidogrel combined with aspirin is being studied in patients with unstable angina (CURE study) and in high-risk patients with recent TIA and ischemic stroke (MATCH study).

The future of antiplatelet therapy in secondary stroke prevention is likely to be combinations of agents that inhibit platelet adhesion, activation and aggregation at various stages of the process. Ongoing trials are evaluating the relative safety and efficacy of combinations of aspirin with dipyridamole, clopidogrel and oral glycoprotein IIb/III a inhibitors.

Summary of antiplatelet therapy for secondary prevention of stroke and other serious vascular events in patients with TIA and ischemic stroke due to atherothromboembolism

Antiplatelet therapy (aspirin 160–300 mg) should be started as early as possible after an acute TIA or ischemic stroke that is thought to be due to atherothrombembolism.

After the acute phase, aspirin should be continued in a lower dose, 75 mg daily, together with control of vascular risk factors and consideration for revascularization of the symptomatic carotid artery. Adding dipyridamole to aspirin, or substituting clopidogrel for aspirin are marginally but significantly more effective interventions to prevent stroke but they are also substantially more expensive. Clopidogrel is clearly indicated for patients who are intolerant of, or allergic to, aspirin.

The decision to use aspirin, the combination of aspirin and dipyridamole, or clopidogrel in patients with atherothrombotic TIA or ischemic stroke should be determined by the patient's absolute risk of a recurrent stroke or other serious vascular event, the patient's capacity to tolerate the potential adverse effects of the medication, and the patient's (and country's) capacity to pay for the medication. The absolute benefits of antiplatelet regimens are likely to be greater in patients with higher absolute baseline risk of a vascular event because the proportional risk reductions of antiplatelet regimens appear to be similar, irrespective of the baseline absolute risk. For example, among patients with a low baseline absolute risk of subsequent serious vascular events of about 5% per year, antiplatelet therapies reduce this risk by about one-quarter to one-third, which is about 1–2% per year, respectively. In these patients the number needed to treat with antiplatelet therapy to prevent one serious vascular event per year is 50–100 (100/1–2). However, among patients with a higher baseline absolute risk of subsequent serious vascular events of about 40% per year, antiplatelet therapies may reduce this risk by about one-quarter to one-third, which is about 10–13% per year respectively. In these patients the number needed to treat to prevent one serious vascular event per year is only 8–10 (100/10–13).

Antiplatelet therapy in TIA and ischemic stroke patients with atrial fibrillation

In the APT overview, patients with atrial fibrillation experienced similar reductions in vascular events to the other categories of high risk patients[54]. A recent systematic review of antithrombotic therapy for patients with atrial fibrillation showed that, compared with control, aspirin reduced the risk of stroke by 22% (95% CI 2% to 38%). However, adjusted-dose warfarin reduced stroke risk by 62% (95% CI 48% to 72%) compared with control and by 36% (95% CI 14% to 52%) compared with aspirin[97]. Patients with atrial fibrillation and a history of a prior stroke or TIA have a particularly high stroke risk (about 12% per year)[98]. Treatment with warfarin instead of aspirin among 1000 such patients was estimated to prevent 48 strokes per year, with an excess of two major extracranial hemorrhages[97]. Oral anticoagulation (with a target INR of about 2.5) is therefore likely to outweigh the bleeding hazards (and inconvenience of monitoring) for many such patients, providing a net benefit greater than that produced by aspirin. But, aspirin is a suitable alternative for those whose risk of bleeding on anticoagulants is likely to be substantial (for example, those with a history of recent gastrointestinal bleeding, dementia or a tendency to falls).

Antiplatelet treatment in peripheral vascular disease

Raymond Verhaeghe

Department of Molecular and Cardiovascular Research, University of Leuven, Belgium

Progressive atherosclerosis complicated by thromboembolic events is by far the most common cause of peripheral arterial disease. Atherothrombosis, the fashionable term to describe the stenotic/thrombotic process, is a generalized disorder, which is almost invariably ubiquitous and therefore any patient who presents with symptoms or signs suggestive of arterial disease in one vascular bed is likely to have other territories involved as well. The common risk factors for atherosclerosis also apply to peripheral arterial disease, but the order of importance varies: smoking correlates most strongly with disease of the leg arteries and predicts its progression. The disease in the leg arteries remains clinically silent as long as no hemodynamically significant obstructive lesions are formed. Subclinical disease is detected with the aid of simple non-invasive tests in three to four times as many middle-aged adults as is symptomatic disease. Intermittent claudication, leg pain on exercise that is relieved by rest, develops when a drop in driving pressure occurs. Progression of the disease to the extent that the blood flow becomes insufficient to meet the metabolic and nutritional demands of resting tissues is clinically manifested by rest pain and skin lesions at the foot. A Working Group defined chronic critical leg ischemia as the presence of restpain requiring regular analgesia for more than 2 weeks and of an ankle systolic pressure of less than 50 mm Hg (and/or toe systolic pressure of less than 30 mm Hg) with or without skin ulceration or gangrene of toes or foot[1].

The pathophysiology of atherothrombosis and particularly the contribution of platelets is detailed in Chapter 30. The importance attributed to platelets led to development and application of many tests which aim to detect ‘hyperactive’ platelets with the hope that they would predict future thrombotic events. Studies which assess platelet specific proteins or which test platelet adhesion or aggregation in vitro have produced conflicting data in patients with peripheral arterial disease; they may be too insensitive to detect in vivo platelet activation. Measurement of urinary excretion of 11-dehydro-thromboxane B_2 appeared to provide a more sensitive index of platelet activation in a study on 64 claudication patients. The rate of excretion of the thromboxane metabolite was related to the presence of cardiovascular risk factors and predicted future thrombotic complications of peripheral arterial disease[2,3]. Decreased availability of biologically active NO in the blood vessel wall, in accordance with the clinical severity of the disease, is one possible mechanism of platelet activation in these patients[4].

The fate of the patient with intermittent claudication is relatively benign as regards local arterial disease in the legs, but is increasingly malignant in terms of serious fatal and non-fatal cardiovascular events[5]. A fair minority of claudicants require surgical or endovascular intervention over 5 years after diagnosis because of increasing severity of their functional handicap or because of deterioration to critical ischemia. Only 2% will ever need a major amputation. By contrast, they have a high prevalence of coronary artery and cerebrovascular disease and therefore a significantly increased risk of stroke, myocardial infarction and cardiovascular death. Their 5-, 10-, and 15-year mortality rates from all causes are approximately 30, 50 and 70%, respectively, 2.5 times higher than expected. Thus the real danger is not losing a leg but rather suffering premature cardiovascular complications or death (Fig. 71.1).

Patients with critical limb ischemia carry a worse prognosis, not only in terms of mortality and cardiovascular morbidity, but also as regards the fate of their leg. Those who are either unsuitable for revascularization or in whom revascularization failed are probably the subgroup of patients with leg arterial disease with the worst outcome: placebo groups of pharmacotherapy trials that select such patients indicate a 20% death rate and a 40% major amputation rate at 6 months.

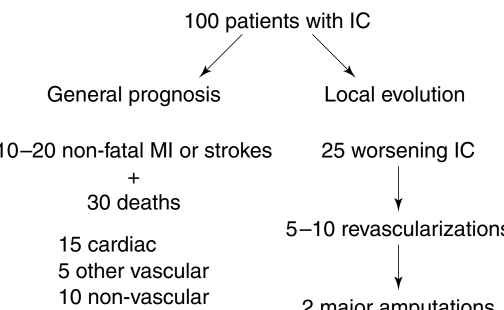

Fig. 71.1. Natural history of patients with intermittent claudication over 5 years after diagnosis. IC: intermittent claudication; MI: myocardial infarction.

Management of patients with arterial disease in the leg involves several aspects, of which risk factor control is of primary importance. This chapter focuses on the use of antiplatelet drugs which are being prescribed with the aim of improving the general prognosis and retarding the local progression of atherosclerosis in the legs. Although recent studies have reported similar findings with other classes of pharmacological agents such as statins and angiotensin-converting-enzyme inhibitors, these drugs are not discussed here.

Do antiplatelet drugs prevent vascular events?

In general, patients with symptomatic peripheral arterial disease receive aspirin, ticlopidine or clopidogrel to decrease the incidence of thrombo-embolic vascular events. This aim is not well demonstrated in this category of patients. Particularly, the data on aspirin are poor: no single study with clinical endpoints yields significant results. The collaborative overview of randomized trials of antiplatelet therapy, the meta-analysis of the Antiplatelet Trialists' Collaboration, calculated that the vascular risk was reduced to a similar extent (odds reduction of 27 ± 2%) in a category of high-risk patients of mixed origin as in patients with prior myocardial infarction (25 ± 4%), with acute myocardial infarction (29 ± 4%) or with prior stroke/TIA (22 ± 4%). This mixed category was subdivided, and peripheral vascular disease was one of the major subgroups. In this subgroup, the risk reduction in patients with intermittent claudication (almost 3300 patients in 22 trials) was not significant. However, there was no evidence of significant heterogeneity either between the results of the subgroups. In addition, in almost all of the subgroups results appeared to favour active treatment. The authors therefore concluded that it 'may well be that antiplatelet therapy is likely to be protective for any high-risk patients with clinically evident occlusive vascular disease unless there is some special contra-indication'[6]. The popular name of this meta-analysis is 'the Aspirin Papers', but scrutiny of the analysed trials indicates that the number of included patients on ticlopidine by far exceeds that on aspirin. Another ticlopidine trial was published later: it enrolled 615 patients of whom 304 were assigned to ticlopidine treatment and 311 to placebo for 24 weeks. Four patients in the ticlopidine group and 12 in the placebo group experienced a vascular event (sudden death, myocardial infarction or stroke) during the follow-up period (relative risk 2.93 with 95% CI 0.96–8.99; risk reduction 68%; $P = 0.04$; intention-to-treat analysis). The risk reduction was consistent when subgroups (diabetic and non-diabetic patients) were analysed separately[7]. Clopidogrel (75 mg daily), the new thienopyridine, was compared to aspirin (325 mg daily) in the large CAPRIE-trial which studied patients with stroke, myocardial infarction or peripheral arterial disease. The subgroup of 6452 patients with symptomatic peripheral arterial disease followed for 1–3 years sustained significantly fewer endpoints (stroke, myocardial infarction and vascular death) when treated with clopidogrel than with aspirin: the yearly event rate was 3.71 and 4.86% in the two treatment groups, respectively (relative risk reduction of 24%, $P = 0.0028$). Virtually all of the benefit obtained with clopidogrel in this study, was observed in this subgroup of patients[8]. A recent meta-analysis evaluated the evidence of the effectiveness of individual antithrombotic drugs to reduce vascular events and/or mortality in patients with intermittent claudication and concluded that only ticlopidine and clopidogrel have proven efficacy in level 1 studies (randomized and double-blind or assessor-blind studies)[9].

Although ticlopidine and clopidogrel appear to have better credentials than aspirin, most authorities still advise to use aspirin as a first choice and to change to ticlopidine, or preferentially to clopidigrel because of its better safety profile, in patients who do not tolerate aspirin or who experience a major cardiovascular event despite aspirin intake. The preference for aspirin cannot be based on direct evidence, but on analogy with coronary and cerebral disease where efficacy is well documented. Cost–benefit is an important aspect to justify this choice, and this applies as well for clopidogrel as for ticlopidine[10,11].

Should antiplatelet drugs be started before claudication symptoms develop? In patients with subclinical disease (thus with a decreased ankle–arm pressure index) this would seem reasonable since they appear to have the same increased risk of cardiovascular events and death found in

claudicants. However, a formal study to sustain this view has not been published.

Antiplatelet treatment and ischemic symptoms in the limb

The ultimate 'local' goal of therapy in chronic arterial occlusive disease is to relieve ischemic symptoms (intermittent claudication and rest pain) and to prevent progression of atherosclerosis that might lead to tissue and limb loss. Three trials in the 1980s studied the angiographic evolution as a surrogate endpoint: in one antiplatelet treatment reduced the rate of progression to total occlusion and in the other two treatment reduced an angiographic score which evaluates the extent and severity of the obstructive lesions[12–14](Table 71.1). One of the two latter reports mentions newly developed occlusions in arterial segments as well: 30/1838 with active treatment (aspirin or aspirin/dipyridamole) vs. 34/972 with placebo (odds ratio 0.46, 95% CI 0.27–0.77)[13]. The clinical relevance of the reported changes is not easily appreciated.

A few studies focused on the need for intervention as a clinical endpoint. The US Physicians' Health Study reports

Table 71.2. Need for further vascular surgery in ticlopidine trials

that aspirin (325 mg taken on alternate days) significantly reduces the need for peripheral arterial surgery in males without a history of myocardial infarction, stroke or transient cerebral ischemia. During an average 5 year follow-up period (over 100 000 person years) 56 trial participants underwent arterial surgery: 20 assigned to aspirin and 36 to placebo (relative risk with aspirin 0.54, 95% CI 0.30–0.95; $P=0.03$). The benefit was more pronounced in the subset of individuals who reported claudication at entry into the study. By contrast, the incidence of self-reported new claudication was almost identical in the two groups (112 and 109, respectively). Thus, aspirin appeared to have more impact on the later than on the early stages of the disease, suggesting an antithrombotic rather than an anti-atherogenic effect[15]. The number of patients with further vascular surgery was also assessed in two studies with ticlopidine (Table 71.2)[7,16]: a statistically significant reduction in need for revascularization was observed when the two trials were analyzed together (odds ratio 0.62, 95% CI 0.41–0.93)[9].

Walking distance provides information on the functional capacity in patients with impaired arterial circulation in the leg. It is a soft, but clinically relevant, endpoint for patients with intermittent claudication. Several studies with ticlopidine provide data on the evolution of walking distance. A meta-analysis on four placebo-controlled trials[17,18] and a fifth controlled study[19] all conclude to a significantly better evolution of walking capacity with ticlopidine. By contrast, ticlopidine did not improve walking distance significantly over placebo in the Argentinian multicenter study[7].

Statistically significant improvement of walking distance was obtained with several other drugs which exhibit antiplatelet effects, although their use in leg arterial disease does not intend to compete with aspirin or the thienopyridines. The benefit with pentoxifylline has not been very consistent throughout the many conducted studies[20]. The drug improves red cell deformability, lowers fibrinogen levels and decreases platelet reactivity; its clinical effects may thus stem from other pharmacological properties than

Cambridge Books Online © Cambridge University Press, 2009

from its weak antithrombotic action. Cilostazol acts by selectively inhibiting phosphodiesterase type 3, an enzyme that breaks down cAMP. The final result is a lower level of intracellular Ca^{2+} within platelets which, in turn, represses platelet activity. In addition to its antiplatelet effects, cilostazol acts as an arterial vasodilator: it inhibits the function of contractile proteins by an analogous mechanism. Synthesis of prostaglandins is not affected. The drug was first marketed in Japan for patients with intermittent claudication and ischemic leg ulcers. Recently, 6 multicentre placebo-controlled trials were conducted in the US. They involved more than 2000 patients with intermittent claudication and established the efficacy of cilostazol to improve walking distance in these patients[21,22]. Prostaglandins with antiplatelet and vasodilatory effects (mainly E_1 and I_2) and some of their analogues have been used primarily in studies on patients with critical limb ischemia; the reported results varied but there is some evidence that the prostacyclin analogue iloprost may improve amputation-free survival in these patients. A prodrug of prostaglandin E_1 administered intravenously appeared to have a positive effect on walking distance of claudication patients in two placebo-controlled studies of short duration[23,24]. Beraprost is an orally active prostaglandin I_2 analogue that was recently tested in a study on 549 patients with intermittent claudication. Their walking distance improved significantly over 6 months in comparison with placebo. In addition, the incidence of cardiovascular events was markedly reduced (mainly arterial thrombosis of the leg) but the trial was not powered to study this endpoint[25]. Effects of other less common antiplatelet agents are discussed in Chapter 65.

No published study has yet proved that aspirin will prevent the primary claudication symptoms in a healthy population. Because such a study would require very large numbers to be enrolled, an alternative approach is to select a population at higher risk, such as individuals with a (still) asymptomatic decrease in ankle pressure index or patients with diabetes. Such studies are under way.

Is antiplatelet treatment useful in arterial surgery?

Thrombosis, restenosis at the anastomosic sites and late occlusion are the main problems after implantation of a graft or after a thrombendarterectomy. Antithrombotic drugs are primarily expected to decrease the risk of early thrombosis; in a clinical setting, they have never been shown to influence intimal hyperplasia, the mechanism underlying restenosis.

To what extent does antiplatelet therapy contribute to maintain patency of peripheral arterial reconstructions? Clinical trials in this field are not numerous, usually small, and fewer than half of them have a randomized and double-blind design. Many are single centre studies including a mixture of different surgical procedures and patients with varying degrees of lower limb ischemia[26]. The American College of Chest Physicians (ACCP) Consensus Conference (2001) recommends not to use antithrombotic drugs to maintain patency of vascular reconstructions involving high-flow low-resistance arteries greater than 6 mm in diameter. Thus aorto-iliac and aorto-femoral grafts do not require antithrombotic prophylaxis because thrombotic occlusion is unusual and patency rates in the range of 80 to 90% can be expected after 5 to 10 years[27]. An exception to this rule are long axillo-femoral bypasses that appear particularly vulnerable to thrombotic occlusion.

By contrast, reconstructions below the inguinal ligament are more prone to thrombosis because of the lower flow rates, the length of the bypasses and their frequent bending at flexion points of knee and groin. In addition, prosthetic grafts should be distinguished from vein grafts because they have an inherently higher thrombogenicity. As a consequence, the ACCP Consensus Conference proposes the use of aspirin (with or without dipyridamole) in patients having prosthetic infrainguinal bypass operations and to start antithrombotic therapy preoperatively. This recommendation is largely based on six trials published between 1982 and 1997[28–33]. They are summarized in Table 71.3. A recent meta-analysis included five randomized controlled trials comparing long-term aspirin (with or without other antiplatelet therapy) with placebo after infrainguinal bypass surgery[26]. In 423 patients treated with antiplatelet drugs, 120 (28.4%) of the bypasses occluded compared with 144 (36.6%) occlusions in 393 randomized placebo-treated patients, giving a relative risk of 0.78 (95% CI 0.64–0.95) or a proportional risk reduction of 22%; the absolute risk reduction was 8.2%. No distinction was made between prosthetic and venous bypasses. The importance of graft material is emphasized in another meta-analysis on 11 randomized controlled trials of platelet inhibitors after peripheral bypass procedures involving 2302 patients. In this meta-analysis there was a clear treatment benefit of platelet inhibitors but also a significant heterogeneity which was explained by the proportion of patients with a prosthetic graft in an individual trial. Aspirin did not appear to prevent occlusion of vein grafts[34]. The Antiplatelet Trialists' Collaboration meta-analysis[35] on 11 randomized trials (a large number are the same trials), also included over 2000 patients with peripheral vascular grafts and concluded that antiplatelet drugs reduce the inci-

dence of graft occlusion at the end of the (variable) follow-up period by one-third (from 24 to 16%). This conclusion is, to some extent, upheld in a new meta-analysis that included trials with several drugs and several types of revascularization procedures: mainly aspirin associated with dipyridamole and ticlopidine appeared to improve the outcome[36]. The multitude of meta-analyses to answer the same question – do antiplatelet drugs improve the patency rate of vascular grafts – illustrates the difficulty and uncertainty in the field due to the lack of large studies with homogenous groups.

Up to now, the French multicentre study[33] is the only controlled trial in which an antiplatelet drug reduces the rate of late occlusion in an homogenous population of saphenous vein bypass grafts below the knee. Therefore, there is currently no strict recommendation for the use of antiplatelet drugs to maintain patency of saphenous vein bypass grafts. Some surgeons even favour the use of oral anticoagulants in patients with this type of vascular graft. A small study suggested adding oral anticoagulants to aspirin to improve patency of infrainguinal vein grafts at high risk of thrombosis[37]. The recent Dutch Bypass Oral anticoagulants or aspirin study (BOA) investigated whether either of these treatments prevented more effectively than the other bypass complications after infrainguinal bypass surgery in 2690 patients, but found no significant difference in overall occlusion rate. The frequency of occlusion was about 14% per 100 patient–years in each treatment group. However, analysis stratified for graft material showed a lower risk of autologous vein–graft occlusion in the oral anticoagulation group than in the aspirin group; conversely, aspirin appeared more effective in patients with a non-venous graft (Fig. 71.2)[38]. Despite careful control of oral anticoagulant therapy (there is a well-organized system of anticoagulation clinics in the Netherlands), bleeding complications were twice as common with oral anticoagulation as with antiplatelet therapy. There were 18 cases of intracranial bleeding, 8 of which were fatal, in the oral anticoagulation group, vs. 4 (3 fatal) in the aspirin group. This surplus was offset by a lower incidence of non-hemorrhagic stroke: 21 with oral anticoagulants vs. 45 with aspirin.

Surgical patients may benefit from antiplatelet therapy to reduce long-term cardiovascular mortality and morbidity as well as non-operated patients.

Antiplatelet drugs in percutaneous endovascular revascularization

The 1998 recommendations of the ACCP Consensus Conference for patients undergoing percutaneous transluminal angioplasty (PTA) are summarized in Table 71.4[10]. A European expert group suggested replacing ticlopidine

Cambridge Books Online © Cambridge University Press, 2009

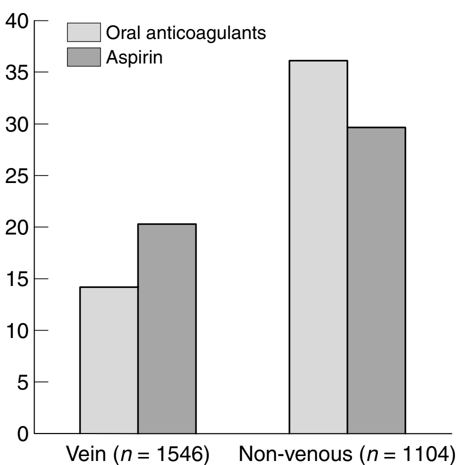

Fig. 71.2. Incidence of graft occlusion with aspirin and oral anticoagulants in the Dutch Bypass Oral anticoagulants or aspirin study[36].

with clopidogrel which has a similar clinical efficacy but a better safety profile[11]. The proposal largely relies on extrapolation from data in coronary angioplasty. The 2001 ACCP document keeps silence on the issue[27].

Aspirin (earlier frequently combined with dipyridamole) started the day before the procedure is the usual antithrombotic drug in most centres. Historically, this practice appears to be based on a few rather small and methodologically questionable studies of short duration from the pioneering period. Studies with longer follow-up after PTA rarely distinguished early reocclusion from late restenosis and/or occlusion.

Two placebo-controlled studies were published in the 1990s. The first randomized 199 patients to placebo, 100 mg or 330 mg aspirin (both combined with 75 mg dipyridamole) three times daily and found the difference between placebo and the highest dose of aspirin to be statistically significant[39]. The second study randomized 223 patients to 50 mg of aspirin combined with 400 mg of dipyridamole daily for 3 months or to placebo and found no difference between the two treatment groups[40]. This study included patients with iliac angioplasty (more than 40% of the patients) which has a lower risk of reocclusion.

Later clinical trials evaluated low-dose vs. high-dose aspirin as antithrombotic prophylaxis in conjunction with PTA, and found no difference in late outcome between the two regimen but serious gastrointestinal side effects were fewer with the lower dose of aspirin[41,42]. One study suggested that some patients may require a higher dose of aspirin or alternative antiplatelet agents such as ticlopidine or clopidogrel: all 8 occlusions that occurred in 100 patients treated with 100 mg aspirin for 18 months after an elective PTA occurred in patients with inadequate platelet inhibition on in vitro aggregation testing[43]. Taken together, the data on the effect of aspirin on late restenosis (and reocclusion) are rather disappointing: the conclusion that a low dose of aspirin is as effective as a high dose has little significance (except for the lower complication rate) as long as we do not know whether aspirin has any effect at all on late events. The problem is that new placebo-controlled trials are judged to be unacceptable in view of the effect of aspirin on the general prognosis even though, as discussed above, this effect is poorly documented in patients with peripheral arterial disease. On the other hand, the practice of prescribing aspirin in conjunction with peripheral angioplasty is not seriously challenged either.

Table 71.4. Antiplatelet therapy in angioplasty (and stent placement)

Use aspirin before and after angioplasty of aorto-iliac arteries to reduce incidence of periprocedural thromboembolic events.
Consider aspirin combined with ticlopidine or clopidogrel in patients undergoing angioplasty of femoral and distal arteries.

Note:
Adapted from ref. [10,11].

The proposal to associate ticlopidine (or clopidogrel) to aspirin for procedures below the inguinal ligament is recent. It is entirely based on extrapolation of data after coronary angioplasty: here, the combined use of aspirin and ticlopidine appears to result in synergistic platelet inhibition compared to monotherapy with either agent and in a better early clinical outcome.

Up to now there are no data which specifically address the value of antithrombotic drugs after insertion of stents in peripheral arteries, despite the inherently thrombogenic nature of the material used. Stents in the aorto-iliac region improve the immediate hemodynamic results of iliac angioplasty (particularly in case of complicated lesions and chronic occlusions) and effectively manage recoil and procedure-related flow-limiting dissections[44]. Experienced centres have demonstrated a 1-year and 3-year patency rate after successful recanalization of 90 and 80%, respectively. These results are, in general, obtained with the same antithrombotic regimen as is used in simple angioplasty, although some centres continue heparin administration for 24 to 72 hours.

On the other hand, stenting of infrainguinal lesions as a primary approach is a debated issue: for many, it is at present indicated only for salvage of failed angioplasty due to dissection and marked recoil. Immediate and early

Cambridge Books Online © Cambridge University Press, 2009

results appear satisfactory but intimal hyperplasia in the stented segment in the first 3 to 9 months after treatment is common and often leads to late failure. Would a modification of the antithrombotic strategy improve results for femoropopliteal stents? The combined use of aspirin and ticlopidine (or clopidogrel) is increasingly popular, certainly in European centres with an aggressive policy of primary stenting of femoropopliteal lesions. Again, their practice is based on extrapolation of coronary data. Extrapolation of data from one vascular bed to another assumes an analogous problem and the same cause and underlying mechanism. In the coronary circulation, early stent occlusion is the targeted dramatic event; in the femoropopliteal region, late reocclusion is of greater concern.

Future prospects

The newest, yet unpublished, analysis of the Antithrombotic Trialists' Collaboration[45], mainly confirms the previous one[6], be it on a much larger patient population: antiplatelet therapy reduces the risk of any serious vascular event by roughly one-quarter in all categories of patients at high risk. Is any further progress to be expected from this category of drugs? It is doubtful whether a simple further increase in numbers of patients studied would alter the basic conclusion. The hope that the powerful glycoprotein IIb–IIIa blockers would open a new era of antithrombotic therapy vanished after the debâcle with the oral preparations. A return to the thromboxane receptor blockers is still in an early phase. On the other hand, too many issues in peripheral arterial disease are currently being solved by extrapolation from other vascular beds, particularly the coronary.

Afterword

Platelets: a personal story

Gustav V.R. Born

William Harvey Research Institute, Charterhouse Square, London, UK

Platelets were a major research interest of mine from the 1960s to the 1980s. During that period descriptive knowledge of platelets was superseded by understanding of their pathophysiological mechanisms and functions. The Editors' invitation was for a brief account of personal work, some of which turned out to be seminal, of course in its wider setting. So I hope this will be as enjoyable to read as it was to write. It has made me look again at our platelet publications of so many years ago that I had forgotten much of what we did and was pleasantly surprised by rediscovering it. The request was for a personal story. So the massive and essential contributions from large numbers of contemporary workers are set out in the historical chapter of this book. This account provides another opportunity of acknowledging the many excellent co-workers, listed below, many of whom carried on with research in various parts of the world and some of whom are contributors to this book.

In 1976 the Royal Society invited me to give a lecture to the British Association of Young Scientists. By then platelets had been my major concern for 15 years. So the title of my lecture was *Why don't we Bleed to Death? The vital defence mechanism of hemostasis.* The abstract, made as attractive as possible for young people, still stands as a reliable summary of what platelets are primarily about:

'As soon as primitive metazoan animals acquired a body cavity containing a fluid different in composition from the environmental fluid they had something to defend against change, a *milieu interieur* to keep constant. Any acute injury was liable to cause a change in the composition or amount of the body fluid. For survival it became necessary, therefore, to develop a defence mechanism, the purpose of which was the prevention of loss of body fluid. This defence mechanism is most simply referred to as "hemostasis" although the name should strictly speaking be reserved for animals with blood circulations.

The defence mechanism against the loss of vital body fluid has three components: (i) change in the physical state of the fluid itself which stops it flowing out through a wound; this is the process called clotting or coagulation; (ii) cellular contraction around the wound opening which makes it smaller and so impedes the loss of fluid; and (iii) the adhesion and aggregation of specialised cells in the wound, tending to close it and so to arrest the outflow of fluid.

Human blood contains a particular type of cell, the platelets, the only known physiological function of which is hemostasis. In healthy people this function is in evidence whenever our closed, high-pressure blood-vascular system is opened somewhere through injury, although the contribution of the platelets to the total hemostatic process depends on the type or types of vessels opened up as well as on other conditions.

Pathologically, platelets constitute a major element of arterial thrombi, whether forming rapidly on atherosclerotic vessel walls or more slowly during graft rejection episodes in the supplying vessels. The hemostatic function of platelets is literally 'vital', i.e. essential to survival; and their pathological role is, of course, potentially lethal. This clinical significance has led to a remarkable increase in platelet research from every conceivable aspect. This research seems likely to result, for the first time, in the discovery of drugs for preventing arterial thromboses such as 'acute coronaries' which are the scourge of this and other developed countries.' Note that this was written in 1976, just about the time the most successful antiplatelet drug – Aspirin – did indeed make its début on the heart attack scene.

The beginnings

How does one come to platelets, such a seemingly insignificant non-cell? Since their discovery about 150 years ago the commonest route has been through clinical hematology; and until platelets became prominent players in coronary heart disease and stroke, their medical importance was mainly *in absentia*, because platelet deficiency causes bleeding. There are many causes of platelet deficiency, one being radiation. As an Army Medical Officer posted close to atom-bombed Hiroshima in defeated Japan, deadly hemorrhages from radiation sickness first made me aware of platelets and how much we need them.

But my own long-term relationship with platelets did not come out of disturbing clinical impressions but through my post-doctoral initiation into pharmacological research. In 1956 I was working in the Oxford Pharmacology Department with Hugh Blaschko on the recently discovered association of adrenaline with ATP in adrenal granules, which contain about three molecules of the cationic amine for each molecule of ATP^{3-}, suggesting ionic binding[1]. It occurred to me that other endogenous amines might be stored similarly elsewhere in the body. Somewhere I had heard or read of platelets containing large amount of the vasoconstrictor amine serotonin (5-hydroxytryptamine, 5-HT). So the initial intention was to utilize this, then comparatively unexplored, circulating pseudocell for pharmacological purposes. As the first person in Britain I used the firefly method, recently introduced by McElroy[2] in the United States, for measuring platelet ATP. With the platelet extract adjusted to ATP concentrations expected from other cell types, the galvanometer pointer flew off the scale – an unforgotten moment[3]. The discovery of excess platelet ATP was followed by evidence for its stoichiometric association with 5-HT, again suggesting ionic binding[4–7].

Platelets and aminergic mechanisms

Most of our subsequent work with platelets related to their physiological function in hemostasis and its pathological aberration, thrombosis. But when I began working with platelets they were of interest also through being thought of as biologically rather simpler and therefore easier to study than other types of cell. This has turned out to be a fortunate fallacy: except for the absence of DNA and of protein synthesis, platelets are as complex as the next cell; but because they are easily obtainable almost homogeneously, they have proved invaluable as models for less accessible and more complex cells such as neurones. It was the ability of platelets to be activated by 5-hydroxytryptamine (5-HT) that led to their use as models for tryptaminergic neurones, so different in function and environment, and for determining the modes of action of psychotherapeutic drugs, particularly by Alfred Pletscher and coworkers. One of our own investigations showed that the beneficial effects of lithium in manic-depressives goes with increases in their platelet 5-HT[8]. Another confirmed with rabbits David Boullin's clinical observation that long-term chlorpromazine treatment increases platelet aggregability to 5-HT, possibly through increasing the number of specific receptors[9]. Our evidence suggested that the uptake of 5-HT is an active process[6, 7] and with Oleh Hornykiewicz (who later discovered the dopamine deficiency in Parkinson's disease) that the uptake of adrenaline and noradrenaline is not[10]. As 5-HT induces platelet aggregation, the mechanisms for uptake and aggregation were compared. Using numerous tryptamine analogues it was

Cambridge Books Online © Cambridge University Press, 2009

shown that uptake is highly specific for 5-HT whereas aggregation is not[11]. Intriguingly, uptake was accelerated with platelets covalently enriched with sialic acids on their outer membranes, possibly explained by increased binding of 5-HT at the cell surface[12]. Effects of lithium and trycyclic and other drugs on amine mechanisms demonstrated with platelets were reproduced with nerve cells in the development of antidepressants by pharmaceutical companies.

Platelets in hemostasis and thrombosis

By far the largest and longest part of my work on platelets had to do with their role in hemostasis and thrombosis; more specifically how platelets reduce blood loss from injuries to vessels larger than the capillaries, where they don't; and how platelets come to initiate – and not infrequently dominate – thrombosis in arteries. In both situations, the physiological and the pathological, the fundamental process is that of platelet aggregation, whereby changes in their normal biochemical and/or hemodynamic environment induce individual platelets to adhere to one another and to aggregate into the growing bodies known respectively as hemostatic plugs and arterial thrombi. The evidence that acute coronary thrombosis is almost always initiated by plaque rupture and hemorrhage has disposed of any uncertainty as to why the platelet aggregation process is the same there as in other hemorrhagic situations.

My interest in platelet aggregation was awakened through the coming together of two previously unconnected observations. One was the discovery of excess ATP in platelets and the demonstration of its rapid breakdown in clotting blood[13]. The other was the Norwegians' discovery of the platelet-aggregating effect of ADP[14]. By then aware that the primary function of platelets is their hemostatic aggregation, I suggested that the two processes are connected through the formation of ADP from ATP released from platelets and from other cells involved in vascular injury[15]. This has turned out to be an oversimplification as far as the platelets themselves are concerned, which release ADP mostly from a different pool than that in which ATP breaks down. Nevertheless, over the years the hypothesis that ADP contributes to platelet aggregation in hemostasis and thrombosis has been supported by experiments[16–18], and by clinical trials of drugs which inhibit platelet activation by ADP, notably the CAPRIE Trial published in the *Lancet* as recently as 1998[19]. Subsequent discoveries of other endogenous aggregating agents, predominantly thromboxane A2 and thrombin, have added to the complexity of the process. But the evidence stands that ADP and thromboxane A2 contribute about equally to hemostatic aggregation in vivo[20].

Platelets in vitro: optical aggregometry

For investigations of platelet physiology I invented and developed the optical aggregometer for quantifying and analysing platelet reactions in vitro. The idea came to me from so-called 'turbidimetric' measurements of ribonuclease activity in *Streptomyces* culture filtrates done for my D.Phil. (as the Ph.D. is termed in Oxford which must always be different!). I made the simple adaptations appropriate for measuring platelet aggregation in plasma. This new method brought exciting results quickly and reproducibly. Having had an important part of my scientific upbringing in Professor Joshua Burn's excellent Pharmacology Department in Oxford, where free and noisy communication between members and visitors was strongly encouraged, I had no hesitation in demonstrating the technique immediately to anyone who asked. The method was published in 1962[15,21] and the first detailed description of observations made with it in the following year[22]. We quantified the relation of aggregate formation to the optical changes[23,24] and showed that they could be accounted for on classical light-scattering theory[25].

The optical aggregometer has ever since been used worldwide in fundamental, clinical and epidemiological investigations. Within a few years the original papers became *Citation Classics*; and by January 2001 the *Nature* paper had been cited 3796 times and the *Journal of Physiology* paper 1902 times (P.D. Richardson, personal communication). Many more papers – probably many thousands – have been based on optical aggregometry without reference to the original publications. Commenting on the first *Citation Classic* in 1977, I wrote: 'To be told that this paper is one of the most cited articles ever published is astonishing and interesting. I can think of three possible reasons. First, the paper helped to make platelets interesting research objects by suggesting functions for two, then recent, observations, *viz.* ATP breakdown during clotting and platelet aggregation by ADP. The paper suggests that these processes are connected through the formation of ADP from ATP in cells damaged by or involved in vascular injury . . . much evidence now supports this original proposition.

Secondly, the paper introduced the photometric method which later acquired the horrible name of 'aggregometry'. It soon became widely used, presumably because of its simplicity and reproducibility. It has been responsible for major discoveries in platelet function, notably the second phase of aggregation. This is the optical manifestation of

Cambridge Books Online © Cambridge University Press, 2009

the platelet release reaction, much investigated since as an example of exocytosis and because the discovery of its inhibition by acetyl salicylic acid is the origin of the Aspirin trials in coronary thrombosis.

This brings up the third reason for the popularity of the 1962 paper. It showed that platelet aggregation by ADP can be inhibited and reversed by the closely related substances AMP or ATP. The last paragraph of the paper reads: 'If it can be shown that ADP takes part in the aggregation of platelets in blood vessels it is conceivable that AMP or some other substance could be used to inhibit or reverse platelet aggregation in thrombosis.' Cross and I soon found that AMP was much less inhibitory than adenosine which, in turn, is much less effective than several inhibitors unrelated to ADP which have been discovered since, such as some prostaglandins. Elucidation of these inhibitory mechanisms has made rapid progress, not only because platelets are advantageous models for other cell systems but also because it may result in important advances in drug treatments.' This has indeed turned out to be so.

I have been told there are thousands of optical aggregometers around the world and asked why I did not patent the device. The reason is that before the Thatcherite degradation of everything in life to money, it did not occur to me nor to most members of the medical research community to patent inventions or discoveries; indeed my Oxford Professor Howard Florey was against patenting anything of potential medical value. So the idea just never came up.

As an aside, it occurred to me that the aggregometer might be useful in other biological systems. The life cycle of the slime mould *Dictyostelium discoideum* includes a phase in which thousands of separate cells aggregate into elegant fruiting bodies. So this process was quantified with the aggregometer and the effects of temperature and ionic strengths were determined[26,27]. Interestingly, recalling the platelet effect of lithium referred to earlier, *Dictyostelium* is helping to elucidate the antidepressant action of lithium[28,29].

Up to the molecular biology era, it is probably true to say that much if not most of the new information about platelets has depended on optical aggregometry. Aggregation was characterized with respect to velocity and temperature and pH dependence[22]. Two essential cofactors of aggregation were discovered, viz., calcium and fibrinogen[30,31]; and the suggestion that fibrinogen forms 'bridges' linking aggregating platelets[32] was later confirmed at the electromiscroscopic and molecular levels. Nowadays this bridging function, and thereby platelet aggregation, can be prevented by various molecules which inhibit binding of fibrinogen to its receptor, the activated conformer of Glycoprotein IIb–IIIa, on the platelet surface. So far, meta-analyses of clinical trials indicate that these agents given orally do not decrease and may even increase mortality, whereas given intravenously they improve the outcome of coronary stents[33,34].

The rapid shape change of platelets (time constant about 1 second at 37 °C) which is the first visual evidence of their activation was quantified and shown to conform to Michaelis–Menten kinetics[35]. The results suggested that aggregation agonists such as ADP react with specific membrane receptors leading to structural changes; now of course the receptors are fully identified. The same paper contains the proof, by means of a novel thrombocrit technique for determining cell volumes directly, that the rapid shape change is not accompanied by an increase in mean platelet volume, as had been widely accepted on the basis of Coulter Counter measurements. This finding threw doubt on the validity of cell volume measurements by such widely used indirect methods.

Optical aggregometry made possible the discovery by Macmillan and Oliver in 1963 of the second phase of aggregation[36] – Michael Cross and I had failed to notice or to think about the anomalous deformations in our manually plotted aggregometer tracings (this was before the availability of continuous recording) which turned out to be the optical manifestation of the platelet release reaction. In this reaction, enough ADP is released[37] to account for the positive feedback mechanism of aggregate growth already proposed. It is this second phase of aggregation which, as discovered in 1967 by Mustard and coworkers[38] and by Harvey Weiss and Louis Aledort[39], is inhibited by Aspirin. Therefore optical aggregometry is at the beginning of a very important medical story. Ever since I have enjoined my students to look for odd or unexpected findings and never to disregard what could be an experimental error but could also be something real and important. It was a salutary lesson, in principle – but only in principle – analogous to the unexpected and curious astronomical tracings obtained by S.J. Bell and A. Hewish which led to their discovery of the pulsars. The feedback hypothesis has received much experimental support. Feedback is promoted by adrenaline[40] and inhibited by drugs which prevent the release of ADP from platelets.

Optical aggregometry soon led also to the discovery of the first aggregation inhibitors, viz., ATP and adenosine, looked at first because of their close chemical relationship to pro-aggregatory ADP[15,41]. As it has turned out, inhibition was the most exciting and far-reaching discovery because it established the therapeutic possibility of preventing arterial thrombosis by means of antiplatelet drugs and initiated the era of their use for the prevention of myocardial infarction and stroke. Much effort was devoted to inhibitory mechanisms. We showed that ATP inhibited competitively whereas adenosine did not but was significantly more

Cambridge Books Online © Cambridge University Press, 2009

effective[42]. More effective still were the 2-substituted adenosine derivatives, particularly 2-chloroadenosine, out of many related substances[43]. In experiments on ourselves, which could conceivably have been harmful and which would now be strictly forbidden, we showed that the relative effectiveness of adenosine analogues as aggregation inhibitors and as arterial vasodilators was the same[44]. Since then this has been explained by the similarity of the cyclic AMP mechanism in platelets and in vascular smooth muscle. We showed later that ATP as a competitive inhibitor of aggregation by ADP is able to reverse the rapid shape change of platelets, bringing them back to their normal disc-like appearance. To demonstrate this rigorously required correlating optical aggregometry with quantitative electron microscopy[45]. Noel Cusack and Susanna Hourani developed nucleosides, nucleotides and several synthetic analogues into important pharmacological tools for investigating platelet mechanisms[46]. By now, three types of receptors for extracellular nucleotides (P2 purinoceptors) are recognized as participants in platelet activation[47].

The drug dipyridamole was shown to inhibit the uptake of adenosine by platelets and to potentiate its inhibitory effects on aggregation[48]. So, as an aside, when Dinah James, Professor of Pharmacology in Ibadan and an authority on African sleeping sickness, joined me for a year and told me that the causative trypanosome cannot synthesize nucleotides *de novo* but only from adenosine taken up from the surrounding tissue fluid, we looked at dipyridamole as an uptake inhibitor[49]. I do not know whether this idea has been taken further – probably not, or I would have heard of it.

Platelets in vivo: hemostatic and thrombotic mechanism

From the time of Bizzozero (1882) it has been known that bleeding from small vessels induces platelets to aggregate before clotting begins. Our first question was whether ADP is involved in activating platelets in vivo as had been shown in vitro. Novel techniques were developed for reproducible bleeding time determinations from small arteries in the superior mesenteric territory of rats and rabbits. In both species, local infusions of active but not of inactive ADP-removing enzyme systems increased bleeding time significantly, supporting the conclusion that platelet aggregation in primary hemostasis involves ADP[16,17]. In rats these bleeding times were also prolonged by ADP receptor antagonists[50] (– this et al. includes a great-granddaughter of Charles Darwin!). With ultra-sensitive luminescence measurements blood at arterial puncture sites was shown to contain micromolar ATP for at least 2 seconds[51,52]. Its rapid dephosphorylation supported the proposition[21] that ADP is involved in initiating hemostatic platelet aggregation[15].

Quantifying platelet adhesiveness and aggregation in uninjured vessels required a methodological innovation. This was to apply ADP by micro-iontophoresis to the outsides of small blood vessels[53]. The technique permitted highly localized measurements of small vessel reactions to pharmacological agents, thereby minimizing other tissue and blood flow effects. ADP thus applied showed that platelet thrombi can be made to form many times on the same site in small blood vessels without damaging their endothelial lining, thereby disposing of claims to the contrary. Aggregates grew exponentially, the rate constant providing a measure of the effects of blood flow and of inhibitors[54]. The technique also permitted a first determination of platelet activation time (of the order of 100 ms, since revised downwards)[55]. Histamine, which has no direct effect on platelets, applied iontophoretically to venules contracts their endothelial cells[56] and reversibly accelerated intravascular platelet aggregation by iontophoretic ADP at the same site, evidence that effects within blood vessels of extravascular agents may be influenced by endothelial contractility[57]. Incidentally, the technique also permitted quantification of the reversible contractility of endothelial cells in vivo and determination of their 'relaxation time'. Platelet–endothelial interactions were shown to be minimal in normal vessels, with only a small proportion adhering for very short times (less than 1 second)[58]. On the other hand, reduction of endothelial negative surface charge greatly increased platelet adhesion[59].

As an aside, we showed that the negative charge densities on endothelia in different blood vessel types greatly exceed those on the surfaces of other cells[60]. This suggested a physiological answer to the long-puzzling question, which had been considered theoretically by Sir James Lighthill, how the blood manages to flow through capillaries with diameters smaller than those of the circulating cells. Our experiments gave evidence that microvascular blood flow is made possible by electrostatic repulsion between the negative charges on endothelial and red cell surfaces[61]. (I often think of this work, which in a sense continues Harvey's and Malpighi's discoveries of how the blood circulates, as the most interesting I have done!)

Overall our findings do little to support the claims of functionally significant interchanges of prostaglandin precursors between platelets and vessel walls, nor of the so-called prostacyclin–thromboxane balance hypothesis[62] which claimed that these two mutually antagonistic agents play a major role in acute coronary thrombosis. The hypothesis, attractive by being simple, was accepted uncritically for many years. But every medical student sees

Cambridge Books Online © Cambridge University Press, 2009

for himself in the postmortem room the gross damage caused by coronary plaque rupture, which makes it inconceivable that these evanescent agents could possibly have any significant effects on the overwhelming thrombogenetic sequelae[63]. The lesson is to stay in touch with real life or, in this case, real death.

As it has turned out, great importance attached to the demonstration that inhibitors of in vitro aggregation are also effective in vivo. The first paper on this[64] showed that the formation and embolization of platelet thrombi is inhibited by adenosine and 2-chloroadenosine. Regional administration of aggregation inhibitors prevented thrombus formation in artificial organs[65].

During the years devoted mainly to platelets, work was also done on other blood cells. The red cells are a source of proaggregatory ADP, as first demonstrated by the Norwegians[14]. We produced evidence that intravascular platelet aggregation is inhibited by chlorpromazine and similar drugs through an action on the red cells rather than on the platelet themselves[66], an effect depending on properties of the erythrocyte membrane[67]. Interactions between red cells and platelets were analyzed under various flow conditions[68].

Platelets in humans

Great advances in the understanding and the therapeutic control of platelets came in the 1970s and 1980s, which were the heyday of the prostaglandins. For platelet people the most important discoveries were proaggregatory thromboxane A2 produced by platelets and antiaggregatory prostacyclin produced by vessel walls; and of course the Nobel Prize-winning discovery by John Vane of the action of Aspirin in inhibiting prostaglandin biosynthesis, plus the immediate demonstration of its applicability to platelets by our graduate students Bryan Smith and Jim Willis. These events are very well known, and the therapeutic advances they brought with them are very great: through its antiplatelet action Aspirin reduces the risk of heart attacks and strokes by up to 40%. Based on evidence that thromboxane A2 and ADP contribute about equally to thrombotic platelet aggregation, large-scale clinical trials are now under way in which Aspirin as thromboxane A2 inhibitor together with Clopidogrel as ADP antagonist are administered together, against Aspirin itself. The results should show whether inhibiting two different platelet activating mechanisms is clinically more effective than inhibiting only one. (Note added in proof: it is!)

Also during that period great interest began in the influence of diet on atherosclerosis and its thrombotic complications. Again, much of this turned on prostaglandins and their precursors. Animal and human evidence, for example from Greenland Eskimos, had established that diets rich in polyunsaturated marine lipids, particularly eicosapentaenoic acid, increased blood loss from injuries and from clinical bleeding time measurements. (The late Hugh Sinclair of Magdalen College Oxford took the diet to such extremes that his bleeding time became virtually infinite!) These effects were generally attributed to a decrease of thromboxane A2 production by platelets demonstrable in clotting blood. Joined by Margaretha Thorngren, who had already been experimenting on her fish-fed husband, we muddied this seemingly clear explanatory pool. Techniques were devised for measuring thromboxane A2 in the blood coming from standardized bleeding time incisions, just where the aggregating platelets should be releasing it. Compared to blood clotting in vitro bleeding time blood contained very little thromboxane A2, suggesting that it is not a major determinant of that parameter[69]. Secondly, volunteers on a fish diet for 4 weeks had the expected increase in bleeding time and decrease in clotted blood thromboxane A2 but no diminution in its output in bleeding time blood[70]. Our evidence also indicated that the bleeding time increases produced by fish diets and by Aspirin are brought about by different mechanisms[71].

So we looked into another possible explanation, namely that diet diminishes the local vasoconstriction caused by injuries such as cutting. We found that in rats on a diet enriched in eicosapentaeonic acid the contractile effect on small mesenteric arteries of noradrenaline as the primary endogenous vasoconstrictor was decreased up to fourfold[72]. It all adds up to the conclusion that the increased hemorrhagic tendency of fish-eating populations has less to do with platelets than with vascular contractility – at the time an heretical proposition which may however have been followed up more than I am aware of.

Envoi

By the mid-1980s, understanding of the physiological behaviour and pharmacologial control of platelets was well advanced. New questions were increasingly answered by the techniques of molecular biology, with which I am not familiar. So it seemed natural to turn for my last research decade to atherosclerosis, particularly because, to the extent that it becomes preventable, the clinical importance of thrombosis and therewith of platelets will diminish. Many years before we had demonstrated experimentally that lipemia accelerates the growth of

Cambridge Books Online © Cambridge University Press, 2009

platelet thrombi in vivo[73] establishing a link between thrombogenesis and atherogenesis. Work by many people has elucidated the interactive contributions of plasma lipids and platelets to arterial thrombotic events. The early finding has been refined by showing that the aggregability of platelets may be significantly increased by low density lipoprotein (LDL)[74]. And so this vascular journey continued in opposite directions – upstream towards atherogenesis by investigating factors which determine the flux of atherogenic plasma proteins from the blood into arterial walls; and downstream to the terminating event of plaque fissure, the immediate cause of coronary thrombosis in which platelets are heavily involved. With two outstanding colleagues, the pathologist Michael Davies and the physicist Peter Richardson, the first quantification was made of the roles of plaque configuration, stress distribution and macrophage density as determinants of plaque rupture[75]. Plaque fissure represents the link between atherosclerosis and thrombosis[63]. Therefore, why plaques rupture and how that may be prevented are questions of clear and present concern to the platelet community.

Looking back, I suppose that the greatest change to have happened to platelets is their enormously increased importance in clinical medicine – from somehow being involved in the rather uncommon conditions of idiopathic thrombocytopenia and radiation sickness to being recognized as a dominant factor in arterial thromboses causing myocardial infarction and stroke, which together cause almost half of all deaths in industrialized populations. Surprisingly, the exact mechanism whereby platelet deficiency is associated with petechial bleeding is still uncertain. In contrast, the mechanism of platelet aggregation at vessel injuries is now well understood. It is gratifying that the feedback hypothesis of platelet aggregation turned out to be explanatory of the remarkable effectiveness of antiplatelet drugs of the Aspirin type in the prevention of heart attacks and strokes. The continuing medical importance of platelets is attested by the development of antiplatelet agents with other modes of action, some already in use and others undergoing clinical trials[33]; and by the existence of the Anti-Platelet Trialist Organization in Oxford which has been monitoring progress worldwide.

Thought-provoking developments in the platelet story keep me interested and involved; for example, by helping to evaluate the comparative clinical merits of Aspirin and Clopidogrel[76]. And recently there was the unexpected and curious result of the Thrombosis Prevention Trial[77], that non-fatal events were significantly reduced by Aspirin but not by Warfarin which however significantly reduced fatal events. If substantiated this finding cries out for a reasonable, perhaps even testable, hypothesis. I suggested that the simplest assumption might be differences in fissure size, such that non-fatal events were associated with small fissures inducing non-occlusive embolizing platelet thrombi, rather like unstable angina, whereas fatal events would be caused by large fissures where platelet aggregation is rapidly superseded by occlusive coagulation, so accounting for the great effectiveness of Warfarin. Perhaps it is conceivable that further improvements in high-resolution ultrasonography or magnetic resonance imaging techniques might show up differences in fissure size, at least in carotid arteries[78].

Platelet research has been continuously interesting itself and has also permitted following up promising side alleys. It would be a pity if career pressures on research workers were to prevent them from following up ideas not on their main road. I myself have still been lucky enough to do that – the three or four ‘asides’ referred to above were not the only ones. Of course there was a downside: to quote from my graduation anniversary, ‘years on minimal income at the beginning, and not much more at the end; but an amazing amount of fun’. And now, late in the day, there beckons the possibility of following up an exciting idea in a different field altogether, namely cancer. But that is another story. At all events, I am glad to have contributed in a small way to knowledge of a vital physiological process – hemostasis – and to an advance in Medicine, which Dr Samuel Johnson rightly called ‘the greatest benefit to mankind’.

In the platelet work the following were my principal colleagues and coworkers, whose contributions and friendship I wish to acknowledge with pleasure and gratitude:

Karl Afors: Sweden
Mara Baldacci: Italy
Massímo Baldacci: Italy

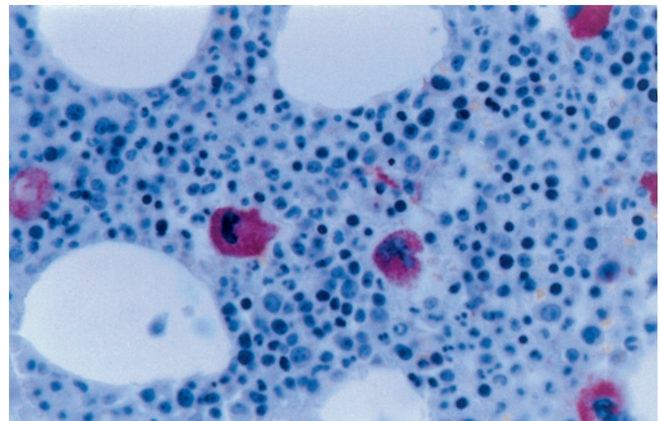

Fig. 2.1. Human bone marrow section stained for fibrinogen by the APAAP technique: MKs specifically stain red. They display a large size and polylobulated nucleus, and are quite seldom in the marrow space compared with the other hematopoietic cell lines. They often stand close to a vascular sinusoid.

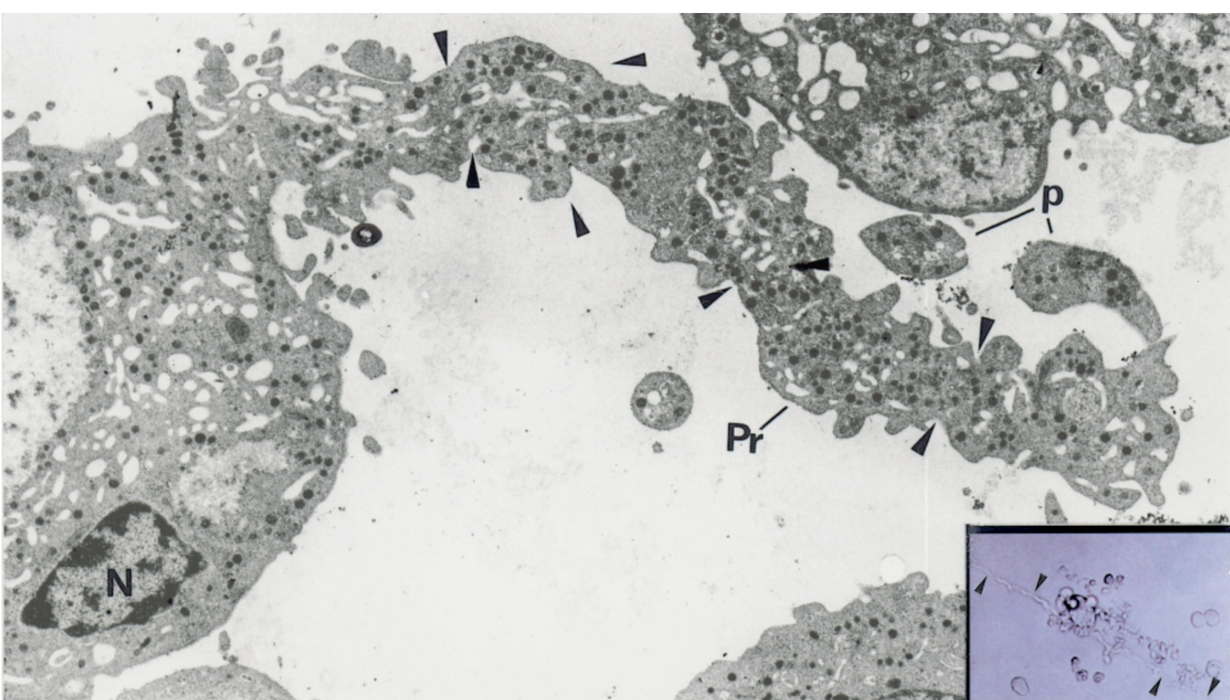

Fig. 2.3. After reaching full maturation, MK cytoplasm extends away from the cell core of the mother cell forming one or several long extensions called proplatelets (pr). Some platelets (p) have detached from its tip. N = nucleus (M × 3354).
Inset: Phase contrast microscopic view of a mature MK extending proplatelets (arrowheads).

Platelet shape	Actin	Actin filament ends	Main signals
Discoid	40 % of actin polymerized into filaments	CapZ and adducin cap actin filament barbed ends	$[Ca^{2+}] < 100$ nM ppl's sequestered
Round	40 % of actin polymerized into filaments	Gelsolin severs actin filaments CapZ, adducin and gelsolin are on barbed ends	PLC-mediated hydrolysis of ppl's Cytosolic calcium rises to 0.5-3 μM
Spread	80 % of actin polymerized into filaments	Gelsolin and adducin dissociate from barbed ends Arp2/3 is activated and nucleates actin assembly de novo CapZ associates with barbed ends	ppl's are synthesized: PI_4P up by 80 μM $PI_{4,5}P_2$ up by 60 μM $PI_{3,4}P_2$ up >20 fold $PI_{3,4,5}P_3$ up transiently

Fig. 6.3. The role of calcium and ppIs in the regulation of the platelet actin cytoskeleton. This diagram links platelet shape change during activation with changes in the actin cytoskeleton, proteins that regulate actin filament ends and the primary signals that effect changes in filament ends. The actin filaments in the discoid resting platelet are shown in a mustard-yellow colour, while the capping proteins are shown in pink and purple. Actin monomers that add to the barbed end of filaments in the spread platelet are illustrated as blue subunits.

Cambridge Books Online © Cambridge University Press, 2009

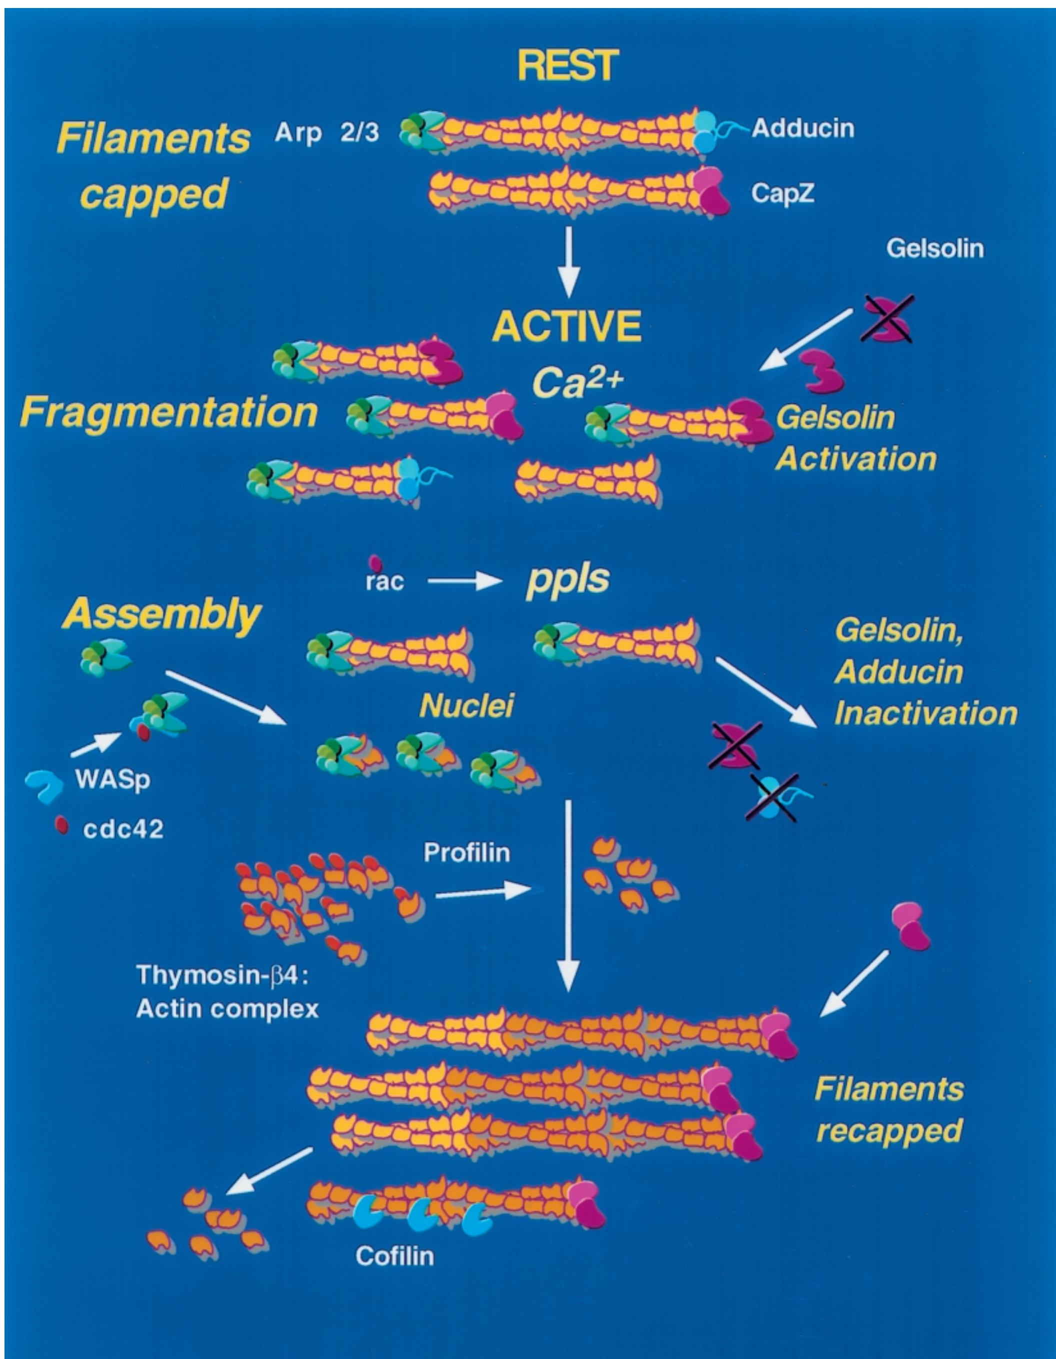

Fig. 6.4. Regulation of platelet actin assembly. The role of known platelet proteins in the actin assembly reaction is shown. In the resting platelet, adducin and CapZ cap actin filament barbed ends. Activation leads to calcium release and the activation of gelsolin. Gelsolin fragments the cortical actin filament network and this event is responsible for the loss of the discoid shape of the resting platelet, which now assumes a more rounded morphology. Polyphosphoinositides are robustly generated at the cytoplasmic surface of the platelet plasma membrane and lead to the initiation of actin assembly onto exposed barbed ends of actin filaments. PpIs serve to both inactivate capping proteins (adducin and gelsolin) and to maximally activate the Arp2/3 complex through the WASp family of proteins. Profilin and thymosin β4, by binding to actin monomers, maintain the large actin pool that drives filament assembly. Actin filaments are subsequently buffered by CapZ, which recaps the filaments, and terminates the assembly reaction. Subsequent actin filament turnover if it occurs in platelets is stimulated by cofilin.

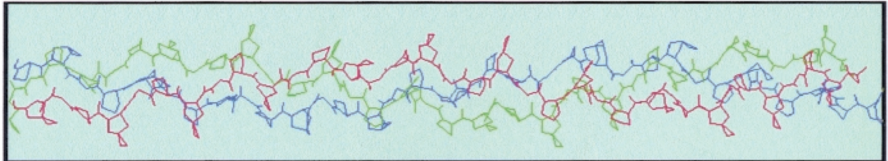
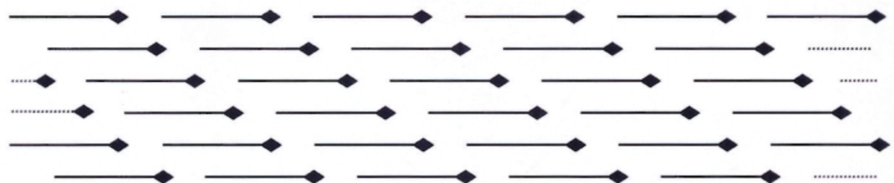
Triple-helical collagen monomer



Monomers assemble to form fibril



Native collagen fibre

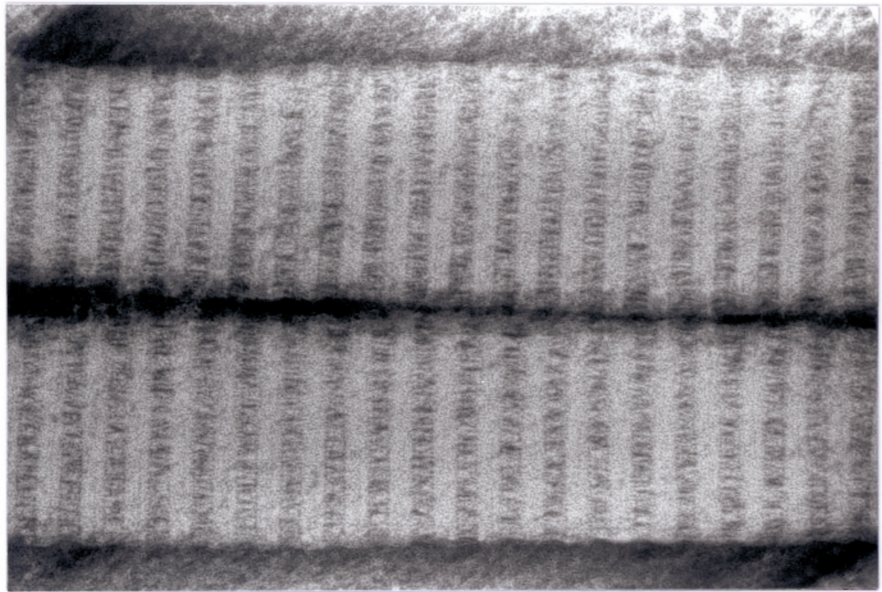


Fig. 11.1. illustrates the hierarchical structure of collagen: the monomer is represented using the crystal coordinates of $[GPO]_{12}$, obtained from 2clg.pdb, with its individual alpha chains shown in different colours, and the proline and hydroxyproline residues protruding into the external medium. The tropocollagen monomers assemble head-to-tail in a quarter-staggered array into fibrils, and their organization into fibres is clearly visualized by transmission electron microscopy. ◆ indicates the N-terminus of the tropocollagen molecule. (Transmission electron microscopy, courtesy of M. Hess, University of Helsinki.)

Cambridge Books Online © Cambridge University Press, 2009

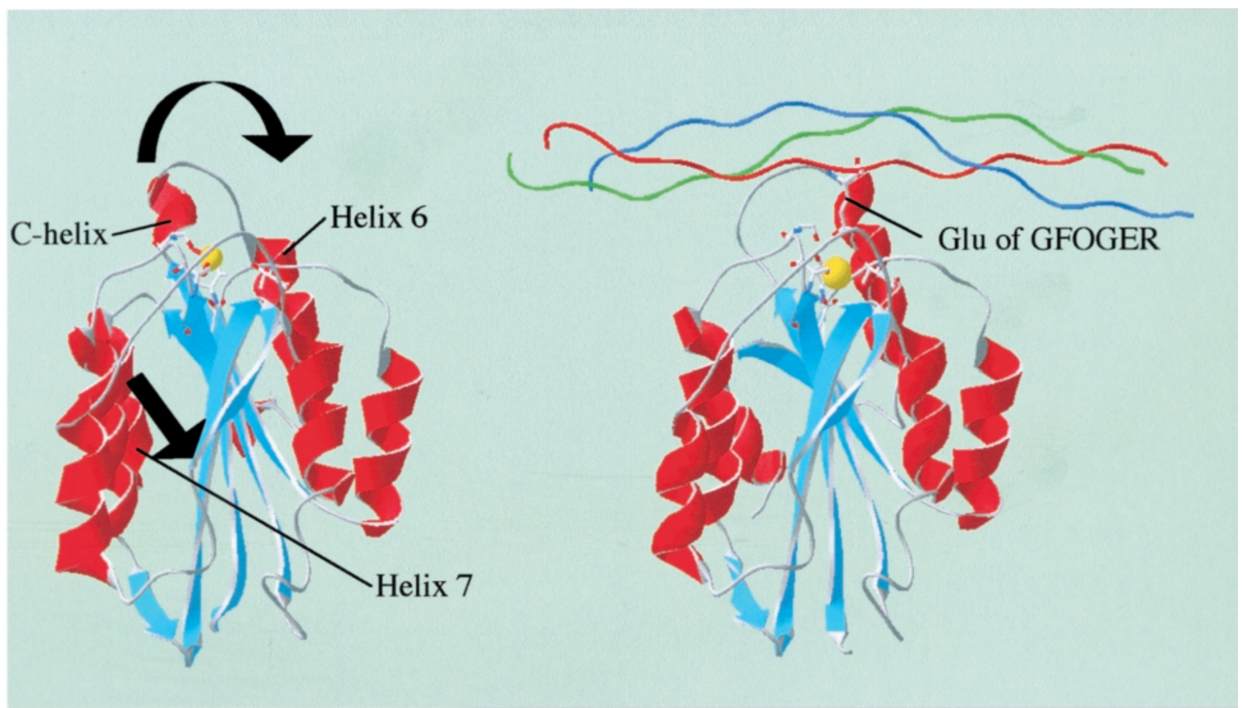

Fig. 11.2. Shows the differing conformation of the free integrin $\alpha 2$ I-domain compared with that bound by collagen. As indicated by the black arrows, the resting I-domain moves upon ligation by the collagen- like peptide. The C-helix unwinds and is added to the top of helix 6. Helix 7 moves axially towards the base of the I-domain. Note that the I-domain construct contains a truncated helix 7, the native form of which, in the active conformation, would protrude from the I-domain and alter its relationship with the rest of the $\alpha 2$ subunit. The metal ion in the MIDAS is shown as a yellow sphere. Crystal coordinates, free I domain, 1aox,.pdb; peptide-I-domain complex, 1dzi.pdb. (Molecular graphics courtesy of Dr D. Tuckwell, University of Manchester.)

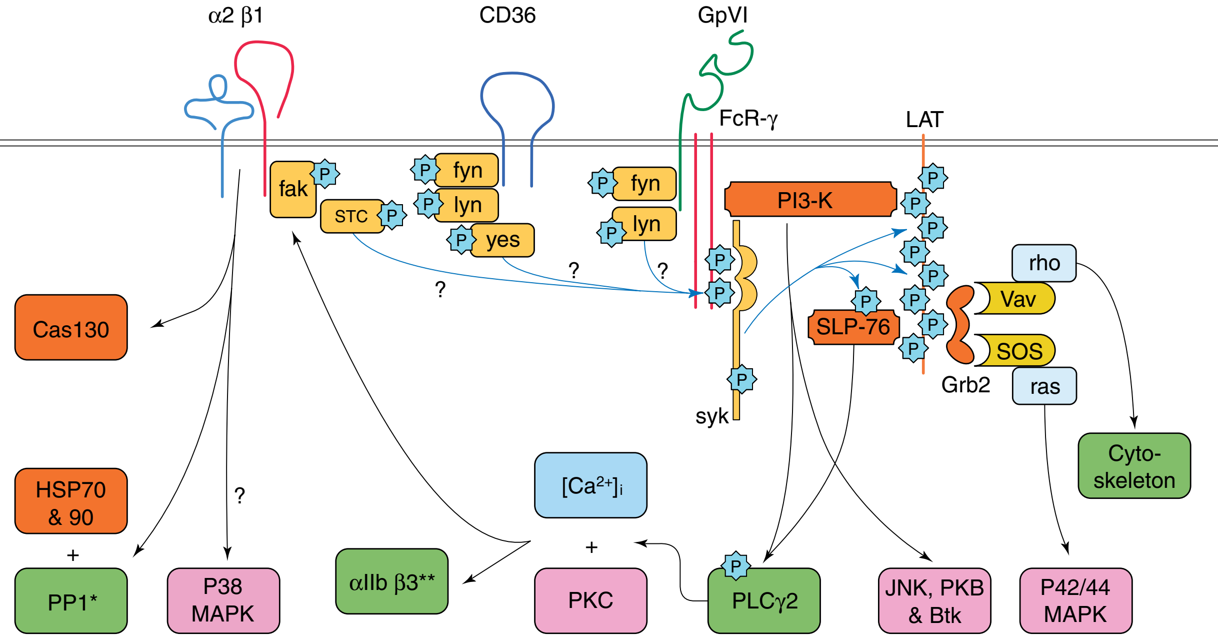

Fig. 11.4. Depicts proposed signalling pathways from the major collagen receptors, $\alpha 2\beta 1$, CD36 and GpVI. Phosphorylation events are shown using blue arrows, and other signalling pathways in black. Question marks indicate possible signalling pathways, lacking specific detail at present. Signalling molecules are defined in the text. Tyrosine kinases are coded *beige*, serine/threonine kinases *pink*, adapter proteins in *orange*. Tyrosine phosphorylation is indicated by stars on the relevant proteins. Other collagen receptors and possible signals arising from the GpIb/IX/V axis are omitted for clarity.

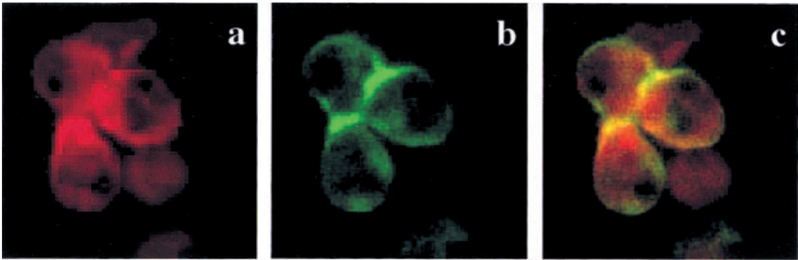

Fig. 28.4. Formation of Mac-1 clusters and colocalization with F-actin patches in PMN leukocytes at the site of cell–cell contact. Confocal laser scanning microscopy of PMN, preincubated with an anti-PSGL-1 antibody, stained with FITC-conjugated anti-CD11b antibody and rodamine-phalloidin: (*a*) and (*b*) show F-actin (red) and CD11b (green) staining, respectively. In the overlay (*c*), the yellow colour represents colocalization of the two stainings. (For more details[141].)

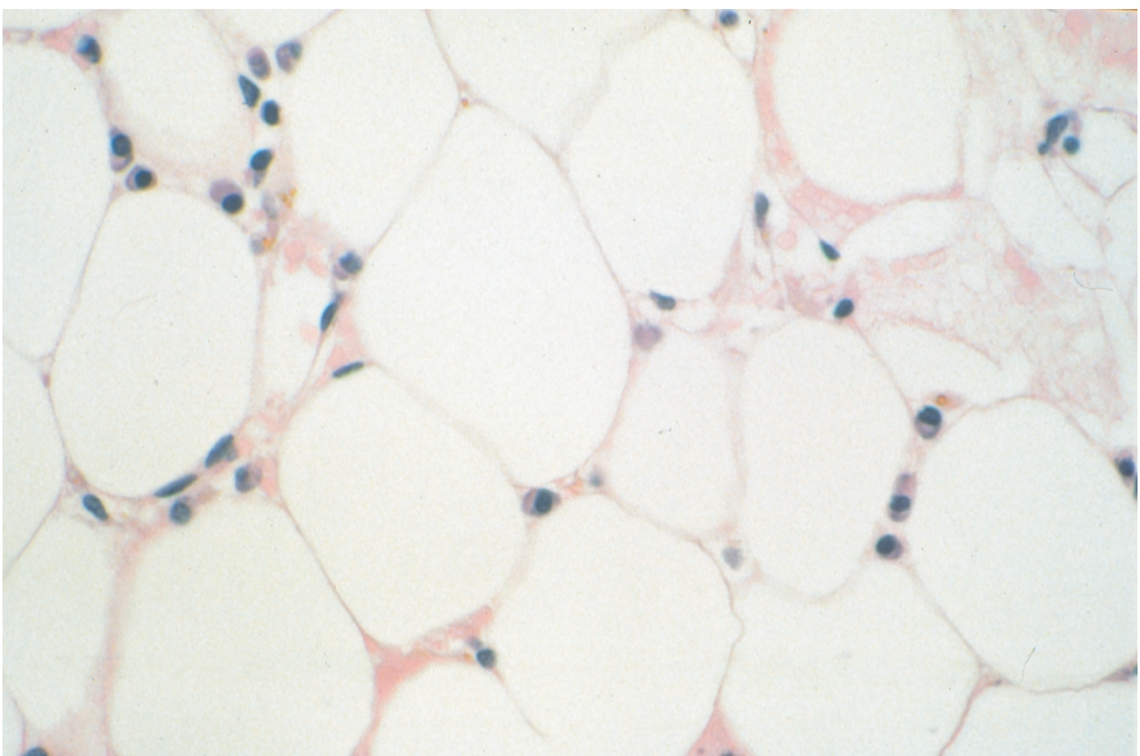

Fig. 35.2. A bone marrow trephine biopsy of a patient (male, 25 years of age) with aplastic anemia. It shows predominantly adipose spaces and stromal cells but very few hematopoietic cells.

Cambridge Books Online © Cambridge University Press, 2009

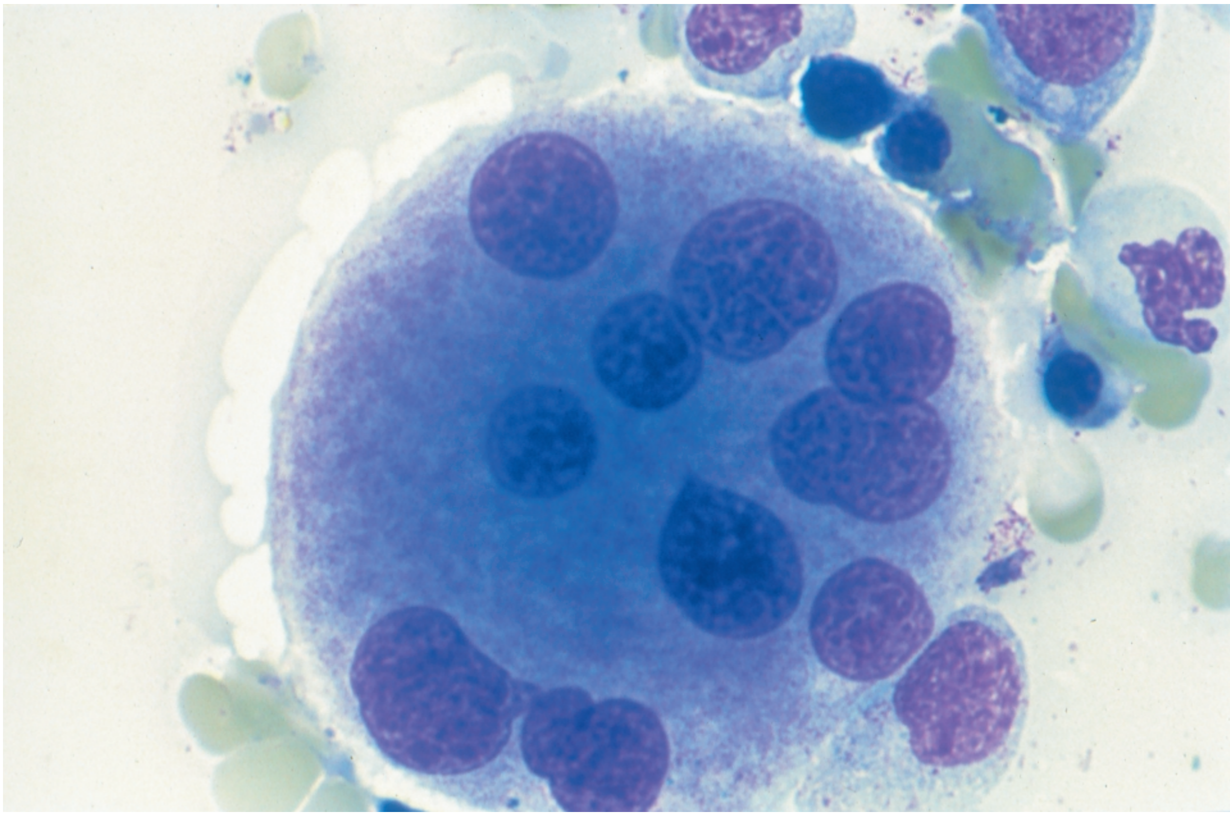

Fig. 35.3. This shows an abnormal megakaryocyte with dysplastic changes in a patient with HIV-1 infection and thrombocytopenia. It is a huge cell with nuclear fragmentation.

Cambridge Books Online © Cambridge University Press, 2009

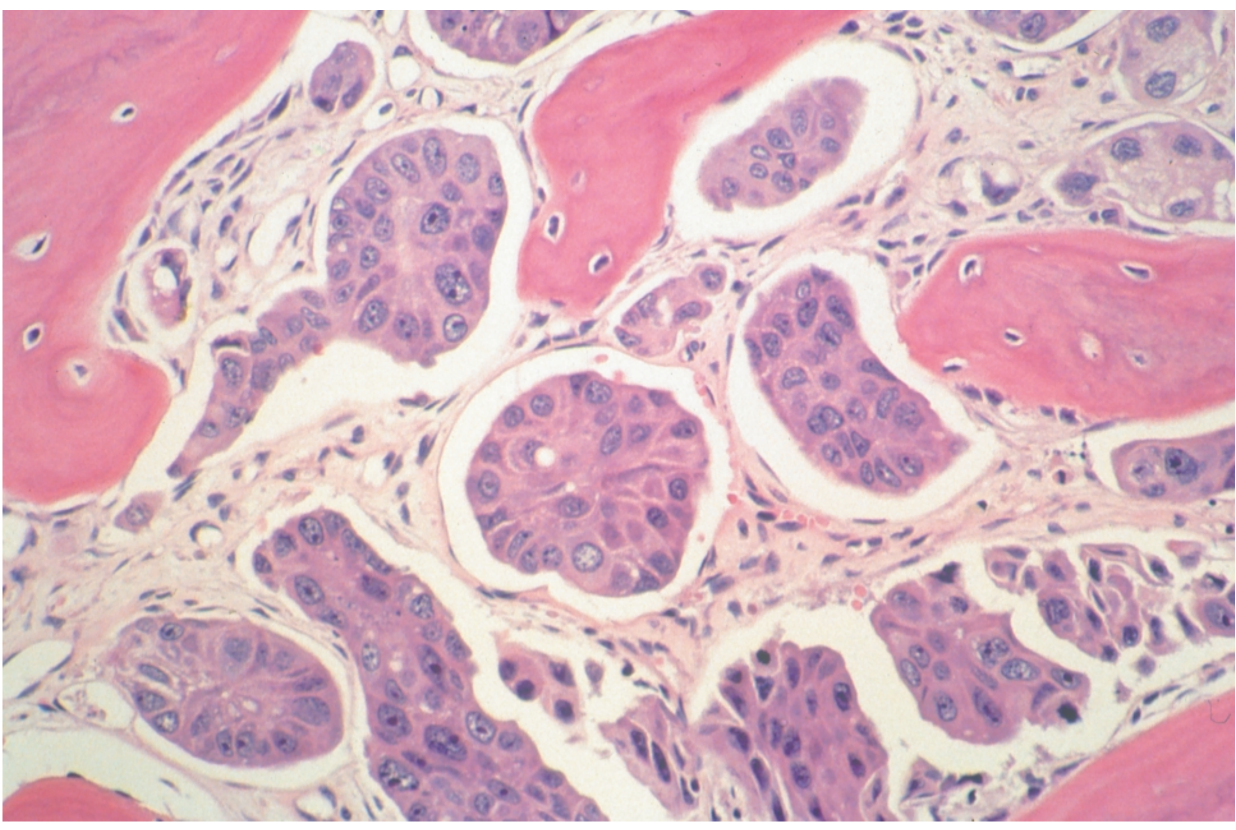

Fig. 35.4. A bone marrow trephine biopsy of a patient with metastatic breast cancer showing bone marrow infiltration by malignant cells. The cancer cells are arranged in a gland-like formation (acini).

Cambridge Books Online © Cambridge University Press, 2009

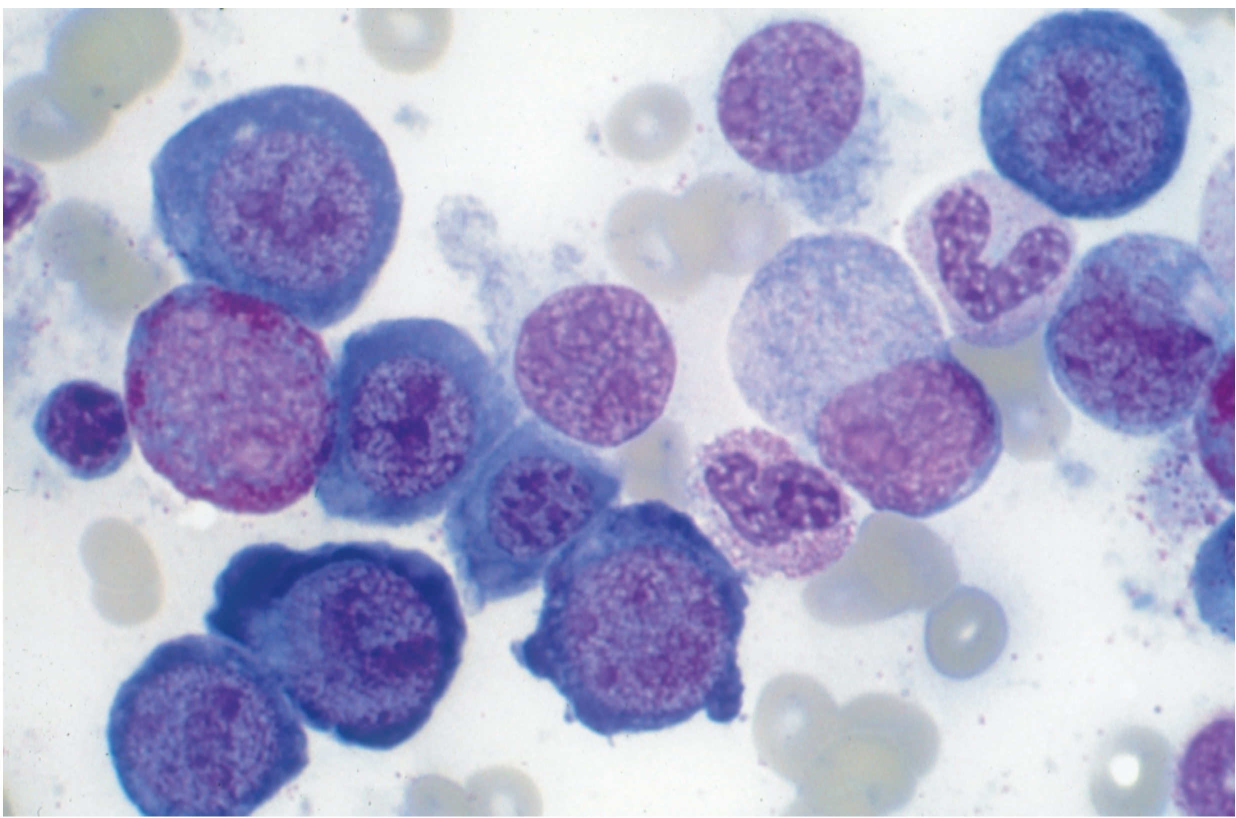

Fig. 35.5. A bone marrow smear of a patient (female, aged 76) with pernicious anemia. It shows florid megaloblastic changes with many megaloblasts and a giant band form.

Cambridge Books Online © Cambridge University Press, 2009

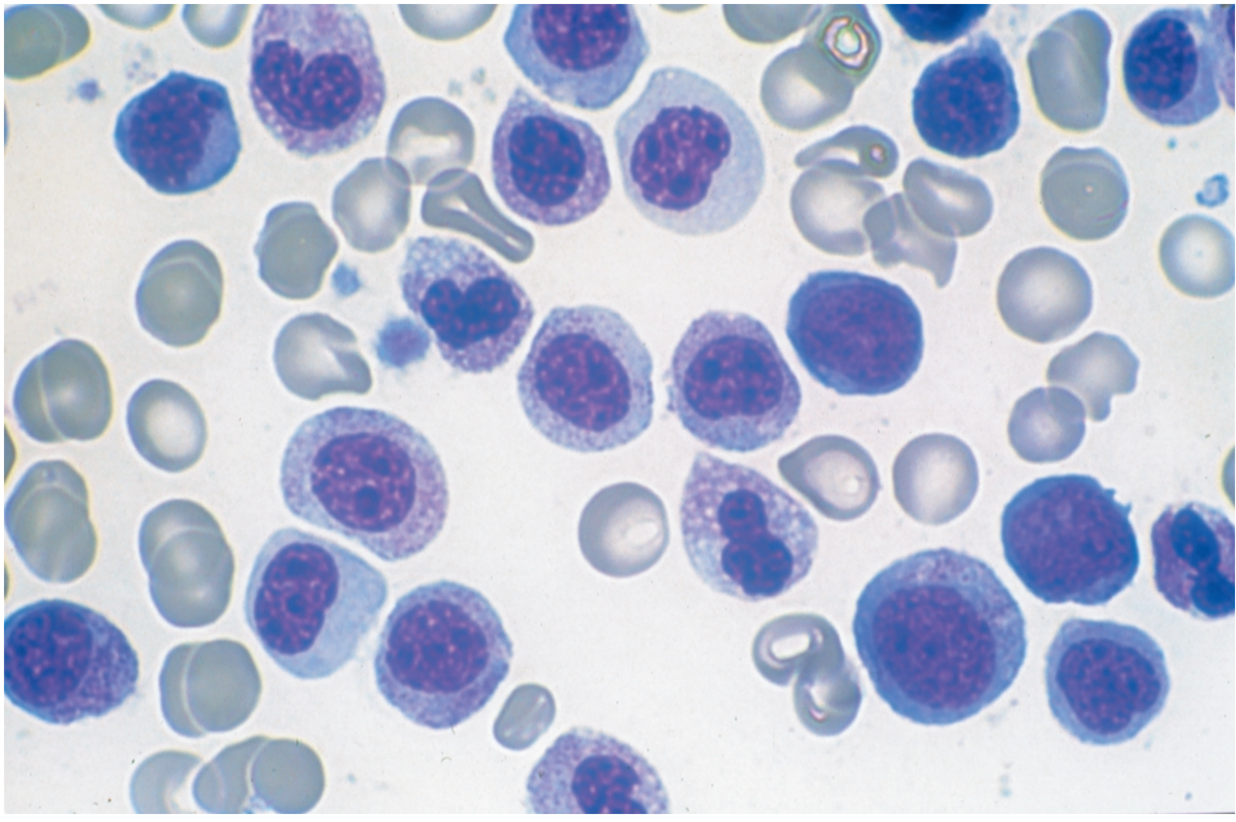

Fig. 35.6. A bone marrow smear of a patient (male, aged 64) who had myelodysplastic syndrome. It shows dysplastic changes in granulocyte precursors, namely hypogranular forms and Pelger–Huet anomaly.

Cambridge Books Online © Cambridge University Press, 2009

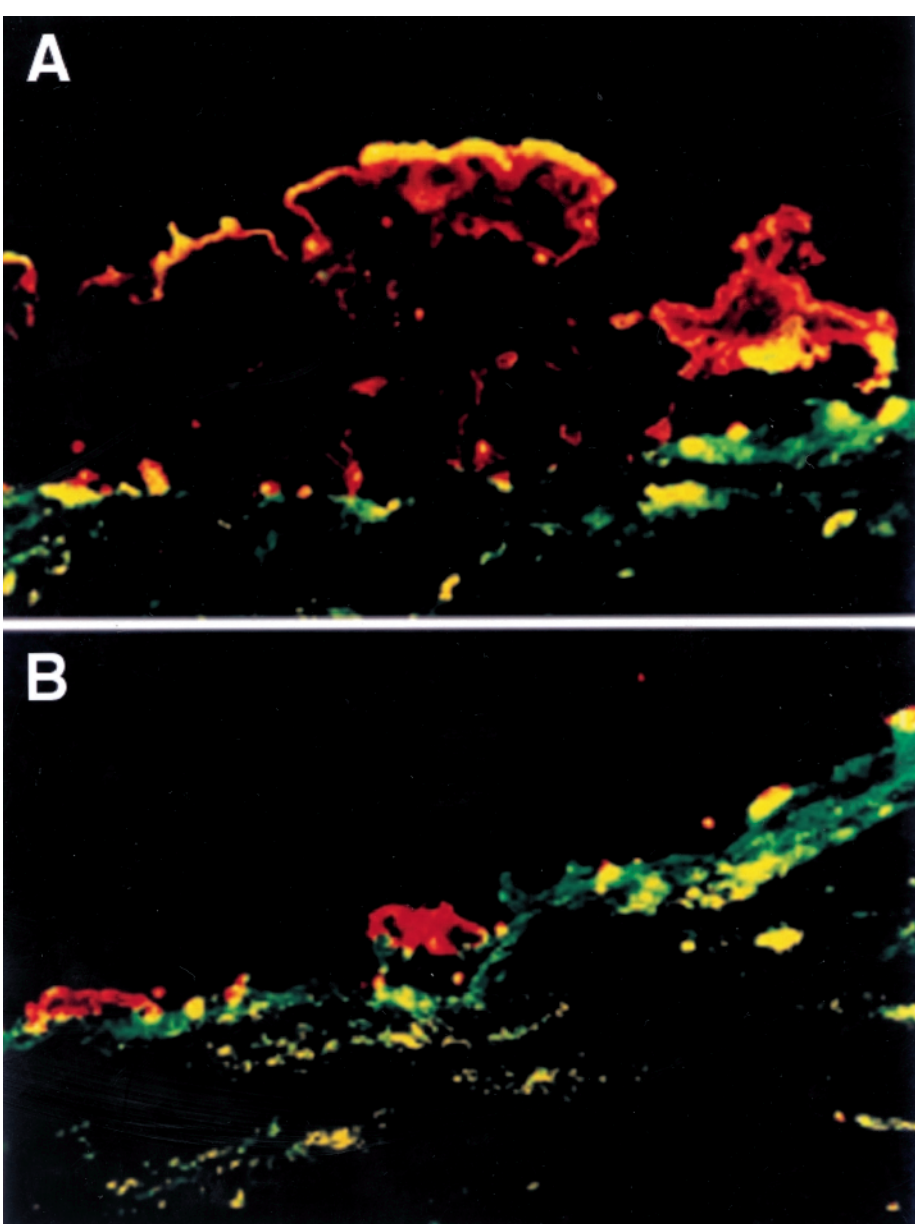

Fig. 47.5. Effects of TFPI on thrombogenicity of disrupted lipid-rich human atherosclerotic lesions: Control (*a*) and TFPI-treated (*b*). Fibrinogen deposition is shown as green, platelet deposition as red, and their colocalization as orange. Note the significant antithrombotic effect of rTFPI on deposition of platelet and fibrin(ogen) deposition.

Cambridge Books Online © Cambridge University Press, 2009

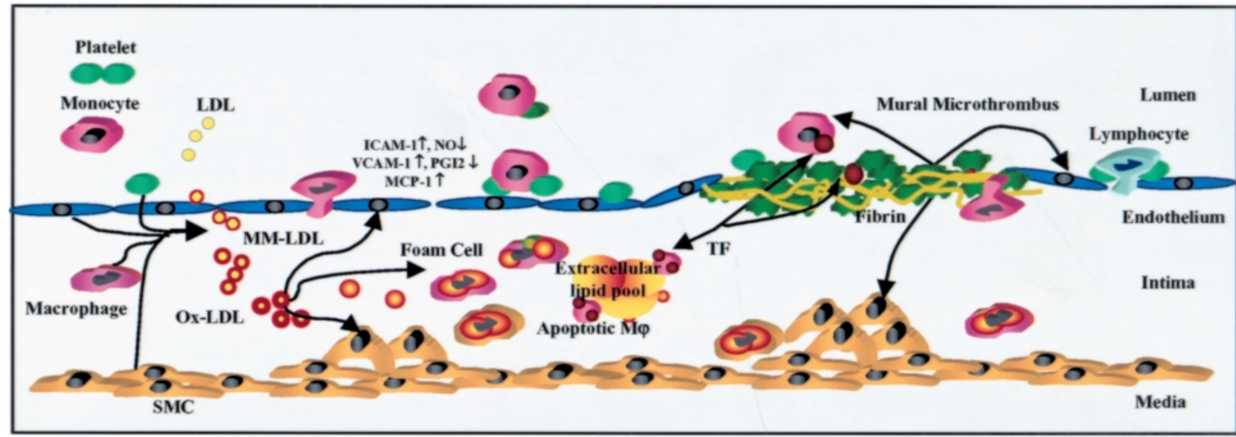

Fig. 48.2. Endothelial cells, platelets, smooth muscle cells and macrophages mediate oxidative modifications of LDL. MM-LDL activates endothelial cells and promotes smooth muscle cell migration and proliferation. Uptake of oxidized lipoproteins by macrophages and smooth muscle cells generates foam cells. Activated platelets adhere to, and activate, endothelium and facilitate monocyte adhesion. Endocytosis of platelet-derived vesicles contributes to foam cell formation. Endothelial erosion initiates platelet adhesion and aggregation and fibrin deposition on the subendothelial matrix. Tissue factor is closely associated with macrophages in the lipid core. Propagation of a thrombus may also depend on blood-borne tissue factor. Platelets release a number of growth factors propagating smooth muscle cell proliferation. Re-endothelialization and cap formation by smooth muscle cells incorporates the mural thrombus into the expanded lesion. (ICAM-1: intercellular adhesion molecule-1, M*ψ*: macrophage, MCP-1: monocyte chemotactic protein-1, MM-LDL: Minimally modified LDL, NO: nitric oxide, ox-LDL: oxidized LDL, PGI_2: prostacyclin, SMC: smooth muscle cell, TF: tissue factor, VCAM-1: vascular cell adhesion molecule-1.)

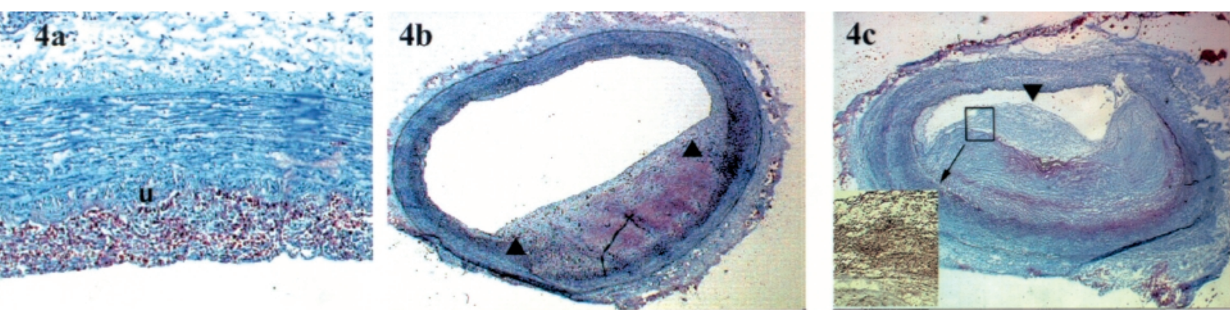

Fig. 48.4. (*a*) Oil Red O staining of a fatty streak (Stary type II lesion). The lesion is rich in foam cells. Smooth muscle cells (▶) migrate towards the intima.(*b*) Oil Red O staining of a fibroatheroma (Stary type IV–V). The eccentric lesion consists of a large lipid core with a rather thin fibrous cap. Plaque rupture occurs most frequently at the shoulder regions of the plaque (▲). (*c*) Oil Red O staining of a complicated lesion (Stary type VI). The layered aspect and the organized thrombus (▼) are hallmarks of healed disruption. Immunostaining (➔) for fibrin shows fibrin at the basis of the most recently formed cap.

Cambridge Books Online © Cambridge University Press, 2009

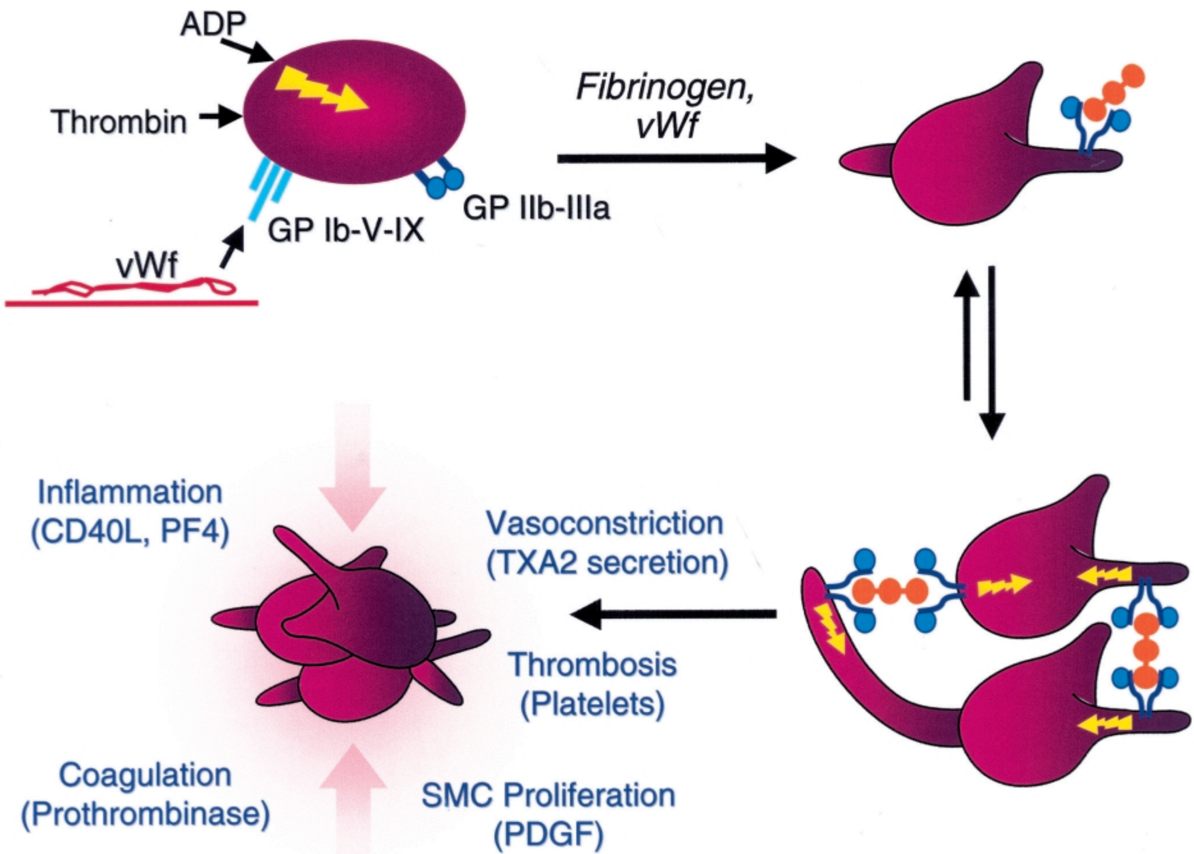

Fig. 63.1. Schematic illustrating the role of GP IIb–IIIa in platelet aggregation. On resting, discoid platelets the GP IIb–IIIa is present in an 'inactive' conformation and is unable to bind soluble fibrinogen. Upon activation by classical agonists such as collagen, thrombin or adenosine diphosphate (ADP) the platelet undergoes a shape change and the GP IIb–IIIa is activated such that it can now bind its soluble ligands, fibrinogen and von Willebrand factor (vWf). Platelet aggregation is mediated by the bivalent fibrinogen forming bridges between GP IIb–IIIa molecules on the surfaces of neighbouring, activated platelets.

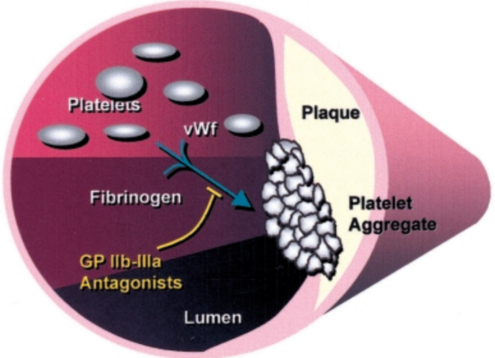
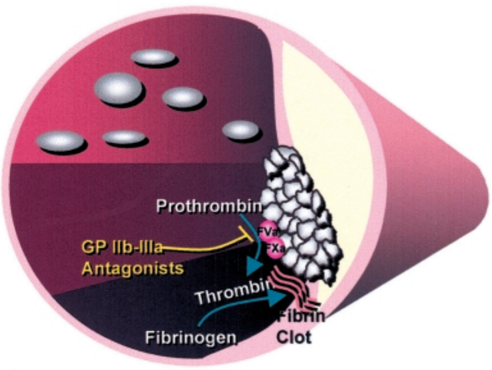
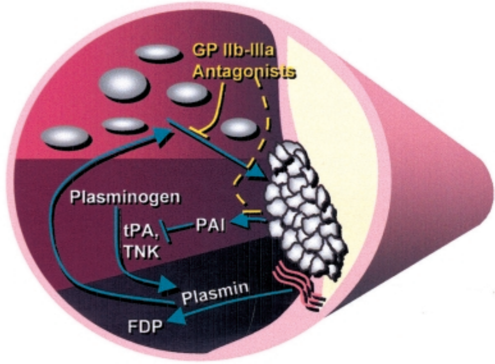
Cambridge Books Online © Cambridge University Press, 2009



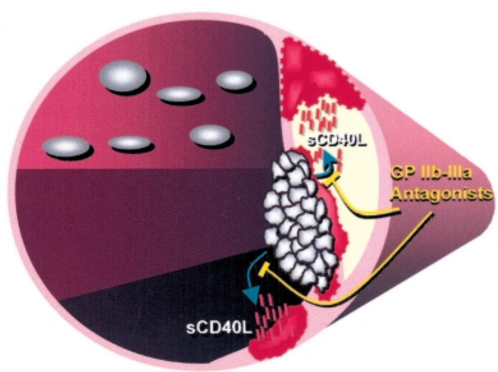
A. Thrombosis



B. Coagulation



C. Fibrinolysis



D. Inflammation

Fig. 63.2. Diagrams depict the multiple benefits of GP IIb–IIIa antagonists. (*a*) GP IIb–IIIa antagonists block platelet aggregation and recruitment to prevent thrombosis. (*b*) The prothrombinase complex (FVa, FXa) is predominantly formed on the surface of aggregated platelets. The anticoagulant activity of GP IIb–IIIa antagonists can be attributed to their antiaggregatory activity. (*c*) GP IIb–IIIa antagonists inhibit platelet aggregation induced by plasmin and thrombin which are generated during thrombolysis. These antagonists also inhibit the aggregation-induced release of PAI-1, an inhibitor of fibrinolysis. The apparent 'fibrinolytic' activities of GP IIb–IIIa antagonists can be attributed to these synergistic activities with fibrinolytic agents. (*d*) Platelet aggregation induces the expression and release of the potent proinflammatory protein CD40L. Inhibition of platelet adhesion to vascular cells and sCD40L release from platelets by GP IIb–IIIa antagonists may allow this class of drugs to be anti-inflammatory.
